As already mentioned, in the gas-phase oxidation reactions, in catalytic processes, and in the chemistry of the atmosphere, the role of the stages involving the interaction of radicals with various surfaces is considerable. As a rule, the rate constants for these stages (or the probabilities of the reactions on collision of the radical with the surface) are high and methods with a high time resolution are needed for their investigation.

In the traditional RFM scheme when the entire gas stream is directed to the freezing out trap (direct sampling), the velocity of the gas jet is restricted by the considerable convective heat exchange which impairs the regime under which the matrix is frozen and the radicals are stabilised within it. As a result, the interaction of the radicals with the solid substance investigated,

deposited on the wall or placed along the axis of a cylindrical reactor, takes place in the diffusional regime.[104,105]

The time resolution can be increased by means of diffusional sampling,[106-108] in which the freezing out trap is placed in the vicinity of the axis of the gas stream but outside it, so that the gas should not heat it convectively. In order to increase the rate of the diffusional removal of radicals to the freezing out trap, helium is employed as the carrier gas. Since only a proportion of the radicals enter the matrix under the conditions of diffusional sampling, the sensitivity of the method is reduced by a factor of 5-6 compared with direct sampling. However, the velocity of the jet can then be increased to 30 m s^{-1} and the time resolution can be raised to $\sim 10^{-3}$ s, which renders the reactions of radicals with a surface, whose probability is close to unity, susceptible to measurement. This method has been employed to investigate the interaction of $HO_2^{\cdot}$ radicals with the surfaces of ice, carbon black, Al_2O_3, and various salts,[105] of the $CH_3^{\cdot}$ and $CH_3O_2^{\cdot}$ radicals with the surfaces of quartz and NaCl,[107] and of the $HO_2^{\cdot}$, $CH_3O_2^{\cdot}$, and $FO_2^{\cdot}$ radicals with the surface of quartz.[108]

b. Mass spectrometry

Repeated attempts to employ the mass-spectrometric (MS) method in the study of heterogeneous-homogeneous oxidation reactions have been made.[28,109-111] However, the problem is that in the usual method the fragments of saturated molecules generated on exposure to an ionising electron beam can give rise to the same peaks (m/z) in the spectrum as the radicals present in the system. The concentration of the latter is then usually several orders of magnitude lower, which virtually precludes their differentiation from the overall spectrum in practice.

The possibility of studying reactions involving free radicals increased sharply when photoionisation mass spectrometry (PIMS) was employed.[112] The ionisation thresholds of radicals are generally much lower than for the saturated molecules from which they are formed. Therefore the use of, for example, a UV radiation source with a set of filters designed for different light wavelength ranges or of lasers (multiphoton ionisation processes are then most often employed[113]) permits the selective ionisation of species (radicals) of one kind without ionising others (saturated molecules). This method has been used to investigate the generation of $CH_3^{\cdot}$ radical on the Sr/La_2O_3 catalyst for the oxidative condensation of methane (OCM)[72] and the interaction of these radicals with the surface.[114]

Time-of-flight mass spectrometry with multiphoton ionisation by laser radiation has been employed[115] for the detection of the methyl radicals formed in the OCM reaction on the Ca/Al_2O_3 and Sr/La_2O_3 catalysts. The use of mass spectrometry with chemical ionisation (MSCI) may also prove to be promising, but we are not aware of any examples of the application of this method in the study of heterogeneous-homogeneous processes.

A study has been published recently[73] in which the detection of radical species by mass spectrometry was combined with the TAP technique which make it possible to investigate processes on heterogeneous catalysts with a high time resolution.[116] This aspect is also extremely promising.

Hitherto it has been possible to consider the rates of reaction of radicals with a surface in only a small number of instances. The high sensitivity and selectivity ensured by the PIMS and MSCI methods make it possible to solve one of the most complex problems — the elucidation of the stoichiometry of heterogeneous radical reactions.

c. Molecular beams

The general term 'molecular beam method (or technique)' (MB) is usually understood as the set of methods for the investigation of the kinetics and mechanisms of reactions (both homogeneous gas-phase and heterogeneous reactions) in which the reactants and/or products are investigated and in which the directions of their velocities are rigorously specified (see, for example, the relevant reviews[117,118]). The methods for the generation and detection of the beam may be varied. For example, the distribution of the species with respect to different energy modes can be varied under these conditions from the Maxwell-Boltzmann equilibrium distribution to a fairly narrow distribution, which is different for different partner species. This makes it possible to investigate not only the reaction kinetics but also the dynamics of the energy transfer processes during collisions or the form of the potential energy surface for the system.

An additional advantage of the MB technique when applied to the study of heterogeneous processes is associated with the possibility of monitoring precisely the surface coverage and also of investigating the steric effects (the distribution of the species reflected by the surface or arising from it, the possibility of interaction as a function of the angle of incidence of the beam).[119] The combination of the MB technique with the methods for the simultaneous investigation of the surface and surface compounds (thermoprogrammed desorption and photoelectron spectroscopy,[120] IR spectroscopy with isotope substitution[121,122]) is particularly fruitful in the study of the reactions of radicals with various surfaces.

d. Laser induced fluorescence

The detection and the determination of the concentrations of species by the method based on the laser induced fluorescence (LIF) are based on the measurements of the emission by the excited species. The greatest advance in the application of fluorescence methods in the study of atoms and radicals was achieved when the excitation sources employed comprised pulsed or continuous broad-band and frequency-tunable dye-based lasers, which could be tuned to the narrow absorption bands of the test species.[123]

An advantage of the LIF method applied to heterogeneous-homogeneous processes is the possibility of measuring the concentration of species with a fairly high spatial resolution. This is in fact why it has been possible to determine the spatial profiles of the concentrations of $OH^{\cdot}$ radicals and O atoms in stabilised combustion processes.[52,55-57,124,125]

The use of the LIF method in the study of OCM process made it possible to demonstrate[126] that $OH^{\cdot}$ radicals are formed under the conditions of this reaction and also in the 'oxidation of water'.

e. Other methods

The method for the detection of species from the disappearance of a metallic mirror, used to confirm the involvement of radicals in the OCM reaction,[127] is based on the formation of volatile organometallic compounds in the interaction of, for example, thin films of metallic lead (a 'mirror' deposited beforehand on the reactor surface) with radicals (in the given instance tentatively identified with $CH_3^{\cdot}$). Although according to the data of Rice and Tweedell[128] certain mirrors (for example, tellurium or antimony mirrors) disappear only on exposure to radicals of a particular type ($CH_3^{\cdot}$, $C_2H_5^{\cdot}$), this method [as well as the low-temperature reduction of copper and tungsten oxides by hydrogen at a certain distance from the catalyst (Pd, Pt) employed in early investigations[129-131] and the disappearance of the glow in the gas under analogous conditions[132]] can serve as only a qualitative indication of the release of active species into the free volume.

Various modifications of IR spectroscopy have been employed to investigate the radical generation processes and the repeated interaction of the radicals with the surface of oxides.[74,133-136] However, one should note that only surface compounds (alkoxy- and hydroxy-groups), appearing as a result of the interaction of the active surface centres with hydrocarbons and with the radicals formed, were detected spectroscopically in the above investigations. Like other methods for the investigation of the surface and surface compounds, IR spectroscopy yields most information when it is combined with methods for the direct

detection of free radicals, as happens for example in the MB technique.

4. The mechanism of the heterogeneous formation of free radicals

As already mentioned, heterogeneous free radical formation reactions may play the role of chain initiation stages in RCP and of reactant activation stages in heterogeneous-catalytic processes. Therefore the elucidation of the mechanisms of such reactions is extremely important for the understanding of the process as a whole. Here we shall consider the energy relations of the interaction of reactant molecules with the active surface centres and the available data on the detailed mechanisms for these reactions.

a. Thermochemistry of the interaction of molecules with active surface centres

It follows from Table 1 that the propagation of heterogeneous-catalytic processes in the free volume occurs widely in the oxidation of substances of different classes. This indicates the existence of a universal cause which makes the formation of radicals in heterogeneous processes extremely probable.

Two cases in which the heterogeneous formation of radicals may become energetically more favourable than their homogeneous formation have been analysed.[2]

1. In the dissociative adsorption of a molecule with subsequent desorption of one of the adsorbed fragments:

$$AB + 2Z \rightarrow ZA + ZB, \quad (9)$$

$$ZA \rightarrow Z + A^{\cdot} \quad (10)$$

2. In the binding to the surface of only one of the fragments of the activated molecule (the second fragment escapes into the free volume under these conditions).

$$AB + Z \rightarrow ZB + A^{\cdot}. \quad (11)$$

In the first case, the bond dissociation energy in the initial molecule decreases more the higher the energy of the bond between its fragments and the surface centres Z; however, under these conditions the activation energy for the abstraction of a radical from the surface increases.

In the second case, the bond dissociation energy diminishes less, but there is no need for additional energy consumption on the abstraction of a radical from the surface. According to the authors,[2] the formation of radicals via the second mechanism in one stage is more probable.

On the other hand, when one considers the probability of the release of radicals into the free volume in a particular reaction, then a different assessment must be made, namely one must compare the energy relations for the formation of radicals in the interaction of various molecules with the surface of the solid with the energy relations for other possible types of interaction leading to the activation of the reactants. Such analysis may be performed on the basis of the available thermochemical literature data (see, for example, Refs 137–139).

Table 2 presents estimates of the energy expenditure ($\Delta H + E_{st}$, where ΔH is the overall enthalpy change and E_{st} is the energy evolved in the stabilisation on the surface of an activated molecule or its fragment) in the following processes leading to the activation of certain molecules in catalytic reactions on the surface: (1) abstraction of a hydrogen atom from the RH molecule by a powerful oxidative centre on the oxide surface $[O]_s$ or by a surface metal atom [M] with formation of a radical $R^{\cdot}$:

$$[O]_s + RH \rightarrow [OH]_s + R^{\cdot}, \quad (12)$$

$$(\Delta H_1 + D_{O-H}) = D_{R-H},$$

Table 2. Energy expenditure (kJ mol^{-1}) on the activation of molecules via different mechanisms.

Molecule	Energy expenditure in processes			
	12 (or 13)	14	15	16
H_2	431	1668	1668	1484
CH_4	431	1630	1308	1250
C_2H_6	410	1584	1183	1120
C_3H_8	398	1609	1162	1078
n-C_4H_{10}	393	1605	1154	1037
iso-C_4H_{10}	389	1601	1120	1016
C_2H_4	435	–	1275	1012
C_3H_6	322	1421	1033	936
C_6H_6	427	–	1258	886
CH_3OH ($R = CH_2OH$)	385	–	1099	1049
HCHO	314	–	1195	1045
NH_3	439	1630	1463	991

or

$$[M] + RH \rightarrow [M-H] + R^{\cdot}, \quad (13)$$

$$(\Delta H_1 + D_{M-H}) = D_{R-H};$$

2) Heterolytic dissociation with abstraction of a proton from a strong basic centre $[O^{2-}]_s$ with formation of an anion R^-:

$$[O^{2-}]_s + RH \rightarrow [O^{2-}...H^+]_s + R^-, \quad (14)$$

$$\Delta H_2 + Q_{H^+} + Q_{R^-} = D_{R-H} + I_H - I_{R-R^-};$$

(3) Heterolytic dissociation into a hydride ion, which is bound to the cation $[M^{n+}]_s$ and the cation R^+:

$$[M^{n+}] + RH \rightarrow [M^{n+}...H^-]_s + R^+, \quad (15)$$

$$\Delta H_3 + Q_{R^+} + Q_{H^-} = D_{R-H} + I_R - I_{H-H^-};$$

4) Ionisation of the molecule with formation of a molecular ion RH^+, whereupon

$$\Delta H_4 + Q_{RH^+} = I_{RH}. \quad (16)$$

In the above equations, ΔH_i represents the enthalpy changes in the corresponding processes, D_{R-H} is the energy of the homolytic association of the R–H bond, I_j represents the ionisation potentials of the species, and Q_j are the heats of adsorption of the species.

It is easy to demonstrate that in all these processes the sign and magnitude of the heat change depend on the compensation of the energy by binding the fragments of the activated molecule to the surface centres. The energy which has to be compensated is as a rule minimal for the first process. For example, in the case of oxide catalysts one may expect that the energy of the O–H bond formed in this process is comparable to the energy expenditure on the homolytic dissociation of the R–H bond, i.e. its compensation does not require the binding of the second fragment. In the heterolytic dissociation of bonds [reactions (14) and (15)], the energy expenditure is so large that its compensation requires the binding of both fragments, which must occur synchronously in a single reaction step, i.e. the activation of the molecule requires the presence of paired centres with unusual configurations and energy relations. For process (12) [or (13)], it is sufficient to have single oxidative centres.

The above analysis shows that the formation of free radicals in the interaction of molecules of substances of various classes with the surfaces of metals and oxides may prove to be energetically preferable compared with other mechanisms of their activation. Furthermore, this process requires only one type of single centres and it takes place in a single stage. The combination of these factors may render such a process the most

favourable. This conclusion is the opposite of that arrived at by Gorokhovatskii et al.,[2] but it is based on quantitative thermochemical data. It may be that this in fact explains the more common employment of the approach based on the homogeneous propagation of oxidative heterogeneous-catalytic reactions (Table 1).

b. Generation of free radicals in catalytic reactions

The considerable progress in the study of heterogeneous–homogeneous radical reactions in recent years has been due to the considerable attention devoted by investigators to the catalytic oxidative condensation of methane (OCM) to higher hydrocarbons on oxide catalysts, which proved to be a convenient model in the study of such reactions.[5–8]

The formation of radicals in the presence of OCM catalysts under catalytic conditions (or close to such conditions) has been demonstrated by means of a whole series of methods (Table 1). The rates of formation of the radicals are close to the rates of reaction of the reactants.[59] According to current ideas, the overall mechanism of this reaction is the same on all oxide catalysts. The primary OCM product (ethane) is formed as a result of the recombination of the methyl radicals generated by the oxide surface. The differences between the catalysts, which determine their different efficiencies, are themselves determined by the properties and concentrations of the radical-generating active centres and also by the specific surface, porosity, and morphology, on which the relative rates of the secondary heterogeneous and homogeneous radical reactions depend. Results important for the understanding of the mechanisms of the generation and secondary reactions of the radicals in heterogeneous processes have in fact been obtained precisely in the study of the OCM process (the discussion below is based mainly on these results).

One of the mechanisms of the formation of free radicals in oxidation processes on oxide catalysts most frequently discussed in the literature presupposes the homolytic dissociation of the bond in the RH molecule when it collides with a strong oxidative surface centre $[O]_s$ with the simultaneous formation of a free radical and a surface hydroxy-group $[OH]_s$ in a single stage:[59,60,69–71,74,75]

$$[O]_s + RH \rightarrow [OH]_s + R^{\cdot} \qquad (17)$$

There exists an alternative point of view, according to which the process proceeds via dissociative adsorption and the key factor is the presence on the oxide surface of strong basic centres $[O^{2-}]_b$, which ensure the heterolytic dissociation of a C–H bond in the hydrocarbon molecule:[140–146]

$$[O^{2-}]_b + RH \rightarrow [O^{2-}...H^{+}] + (R^{-})_{ads} . \qquad (18)$$

The conversion of the anion R^{-}_{ads} produced into a radical requires that it should lose an electron on interaction with an electron-accepting (hole) centre $[h^{+}]$:

$$[h^{+}] + (R^{-})_{ads} \rightarrow [h^{0}] + R^{\cdot}_{2}. \qquad (19)$$

A model of the heterolytic dissociation of the C–H bond was initially formulated for the activation of alkenes and aromatic hydrocarbons in their partial oxidation reactions; subsequently it was transferred to the activation of methane.[140,147,148] This was based on the presence in many catalysts of the OCM process of alkali, alkaline earth, and lanthanide ions. In certain cases, the efficiency of the catalyst increases after the introduction of an alkaline modifying agent.

It follows from the data in Table 2 that the heterolytic bond dissociation in lower alkanes is energetically extremely unfavourable. It has been suggested that the role of the basic centres $[O^{2-}]_b$ actually consists in compensating for the energy expenditure on the dissociation of the C–H bond by binding the proton. If the energy of the interaction of these centres with Lewis acids (proton, CO_2) is adopted as a measure of the basicity, then its increase would entail an increase in the efficiency of the catalyst.

The rates of formation of the OCM products on different oxide catalysts (M/Al_2O_3 and M/MgO, where M = Li, Na, K, Cs, Pb, or Nd) have been compared[149,150] with the numbers of active centres and their strengths, which were determined from the adsorption of CO_2 by programmed thermal desorption and calorimetric methods. There is no direct correlation between the rate of formation of the OCM product and the basicity, but in a number of cases (the Pb/Al_2O_3 and Nd/MgO catalysts with different contents of the deposited component and MgO–alkali metal cation systems) an inverse correlation has been observed between the rate and the heats of adsorption. The introduction of alkaline components into oxide systems apparently leads not only (or even not so much) to an increase in their basicity but also to the modification of the oxidative properties of the lattice oxygen.[151]

Indeed, it has been shown[150] that an increase in the Na content in the Li/MgO and and Nd/MgO catalysts leads to an increase in the concentration of the oxidative centres. At the same time the rate of formation of the OCM product increases. Similar results have been obtained also for other oxide catalysts.[151–153] Furthermore, the interaction of oxide systems containing strong oxidative centres with methane leads to the formation of OCM products even in the absence of oxidants from the gas phase.[115,152–158]

Thermochemical studies have shown[153,157] that the relation between the activation energy for the formation of C_2 hydrocarbons in the interaction of methane with these oxides and the O–H bond energy in the hydroxy-group formed simultaneously corresponds to the Polanyi–Semenov relation obtained for the homolytic abstraction of a hydrogen atom from a methane molecule by various species in the gas phase:

$$CH_4 + X^{\cdot} \rightarrow CH^{\cdot} + XH , \qquad (20)$$

where X = F, OH, H, CH_3, O, Cl, Br, I, HO_2, CH_3O, CH_3O_2, etc.

Data concerning the applicability of the Polanyi–Semenov relation to the dissociation of the C–H and H–H bonds in hydrocarbon and hydrogen molecules on the active centres arising in the mechanical treatment of quartz and aerosil were presented above.[42,43] Although the formation of free radicals was not recorded directly in the above investigations, analysis of the kinetic isotope effects and the characteristics of the formation and reactions of the surface compounds, which according to the authors are products of radical capture, enabled them also to drawn an analogy between heterogeneous and the gas-phase reactions of type (12) [or (13)] and (20).

Similar conclusions concerning the mechanisms of the processes under consideration were reached in a study of the interaction of various molecules with irradiated (in the visible, UV, X-ray, and γ-ray ranges) oxides – MgO,[74,159,160] TiO_2,[161–163] and others,[164,165] as well as SiO_2 and Al_2O_3, modified by vanadium, molybdenum, and tungsten ions.[161,166–168] Irradiation, which leads to the formation of hole O^{-} centres with powerful oxidative properties, induces a sharp increase in the reactivity of the oxides. As a result, in the reaction of methane, for example, it is possible to detect the formation of ethane even at room temperature.[162] According to Kotova's data,[165] the process proceeds via the homolytic dissociation of a C–H bond with formation of excited surface OH groups. The presence of molecular hydrogen in the system inhibits the reaction of methane.

Thus the combination of the available data on the mechanism of the interaction of hydrocarbons and hydrogen with oxides confirms the conclusion reached earlier on the basis of thermochemical data that free radicals may be formed as a result of the homolytic dissociation of R–H bonds under the influence of oxidative surface centres. We may add only that the oxygen ions bound to the readily reducible cations,[115,155] the radical-ions $O^{\cdot -}$,[69,70,74,75,169,170] the surface oxygen ions O^{2-}_{LC} with a lower coordination,[70] and peroxide ions O^{2-}_{2} [156–158,170,171] are included in the literature among the centres possessing such properties.

However, one cannot rule out the possibility that at elevated temperatures all these types of active oxygen are converted into a single type, most probably the radical-ion $O^{\cdot -}$.[170,172-174]

$$O^{2-} + [h^+] \text{ (or } M^{n+}) \rightarrow O^{\cdot -} + [h^0] \text{ [or } M^{(n-1)+}], \quad (21)$$

$$O_2^{2-} \rightarrow 2\ O^{\cdot -}. \quad (22)$$

The results of quantum-chemical calculations[175-180] confirm the high probability of the formation of methyl radicals in the interaction of methane with $O^{\cdot}$ surface centres. On different oxide systems (MgO, MoO_3, $CuMoO_4$), the $O^{\cdot -}$ centres are equally active and have similar properties regardless of the pathways leading to their formation (their appearance as a consequence of the nonstoichiometry of the oxide or as a result of electron transfer under the influence of radiation).[181] Hole centres, having similar electronic properties but present in other systems (for example N^{2-} and AlN), possess also a similar activity in relation to the generation of radicals.[182]

Hitherto we have dealt with the mechanism of the formation of radicals in the interaction of the molecules of the substances being oxidised with the surface centres of catalysts. However, the available experimental data show that, apart from such 'primary' radicals which are products of the abstraction of a hydrogen atom from the RH molecule, and $RO_2^{\cdot}$ radicals, species can also be detected in the gas phase the products of which must be a series of far reaching consecutive transformations of the initial molecules.

As regards the $OH^{\cdot}$ radicals and oxygen atoms formed in stabilised combustion processes,[47,52-57] the available data are insufficient to consider the mechanism of their formation. In particular, it has been suggested[57,124,125] that $OH^{\cdot}$ radicals are formed on recombination of the oxygen and hydrogen atoms adsorbed on the metal surface, but one cannot rule out also their formation in secondary homogeneous reactions. On the other hand, according to some data, in the OCM reaction the generation of secondary $OH^{\cdot}$ radicals is important for the dynamics of the active centres of the catalysts.[128] We shall therefore consider their generation in greater detail.

In one of the first studies devoted to the formation of radicals in the OCM reaction,[69] it was shown that, when molecular oxygen is used as the oxidant, the rate of generation of radicals in the presence of the Li/MgO catalyst is constant, whilst in the case where N_2O is employed it decreases monotonically. The differences in the occurrence of the OCM in the presence of O_2 and N_2O are also indicated by the results obtained on the Sm_2O_3 catalyst:[183] and replacement of O_2 by N_2O lowers significantly the rate of the process.

Studies of the kinetic isotope effect occuring when CH_4 is replaced by CD_4 showed that, in the oxidation by oxygen, one cannot postulate the existence of a single stage determining the rate of the process,[184] whilst in the oxidation by N_2O such a stage is the reoxidation of the catalyst active centres.

The study of the oxidation–reduction properties of the Li/MgO catalyst showed that its reduction by hydrogen-containing reductants is not accompanied by the evolution of water, or at least that the dehydration of the reduced surface is a very slow process.[153,185] However, when oxygen is supplied to a specimen reduced by hydrogen or hydrocarbons, a rapid evolution of water is observed. When N_2O is introduced, the specimen is reoxidised at temperatures below 700 °C solely by the molecular oxygen formed to a small extent in the catalytic decomposition of N_2O. This led to the conclusion that the traditional mechanism of the oxidation-reduction processes, according to which stage (17) is followed by the dehydroxylation stage

$$2\ [OH]_s \rightarrow [O^{\cdot -}]_s + [O]_s + H_2O, \quad (23)$$

and the oxygen vacancies $[O^{\cdot -}]$ formed are filled as a result of the chemisorption of oxidants from the gas phase, i.e.

$$[O^{\cdot -}]_s + \tfrac{1}{2}O_2 \rightarrow [O]_s, \quad (24)$$

or

$$[O^{\cdot -}]_s + N_2O \rightarrow [O]_s + N_2, \quad (25)$$

does not operate in oxide systems with a high lattice oxygen $[O]_s$ bond energy because stage (23) is reversible and the equilibrium is greatly displaced to the left. This conclusion has been confirmed by thermochemical data.[186] Naturally, in the absence (or at a very low concentration) of oxygen vacancies, the reoxidation via reaction (24) or (25) is impossible. However, molecular oxygen is nevertheless capable of reoxidising a surface coated by hydroxy-groups via the overall reaction

$$4\ [OH]_s + O_2 \rightarrow 2\ H_2O + 4\ [O]_s. \quad (26)$$

According to the data of Sinev et al.,[185] this unusual 'oxidative dehydrogenation' of the catalyst active centres can proceed via the following stages:

$$[OH]_s + O_2 \rightarrow [O]_s + HO_2^{\cdot}, \quad (27)$$

$$[OH]_s + HO_2^{\cdot} \rightarrow [O]_s + H_2O_2, \quad (28)$$

$$H_2O_2 \rightarrow 2\ OH_2^{\cdot}, \quad (29)$$

$$[OH]_s + OH^{\cdot} \rightarrow [O]_s + H_2O. \quad (30)$$

The sum of stages (27)–(30) gives rise to the oveall equation (26). Among the heterogeneous stages leading to the reoxidation of the active centres, stage (27) is slowest. Its rate constant is higher the lower the O–H bond energy in $[OH]_s$.

The modelling of the reoxidation process via the proposed mechanism using the rate constants for stages (27), (28), and (30), estimated from Sinev's thermochemical data,[187] and the known rate constant for the homogeneous decomposition of hydrogen peroxide demonstrated a satisfactory agreement with experimental kinetic data.[186] There is so far no direct evidence that the reoxidation proceeds via the proposed mechanism. However, the data[126] indicating the presence of $OH^{\cdot}$ radicals in the gas phase may serve as indirect evidence for the validity of the mechanism (27)–(30) and hence for the heterogeneous–homogeneous radical nature of the reoxidation of the reduced oxide surface.

It is important to note that reaction (27), which is of key importance in the mechanism (27)–(30), is stoichiometrically identical with reaction (3), which, according to Azatyan,[23] is responsible for many of the characteristics of the RCP involving the oxidation of various hydrogen-containing compounds or mixtures (see Secion II). This confirms yet again the close relation between heterogeneous processes (in the given instance, the transformation of the active surface centres on oxide catalysts) and radical reactions.

In conclusion of this Section, we may note that there are numerous publications in the literature devoted to the mechanism of the formation of radicals under the conditions of oxidation reactions on oxide catalysts. Unfortunately, this cannot be said about metallic catalysts, although fairly extensive factual data on the release of radicals from the surfaces of metals into the free volume have accumulated.

5. The mechanism of the interaction of radicals with the surface of a solid

One can postulate that the subsequent fate of the radicals formed in particular heterogeneous reactions depends in the general case on the relation between the number of collisions of the radicals in the gas phase and with the surface and also on the nature and reactivity of the surface centres.

The reactions of radicals in the gas phase have been investigated widely by various methods and for many of them reliable kinetic data have been obtained and have been treated systematically in numerous monographs, reviews, and data banks (see, for example, Refs 188–190). Unfortunately, this cannot be said about the heterogeneous reactions of radicals, for which, as already mentioned, it is frequently difficult to specify even their stoichiometry. On the other hand, if the catalyst pores are

sufficiently narrow and tortuous and the species diffuse in them in Knudsen or transitional regimes, then the number of collisions of the radicals with the surface is large and the contribution of these reactions to the overall formation of the catalytic reaction products and to the process selectivity may be decisive.

The influence of the porosity on the heterogeneous radical destruction processes has been investigated.[191] The radicals ($CH_3O_2^{\bullet}$, $C_4H_9O_2^{\bullet}$, $C_3H_5^{\bullet}$, and $C_3H_5O_2^{\bullet}$) were generated in the first part of a two-section reactor and were then directed to SiO_2 and Al_2O_3 specimens having different specific surfaces and porosities. The peroxy-radicals proved to be more reactive than the corresponding hydrocarbon radicals. An increase in pore radius leads to an increase in the rate of destruction of the radicals, which indicates easier permeation of the radicals into the grain and an increase in the effective area of the surface on which their destruction takes place. The recapture of the radicals formed from C_1-C_4 hydrocarbons on irradiated MgO [74] leads to the surface alkoxy-groups $[OR]_s$. Their decomposition under the conditions of programmed thermal desorption results in the formation of the corresponding alkenes from the C_2-C_4 alkanes:

$$[OC_nH_{2n+1}]_s \rightarrow [OH]_s + C_nH_{2n}, \quad (31)$$

and of CO and H_2 from methane:

$$[OCH_3]_s \rightarrow CO + \tfrac{3}{2}H_2. \quad (32)$$

In view of the unusual importance of the heterogeneous radical reactions for the OCM process, numerous studies have been devoted to the interaction of methyl radicals with various oxides. The types of reactions of the $CH_3^{\bullet}$ radicals on different surfaces are apparently determined by the differences between the properties of the active centres and in the first place the surface oxygen. Depending on the electronic properties of the oxide and on the cation in the coordination sphere of which the oxygen ion is present, the probability of the formation of methoxy-groups and their reactivity may vary greatly.

The kinetics of the accumulation and consumption of the $[OCH_3]_s$ groups formed on recapture of the methyl radicals by the oxidised Al_2O_3, CaO, and BaO surfaces have been investigated[133-136] by the IR spectroscopy of surface electromagnetic waves and by reflection-absorption IR spectroscopy. The activation energy for the formation of methoxy-groups from methane varied in the range from 63 (BaO) to 126 (Al_2O_3) kJ mol^{-1}, while the activation energy for their subsequent conversion into formate groups was 21 – 33 kJ mol^{-1}.

Quantum-chemical calculations for the interaction of $CH_3^{\bullet}$ radicals with MoO_3 showed [175,176] that methoxy-groups of two different types may be formed: with $O-CH_3$ bond energies of ~38 and ~272 kJ mol^{-1}. The methoxy-groups of the first type may be formed when the radicals are captured by the O^{2-} or O^- ions formed on irradiation. The presence of stable (chemically generated) O^- ions on the surface was responsible for the strong binding of the radicals and the formation of stable methoxy-groups (second type).

The study of the reactivities of various oxides in the relation to the $CH_3^{\bullet}$ radicals generated catalytically in the CH_4+O_2 reaction showed that the typical OCM catalysts (MgO, Li/MgO) are almost 'transparent' towards the radicals, while the catalysts for the extensive (ZnO, NiO, CeO_2) and partial (MoO_3/SiO_2) oxidation capture them effectively.[192,193] An electron is transferred when the $Mo^{6+} \rightarrow Mo^{5+}$ transition takes place in the interaction of the methyl radical with MoO_3/SiO_2; in the case of CeO_2, an electron is transferred to an adsorbed oxygen molecule with formation of $O_2^{\bullet}$. The methoxy-group is successively converted into a formate group, which ultimately leads to the formation of carbon oxides.

A similar investigation but with azomethane as the source of radicals and a Knudsen cell as the reactor showed that at 650 °C the probability of the capture of $CH_3^{\bullet}$ radicals by the surfaces of typical OCM catalysts (La_2O_3, Li/MgO, Sr/La_2O_3) in the absence of oxygen from the gas phase is ~10^{-7}, increases to ~10^{-6}, and remains unchanged at $P_{O_2} = (1-18) \times 10^{-4}$ Torr.[194] The absence of a dependence of the probability of capture on the oxygen pressure in this range shows that the species interacting with the surface is the $CH_3^{\bullet}$ radical and not $CH_3O_2^{\bullet}$, the concentration of which increases in proportion to P_{O_2}. On ZnO and CeO_2, the probability of capture in the absence of oxygen is close to 10^{-5}, diminishing somewhat with increase in P_{O_2} from 0 to 1.8×10^{-3} Torr. The introduction of N_2O into the gas phase does not affect the process. The activation energy for the capture of the radicals on different oxides is 13 – 33 kJ mol^{-1}.

An attempt has been made[195] to determine the types of the reactions of the $CH_3^{\bullet}$ radicals obtained by irradiating different oxides under a methane atmosphere. In the absence of a catalyst, the formation of any kind of product has not been detected; on the other hand, in the presence of catalysts ethane and CO appear, the rates and selectivities of the formation on different oxides differing significantly and depending on the preliminary treatment. The authors suggest that irradiation promotes the generation of $CH_3^{\bullet}$ radicals and their capture by the surface oxygen ions leads to the formation of methoxy-groups, which decompose with evolution of CO and H_2.

Whereas the capture of methyl radicals by the surfaces of the OCM or extensive oxidation catalysts leads to the formation of carbon oxides, in the case of vanadium, molybdenum, and possibly tungsten oxides the conversion of the methoxy-groups into partial oxidation products has been postulated.[161] This has been demonstrated[196] by direct experiments involving the interaction of the $CH_3^{\bullet}$ radicals, obtained as a result of the decomposition of azomethane, with the MoO_3 and MoO_3/SiO_2 catalysts. In the presence of water vapour, the authors observed the formation of methanol, while under a dry atmosphere formaldehyde was formed, which confirms the possibility of the partial oxidation of methane on MoO_3-containing catalysts via the formation and recapture of a surface methyl radical:

$$Mo^{VI}O^{2-} + CH_3^{\bullet} \rightarrow Mo^{V}OCH_3^{-}. \quad (33)$$

Depending on the presence or absence of water in the gas phase, either the hydrolysis of the methoxy-groups with formation of methanol or their decomposition with formation of formaldehyde may take place.

There are also data showing that the methoxy-groups can themselves be a source of methyl radicals.[197,198] In particular, the formation of methyl radicals has been observed in the temperature range 525 – 650 K on programmed heating of a molybdenum single crystal, on the (110) face of which initially oxygen (0.15 – 0.50 of a monolayer) and then methanol (at 120 K) are adsorbed.[197] This may indicate the reversibility of reaction (33) and the validity of the quantum-chemical calculations.[175,176]

The results of studies on the interaction of $CH_3^{\bullet}$ radicals with clean and oxidised metal surfaces have been published recently.[120-122] The molecular beam method combined with methods involving the simultaneous investigation of the surface and surface compounds were employed in these studies.

On the oxygen-modified (100) face of a molybdenum single crystal, the adsorption of radicals is observed even at room temperature.[120] If the surface coverage by oxygen is incomplete, then the dehydrogenation and disproportionation of the methyl fragments take place on heating with evolution of methane and hydrogen into the gas phase and the formation of surface carbon, which reacts in its turn with the oxygen present on the surface, affording CO. The maximum rates of evolution of methane, hydrogen, and CO are attained at ~500 K; the CO evolution curve has a second maximum at 950 K. If no free metal atoms (not coated by oxygen) remain on the surface, then the second CO evolution peak is absent and the rate of evolution of methane diminishes, tending to a constant value on the surface the composition of which corresponds to MoO_2. Hence it follows that the dehydrogenation and disproportionation processes takes place more vigorously on a metal surface than on an oxide surface.

Programmed thermal desorption and reflection-absorption IR spectroscopic methods have been used[121] to investigate the interaction of methyl radicals with the (111) face of a platinum single crystal. The formation of the $Pt-CH_3$ and Pt_3CCH_3 groups (at a much lower concentration) was observed at 150 K. On heating, the liberation of ethene is observed, but ethane is not formed. The authors suggest that the methyl fragments dissociate partially to CH_2 and, tentatively, that ethene is formed in the course of one of two reactions:

$$CH_3 + CH_2 \rightarrow C_2H_5 \rightarrow C_2H_4 + H, \quad (34)$$

$$CH_2 + CH_2 \rightarrow C_2H_4. \quad (35)$$

Hall et al.[122] investigated the interaction of methyl radicals with the clean and oxidised (100) and (111) faces of a nickel single crystal. If the surface contains hydrogen or a preadsorbed hydrocarbon (for example, ethane), then methane is rapidly evolved when radicals are introduced. The adsorption of radicals on the (100) face and subsequent heating lead to the recombination of the methyl fragments with the hydrogen atoms and the evolution of methane at 220 K. On the (111) face, this process is much more vigorous. It has been shown in experiments that isotope-substituted molecules that at 240 K the methyl groups abstract a hydrogen atom from the adsorbed species and no longer from the surface. The oxidation of the surface alters completely the type of reactions: at temperatures of about 300 K, the adsorbed methyl fragments recombine with formation of ethane and the desorption of $CH_3^{\bullet}$ radicals is also observed.

Overall, one has to conclude that, although the reactions of the radicals with the solid surface are extremely important in both homogeneous gas-phase and heterogeneous-catalytic oxidation processes, their kinetics and mechanisms have not yet been investigated adequately.

IV. Conclusion

Analysis of the literature data shows that it is difficult to find examples of purely homogeneous oxidation processes in the gas phase, which are not influenced by heterogeneous factors. On the other hand, the reactions on heterogeneous catalysts are frequently accompanied by the release of free radicals into the gas phase and this is not a side process in relation to the main reaction pathway in the adsorbed layer but is an essential stage leading to the formation of the final products in homogeneous or secondary heterogeneous stages.

Taking into account the data obtained in recent years in the course of intensive investigations of the OCM and stabilised combustion processes, one may ask the question what is the meaning of the expression 'proportion of the reaction occurring in the free volume (or on the surface)' if the heterogeneous and homogeneous stages are equally inseparable components of the conversion of the reactants into products?

Another question also arises: how fundamental is the difference between the 'gas-phase' reactions, on the one hand, and 'heterogeneous–homogeneous catalytic' reactions, on the other, if in either case both the rates of the elementary processes in the gas phase and the entire set of factors determining the rates of heterogeneous processes (the chemical nature and morphology of the solid, the surface area, the purity of the surface, etc.) are equally important?

In the light of the above analysis, these differences are completely indeterminate. Refraining from more wide scale generalisations, we may venture to express the view that the boundary between the gas-phase and heterogeneous-catalytic oxidation is arbitrary and its existence is associated mainly with the fact that the studies in these two fields developed almost independently for decades. Such isolation had to some extent also a positive aspect, since it made it possible to concentrate on the 'main' process and to differentiate and investigate the characteristic features of the elementary reactions in the gas phase or on the surface of a solid, refraining from dealing with 'side' factors. However, the combination of the efforts of specialists dealing with the study of the kinetics and mechanisms of reactions in the gas phase, heterogeneous catalysis, solid state chemistry, and surface phenomena appears extremely promising. The greatest progress is to be expected in this connection as regards the development and adaptation of highly sensitive methods for the study of radical processes in heterogeneous reactions, the creation of kinetic models of complex heterophase processes, and ultimately a deeper understanding of the mechanisms of the oxidation reactions and the possibility of controlling them.

The authors acknowledge their indebtedness to the International Scientific Fund and the Russian Fundamental Research Fund for financial support (ISF Grant MN2000, RFRF grant No. 93-03-18479).

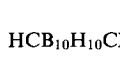
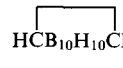
VI.	Conclusion	386



Abstract. The results of studies on polymers with arylene dicarbadodecaborane fragments in the chain are surveyed. The characteristic features of the formation of these polymers, their properties, and their unusual thermal behaviour are examined. The mechanism of the thermal transformations of polyarylenedicarbadodecaboranes is discussed. The probable usefulness of the radical arylation of dicarbadodecaboranes(12) is demonstrated. Certain aspects of the practical employment of dicarbadodecaborane-containing polymers are considered. The bibliography includes 135 references.

I. Introduction



Communications appeared in 1962–1964 about the synthesis of new organoboron compounds having the empirical formula $C_2B_nH_{n+2}$ and, in particular, the compound $C_2B_{10}H_{12}$ – dicarba-*closo*-dodecaborane(12) (its trivial names are 'carborane' or 'barene'),[1–10] for which three isomeric forms are known:

1,2-Dicarba-*closo*-dodecaborane(12) (*o*-carborane)†

1,7-Dicarba-*closo*-dodecaborane(12) (*m*-carborane)

1,12-dicarba-*closo*-dodecaborane (12) (*p*-carborane)

The first dicarbadodecaborane-containing polymers were also obtained almost at the same time.[10,11] A large number of various heterochain and carbochain polymers with 1,2-, 1,7-, and 1,12-dicarbadodecaborane fragments in the chain have been synthesised since that time and data on these polymers have been described in numerous review-type communications.[12–28]

The introduction of dicarbadecaborane-containing fragments into the polymer chain appeared attractive, since investigators hoped to obtain polymers with improved thermal characteristics, because dicarbadodecaboranes are thermally stable: 1,2-dicarbadodecaborane withstands heating under an inert atmosphere to 475 °C, after which it isomerises to the more stable 1,7-dicarbadodecaborane;[29] when 1,2-dicarbadodecaborane is heated at 700 °C, a mixture of 1,7- and 1,12-dicarbadodecaboranes is obtained;[30] prolonged heating of 1,7-dicarbadodecaborane at 615 °C afforded 1,12-dicarbadodecaborane.[31]

At the same time, in the first stages investigators encountered difficulties in the preparation of high-molecular-mass polymers from bifunctional dicarbadodecaborane derivatives [for example, 1,2- and 1,7-bis(hydroxymethyl)dicarbadodecaboranes, 1,2- and 1,7-bis(carboxymethyl)dicarbadodecaboranes, and their derivatives].[12,24–27,32] It was suggested[12,23,25,27] that this is due to the specific properties of dicarbadodecaborane, which constitutes a strongly electron-accepting group, and also the structural characteristics and the associated steric hindrance in the reactions involving the synthesis of the polymers. However, by virtue of the development and the determination of the principal characteristic features of the polymer formation reactions and in particular polycondensation, the difficulties in achieving high molecular masses in the synthesis of dicarbadodecaborane-containing polymers were overcome and true high-molecular-mass polymers were obtained.

Dicarbadodecaborane-containing monomers with functional groups directly attached to the dicarbadodecaborane nucleus [1,7- and 1,12-dicarbadodecaborane-dicarboxylic acid, 1,7- and 1,12-dicarbadodecaboranylenediamines, and 1,2- and 1,7-bis-(hydroxymethyl)dicarbadodecaboranes] have been widely used in the synthesis of dicarbadodecaborane polymers. Diverse heterochain polymers have been obtained from these starting materials: polyesters, polyamides, polybenzimidazoles, polyoxadiazoles, polybenzoxazoles, polyimides, and many others.[12,19–27,32–34] However, the search for methods of synthesis of polymeric systems with enhanced thermal characteristics led to the conclusion that the use of functional aromatic derivatives of dicarbadodecaborane is promising for the synthesis of dicarbadodecaborane-containing polymers. Since the end of the 1960s, the chemistry of dicarbadodecaborane-containing polymers began to develop successfully. The results of studies in this field are examined and surveyed in the present review.

† Unless otherwise stated, henceforth dicarba-*closo*-dodecaborane(12) will be abbreviated to dicarbadodecaborane (Translator).

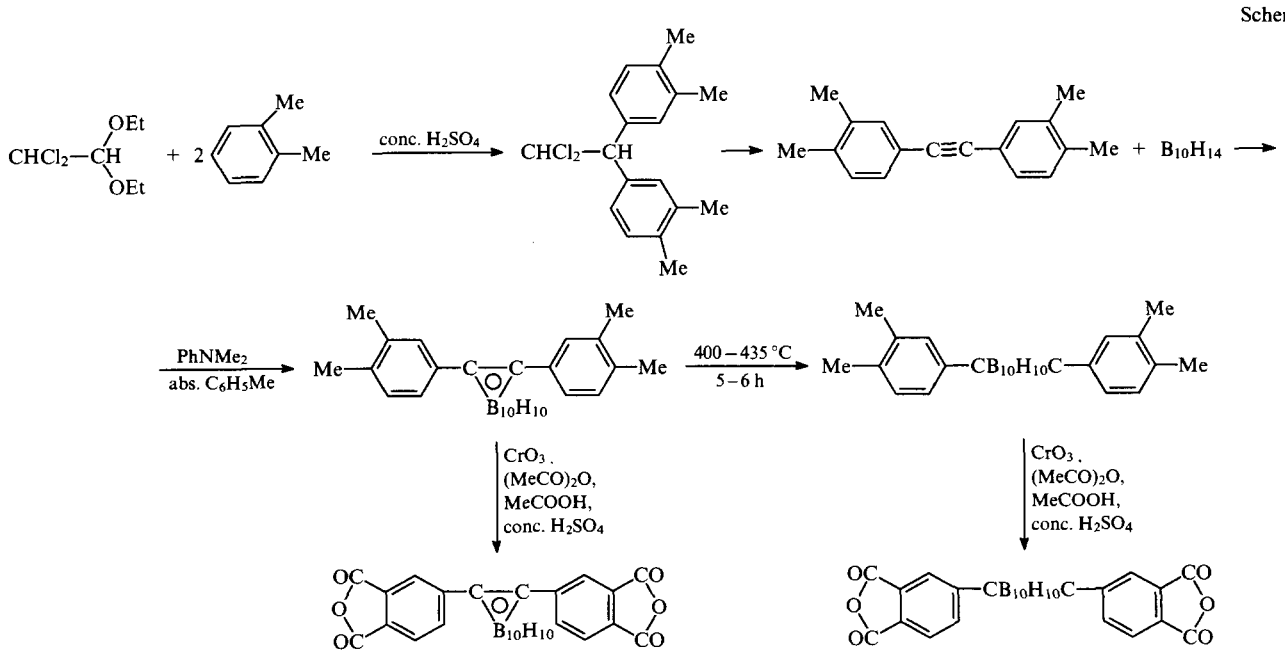
II. Synthesis of aromatic bifunctional derivatives of dicarbadodecaborane(12)

Synthesis of polymers with diarylenedicarbadodecaborane fragments in the macromolecule requires functional aromatic derivatives of dicarbadodecaborane with the corresponding structure. At the beginning of studies in this field, there was no information in the literature about the synthesis of di- and tetrafunctional aromatic derivatives of dicarbadodecaborane. Therefore, in the first stage of this research, much attention was devoted to the chemistry of these monomers. This led to the development of methods of synthesis of compounds such as 1,2- and 1,7-bis(4-carboxyphenyl)dicarbadodecaboranes, their chlorides, and their dihydrazides, 1,2-bis(4-hydroxyphenyl)-dicarbadodecaborane, the dianhydrides of 1,2- and 1,7-bis-(3,4-dicarboxyphenyl)dicarbadodecaboranes, etc.[35-39] Schemes for the synthesis of some of them are presented below as examples.



Scheme 1

Scheme 2

Scheme 3

Thus 1,2- and 1,7-bis(4-carboxyphenyl)dicarbadodecaboranes were obtained by oxidising the corresponding ditolyl derivatives of 1,2- and 1,7-dicarbadodecaboranes with chromium trioxide.[35] Scheme 1 illustrates the synthesis of these dicarboxylic acids and their chlorides. 1,2-Bis-(4-hydroxyphenyl)-dicarbadodecaborane was synthesised in accordance with Scheme 2.[36]

The dianhydrides of 1,2- and 1,7-bis(3,4-dicarboxyphenyl)-dicarbadodecaborane were obtained in accordance with Scheme 3.[37,38] The tetramethyltolane required for this purpose was synthesised both by the reaction of asymmetric dichlorodisilylethanes with $NaNH_2$ in aromatic hydrocarbons and by the dehydrochlorination of the same compounds with the aid of KOH in dimethyl sulfoxide.

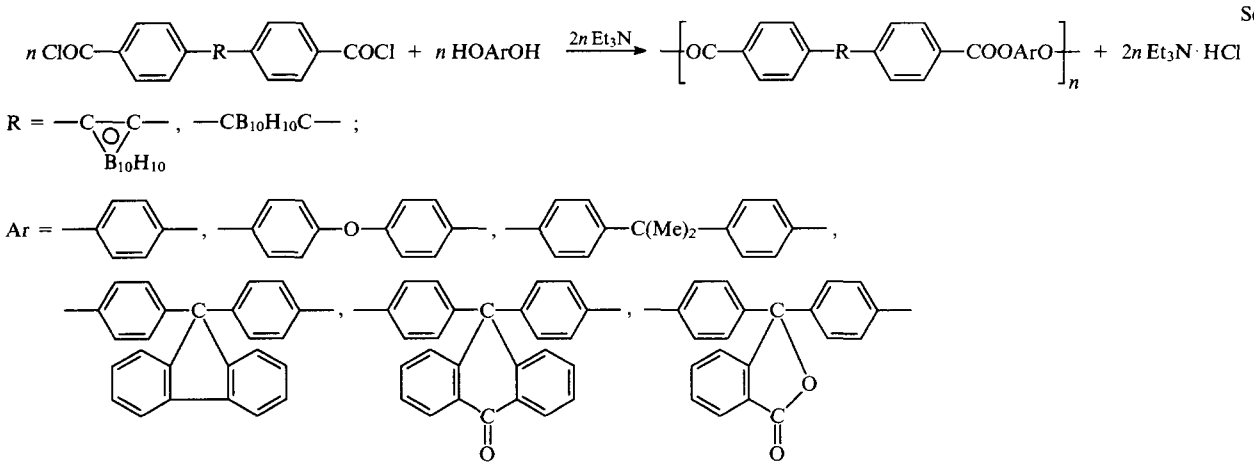
A fairly large set of the initial functional diarylenedicarbadodecaboranes made it possible to synthesise a wide variety of linear aromatic dicarbadodecaborane-containing heterochain polymers, including polymers with heterocycles in the chain: polyarylates, polyesterketones, polyamides, poly-1,3,4-oxadiazoles, polyimides, polyazophenylenedicarbadodecaboranes, as well as thermoreactive polymers of the type of polyphenylene, and phenol-formaldehyde and epoxide polymers.

III. Linear heterochain polymers with diarylenedicarbadodecaborane fragments in the chain

Polyarylates, polyesterketones, aromatic polyamides, poly-1,3,4-oxadiazoles, polyimides, and polyazophenylenedicarbadodecaboranes with diarylenedicarbadodecaborane fragments in the chain are considered in this section.

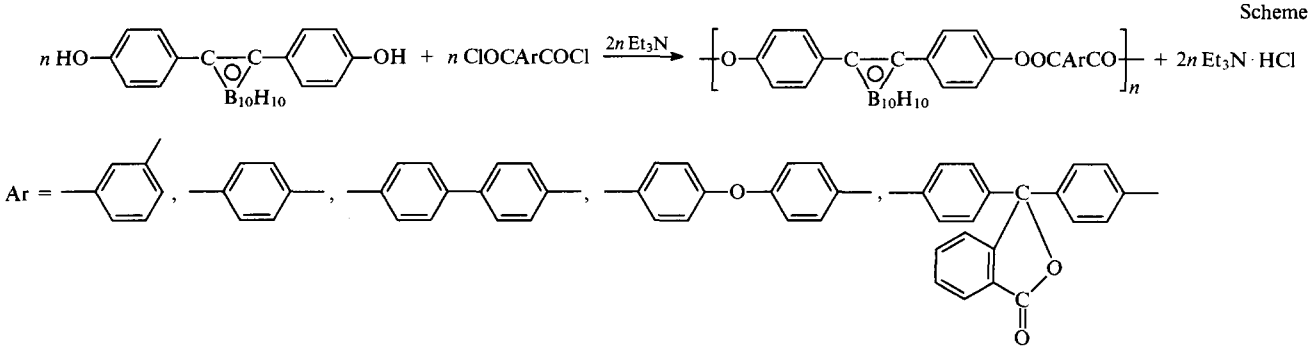
1. Polyarylates

The synthesis of dicarbadodecaborane-containing polyarylates with diarylene-dicarbadodecaborane fragments in the chain was achieved by the high-temperature or acceptor-catalytic [in the presence of triethylamine (Schemes 4–6)] polycondensation in three versions:



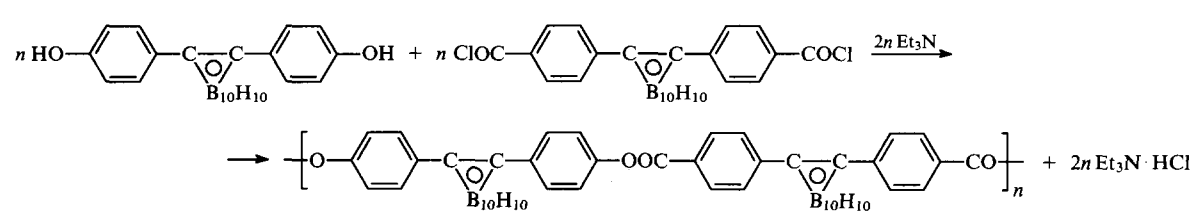
(1) by the reaction of the chlorides of 1,2- and 1,7-bis-(4-carboxyphenyl)dicarbadodecaboranes with various dihydric phenols;

(2) From 1,2-bis(4-hydroxphenyl)dicarbadodecaborane (phenolcarborane) and the chlorides of various aromatic dicarboxylic acids;



(3) By the reaction of 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane with the chloride of 1,2-bis(4-carboxyphenyl)dicarbadodecaborane.

The characteristics of formation of these polymers and their properties have been examined in a series of studies.[21,25,40–60]



Scheme 4

Scheme 5

Scheme 6

In order to find ways of synthesising high-molecular-mass polyarylates derived from 1,2- and 1,7-bis(4-carboxyphenyl)-dicarbadodecaborane, a series of characteristics of the synthesis of these polymers under the conditions of acceptor-catalytic and high-temperature polycondensation in solution have been investigated in relation to the polycondensation of the chlorides of these acids with 9,9-bis(4-hydroxyphenyl)fluorene (phenol-fluorene). The influence of the nature of the solvent, the concentrations of the starting materials, the reaction temperature, the reaction time, and the method used to introduce the monomers on the molecular mass and yield of the polymers were studied. It was found that both procedures can be successfully employed to synthesise high-molecular-mass polymers (Table 1).

In the acceptor-catalytic polycondensation, polymers with a high molecular mass are obtained when the process is carried out in acetone at 45–50 °C for 1 h with a solid acid chloride introduced into a solution of the bisphenol and triethylamine.

The study of the polycondensation occurring on heating in high-boiling solvents showed that the molecular mass of the dicarbadodecaborane-containing polyarylates is influenced significantly both by the nature of the solvent and by the concentrations of the initial compounds. The most suitable solvent proved to be Sovol (chlorinated biphenyl) and α-chloronaphthalene. The optimum concentrations of the starting materials were 1–2 M. The polycondensation was carried out at 220 °C for 10–16 h. The yields of the dicarbadodecaborane-containing polyarylates [of 1,2- and 1,7-bis(4-carboxyphenyl)dicarbadodecaboranes] were nearly quantitative both in the acceptor-catalytic and in the high-temperature polyesterification. Table 2 presents certain properties of the polyarylates derived from 1,2- and 1,7-bis(4-carboxyphenyl)dicarbadodecaboranes.

The interesting influence of the bulky cardo-group on the structure of the dicarbadodecaborane-containing polyarylates under consideration is noteworthy.[40] Thus the polyarylates derived from 1,2-bis(4-carboxyphenyl)dicarbadodecaborane and dihydric phenols containing bulky groups of the cardo-type (phthalide, fluorene, and anthrone) possess a crystallinity with an average degree of order according to X-ray diffraction data.

Table 1. The reduced viscosities (η_{red}) and molecular masses (M_w) of polyarylates obtained from the acid chlorides of 1,2- (**A**) and 1,7-bis-(4-carboxyphenyl)dicarbadodecaboranes (**B**) and various dihydric phenols by acceptor-catalytic (1) and high-temperature (2) polycondensation.

Initial components in the synthesis of polyarylates		η_{red}/dl g^{-1}		$10^{-3} M_w$	
		1	2	1	2
dihydric phenol	acid chloride				
Hydroquinone	**A**	0.6	0.3	–	–
	B	0.6	0.9	–	–
Bis(4-hydroxyphenyl) ether	**A**	0.6	0.9	116	107
	B	2.0	1.9	94	132
2,2-Bis(4-hydroxy-phenyl)propane	**A**	0.9	–	110	–
	B	0.6	2.3	22	–
9,9-Bis(4-hydroxy-phenyl) fluorene	**A**	0.9	2.3	99	80
	B	1.3	1.2	50	27
9,9-Bis(4-hydroxy-phenyl)-10-anthrone (phenolanthrone)	**A**	0.9	0.5	66	52
	B	1.1	0.7	76	–
Phenolphthalein	**A**	1.2	–	–	–
	B	2.0	2.4	–	–

Note. η_{red} was obtained for a 0.5% solution of the polymer in tetrachloroethane at 25 °C; M_w was determined by light scattering in chloroform.

On the other hand, an amorphous or a weakly ordered structure is characteristic of dicarbadodecaborane-containing polyarylates based on dihydric phenols such as hydroquinone, di(4-hydroxyphenyl) ether, and 2,2-bis(4-hydroxyphenyl) propane.

The polyarylates obtained from the more symmetrical 1,7-isomer and dihydric phenols of the type of hydroquinone

Table 2. The properties of polyarylates obtained from the acid chlorides of 1,2- (**A**) and 1,7-bis(4-carboxyphenyl)dicarbadodecaboranes (**B**) and various dihydric phenols by acceptor-catalytic polyesterification.

[a] The temperature corresponding to the point of intersection of the tangents to the thermomechanical curve in the region of the onset of flow was adopted as the softening temperature; the load applied to the specimen was 0.8 kgf cm^{-2} and the heating rate was 70 K min^{-1}.
[b] σ is the tensile strength of a nonoriented film and ε is the relative elongation at break.
[c] Determined from the thermogravimetric curve at a heating rate of 4.5 K min^{-1} in air.
[d] Determined under isothermal conditions in air in the course of 3 h.

or 2,2-bis(4-hydroxyphenyl)propane have a more ordered structure than those derived from the 1,2-bis(4-carboxyphenyl)-dicarbadodecaborane.[42] According to X-ray diffraction data, the former polyarylates have a fairly high degree of order. The polyarylates derived from 1,7-bis(4-carboxyphenyl)dicarbadodecaborane and dihydric phenols with a cardo-group differ little as regards the degree of order from the analogous polymers based on the 1,2-dicarbadodecaborane-containing monomer. On passing to the polyarylates based on the 1,7-isomer, only a slight tendency towards the formation of an amorphous structure may be noted.[42]

The softening temperatures of the polyarylates based on the 1,2- and 1,7-isomers of bis(4-carboxyphenyl)dicarbadodecaborane and dihydric phenols having the same structure are similar for the same phase state. The highest softening temperatures (340–360 °C) are characteristic of the polyarylates derived from dihydric cardophenols.

The polyarylates derived from both isomers of bis(4-carboxylphenyl)dicarbadodecaborane dissolve in many organic solvents, including aromatic hydrocarbons.[42] The study of the hydrodynamic properties of the solutions and of the molecular mass distribution (MMD) of polyarylates based on 1,2- and 1,7-bis(4-carboxyphenyl)dicarbadodecaboranes led to the discovery of the specific nature of the interaction with the solvent of the polyarylates containing 1,2- and 1,7-dicarbadodecaborane fragments in the chain.[43] Whilst the molecular masses of the polyarylates with the 1,7-diphenyldicarbadodecaborane fragments in the chain are similar, the latter have significantly higher specific viscosities than the analogous polymers with the 1,2-diphenyldicarbadodecaborane fragments regardless of the method of synthesis. This made it possible to postulate that the polyarylates based on 1,2-bis(4-carboxyphenyl)dicarbadodecaborane exists in solution as denser macromolecular coils than can be accounted for by both steric factors and by the greater influence of the dipole moment in the case of the polyarylates with the 1,2-dicarbadodecaborane groups.

The parameters K and a in the Mark–Houwink equation have been determined for the polyarylate obtained from 1,7-bis-(4-carboxyphenyl)dicarbadodecaborane and bis(4-hydroxyphenyl) ether.[43] In chloroform and tetrahydrofuran (THF), $K = 4.74 \times 10^{-4}$ and 2.7×10^{-4}, while $a = 0.71$ and 0.70 respectively. The polydispersity coefficient for the polymer under consideration, synthesised by acceptor-catalytic polyesterification, is 1.35, indicating its comparatively narrow MMD.[43]

The mechanisms of the relaxation processes in the polyarylates based on 1,2- and 1,7-bis(4-carboxyphenyl)dicarba-dodecaboranes have been investigated by dielectric proton magnetic resonance spectrometry and by the thermodepolarisation and radiothermoluminescence methods over a wide temperature range (from −196–300 °C).[44,45,50,58] This led to the establishment of the existence of two regions where the resonance line becomes narrower, one of which (the high-temperature region) is near the glass points of the polymers and is due to the segmental motion of the polymer chain, while the other (the low-temperature region −50 to 150 °C) is induced by the local mobility of the dicarbadodecaborane chain frag-ments. The temperature corresponding to the 'unfreezing' of the segmental mobility depends significantly on the chemical structure of the dihydric phenol and depends little on the structure of the diphenyldicarbadodecaborane fragments incorporated in the chain.

It has also been shown that the vibrations of the 1,2-dicarbadodecaborane nucleus are hindered compared with the 1,7-isomer both by the appreciable conjugation of the 1,2-dicarbadodecaborane fragment with the aromatic rings and due to steric effects. This is reflected in the relaxation processes in the dicarbadodecaborane-containing polyesters, the results of the study of which indicate an increase in the rigidity of the macrochain on passing from the 1,7- to the 1,2-dicarbadodecaborane-containing polymers.[44,58]

Colourless films, the strength parameters of which are listed in Table 2, are obtained from the 1,2- and 1,7-bis(4-carboxyphenyl)dicarbadodecaborane-based polyarylates by casting the latter from solution.

A series of studies have been carried out on the thermal properties of the 1,2- and 1,7-bis(4-carboxyphenyl)dicarba-dodecaborane-based polyarylates in air and under an inert atmosphere — under both dynamic and isothermal conditions.[21,25,40–42,46–49,51,59] It was found that the initial polymer degradation temperature is 20–60 °C higher than for the usual polyarylates and, furthermore, the polyarylates have greater 'coke' residues (50%–90% relative to the initial mass on heating in air to 900 °C), whereas the usual polyarylates derived from terephthalic acid and 1,9-bis(4-hydroxyphenyl)fluorene are fully combusted at 650–700 °C. Table 2 shows that, after heating in air at 400 °C for 3 h, the mass of dicarbadodecaborane-containing polymers diminishes by 2%–15%, whereas the 1,9-bis-(4-hydroxyphenyl)fluorene polyterephthalate begins to decompose even before 400 °C and its degree of decomposition after 3 h is 35%. Analysis of the gaseous products of the degradation of the dicarbadodecaborane-containing polyarylates under consideration demonstrated the presence in them of a lower content of carbon oxides and an appreciable content of hydrogen.[21,25,48,49]

The survey of the data obtained established that the dicarbadodecaborane nuclei in the polymer chain have a stabilising effect on the thermal stability of the ester linkage, increasing thereby the thermal stability of the polymer. It has been suggested that this stabilising effect of 1,2-dicarbadodecaborane groups is associated with their conversion into dicarbaundecaborate groups.[48]

A comparative study of the thermal behaviour of the polyarylates obtained by the reaction of 9,9-bis(4-hydroxyphenyl)fluorene with 1,2-bis(4-carboxyphenyl)dicarbadodecaborane and terephthalic acid revealed an interesting feature:[47] in vacuo, gel formation in the 1,2-dicarbadodecaborane-containing polyarylates begins sooner than in polyfluoreneterephthalate [poly(9,9-fluorenylenediphenyl terephthalate)? (translator)] and reaches a maximum at 350 °C, whilst the gel content in the case of polyfluoreneterephthalate is only 2.7%. Under oxidation conditions, the dicarbadodecaborane-containing polyarylate is already fully cross-linked at 275 °C, whereas polyfluoreneterephthalate contains only 30% of the gel at 350 °C.

A study has been made of the structural-chemical transformations of 1,2- and 1,7-dicarbadodecaborane-containing polyarylates during isothermal heating in the temperature range 225–325 °C (at 25 °C intervals) in vacuo and in the presence of oxygen by means of IR spectroscopy and sol-gel analysis.[59] Analysis of the results led to the conclusion that, during vacuum heating and under oxidation conditions, the dicarbadodecaborane fragments participate in the cross-linking of the polymer chain of the dicarbadodecaborane-containing polyarylates, forming inorganic intermolecular B–O–B linkages. In terms of their ability to form three-dimensional structures, the 1,7-dicarbadodecaborane-containing polyarylates are superior to the 1,2-dicarbadodecaborane polymers.

The electrical conductivities of the solid pyrolysis products formed on heat treatment of the polyarylate obtained by the reaction of 1,7-bis(4-carboxyphenyl)dicarbadodecaborane and bis(4-hydroxyphenyl) ether for 1 h in vacuo (10^{-3} Torr) at 600, 900, and 1200 °C have been investigated by electronic spectroscopy.[60] The aromatic rings in the polymer chain of this polyarylate are separated (apart from the dicarbadodecaborane fragments) also by ester groups, which do not transmit π-conjugation along the chain, as a result of which the degree of conjugation of the initial system is low and the system does not exhibit semiconducting properties. The comparatively small changes in the electrical conductivities and activation energies for the specimens heated to 600 °C indicate a low degree of reorganisation of the internal structure of the polymer, leading to the formation of condensed polynuclear systems in the solid pyrolysis products. The electrical conductivity at 150 °C of the specimen heated to 900 °C increases by approximately

twelve orders of magnitude compared with the initial polymer and the electrical conduction process becomes nonactivated ($E \approx 2.89$ kJ mol^{-1}). In terms of the absolute value of the electrical conductivity, this pyrolysis product is at the boundary between semiconductors and metals. The observed change in electrical conductivity is due to the formation of highly conjugated polynuclear systems in the pyrolysis product.

The absolute values of the electrical conductivities of the specimens heated to 1200 °C increase slightly compared with the electrical conductivity of the specimen heated to 900 °C, but, after heating at 1200 °C, a negative temperature coefficient of the resistance, $\alpha = -0.12$ K^{-1} is observed, i.e. with increase in temperature the electrical conductivity of the specimens does not increase, as in typical semiconducting materials, but actually diminishes, which is characteristic of materials with the metallic type of conductivity. Consequently heat treatment of the specimens at 900–1200 °C is accompanied by a significant reorganisation of the internal structure. The thermal e.m.f.'s of the specimens obtained at 900 and 1200 °C are respectively 9.3 and 6.8 μVK^{-1} at 100 °C. The sign of the thermal e.m.f. shows that the principal electric current carriers are electrons. Thus the pyrolysis of the dicarbadodecaborane-containing polyarylate leads to the formation of an extended region of aromatic ring systems cross-linked in space by the residual dicarbadodecaborane fragments.

As noted above, 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane has been used to synthesise polyarylates with diphenyldicarbadodecaborane fragments in the chain.[21,54–56] 1,2-Bis(4-hydroxyphenyl)dicarbadodecaborane was subjected to acceptor-catalytic and high-temperature polycondensation with dicarboxylic acid chlorides (see Scheme 5). A number of characteristic features of these processes have been investigated in relation to the polycondensation of 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane with isophthalic acid chloride: influence of the nature of the solvent, temperature, concentrations of initial substances, and the order in which they are introduced into the reaction sphere, on the reduced viscosities of the solutions of the polymers obtained and their structures.

It was found that, when the acceptor-catalytic polyesterification is carried out in acetone (heterogeneous conditions), changes in the process temperature, in the concentrations of the starting materials, and in the order in which they are introduced into the reaction zone did not lead to the formation of polymers with a high reduced viscosity of the solution. A positive result was not obtained either when the acceptor-catalytic polycondensation was carried out under homogeneous conditions (in dichloroethane, tetrahydrofuran, dioxane, and benzene) and also when the synthesis was performed by high-temperature polycondensation in Sovol and α-chloronaphthalene at 220 °C. In all cases, polymers with low reduced viscosities of the solutions (0.07–0.31 dl g^{-1} in tetrachloroethane) were obtained. The molecular mass of a polymer with a reduced viscosity of 0.07 dl g^{-1}, determined by the light scattering method in tetrahydrofuran, was 8600. The reason for the formation of polymers with low molecular masses is their limited solubility in the reaction medium due to the crystallisation of the polymers during their formation.[55]

The tendency of the 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane-based polyarylates to form highly ordered and sparingly soluble systems is manifested to an even greater extent in the polycondensation of 1,2-bis(4-hydroxyphenyl)-dicarbadodecaborane with terephthalic and biphenyl-4,4′-dicarboxylic acid chlorides. Such polyarylates, obtained by high-temperature polycondensation, have a highly ordered crystal structure according to X-ray diffraction data and do not dissolve in any of the solvents known for polyarylates even such as trifluoroacetic and sulfuric acids. Polymers with a lower degree of order are formed in the acceptor-catalytic polycondensation, but in this case too the terephthalic acid-based polyarylates are insoluble.[55]

Attempts have been made to obtain the above polyarylates by high-temperature polycondensation using finely dispersed magnesium as the catalyst and also by the rapid heating of the initial components in a high-boiling solvent to 250–340 °C with subsequent polycondensation at these temperatures for 1 h and rapid cooling of the initial solution to room temperature. In this case, the poly[1,2-bis(4-hydroxyphenyl)dicarbadodecaborane terephthalate] dissolved immediately after synthesis in a mixture of tetrachloroethane and phenol, but it soon precipitated and then no longer dissolved.[55]

On the other hand, under conditions where the polymers formed are amorphous and readily soluble, it is possible to attain high molecular masses. This occurs in the polycondensation of 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane with the chlorides of oxybis(benzene-4-carboxylic)acid and bis(4-carboxyphenyl)-phthalide. In the former case, it was possible to obtain a polymer with a reduced viscosity in tetrachloroethane (TCE) of 0.92 dl g^{-1} (molecular mass 140 × 10^3), while in the latter the reduced viscosity was 0.62 dl g^{-1} (molecular mass 93 × 10^3). Both polymers are soluble in chloroform, tetrachloroethane, tetrahydrofuran, and benzene.

Since one of the ways of disturbing the order in the polymer is copolycondensation, a series of mixed polyarylates based on isophthalic (or terephthalic) acid, 1,2-bis(4-hydroxyphenyl)-dicarbadodecaborane, and phenolphthalein were obtained.[55] It was found that, for a relatively high content of phenolphthalein residues in such copolymers, the degree of order in the copolymer formed diminishes, which improves its solubility and the reduced viscosity is fairly high. For example, the copolymer obtained from 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane, phenolphthalein, and terephthalic acid chloride in molar proportions of 0.5 : 0.5 : 1 has a crystal structure with a relatively low degree of order, is soluble in chloroform, tetrachloroethane, and tetrahydrofuran, and its reduced viscosity in tetrachloroethane is 1.53–1.67 dl g^{-1}. With increase in the content of 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane residues in the mixed polyarylates, the degree of order in the latter increases, while the reduced viscosity and the solubility diminish.

Mixed 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane and chloro- or methylhydroquinone polyterephthalates have been synthesised recently by acceptor-catalytic polycondensation. The possibility of obtaining them from organoelement liquid-crystal polymers has been investigated.[41,52,53] The liquid-crystal properties of such dicarbadodecaborane-containing copolyarylates are indicated both by the composition of the copolymer and by its microstructure. For example, with increase in the molar proportion of the 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane residues in the copolyarylate derived from 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane and chlorohydroquinone from 0.4 to 0.6, the temperature range corresponding to the existence of the mesophase expands from 245–400 °C to 230–400 °C. In all cases the 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane-based homo- and copolyarylates were obtained in high yields (85%–95%).

Table 3 presents data on certain properties of the 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane-based polyarylates. Comparison of the data in Tables 2 and 3 permits the conclusion that the softening temperatures of the polyarylates are hardly influenced by the presence between the 1,2-dicarbadodecaborane group with hydroxy- or carboxy-phenyl residues. Thus, whereas the softening temperature of the amorphous polyarylates derived from 1,2-(4-hydroxyphenyl)dicarbadodecaborane and oxybis(benzene-4-carboxylic) acid is 275–285 °C, that of the isomeric amorphous polyarylate derived from 1,2-bis(4-carboxyphenyl)dicarbadodecaborane and bis(4-hydroxyphenyl) ether is 280–290 °C. On the other hand, comparison of the melting points of the crystalline polyarylates derived from 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane and terephthalic and isophthalic acids (~400 and 245 °C respectively) with those of the crystalline polyesters of 1,2-bis(4-hydroxymethyl)dicarbadodeca-

Table 3. Certain properties of 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane polyarylates obtained by acceptor-catalytic (I) and high-temperature (II) polycondensation.

Acid chloride	Methods of synthesis	η_{red}/dl g^{-1} (TCE, 25 °C)	Structure[a]	Softening temperature[b]/°C	Temperature of onset of mass loss/°C		Coke residue at 900 °C (%)

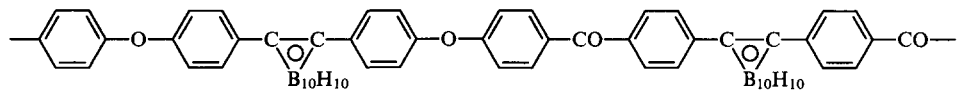
[a] X-Ray diffraction data. [b] See footnote to Table 2. [c] See footnote to Table 2. [d] Heating rate 5 K min^{-1}.

borane and terephthalic and isophthalic acids[61] (221 and 88 °C respectively) clearly demonstrates that it is desirable to introduce the dicarbadodecaborane groups into the polymer chain in the form of diphenyldicarbadodecaborane fragments in order to create heat-resistant polymers.

As can be seen from Table 3, the 1,2-bis(4-hydroxyphenyl)-dicarbadodecaborane-based polyarylates are thermally stable and give rise to high amounts of coke residue on heating to 900 °C both under an inert atmosphere and in air.

A polyarylate with an increased content of diphenyldicarbadodecaborane fragments, the chain of which contains only 1,2-diphenyldicarbadodecaborane fragments together with the ester groups, has been synthesised by the high-temperature polycondensation of 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane with the acid chloride of 1,2-bis(4-carboxyphenyl)dicarbadodecaborane in α-chloronaphthalene at 220 °C for 15–18 h (Scheme 6).[56] This polymer had the most crystalline structure (degree of crystallinity 55%) and was soluble only in tetrahydrofuran. The synthesis of polyarylates by acceptor-catalytic polycondensation in acetone or by high-temperature polycondensation in Sovol with rapid heating of the solution of the starting materials to 320 °C and the maintenance of the reaction mixture at this temperature for 1 h with subsequent rapid cooling to 0 °C gives rise to specimens with a lower degree of crystallinity. In the last case, the polymer is soluble not only in tetrahydrofuran but also in cyclohexanone. None of these polymers melt below 400 °C. Above this temperature, their thermal degradation begins.

However, it was observed that this dicarbadodecaborane-containing polyarylate can be converted into an amorphous form by reprecipitating the polymer from solution in tetrahydrofuran in cooled water or methanol. The specimens, converted into an amorphous form, dissolve in chloroform, tetrachloroethane, and even in benzene, softening at 260–290 °C. The amorphous specimen can be reconverted into a crystalline form by heating a 3% solution of the polymer in tetrachloroethane (from which the polymer begins to precipitate during the crystallisation process) or by slow (over a period of several days) evaporation of the polymer solution in chloroform. The specimens obtained in this way do not melt below 400 °C.



The degree of crystallinity of the polyarylates with 1,2-diphenyldicarbadodecaborane units can be altered also by heat treatment. Thus successive heating of the same specimen with a degree of crystallinity of 55% at 230, 290, and 330 °C in air for 30 min reduces the degree of crystallinity to 26%, 22%, and 16% respectively. On the other hand, when the specimen is heated at 450 °C, its degree of crystallinity falls to 5%–8%.

Thus, by manipulating the conditions in the synthesis or in the subsequent treatment of the polymer, it is possible to alter specifically the structure of this diphenyldicarbadodecaborane-containing polyarylate and hence its heat resistance.

The study of the characteristic features of the thermal and thermooxidative degradation of the polyarylates derived from 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane and 1,2-bis(4-carboxyphenyl)dicarbadodecaborane[56,57] revealed a difference in the behaviour of the crystalline specimen and the specimen converted into an amorphous form on heating, which may be due to the difference between the molecular mobilities in the temperature range 280–380 °C.[57] It was established that the thermal stability of the amorphous polymer is higher. Thus the mass of a specimen of the latter does not change up to ~650 °C, whereas crystalline specimens exhibit a decrease in mass at 400 °C.[56]

The structural transformations of the polyarylate derived from 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane and 1,2-bis-(4-carboxyphenyl)dicarbadodecaborane and, for comparison, the polyarylate obtained from 4,4'-dihydroxybiphenyl and 4,4'-dicarboxybiphenyl on heat treatment (for 1 h) in vacuo (10^{-3} Torr) in the temperature range 300–1200 °C have been investigated and the characteristic regions corresponding to the thermal transformations of the polymers have been determined.[62] The temperature range corresponding to the existence of the EPR absorption for the dicarbadodecaborane-containing polyarylate is much wider (400–1200 °C) than for the usual polyarylate (400–700 °C). The maximum concentration of paramagnetic centres is attained at 800 °C for the dicarbadodecaborane-containing polyarylate and at 600 °C for the usual polyarylate.

It was found that heating of the dicarbadodecaborane-containing polyarylate at 300 °C induces hardly any changes in the crystalline polymer specimen, while the amorphous specimen becomes crystalline under similar conditions. An increase in temperature to 400 °C leads to the complete disruption of the crystal structure of the polymer and to its conversion into an amorphous form. After heating to 500 °C, considerable chemical transformations take place and an appreciable amount of boric acid is formed. This may indicate the interaction of the dicarbadodecaborane groups and the products of their thermal transformations with the oxygen

1

bound chemically in the polymer and in its reaction products. At 600 °C, the polymer structure is fully disrupted and at 700 °C small amounts of graphite particles are formed. A further increase in temperature up to 1000 °C does not lead to significant changes in the structure of the specimen. The latter remains porous and the amount of graphite increases. According to the results of dynamic thermogravimetric analysis (DTGA) in helium at a heating rate of 5 K min^{-1}, specimens of the dicarbadodecaborane-containing polyarylate do not exhibit a region of vigorous decomposition up to 900 °C. The decrease in mass virtually ceases towards 750 °C and the rate of change of the mass in the temperature range 700–750 °C is only 0.01%–0.02% when the temperature is altered by 1 K.

Comparison of the results of X-ray diffraction and of the EPR spectra of the heat-treated polymers (the dicarbadodecaborane-containing and usual polymers) permits the conclusion that the principal difference between the polyheteroarylenedicarbadodecaboranes and their usual organic analogues is the displacement of the extensive decomposition processes and of the rearrangement of the initial structure to higher temperatures and also the specific interaction of the dicarbadodecaborane groups or the products of their thermal transformation with the chemically bound oxygen.[62]

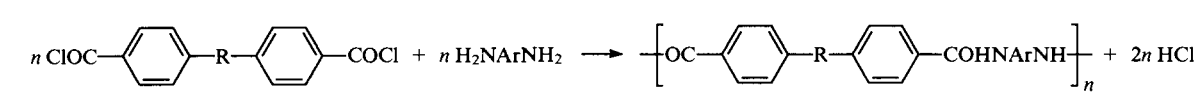
2. Polyesterketones

Brief data have been published recently concerning simple aromatic polyesterketones in which the 1,2-, 1,7-, and 1,12-dicarbadodecaborane groups and phenylene units are joined via oxygen or CO groups (for example, as in a type **1** polymer).[63] These polymers are obtained by the interaction of diphenylenedicarbadodecaboranedicarboxylic acids having the corresponding structure and diphenoxyphenyl derivatives of the dicarbadodecaborane.

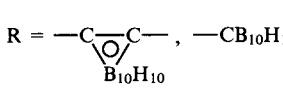
The polymers generally have an amorphous structure and a glass point of 180–220 °C and form films from solutions in methylene chloride and chloroform. According to DTGA data, the polymers begin to lose mass at 350–400 °C without fusion, the overall mass loss at 1000 °C amounting to about 10%–15%. This enabled the authors to postulate that the pyrolysis of such polymers under an inert atmosphere can lead to the formation of a ceramic boron carbide residue dispersed in the graphite matrix.

3. Polyamides

Polyamides with diphenylenedicarbadodecaborane fragments in the chain have been obtained by the reaction of the acid chlorides of 1,2- and 1,7-bis(4-carboxyphenyl)dicarbadodecaboranes with aromatic diamines (Scheme 7) under the conditions of low-temperature polycondensation in solution or by polycondensation in an organic solvent–water–hydrogen chloride acceptor mixture.[21,64–67]



In order to discover the most favourable conditions of synthesis, certain features of the formation reactions of the polyamides (the nature of the solvent, reaction temperature, concentrations of the initial components, etc.) were investigated in relation to the polycondensation of the acid chloride of 1,2-bis(4-carboxyphenyl)dicarbadodecaborane with *m*-phenylenediamine and 1,2-bis(4-carboxyphenyl)dicarbadodecaborane with 9,9-bis(4-aminophenyl)fluorene. It was found that, in the case of the low-temperature synthesis of the polyamide, the polymers with the highest reduced viscosity are obtained when the process is carried out in dimethylacetamide at −30 °C (synthesis for 1 h at −30 °C and maintenance at room temperature for 1–2 h) at a concentration of the starting materials of 1.0 M.



When the polycondensation was carried out in an organic solvent–water system, best results were obtained when tetrahydrofuran and a concentration of the starting material of 0.3 M were employed. In this case, $NaHCO_3$ was used as the hydrogen chloride acceptor. The process was carried out at room temperature for 20 min with vigorous stirring of the reaction mass. Both methods can be used successfully to obtain high-molecular-mass dicarbadodecaborane-containing polyamides.

As an example, Table 4 presents the intrinsic viscosities of 0.5% solutions of the polymers in *N*,*N*′-dimethylacetamide at 25 °C and their molecular masses determined by the light scattering method in *N*-methyl-2-pyrrolidinone.

Outwardly the aromatic polyamides derived from 1,2- and 1,7-bis(4-carboxyphenyl)dicarbadodecaboranes are white fibrous or powdered substances. Many of them are soluble not only in amide solvents but also in tetrahydrofuran, cyclohexanone, a mixture of tetrachloroethane with phenol, and tricresol. The polyamide obtained from 1,4-phenylenediamine and 1,2-bis-(4-carboxyphenyl)dicarbadodecaborane is an exception. It does not dissolve in the solvents listed above and is insoluble even in sulfuric acid. The polyamides synthesised are also insoluble in tetrachloroethane.

Scheme 7

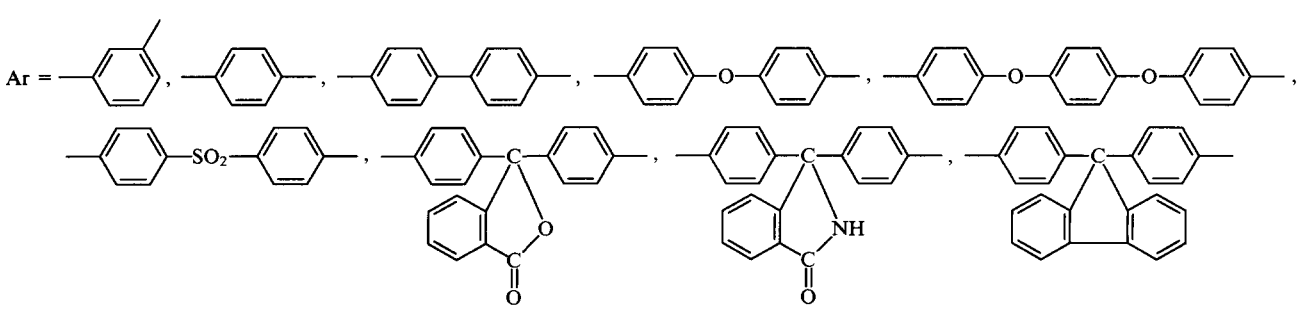


Table 4. The reduced viscosities and molecular masses of the polyamides obtained from various diamines and the acid chlorides of 1,2- (**A**) and 1,7-bis(4-carboxyphenyl)dicarbadodecaboranes (**B**) by low-temperature polycondensation in *N,N*-dimethylacetamide.

Initial components in the synthesis of polyarylates		η_{red}/dl g^{-1} (10^{-3} M_w)

Strong films are formed from solutions of the diphenyldicarbadodecaborane-containing amides. For example, nonoriented films of the polyamides obtained by the reaction of 1,2-bis(4-carboxyphenyl)dicarbadodecaborane with anilinephthalein and the bis(4-aminophenyl) ether of hydroquinone have tensile strengths of 750 and 760 kgf cm^{-2} and relative elongations at breaks of 5% and 30% respectively. The tensile strength of the film obtained from the polyamide derived from 1,7-bis-(4-carboxyphenyl)dicarbadodecaborane and anilinefluorene is 940 kgf cm^{-2} with a relative elongation at break of 20%. At 300 °C, the film of this polymer retains a high strength (370 kgf cm^{-2}) and its relative elongation at this temperature is 111%.

The majority of the polyamides considered are amorphous. The polyamides obtained from anilinefluorene and both bis-(4-carboxyphenyl)dicarbadodecaborane isomers and also the polymer obtained by the reaction of benzidine and 1,7-bis-(4-carboxyphenyl)dicarbadodecaborane, which has a crystalline structure with a low degree of order, are exceptions.

Table 5 presents the thermal properties of aromatic polyamides based on 1,2- and 1,7-bis(4-carboxyphenyl)dicarbadodecaboranes. Evidently high softening temperatures are characteristic of these polyamides. The polyamides derived from benzidine, 1,4-phenylenediamine, and diamines with cardo-groups have the highest softening temperatures (370–400 °C). Comparison of the results of a thermomechanical study of aromatic polyamides derived from 1,7-bis(4-carboxyphenyl)dicarbadodecaborane [64] and 1,7-dicarbadodecaboranedicarboxylic acid [69] permits the conclusion that the use of aromatic bifunctional derivatives of 1,7-dicarbadodecaborane leads to much more heat-resistant polyamides. For example, whereas the softening temperatures of the polyamides obtained by the reaction of 1,7-dicarbadodecaboranedicarboxylic acid with 1,4-phenylenediamine, benzidine, and bis(4-aminophenyl) ether are 210, 250, and 220 °C (in all cases with decomposition), the softening temperatures of the analogous polyamides based on 1,7-bis(4-carboxyphenyl)dicarbadodeca-borane are 380, 400, and 300 °C respectively.

The thermal and thermooxidative behaviour of dicarbadodecaborane-containing aromatic polyamides have been investigated in a number of studies. [64–66, 68, 70, 71]

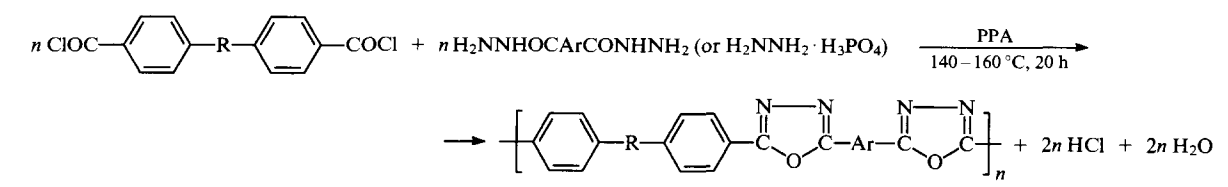

Table 5 (over) shows that the temperature of the onset of a change in mass is in the range 370–435 °C (in air) and 380–450 °C (in an inert medium) for diphenyldicarbadodecaborane-containing polyamides under the conditions of DTGA. [65] The overall rate of degradation of the dicarbadodecaborane-containing polyamides considered is appreciably lower than for the usual aromatic polyamides. On heating to 900 °C in air and especially under an inert atmosphere, the polyamides based on both isomers of bis(4-carboxyphenyl)dicarbadodecaborane give rise to a large amount of a coke residue (up to 30%–60% in air and up to 82%–96% in helium), whereas polyamides based on the reaction of terephthalic acid with cardo-diamines give rise to 13%–16% of coke residue (in air) and 48%–53% (in helium) (Table 5). [65] The nature of the thermal degradation of polyamides with 1,2- and 1,7-diphenyldicarbadodecaborane fragments is close to that of the degradation of polyamides based on 1,7-dicarbadodecaboranedicarboxylic acid, but the onset of vigorous decomposition is displaced towards higher temperatures. The amide groups in the dicarbadodecaborane-containing polyamides possess a greater hydrolytic stability compared with those in the usual polyamides. It is also noteworthy that the 1,2-dicarbadodecaborane groups stabilise the amide linkage in polyamides to a greater extent than the 1,7-dicarbadodecaborane groups. One of the reasons for the increase in the mass of the polyamidodicarbadodecaboranes when the latter are heated in air is believed to be the oxidation of the dicarbadodecaborane nucleus by atmospheric oxygen with formation of involatile oxygen-containing boron compounds. [68]

The electrophysical properties of polyamides based on 1,2- and 1,7-bis(4-hydroxyphenyl)dicarbadodecaboranes and anilinefluorene as well as their molecular mobility have been investigated. [72] It has been noted that the replacement of the 1,2-dicarbadodecaborane nucleus by the 1,7-dicarbadodecaborane nucleus is accompanied by a decrease in the rigidity of the macrochains.

4. Poly-1,3,4-oxadiazoles

For the synthesis of homogeneous and mixed poly-1,3,4-oxadiazoles with diphenyldicarbadodecaborane fragments in the chain, use has also been made of 1,2- and 1,7-bis-(4-carboxyphenyl)dicarbadodecaboranes. [73–75] The study of the characteristic features of this synthesis showed that, even after prolonged interaction of 1,2- and 1,7-bis(4-carboxyphenyl)-

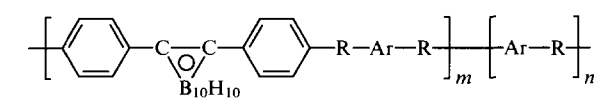
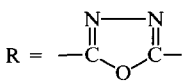
[a] See footnote to Table 2. [b] The range between the two points of intersection of the tangents to the corresponding branches of the S-shaped thermogravimetric analysis curve was adopted as the temperature range.

dicarbadodecaboranes with hydrazine phosphate or dicarboxylic acid dihydrazides in polyphosphoric acid (PPA) at 180–200 °C, the corresponding poly-1,3,4-oxadiazoles are not formed. It was not possible to obtain the polymers also by the interaction of the dihydrazides of 1,2- and 1,7-bis(4-carboxyphenyl)dicarbadodecaboranes with dicarboxylic acids. However, when one begins with the dichlorides of dicarboxylic acids, it is possible to synthesise homogeneous and mixed dicarbadodecaborane-containing poly-1,3,4-oxadiazoles with a fairly high molecular mass. In this case, the process proceeds in accordance with Scheme 8 or 9 and under comparable conditions leads to products differing appreciably in molecular mass and, in the case of 1,2-bis(4-carboxyphenyl)dicarbadodecaborane derivatives, in composition.

Scheme 9





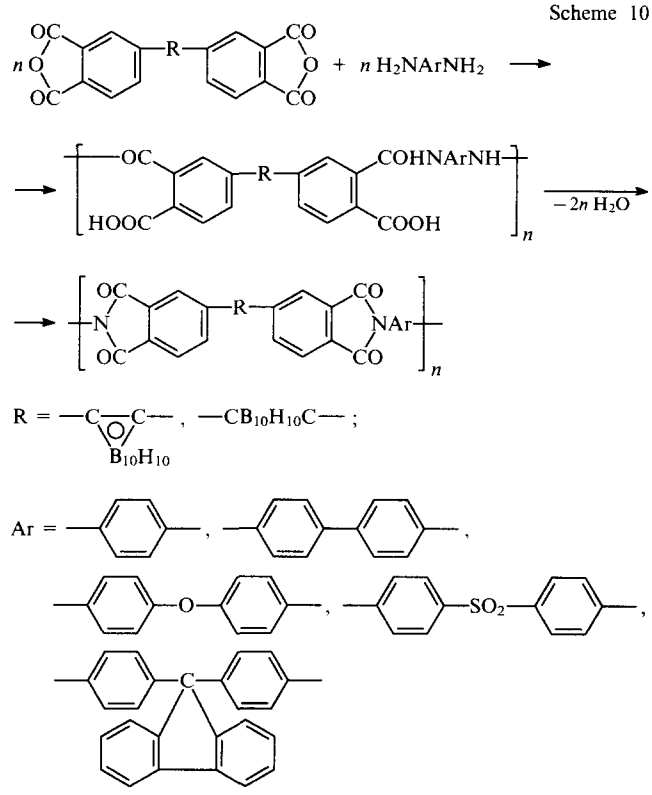
Thus the polymers obtained from the dihydrazides of the dicarbadodecaborane-containing dicarboxylic acids (Scheme 9) have lower reduced viscosities (0.10–0.70 dl g^{-1}) in a 3:1 (by weight) tetrachloroethane–phenol mixture than the products obtained in accordance with Scheme 8 (0.50–3.10 dl g^{-1}). The composition of the mixed poly-1,3,4-oxadiazoles based on 1,2-dicarbadodecaborane derivatives corresponds to the molar ratio of the starting materials only when one of them is the dihydrazide of 1,2-bis(4-carboxyphenyl)dicarbadodecaborane (Scheme 9). In the synthesis in accordance with Scheme 8, the corresponding polymers have a reduced content of the 1,2-bis-(4-carboxyphenyl)dicarbadodecaborane residues compared with the molar ratio of the starting materials. Presumably one of the causes of the formation of polymers with a lower molecular mass via Scheme 9 is the decrease in the reactivity of the NH_2 groups of the dihydrazides of the dicarbadodecaboranedicarboxylic acids caused by the presence in them of the dicarbadodecaborane nucleus and by its electron-accepting nature.

The high-temperature polycyclisation in polyphosphoric acid involves the homopolycondensation of the dicarboxylic acid dihydrazides with formation of poly-1,3,4-oxadiazoles. This process can take place simultaneously with the main one and can lead to the enrichment of the polymer in the aromatic dicarboxylic acid residues, incorporated in the polymer chain in the form of blocks of the corresponding homopoly-1,3,4-oxadiazoles.

The structure of the 1,7-bis(4-carboxyphenyl)dicarbadodecaborane derivatives, which are sterically more favourable, makes it possible to obtain from them mixed poly-1,3,4-oxadiazoles with a composition which is determined by the molar ratio of the starting materials (Scheme 8).[74]

The presence of dicarbadodecaborane groups, especially of the 1,2-dicarbadodecaborane group, in the polyoxadiazoles impart to the latter a high solubility in organic solvents. The softening temperatures of these polymers are in the range 260–350 °C depending on the chemical structure. The homopolyoxadiazoles based on the 1,2- and 1,7-bis(4-carboxyphenyl)-dicarbadodecaboranes and the mixed polyoxadiazole obtained from 1,7-bis(4-carboxyphenyl)dicarbadodecaborane and terephthalic acid have the highest softening temperatures (330–350 °C). Compared with the cardo-polyoxadiazoles based on bis(4-carboxyphenyl)phthalide (softening temperature 390 °C), the dicarbadodecaborane-containing homopolyoxadiazoles soften at a temperature lower by 40–50 °C, which is apparently associated with the fact that the 1,2- and 1,7-dicarbadodecaborane groups weaken the intermolecular interactions of the polymer chains to a greater extent than the phthalide groups.

Strong transparent films, which in a number of instances give rise to an appreciable elongation at break, were obtained from solutions of the polymers (for example, from solution in a tetrachloroethane–phenol mixture). For example, the tensile strength of the polyoxadiazole obtained from 1,7-bis-(4-carboxyphenyl)dicarbadodecaborane and isophthalic acid is 1140 kgf cm^{-2} and the relative elongation at break is ~200%.[74] The majority of the polymers obtained are amorphous or have an amorphous structure with signs of crystallinity. According to DTGA data, the mass of diphenyldicarbadodecaborane-containing polyoxadiazoles changes in air in the temperature range 380–440 °C. For the majority of the polyoxadiazoles with dicarbadodecaborane groups, an increase in mass is observed in air at a temperature of about 500 °C. On heating to 900 °C, the coke residue amounts to more than 90% in a number of instances [for example the coke residues produced by the polyoxadiazoles based on 1,2- and 1,7-bis(4-carboxyphenyl)dicarbadodecaboranes are 98% and 97% respectively].



The study of the thermal degradation of polyoxadiazoles and the corresponding model systems led to the conclusion that at relatively low temperatures (300–400 °C) processes involving the hydrolytic decomposition of the oxadiazole ring becomes dominant whilst, with increase in temperature the role of the homolytic reactions is enhanced. The presence of 1,2- and 1,7-dicarbadodecaborane nuclei in the polyoxadiazoles hinders the occurrence of heterolytic decomposition reactions.[75]

5. Polyimides

The development of a method of synthesis of 1,2- and 1,7-bis(3,4-dicarboxyphenyl)dicarbadodecaboranes, presented in Scheme 3, led to the possibility of obtaining from these compounds and various aromatic diamines and of investigating polyimides with diphenyl-1,2- and diphenyl-1,7-dicarbadodecaborane fragments in the chain.[76–81]

Both two-stage and single-stage high-temperature polycondensations in solution have been used to synthesise dicarbadodecaborane-containing polyimides.[77] Scheme 10 presents the structures of the polyimides synthesised.

Scheme 10

In connection with the two-stage method of synthesis, a study was made of the influence on the formation of polyamidoacids in dimethylacetamide of various low-temperature polycondensation conditions: the concentrations of the reactants (0.3–0.7 M or 10 mass%–30 mass%), the basicity of the initial diamines, the reaction temperature (0–50 °C), and the reaction time (1.5–3.5 h).[77] Polyamidoacids with the maximum reduced viscosities (up to 1.84 dl g^{-1} in dimethylacetamide) were obtained in the case of the most basic diamine (benzidine); on passing from benzidine to bis(4-aminophenyl) ether and then to bis(4-aminophenyl) sulfone, the values of η_{red} diminish appreciably, which, incidentally, has been observed also for the usual polyamidoacids. In the experimental range, changes in reaction temperature and reaction time hardly affect the results of the synthesis. The

optimum conditions for the synthesis of 1,2- and 1,7-dicarbadodecaborane-containing polyamidoacids proved to be as follows: concentration 0.7 M for the 1,2-isomer and 0.3 M for the 1,7-isomer, temperature 20–25 °C, reaction time 1.5 h.

The single-stage polycyclisation method and the two-stage polycondensation method with thermal or chemical cyclisation in the second stage, known in connection with the preparation of the usual polyimides, have been used to synthesise polyimides with diphenyl-1,7-dicarbadodecaborane fragments in the chain. In the two-stage method of synthesis, higher-molecular-mass polyimides with diphenyl-1,7-dicarbadodecaborane fragments in the chain are obtained in the case of the chemical cyclisation. The reduced viscosities of the 0.5% solutions in dimethylacetamide are 1.24–1.70 dl g^{-1}; the molecular mass of the polyimide based on bis(4-aminophenyl) ether with η_{red}= 1.7 dl g^{-1}, determined by the light scattering method in dioxane, is 115 × 10^3.

It was observed that the 1,2-dicarbadodecaborane group in the dianhydride of 1,2-bis(3,4-dicarboxyphenyl)dicarbadodecaborane and in the macromolecules of the polyimides is unstable in relation to the action of aprotic dipolar solvents of the type of *N,N*-dimethylacetamide, *N,N*-dimethylformamide, and *N*-methylpyrrolidinone and also of the cyclising mixture in chemical cyclisation, being converted into derivatives of the dicarbaundecaborate anion. An increase in the pyridine content in the cyclising mixture shortens the cyclisation time, promoting simultaneously an increase in the yield of the dicarbaundecaborate derivative. In the case of the 1,2-bis(3,4-dicarboxyphenyl)-dicarbadodecaborane, the degradation of the dicarbadodecaborane nucleus was also observed in the single-stage method of synthesis, evidently under the influence of the initial diamine.[77] However, it was nevertheless found that polyimides with diphenyl-1,2-dicarbadodecaborane fragments can be synthesised successfully by single-stage polycondensation in a high-boiling solvent (nitrobenzene, *p*-chloronitrobenzene, *p*-nitrotoluene) at 170–190 °C in the presence of hydrogen chloride as the catalyst, provided that the basicity of the amino-group in the aromatic diamines is reduced by employing *N,N*-diacyl derivatives as the starting materials. Among the acyl derivatives of aromatic diamines with HCO, MeCO, PhCO, and CF_3CO groups, the first two are the most reactive.[78] This method makes it possible to avoid the degradation of the 1,2-dicarbadodecaborane nucleus during the synthesis and hence to achieve successfully the synthesis of polyimides with unaffected diphenyl-1,2-dicarbadodecaborane fragments in the chain. Polyimides with 1,2-dicarbadodecaborane groups can be synthesised also by the two-stage polycondensation with thermal cyclisation in the second stage.

Outwardly the dicarbadodecaborane-containing polyimides are powdered or fibrous yellow or greyish-white substances. According to X-ray diffraction data, these polymers are amorphous with the exception of polyimides based on bis(4-aminophenyl) sulfone, which show certain signs of crystallinity.

Polyimides with diphenyl-1,2- and diphenyl-1,7-dicarbadodecaborane fragments in the chain, which generally possess properties characteristic of aromatic polyimides (high heat resistance, satisfactory mechanical and electrical properties of films produced from them) are readily soluble in a wide range of solvents by virtue of the specific influence of the dicarbododecaborane groups. Among the dicarbadodecaborane-containing polyimides obtained, the highest solubility is shown by the polyimides based on bis(4-aminophenyl) ether and anilinefluorene, which are soluble even in dioxane and tetrahydrofuran. Strong films can be obtained by casting from a solution of these dicarbadodecaborane-containing polyimides. For example, the strength of the film obtained from the polyimide based on 1,7-bis-(3,4-dicarboxyphenyl)dodecaborane and bis(4-aminophenyl) ether by the two-stage method with chemical cyclisation of the polyamidoacid is 980 kgf cm^{-2} and their elongation at break is 88%.[77]

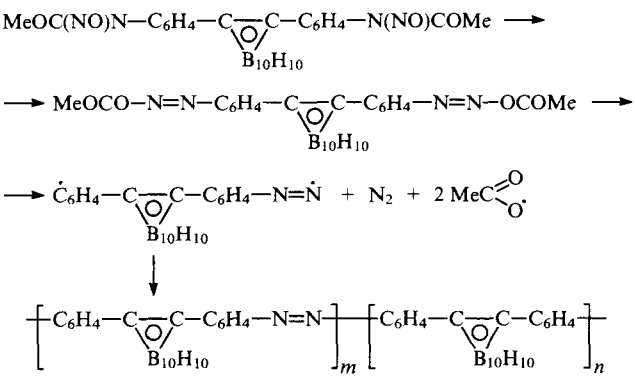
According to the results of thermomechanical tests, the dicarbadodecaborane-containing polyimides based on benzidine do not soften on heating. Among the remaining polyimides, polymers based on 1,7-bis(3,4-dicarboxyphenyl)dicarbadodecaborane with *p*-phenylenediamine and anilinefluorene exhibited the highest heat resistance, their softening temperatures being ~375 and ~380 °C respectively.

The characteristics of the molecular motion in dicarbadodecaborane-containing polyimides have been investigated by electron spectroscopic methods and it has been shown that the intramolecular relaxation process observed in the temperature range 160–180 °C is associated with the vibrations of the heterocyclic fragments adjoining the dicarbadodecaborane groups via the aromatic ring. It has been established that the rigidity of the chain increases on passing from 1,7- to 1,2-dicarbadodecaborane-containing polymers.[80]

The relative permitivities of 1,7- and 1,2-diphenyldicarbadodecaborane-containing polyimides are the same (3.8 at 23 °C and a frequency of 1 MHz) and hardly change in the temperature range from −170 to 270 °C. Numerically this value is close to the dielectric permitivity of polyimides not containing a dicarbadodecaborane fragment. The tangent of the dielectric loss angle at a frequency of 1 MHz is 1.4 × 10^{-3} at 23 °C for the 1,2-dicarbadodecaborane-containing polyimide based on bis-(4-aminophenyl) ether and 2.0 × 10^{-3} for the 1,7-dicarbododecaborane-containing polymer.[79]

According to DTGA data, dicarbadodecaborane-containing polyimides begin to undergo a change in mass in air and in an inert medium at higher temperatures than other polyheteroarylenes with diphenyldicarbadodecaborane fragments and their decomposition reaction is slower. In air, the mass of 1,2-dicarbadodecaborane-containing polyimides begin to change in the temperature range 430–450 °C and that of their analogues with 1,7-dicarbadodecaborane groups begins to change at 450–470 °C and the process takes place with some absorption of oxygen (~1%–9% relative to the initial mass). On heating under an inert atmosphere, the mass of dicarbadodecaborane-containing polyimides begins to change at 500–510 °C; it decreases by only 5%–7%, which is 8–10 times smaller than for the usual polyimides.[81] On heating to 900 °C, the coke residues from dicarbadodecaborane-containing polyimides are in most cases 92%–97% under an inert atmosphere.

On heating under isothermal conditions in air (4 h at 400 °C), the molecular mass of the polyimide based on 1,7-bis(3,4-dicarboxyphenyl)dicarbadodecaborane and *p*-phenylenediamine does not change. The polyimides containing dicarbaundecaborate anions in the chain begin to lose mass at low temperatures; the amounts of their coke residues at 900 °C are also fairly large (78%–95%).[77]



The pyrolysis at 1000 °C of the polyimides obtained from 1,2- and 1,7-bis(3,4-dicarboxyphenyl)dicarbadodecaboranes with bis-(4-aminophenyl) ether or anilinefluorene and, for comparison, also the polyimides based on the dianhydride of oxybis(benzene-dicarboxylic)acid and bis(4-aminophenyl) ether under an argon atmosphere was investigated.[81] Analysis of the pyrolysis products demonstrated an appreciable difference between the dicarbadodecaborane-containing and the usual polyimides. This is manifested by an increased content of hydrogen, carbon monoxide, methane, and benzene in the pyrolysis products and by the absence of products such as aniline and benzonitrile characteristic of the pyrolysis of the usual polyimides. The formation of methane is a consequence of secondary reactions resulting from the increased content of hydrogen in the volatile pyrolysis products. It has been suggested that the absence of a very small amount of decomposition products containing nitrogen derived from the imide ring may be evidence for the binding of these products in the involatile residues, the yield of which is fairly high under the pyrolysis conditions. The products of the decomposition of the diphenyldicarbadodecaborane or diphenyl ether fragments apparently also remain in the carbonised matrix. These results suggested that the section of the polymer chain of the dicarbadodecaborane-containing polyimides most subject to homolytic decomposition is the diphenyldicarbadodecaborane

fragment with the adjacent imide ring, the primary products of the decomposition of which may in fact be hydrogen (from the dicarbadodecaborane nucleus), carbon monoxide, benzene, and also mono- and di-phenyldicarbadodecaboranes.[81]

6. Polyazophenylenedicarbadodecaborane

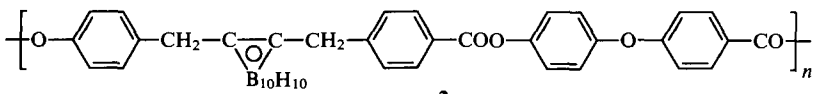
The synthesis and certain properties of polyazophenylene-1,2-dicarbadodecaborane have been described.[82,83] 1,2-Bis(*N*-nitrosoacetamidophenyl)-1,2-dicarbadodecaborane was used as the initial monomer. The recombination of the phenyl and azophenyl products of its decomposition actually leads to the formation of a dicarbadodecaborane-containing polyazophenylene (Scheme 11).

Scheme 11

The polyazophenylenedicarbadodecaborane was obtained in a suspension of cyclohexane in water in which the proportions of the two phases were 1:2. The monomer concentration was 7.5 g litre^{-1}, the temperature was 50 °C, and the reaction time was 4 h. The yield of the polymer was nearly quantitative. Outwardly, the polymer consisted of a pale-brown powder. It was readily soluble in chloroform, benzene, dimethylformamide, tetrahydrofuran, and, partially, in methanol and acetone. The molecular mass of its low-molecular-mass fraction (30%) was 820 and that of the higher-molecular-mass fraction (70%) was 1560. The presence of an EPR signal with an intensity of 3.3×10^{17} spins g^{-1} and the absorption in the long-wavelength part of the electronic spectrum indicated the presence of a conjugated bond system in this polymer.[82,83]

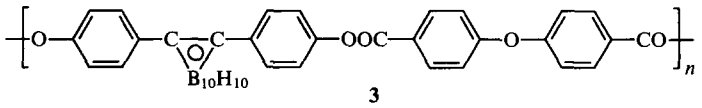
The polyazophenylenedicarbadodecaborane exhibits high thermal and thermooxidative stabilities. On isothermal heating in helium at 400 °C, a decrease in mass to 9% is observed initially, after which it hardly changes for 3 h. According to DTGA data (heating rate 4.5 K min^{-1}), the dicarbadodecaborane-containing polyazophenylene is stable up to 350 °C in air, after which an increase in the mass of the specimen is observed, amounting to approximately 30% at 600 °C. This apparently occurs owing to the addition of oxygen to the B–H bonds. The amount of the coke residue at 800 °C is ~90% of the initial mass.

It has been suggested that the ability of the dicarbododecaborane units of the polymer to combine with oxygen at high temperatures with formation of inactive products is of interest for the employment of such a polymer as a stabiliser[57] and for the inhibition of the thermooxidative degradation of thermally stable polymers.[82,83]



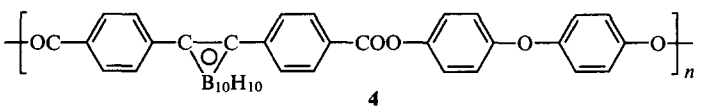
It has also been noted that 1,2-bis(*N*-nitrosoacetamidophenyl)-1,2-dicarbadodecaborane can be used for the synthesis of dicarbadodecaborane-containing copolymers by combining the processes involving the recombination of its decomposition products with those involving the radical polymerisation of various monomers.[82,83] For example, the copolymers of polyazo(hydroxyphenyl)dicarbadodecaborane with styrene, containing from 4 mass% to 38 mass% of polyazophenylenedicarbadodecaborane fragments, have been synthesised by emulsion copolymerisation. The introduction of polyazo(hydroxyphenyl)dicarbadodecaborane into polystyrene macromolecules significantly increases the thermal stability of the latter. Thus intense degradation of polystyrene begins at 300 °C, while that of the copolymer of styrene containing only 4% of polyazophenylenedicarbadodecaborane takes place at 350–360 °C.

* * *



Summarising the foregoing, one should note that the development of new di- and tetra-functional aromatic derivatives of 1,2- and 1,7-dicarbadodecaboranes and the study of the characteristics of the formation of polymers from them have made it possible to obtain various new classes of linear heterochain polymers — polymers with diphenyldicarbadodecaborane fragments in the chain and a high molecular mass. These polymers possess a set of valuable properties and their thermal characteristics and in many cases also their solubilities are significantly superior to those of the usual organic analogues.[83] The introduction of dicarbadodecaborane groups into the polymer chain in the form of diphenyldicarbadodecaborane fragments increases significantly the heat resistance of such polymers compared with polymers based on bifunctional aliphatic derivatives of dicarbadodecaborane.

The study of the behaviour of linear polyheteroarylenedicarbadodecaboranes of the type of the polyarylates **2**–**5**, the polyamides **6** and **7**, and the polyimides **8** and **9** (see over) during the sorption process in the vapour of an effective solvent (THF) showed that structural changes take place in the amorphous polymers with formation of a thermodynamically improved structure.[85] It was found that the temperature for the onset of gel formation depends little on the isomerism of the dicarbadodecaborane nucleus and the framework surrounding it and depends more on the medium in which the heat treatment has been carried out. In air, the temperature for onset of gel formation is 15–20 °C lower than in vacuo. In the cardo-analogues (the polymers **10**–**12**), the gel fraction appears at temperatures higher by 50 °C. After the gel formation point (~280 °C) has been passed, the subsequent structure formation takes place much faster in the polymers with the 1,7-dicarbadodecaborane fragments in the chain, which may be due both to the greater segmental mobility of these polymers and to the smaller extent of the purely degradative reactions occurring simultaneously.



The significant difference between the behaviour of polyheteroarylenedicarbadodecaboranes and that of the usual organic analogues, both as regards the position of the initial gel formation point and the rate of accumulation of the gel fraction, suggested that intermolecular bonds are formed in the experimental temperature range (250–350 °C) mainly with participation of the dicarbadodecaborane groups. This is most characteristic of polymers with 1,7-dicarbadodecaborane fragments and has been confirmed by the fact that a nearly quantitative yield of the gel fraction is observed in these polymers at temperatures below that of the onset of gel formation in the polymers not containing dicarbadodecaborane groups.[85]

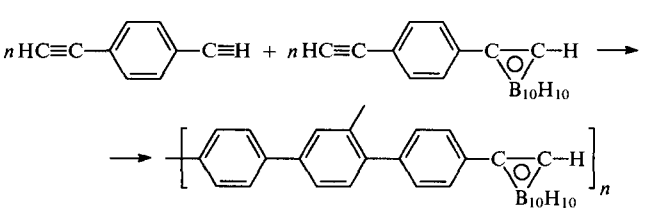
IV. Phenylenedicarbadodecaborane-containing polymers of the thermoreactive type

The study of linear polyheteroarylenedicarbadodecaboranes of the type of polyarylates, polyamides, polyoxadiazoles, polyimides, etc. showed that the specific difference between these polymers and their usual organic analogues is their ability to form already in the temperature range 250–270 °C three-dimensional thermally stable polymers in which the inorganic networks are evidently combined with organic network molecules. It therefore appeared promising to employ this specific property of the aromatic derivatives of dicarbadodecaborane(12) in polymers of the thermoreactive type, containing reactive functional groups together with the dicarbadodecaborane groups. It might have been expected that, as a result of the introduction of dicarbadodecaborane groups into such systems, the properties of the thermoreactive and dicarbadodecaborane-containing polymers would be usefully mutually supplemented, in the first place in those applications, traditional for thermoreactive oligomers and polymers, where, together with the simplicity of processing, a high thermal stability and the formation of secondary coking products are required.

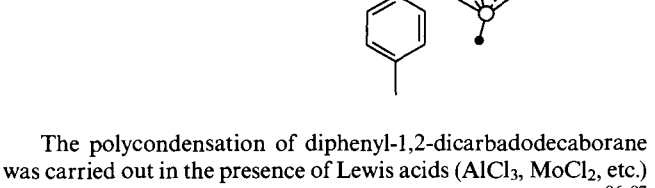
We shall now deal with phenylenedicarbadodecaborane-containing polymers of the polyphenylene, epoxide, phenolformaldehyde, and polycyanurate types.



The 1,2-dicarbadodecaborane-containing oligophenylenes, obtained from diphenyl-1,2-dicarbadodecaborane, are presented below.

The polycondensation of diphenyl-1,2-dicarbadodecaborane was carried out in the presence of Lewis acids ($AlCl_3$, $MoCl_2$, etc.) and oxidising agents (MnO_2, $CuCl_2$, etc.) at 120–220 °C.[86,87] The oligomers have a molecular mass of 1300 and a softening temperature of about 300 °C. They do not melt up to 350 °C and are readily soluble in organic solvents (chloroform, benzene, acetone, etc.) According to DTGA data, the decrease in their mass in air is 1.6% at 600 °C and 11.6% at 900 °C.

The preparation of polydicarbadodecaboranephenylenes by the reaction of 1,7-$Cu_2C_2B_{10}H_{10}$ with *m*-$C_6H_4I_2$ in 1:1 molar proportions has been mentioned.[63] Together with the formation of a polymeric product, there is a possibility in this instance of the formation of macrocyclic systems in which the 1,7-dicarbadodecaborane fragments are linked to 1,3-disubstituted phenylene rings. When *m*-$C_6H_4I_2$ is replaced by 1,3- or 2,6-disubstituted pyridines, macrocyclic systems in which the 1,7-dicarbadodecaborane fragments are linked to pyridine rings are formed together with the polymeric product.

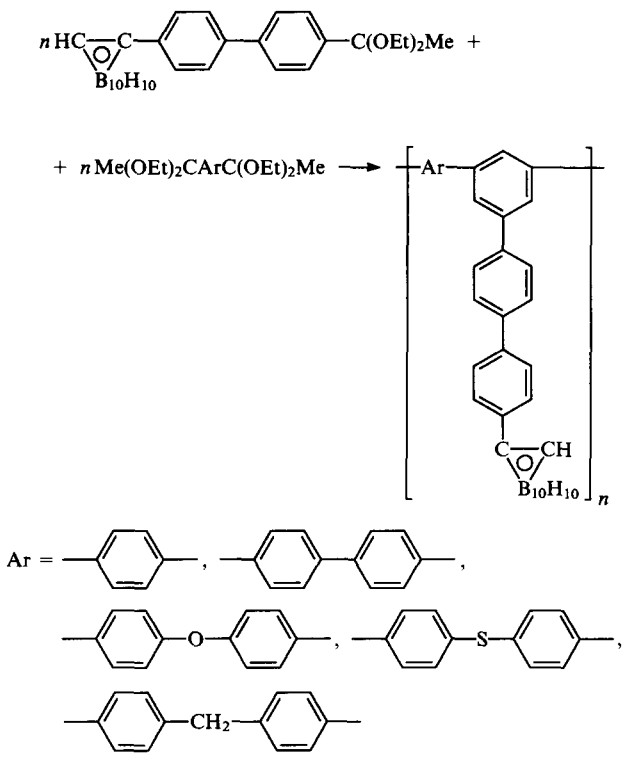


The synthesis of *p*-[1-(1,7-dicarbadodecaboranyl)]phenylethyne has been achieved by the reaction of diethynylbenzene with decaborane in the presence of dimethylaniline in toluene.[88] Dicarbadodecaborane-containing polyphenylenes were obtained by the joint polycyclotrimerisation of this dicarbadodecaborane-containing ethyne with diethynylbenzene (taken in equal proportions) in the presence of the $NiCl_2.2PPh_3.2NaBH_4$ system.

For an equimolecular ratio of the starting materials, fully soluble copolymers containing 18.7% of boron are formed in 75% yield. According to DTGA data, under a helium atmosphere their mass diminishes at 900 °C only to the extent of 6%, whereas the decrease in the mass of the homopolyphenylene obtained from diethynylbenzene is 15%. These boron-containing polyphenylenes are extremely heat-resistant: they undergo only slight deformations up to the temperatures of their thermal decomposition (above 600 °C).

In order to regulate the content of the dicarbadodecaborane groups in the copolymers, the joint polycyclotrimerisation of 1,2-dicarbadodecaboranylphenylethyne (CPE) with diethynylbenzene (DEB) and phenylethyne (PE) was also carried out. For the molar proportions of the starting materials CPE:DEB:PE = 0.5:1:1, copolymers containing 11% of boron were obtained in 73% yield. Up to 27% of an insoluble polymer was formed under these conditions as a result of partial structure formation. It was noted that the mixed dicarbadodecaborane-containing polyphenylenes exhibit an enhanced thermooxidative stability. Thus the mass of the triple copolymer initially increases somewhat (up to 4%) at 350 °C, after which it remains virtually unchanged for 5 h; the mass lost by the polymer after 5 h at 550 °C exceeds only slightly 40%.[88]

It has been shown that the oligophenylenedicarbadodecaboranes of the type considered could be used as the starting materials for the synthesis of π-arenetricarbonyl complexes of transition metals.[89] The introduction of 1,2-dicarbadodecaborane groups into an oligophenylene has also been achieved as a result of the chemical modification of the oligophenylene, containing triple bonds, by decaborane in accordance with the following scheme:[90]



The oligophenylenedicarbadodecaborane is an amorphous pale-brown powder readily soluble in the usual organic solvents. Analysis of the polymer obtained permitted the conclusion that, under the selected chemical modification conditions, the replacement of the ethynyl groups of the oligophenylene by dicarbadodecaborane groups is almost quantitative. The absence from such an oligophenylenedicarbadodecaborane of residual ethynyl groups renders the latter (in contrast to oligophenylene) incapable of passing to an infusible and insoluble state during heating to 300 °C.

A higher thermal stability (both under an inert atmosphere and in air) is characteristic of the oligophenylenedicarbadodecaboranes than of the initial oligophenylene. According to DTGA data, the yield of the coke residue for the oligophenylenedicarbadodecaborane is 84.5% at 900 °C under a helium atmosphere, whereas for the usual oligophenylene it is 68%.

Polyphenylenes with phenyldicarbadodecaborane fragments in the chain can be obtained also by means of the trimerisation polycondensation of aromatic mono- and di-acetyl compounds in which one of the monomers is a dicarbadodecaborane-containing aromatic acetyl derivative.[91–97] In particular, when the 4′-(1,1-diethoxyethyl)biphenylyl-1,2-dicarbadodecaborane was used as the monomer, a prepolymer of the polyphenylene type was obtained.[91,92]

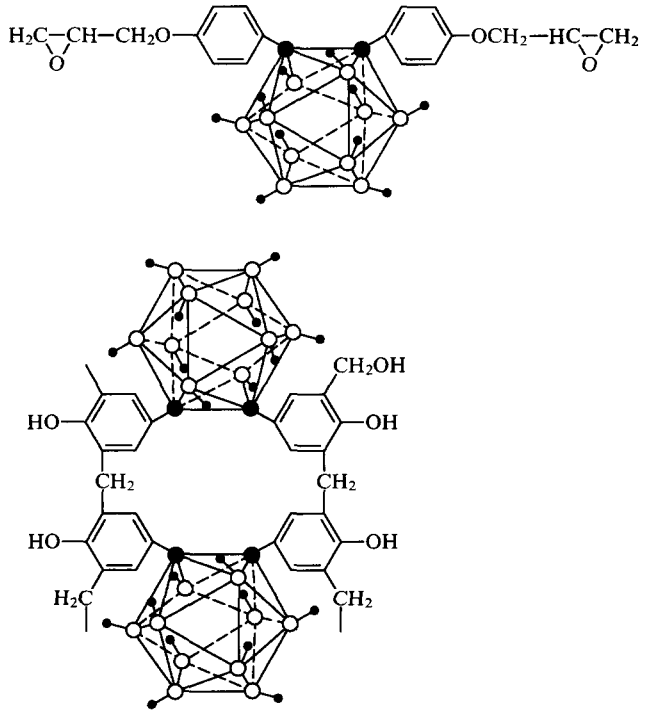
Different versions of the synthesis of the prepolymer were employed: at 0 and 20 °C in solution in benzene through which dry hydrogen chloride was passed; at −20 °C in solution in *o*-dichlorobenzene with dry HCl; at 100 and 150 °C in solution in *o*-dichlorobenzene or ditolylmethane in the presence of 10% toluene-*p*-sulfonic acid as the catalyst.[91,92] The final polymers were obtained by heat treatment at 450 °C.[92]

Dicarbadodecaborane-containing polyphenylenes have also been synthesised from bis(4-acetylbenzyl)- and 4-acetylbenzyldicarbadodecaboranes in which the phenylene group was separated from the dicarbadodecaborane nucleus by a methylene group.[94-96] It is noteworthy that the fraction of the enone side groups [...-R-CO-CH = C(Me)-R-...] and polyvinylene fragments in the oligomer increases (compared with their contents in the prepolymers without dicarbadodecaborane nuclei) in the polycondensation of acetyldicarbadodecaboranes or their ethyl ketals, i.e. heterounit polymers are formed in the polycyclocondensation process.[92,93]

Oligophenylenes containing diphenyl-1,2-dicarbadodecaborane groups were found to be less soluble than the prepolymers based on bis(acetylbenzyl)dicarbadodecaboranes: they dissolved fully only in the reaction solution, chloroform, and *o*-dichlorobenzene and did not dissolve in benzene, toluene and dioxane,[92] whereas the dicarbadodecaborane-containing oligophenylenes based on bis(acetylbenzyl)dicarbadodecaborane derivatives dissolve readily in toluene, cyclohexanone, dioxane, acetone, benzene, etc.[93]

The heat-treated dicarbadodecaborane-containing polyphenylene exhibits a high thermal stability. According to DTGA data, the mass of the polymers obtained from bis(acetylbenzyl)dicarbadodecaboranes increases by 18% at 400 °C as a consequence of the oxidation of the dicarbadodecaborane groups at the B-H bonds; the decrease in mass at 800 °C in air is 17%. Under the conditions of isothermal heating at 700 °C for 7-8 h, the mass of the polymers hardly changes.[93]

It has been noted that[92] the thermal stability of the polymers based on the ethyl ketal of acetylbiphenylyl-1,2-dicarbadodecaborane is higher than that of the analogous polymers based on the ethyl ketal of acetylbenzyl-1,2-dicarbadodecaborane with the same or higher boron content in the latter and for approximately the same intrinsic viscosities of the initial prepolymers. Thermomechanical tests on polymers with biphenylyl-1,2-dicarbadodecaborane groups in the macromolecules on a plastometer showed that they are not deformed up to 280 °C and for loads up to 200 kgf cm^{-2}.[92]



Epoxides and phenolformaldehyde oligomers based on 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane have been developed.

Not only the individual 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane but also mixtures of boroxyphenylenedicarbadodecaboranes [usually mono-, di-, and trisubstituted 1,2-bis-(4-hydroxyphenyl)dicarbadodecaboranes without their separation into the individual substances], obtained by the hydrolysis of (*B*-1,7-dicarbadodecaboranyl)phenyl borates and (*B*-1,7-dicarbadodecaboranyl)phenyl silicates, synthesised by the high-temperature condensation of 1,2-dicarbadodecaborane with the phenylesters of orthosilicic and orthoboric acids, may be used successfully for the synthesis of epoxide and phenol-formaldehyde phenylenedicarbadodecaborane-containing oligomers and polymer systems based on them.[98-100]

The synthesis and properties of the thermoreactive epoxyphenylenedicarbadodecaborane and 1,2-bis(4-hydroxyphenyl)-dicarbadodecaborane formaldehyde oligomers have been examined.[19,21,98-111]

Epoxide oligomers based on 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane have been synthesised by a two-stage method.[101] The reaction of the 1,2-bis(4-hydroxyphenyl)-dicarbadodecaborane with epichlorohydrin was initially carried out in the presence of catalytic amounts of a tertiary amine at 50-90 °C for 6-12 h. The dichlorohydrin formed was isolated and treated in a dry inert solvent (chlorinated hydrocarbons, etc.) with solid alkali in stoichiometric proportions at a temperature not exceeding 40-50 °C. Depending on the selected 1,2-bis-(4-hydroxyphenyl)dicarbadodecaborane : epichlorohydrin molar ratio selected, oligomeric products with different molecular masses or the diglycidyl ether of 1,2-bis(4-hydroxyphenyl)-dicarbadodecaborane (see compound **13**) were obtained. For a 1 : 5 component ratio, a compound with the composition closest to that of the diglycidyl ether is formed; its melting point is 130-135 °C. The 1,2-dicarbadodecaborane-containing epoxide oligomers are readily soluble in ethanol, acetone, chloroform, tetrahydrofuran, benzene, etc.

An epoxyphenyldicarbadodecaborane oligomer with a molecular mass of 400 and a softening temperature of 30 °C was synthesised in one stage from a mixture of mono-, di-, and trihydroxyphenylenedicarbadodecaboranes[98,99] in epichlorohydrin in the presence of a 40% aqueous solution of sodium hydroxide [with boroxyphenylenedicarbadodecaboranes : epichlorohydrin : alkali molar ratios of 1 : 10 : (2-4)] at 60 °C for 2-3 h.

13

The epoxyphenylenedicarbadodecaborane oligomers obtained are hardened with the aid of familiar hardening agents (acid anhydrides, amines).[99,101] The study of the hardening of oligoepoxyphenylenedicarbadodecaborane in the presence of 30 mass% of an anilinoformaldehyde oligomer (specimen 1) or 15 mass% of a polyethyleneamine (specimen 2) showed that the oligopeptide is structured most vigorously in the latter case.[97] Heating of a composition comprising the oligoepoxide and the polyethyleneamine for 1 h at 100 and 125 °C leads to ~97% hardening. The structure formation process takes place more slowly for the composition comprising the oligoepoxide and the anilinoformaldehyde oligomer. The degree of hardening of this composition in the temperature range 100–200 °C increases continously, attaining approximately 91% after heating for 8 h. According to DTGA data, in air (at a heating rate of 5 K min^{-1}) both oligoepoxide specimens, hardened at 200 °C, begin to lose mass in the temperature range 250–300 °C, the rate of degradation of specimen 1 being somewhat higher than that of specimen 2: at 350 and 600 °C, the mass of specimen 1 diminishes by 24% and 37%, while that of specimen 2 diminishes by 8% and 21% respectively. However, the overall decrease in the mass of both specimens is the same at 900 °C and amounts to 35%. On the other hand, the usual (not containing dicarbadodecaborane groups) epoxyoligomer, hardened by the anilinoformaldehyde oligomer, is fully combusted at 600 °C.[97]

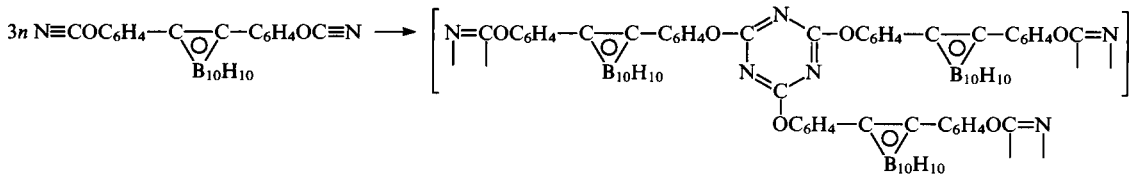
Homogeneous and mixed phenolformaldehyde polymers with diphenylenedicarbadodecaborane fragments in the chain have been synthesised by the reaction of formaldehyde with 1,2-bis-(4-hydroxyphenyl)dicarbadodecaborane or with a mixture of the latter and phenol using different ratios of the starting materials.[21,100,101,104,109] The study of the polycondensation of 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane with formaldehyde (the reaction was carried out in isopropyl alcohol at 93–94 °C in the presence of NaOH using an aqueous formaldehyde solution) and of the structure of the product showed that, according to IR spectroscopic data, dicarbaundecaborate derivatives are not formed in this process.[103] It has been noted that, depending on the nature of the catalyst, the process conditions, and the ratio of the initial components, oligomers of both the resol and novolac type may be obtained.[111] Oligomers of the resol type are formed in the presence of basic catalysts [for example, NaOH, NH_4OH, and $Ba(OH)_2$] whereas oligomers of the novolac type are formed in the presence of acid catalysts (for example, hydrochloric acid and toluene-*p*-sulfonic acid) for 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane : formaldehyde at molar ratios ranging from 1 : 0.8 to 1 : 4.

The synthesis of mixed resols based on 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane and phenols taken in proportions ranging from 1 : 3 to 1 : 21 for a 1.5 : 1 molar ratio if the formaldehyde and phenolic components has been described.[107] The polycondensation was carried out without a solvent in the presence of a 25% aqueous solution of ammonia (0.3 mol per mole of phenols) at 90 °C for 3 h. With decrease in the content of the dicarbadodecaborane-containing groups in the oligomer, the softening temperature of the latter fell from 110 to 60 °C, while its molecular mass increased from 650 to 890. In contrast to the resol obtained solely from the 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane, the mixed dicarbadodecaborane-containing resols exhibit an increased fluidity. These oligomers are hardened under the conditions usual for phenolformaldehyde resols, forming resites containing only 2%–4% of the acetone-soluble fraction.

The study of the chemical transformations on heating dicarbadodecaborane-containing resols and the corresponding resites showed that, in the temperature range from 50 to 200 °C, structure formation in the dicarbadodecaborane-containing oligomer takes place via the mechanism usual for resols. At temperatures of 200–300 °C and above, the dicarbadodecaborane groups of the resites undergo appreciable chemical transformations, the extent of which depends significantly on the heating conditions (air, vacuum).[104] It has been suggested that the chemical transformations involving the dicarbadodecaborane groups of the resites are in fact responsible for their enhanced thermal stability and the high yields of the coke residue compared with the known polymers.

The greatest differences between the stabilities of the usual phenolformaldehyde and dicarbadodecaborane-containing resites are observed in thermooxidative degradation. According to DTGA data, in air the mass of the dicarbadodecaborane-containing resite begins to increase at 350 °C and above (at 900 °C the increase is 4%), whereas the usual hardened resol decomposes fully under these conditions.[104]

The mixed dicarbadodecaborane-containing resites based on 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane and phenol also exhibit an increased thermal stability, the decrease in their mass on heating in air depending in a definite manner on the content of the dicarbadodecaborane groups. However, the introduction of even small amounts of dicarbadodecaborane groups into the copolymer decreases significantly the mass loss. Thus the decrease in the mass of the hardened cooligomer obtained for the 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane : phenol = 1 : 21 molar ratio is 45% at 900 °C.[106]

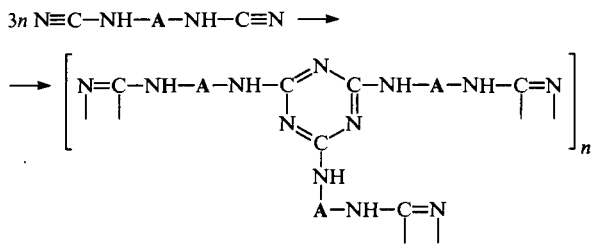


A number of studies have been devoted to the elucidation of the nature of the high thermal stability of the dicarbadodecaborane-containing resites.[105,107–110] Analysis of the structural transformations in the dicarbadodecaborane-containing resites over a wide temperature range (200–2500 °C), resorting to X-ray diffraction and various spectroscopic research methods, suggested that the oxidation of the B–H groups of the dicarbadodecaborane fragments and other processes involving their consumption, which is accompanied by the evolution of an appreciable amount of hydrogen, is most characteristic of the 1,2-bis(4-hydroxyphenyl)dicarbadodecaboraneformaldehyde resites in the temperature range 300–450 °C. This leads to an increase in the density of the network in the resites as a result of the formation of the energetically strong B–B, B–O–B, and B–C bonds.

By virtue of the presence of such a thermally stable macronetwork system, the radical species produced (large molecular formations or low-molecular-mass degradation products) are unable to emerge from the 'cage' and undergo secondary recombination processes. Nor can one rule out the possibility that the hydrogen split off from the B–H groups may interact with the radical species, inhibiting further polymer decomposition processes.[108]

The high thermal stability of the 1,2-bis(4-hydroxyphenyl)-dicarbadodecaboraneformaldehyde and epoxyphenylenedicarbadodecaborane polymers has also been used to enhance the thermal characteristics of the hardened polymer compositions based on the usual polymers of this type.[98,112] Thus the hardened compositions comprising phenolphthaleinformaldehyde and 1,2-bis(4-hydroxyphenyl)dicarbadodecaboraneformaldehyde (based on boroxyphenylene-1,7-dicarbadodecaboranes) resols are destructured to a lesser extent than the phenolphthaleinformaldehyde resite. According to DTGA data, the decrease in the mass of a hardened specimen (obtained for a 1 : 1 mass ratio of the resols) in air at 900 °C is 40%, whereas the phenolphthaleinformaldehyde resite decomposes almost completely at the same temperature. In the presence of 50 mass% of the epoxyphenylenedicarbadodecaborane oligomer, the yield of the coke residue is 60% greater than in the case of the unmodified phenolphthaleinformaldehyde resite.[98]

Modification of an epoxide oligomer [based on 1,1,3-tris-(hydroxyphenyl)propane and epichlorohydrin] by a dicarbadodecaborane-containing phenolformaldehyde oligomer [based on 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane and formaldehyde] makes it possible to increase the thermal stability and the coke number of the hardened epoxyphenolformaldehyde polymer.[112] Thus, whereas for the hardened polymer obtained for the epoxide : dicarbadodecaborane-containing resol = 3.3 : 1 mass



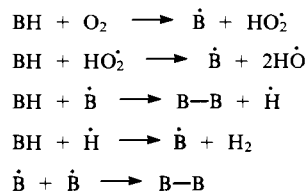
Scheme 12

ratio, the temperature of the onset of decomposition in air is about 260 °C, the yield of the coke residue on heating to 600 °C is 60%, and the decrease in mass on heating in vacuo at 350 °C for 3 h is 15%, for the corresponding hardened epoxyphenolformaldehyde polymer based on the same oligoepoxide and an anilinephenolformaldehyde oligomer the temperature of the onset of decomposition in air is about 200 °C, the yield of the coke residue on heating to 600 °C is 20%, and the decrease in mass on heating in vacuo at 350 °C for 3 h is 45%.

We shall consider yet another type of polymer with diphenyldicarbadodecaborane fragments in the chain. The diphenyldicarbadodecaborane fragments were introduced into the macromolecules by means of the thermal polycyclotrimerisation of the dicyano-esters of 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane (Scheme 12).[113] Such dicarbadodecaborane-containing polymers with *s*-triazine rings in the macromolecule are obtained with a high degree of conversion (98%) of the functional groups, i.e. in the final stage of the process these polymers are regularly cross-linked dense-network systems. The temperature of the onset of the deformation of such a polymer is 375 °C when a load of 0.8 kgf cm^{-2} is applied to the specimen; according to DTGA data, the temperature of the onset of decomposition in air is 385 °C; the polymer has an amorphous structure.

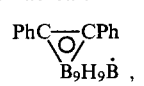
Dicarbadodecaborane-containing cross-linked thermally stable and heat-resistant polymers containing melamine structures in the main chain have been synthesised by the polycyclotrimerisation of diphenyl-1,7-dicarbadodecaborane-containing biscyanamides or their mixtures with aromatic mono- and bis-cyanamides.[113,114]

A = C_6H_4—$CB_{10}H_{10}C$—C_6H_4



The temperature of the deformation of the polymelamine based on 4,4′-bis(4-cyanamidophenyl)dicarbadodecaborane is 490 °C; the temperature of the onset of the decrease in mass in air is 370 °C. According to X-ray diffraction data, the polymer has an amorphous structure with signs of crystallinity.

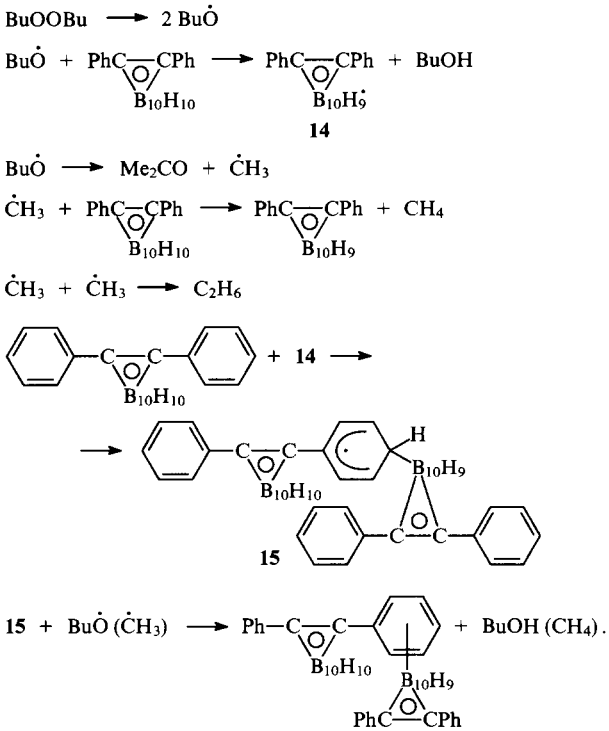
V. The mechanism of the thermal transformations of polyarylenedicarbadodecaboranes and the radical arylation of dicarbadodecaborane(12)



The study of the linear polyheteroarylenedicarbadodecaboranes showed (see Section III) that the formation under comparatively mild conditions (250–300 °C) of three-dimensional networks as a result of reactions involving the dicarbadodecaborane groups is most characteristic of these polymers. In the presence of oxygen, the formation of new bonds in the dicarbadodecaborane-containing polymers occurs more vigorously under these conditions compared with an inert medium or a vacuum. There is no doubt that the elucidation of the nature and mechanism of the formation of new thermally stable bonds with participation of the dicarbadodecaborane groups is of fundamental importance for the explanation of the behaviour of polyarylenedicarbadodecaboranes at elevated temperatures and of the formation of thermostable secondary products. Taking this into account, a study of the thermal transformations of 1,2-diphenyl-1,2-dicarbadodecaborane was undertaken.[115]

It was established that, when diphenyl-1,2-dicarbadodecaborane is heated in air in the temperature range 260–300 °C, the product of the reaction occurring with evolution of hydrogen contains, together with the initial compound, a substance which is a diphenyl-1,2-dicarbadodecaborane dimer according to gel-permeation chromatographic, ebullioscopic and mass-spectrometric data. Detailed analysis of this compound by various spectroscopic methods suggested that under these conditions the diphenyldicarbadodecaborane fragments in the dimer are linked by a single B–B bond, the formation of which most probably involves the boron atoms in the 9- or 12-position which are most remote from the carbon atoms in the dicarba-*closo*-dodecaborane(12) icosahedron.

The study of the conditions under which this reaction is carried out showed that, in the presence of phenols (familiar inhibitors of free-radical reactions), the yield of the dimer falls sharply, whereas heating of 1,2-diphenyl-1,2-dicarbadodecaborane in the presence of *tert*-butyl peroxide—a source of free radicals—is accompanied by the formation of the dimer under much milder conditions. The results suggested that the reaction constituting the basis of the dimerisation of 1,2-diphenyl-1,2-dicarbadodecaborane is of a radical type and, when the dicarbadodecaborane is heated in air, the reaction is initiated by oxygen.

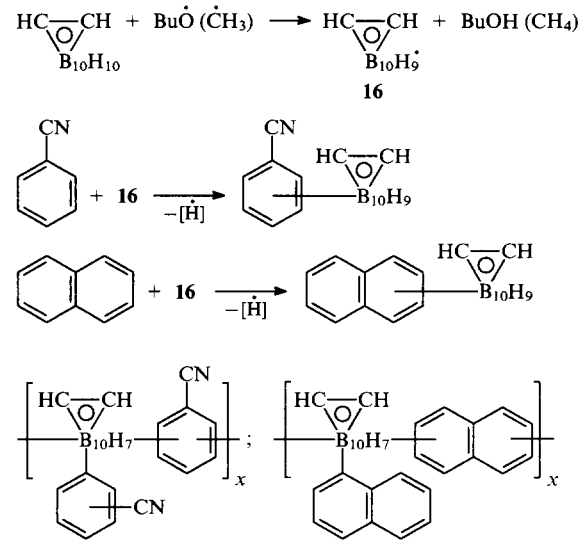


It is noteworthy that the dimer is also formed on heating in vacuo, but this requires much more severe conditions (500 °C and above). Evidently during the high-temperature heat treatment, homolytic dissociation of the B–H bond of the dicarbadodecaborane nucleus takes place with formation of the radicals

the recombination of which leads to the dimer. Such severe conditions, necessary for the formation of the dimer in vacuo, indicate that oxygen is an initiator of both the formation of the diphenyl-1,2-dicarbadodecaborane dimer and evidently of the structure formation in the dicarbadodecaborane-containing polymers.

The study of the thermal decomposition of *tert*-butyl peroxide in 1,2-diphenyl-1,2-dicarbadodecaborane at 150 °C for 5 h showed that it results in the formation of *tert*-butyl alcohol, acetone, methane, ethane, and small amounts of hydrogen together with polymeric dicarbadodecaborane-containing products with the maximum degree of polarisation (n = 10)

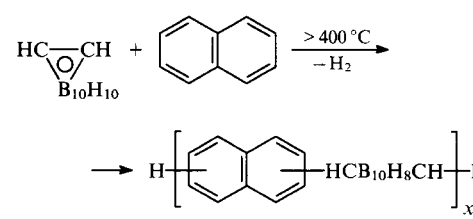
determined from gel-permeation chromatographic data.[116] The yield of the polymeric products is directly proportional to the amount of decomposed peroxide and amounts to 58%–70% of theoretical. The calculated yield of the products of the polymerisation of 1,2-diphenyl-1,2-dicarbadodecaborane and the total amount of the butyl alcohol and methane obtained are similar. The study of the structure of the dicarbadodecaborane-containing products by ^{13}C and ^{11}B NMR spectroscopy permitted the conclusion that dimers and oligomers (via a boron–carbon bond) are formed under these conditions. They are mixtures of isomers in terms of the boron atoms of 1,2-diphenyl-1,2-dicarbadodecaborane and the position in the aromatic ring. The reactions occurring in the thermolysis of *tert*-butyl peroxide can be represented schematically as follows:



The virtually total absence of molecular hydrogen from the reaction products, the agreement between the total molar amounts of methane and butyl alcohol and the total number of B–C bonds in the products of the oligomerisation of 1,2-diphenyl-1,2-dicarbadodecaborane, and the formation of a B–C bond suggested that the mechanism of the radical reaction of 1,2-diphenyl-1,2-dicarbadodecaborane involves bimolecular aromatic homolytic substitution via the formation of an intermediate radical σ-complex between the 1,2-dicarbadodecaboranyl radical and the aromatic compound.

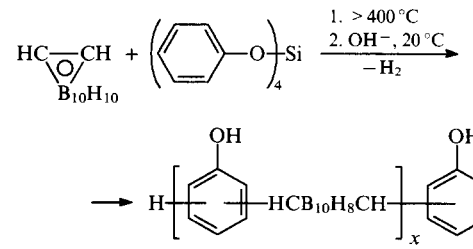
The boron-centred dicarbadodecaboranyl radicals were obtained as a result of the abstraction of the hydrogen atom from the B–H groups in 1,2-, 1,7-, and 1,12-dicarbadodecaboranes by the *tert*-butoxyl radicals. They were detected by the EPR method in the form of spin-adducts with 2,4,6-tri-*tert*-butyl-4-methylcyclohexa-2,5-dien-1-one.[117]

In order to confirm this mechanism of the dimerisation and oligomerisation of 1,2-diphenyl-1,2-dicarbadodecaborane in the presence of a free radical source, a study was made of the interaction of 1,2- and 1,7-dicarbadodecaboranes with aromatic compounds such as benzonitrile and naphthalene in the presence of *tert*-butyl peroxide at 200 °C.[118] It was established that the reactions occur in this case in accordance with the following scheme:



x = 5–10

Under conditions where the intermediates are not removed, only oligomeric products with x = 5–10 are formed. The products of the recombination of the dicarbadodecaboranyl radicals and the aromatic compounds were not detected.



Since the products of the homolysis of the bonds at elevated temperatures can also serve as sources of free radicals, the dicarbadodecaboranes(12) were heated at 350–490 °C in the presence of aromatic compounds (naphthalene)[119] and also in the gas phase at 630–750 °C.[120] It was indeed established that under these conditions the dicarbadodecaboranes(12) undergo thermal radical condensation with the aromatic compounds in both condensed and gas phases with evolution of hydrogen.

In the condensed phase for degrees of conversion of 85%–95% [with respect to the dicarbadodecaborane(12)], oligomers soluble in aromatic hydrocarbons, ketones, and other solvents are formed (Scheme 13).

Scheme 13

x = 8–10

x = 2–3

The thermal condensation in the gas phase (at 630–750 °C) was investigated in relation to the interaction of 1,7-dicarbadodecaborane with benzene.[120] It was found that the products of this condensation for low degrees of conversion of 1,7-dicarbadodecaborane (up to 33%) are isomeric boron-substituted phenyl-1,7-dicarbadodecaboranes, namely 2-, 4-, 5-, and 9-phenyl-1,7-dicarbadodecaboranes, 2-phenyl-1,12-dicarbadodecaborane, and biphenyl. For high degrees of conversion, attained by

reintroducing the reaction solution into the reactor, the appearance of unidentified products with a higher molecular mass, tentatively disubstituted 1,7-dicarbadodecaboranes, was observed. An increase in the reaction temperature led to an increase in the yield of biphenyl, which is apparently due to the higher activation energy for this side reaction compared with the activation energy for the thermal condensation of 1,7-dicarbadodecaborane and benzene. The latter evidently proceeds, as in the condensed phase, via a stage involving the formation of an intermediate boron-centred radical. The products of the thermal condensation in the gas phase are similar to those of the condensation in the condensed phase and constitute a mixture of all possible isomers of 1,7-dicarbadodecaborane, their content in the mixture corresponding to the number of equivalent boron atoms in the 1,7-dicarbadodecaborane molecule and being almost independent of the temperature in the experimental temperature range. The carbon atoms of 1,7-dicarbadodecaborane do not participate in this reaction.[120]

The study of the kinetics of this process was undertaken in relation to the interaction of 1,7-dicarbadodecaborane with naphthalene at 350–490 °C.[119] The reaction was carried out in glass bulbs in the gas phase. The concentrations of the initial reactants were measured with the aid of gas–liquid chromatography.

The partial reaction orders with respect to each component were calculated from the equation

$$\ln W_0 = \ln k + n \ln[HCB_{10}H_{10}CH]_0 + m \ln[C_{10}H_8]_0 \ ,$$

where W_0 is the initial rate of consumption of 1,7-dicarbadodecaborane (mol litre^{-1} s^{-1}), k the reaction rate constant, n the reaction order with respect to 1,7-dicarbadodecaborane, m the reaction order with respect to naphthalene, $[HCB_{10}H_{10}CH]_0$ the initial molar concentration of 1,7-dicarbadodecaborane, and $[C_{10}H_8]_0$ the initial molar concentration of naphthalene. It was found that the reaction orders with respect to 1,7-dicarbadodecaborane and naphthalene are close to unity. The effective activation energy for the reaction in the temperature range 440–490 °C is 221 ± 6 kJ mol^{-1}, which is significantly less than the C–H bond stength in naphthalene, the latter amounting to ~419 kJ mol^{-1}.[119]

It was established that the rate of the reaction between 1,7-dicarbadodecaborane and naphthalene is described by the following equation for degrees of conversion between 0% and 30% and at temperatures in the range 440–490 °C:

$$-\frac{d[C_{10}H_8]}{d\tau} = \frac{d[HCB_{10}H_{10}CH]}{d\tau} = k[HCB_{10}H_{10}CH]_0^{0.95\pm0.04}[C_{10}H_8]_0^{1.01\pm0.03} \ ,$$

where

$$k = 6.3 \times 10^{11.0\pm1.0} \exp\left(-\frac{221 \pm 6}{RT}\right) \Big/ \text{litre mol}^{-1}\ \text{s}^{-1}.$$

Hence it was concluded that the interaction of the dicarbadodecaborane(12) with aromatic compounds at high temperatures is described by the following scheme:

$$ArH \xrightarrow{k_0} Ar^{\cdot}$$

$$Ar^{\cdot} + BH \xrightarrow{k_1} ArH + \dot{B}$$

$$\dot{B} + ArH \underset{k_3}{\overset{k_2}{\rightleftharpoons}} ArH\dot{B}$$

$$ArH\dot{B} + BH \xrightarrow{k_4} ArH_2B + \dot{B}$$

$$ArH_2B \xrightarrow{k_5} ArB + H_2$$

$$ArH\dot{B} + \dot{B} \xrightarrow{k_6} ArB + BH$$

where ArH is the aromatic compound and BH is the dicarbadodecaborane(12).

In principle, this scheme is analogous to the mechanism of the reaction involving chain radical addition to alkenes known as the Kharasch reaction.[119] In conformity with this scheme, the rate of reaction of the dicarbadodecaborane(12) is then equal to the rate of reaction of the aromatic compound:

$$-\frac{d[BH]}{d\tau} = -\frac{d[ArH]}{d\tau} = k_4[ArHB^{\cdot}][BH] \ ,$$

and subject to the conditions $k_3 \gg k_4[BH]$, we obtain

$$-\frac{d[BH]}{d\tau} = -\frac{d[ArH]}{d\tau} = k_4\left(\frac{k_2}{k_3}\right)^{1/2}\left(\frac{k_0}{k_6}\right)^{1/2}[ArH][BH] \ .$$

Since the reactants in this reaction are polyfunctional, it is possible to employ the initial concentrations instead of the current concentrations for low degrees of conversion. In this scheme, the bimolecular abstraction reaction is an aromatic homolytic substitution reaction.[119]

The proposed reaction scheme and the experimental data yield an overall reaction order of 2, which is due to the appreciable acceleration of the reaction under the influence of the radical fragments formed. It is to be expected that the factor determining the rate of the molecular chain propagation in the reaction investigated is the stability (thermodynamic stability) of the σ-radical complex at high temperatures.

This is confirmed by the data obtained in the condensation of monosubstituted benzene derivatives, which leads, as can be seen from Table 6, to the formation of two isomers (*ortho*- and *para*-) in terms of the position of the dicarbadodecaboranyl group in the aromatic ring, each of which consists of four isomers in terms of the position in which the aryl group is substituted in the 1,7-dicarbadodecaborane nucleus.

Table 6 shows that the nature of the substituent influences the ratio of the isomers involving the 2- and 9-positions in the 1,7-dicarbadodecaborane. Since the 1,7-dicarbadodecaboranyl group exhibits different inductive effects in the 2- and 9-positions[122] (positive in the 9-positive and negative in the 2-position), it is to be expected that the presence of an electron-donating substituent in the benzene ring increases the stability of the radical complex with the 1,7-dicarbadodecaboranyl radical involving the 2-position, whilst the presence of an electron-accepting substituent increases the stability of the complex involving the 9-position, increasing thereby the rate of formation, i.e. the content, of a particular isomer in the reaction products.

Table 6. The compositions of the *B*-aryl-1,7-dicarbadodecaboranes obtained from PhX and 1,7-dicarbadodecaborane by thermal condensation at 440 °C and for the molar ratio arene:1,7-dicarbadodecaborane = 1:15.

Substituent X	Content of *para*-isomers (%)			Content of *ortho*-isomers (%)			*para*:*ortho*
	2-	4-, 5-	9-	2-	4-, 5-	9-	
H	21.5	6.5	15.0	–	–	–	–

Note. The totals for isomers of the *B*-aryl-1,7-dicarbadodecaborane with the aryl group in the 4- and 5-positions in the dicarbadodecaborane nucleus are given.

Oligophenylene-, oligonaphthalene-, and oligoanthracenedicarbadodecaboranes, obtained by the high-temperature polycondensation of 1,2-dicarbadodecaborane with the corresponding aromatic compound under pressure at 400–460 °C, are coloured powders, the colours of which range from pale-yellow (benzene) to dark-brown (anthracene). For a degree of reaction of 95%, the oligomers are readily soluble in acetone, benzene, and chloroform. It was found that the Mark–Kuhn–Houwink equation for oligophenylenedicarbadodecaborane is

$$[\eta] = 4.622 \times 10^{-4} M^{0.59\pm0.09}.$$

(The reduced viscosity was determined in toluene). The average length of the Kuhn segment for this oligomer, which is 12.0 Å, makes it possible to assign the structure to the flexible-chain type.[123]

Thermal condensation of dicarbadodecaborane(12) with ferrocene is also possible. In order to investigate the mechanism of this reaction, a study was made of the process kinetics at 440 °C. It was found from the dependences of the initial rates of consumption of ferrocene on the initial concentration in the absence of dicarbadodecaboranes(12) that the rate of consumption of ferrocene under these conditions is described by the relation

$$-\frac{d[(C_5H_5)_2Fe]}{d\tau} = k[(C_5H_5)_2Fe]^{2.48\pm0.17},$$

where $k = (1.2 \pm 0.5) \times 10^3\ s^{-1}$.

The study of the dependence of the initial rates of consumption of ferrocene and the dicarbadodecaborane(12) on the initial concentration of the dicarbadodecaboranes(12) showed that variation of the concentration of the latter hardly affects the rate of consumption of ferrocene. Thus the rate of consumption of ferrocene in the course of the reaction with dicarbadodecaboranes(12) is also described by the relation presented above.

The rate of consumption of dicarbadodecarboranes(12) is proportional to their concentration in accordance with the relation

$$\frac{d[C_2B_{10}H_{12}]}{d\tau} \sim [C_2B_{10}H_{12}]^{1.76\pm0.12}.$$

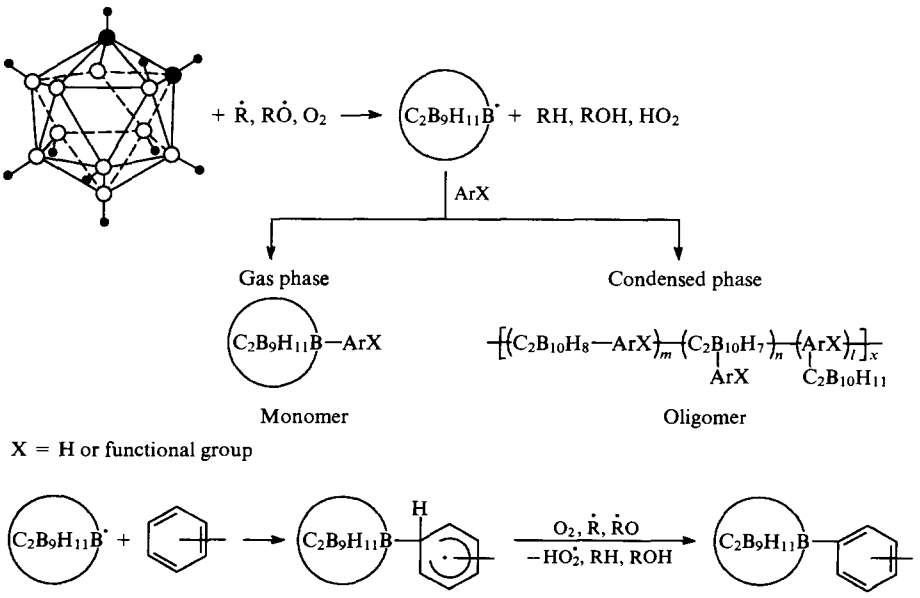
The data obtained permitted the conclusion that the condensation of ferrocene with dicarbadodecaborane(12) differs fundamentally from the reaction of dicarbadodecaborane(12) with aromatic compounds[119] apparently mainly as a consequence of the high rate of the thermal degradation of ferrocene.

One can assume with a high degree of justification that the condensation of ferrocene with dicarbadodecaboranes(12) is achieved exclusively as a result of the presence of the radical products of the degradation of ferrocene, which is in its turn a heterogeneous autocatalytic process. The rate of the radical degradation of the radical products is then higher than the rate of their diffusion into the bulk of the gas phase, which is the reason for the strong dependence of the rate of consumption of dicarbadodecaboranes(12) on their concentration.

The presence of cyclopentadiene and its dimer among the products of the degradation of ferrocene in the presence of dicarbadodecaborane(12) at temperatures in excess of 350 °C shows that the primary products are cyclopentadienyl radicals.

$$(C_5H_5)_2Fe \xrightarrow{>350\ ^\circ C} 2\,C_5H_5^{\bullet} + Fe$$

$$C_5H_5^{\bullet} + 1,2\text{-},1,7\text{-}C_2B_{10}H_{12} \longrightarrow C_5H_6 + 1,2\text{-},1,7\text{-}C_2B_{10}H_{11}$$



$$2\,C_5H_6 \longrightarrow \text{cyclopentadiene dimer.}$$

The formation of the unstable and reactive 1,2- and 1,7-dicarbadodecaboranyl radicals apparently constitutes a sufficient condition for the formation of the products of the condensation of *B*-ferrocenyl-1,2- and *B*-ferrocenyl-1,7-dicarbadodecaboranes in the course of their further transformations as a result of reactions analogous to homolytic aromatic substitution reactions.

The reaction involving the direct thermal arylation of dicarbadodecaboranes(12) differs from the arylation reaction examined at the beginning as regards the mechanism of the homolytic radical aromatic substitution in the presence of a free-radical source evidently only in the mechanism of the formation of the boron-centred radicals. In a general form, the radical arylation of dicarbadodecaboranes(12) may be represented by Scheme 14.

The results of the investigation presented above are important for the understanding and practical solution of the problem of the preparation of polymers based on dicarbadodecaboranes(12) and having a high thermal stability. Firstly, the transformations in such polymers at elevated temperatures, leading to the formation of dense network three-dimensional systems and giving rise to materials with a long useful life, become comprehensible. Secondly, dicarbadodecaboranes(12) can be and should be regarded as inhibitors of the thermal and thermooxidative degradation, since the radical products of the degradation of the organic fragments of the polymers interact with the

Scheme 14

dicarbadodecaborane groups and are converted into an inactive form. The dicarbadodecaborane groups are capable of forming new stable bonds of the B–C type with the boron-centred radicals (Scheme 14); nor can one rule out the formation of B–B bonds by a recombination reaction. Thus one can represent the dicarbadodecaborane-containing polymer matrix at elevated temperatures as a system involving a definite dynamic equilibrium in which the thermal destruction of the chemical bonds is compensated by the formation of new ones. A necessary consequence of these results is also that the dicarbadodecaborane groups must be introduced into polymer systems in combination with aromatic compounds in order to ensure the conditions for the transformations examined above. Thirdly, an important factor is undoubtedly the fact that the observed direct arylation of dicarbadodecaboranes(12) permits a new and much simpler solution of the problem of the synthesis of dicarbadodecaborane-containing monomers and reactive oligomers. For this purpose, it is essential to introduce the corresponding aromatic compounds into the thermal condensation reaction.

The example involving tetraphenoxysilane, presented in Scheme 13, the product of the interaction of which with 1,2-dicarbadodecaborane affords a reactive monomer with the more stable 1,7-dicarbadodecaborane groups, capable of being employed as such, constitutes an adequate illustration of the process in the condensed phase. On the other hand, the products of its hydrolysis are dicarbadodecaborane-containing phenols, which serve as starting materials for the synthesis of polymers of practical importance, in particular those of the phenolformaldehyde and epoxide types.[98] For the gas-phase arylation of dicarbadodecaboranes(12) in a flow system, it is sufficient to employ the corresponding benzene derivatives.

VI. Conclusion

Since the end of the 1960s, an extensive series of studies have been carried out on the development of new polymers with arylenedicarbadodecaborane fragments in the chain. Novel methods have been developed for the synthesis of various bifunctional dicarbadodecaborane-containing aromatic monomers and processes involving the formation from the latter of new high-molecular-mass dicarbadodecaborane-containing polymers have been investigated. A detailed study has been made of the mechanisms of the chemical reactions of polyarylenedicarbadodecaboranes, which makes it possible to understand the causes of their unusual thermal behaviour and to find new promising methods of synthesis of dicarbadodecaborane-containing monomers and polymers.

Naturally, dicarbadodecaborane-containing polymers are not produced on a large scale and in the foreseeable future will not be produced on such a scale, which, incidentally, applies also to many other interesting polyheteroarylenes with specific properties. Dicarbadodecaborane-containing polymers are special-purpose polymers used primarily in those fields where improved thermal characteristics are required for the polymeric materials.[17,19–25,124–133]

Thus the employment of dicarbadodecaborane-containing phenolformaldehyde polymers as a base for adhesive compositions proved to be promising[125,132] because hardened dicarbadodecaborane-containing resols are distinguished by a high thermal stability. Dicarbadodecaborane-containing resites hardly undergo any change in mass during ageing for 1000 h at 350 °C, whereas the usual phenolformaldehyde polymers are fully destructured under these conditions.

The combination of effective thermal properties of the dicarbadodecaborane-containing resites with the improved adhesion characteristics which are in general specific to phenolformaldehyde polymers made it possible to obtain adhesive compositions with a long useful life at 350–500 °C. The strength characteristics of certain adhesives hardly change after prolonged ageing at 500 °C. Thus when steel components are glued together by means of the adhesive based on the dicarbadodecaborane-containing phenolformaldehyde polymer, the breaking stress is 120 kgf cm^{-2} when the glued junction is subjected to shear before ageing at 20 °C and 500 °C, while after ageing for 500 h at 20 and 500 °C the breaking stresses are 116 and 118 kgf cm^{-2} respectively.

The use of the dicarbadodecaborane-containing epoxide polymers in thermostable adhesive compositions also proved successful.[19,22,23,25,125,130,132] The employment of epoxydicarbadodecaborane oligomers in compositions with furan polymers, as activators of the graphitisation process, in the technology for the preparation of carbon materials has also had a positive effect.[131]

The application of dicarbadodecaborane-containing polyphenylenes, synthesised by the polycyclocondensation of dicarbadodecaborane-containing aromatic acetyl compounds and their ketals, as thermostable binders for glass plastics with a working temperature of 400 °C and in the manufacture of thermostable constructional materials has been described.[97,126–128]

It has been suggested that dicarbadodecaborane-containing polymers of various classes be used to obtain thermostable antifriction self-lubricating coking plastics ensuring the operation of dry friction units at extreme temperatures of 350–500 °C and above: polyamides, polyarylates, polyimides, and polyoxadiazoles, capable of being converted during the preparation of the material into a high-strength coke which consists of a three-dimensionally structured polymer system, without change in the initial mass and shape of the article.[124,129,133] For example, heat-treated materials derived from dicarbadodecaborane-containing polyarylates [obtained from the acid chloride of 1,2-bis(4-carboxyphenyl)dicarbadodecaborane and 1,9-bis(4-hydroxyphenyl)fluorene or 1,2-bis(4-hydroxyphenyl)dicarbadodecaborane] and graphite has the following physicomechanical characteristics: hardness of 18–20 kgf mm^{-2}, coefficient of friction 0.05–0.09, intensity of linear wear $(2.5–5) \times 10^{-9}$, and limiting working temperature 500 °C. The use of the polyoxadiazole based on 1,2-bis(4-carboxyphenyl)dicarbadodecaborane or the polyimide based on 1,7-bis(3,4-dicarboxyphenyl)dicarba-dodecaborane and bis(4-aminophenyl) ether as dicarbadodecaborane-containing polymers in compositions makes it possible to obtain materials with a limiting working temperature of 600 °C whilst retaining effective physicomechanical characteristics.

By virtue of their specific behaviour at elevated temperatures, dicarbadodecaborane-containing polymers can also be used as stabilisers in the thermal and thermooxidative degradation of other polymers,[11,21,25,82,83,134,135] in the preparation of thermostable thermoprotective materials, and for other purposes.

VI.	Technological polymorphism and classification of disperse amorphous silicas	404
VII.	Computational modelling of the initial structures of amorphous silicas	406

Abstract. The review gives a systematic account of the results of detailed studies of the vibrational spectra of a series of industrial amorphous highly disperse silicas (aerosil, silica gel, aerogel) with the aid of inelastic neutron scattering. The observed phenomenon of technological polymorphism and the results of the quantum-chemical modelling of the structures and vibrational spectra of the corresponding polymorphic modifications are discussed. The bibliography includes 113 references.

I. Introduction

Silicas are substances whose structures are based on silicon dioxide.[1] This class of compounds combines both natural substances (ranging from quartz and cristobalite to semiprecious stones) and artificial substances (ranging from quartz glass to aerogel). The family of amorphous highly disperse silicas, incorporating aerosils, aerosilogels, silica gels, porous glasses, silochromes, and aerogels, occupies a special place among them.[2,3]

It is difficult to overestimate the importance of highly disperse silicas for chemistry and chemical engineering. They are used in large amounts in the chemical industry as adsorbents, fillers, and loosening agents[4] and also in medicine as medicinal drugs, intensifiers of biological activity of substances and medicinal drugs, chemisorbents, preservatives for live vaccines, etc. The uniqueness of silicas is due to their high surface activity, the nature of which is being vigorously investigated.[5,6]

Numerous studies have been devoted to the surface activity of disperse silicas, most of them having been carried out by empirical chemical methods. It was not until the end of the 1960s that spectrometric methods — vibrational IR and Raman spectroscopy[7–13] and NMR spectroscopy[14] – began to be used for the investigation of silicas. However, both due to experimental complexities and the difficulties in the interpretation of the data, the results proved in many respects to be qualitative, which hindered the employment of optical vibrational spectroscopy for the investigation of the structures and compositions of these substances.

In contrast to the optical vibrational spectroscopy, considerable progress on these lines has been achieved in recent years in neutron vibrational spectroscopy[15,16] because of the possibility of the reliable isolation of the parts of the spectrum corresponding to definite structural fragments of the system, including also the surface. This last advance should be noted particularly, since it is well known that inelastic thermal neutron scattering (INS) constitutes in the general case a bulk-phase research technique owing to the considerable mean free path of neutrons in the medium (of the order of 10^{-2} m).[17] However, if the specific surface increases, as happens in the case of highly disperse substances, or if the surface of the specimen is coated by hydrogen-containing substances [the nuclei of the lightest hydrogen isotope (protium), referred to below simply as hydrogen, have an exceptionally high neutron scattering cross-section and the amplitude of their displacements during vibrations is also high], then the contribution of the scattering by the surface vibrations increases significantly. The situation is favourable not only for hydrogen-containing adsorbents but also for the vibrations of the support as a result of the 'riding effect'.[18,19] Disperse silicas satisfy both conditions examined above, so that the application to them of INS spectroscopy proved extremely successful. As a result of a special series of experiments,[20–29] it has been possible to determine both the vibrational spectra of the bulk (or core) of a series of representatives of these substances and the vibrational spectra of the surface regions. The data obtained for a set of different industrial silicas proved fundamentally significant. It was shown that different vibrational spectra of the cores and surface regions corresponding to the silicas investigated are so different that it became necessary to assign these substances to fundamentally different structural formations.[30–32] Thus a phenomenon, called technological polymorphism, has been observed spectroscopically.[30] It served as the basis of a new algorithmic approach to the computational modelling of the substances investigated.[30–32] The modelling, carried out at the level of modern quantum-chemical methods,[33–35] made it possible to construct models of

Uspekhi Khimii **64** (5) 419–445 (1995); translated by A K Grzybowski

the structures which explain the behaviour of the vibrational spectra of different types of silicas and to establish an unambiguous relation between this phenomenon and the differences between the chemical technologies employed for the preparation of the products. The validity of the proposed approach was demonstrated by the successful comparison of the calculated and experimental vibrational spectra measured with the aid of INS.

The aim of the present review is to give a systematic account of the results obtained and the methods for their treatment in order to discover and develop an approach to the study of a specific phenomenon — technological polymorphism. This phenomenon, first thoroughly investigated for disperse silicas, proved to be one of the distinctive features of nanomaterials of virtually any class [36] and its understanding is one of the decisive factors for the creation of the basic materials for the immediate future.

II. General characteristics of disperse silicas

1. Structural properties and IR absorption

Disperse amorphous silicas are obtained in the condensation and polymerisation accompanying the hydrolysis of silicon tetrahalides, their organic orthoesters, and silicic acid salts. [1] The polymerisation leads to the formation of siloxane (SiOSi) chains and nonplanar rings with different numbers of atoms. The spatial disposition of these chains and rings gives rise to the bulk structure (core) of the silica. The same chains and rings make up its surface. The valence bonds involving the surface silicon atoms are then saturated only on the inner side of the surface. On the outer side there is a 'valency excess', which is saturated by hydroxy-groups in the presence of water molecules. The active surface centres produced readily adsorb water, as a result of which a characteristic shell consisting of hydroxy-groups and adsorbed water arises around the siloxane core. This view of the structure of amorphous disperse silicas has been described in the well known monograph by Iler. [1] During the years which have elapsed since its publication, this view has not undergone significant changes despite the solution of many of the specific problems (see the latest monographs [4,5]). Fig. 1 illustrates a structural scheme for disperse silica, which was implicitly adopted for products of any origin as recently as three years ago. The siloxane chain represents the surface layer of the atoms of the base, the fragments of its inward branching simulating the development of bulk-phase structure. The unsaturated bonds of the surface silicon atoms are blocked by hydroxy-groups, but both the number of groups per silicon atom and their distribution on the surface have not been in general clearly determined. The outer layer of the fragment is occupied by the molecules of adsorbed water, the positions of which relative to the surface groups are illustrated to a large extent arbitrarily. In essence, the model clearly presents the interpretation of the atomic structure of the bulk phase and the surface of disperse silica which has arisen on the basis of the study of their IR absorption spectra.

Attempts to investigate the vibrational spectra of disperse silicas by optical spectroscopic methods (IR absorption and total internal distorted IR reflection, Raman scattering) have been undertaken repeatedly. [7-13] However, owing to the intense absorption by the siloxane matrix, [37] the studies have been concentrated mainly in the spectral range 3000–4000 cm^{-1}, which contains the stretching vibrational frequency of the hydroxy-groups and water. The results obtained yield a contradictory picture even when combined with deuterium–hydrogen exchange data [11,13] and remain to a large extent qualitative, which can be seen from the generalised picture presented in Table 1. It follows from the table that it is virtually impossible to establish the differences between, for example, aerosil, silica gel, and aerogel on the basis of data obtained in the range 3000–4000 cm^{-1}. As regards the most structure-sensitive regions in the ranges 0–400 cm^{-1} and 500–1000 cm^{-1}, the first is fully obscured in the IR spectra by the absorption due to the siloxane core, while the second has been little investigated (for the same reason). [37-39] The available information about this spectral range is derived mainly from the analysis of compound frequencies.

The main conclusions reached on the basis of the study of the IR absorption reduced to the following:

1. The similarity of the behaviour of different disperse silicas in a series of basic reactions [1-5] suggests the similarity of the structures of their surfaces and for this reason investigations are mainly carried out on different specimens of aerosil as the chemically purest silica.

2. As a result of the concentration of studies mainly in the spectral range 3000–4000 cm^{-1}, the principal objects of study are the hydroxyl coating and the adsorbed water.

3. The surface of aerosil is uniformly coated by silanol groups with a density of ~0.046 of a group on 1 $Å^2$, which corresponds to an average distance between them of 0.7 Å. [5] The existence of silanediol groups is not disputed, but according to the data of different workers their proportion varies from 4% to 40%. [5,14] Silanetriol groups have not been detected on the surface of aerosil under the usual conditions. [40]

4. The adsorbate–support system in the case of the water–silica system consists of two partners: the silanol group and the water molecule. The problem reduces to the type of interaction between the partners. Some workers support the view that the interaction between water and silica is of the coordinative type, [6] whilst others suggest that the water molecule is bound to a hydroxyl centre via a hydrogen bond. Among the recent studies devoted to this question, special mention must be made of the studies by Lygin and coworkers, [14,41,42] who attempted to account for the mechanism of the adsorption of water on the basis of the investigation of the dynamics of the deuterium–hydrogen exchange involving the hydroxy-groups by monitoring the intensities of the absorption bands due to the OH and OD

groups (at 3749 and 2761 cm^{-1} respectively). Two conclusions were reached on the basis of these investigations: (1) water is adsorbed on hydroxy-groups and (2) on the surface of aerosil there are sections with significantly different rates of adsorption of water, i.e. there are hydroxy-groups with significantly different structures. Similar conclusions have been reached[43] from calculations by the method of molecular dynamics. The possible positions of the water adsorbed on silica are illustrated in Fig. 2.

Overall, studies of the IR absorption failed to provide answers to the following principal problems of the chemistry of disperse silicas:

to what extent are the structures of the cores of different industrial forms of amorphous disperse silicas identical;

how are their surfaces formed and what is the distribution of the hydroxy-groups on the latter;

what are the conditions for the existence of silanol, silanediol, and silanetriol groups on the surface;

what are the mechanisms of the adsorption of different substances, primarily water, on the surfaces of these products.

This situation made it necessary to seek new ways for discriminating between substances. Inelastic neutron scattering is an effective spectroscopic method. This made it possible to transfer the study of the vibrational spectrum to the range 0–1500 cm^{-1}, which contains the most structure-sensitive deformation and torsional vibrations of the hydroxy-groups, water, and the siloxane cores, and to raise the question of the measurement of the vibrational spectra of individual structural components of each silica specimen.

2. Application of inelastic neutron scattering spectroscopy to the study of vibrational spectra

INS spectroscopy is a comparatively new method for the study of surfaces. Initially studies with the aid of elastic (diffraction) and inelastic (vibrational spectroscopy) neutron scattering[17,44] were directed to the study of the bulk-phase characteristics, because, owing to the high penetrating capacity of the neutron, the contribution of the surface atoms to the scattering spectrum of the specimen was small. However, as stated in the Introduction,

the situation became more favourable for highly disperse specimens, which has been confirmed in relation to disperse silicas. In the study of the INS by these specimens, the principal advantages of neutron spectroscopy were fully manifested: sensitivity to the nuclei of hydrogen atoms and to the hydrogen–deuterium isotope substitution, the absence of selection rules in energy transfer, the involvement of a broad spectrum of vibrational states in the scattering process, etc.

One of the first productive studies of the vibrations of water adsorbed on a silica surface was carried out in 1981.[45] The preceding studies in the period 1964–1975[46–48] devoted to this problem were carried out at room temperature, which limited the possibility of studying low-frequency vibrational modes. Two specimens of silicas (silica gel) were investigated[45] at 15 K: Gasil 200 (calculated pore diameter 21 Å, specific surface 850 $m^2 g^{-1}$) and Spherisorb S20W (89 Å and 232 $m^2 g^{-1}$ respectively). The main result of this investigation was the demonstration that the spectrum of the vibrations of water within the silica gel pores differs from the vibrational spectrum of ordinary ice (Fig. 3) and that the spectral maximum, located at 80 meV (640 cm^{-1}) undergoes a bathochromic shift on passing from silica gel with a small pore diameter to one with a large pore diameter. Thus it is seen from Fig. 3 that, for the maximum moisture content in the specimen, the principal peak of the spectrum virtually coincides with the principal band in the spectrum of H_2O ice, the position of which is indicated by a vertical straight line. When the specimen is dried, the position of this peak in the silica gel spectrum shifts towards lower frequencies. A similar effect has been observed also on passing to a specimen with a smaller pore size. In the discussion of the causes of this shift, a model involving the adsorption of water on neighbouring surface hydroxy-groups was proposed, but this model was merely qualitative.

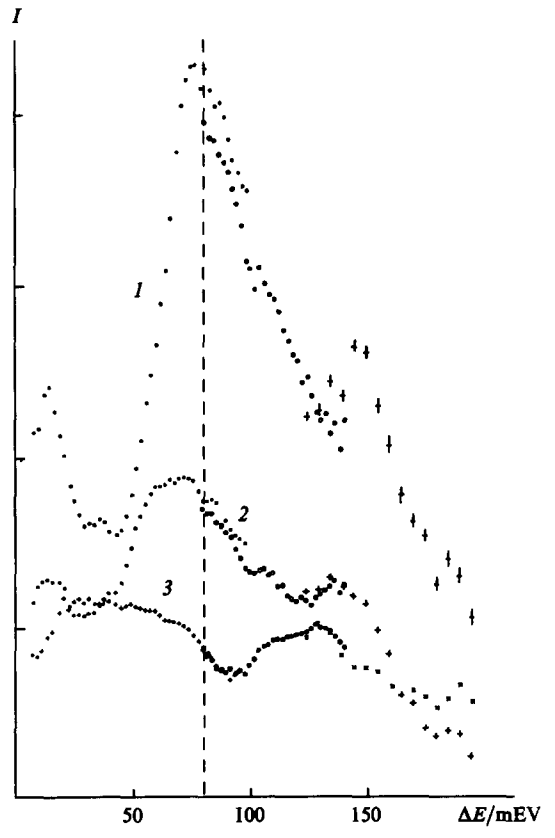

Figure 3. INS spectra of the silica gel Gasil 200 ($T = 15$ K) for different moisture contents in the specimen.[45] Moisture content (%): (*1*) 13; (*2*) 4; (*3*) specimen dried at 150 °C.

It was also established that the properties of water in the region of contact with the surface differ significantly from its properties in the bulk phase. Thus the density,[49] diffusion coefficient,[50] and viscosity of water[51,52] change in the vicinity of the silica surface. A diffraction study[52–55] showed that the water in the pores has the structure of ice in the cubic modification *Ic*; under these conditions, ordinary ice consists of hexagonal crystals *Ih*. This effect can be explained by the change in the structure of water near the silica surface, but the explanations remain qualitative particularly bearing in mind the remark made by Li et al.[56] that the structures of the surfaces of the silicas themselves are different. On the basis of model calculations and experiments at 15 K on a Vycor glass specimen (a boron-containing glass) with an average pore diameter of 30 Å and a specific surface of 180 $m^2 g^{-1}$, it was shown in the same study that there is no distinct interface in the form of layers of different density in the silica–water system. It was postulated that in fact the ice structure in the layers subject to a marked influence of the surface is similar to the structure of liquid water, where a large number of hydrogen bonds have been broken. Comparison of the vibrational spectra of water adsorbed on glasses with the spectra of ordinary ice,[57] which proved to be fairly similar (Fig. 4), led to the conclusion that the water in the Vycor glass pores is present in two forms: as the bulk-phase water and as the water adsorbed on the walls of the pores. This conclusion has been confirmed by the considerable similarity between the difference spectrum of the 'air-dry specimen – ice' and the spectrum of a 'dried specimen' (Fig. 5). On the basis of this similarity, the hypothesis that quasi-free water is present in the pores was put forward.[56] However, the paper presents only qualitative considerations concerning the contribution of the ice spectrum to the spectrum of the glass specimen with a 100% moisture content.

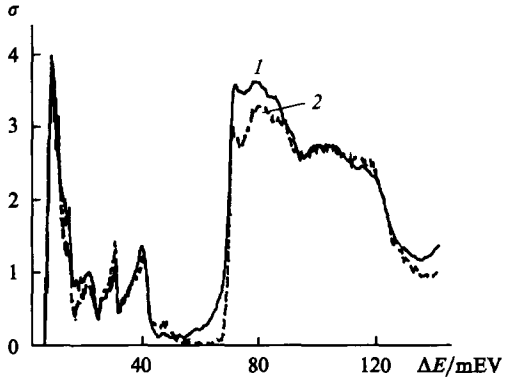

Figure 4. INS spectra of ice: (*1*) ice in the porous Vycor glass;[56] (*2*) hexagonal ice.[57]

Among the latest studies on the vibrational spectroscopy of surfaces using INS, mention should be made of investigations of silicas the surfaces of which were modified by various organic compounds,[58] the surface vibrations of hydrogen adsorbed on nickel[59] and molybdenum,[60] the vibrations of water and ammonia adsorbed on manganese and zirconium oxides,[61] and the vibrational spectra of quartz glass[62] and natural silica minerals such as zeolites[63] and opal.[64] A large series of studies has been devoted to the vibrational spectra of different modifications of ice.[65–76] A series of studies[77–81] devoted to fractal excitations in aerogel should be considered separately.

It is seen from the above survey that INS makes it possible to raise the question of the study of the surfaces of disperse silicas. However, the inadequate number of systematic experimental spectroscopic studies and failure to consider the problem of the differentiation of the surface components of the vibrations from the overall spectrum have led to failure to obtain virtually any important results at this point.

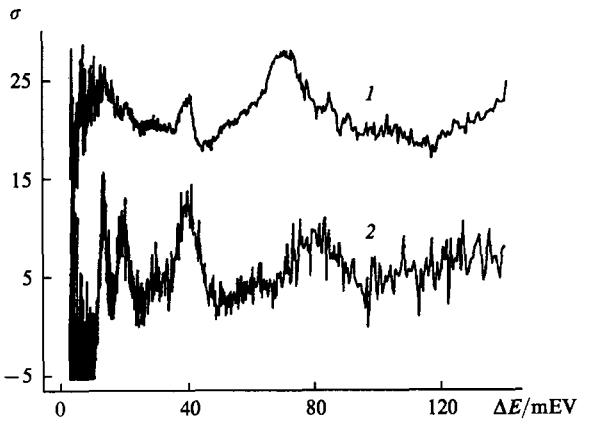

Figure 5. INS spectra of water adsorbed on the walls of the pores in the porous Vycor glass:[56] (*1*) residual moisture content in the dried specimen 10%; (*2*) 'specimen with 100% moisture content – hexagonal ice' difference spectrum.

The problem of discriminating between different silicas has been to a large extent solved in a series of investigations[20-29] undertaken with the aim of systematic study of the vibrational spectra of specimens of different disperse silicas prepared in a definite manner. They included a detailed consideration of the additive model of the composition of a disperse silica and a refinement of the concepts of the core and of the hydroxyl and water shells. A differential-correlation method for the determination of the spectra of the system from the experimentally measured spectra on the basis of the postulate that the spectra of independent systems are not correlated has been proposed and justified. The principal stages of this investigation, which led to a new type of formation of polymorphic modifications — technological polymorphism — are presented below. The results of computational modelling designed to understand this phenomenon at the atomic level will be presented in the succeeding Sections.

III. Techniques for the measurement and treatment of inelastic neutron scattering spectra

1. Primary treatment of the spectra

INS vibrational spectroscopy is based on the fact that, having entered the test specimen, a thermal energy neutron can transfer part of its energy in the excitation of a vibrational mode in the substance or can absorb this excitation, acquiring the corresponding energy and undergoing inelastic scattering thereby. The change in the energy of the neutron can be detected by various procedures.[17,44] The scattering of the next neutron takes place independently of the previous one with excitation – absorption of the same or a different vibrational mode, as a result of which it is possible to obtain the vibrational spectrum of the test specimen by measuring the neutron scattering intensity during the scanning of the energy transferred or acquired by the neutron.

In the experimental method for the determination of the energy lost by the neutron during time of flight, which is the principal procedure for the measurement of the INS in a high-flux IBR-2 reactor,[82] the INS spectrum can be described (see, for example, Bokhenkov et al.[83]) by the function

$$N(t_0) = \Delta t_0 \iiint dE_0\, dE\, dt\, F(E_0,E,t_0,t)\sigma(E_0,E,\phi,T) \ , \qquad (1)$$

where $N(t_0)$ is the number of neutrons which have arrived in the analyser during the time interval Δt_0 at time t_0, $\sigma(E_0, E, \phi, T)$ describes the scattering law for the nuclei (E_0 and E are the energies of the incident and scattered neutrons, ϕ is the scattering angle, and T is the temperature), and $F(E_0, E, t_0, t)$ is the instrument function, which includes the energy distribution of the incident and scattered neutrons and the time synchronisation condition. The neutron scattering cross-section σ is described by the following sum in the general case:

$$\sigma(\omega,t) = \sigma^{(1)}(\omega,T) + \sigma^{(\mathrm{mph})}(\omega,T) + \sigma^{(\mathrm{mpl})}(\omega,T) \ , \qquad (2)$$

where the superscripts (1) (mph), and (mpl) correspond to single-phonon, multiphonon, and multiple scattering.

The single-phonon incoherent scattering cross-section has the form

$$\sigma^{(1)}(\omega,\phi,T) = \sum_i \frac{d^2\sigma_i^{\mathrm{inc}}}{d\omega\, d\Omega} \qquad (3)$$

$$= \frac{k}{k_0}\frac{\hbar|Q|^2}{2M\omega}\sum_i (b_i^{\mathrm{inc}})^2 \frac{\exp(-2W_i)}{1-\exp(-\hbar\omega/kT)} G_i(\omega) \ ,$$

$$G_i(\omega) = \frac{1}{M_i}\sum_j \int dq |A_j^i(q)|^2 \delta[\omega - \omega_j(q)] \ . \qquad (4)$$

Here $G_i(\omega)$ is the density of the vibrational states of the substance weighted quadratically in terms of the amplitudes of the displacements of the ith nucleus,[83,84] k_0 and k are the wave vectors of the incident and scattered neutrons, Q is their difference, b_i^{inc} is the amplitude of the incoherent scattering by the ith nucleus (the cross-sections for scattering by the nuclei forming part of the composition of the silicas are presented in Table 2), M_i is the mass of the ith nucleus, W_i is the Debye – Waller factor, A_j^i is the amplitude of the displacement of the ith nucleus corresponding to the jth vibrational mode, and $\hbar\omega = E_0 - E$ is the transmitted energy. The quantity

$$G(\omega) = \sum_i (b_i^{\mathrm{inc}})^2 G_i^{\mathrm{inc}}(\omega) \ , \qquad (5)$$

is referred to as the doubly amplitude-weighted density of states (AWDS). This quantity can in fact be obtained from the experimental spectrum (1) by solving the converse problem subject to the condition that the scattering spectrum is determined by single-phonon processes. However, deconvolution problems are in general not soluble, so that in experimental practice involving INS a somewhat approximate function $\tilde{G}(\omega)$ serves as an analogue of the exact function $G(\omega)$. It is defined[82] as

$$\tilde{G}_T(\omega) = \frac{N_T[t(\omega)]}{\phi[t(\omega),E(\omega)]K(\omega,T)} \ . \qquad (6)$$

Table 2. Overall neutron scattering cross-sections.[17]

Atom/substance	Overall scattering cross-section σ°/barn[a]
H	81.5
D	7.6
O	4.24
Si	2.2
OH	85.74
OD	11.84
H_2O	167.24
D_2O	19.44
SiO_2	10.68

[a] σ° is determined by the sum of the cross-sections of the nuclear coherent and incoherent scattering by the nth type nucleus.

Here $\phi[t(\omega),E(\omega)]$ is the transformed apparatus function of the spectrometer, while the function $K(\omega, T)$ has the form

$$K(\omega,T) = \frac{k}{k_0}\frac{\hbar|Q|^2}{2\omega}\frac{\exp(-2W_i)}{1-\exp(-\hbar\omega/kT)}, \quad (7)$$

and can be readily calculated, provided that the angular configuration of the experiment is known.

The spectra $N(t)$ presented below were obtained on a KDSOG-1M time-of-flight spectrometer with inverse geometry in the IBR-2 high-flux reactor.[82] All the spectra were normalised with respect to the same number of scattering nuclei (per 100 g of the substance) and the same time of measurement. This makes it possible to carry out a quantitative comparative analysis of the spectra obtained. The low temperature served as a sufficient basis for the hypothesis that single-phonon scattering processes play a dominant role in the $N(t)$ spectra,[84] which made it possible to determine the required AWDS spectra in conformity with Eqn (6).

2. The set of disperse silicas

The series of studies discussed were carried out for three industrial highly disperse silica products: type A380 aerosil (specific surface 380 $m^2\ g^{-1}$), the silica gels SG100 and SG20 (average pore diameters 100 and 20 Å respectively), and the aerogel AG200 (density 200 kg m^{-3}). In conformity with the principal model according to which disperse silicas of any origin are three-component systems consisting of a silica core and hydroxyl and hydrate shells,[1] specimens differing in the partial contributions of these components were prepared. Each of the silicas investigated was represented by an isotypical set of specimens.

An air-dry specimen is the final product of the corresponding technological chain. It was stored in the open air at room temperature and the corresponding humidity. The spectrum of the air-dry specimen will be henceforth designated by $\mathcal{S}p^{(1)}$. The dried specimen was obtained by drying the air-dry specimen in air at a temperature specific to each specimen. The spectrum of the dried specimen will be designated by $\mathcal{S}p^{(2)}$.

A deuteriated specimen was obtained by a deuterium exchange procedure involving the successive drying of the specimen in a closed vessel with subsequent cooling in heavy water vapour; the drying–cooling cycle was repeated several times. The spectrum of the deuteriated specimen will be designated henceforth by $\mathcal{S}p^{(3)}$.

The set of spectra $\{\mathcal{S}p^{(j)}\}$ constitutes the basis for the determination of the spectra of the individual components of the silicas using the differential-correlation method for the resolution of the initial spectra.[85]

3. The construction of the basis for the spectrum of a complex system. Criterion of a zero linear correlation coefficient

Any method for the resolution of the spectrum of a complex system into the spectra of its components is based on an additive model, according to which the overall spectrum of the system $\mathcal{S}p^{(j)}$ can be represented by the sum of spectra:

$$\mathcal{S}p^{(j)} = \sum_{i=1}^{m} k_i^{(j)} Sp_i\ . \quad (8)$$

Here $k_i^{(j)}$ are the weighting factors of the spectra, the product $k_i^{(j)}Sp_i$ represents the partial spectrum of the ith component in the overall compound spectrum $\mathcal{S}p^{(j)}$, and j are the numbers of the independent spectra of the test system referring to its modifications differing in the partial contributions of the components. The spectra Sp_i are referred to as the basis spectra.

Two limiting cases are known for which the resolution of the compound spectrum $\mathcal{S}p^{(j)}$ has been achieved. In the first, which may be called the case of the complete set of basis spectra, all the basis spectra Sp_i are known and the order n of the system of the initial Eqns (8) is unity. The solution of the problem involves the finding of the coefficients $k_i^{(j)}$. It is usually believed that the best solution is that which corresponds to the condition for a minimum in the discrepancy functional[86]

$$\chi^{(j)} = \sum_{r}^{N}\left[\mathcal{S}p^{(j)}(r) - \sum_{i=1}^{m} k_i^{(j)} Sp_i(r)\right]^2\ , \quad (9)$$

where the summation is carried out with respect to N points in the spectrum. The method based on this criterion is well known as the method of least squares. Both the experimentally measured spectra and model functions of the exponential, Gaussian, Lorentzian, etc. types can be used as the spectra Sp_i.[86] The parameters of the resolution to be determined are the weighting factors $k_i^{(j)}$ and the parameters of the model functions.

In the second case, or in the case of a complete set of weighting factors, all the coefficients $k_i^{(j)}$ are known, the order of the system of initial equations is $n = m$, and the basis spectra Sp_i are to be determined. Eqns (8) reduce to a system of linear algebraic equations. The main problem in its solution is that of determinedness.[87,88] The interpretation of the AWDS spectra of disperse silicas, the problem of the resolution of the overall spectrum into those of the core and the hydroxyl and water components arose naturally. From the mathematical standpoint, it involved the resolution of the compound spectrum when neither the basis spectra nor the corresponding weighting factors were fully known. A differential-correlation method was proposed for the solution of this problem.[85] It involves the construction of a physically significant basis Sp_i for the system, which is based on the equation

$$Sp_i = \sum_{j=1}^{n} æ_i^{(j)} \mathcal{S}p^{(j)}\ ,\ i = 1,\ 2,\ \ldots,\ m, \quad (10)$$

on the assumption that there is no linear correlation between the basis spectra Sp_i. This requirement was formulated as the criterion of a zero correlation coefficient of the basis spectra (the ZCC criterion), which is an analogue of the condition for the orthogonality of n-dimensional vectors. In other words, if the components of the complex system can be regarded as independent, then their basis spectra are also not correlated. Using the expression for the second moment of the standard deviations of two physical quantities,[86] it is possible to obtain a mathematical expression for this criterion in the form

$$\rho = \frac{\sum_{r}^{N}\left[Sp_i(r) - \overline{Sp_i}\right]\left[Sp_k(r) - \overline{Sp_k}\right]}{\left\{\sum_{r}^{N}\left[Sp_i(r) - \overline{Sp_i}\right]^2 \sum_{r}^{N}\left[Sp_k(r) - \overline{Sp_k}\right]^2\right\}^{1/2}}\ , \quad (11)$$

where

$$\overline{Sp_i} = \frac{1}{N}\sum_{r}^{N} Sp_i(r)\,, \quad (12)$$

represents the average spectral line, and N denotes the number of points in the spectrum. The condition involving the equality $\rho = 0$ implies that the numerator in Eqn (11) is zero, which is represented conventionally as follows:

$$C(Sp_i, Sp_k) = 0\ . \quad (13)$$

It is easy to show that Eqn (13) is valid not only for the pair of spectra Sp_i and Sp_k but also for their linear combinations of the type

$$C\left(Sp_i, \sum_{s\neq 1}^{m} k_s\, Sp_s\right) = 0\,,$$

or

$$C(Sp_i + Sp_l, \sum_{s\neq i,l}^{m} k_s\, Sp_s) = 0. \quad (14)$$

The practical employment of the ZCC criterion begins with finding the simplest linear combination (10) in order to express the left-hand component in Eqn (14). In the limit, it is a simple difference $D\mathcal{S}p^{(ij')} = \mathcal{S}p^{(j)} - \mathcal{S}p^{(j')}$. This difference spectrum should correctly reproduce either the form of the Sp_i spectrum or the sum of the spectra $Sp_i + Sp_l$, i.e. it should define them to within a constant multiplier. The right-hand component in Eqn (14) can be represented as the residual spectrum

$$R\mathcal{S}p^{(iij')} = \mathcal{S}p^{(j)} - a^{(iij')}D\mathcal{S}p^{(ij')},$$

where $a^{(iij')}$ is a parameter ensuring the absence of correlation between the spectra $R\mathcal{S}p^{(iij')}$ and $D\mathcal{S}p^{(ij')}$ in the form of Eqn (14).

By solving Eqns (14) for $a^{(iij')}$, we find the required value of this parameter:

$$a_0^{(iij')} = \frac{\sum_r^N D\tilde{\mathcal{S}}p^{(ij')}(r)\tilde{\mathcal{S}}p^{(j)}(r)}{\sum_r^N \left[D\tilde{\mathcal{S}}p^{(ij')}(r)\right]^2}, \qquad (15)$$

where

$$D\tilde{\mathcal{S}}p^{(ij')} = D\mathcal{S}p^{(ij')} - \overline{D\mathcal{S}p}^{(ij')},$$

while

$$\tilde{\mathcal{S}}p^{(j')} = \mathcal{S}p^{(j)} - \overline{\mathcal{S}p}^{(j')}.$$

The bar above the expression denotes the average spectral lines [Eqn (11)]. The spectrum $a_0^{(iij')}D\mathcal{S}p^{(ij')}$ represents either the basis spectrum Sp_i or the sum of the basis spectra $Sp_i + Sp_l$. On the other hand, the residual spectrum

$$R_0\mathcal{S}p^{(iij')} = \mathcal{S}p^{(j)} - a_0^{(iij')}D\mathcal{S}p^{(ij')}$$

describes the residual combination of basis spectra entering into $\mathcal{S}p^{(j)}$ after the subtraction of the spectrum $a_0^{(iij')}D\mathcal{S}p^{(ij')}$ from the latter. By repeating this procedure and scanning with respect to the indices j and j', it is possible to determine the entire set of basis spectra $\{Sp_i\}$. This method has been used successfully to obtain the basis spectra of aerosil, silica gel, and aerogel.[25-27]

IV. Vibrational spectra of disperse silicas

1. Aerosil

a. Specimens and initial spectra

An air-dry specimen of the aerosil A380 is a powder consisting of small spherical particles with a specific surface of 380 $m^2\ g^{-1}$. According to low angle X-ray measurements, the average particle size is 150 Å.[19] After the specimen had been heated in air for 6 h at 750 °C, dried A380 was obtained. In its turn, the dried specimen was subjected to isotopic substitution of hydrogen atoms in the hydroxyl and water shells by deuterium atoms in the following sequence: three heating steps in air (750 °C, 4 h) with subsequent cooling in heavy water vapour to room temperature. This resulted in the formation of a deuteriated A380 specimen.

The set of these three specimens comprised the aerosil A380 family. The time-of-flight INS spectra of the specimens of this family together with the AWDS spectra obtained in accordance with Eqn (6) are presented in Fig. 6. In addition to the spectra of the three specimens indicated above, the figure presents the $N(t)$ and AWDS spectra of the glass obtained by sintering the aerosil. In a certain sense, these are reference spectra representing the spectrum of the bulk-phase vibrations of close-packed silica (see below).

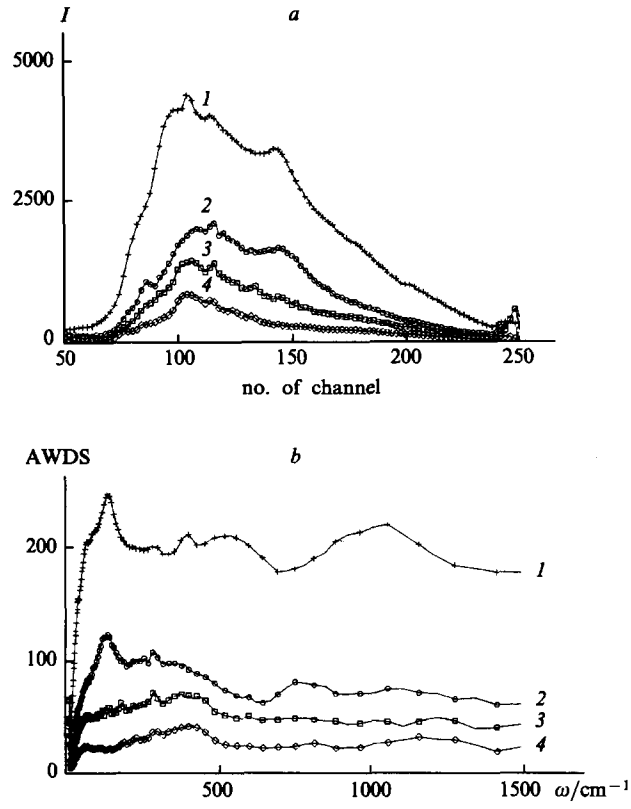

Figure 6. Experimental vibrational spectra of the A380 aerosil family ($T = 10$ K):[20] (*a*) time-of-flight INS spectra; (*b*) AWDS spectra; (*1*) air-dry specimen; (*2*) dried specimen; (*3*) deuteriated specimen; (*4*) aerosil glass.

b. Basis spectra of components of aerosil

Formulation of the problem of the resolution of the initial spectra. The spectra of the aerosil components constitutes a set of three basis spectra $\{Sp_i\}$, where the indices $i = 1, 2, 3$ correspond to the spectra of the water shell, the OH shell, and the silica core. Whereas the physical significance of the basis spectrum Sp_3 is fairly clear, a more detailed consideration is needed for the first two spectra. Apart from the vibrations of water and the hydroxy-groups, they include the vibrations of groups of atoms with which these differentiated systems interact. Thus one should include in the vibrational spectrum of the hydrate shell the vibrations of the silicon–oxygen centre (with the corresponding composition) linked to it. The number of such centres, interacting with water, is known[1,5] to be much smaller than the total number of hydroxy-groups on the surface even under the conditions of the complete saturation of the surface by adsorbed water. The remaining three groups form the hydroxyl shell. The vibrations of these groups constitute the basis of the vibrational spectrum of the hydroxyl shell. However, in addition to this, the vibrations of the surface silicon atoms and of the oxygen of the silica core make an appreciable contribution to the given vibrational spectrum. The above two types of vibrations affect the hydrogen atoms of the hydroxy-groups participating in the corresponding vibrational motions as a consequence of the familiar 'riding effect'.[18,19]

The experimental AWDS spectra of the initial and modified aerosils normalised with respect to 100 g of the mass of the specimen give rise to the set $\{\mathcal{S}p^{(j)}(\omega)\}$, in which the quantities $j = 1, 2, 3$ correspond to the spectra of the air-dry, dried, and deuteriated specimens. If the partial spectra of the air-dry specimen are designated as the basis spectra, then Eqns (8) assume the form (overleaf):

$$\mathcal{S}p^{(1)} = Sp_1^{(1)} + Sp_2^{(2)} + Sp_3^{(3)} ,$$
$$\mathcal{S}p^{(2)} = \alpha_1 Sp_1^{(1)} + \alpha_2 Sp_2^{(2)} + \alpha_3 Sp_3^{(3)} , \quad (16)$$
$$\mathcal{S}p^{(3)} = \beta_1 Sp_1^{(1)} + \beta_2 Sp_2^{(2)} + \beta_3 Sp_3^{(3)} .$$

Before proceeding to the construction of this basis, it is necessary to derive the relations between the coefficients of Eqn (16), the knowledge of which makes it possible to optimise the construction of the difference spectra. We shall consider this procedure in relation to aerosil. The parameters α_3 and β_3 are determined from the equality

$$Sp_3^{(1)} = \alpha_3 Sp_3^{(1)} = \beta_3 Sp_3^{(1)} ,$$

which follows from the identity of the spectra of the silica core in all the specimens. Thus

$$\alpha_3 = 1, \quad \text{and} \quad \beta_3 = 1 . \quad (17a)$$

It is known from literature data [1] that, when aerosil is dried at 750 °C, the adsorbed water and some of the hydroxy-groups are fully removed from the surface and the following two relations are established thereby:

$$\alpha_1 = 0, \quad \text{and} \quad \alpha_2 < 1 . \quad (17b)$$

The weighted contributions of the partial spectra of water and the hydroxyl shell to the spectrum of the deuteriated specimen $\mathcal{S}p^{(3)}$ must be much less than unity because, as a consequence of the strong suppression of the scattering by hydrogen nuclei, the intensity of the scattering by this specimen is much lower than the intensity of the scattering by the air-dry specimen, which follows from Fig. 6. Thus

$$\beta_1 \ll 1, \quad \text{and} \quad \beta_2 \ll 1 . \quad (17c)$$

It is also known [1] that the percentage content of the atoms substituted as a result of deuterium exchange in the water and hydroxyl shells is fairly accurately the same, so that

$$\beta_1 = \beta_2 = \beta . \quad (17d)$$

Thus the following conditions are imposed on the coefficients of Eqn (16):

$$\begin{aligned} &\alpha_3 = 1, \quad 0 < \beta_1 < 1 \\ &\beta_3 = 1, \quad 0 < \beta_2 < 1 \\ &\alpha_1 = 0, \quad \beta_1 = \beta_2 = \beta \\ &\alpha_2 < 1. \end{aligned} \quad (18)$$

In conformity with Eqns (18), the system of basic Eqns (16) is transformed into

$$\mathcal{S}p^{(1)} = Sp_1^{(1)} + Sp_2^{(1)} + Sp_3^{(1)}$$
$$\mathcal{S}p^{(2)} = 0 + \alpha_2 Sp_2^{(1)} + Sp_3^{(1)} \quad (19)$$
$$\mathcal{S}p^{(3)} = \beta Sp_1^{(1)} + \beta Sp_2^{(1)} + Sp_3^{(1)} .$$

Construction of the basis. When the differential-correlation method for the resolution of the spectrum of multicomponent systems is used, there is a possibility of a set of different versions determined by the selection of the initial difference spectrum in Eqns (14). It has been shown that [25-27] the same final result is then achieved with an adequate accuracy. We shall consider as an example one such version. We construct the initial difference spectrum in the form

$$D\mathcal{S}p^{(13)} = \mathcal{S}p^{(1)} - \mathcal{S}p^{(3)} . \quad (20)$$

It is a linear combination of the basis spectra Sp_1 and Sp_2 and, in conformity with Eqns (19), it assumes the form

$$D\mathcal{S}p^{(13)} = (1-\beta)[Sp_1^{(1)} - Sp_2^{(1)}] . \quad (21)$$

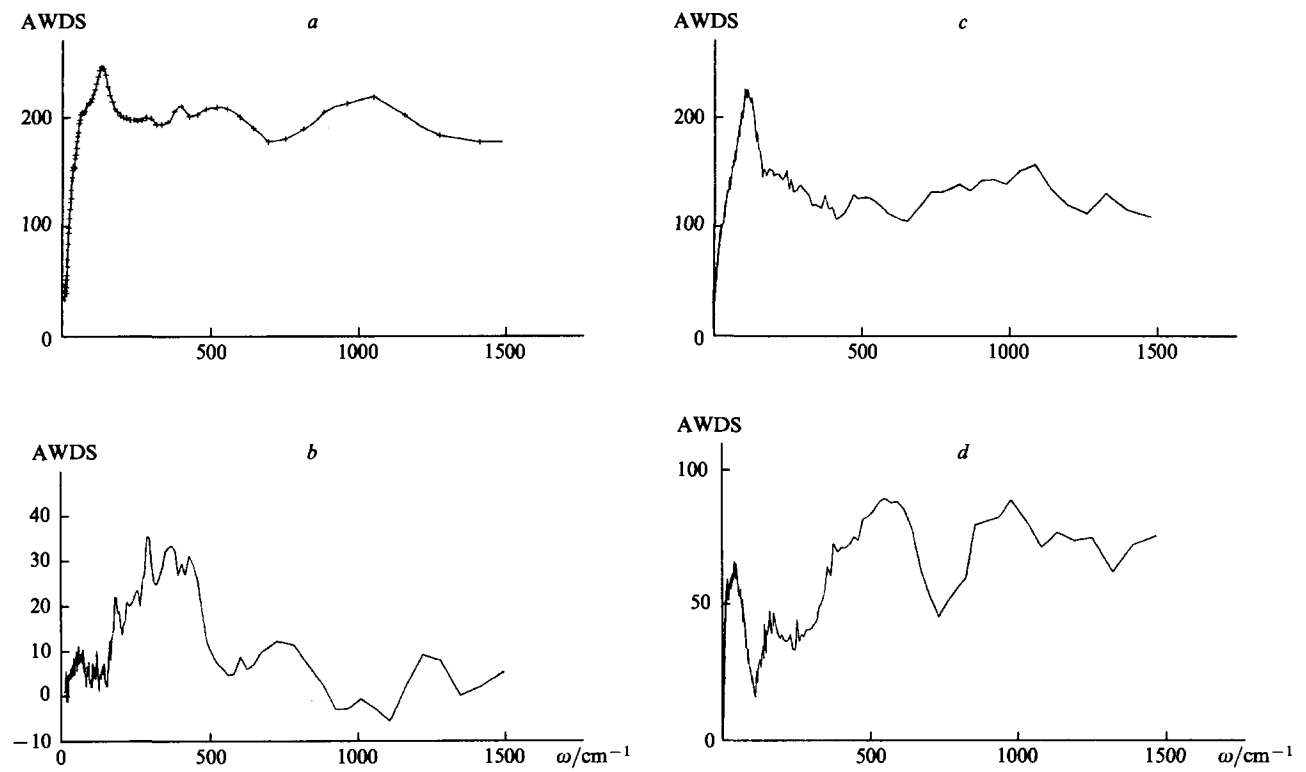

Figure 7. Overall AWDS spectrum of an air-dry specimen (*a*) and the basis spectra of the components of the aerosil A380: (*b*) core; (*c*) hydroxyl shell; (*d*) adsorbed water ($T = 10$ K).[25]

We construct the residual spectrum

$$R\mathcal{S}p^{(113)} = \mathcal{S}p^{(1)} - a^{(113)}D\mathcal{S}p^{(13)}, \quad (22)$$

and impose the requirement that it is not correlated with the spectrum $D\mathcal{S}p^{(13)}$,i.e. that condition (14) holds in the form

$$C(R\mathcal{S}p^{(113)}, D\mathcal{S}p^{(13)}) = 0 . \quad (23)$$

Ultimately we obtain the spectra

$$a_0^{(113)}D\mathcal{S}p^{(13)} = Sp_1^{(1)} + Sp_2^{(1)} , \quad (24)$$
$$R_0\mathcal{S}p^{(113)} = Sp_3^{(1)} .$$

The corresponding coefficient $a_0^{(113)}$ is calculated by Eqn (15).

We now consider the difference spectrum

$$D\mathcal{S}p^{(21)} = \mathcal{S}p^{(2)} - Sp_3^{(1)} . \quad (25)$$

According to Eqns (19), it is given by $\alpha_2 Sp_2^{(1)}$, i.e. it represents the partial spectrum of the hydroxyl shell in the spectrum of the dried A380. Using the difference spectra $a_0^{(113)}D\mathcal{S}p^{(13)}$ and $D\mathcal{S}p^{(21)}$ obtained, we construct the residual spectrum

$$RD\mathcal{S}p = a_0^{(113)}D\mathcal{S}p^{(13)} - a^{(21)}D\mathcal{S}p^{(21)}, \quad (26)$$

and impose the requirement that the ZCC conditions hold between this spectrum and the spectrum $D\mathcal{S}p^{(21)}$ in the form

$$C(RD\mathcal{S}p, D\mathcal{S}p^{(21)}) = 0 . \quad (27)$$

Having determined $a_0^{(21)}$ in conformity with Eqn (15), we obtain

$$a_0^{(21)}D\mathcal{S}p^{(21)} = Sp_2^{(1)}, \quad \text{and} \quad R_0D\mathcal{S}p = Sp_1^{(1)} . \quad (28)$$

Thus the basis of Eqns (19) has been constructed. Fig. 7 presents the AWDS spectra of an air-dry aerosil specimen together with the spectra of its three components.[25] It has been established[24] that the initial spectra of air-dry aerosils with different specific surfaces (and particle sizes) agree satisfactorily, so that the basis spectra constructed refer to the entire class of aerosils.

2. Silica gels

a. Specimens and initial spectra

The series of studies under discussion dealt with the vibrational spectra of two families of silica gels originating from industrial specimens of type KSM-G (lumpy, finely porous, granulated silica) manufactured by the Mendeleev Chemical Factory and characterised by different pore sizes, namely 20 and 100 Å (SG20 and SG100 respectively). The family of each silica gel included three specimens:[26] $j = 1$ — air-dry initial industrial specimen stored at room temperature and under the usual conditions of humidity; $j = 2$ — dry specimen obtained from the initial specimen by drying in air for 72 h at 135 °C; $j = 3$ — deuteriated specimen obtained from the initial specimen as a result of three drying cycles at 135 °C with subsequent maintenance for 24 h in heavy water vapour at room temperature.

An additional study was made of the spectrum of rapidly frozen water, which is necessary for the comparative analysis of the spectrum of the aqueous component.

The experimental INS spectra of specimens belonging to the SG20 and SG100 families and the corresponding AWDS spectra obtained in conformity with Eqn (6) have been described in detail.[20]

b. Basis spectra of components of silica gels

The procedure used to obtain the basis spectra of silica gels is similar to that described above for aerosil with the sole difference that, as a consequence of somewhat different relations between the coefficients of Eqn (16), the basic system of equations assumes the form[26]

$$\begin{aligned} \mathcal{S}p^{(1)} &= Sp_1^{(1)} + Sp_2^{(1)} + Sp_3^{(1)} , \\ \mathcal{S}p^{(2)} &= \alpha_1 Sp_1^{(1)} + Sp_2^{(1)} + Sp_3^{(1)} , \\ \mathcal{S}p^{(3)} &= \beta Sp_1^{(1)} + \beta Sp_2^{(1)} + Sp_3^{(1)} . \end{aligned} \quad (29)$$

Figs 8 and 9 present the spectra of air-dry specimens together with the basis spectra of their components. Two features of the spectra obtained are striking. First, the basis spectra of the test silica gel specimens are significantly different. This factor, i.e. the

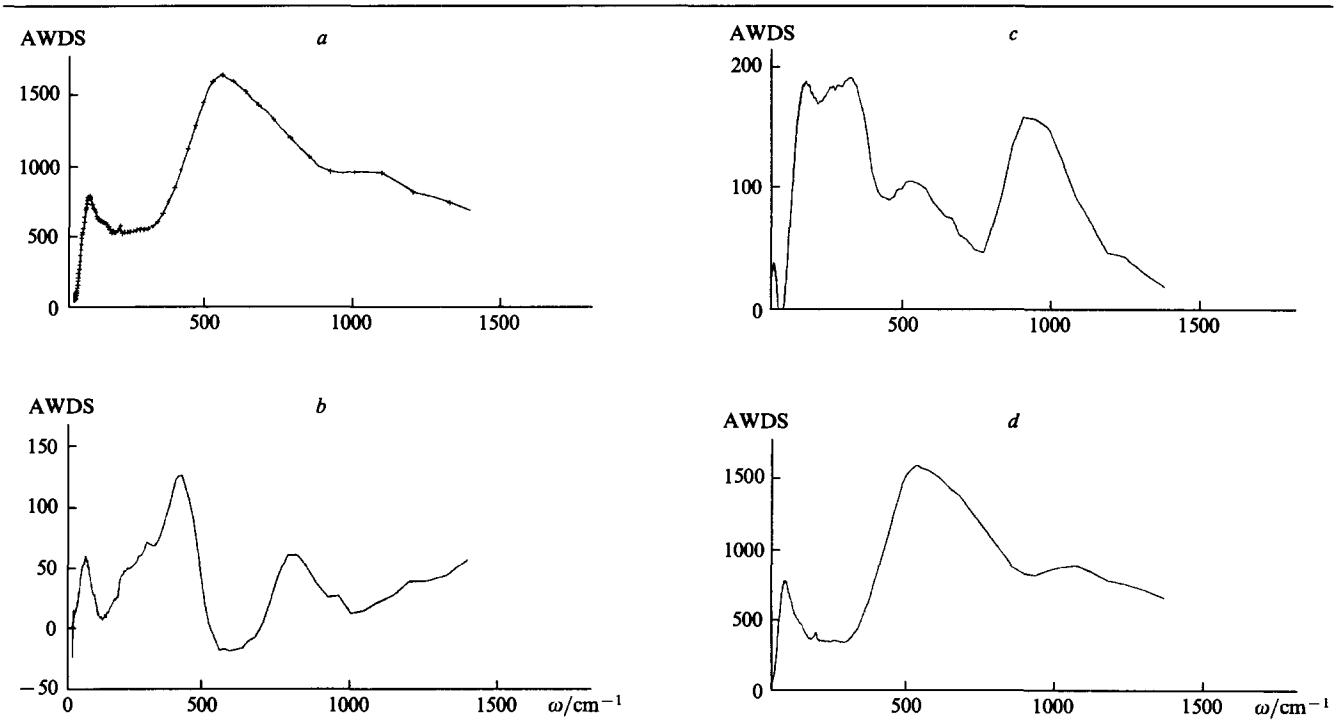

Figure 8. Overall AWDS spectrum of an air-dry specimen (*a*) and the basis spectra of the components of the silica gel SG20: (*b*) core; (*c*) hydroxyl shell; (*d*) aqueous component ($T = 10$ K).[26]

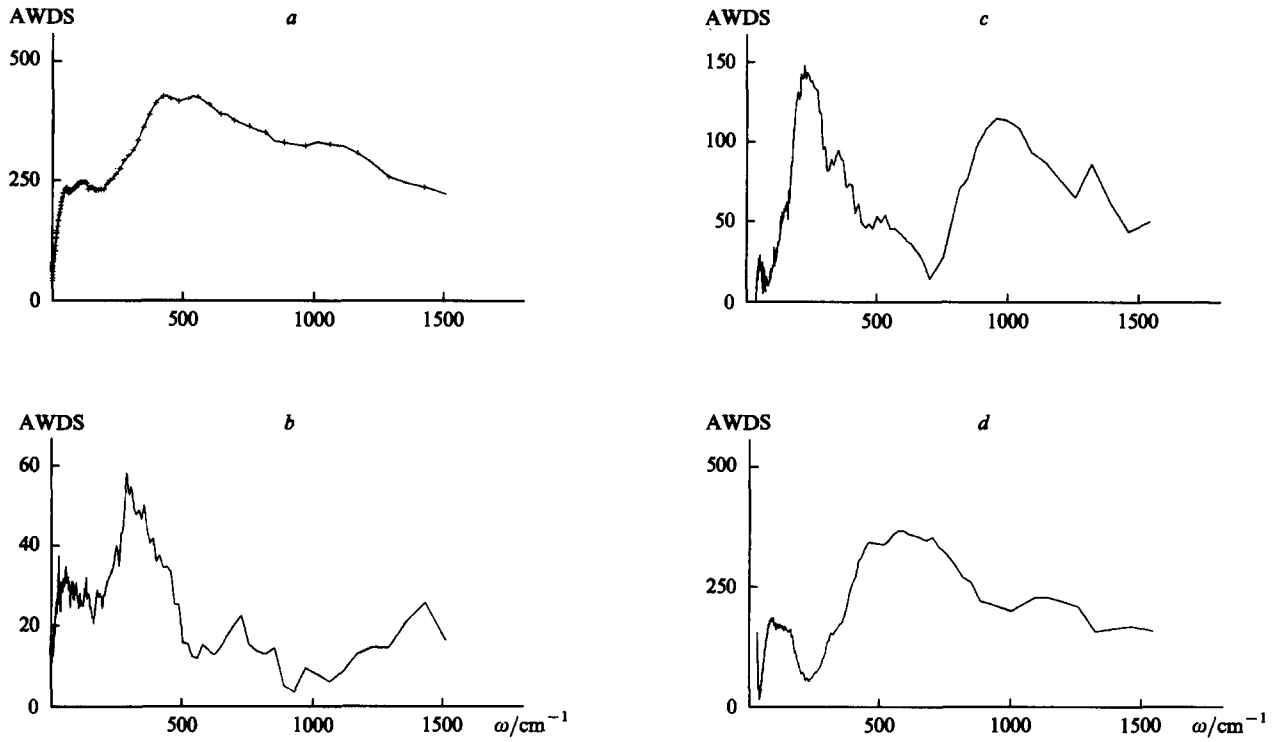

Figure 9. Overall AWDS spectrum of an air-dry specimen (*a*) and the basis spectra of the components of the silica gel SG100: (*b*) core; (*c*) hydroxyl shell; (*d*) aqueous component ($T = 10$ K).[26]

poor reproducibility of the absorption spectra of silica gels, has also been noted in the study of their IR absorption.[8,11,12] As will be shown below, this difference is not associated with the difference between the values of the numerical parameter describing the pore sizes and is determined by the exceptional lability of the structure of the silica gels, as a consequence of which it is virtually impossible in principle to achieve the reproducibility of the spectra on passing from one silica gel specimen to another.

The second feature concerns the basis spectra of the water shells. In contrast to aerosil with its globular structure, in the porous structures of silica gels water may be not only adsorbed but may be also retained in a quasi-free form. Therefore, in characterising the aqueous component of this substance, it is more correct to speak of the retained water. Fig. 10 presents the AWDS basis spectra of the aqueous components of the silica gels SG20 and SG100 together with the spectra of the rapidly frozen water. Despite the clear-cut difference between the spectra of the aqueous components of both specimens, the similarity of both spectra of the rapidly frozen water is striking. Such an evident similarity, which has been observed also by other investigators[45,56] (Figs 3 and 4), confirms the earlier conclusion[56] that the silica gel pores contain water of two types: water adsorbed on the inner surfaces of the pores and quasi-free water.

In conformity with this view, it has been postulated[26] that the basis spectra *1* and *2* in Fig. 10*a* consist of the spectra of the adsorbed and quasi-free water. The observed difference between the spectra of water in the silica gels SG20 and SG100 can then be explained qualitatively. The finely porous silica gel SG20 contains more water [about 16 mass% (it is known that the smaller the pore, the greater the amount of water retained in it as a consequence of the greater surface tension)][1] and its main bulk comprises quasi-free water. This is the reason why the AWDS spectrum of the water component of SG20 is in this case so similar to the spectrum of rapidly frozen water. Owing to the large pore size, silica gel SG100 retains less water (~5 mass%) and its AWDS spectrum therefore manifests the spectrum of the adsorbed water, which is almost completely masked in the first case. [A similar conclusion has been reached by Li et al.[56] (Figs 4 and 5).]

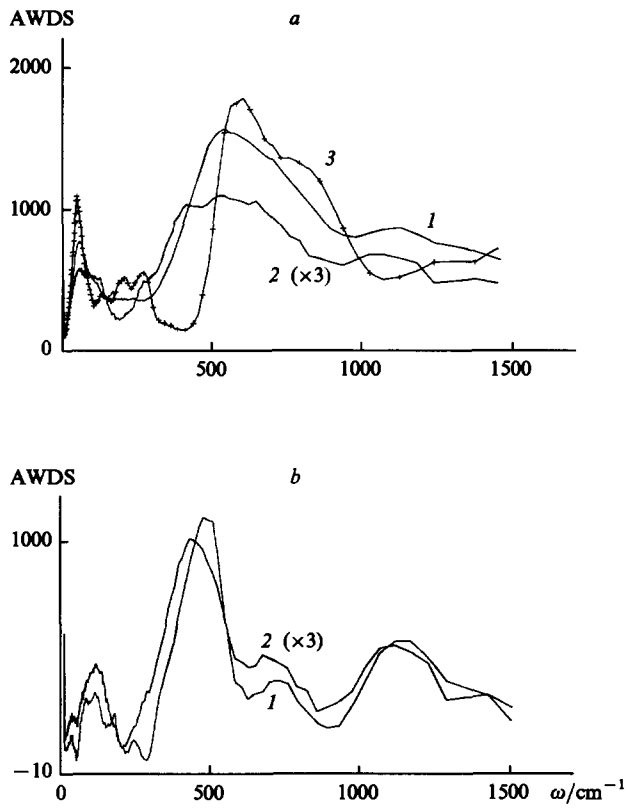

Figure 10. AWDS basis spectra of the aqueous components of silica gels ($T = 10$ K):[26] (*a*) overall spectra; (*b*) spectra of adsorbed water; (*1*) silica gel SG20; (*2*) silica gel SG100; (*3*) rapidly frozen water.

The spectra of water of both types have been obtained separately by means of qualitative analysis using the differential-correlation method for the resolution of the spectra of a complex system. It was postulated that the quasi-free and adsorbed water are separated in space. As in the case of aerosil, the adsorbed water is understood as complex structural formations incorporating water molecules interacting with the adsorption centres. It has also been postulated that the internal coordinate systems of the adsorbed and quasi-free water are independent, so that their vibrational spectra should not be correlated if one disregards the false correlation induced by the random coincidence of the frequencies of the vibrational modes.

The procedure used to resolve the initial basis spectra of the aqueous components were as follows.[26] In conformity with Eqns (16), it is possible to set up the following system of equations:

$$\begin{aligned} \mathcal{S}p^{(1)}(\omega) &= Sp_1 + Sp_2 \ , \\ \mathcal{S}p^{(2)}(\omega) &= \alpha_1 Sp_1 + \alpha_2 Sp_2 \ , \\ \mathcal{S}p^{(3)}(\omega) &= \beta Sp_1 \ , \end{aligned} \tag{30}$$

where superscript j denotes the number of the initial spectrum: $j = 1$ corresponds to the AWDS basis spectrum $Sp_1^{(1)}$ of the water shell of the silica gel SG20 (curve *1*, Fig. 10*a*), $j = 2$ corresponds to the AWDS basis spectrum $Sp_1^{(1)}$ of the silica gel SG100 (curve *2*, Fig. 10*a*), and $j = 3$ corresponds to the AWDS spectrum of 1 g of the rapidly frozen water (curve *3*, Fig. 10*a*).

The quantities Sp_1 and Sp_2 in Eqns (30) denote the basis spectra of the quasi-free and adsorbed water, which are assumed to be the same for both silica gels. On the basis of studies[55,56] in which it is claimed that the INS spectra of free ice and the ice within the pores are virtually maintained [remain the same?], it was postulated that the vibrational spectrum of free water $\mathcal{S}p^{(3)}$ determines the form of the basis spectrum Sp_1.

If one constructs two difference spectra

$$\begin{aligned} D\mathcal{S}p^{(13)} &= \mathcal{S}p^{(1)} - a^{(13)}\mathcal{S}p^{(3)} \ , \\ D\mathcal{S}p^{(23)} &= \mathcal{S}p^{(2)} - a^{(23)}\mathcal{S}p^{(3)} \ , \end{aligned} \tag{31}$$

and imposes the requirement that the ZCC criterion holds in the form

$$\begin{aligned} C(D\mathcal{S}p^{(13)}, \mathcal{S}p^{(3)}) &= 0, \\ C(D\mathcal{S}p^{(23)}, \mathcal{S}p^{(3)}) &= 0, \end{aligned} \tag{32}$$

then, by solving these equations it is possible to determine the coefficients $a_0^{(13)}$ and $a_0^{(23)}$ in accordance with Eqn (15) and to obtain the spectra $D_0\mathcal{S}p^{(13)} = Sp_2(1)$ and $D_0\mathcal{S}p^{(23)} = Sp_2(2)$. These spectra are presented in Fig. 10*b*. They proved to be virtually identical. The percentage contents of free (η_{fr}) and adsorbed (η_{ad}) water in the test silica gel specimens corresponding to the coefficients $a_0^{(13)}$ and $a_0^{(23)}$ are presented in the equations for the ZCC criterion [Eqns (32)].[26]

Specimen	η_{fr}	η_{ad}
Silica gel SG20	14.0	3.7
Silica gel SG100	1.8	1.3

However, the identity of the AWDS spectra of the adsorbed water in the two silica gels is surprising against the background of the large difference between their two other basis spectra. This finding is apparently based on the competition between two processes: the formation of a 'drop' of the quasi-free water and adsorption. Evidently, among the set of silicon–hydroxyl centres of three types, forming the hydroxyl shell of silica gel and ensuring the adsorption of water, only one centre may prove capable of competition (otherwise, the water would not have collected into drops). Naturally, this centre is the same in each silica gel, which is in fact the reason for the identity of the AWDS spectra of the water adsorbed on it. As will be shown below, this explanation received a well-founded confirmation in the quantum-chemical modelling of the model structures of silica gels.

3. Aerogel

a. Specimens and initial spectra

The test specimen of the aerogel AG200[27] consisted of a monolithic lump of a solid substance with a mass density of 200 kg m^{-3}. The specimen, stored in air, was initially air-dry; it was dried in air at 100 °C for seven days, which resulted in a dried specimen. The latter was in its turn subjected to the H → D isotope exchange. The specimen was maintained at 100 °C under atmospheric conditions for 12 h and was then placed in a desiccator, where it was kept for 12 h in heavy water vapour. The cycle was repeated with the specimen maintained for 6 h at each stage, which resulted in a deuteriated specimen. The time-of-flight INS spectra of the family of the above aerogel specimens and the corresponding AWDS spectra, obtained in conformity with Eqn (6), have been described in detail.[27]

b. Basis spectra of the components of the aerogel

In contrast to aerosil and silica gels, the chemistry of the surface of the aerogel has been studied to a much lesser extent. The initial inferences concerning the structure of the aerogel surface were made on the basis of the analysis of the chemical-technological process involving its preparation. According to the scheme employed in this process,[3] the principal component of the aerogel cores is a siloxane chain and the main contribution to the hydrogen-containing surface region comes from the hydroxy-groups, the number of which increases with increase in the length of the polymer chain.

In the isolated chains, each silicon atom of the siloxane core is linked to two hydroxy-groups. Consequently, the polymer structure formed consists of a chain of silanediol groups. On the other hand, if the chains are cross-linked in pairs, giving rise to a strip, then the silicon atoms of the strip each carry only one hydroxy-group. It has been suggested that this type of cross-linking process actually occurs in gel formation.[3]

The presence of silanol or silanediol groups on the surface of the silica core usually leads to the adsorption of water under atmospheric conditions. The existence of adsorbed water on the surface of the aerogel has been confirmed by the mass-spectrometric study of the products desorbed from its surface on heating to 100–150 °C.[3] This is also indicated by the analysis of the measured INS spectra.[27] Thus, when the specimen is dried under conditions corresponding to the preferential desorption of water, its vibrational spectrum undergoes a significant change in form and its integral intensity diminishes almost by a factor of two. Comparison of the AWDS spectra within the family of the AG200 specimens shows that the maintenance of the initial AG200 specimen in heavy water vapour reduces the intensity of the spectrum almost by a factor of three. This shows that the surface region of the air-dry aerogel contains an appreciable number of hydrogen atoms, because isotope exchange is concentrated mainly in this region. The marked smearing of the structure of the spectrum on raising the temperature may be regarded as another confirmation of the presence of water in the surface region of the aerogel.[27] Such smearing is similar to that observed in the spectra of air-dry aerosil and silica gel specimens,[22] which has been attributed to the facilitation of the diffusion of water on the surface with increase in temperature.

Thus the surface region of the air-dry aerogel contains hydroxy-groups and adsorbed water. By analogy with other disperse silicas, the aerogel becomes as a result of this a three-component system consisting of a silica core and hydroxyl and aqueous components.

The ratios of the coefficients in Eqn 16, describing three experimental spectra of aerogel specimens, proved similar to the ratios for silica gels, so that Eqns (29) serve as a basis also for the aerogel. By repeating the procedure described above for silica gel, it is possible to obtain a set of basis spectra of the aerogel, which

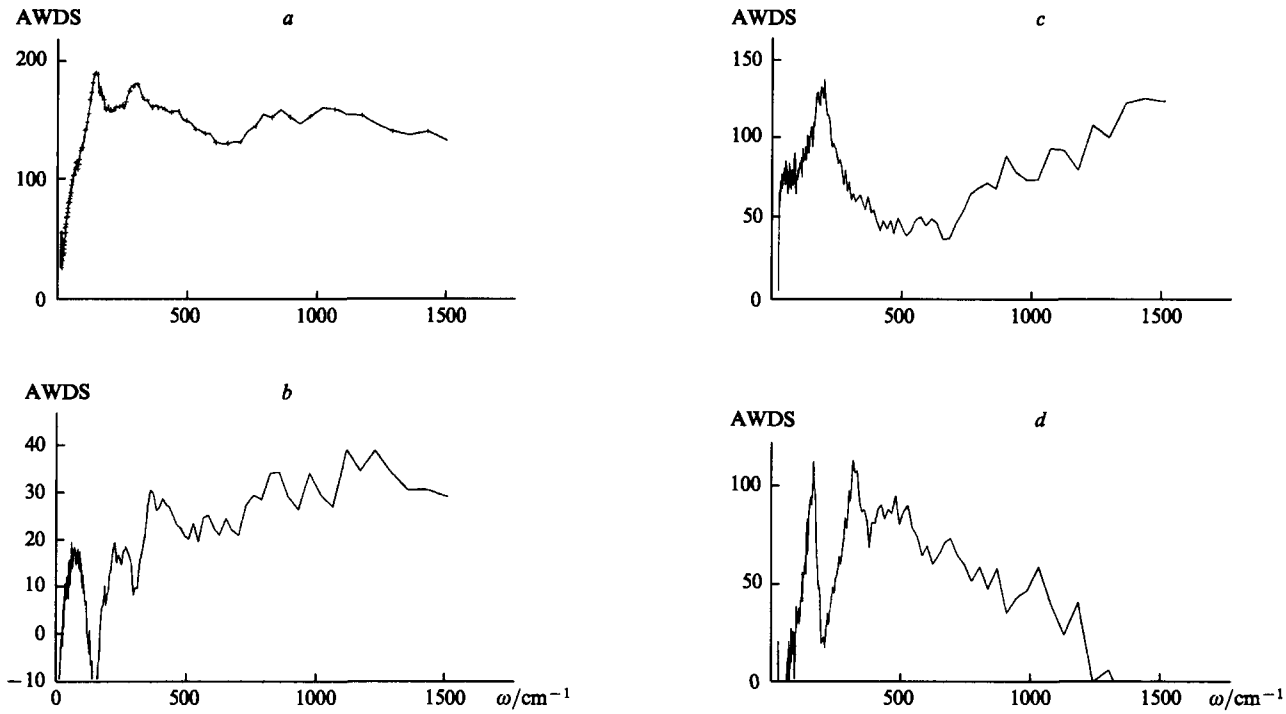

Figure 11. Overall AWDS spectrum of an air-dry specimen (*a*) and the basis spectra of the components of the aerogel AG200: (*b*) core; (*c*) hydroxyl shell; (*d*) adsorbed water ($T = 10$ K).[27]

are presented in Fig. 11 together with the spectra of the air-dry specimen. The clearly expressed 'quasi-molecular' structure of the spectra presented can be seen. As regards the vibrational spectrum of the core, its structure is more characteristic of polymers than a close-packed amorphous solid (see, for example, Gribov[89]). This agrees with the chain model of the aerogel core, which is a consequence of specific polymerisation and condensation processes in the preparation of disperse silica.[90] The narrow band form of the spectra of adsorbed water indicates, on the one hand, the absence of a collective interaction between the molecules, and, on the other, the same type of orientation of the adsorbed water molecules. The latter indicates in its turn a definite uniformity of the adsorption centres and that they are fairly widely scattered.

V. Comparative analysis of the vibrational spectra of disperse silicas and their components

1. Vibrational spectra of silica cores

The basis vibrational spectra of the cores of the test silicas are presented in Fig. 12. In addition, the figure shows (curve *2* in Fig. 12*a*) the vibrational spectrum of the glass obtained by sintering the aerosil A380. It is seen that the spectra of the cores of all the substances have a similar form and resemble the spectrum of the glass, which corresponds to the bulk-phase vibrations of close-packed silica (each consists of four bands located in the same spectral regions). At the same time, considerable differences are observed both between the spectra of disperse silicas and between the latter and the spectrum of the glass. This concerns the distribution of the intensities in each spectrum and of the absolute intensities of each of them. The vibrational spectrum of the aerosil core is closest to that of the spectrum of the glass, while the vibrational spectrum of the aerogel is most different. It is a remarkable fact that the spectra of the cores of the two silica gels investigated (SG100 and SG20) with different average core sizes (100 and 20 Å) differ significantly from one another.

Analysis of the differences observed in the form of the spectra can be conveniently begun with a brief description of the spectrum of the glass. Four bands in the regions 0–200 cm^{-1} (*I*), 200–500 cm^{-1} (*II*), 500–950 cm^{-1} (*III*), and 950–1300 cm^{-1} (*IV*) clearly stand out in this spectrum. According to the analysis of the vibrational spectrum of the free SiO_4^- ion[6] and the α-quartz crystal,[91] the deformation vibrations associated with the variation of the O–Si–O angle make the main contribution to region *II*. In regions *III* and *IV*, this role is assumed by the symmetrical and asymmetric stretching vibrations of the Si–O bond. Calculation of the vibrational spectra of a series of large model clusters has shown that this assignment can be extended also to amorphous structures. According to the calculation, region *I* of the vibrational spectrum of the core is made up of the vibrational modes of the translational motion of the atoms and the deformation vibrations associated with changes in the Si–O–Si angles. The assignment of the frequencies in regions *II*–*IV* agrees with that quoted above.

The aerosil glass and aerosil. As already stated, the spectra of this pair of substances (Fig. 12*a*) are closest to one another. A similar conclusion was reached on the basis of IR absorption spectra.[39] This finding undoubtedly indicates that the structure of the aerosil core is close-packed. The AWDS spectra of the glass show that the intensity of the bands in the ranges 0–220 cm^{-1} and 560–1500 cm^{-1} appreciably exceeds that of the aerosil spectrum. A detailed analysis of the difference spectrum suggested[25] that this difference is caused by the presence in the glass, in contrast to the 'absolutely dry' (by definition) aerosil core, of small amounts of adsorbed water. For a quantitative explanation of the observed difference, 0.3 mass%–0.5 mass% of water is sufficient. The possibility of the existence of such amounts of water in the glass has been confirmed by several pieces of chemical evidence.[6]

Silica gels. Regions *I*–*IV* again stand out clearly in the basis spectra of the silica gel cores (Figs 12*b* and 12*c*). However, a significant rearrangement of the spectra and an increase in their

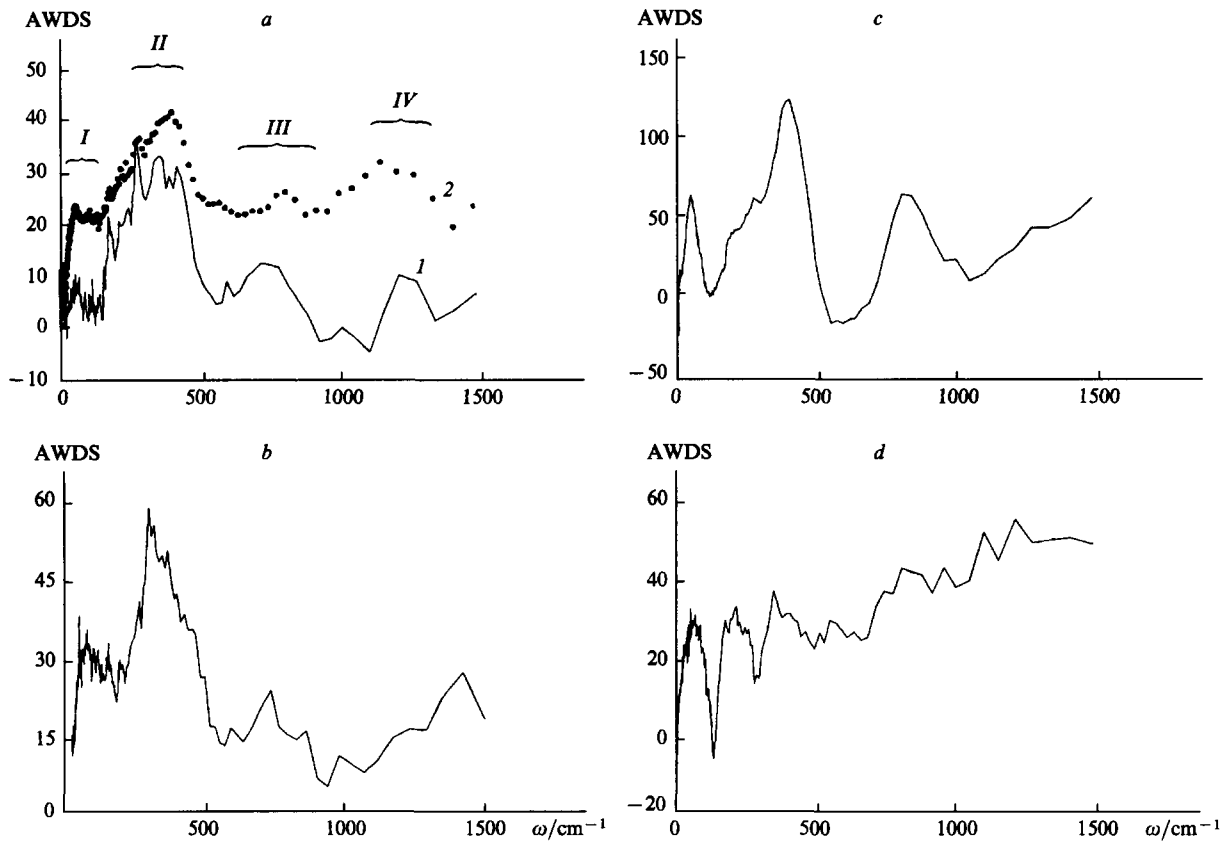

Figure 12. Basis vibrational spectra of the cores of disperse silicas (T = 10 K):[28] (*a*) aerosil A380 (curve *1*) and glass (curve *2*); (*b*) silica gel SG100; (*c*) silica gel SG20; (*d*) aerogel AG200.

intensity compared with the spectrum of aerosils are striking. The main characteristic feature of these spectra is, as stated above, the fact that they differ for different silica gels. This is manifested to the greatest extent in regions *I* and *II* corresponding to deformation vibrations. These changes can be understood if one postulates that a fairly broad distribution of the Si–O–Si and O–Si–O angles exists in the silica gels and that, on passing from one specimen to another, the distribution changes. The changes in the region of the deformation vibrations are accompanied by appreciable changes also in regions *III* and *IV* of the Si–O bond stretching vibrations. The combination of these findings permits the conclusion that the structures of the silica gels investigated differ from one another and that they all differ appreciably from the close-packed structure.

Aerogel. The principal characteristic feature of the basis vibration spectrum of the aerogel core (Fig. 12*d*) is its narrow band 'quasi-molecular' structure, as a result of which it resembles the vibrational spectra of polymers.[89] On the other hand, the narrow-band structure of the basis spectrum in regions *I* and *II* indicates narrow distributions of the deformation modes in the region where the angles in the silicon–oxygen tetrahedra vary, which indicates, in its turn, a quasi-regular structure of the test substance. Consequently, the aerogel core constitutes a new type of structure in addition to the aerosil and silica gel structures.

Comparative analysis of the basis vibrational spectra of the cores of the test silicas permitted the conclusion that there is a qualitative difference between the structures of these substances, which indicates the presence of several polymorphic modifications of disperse amorphous silica. The difference between the core structures entails also a difference between the structures of the surface regions of the test materials.

2. Vibrational spectra of the hydroxyl components

The basis vibrational spectra of the hydroxyl components of the set of disperse silicas under discussion are presented in Fig. 13. Despite the appreciable differences between the spectra, it is possible to distinguish in all of them two vibrational regions characteristic of and common to all of them: 0–380 cm^{-1} (*I*) and 700–1100 cm^{-1} (*II*). The differences between the spectra may be characterised in terms of the differences between the structures in these regions and also in terms of the intensity of the continuous spectrum of the support and the absolute intensity.

The torsional vibrations of the OH group relative to the Si–OH bond (region *I*) and the deformation vibrations of this bond (region *II*) make a significant contribution to the vibrational modes corresponding to the differentiated regions *I* and *II*. The third structural element of the basis spectra of the hydroxyl components is the vibrations of the set of atoms of the silica core affecting the hydroxy-groups (the 'riding effect').[18,19] This effect consists of the following features. The hydrogen atoms linked to the oxygen atoms of the hydroxy-group participate also in other vibrational modes, describing, for example, the deformation of the Si–O–Si and O–Si–O angles, the stretching and deformation vibrations of the Si–O bond, etc. Owing to the anomalously high sensitivity of neutron scattering to hydrogen atoms, there is a response to the set of core vibrations, so that the frequencies due to the corresponding support arise in the AWDS spectra of the hydroxyl components, the range of which coincides with the range of the bulk-phase vibrations of the base illustrated in Fig. 12.

The narrow-band structure of the vibrational spectra of the hydroxyl components of aerosil and aerogel in region *I* indicates a certain uniformity of the orientations of the OH groups relative to the silicon atoms to which they are bound. From this one may conclude that the hydroxy-groups on the surfaces of both

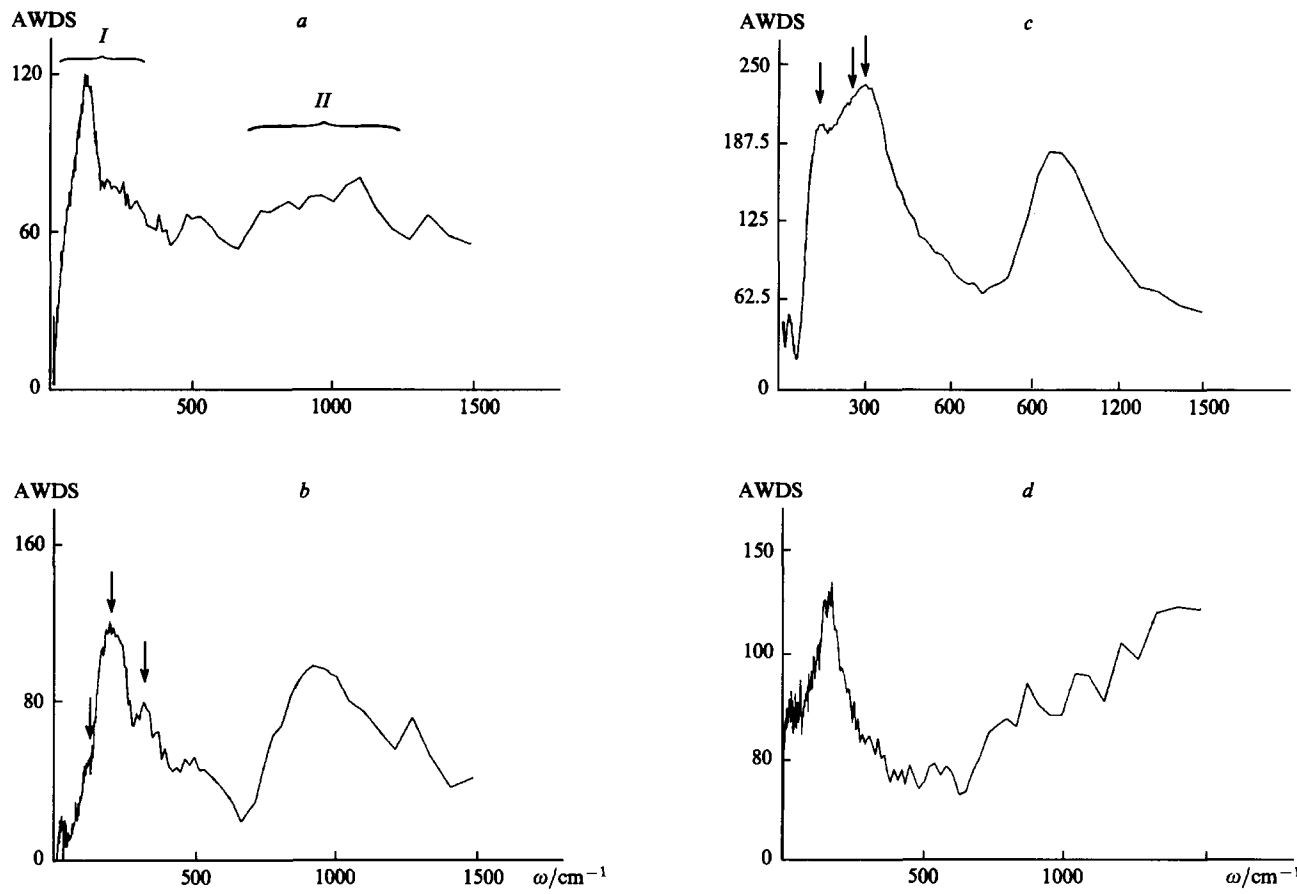

Figure 13. Basis vibrational spectra of the hydroxyl components of disperse silicas (T = 10 K): [28] (*a*) aerosil A380; (*b*) silica gel SG100; (*c*) silica gel SG20; (*d*) aerogel AG200.

substances are predominantly of the same type. This agrees with the results of studies on the structure of the hydroxyl coating on aerosil,[5] which established that 80%–85% of the surface hydroxy-groups are of the silanol type. The closeness in frequency of the first peaks in the aerosil and aerogel spectra and the similarity of their shapes suggests that silanol groups play the main role on the aerogel surface.

In contrast to the spectra of the hydroxyl components of aerosil and aerogel, the vibrational spectra of these components in different silica gels have a complex structure in region *I* and an intense and distinct peak in region *II*. The spectra of different silica gels also differ significantly from one another. The line intensities in the spectrum of the hydroxyl vibrations in the silica gel SG20 are twice as high as in the spectrum of the silica gel SG100. The principal structural differences are concentrated in region *I*: a redistribution of the intensities between the three characteristic peaks at frequencies of 80, 230, and 380 cm^{-1}, designated by arrows in Figs 13*b*, and 13*c*, is observed. The position of the first peak coincides with the positions of the peaks in the vibrational spectra of aerosil and aerogel.

The observed characteristics of the vibrational spectra of the hydroxyl components of silica gels have been explained qualitatively on the basis of the analysis of the possible structure of the hydroxyl shell on silicas.[28] The hydroxyl components may be made up of silicon–hydroxyl groups of three types: silanol $(OH)_1$, silanediol $(OH)_2$, and silanetriol $(OH)_3$. They all exhibit deformation vibrations of the Si–OH bond with similar frequencies,[5] so that the vibrational spectrum of the hydroxyl component of any composition should contain a band in the region of 1000 cm^{-1}, which can in fact be observed in the spectra in Fig. 13. We may note that the band in the spectra of silica gels is much more distinct than in the spectra of aerosil and aerogel.

The vibrational spectrum of the hydroxyl component of aerosil is in essence the vibrational spectrum of silanol groups. The difference between this spectrum and the vibrational spectra of the hydroxyl components of silica gels can be interpreted as evidence that the silanol groups, even if they are present in the hydroxyl component of the silica gel (which is indicated by the presence in the silica gel spectra of a peak with a maximum at 80 cm^{-1}), they are not the main element. It has been concluded that silanediol and silanetriol groups should participate in the formation of the hydroxyl components of silica gels. The possible presence of these groups in the loose structure of silica gel had already been reported.[40]

Thus the hydroxyl component of silica gel is a set of different silicon–oxygen groups, the weighting factors of which depend on the structure of the silica core. The difference between the structures of the silica cores of both silica gels determine also the different structures of the hydroxyl components.

3. Vibrational spectra of the adsorbed water

Fig. 14 presents the basis vibrational spectra of the aqueous components of aerosil, aerogel, and silica gel.[26]

The results of quantum-chemical calculations on the interaction of water with an isolated silanol centre have shown[92,93] that the nature of the vibrational modes changes significantly when the number of water molecules attached to the centre is altered.[93] In the case of a single molecule, the vibrational spectra of the water molecule coordinated to the silicon atom and the molecule bound to the centre by a hydrogen bond are strikingly characteristic. When the number of attached molecules reaches six, the overall spectrum acquires features typical for both characteristic spectra indicated above. However, in conformity with the analysis of the vibrational modes, the adsorption

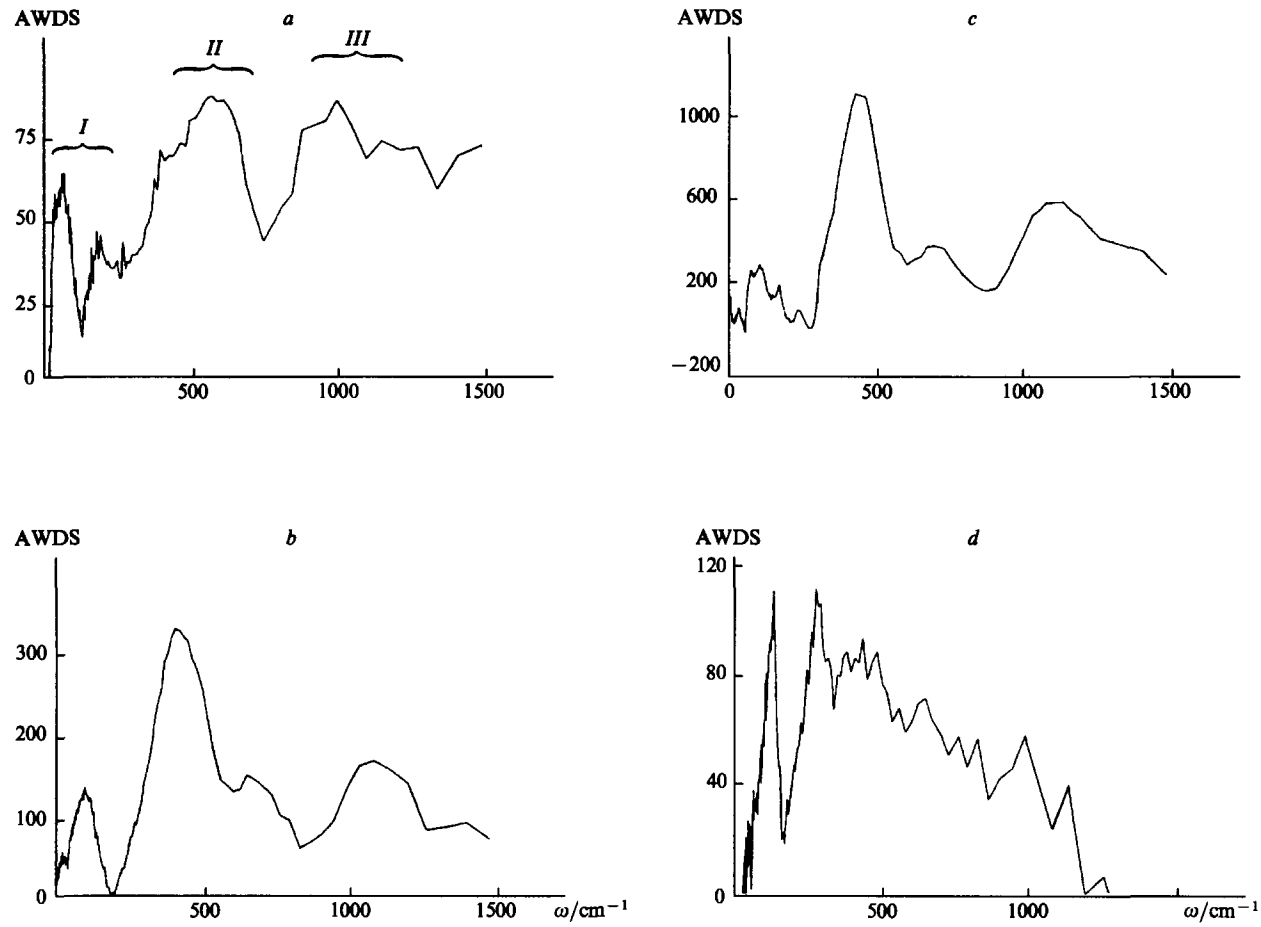

Figure 14. Basis vibrational spectra of water adsorbed on disperse silicas ($T = 10$ K):[28] (*a*) aerosil A380; (*b*) silica gel SG100; (*c*) silica gel SG20; (*d*) aerogel AG200.

complex vibrates under these conditions as a single whole in which the structurally differentiated coordinated and hydrogen-bonded molecules are not dynamically distinguishable. The details of this analysis can be found in the communication of Khavryuchenko and Sheka.[93] The characteristic nature of the vibrational spectra of single water molecules will be used below for a qualitative description of the characteristic features of the spectra illustrated in Fig. 14.

Three spectral ranges may be distinguished in these spectra. The low-frequency range 0–350 cm^{-1} (*I*) contains the stretching vibrational frequencies of the Si...OH_2 groups, the torsional vibrational frequencies of these groups, and the deformation vibrational frequencies of the hydrogen bonds of the interacting water molecules. The middle frequency range 350–850 cm^{-1} (*II*) is characterised by an intense structural peak and is mainly due to the deformation vibrations of the hydrogen bonds. This peak is the principal structural element in the spectrum of rapidly frozen water (Fig. 10*a*). The high-frequency region of the spectrum (850–1200 cm^{-1}) contains two peaks, which are associated with the deformation vibrations of the water molecule coordinated to the silicon atom and with the deformation vibrations of the Si–OH bond forming part of the adsorption centre.

The adsorbed water in the silicas investigated has been subjected to structural-dynamic analysis based on the above assignment of the vibrational modes.[28] The spectrum of the water adsorbed on aerosil shows that the adsorption of water on its surface is of a collective type, i.e. the water molecules form a 'quasi-drop' on the silanol centre during the adsorption process.[24,28,93] This hypothesis has been confirmed by calculations of the equilibrium configurations of the water molecules on large clusters, modelling the aerosil structure (see Section VII).

The spectrum of the water adsorbed on silica gel (Figs. 14*b* and 14*c*) differs significantly from the spectrum of water adsorbed on aerosil. This shows that the nature of the centres responsible for the adsorption of water on these silicas is different, which agrees with the conclusion reached in the previous section. Analysis of the spectrum of the water adsorbed on silica gel from the standpoint of the assignment of the frequency ranges *I*–*III*[28] led to the following conclusions. As in the case of aerosil, the adsorption of water on silica gel takes place collectively because the double peak in region *II* predominates in the vibrational spectrum. The form of this peak is similar to that of the analogous peak in the spectrum of rapidly frozen water (Fig. 10*a*), but the former is displaced towards lower frequencies and the ratio of the intensities of its components is different. This may be a consequence of the binding of the water 'drop' to the adsorption centre. Comparison of the spectra of water adsorbed on aerosil and silica gel shows that such binding of the drop is weaker in the case of silica gel than in the case of aerosil. The 900 cm^{-1} peak is absent from the spectrum of water adsorbed on silica gel, which indicates the virtually complete absence of coordinated water on the surface. The considerable width of the peak in region *I* indicates, as in the case of aerosil, the collective nature of the adsorption of water. The surprising coincidence of the spectra of adsorbed water for both silica gels noted above can be naturally explained by the above analysis and also the analysis of the structure of the hydroxyl shells of silica gels. Since these shells consist of a set of three silicon–hydroxyl groups, the water

molecule interacts with each independently, so that a competition of the groups in relation to the adsorption of water arises. The 'strongest' group, corresponding to the highest energy of the bonds between the water molecules and the centre, wins under these conditions. Since this group is one of the three indicated above, it should be the same both for the silica gel SG100 and the silica gel SG20. Thus the spectra of the adsorbed water should be identical for both silica gels and the difference between them reduces merely to the difference between the absolute intensities, which is associated with the fraction of the adsorption centres on the surfaces of silica gels differentiated in this way.

The AWDS spectrum of the water adsorbed on aerogel (Fig. 14*d*) differs markedly from the spectra presented above. In the first place, one should conclude that there is no distinct intense peak in region *II* of this spectrum, which indicates a significantly smaller number of hydrogen bonds between the water molecules on the aerogel surface. It has therefore been postulated[28] that the layer of adsorbed water is formed not by drops, as in the case of aerosil and silica gel, but predominantly by isolated molecules. This conclusion has also been confirmed by the distinctly structured nature of the vibrational spectrum of the low-frequency region *I*. The positions of the peak maxima in this region are nevertheless close to the positions of the peak maxima in the aerosil spectrum (Fig. 14*a*). This shows that the main water adsorption centre in aerogel is also a silanol group, which is in full agreement with the conclusions reached in the preceding section. The conclusion reached has been confirmed also by the presence of a maximum at 900 cm^{-1}. It is less pronounced than the maximum in the spectrum of water in aerosil but is observed quite reliably. According to Markichev et al.,[28] the change in the ratio of the intensities at the maxima in the spectra of water in aerosil and aerogel reflects the fundamentally different character of the adsorption in these substances: collective in the case of aerosil and individual in the case of aerogel. The latter conclusion is quite natural if we recall that water is adsorbed on the free outer surfaces of small aerosil particles. The steric hindrance to the formation of a drop is determined solely by the density of the silanol groups on the surface. It has been established experimentally that this density is such that it corresponds to an average distance between the silanol centres of ~ 7 Å.[6] This is sufficient for the formation of a quasi-drop, consisting of several water molecules, on an isolated silanol centre. In contrast to this, the active surface of aerogel is internal,[3] so that the role of steric hindrance to the formation of a quasi-drop is enhanced.

The above comparative analysis of the basis spectra of the components of the disperse silicas investigated made it possible to establish, despite its qualitative nature, that aerosils, silica gels, and aerogels should be regarded as fundamentally different structural formations. Here it is important to note that these differences extend to both bulk-phase, core structures and to the structures of the surface regions on these substances. Since the substances differ solely by the technology used in their preparation, the observed structural variability constitutes the phenomenon of technological polymorphism in an amorphous disperse silica.

VI. Technological polymorphism and classification of disperse amorphous silicas

The establishment of the existence of technological polymorphism in amorphous disperse silicas is important both intrinsically and as a basis for a new approach to the formulation of the problem of the computational modelling of these substances. In the development of this approach, it proved convenient to classify the observed modifications, formulating for each of them a set of distinctive features.[32] This was achieved by employing the principal crystal-chemical criteria proposed by Liebau.[94]

1. Fundamentals of the crystal chemistry of silicates

In his fundamental study, Liebau showed[94] that silicates are characterised by an extremely pronounced variability of their chemical and structural properties of a much greater extent than any other group of chemical compounds (with the exception of organic carbon compounds). At the same time, analysis of about 1000 compounds established that all the silicates can be divided into a small number of classes and subclasses in conformity with the classification based on the following fairly simple crystal-chemical principles:

1. Since the Si–O bond is the strongest in all the silicates investigated, the principal fragment determining the structure of the silicate is the polyhedron (SiO_n) and the type of structure is determined by the ways in which the polyhedra are linked to one another.

2. The coordination number of silicon (CN) in compounds having the general formula $M_xSi_yA_z$ and Si–A–M bonds tends to increase (CN > 4). This tendency is stronger the higher the electronegativity of the nearest neighbours — the A atoms. Oxygen has an intermediate electronegativity and may be incorporated in both the tetrahedra (SiO_4) and the octahedra (SiO_6), the tetrahedra being preferred.

3. The tetrahedra (SiO_4) are linked to one another usually via the vertices and not via their edges and faces.

4. One oxygen atom can participate in not more than two tetrahedra (SiO_4).

5. For each silicate anion, the difference between the number of junctions Δs between different tetrahedra (SiO_4) [where s is the number of junctions, i.e. the number of oxygen atoms in the tetrahedron (SiO_4) incorporated in other tetrahedra (SiO_4)] tends to decrease.

6. The bond lengths and bond angles tend to deviate from the average values $(Si-O)_{av} = 1.62$ Å, $(O-Si-O)_{av} = 107.47°$, and $(Si-O-Si)_{av} = 140°$ as little as possible. These six rules are not laws, exceptions to them being known,[94] but nevertheless their infringement is in most cases energetically unfavourable and therefore improbable.

A series of parameters have been introduced in order to describe the way in which the tetrahedra (SiO_4) are linked to one another in silicates. Without listing all the parameters, we shall consider the most important of these for further consideration, namely the dimensionality and multiplicity. The dimensionality of tetrahedral silicate structures D characterises the type of packing in the initial structural units and assumes the values $D = 0-3$. Thus isolated tetrahedra (SiO_4) as well as isolated cyclic and acyclic fragments have the dimensionality $D = 0$: $D = 1$ for isolated chains, $D = 2$ for isolated layers, and $D = 3$ for skeletal structures.[94] The multiplicity M characterises the formation of multiple tetrahedral structures with the same dimensionality as the initial structural units [isolated tetrahedra (SiO_4), isolated chains, isolated rings, and isolated layers].

The general nomenclature for silicates, presented in Table 3, has been introduced in conformity with the values of these parameters. Silicates with isolated tetrahedra (one, two, and three) belong to the class of oligosilicates. Silicates whose anions consist of rings comprising the tetrahedra (SiO_4) are referred to as cyclosilicates. Depending on whether they contain isolated, double, or triple rings, the prefixes mono-, di-, etc. are added to their names. Structures containing silicate chains are called polysilicates. They can be further subdivided into monopolysilicates with isolated chains, dipolysilicates with double chains or strips, etc. Phyllosilicates are made up of layers of tetrahedra (SiO_4); they can also be subdivided into mono- and diphyllosilicates. Silicates with a three-dimensional framework consisting of the tetrahedra (SiO_4) are called tectosilicates.

Further subdivision of silicates into subclasses is determined by the operation of the general parsimony principle, which presupposes that, for a specified composition, the system tends to have the minimum possible number of geometrically and chemically different groups.[94]

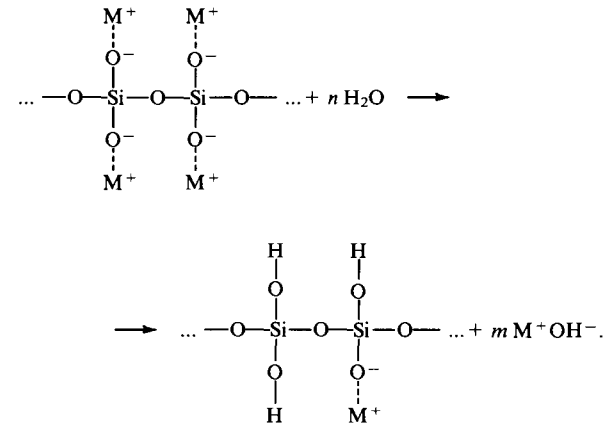
Table 3. The chemical nomenclature for silicates.[94]

Class	Dimensionality	Multiplicity (M)		
		1	2	3
Oligosilicates	0	Monosilicates	Disilicates	Trisilicates
Cyclosilicates	0	Monocyclosilicates	Dicyclosilicates	Tricyclosilicates
Polysilicates	1	Monopolysilicates	Dipolysilicates	Tripolysilicates
Phyllosilicates	2	Monophyllosilicates	Diphyllosilicates	Triphyllosilicates
Tectosilicates	3	Tectosilicates		

2. Classification of disperse silicas in conformity with the crystal chemistry of silicates

The principal crystal-chemical rules presented above contain nothing specific to crystal structures and it was therefore natural to suppose that they hold also in the case of amorphous structures.[32]

Crystalline silicates with mixed dimensionality and multiplicity are unknown in nature. This is apparently to be expected also for the amorphous state, so that amorphous structures can also be classified in accordance with Table 3. A specific feature of the test substances is the establishment of a classification mode for each of them, which is possible in the analysis of the technological procedure used in their preparation.[32]



Disperse silicas are obtained under the conditions of the simultaneous occurrence and competition of two processes: the hydrolysis of the initial product, which leads to the formation of silicon–oxygen tetrahedra containing between one and four hydroxy-groups, and the subsequent polycondensation of these fragments.[1-3] Polycondensation results in the formation of the nucleus of the future structure of the final product: particles of aerosil, a silica gel sol, and an element of the capillary structure of aerogel. The technological procedures differ in the initial products subjected to hydrolysis, the medium in which these processes are carried out, and external conditions (temperature, pressure, etc.).

Aerosil. Silicon tetrachloride is used to obtain aerosil. It is hydrolysed in an oxygen–hydrogen flame at atmospheric pressure and a temperature of about 2000 K. The hydrolysis, which proceeds in accordance with the reaction

$$SiCl_4 + 4H_2O = 4HCl + Si(OH)_4 ,$$

results in the formation of orthosilicic acid, the product of the polycondensation of which is in fact aerosil. The solid nuclei formed in the plasma are carried away from this zone and enter a cold zone, forming larger agglomerates, which are virtually ideal spherical particles of amorphous silica. The process involving polycondensation, the formation of nuclei, and their agglomeration is in many respects similar to the formation of small metal particles.[95]

Silica gel. Silica gel is usually obtained from aqueous solutions of alkali metal silicates in the presence of an acid.[2] The silicates employed are known to contain even in the initial state chains of the tetrahedra (SiO_4), which serve as the nuclei of the future solid-state structure. The essential feature of the process may be represented by considering the following simplified scheme:

The metal silicate hydrolyses in aqueous solution, which leads to the formation of chains of the tetrahedra (SiO_4) of differing length in which each silicon atom is linked to two hydroxyls. Such chains are known to cyclise at high concentrations to form rings with different numbers of silicon atoms. The hydroxide anion is capable of rupturing the Si–O–Si linkage connecting neighbouring tetrahedra, so that a dynamic equilibrium is established after a time in solution between the ring formation and disruption processes. In order to shift the equilibrium towards polycondensation, an acid is added to the solution, whereupon the ring disruption process virtually ceases and rings are actively formed in the medium and merge with one another. The primary hydrolytic process does not usually go to completion, so that negative oxygen ions are retained in the rings, holding solvated metal ions in their vicinity. It has been established[2] that the presence of such solvated ions plays a decisive role in the stabilisation of the gel.

Aerogel. The technological industrial process for the preparation of this product is based on the acid- or alkali-catalysed hydrolysis of tetraethyl orthosilicate (TEOS):[90]

$$Si(OEt)_4 + nH_2O \longrightarrow (RO)_3SiOH + m\,EtOH ,$$

R = H, Et.

The 'initial silanol' obtained as a result of this reaction can have a complex composition depending on the nature of the group R. The hydrolysis is accompanied by the condensation of the 'silanols', completed by the formation of a silicate polymer:

$$(RO)_3SiOH + OH^- \longrightarrow (RO)_3SiO^- + H_2O ,$$

$$(RO)_3SiO^- + (RO)_3SiOH \longrightarrow (RO)_3SiOSi(RO)_3 + OH^- .$$

The growth of the polymer chain is controlled by the concentration of water and TEOS and by the pH of the solution. The acid-catalysed processes lead to the formation of short chains as a rule. If the catalyst is an alkali, longer chains are obtained. The combination and cross-linking of the chains results in the formation of the gel.

Analysis of the technological processes for the preparation of various disperse silicates has shown that the structural fragments making up the structure of the future product are different in all three cases.[32] Thus the 'principle of close packing' of the tetrahedra (SiO_4) in the bulk phase operates in the formation of the aerosil particles. According to Liebau's classification,[94] the dimensionality of the structure obtained is three and, by analogy with tectosilicates, aerosil was assigned to the class of amorphous tectosilicas.

The principal structural unit in silica gels comprises ring structures of arbitrary composition, the dimensionality of which is $D = 0$, as a result of which they were assigned to the class of amorphous cyclosilicas, analogous to cyclosilicates.

The principal structural element of the aerogel framework comprises chains. In this case, the dimensionality of its structure is unity and it was therefore classified as an amorphous polysilica analogous to polysilicates.

Thus amorphous tecto-, cyclo-, and poly-modifications are the technological polymorphic forms of disperse silicas. This idea served as the basis of an algorithm, which was used in the construction of model structures of amorphous silicas.

VII. Computational modelling of the initial structures of amorphous silicas

The concept underlying the computational modelling of polyatomic systems, which has made it possible to achieve the closest approach to the description of the properties of real nanomaterials, has been actively developed during the last few years.[15,31,36] This concept is based on a joint spectral experiment including computational and real experiments linked by feedback. The modelling process is regarded as a problem the successful solution of which is determined by the optimum selection of four of its main components, namely: (a) the quantum-chemical method for calculations relating to polyatomic clusters of nanometer size; (b) the procedure for calculations on the available powerful high-speed computers; (c) a structure-sensitive experimental method for testing the validity of the results obtained; (d) an adequate experimental object ensuring the establishment of a feedback between the calculations and the real experiment.

The need to operate with clusters of nanometer size leads to a conclusion in favour of one of the quantum-chemical semiempirical methods. Significant progress in this field has been achieved in recent years both by virtue of the stimulating studies of Dewar's school[96] and as a result of the development of new computational methods or new versions of those already existing. Zaets's program packs on computational chemistry, based on the MNDO, MNDO/H, AM1 (*sp* basis set) (CLUSTER-Z1 program pack),[97] and NDDO (*spd* basis set) (CLUSTER-Z2 program pack)[98] methods, should be included among the latter. These program packs have been executed in a form, which ensures a high accuracy of the computation for polyatomic systems combined with a comparatively small expenditure of computing time. When installed on the personal computers of the PC AT 486/Pentium and SUN SPARCstation class, they made it possible to perform calculations in a short time for a wide variety of polyatomic clusters of nanometer size, in particular systems such as silica, silicon nitride, nickel, aluminium, etc. (for a brief review of the results, see Sheka et al.[36]).

However, the calculated data obtained do not as yet solve the problem of modelling, since the question of the correspondence of these data to reality arises. The nanometer clusters used as the model have no molecular analogues, so that the principal characteristic of the molecular system — the energy and other integral characteristics — become merely descriptive quantities and cannot be subjected to an experimental test. Only vibrational spectra, which are largely determined by a short-range interaction, are the actual the property of the system for which the cluster approximation is sufficiently accurate. From the standpoint of the numerical experiment, the modelling of the surface does not differ from the modelling of the core structure. However, the need for a feedback in relation to the real experiment at the level of the investigation of the vibrational spectra requires that the investigator select an object which is as close as possible to the clusters being modelled. This is why in the course of the numerical modelling of the adsorption properties of the surfaces of nickel,[19,99,100] silica,[32-35] and silicon nitride[101] the vibrational spectra of the corresponding modifications of these substances having nanometer size were employed as the experimental parameter.

When the problem of the computational modelling of a large cluster is formulated, the qualitatively new problem of the selection of the procedure for the modelling of the initial structure arises. It is well known[102] that in most cases chemical interactions are of the short-range type, so that structural elements separated by distances exceeding the chemical bond length hardly affect one another. As a result of this, there arises the risk that the site and direction of the development of the structure 'will not be guessed correctly'. The situation is frequently aggravated by the fact that nonrigid structures, to which those of silica belong in particular, are characterised by a large set of close minima on the total electronic energy surface. One of the ways of solving this problem involves algorithmic modelling, the essential feature of which consists in the construction of the initial structure of the cluster with the aid of a definite algorithm based on 'evidence of the origin' of the corresponding product containing a set of distinctive features characteristic only of the latter.[103] This approach has been used in the modelling of the structures of disperse silicas.[32-35]

1. Computational modelling of aerosil

The computational modelling of the structure and adsorption properties of aerosil[33] consisted of the following stages:

1. the construction of the initial structures of polyatomic clusters of nanometer size;
2. computational modelling by means of semiempirical quantum-chemical methods of the structures constructed;
3. computational modelling of the adsorption properties of the clusters investigated in relation to water molecules;
4. calculation of the doubly amplitude-weighted density of the vibrational states of the cluster and of inelastic neutron scattering spectra with subsequent comparison of the calculated and experimental spectra.

a. Initial structural models

On proceeding to the construction of the initial clusters, it is useful to introduce the concept of small, medium, and large clusters having brought them into correspondence with the principal ideas concerning crystal-chemical fragments and the types of their packing in conformity with the assignment of the test structure to a particular structural class. The main structural fragment of silicates and silicas is the silicon – oxygen tetrahedron (SiO_4). This tetrahedron is in fact usually considered in the computational modelling of silica systems (see, for example, Refs 6, 92, 104, and 105). However, in the light of the multivariability of the structures of disperse silicas, such a model cluster is inadequate for the description of their properties. Therefore, in the computational modelling of this family of substances, special definitions were formulated and introduced: the concept of a small cluster as a structural model of a peripheral (surface) functional group was introduced; the concept of a cluster of medium size as a structure describing the packing of small clusters in accordance with the classification of the structure and reproducing correctly the short-range distribution of atoms; the concept of a large cluster as a structure in the ideal version designed to reflect the correct bulk-phase structure of the substance and the distribution of functional groups on its surface.

Since aerosil is an amorphous tectosilica, the clusters modelling the structure of its core must be of the skeletal close-packed type. The close-packed crystal structures of silica are known to contain rings of siloxane chains with a small number of members: four-membered in quartz[106] and six-membered in cristobalite[107] and tridymite.[108]

The structural models of individual small rings are presented in Fig. 15. They were obtained as a result of total optimisation by the AM1 method with the aid of the quantum-chemical programs of the CLUSTER-Z1 pack.[33] These and all subsequent calculations were performed on personal computers of the type PC AT 386/387-33 and 486-66. The clusters are presented in a projection 'from above'.

We may note that, although the silicon atoms are located in one plane only in the Si3c cluster, in the remaining clusters the

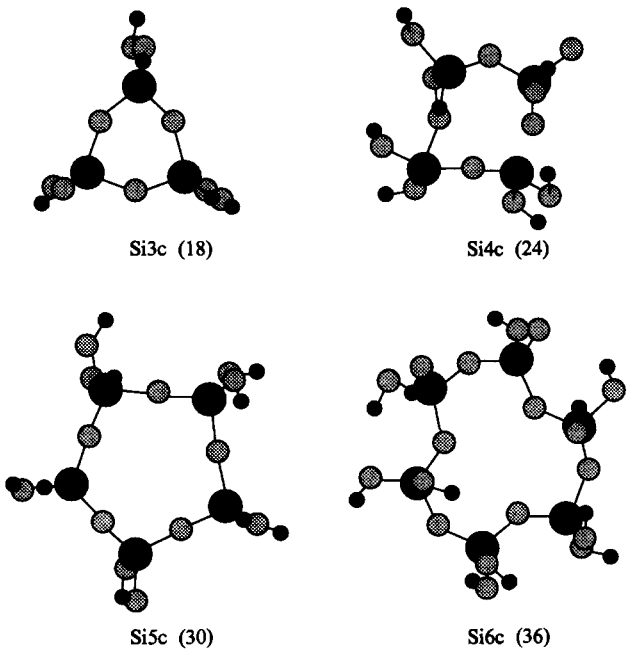


Figure 15. Small rings of silicon–oxygen tetrahedra Si*n*c (calculation by the AM1 method);[33] *n* is the number of silicon atoms in the ring (c) (here and in Fig. 16 the numbers of atoms in the cluster are indicated in brackets).

silicon rings are also close to planarity. In contrast to these, large rings with more than six carbon atoms have a distinctly nonplanar structure. The structure made up of large rings is inevitably looser. Thus polyhedra the faces of which consist of small rings served as a model of the bulk-phase structure of aerosil. In constructing model 'structures', preference was given to nonplanar six-membered rings ('hexagons') because the nuclei of the aerosil particles are formed at a high temperature where the β-cristobalite crystal structure is more stable.[33] The choice of the 'hexagon' motif made it possible to propose a fairly simple algorithm for the successive growth in the size of the model cluster, which can be represented by the formula

$$\mathrm{Si6c} + 4n\,\mathrm{Si} + 6m\,\mathrm{Si},$$

where $n = 1, 2, 3$ and $m = 1, 2, 3\ldots$ for $n > 3$. This algorithm corresponds to a development of the cluster structure such that the addition of the first four silicon atoms to the basic Si6c six-membered ring is accompanied by the formation of an adamantane-like skeleton containing three 'hexagons' (Fig. 16*a*). The addition of each succeeding group of four silicon atoms leads to the formation of three new 'edges', from which new 'faces' of the cluster being formed are produced, so that the Si10 cluster is converted into a Si14 cluster and the latter into a Si18 cluster, etc. Under these conditions, the cluster grows in width and its development in depth, starting with $n = 3$, requires the addition of six silicon atoms. The set of Si10, Si18, and Si24 clusters obtained as a result of the application of this algorithm is presented in Fig. 16.

b. Analysis of the model structures of aerosil

Whereas the first member of this series can be assigned to clusters of medium size, the last two clusters belong to the class of large ones. Analysis of their structure shows that the selected algorithm for the growth in the size of the cluster not only reproduces the bulk-phase structure of the substance but also makes it possible to discover the trend in the distribution of the functional groups on its surface. In the test system, these are silanol $(OH)_1$ and silanediol $(OH)_2$ groups. With increase in the size of the cluster, the silanediol groups, which are the only ones present in the isolated rings (Fig. 15), are gradually substituted by silanol groups

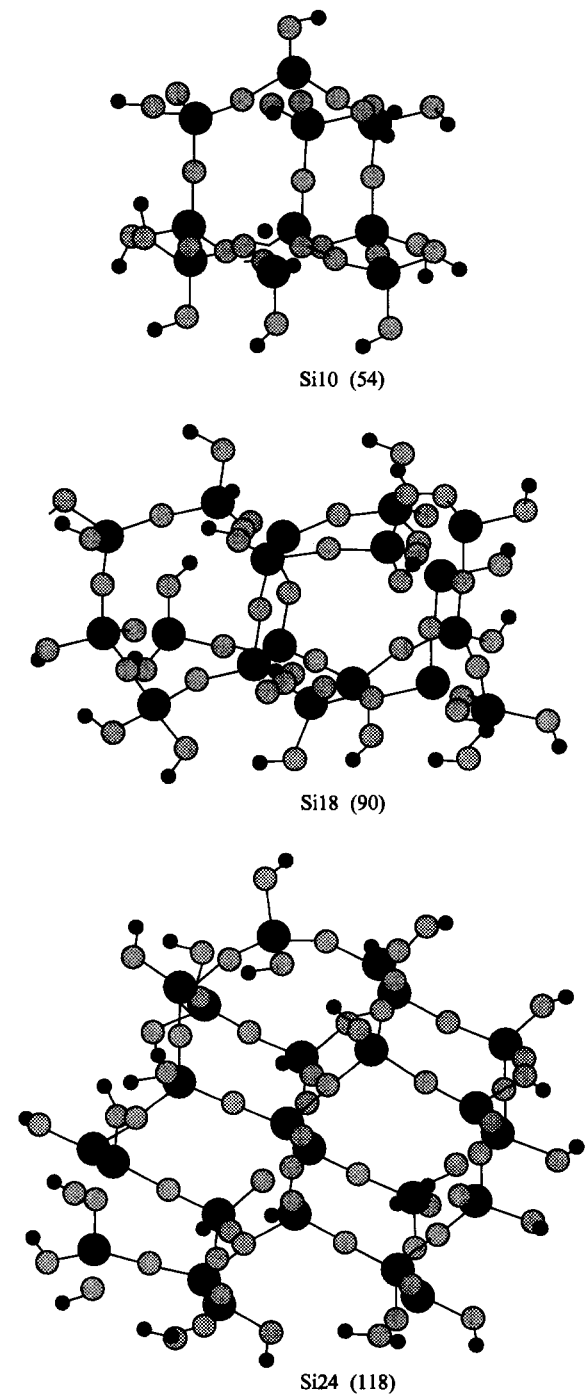

Figure 16. Clusters with a close-packed structure (calculation by the AM1) method.[33]

and are displaced to the periphery. Fig. 16 shows that cyclic close-packed structures contain no silanetriol groups. These groups arise only when a kind of branching of the structure takes place.[33]

Table 4 presents the numerical characteristics of the clusters demonstrating the dynamics of the variation in the numbers of silanol and silanediol groups in the clusters of the close-packed structure. The table shows that there are no $(OH)_1$ groups in the isolated cyclic clusters. These groups appear only in the compactly bound structure of the Si10 cluster. The ratio of the numbers of the $(OH)_1$ and $(OH)_2$ groups still indicates the predominance of the silanediol groups under these conditions. It is known from experimental results that the hydroxyl shell of the aerosil particles may contain not more than 20% of

Table 4. Quantitative characteristics of the model clusters of aerosil.[33]

Cluster	Number of atoms			Number of groups		Linear size/Å	
	Total	Si	O	$(OH)_1$	$(OH)_2$	min.	max.
Rings							
Si3c	18	3	3	–	3	3.57	6.62
Si4c	24	4	4	–	4	3.62	8.11
Si5c	30	5	5	–	5	3.65	9.00
Si6c	36	6	6	–	6	3.62	8.72
Si8c	48	8	8	–	8	5.60	11.34
Si10c	60	10	10	–	10	5.18	13.07
Si14c	84	14	14	–	14	5.18	15.71
Bulk-phase structures							
Si10	54	10	12	4	6	8.57	11.16
Si14	72	14	18	8	6	9.00	14.30
Si18	90	18	24	10	7	10.52	15.41
Si24	118	24	36	15	7	10.52	16.02

silanediol groups.[5] Thus it is evident that neither the free rings themselves nor the compact structures made up of a small number of rings can serve as an acceptable model of the structure of an aerosil particle. With increase in the size of the cluster, the ratio of the hydroxy-groups changes in favour of silanols (see the Si14 cluster and so on) and tends to increase. This increase is slow, but estimates have shown that, when the selected algorithm for the increase in the size of the cluster is used, the ratio of the numbers of the $(OH)_1$ and $(OH)_2$ groups may reach 5 – 6 in favour of the former when the size of the cluster increases to dimensions comparable with 100 – 200 Å. It is then evident from the analysis of model structures that the silanediol groups exist mainly at the apices of the terminal edges, i.e. on the irregularities of the structure of a real particle. The tendency in the variation of the structure of the hydroxyl shell of the clusters thus discovered means that the specific content of the hydroxy-groups on the surface of aerosil should vary in opposition to the variation of its specific surface (radius), which has in fact been observed experimentally.[109]

The proposed algorithm for the growth of the cluster is undoubtedly not the only one possible — it merely corresponds to the most probable structures of the close-packed amorphous silica, reflecting fully the quaternary coordination of the silicon atoms in the dense structure formed by the 'hexagons'. The irregularity of the structure over the macroscopic distances characteristic of the amorphous state is apparently due to the fact that four-, five-, and six-membered rings adjoin one another among close-packed atoms. However, the considerations presented above concerning the tendency towards the distribution of the functional groups in a real particle remain valid for rings of all sizes.

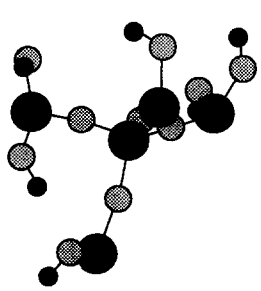

Figure 17. A fragment of the Si18 cluster (calculation by the AM1 method) demonstrating the alternating distribution of the surface Si atoms with the hydroxy-groups and tetrahedral Si atoms coordinated only to the siloxane oxygen atoms.[33]

Taking into account the foregoing, the Si18 cluster may be regarded as the real model of the surface of an aerosil particle. This applies not only to the distribution of the hydroxy-groups but also to the formation of the experimentally established[5] alternating structure comprising silicon atoms in which a silicon atom attached to a hydroxy-group adjoins another surface silicon atom involved in tetrahedral coordination with only four siloxane oxygen atoms (Fig. 17).

On the basis of the results obtained, the following models of the small, medium, and large clusters of the model structures of aerosil may be proposed.

The principal functional group on the surface of aerosil is an isolated silanol group. As a result of this, the simplest model of a small cluster may be a silicon – oxygen tetrahedron based on three silicon atoms and containing one OH group. The interaction of this cluster with water has been considered as the basic model.[15,92,100,110] The results agree satisfactorily with experimental vibrational spectra of water adsorbed on the surfaces of aerosil particles.

A similar small cluster with a silanediol group may serve as the simplest model of isolated silanediol groups on the surface of aerosil. These groups are located on structural irregularities and their contribution to the aqueous and hydroxyl components of aerosil is comparatively small. As shown above, silanetriol groups are foreign to the close-packed aerosil structure and as external formations are naturally unstable; their presence on the surfaces of aerosil particles is hardly possible.

The model Si10 cluster is an example of a cluster of medium size reproducing the packing of small clusters. The Si18 and Si24 model clusters are large clusters which not only model the bulk-phase packing in the core of an aerosil particle but also describe the distribution of the hydroxy-groups on its surface. Apparently a further increase in the size of the cluster is hardly useful because it is unlikely that qualitatively new information would be obtained in view of the small radius of action of the chemical interaction forces.

The structures presented have been used to calculate the vibrational spectra of the core and the hydroxyl component of aerosil and also the spectra of the water adsorbed on them.

c. Vibrational spectra of the core and the hydroxyl component

Fig. 18 presents the experimental AWDS basis spectrum of the aerosil core and two calculated spectra. The latter were obtained with the aid of the COSPECO program pack for computational vibrational spectroscopy.[111] The field strength data were obtained in a quantum-chemical calculation in terms of the AM1 approximation (with the CLUSTER-Z1 program pack). The first spectrum refers to the Si18 cluster (Fig. 18, curve *2*). It has already been stated above that this cluster is a realistic model of a

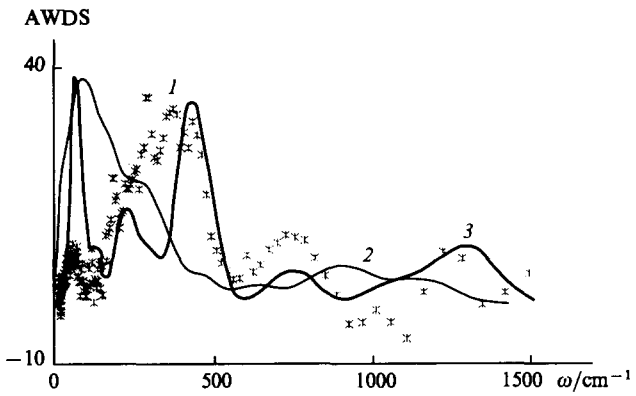

Figure 18. Vibrational spectrum of the aerosil core: (*1*) experimental curve ($T = 10$ K);[25] (*2*) calculation for the Si18 cluster; (*3*) calculation for the Si10ch siloxane chain under cyclic boundary conditions.[103]

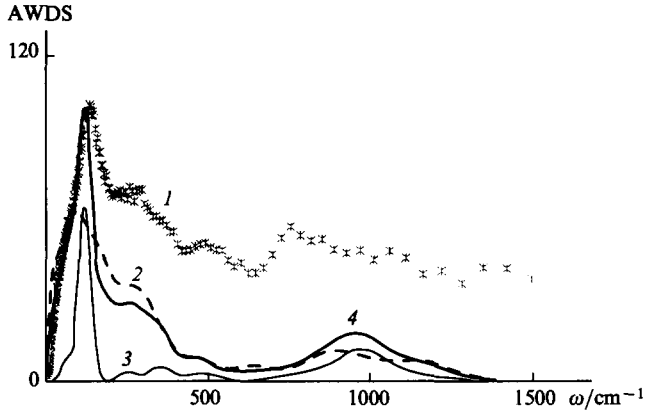

Figure 19. Vibrational spectrum of the hydroxyl coating on aerosil: (*1*) experimental curve ($T = 10$ K);[25] (*2*) calculation for the hydroxyl coating on the Si18 cluster; (*3*) calculation of the surface vibrations of the Si18 cluster; (*4*) the sum of curves *2* and *3*.[103]

large cluster. At the same time, the calculated spectrum differed so much from the experimental one that this appeared discouraging at first sight. Analysis of the causes of the observed discrepancy revealed a completely new problem. The point is that the vast majority of the silicon atoms of this cluster are found to be surface atoms after careful examination, so that their kinematic behaviour differs significantly from the behaviour of the inner atoms while the force constants are fully retained for each selected pair of atoms. In order to eliminate this effect within the framework of the clusters considered, it was necessary to increase their size almost by an order of magnitude, which rendered any computational study unrealistic. However, another approach to the solution of this problem is also possible. In considering the structures of the close-packed Si18 and Si24 clusters, one may note that they consist of a set of Si–O–Si chains inclined to the basis plane† of the clusters. Each three neighbouring chains in sections parallel to this plane form a typical close-packed hexagonal structure. Thus the chain may be regarded as a translationally equivalent structural unit with the aid of which the bulk-phase structure of aerosil may be constructed. Fig. 18 presents the results of the calculation of the vibrational spectrum corresponding to a chain containing ten silicon atoms for cyclic boundary conditions (curve *3*). The force constants in this chain were taken from the Si18 cluster. Evidently, the calculated and experimental spectra agree well. The band at 80 cm^{-1} is an exception. It is due to the out-of-phase translational motion of the silicon–oxygen tetrahedra. With increase in the length of the chain, it splits into an increasing number of components and its maximum diminishes, so that for several hundred silicon atoms it will undoubtedly assume a form consistent with experiment. The complete agreement between the positions of the maxima of all the bands in the calculated and experimental spectra is striking.

Fig. 19 presents the experimental and calculated AWDS spectra of the hydroxyl coating of aerosil. Curve *2* corresponds to the spectrum presented above for the Si18 cluster, which represents the vibrational spectrum of the surface atoms. Curve *3* represents the vibrational spectrum of the atoms bound to the ten $(OH)_1$ groups contained in the Si18 cluster. As stated in Section IV, the hydroxyl component of the AWDS spectrum of aerosil should consist of the vibrational spectra of the hydroxy-groups and the surface core atoms sensitised by these hydroxy-groups as a result of the 'riding effect'. The real AWDS spectrum represents a combination of these spectra with the correct ratio of the hydroxy-groups and surface silicon atoms. Curve *4* in Fig. 19 corresponds to the sum of the spectra *2* and *3* in proportions of 1:1. Evidently, this spectrum agrees very well with the experimental one.

† The introduction of the term basis plane is in this case arbitrary. It implies the section which reveals the hexagon ornament of the structure.

d. Compositional structure and vibrational spectrum of adsorbed water

The reliability of the results of the modelling of the structure of an aerosil particle made it possible to consider in greater detail the problem of the adsorption of water.[93] As stated above, the Si10 cluster belongs to the class of medium-size clusters, which makes it possible to reproduce the real structural correspondence between an isolated functional group and the core of the substance. Fig. 20 presents the optimised structure of this cluster (for further details, see Khavryuchenko and Sheka[93]), interacting with six water molecules (MNDO/H approximation, CLUSTER-Z1 program pack).[97]

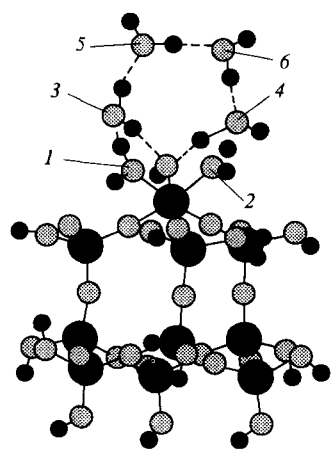

Figure 20. The Si10w6 (72) cluster with six water molecules (calculation by the MNDO/H method).[103]

Water molecules are adsorbed collectively on the aerosil surface, which confirms the conclusion reached as a result of a qualitative analysis of the experimental spectrum of the water adsorbed on aerosil (see Section V). The first two molecules are coordinated to the silicon atom of a silanol group, whereupon its coordination number becomes six. The remaining water molecules are hydrogen-bonded. Fig. 21 presents the

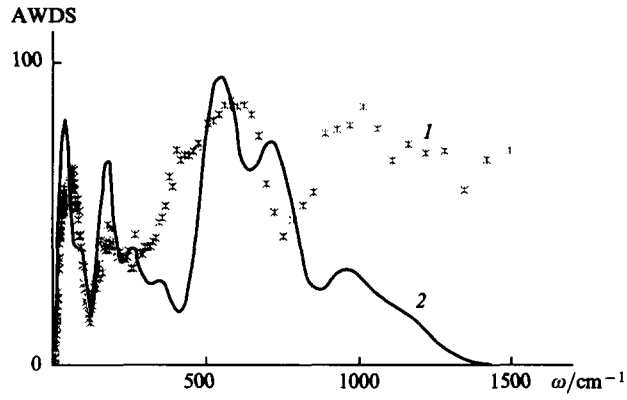

Figure 21. Vibrational spectrum of the water adsorbed on aerosil:[103] (*1*) experimental curve ($T = 10$ K);[25] (*2*) calculation for the Si10w6 cluster.[103]

experimental and calculated AWDS spectra. As in the preceding spectra, the calculated spectra were slightly corrected as regards frequency.

Evidently, the principal features of the calculated and measured spectra agree. The higher intensity of the experimental spectrum compared with the calculated one in the high-frequency region may be associated with the contribution of two and more multiphonon states in the experimental spectrum. The unduly low intensity in the low-frequency region is associated with the fact that the composition of the water adsorption complexes on the surface of aerosil is nonuniform:[93] apart from the centres containing six molecules, there are centres in which the number of molecules ranges from one to five. The problem of obtaining complete agreement between the calculated and experimental spectra thus includes the problem of the determination of the number of these centres.

The satisfactory agreement obtained between the calculated and experimental basis spectra of the aerosil components on the whole indicates the legitimacy of the models presented, describing the close-packed structure of amorphous silica.

2. Computational modelling of silica gels

Silica gel is known to be characterised by a considerable variability of its properties.[2] This applies both to the poor reproducibility of the product already in the stage involving its preparation and to the variation of its properties and their sensitivity to external conditions. One may claim that the principal property of silica gel is the 'flow' of its structure, so that each silica gel specimen does not represent the same and fixed structural state of amorphous silica but constitutes an 'instantaneous photograph' in a chain of structural transformations. In view of the foregoing, the problem of the modelling of the silica gel structure is by no means simple, since it is not known which particular 'instantaneous photograph' of the real structure is to be reproduced. Proceeding to the modelling of the structural clusters of silica gel, Khavryuchenko and Sheka[34] did not have as their aim the reproduction of a particular structural configuration. Their aim was to find answers to the following principal questions which are associated nowadays with the silica gel structure,[28] namely: how are the silica gel pores formed; on what factors does their size depend; why do the vibrational spectra of the core and hydroxyl shell of silica gel depend on the pore size; what does the experimentally observed adsorbed and quasi-free water in the pores represent; why does the vibrational spectrum of the adsorbed water not depend on the pore size.

The structure of silica gel (cyclosilica) is based on rings of silicon–oxygen tetrahedra of different size. It has been noted that the loose structure characteristic of silica gel is made up of rings of fairly large size. The structural models of several such large rings were first constructed and optimised within the framework of the MM2 program[112] and were then additionally optimised by the AM1 method with the aid of the CLUSTER-Z1 program pack.[97] It was found that, with increase in its size, the structure of the ring increasingly deviates from planarity. At the same time, an appreciable tendency towards the 'cellular subdivision' of the ring with formation of smaller rings is observed.

It is natural to suppose that the silica structure is produced as a result of rings of different size being joined together. It is noteworthy that the rings must be sufficiently large, since the condensation of rings with four, five, and six silicon atoms leads to the formation of close-packed structures of the type of aerosil or quartz glass.[33] There is no doubt that these small rings also participate in the formation of the silica gel structure, but they are most likely to play merely a binding role.

Large rings are as a rule highly distorted and nonplanar, so that on combination of, say, two such rings, they may 'fold up'. Bearing in mind that the gel is formed in the presence of solvating alkali metal ions, it is logical to suppose that the main role of the ion is to stabilise such a structure. Fig. 22 presents one of the possible structures formed by two rings containing seven and eight silicon atoms and having two common siloxane bonds. Evidently, these rings represent the 'folds of a half-open blister'. The presence of a solvated ion within this structure probably prevents its folding up and promotes the extension of the rings. On this basis, it has been postulated that silica gel consists of a solid framework having the structure of an open network similar to the pattern on a poorly inflated football with an irregular shape.[34] In contrast to the cells on the usual football or the regular fullerene structures of the C_{60} and C_{70} types, the cells in this framework do not consist of ideal hexagons and pentagons but are nonplanar rings of silicon–oxygen tetrahedra of different size. The retention of the form of the framework during synthesis is ensured by the solvated ions (one or several), after the removal of which pores of different size remain.

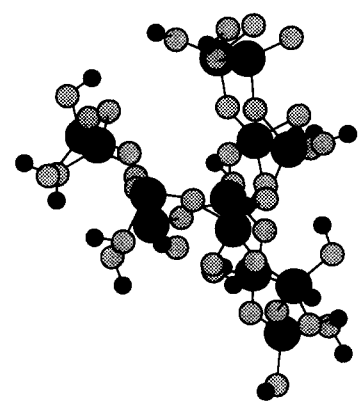

Figure 22. The Si13dc(75) cluster consisting of two rings (Si7c and Si8c) (initial model).[34]

It is important to note that the formation of the rings, contact between them, and the formation of the framework bounding the pore are undoubtedly statistical processes. They are naturally subject to the influence of external conditions. Thus certain rings may be opened in some cases. Their number is determined, in particular, by the concentration of acid. This probably explains the difficulty of reproducing the silica gel structures, mentioned above. The aggregation of such elementary frameworks in accordance with the close-packing principle, applied to spherical or quasi-spherical particles, leads in its turn to the formation of a globular mesostructure, which has in fact been observed experimentally.[2]

In conformity with the foregoing, the hierarchy of clusters describing the silica gel structure is as follows. The small structures modelling the peripheral functional groups (in the given case hydroxy-groups) are closed and open cyclic structures comprising eight and more silicon atoms as well as the sites of contact between two rings. The clusters of medium size, reproducing the packing of small clusters and the short-range distribution of atoms, are model macrocyclic structures, which may differ in the type of junctions incorporating one, two, and more silicon atoms. The large clusters, representing the distribution of atoms over long distances and the distribution of functional groups, may be considered to comprise a fragment of the surface of the framework consisting of 2–3 junctions.

The proposed model of the silica gel structure does not conflict with the known macroscopic properties of this substance. Furthermore, it makes it possible to explain qualitatively a number of microscopic properties which have not been accounted for hitherto, including vibrational spectra. It is seen from the models presented that the silica gel core consists of an open network comprising chains of siloxane bonds. The large width of the size distribution of the rings in this structure and its lability are evident, as a result of which there is a possibility of the variability of the distribution of the Si–O–Si and O–Si–O bond angles from specimen to specimen, with which the principal changes in the observed spectra of the core are associated (Fig. 8).[26]

The hydroxyl components of silica gels represent a set of three silicon-hydroxyl groups, namely the silanediol groups of the closed rings, the silanetriol groups at the ends of the opened rings, and the silanol groups at the points of contact between the rings. Thus their vibrational spectra are compound. They depend on the number of silicon-hydroxyl groups of different types. On the other hand, it is evident that the ratios of the numbers of these groups are statistically distributed over a fairly wide range of values and may be different even for different fractions of the products of the same technological cycle. It has been postulated[34] that the difference between the observed vibrational spectra of the hydroxyl components of the silica gels SG100 and SG20, presented in Fig. 9, is in fact associated with this factor.

As regards the vibrational spectrum of the adsorbed water (Fig. 13*b*), its constancy under conditions such that the adsorption centres are heterogeneous and compete with one another reflects the fact that the same centre wins this competition in each specimen. Since such a centre is one of the three possible silicon-hydroxyl groups, it is common to all the specimens. Calculations, which are being continued, will make it possible to discover which particular silicon-hydroxyl groups determine the adsorption of water in silica gel. In contrast to aerosil, in the structures of silica gels both identical and different silicon-hydroxyl groups adjoin one another, so that the simplest small clusters, representing isolated groups in aerosil, cannot be regarded as suitable structural models. This is why the rings themselves or fairly extended fragments of these rings as well as their junctions should be considered as small clusters in the case of silica gel.

3. Computational modelling of aerogel

The simplest model of the structure of aerogel (a polysilica) is a chain of silicon–oxygen tetrahedra.[32] Each silicon atom in this chain is linked to two oxygen atoms of the siloxane chain and to two hydroxy-groups. Thus the principal functional group of the hydroxyl component of aerogel, consisting of isolated chains, should be a silanediol group. However, comparative analysis of the basis vibrational spectra of the hydroxyl components of different disperse silicas (see Section V) established that the main element of the hydroxyl component of aerogel is a silanol group. It is natural to postulate that aerogel is not a monopolysilica made up of single chains but is a dipolysilica or a more complex one (see Liebau's classification[94]), the structural fragments of which are double or more complex strips. In view of the large number of capillary cavities in the macrospecimen, it is difficult to suppose that it consists of multichain strips, since its density should then be fairly high. It is most likely that the number of chains in the strips hardly exceeds 2–3. One of the possible structures of this kind is presented in Fig. 23. The structure is nonplanar. Attention should be drawn to the quasi-regular structure of the cells in the middle section of the chain. The principal size parameter of the model cluster is the length of the strip and therefore the boundary between a cluster of medium size and a large cluster is fairly arbitrary. The point of junction of several strips, one of the possible models of which is illustrated in Fig. 24, constitutes a special site within the structure.

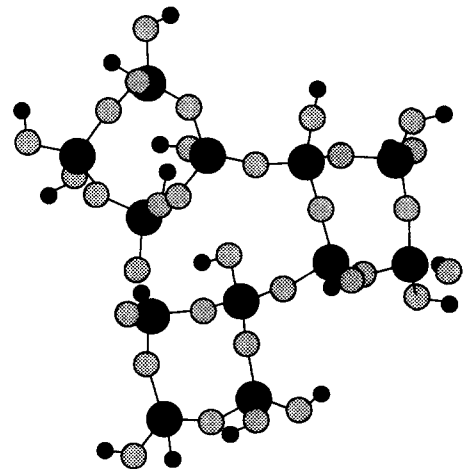

Figure 24. Cluster involving the junction of the Si12b(63) strips (initial model).[35]

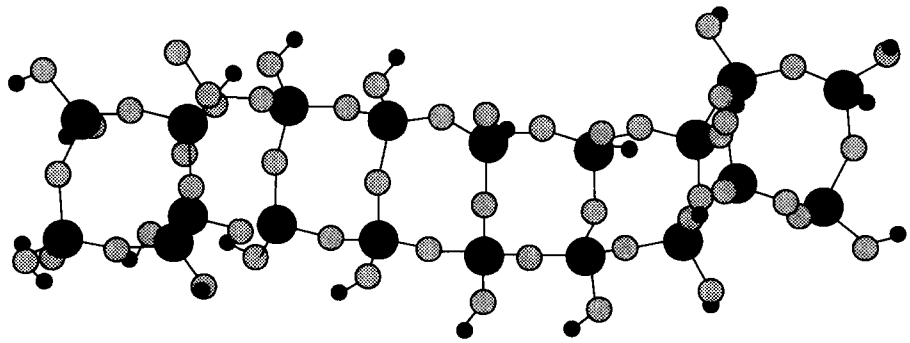

Figure 23. The Si20b(96) strip cluster (initial model).[35]

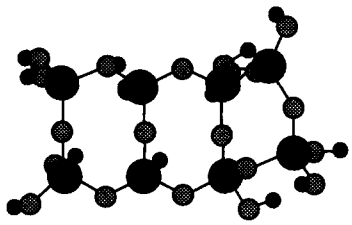

Figure 25. A small cluster of the structure of aerogel Si8b(42) (initial model).[35]

The main functional groups on the periphery of the strip are silanols. Nevertheless, it is evident from the analysis of the model of the aerogel structure that the cluster containing an isolated silanol group and constituting a satisfactory model of the silanol groups of aerosil cannot model the functional groups of aerogel. The reason for this is the fact that, in contrast to aerosil, the silanol groups in aerogel are arranged in a sequence where they adjoin one another at a distance of ~ 3.5 Å, so that several groups participate in the interaction of the chain-strip with water. Another cause is the significant different between the core chain structure of the siloxane bonds of aerogel and the close-packed aerosil structure. As a consequence of this, the small cluster, needed according to Khavryuchenko and Sheka[35] for the modelling of the functional groups and for the consideration of the interaction of aerogel with water, must have a fairly complex structure. One of the possible models of this cluster is illustrated in Fig. 25.

The model structures of aerogel presented here agree well with the existing ideas about its structure[3] specified in detail at the atomic level. At the same time, they make it possible to explain a distinctive feature of the vibrational spectra of its components — the narrowness of their bands. This form of the spectra is known to be characteristic of polymers,[89] which yet again confirms that the model presented for this silica is reasonable.

* * *

The physicochemical phenomenon examined above has been called technological polymorphism. This verbal construction does not imply simply following the fashion for new terms but has proved to have a rich inner significance. The polymorphism of amorphous silicas has been established reliably from the vibrational spectra which constitute 'fingerprints' of the structure of the substance. The existence of such polymorphism is well known for labile systems.[113] One could confine oneself to this reference and attempt to describe qualitatively the disperse amorphous silicas investigated in terms of the degree of their lability. However, the path based on the properties of the substance which are characteristic of it alone and which permit the introduction of a characteristic numerical parameter (or parameters), with the aid of which it is possible to achieve their classification, proved much more productive. Thus, in the case of amorphous substances with a molecular structure, success in the understanding of the polymorphic modes of the amorphous state was achieved by considering these modes as the corresponding prototypes of the mesophases in the liquid crystal state.[113] The classification of the amorphous phases made it possible to discuss immediately specific structural models of the substance. In the case of disperse silicas, such a classification guide proved to be the technology of the preparation of the products and the classification parameters were the dimensionality and multiplicity of the structures formed on packing the silicon–oxygen tetrahedra. The structural classification modes established made it possible not only to take a new look at various representatives of the substance considered, but also to propose a fairly unambiguous algorithm for the modelling of the corresponding structures.

Another indication of the fruitfulness of the terminology introduced here is the possibility of extending it to the entire class of nanomaterials to which the silicas presented above belong. A characteristic feature of these substances is the considerable contribution of surfaces and interfaces to their structure. This factor renders, in its turn, the nanomaterials exceptionally sensitive to the technology of their preparation and to the conditions under which they are kept. As is well known to technologists, because of this the chemical formula of the substance in reality describes a whole family of nanoproducts. The situation frequently arises where the investigator of the fundamental effects in such materials is extremely concerned by the 'dirt' on the surface of the specimen. However, this 'dirt' on the surface and on the interfaces of the nanomaterials obeys strictly the laws of chemical interaction and can be identified or predicted with the aid of a combined study of the same technological polymorphism. This approach has been applied successfully, for example, in the case of the family of silicon nitride powders of different origin.[101] Particular attention should be drawn to the fact that in this combined approach quantum-chemical modelling is converted into an active computational procedure and acquires the importance of an analysing instrument. This is particularly important in connection with the gradual onset of the era of nanotechnology, which brings our accustomed material world to the level of practical manipulation of atoms.

Abstract. This review is part of a continuing study of the many applications of van der Waals radii (WR) in various fields of chemistry, and especially in crystal chemistry and stereochemistry. An analysis of relevant publications has shown that WR systems are used most often and most successfully in studies of the conformation of molecules, though their original source is usually an analysis of intermolecular contacts. This review will deal with traditional applications of WR and with some new aspects, including the geometrical modelling of chemical reactions and new types of specific intermolecular interactions. The bibliography includes 149 references.

I. Introduction

Our previous review of the application of van der Waals radii in chemistry, published[1] in 1989, dealt with information published between the mid-1930s and 1988. However, for a number of reasons several interesting publications (especially those published in the second half of 1987, when our review had been completed) failed to be included. In recent years the flow of information on the application of WR has grown steadily, and the areas of application have also increased. Because of its universality, simplicity, and objectiveness the WR method is convenient for rapid qualitative estimates, and it is often used in the final solution of many problems of practical importance, though (as we have already pointed out) the detailed features of crystal structures are more satisfactorily identified and explained by using concepts such as molecular orbitals, energy calculations, and atom–atom potentials.

These omissions compelled us to extend our critical analysis of the use of WR radii in chemistry, and resulted in the publication of the present review. But even now we cannot be certain that our review is exhaustive, in spite of the very large volume of information which we have assembled and presented. The theme of this review differs substantially from that of our earlier review.[1] Firstly, the section entitled 'Conformations of molecules' has been enlarged significantly, in keeping with the increasing amount of space devoted to the structure of the molecules (as opposed to the description of the molecular packing in the crystals) and to the effect of the molecular structure on the reactivity of compounds. Secondly, the present review introduces new methods of using the WR, and identifies situations not previously discussed which show, in particular, that steric effects can not only stretch the valence bonds but also initiate bond shortening, and that in some parts of the molecule these effects produce an enforced approach of atoms not joined by a valence bond in other parts of the same molecule, leading (under favourable conditions) to the formation of a valence bond. Thirdly, some already traditional methods of using the WR and the results of their application, which had not been adequately dealt with in Ref. 1, are discussed more fully: these include the geometric modelling of chemical reactions, new types of specific interaction, some new types of hydrogen bond, etc. Because of the very large (and continuously growing) number of studies in which WR are used we cannot claim that the whole of this information has been assimilated into this review. To some extent our choice has been arbitrary, but we have at all times endeavoured to make the choice balanced and representative of the methodological aspects of the problem (by the correct use of the optimum WR values). This task could be adequately satisfied by examining in the first instance the work of Russian workers. It should be noted that successful applications of the WR are more often found in studies carried out in this country than in reports from foreign workers. This is not fortuitous: the science of organic crystal chemistry (and its associated field, the concept of WR) were created largely by the work of Kitaigorodskii in this country).

The WR are most often used to detect contracted (or shortened) contacts between atoms which are not covalently bound. These contacts can be intermolecular or intramolecular. A correct choice of the reference point is important in the determination of the shortening. If the length of the contact (whether taken as the sum of the WR or as twice the geometric mean, $2\sqrt{R_i R_j}$) is close to this point the choice of the value from which the difference is calculated assumes an even greater importance. In our work the most probable length of the reference contacts between different atoms (by using the statistically averaged WR values, see below) was determined by giving priority to the doubled geometric mean. Nevertheless in our presentation of published material we quote (following the appropriate authors) a comparison of the length of the atom–atom contacts with the sum of the WR. On the whole no serious discrepancies were found, because the quantities $2\sqrt{R_i R_j}$ and

Note. $2\sqrt{R_iR_j}$ is the mean length of the normal van der Waals contact; d_{ij} is the boundary between the shortened (by van der Waals interaction) and the contracted contacts, or in other words between the ordinary van der Waals interactions and the specific interactions.
[a] See Section II.

$R_i + R_j$ do not usually differ very markedly. We should note that the term bearing contact refers to interatomic molecule–molecule contacts whose existence is a necessary and sufficient condition for the creation of a three-dimensional system of contacting molecules in the crystal.

There is a group of WR systems for which the difference between the members is determined both by the chosen set of structural data and by the procedure used to define the WR. They were analysed in Refs 1 and 2. However, we should stress once again that in many cases the procedures used by some authors were not followed strictly, or they were approximated to an unacceptable degree, and that occasionally a single standard structure was used to determine the radius, thus invalidating the statistical nature of the WR. An important constituent of each system should be not only the averaged WR values but also a clear statement of the 'normal' van der Waals contact limits. This is because the length of the intermolecular contacts formed by the van der Waals interaction depends on many factors: the size of the molecules, their mutual orientation, the distribution of effective atomic charges, etc. These limits were first stated for contacts involving the H, C, N, O, and Cl atoms (see Ref. 3). The statistically averaged values for these atoms [H (1.16 Å), C (1.71 Å), N (1.50 Å), O (1.29 Å), and Cl (1.90 Å), see Ref. 3], were later supplemented with statistically averaged WR values for the sulfur (1.84 Å),[4] fluorine (1.40 Å),[5] bromine (1.97 Å), and iodine atoms (2.14 Å) (see Ref. 6). In the same study[6] the value for chlorine was redetermined by a different method, and was again found to be 1.90 Å. This is the only system of statistically averaged WR values which quotes the maximum deviations (δ) of the length of van der Waals reference contacts from their average values. For the contacts not involving hydrogen atoms $\delta \leqslant 0.15$ Å, whereas for the contacts involving hydrogen atoms $\delta \leqslant 0.30$ Å.

In this review (as in the previous one[1]) we shall use the terms 'contracted' and 'shortened' contacts. A shortened contact is shorter than the statistically average value for the van der Waals interaction, but does not go beyond the limit

$$d = 2\sqrt{R_iR_j} - \delta, \qquad \text{or} \qquad d = R_i + R_j - \delta,$$

or in other words, it can be defined as a contact of length r_{ij} for which

$$d < r_{ij} < d + \delta.$$

If $r_{ij} < d$ the intermolecular contacts are referred to as contracted.

In our analysis of the length of atom – atom contacts we shall use the parameters listed in Table 1.

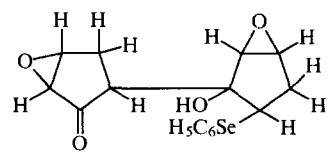
In some of the studies examined in this review the noncovalent contacts between silicon and other atoms are discussed. Because of the lack of statistically averaged WR values for silicon in these Si···X contacts we compare them in our discussion with tentative values of the sum of the WR for the corresponding atoms. We take the van der Waals radius of silicon atom to be $\sim 2.1 \pm 0.1$ Å, because the WR of nonmetal atoms of the third period is $\sim 0.4 - 0.5$ Å greater than the WR of the corresponding atoms in the second period, and the WR of the carbon atom is 1.71 Å.

The WR system closest to the system of statistically averaged WR values[3–6] is the Pauling system,[7] except for the radii of oxygen and chlorine. The Pauling system is a system of rounded-off ionic radii (except for the Group V elements), which could be identified (according to Pauling) with the van der Waals radii. Pauling lowered the rounded-off values of the ionic radii of the Group V elements by 0.2 Å. We believe that when statistically averaged values of the WR are not available the best procedure is to adopt the values proposed by Pauling.

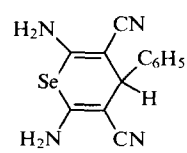
Descriptions of structures which are pierced by weak or very weak 'hydrogen bonds' of the X–H···Y type are often met in recent publications. In many of these 'H-bonds' the H···Y distance is equal to or even greater than (by a large amount in some cases) the average length of the normal van der Waals contact. Wherever hydrogen atoms exist these 'contacts' can be found with great ease. In the present review we shall be concerned only with H-bonds which form real associations of molecules, as indicated (when appropriate measurements are carried out) by the physical properties of the crystals.

II. Normal intermolecular contacts

In studies of a new substance, if a comparison of the shortest intermolecular (atom–atom) distances with the sum of the WR or with the parameters $2\sqrt{R_iR_j}$ in conjunction with data on the dispersion of the length of the reference contacts gives the expected molecular packing in the crystals we may call the intermolecular interactions 'normal'. This concept can be formulated in different ways: (1) the intermolecular contacts are similar to the normal contacts; (2) the structure consists of a packing of discrete molecules connected by van der Waals contacts; (3) in the structure the intermolecular contacts correspond to van der Waals interactions, etc. (see, for example, Refs 8–15).



Among the normal intermolecular contacts recognised in the past few years special attention should be paid to the O···O contacts without a hydrogen bond, 2.58, 2.62, 2.68, and 2.72 Å long in different organic crystals.[16] These contacts are among the shortest intermolecular contacts of this type, and are close to twice the statistically averaged value of the oxygen WR (2.58 Å). The latter observation is also of interest, because the 1.29 Å value[3] for the oxygen atom, which 'works' well in intermolecular contacts between oxygen and other atoms, usually involving interactions between atoms with large residual charges of the same sign, appears too low in O···O contacts. This problem has been examined in depth in previous reviews.[1,2]



A broader concept of the structure of a van der Waals crystal in terms of the WR is obtained by determining the molecular coordination number (MCN), which is often a useful characteristic of the packing of the molecules in the crystal. In homomolecular crystals a continuous series of MCN between 9 and 18 was reported,[17] the number 9 being found only once (in the pyrene structure), and 18 also only once [in the structure of dichlorobis(vinylbenzotriazole)cobalt(II)].[18] The most widely found MCN are 14 and 12 (in ~50% and ~30% of cases respectively).[17,19] An analysis of the intermolecular contacts in the structure of molybdenum(IV) dioxobispropiohydroxamate, based on the rules laid out in Ref. 17, showed that the MCN for this complex is 8 (see Ref. 20). Thus the MCN series in homomolecular crystals has now been extended slightly and covers the range from 8 to 18.

In order to obtain a more complex picture of the structure of a van der Waals crystal, and to identify the molecules which are most strongly bound and form various types of association (dimers, chains, layers), the geometrical analysis must be supplemented by energy calculations, since the energies of the van der Waals interactions even in the first coordination sphere can be markedly different (in some cases by a large factor).[21] According to a calculation of the intermolecular interaction energies the molecules in a crystal of nickel(II) bis-[4-(n-heptyloxy-*N*-(4′-methoxyphenyl)benzaldimino-2-olate] form layers parallel to the (100) plane; the energy within the layer (54.3 kcal mol^{-1}) exceeds the interlayer energy (11.2 kcal mol^{-1}) about 5-fold.[22] In spite of the well known difficulties associated with the calculation of effective charges on atoms (resulting from the need to reconcile the methods of calculating the different components of the overall energy of the molecular crystal †) the intermolecular interaction energies should be calculated allowing for the electrostatic component, which can have a substantial influence on the total (overall) interaction energy of the molecules.[21]

The role of the steric factor is most clearly seen in the packing of molecules of the fluorine derivatives of *p*-methoxybenzylidene-*p*′-butylaniline in crystals. Combining the WR with an energy calculation showed that the replacement of hydrogen atoms (WR 1.16 Å) by fluorine atoms (WR 1.40 Å) in the $F_3C-C_6H_4-CH=N-C_6H_4-C_4F_9$ molecule increases the volume of the two end substituents, making the packing arrangements which are standard in liquid-crystalline phases seriously unfavourable.[23]

The identification by WR of the unreal (extremely contracted) intermolecular contacts was used in an unexpected way to establish the real structure of partially disordered crystals. The first studies of this type were reported in our previous review.[1] Their further development (for example, in Refs 24 and 25) will be considered here. The fundamental idea of these studies is that by using the WR we can reveal the unreality of the statistical structure given by X-ray structural analysis, in which the benzene rings are located (with assumed equal probabilities) in two mutually perpendicular positions, and in which the true structure of the crystral (domains or layer block) is thus established almost unequivocally.[24] Thus, crystals of the selenium compounds $C_{16}H_{16}O_4Se$ and $C_{13}H_{10}N_4Se$ consist of fully ordered layers each of which displays one of the two possible methods (*a* or *b*) of accommodating the benzene rings which form the core of the layer and are packed (in both cases) in a parquet floor pattern, so that rings having both a primary and a secondary orientation are matched in a well defined way. The surface of the layer, and therefore also the method of superposing the layers, remain unchanged. This creates the possibility of obtaining a special kind of polytype: (1) the crystal consists of *a* layers: (2) the crystal consists of *b* layers; (3) the crystal consists of a random (or a regular) alternation of *a* and *b* layers. The latter situation is seen in these compounds, in which blocks of *a* layers alternate with blocks of *b* layers.

A similar result was obtained for the crystal structure of 3-bromobicyclo{3.3.1}non-2-en-4-one. According to X-ray structural analysis data[25] the oxygen atoms in these crystals are accommodated randomly in two positions (with populations of 2/3 and 1/3 respectively). This means that the substance contains L and D enantiomers, but (as was pointed out[25]) these cannot have a random distribution because it would lead to unrealistic intermolecular contacts. By using the WR and calculating the intermolecular interaction energy it was shown[26] that the crystal most probably consists of an assembly of domains of two types: (1) racemic [L, D] domains, containing equal amounts of the L and D enantiomers, and (2) [L] (or [D]) domains, consisting of L (or D) enantiomers. A domain structure of the [L], [D] type, in which each domain contains only enantiomers of one type, must of course be excluded.

In addition to the above comments many examples of the use of WR to identify the normal intermolecular contacts in problems of structural biology and to interpret the physicochemical properties of substances are discussed in our previous review[1] and in Section V of the present review.

III. Contracted intermolecular contacts

Contracted intermolecular contacts usually denote the presence of specific interactions (SI), which are much stronger than ordinary van der Waals interactions. Specific interactions are of the attractive type, and they have a marked effect on the structure and properties of molecular crystals. Unlike contracted intermolecular contacts, contracted intramolecular contacts are only seldom associated with attractive interactions, and they are much more frequently the result of steric stress. In the present review we shall examine, in addition to the types of SI previously discussed, other types of SI not considered in Ref. 1.

† See the review by T V Timofeeva et al. in *Uspekhi Khimii* **49** 966 (1980) [*Russ Chem. Rev.* **49** 509 (1980)]

The validity of the conclusions on the contraction of intermolecular contacts and on SI of the O···X type can be tested by using 1.29 Å as the WR of oxygen (i.e. the value recommended by the present writers[3]): this value is substantially lower than the values proposed by other workers. Its use has allowed the SI to be identified in the packing of 2-bromo-1,4,8-trinitro-6(5H)-phenanthridinone molecules.[27] In this case we have the Br···O contact 2.967 Å long (for an average length of the normal contact of 3.19 Å and a lower limit d of the normal van der Waals interaction for these atoms of 3.04 Å). The C–Br···O angle (171.1°) probably denotes the direction of the SI.[27]

The contracted intermolecular contacts, which indicate the presence of SI, justify the conclusion that molecular associations of various types are present in the various structures. Thus, in the crystal structure of 4-methylbenz-2,1,3-thiadiazolecopper(I) iodide a strongly contracted N···S intermolecular contact (3.01 Å) has been detected,[28] whereas the length of the normal contact between these atoms is 3.32 Å, and $d = 3.17$ Å.[29] In this structure we have chains of molecules connected by pairs of antiparallel contracted intermolecular contacts of this type.

Among the crystal structures studied in recent years we again find structures with strongly contracted Cl···Cl intermolecular contacts. They include the 1,3-dichloro-2,2,4,4-tetrachlorodiphosphethane structure,[30] with contracted (3.311 Å) Cl···Cl intermolecular contacts, and the *O*-carbamoylacetohydroximoyl chloride structure with contracted Cl···Cl intermolecular contacts 3.333 Å long, which is much less than double the WR of chlorine (3.800 Å). These contacts lie at the very beginning of an almost continuous series of contracted Cl···Cl intermolecular contacts, beginning with 3.26 Å. In a crystal of the dichloroneopentylglycollic ester of 3,4-dichloro-1,3-butadiene-2-chloro-2-butene-2-phosphonic acid we can distinguish chains of molecules which contain contracted (3.386 Å) Cl···Cl contacts,[32] and in the structure of the dichloroneopentylglycollic ester of 1,3,4-trichloro-2-butene-2-phosphonic acid the contracted Cl···Cl intermolecular bonds (3.408, 3.540, and 3.550 Å) are said[32] to be retained in the structure of the corresponding polymer, thus creating bonds between the units of one polymer chain or of neighbouring polymer chains.

A recent paper from our laboratory[33] describes an extension of an earlier study[34–36] of the geometric aspects of halogen···halogen intermolecular contacts in organic crystals. A statistical analysis of the geometric characteristics of 330 Cl···Cl intermolecular contacts in organic crystals without hydrogen bonds was carried out. The contacts were divided into four groups: strongly contracted in comparison with double the WR of chlorine, weakly contracted, normal, and stretched.

Occasionally contracted Cl···Cl intermolecular contacts can coexist with hydrogen bonds. In this case the Cl···Cl contacts and the hydrogen bonds jointly give rise to complex associations of molecules. In crystals of the Graw salt $[Pt(NH_3)_4Cl_2]Cl_2$ the $Pt(NH_3)_4Cl_2$ complexes are combined into infinite columns arranged on the tetrad symmetry axis[37] through the axial chlorine atoms, which form contracted Cl···Cl intermolecular contacts 3.54 Å long. the N–H···Cl hydrogen bonds (N···Cl 3.44, N–H 0.9, H···Cl 2.47 Å, NHCl angle 172.6°) connect the columns into a framework through the bridging chlorine atoms. We have discussed[38] the topology of the chlorine derivatives of phenol containing cooperative hydrogen bond systems (CHBS). Three examples of the association of molecules of this type with contracted intermolecular contacts shorter than 3.5 Å were given. In the pentachlorophenol structure the chains containing helical CHBS are connected into a framework by Cl···Cl contacts 3.43, 3.46, 3.48, and 3.54 Å long. The shortest contracted Cl···Cl intermolecular contacts in these structures (3.27 Å) are observed in the 3,4-dichlorophenol structure. There are also clusters containing four chlorine atoms each which are connected by Cl···Cl contacts 3.48 Å long. Paired and fourfold Cl···Cl contacts connect the chains of the CHBS into a framework. In the tetrachlorohydroquinone structure contracted Cl···Cl contacts (3.37 and 3.43 Å) connect the layers containing CHBS into a framework.

In the *p*-bromo-[*N'*-(5-nitrofurfurylidene)benzhydrazide] structure contracted Br···Br intermolecular contacts (3.381 Å)[39] are formed between the molecules of neighbouring chains (double the WR of bromine is 3.94 Å).[6] This contact denotes an intermolecular SI between the bromine atoms in the crystal, which hinders the packing of the ketohydrazone molecules into stacks by the 'head-to-tail' principle, as in crystals where the Br atom is replaced by H or by the SO_2CHF_2 group.

More than 150 symmetrically independent contracted S···S intermolecular contacts have been identified in crystals of cation-radical salts.[40–45] The cations of these salts are usually packed into stacks, often with formation of contracted S···S contacts, and the stacks into layers, often with formation of S···S contacts between the stacks. These contacts are now observed as commonly as the contracted halogen–halogen intermolecular contacts (except the F···F contacts, in which no SI exists).[5] Thus the most recent work has filled all the gaps in the series of S···S contacts from double the WR of sulfur (3.68 Å) to 3.27 Å (a contraction of 0.4 Å).[4]

In the crystals of organometallic compounds contracted intermolecular contacts involving metal atoms can be found. This problem is often very difficult to discuss, because no reliable WR for these atoms are available. For example, the WR values for the mercury atom quoted in the literature vary from 1.5 to 1.9 Å or more.[1] Nevertheless in some cases the presence of SI and of contracted intermolecular contacts in these crystals can be established unequivocally. In the structure of *Z*-1-methyl-2-chloromercury-2-phenylethenyl acetate Hg(B)···Cl(A) contacts (3.110 Å) are observed between the A and B molecules: these can undoubtedly be classified as contracted if the WR of mercury is taken as 1.50 Å and that of chlorine as 1.90 Å.[46] The presence of intermolecular SI in this contact is confirmed by the deviation from 180° of the bond angle C–Hg–Cl (171.2°) in the B molecule. In the A molecule the deviation of the bond angle C–Hg–Cl is smaller (177.4°), and the Hg(A)···Cl(B) contact is longer (3.326 Å), denoting a weaker attractive interaction in this contact. An Hg···Cl intermolecular contact shorter (3.082 Å) than those previously observed[46] was found in the dimethyl ester of *cis-exo*-3-chloromercuro-4-azidotricyclo-[4,2,2,$0^{2,5}$]dec-7-en-*cis-endo*-9,10-dicarboxylic acid.[47] In this molecule the Cl–Hg–C bond angle has fallen to 173.2°. In the structure of the monohydrate of the *N*-phthaloylglycinate of trimethyltin the SI between the tin atom and the oxygen atom of a water molecule (contracted Sn···O contacts of 2.385 Å and 2.520 Å for a tin WR of 2.122 Å[49] and an oxygen WR of 1.29 Å)[3] replaces the tetrahedral coordination of the Sn atoms by a distorted trigonal bipyramid.[48] The contract Sn···O intermolecular contact (2.385 Å) is the shortest of the contacts of this type known when the paper by Ovsetsina et al. was published.[48]

In the research on intermolecular SI a special place must be given to studies of hydrogen bonds, because their presence (or absence) in the structure is often postulated to account for the different methods of packing molecules in crystals, for some conformational properties of the molecules, and even some physicochemical properties of substances. We have previously discussed[1] the geometrical criteria of the H-bond, and in particular we have pointed out that conclusions based on geometrical criteria obtained from structural data and from IR spectral data are often inconsistent. Therefore the criteria for the existence of hydrogen bonds are still an active topic of discussions (see, for example, Refs 50 and 51).

In this context we shall discuss only the relatively short hydrogen bonds which have a marked effect on the methods of packing molecules in crystals or on their physicochemical properties. From the very large number of new methods of using WR to describe H-associations of molecules we shall choose only examples which unambiguously characterise the different types of associations.

Crystals of 1-(2-methylphenyl)-3-methyl-5-(benzothiazol-2-yl)formazane contain A and B conformers (the contact conformation phenomenon).[52] In this structure two intermolecular H-bonds of the N–H···N type have been detected: N···N 2.910, N–H 0.89, H···N 2.08 Å, NHN 155°, and N···N 2.991, N–H 0.85, H···N 2.16 Å, NHN 165° (for d=2.34 Å), which combine the A and B molecules into dimers.‡ As a result of the presence of N–H···O bonds (N···O 3.00, N–H 1.05, H···O 2.01 Å, NHO 155° for d=2.15 Å) the molecules in the $C_{39}H_{56}N_2OBP$ crystal (see Litvinov and Naumov[53]) form centrosymmetrical dimers. In the α-diphenylphosphoryl-*o*-cresol crystal the molecules are connected into 16-member dimeric associations by pairs of P=O···H–O bonds in which the O···H distances are 1.81 Å,[54] and in the β-diphenylphosphorylethyl alcohol crystal three independent molecules are connected into an overall chain by P=O···H–O bonds (H···O distances 1.80, 1.84, and 1.86 Å).[54] Because of the presence of N–H···N bonds (N···N 2.828, N–H 0.94, H···N 1.96 Å for d=2.34 Å, NHN 165°) the molecules of 3,5-dichloro-1*H*-1,2,4-triazole form strong rings of three molecules arranged round the six-fold inversion axis of the crystal. Contracted N···Cl intermolecular contacts (3.149 Å for a sum of the WR of nitrogen and chlorine of 3.40 Å)[3] connect these rings into layers.[55] The existence of these layers, i.e. the fact that the most strongly bound molecules are combined, is confirmed by the anisotropy of the thermal deformation of these crystals (see Section V).

In the structure of *N*-(3-nitrocinnamoyl)-*N*-(2-chlorophenyl)-hydroxylamine a system of H-bonds often seen in hydroxamic acids has been detected: it includes two crystallographically independent O–H···O bonds (O···O 2.617, O–H 0.99, H···O 1.63 Å, OHO 176°, and O···O 2.634, O–H 0.81, H···O 1.82 Å, OHO 179°).[56] These hydrogen bonds connect the molecules into chains. O–H···Cl hydrogen bonds (O···Cl 3.00, O–H 1.04, H···Cl 2.02 Å for d=2.67 Å, OHCl 155°, and O···Cl 3.00, O–H 1.16, H···Cl 1.88 Å, OHCl 158°) were found in the complex anion $[2Cl^- + H_5O_2^+]^-$ of the $(BT)_2 \cdot 2Cl \cdot H_5O_2$ structure, where BT is bis-(butylenedithio)tetrathiafulvalene.[57] In the hydroxonium ion $H_5O_2^+$ a symmetrical O–H···O bond is formed (O···O 2.475, H···O 1.24 Å, OHO 168.1°). The hydroxonium ions are arranged on the diad symmetry axis and are interconnected through bridging Cl^- ions into an infinite chain by O–H···Cl hydrogen bonds.

A slightly different behaviour is observed in the cation···anion contacts of complex ions consisting of twenty or more atoms over which an excess of charge is distributed. In these contacts the distance between the X and Y atoms is not necessarily shorter than the average normal van der Waals contact. In the 1,2-dimethylacenaphthylene-1,2-*S*-phenylepisulfonium tetrachloroaluminate structure the $C_{20}H_{17}S^+$ cations and the $AlCl_4^-$ anions are grouped into stacks arranged in a checkerboard pattern, and the S···Cl contacts are found to be longer than the sum of the WR for sulfur and chlorine (3.74 Å).[58] The cation···anion contacts are occasionally shortened within limits acceptable for van der Waals interactions: for example, the S–Cl contacts of 3.602 and 3.691 Å,[40] 3.635 Å (see Ref. 59), and 3.65 Å[60] (for a sum of WR of 3.74 Å). However, in cation-radical salts we also find contracted cation···anion contacts, including strongly contracted contacts. Thus, a group of strongly contracted S···Cl cation···anion contacts forming in almost continuous series from 3.25 to 3.49 Å has been observed[40,42,59,60,61] in cation–radical salts (d=3.59 Å). In the $(ET)_3(ZnCl_4)_2$ structure, where ET is bis(ethylenedithio)tetrathiafulvalene, the strongly contracted S···Cl contacts of 3.253, 3.261, 3.295, 3.367, 3.371, and 3.424 Å have been observed,[60] in $(ET)_3Cl_2 \cdot 2H_2O$ the 3.328, 3.434, and 3.485 Å contacts,[61] in $(ET)_4ZnCl_4 \cdot C_6H_5CN$ the 3.356 and 3.488 Å contacts,[40] in $(ET)_4PtCl_6 \cdot C_6H_5CN$ the 3.410, 3.433, and 3.474 Å contacts[59] at T=293 K and 3.404 and 3.413 Å at T=218 K, and in the $(ET)_3CuCl_4 \cdot H_2O$ structure the 3.372 Å contact.[42]

Contracted S···Br cation···anion contacts of 3.536 and 3.614 Å,[45] and also of 3.625 and 3.638 Å (d=3.66 Å)[62] were found in the $(ET)_4PtBr_6$ and $BT \cdot IBr_2$ structures respectively.

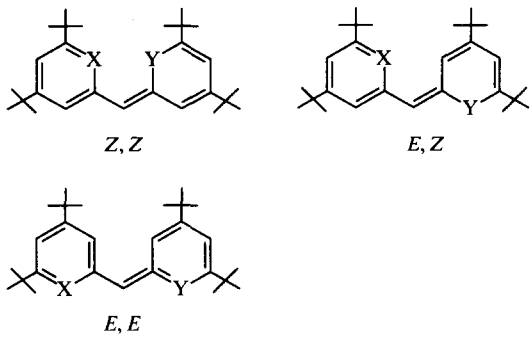
As reported,[60] in $(ET)_3(ZnCl_4)_2$ the presence of a series of strongly contracted S···Cl contacts (see above) and also of a strongly contracted C···Cl contact (3.34 Å, d=3.45 Å)[60] can account for the nonequivalence in the $(ZnCl_4)_2^{4-}$ dianion of both the bond angles (from 105.9° and 115.6°) and the Zn–Cl distances (from 2.258 to 2.305 Å). We should stress the fact that these anomalies are produced not by internal steric stresses, which will be discussed in the next section, but by strong attractive external interactions. Similar phenomena were discovered in crystals of chlorine trifluoride at −100 °C (see Antipin et al.[63]) and of bromine trifluoride at −120 °C.[64] In the ClF_3 structure Cl···F contacts were found at 2.706 and 2.740 Å, shortened as compared with the normal Cl···F van der Waals contact (3.26 Å) by 0.52–0.55 Å but causing an extension of the Cl–F bridging bonds of 0.03–0.05 Å with respect to the axial bonds and of 0.16 Å with respect to the equatorial. In the BrF_3 structure we find Br···F contacts (2.45 Å) shortened by 0.87 Å with respect to a normal contact (3.32 Å) and extending the Br–F bridging bonds by 0.11 Å with respect to the axial and by 0.18 Å with respect to the equatorial Br–F bonds. Judging by the size of the contacts the stronger intermolecular SI in BrF_3 as compared with ClF_3 is responsible for the more substantial extension of the bridging bond in the former. By means of the SI mentioned above the molecules in crystals of ClF_3 form centrosymmetric cyclic tetramers, and in BrF_3 crystals they form chains. The strongly contracted B···F intermolecular contacts (2.663–2.705 Å) previously observed[65] in the BF_3 structure at 145 °C interconnect the molecules into infinite layers.

The above examples show that fluorine atoms tend to undergo strong attractive interactions with many other atoms (B, Cl, Br, and others). An example of the F···S intramolecular specific interaction is given below. However, as has already been pointed out, fluorine does not produce contracted F···F intermolecular contacts, and therefore specific F···F interactions are atypical.[5]

These effects of intermolecular SI on covalent bonds are well known in the case of intermolecular hydrogen bonds, and in particular of O–H···O symmetrical H-bonds.

A complex system of three types of SI has been observed[66] in 1,2-dimethyl-4-amino-5-ethoxymethylpyrimidinium iodide. In these crystals the cations are connected into dimers by pairs of antiparallel N–H···N hydrogen bonds (N···N 3.10, H···N 2.32 Å for d=2.34 Å, NHN 155.8°) The bridging $I^-(2)$ anions, which occupy individual positions at the inversion centres, form strong N–H···I H-bonds (N···I 3.66, H···I 2.58 Å for d=2.84 Å, NHN 156.6°) which connect the dimers in the direction of the a axis. The bridging $I^-(1)$ anions, which occupy individual positions on the 2 axes, interconnect the dimers in the direction of the b axis as a result of I···C specific interactions (3.573 Å for d=3.67 Å and a sum of WR of the iodine and carbon atoms of 3.85 Å). The resulting corrugated layers create the crystal structure by superimposing in the direction of the c axis in response to the van der Waals interaction.

IV. Conformations of molecules



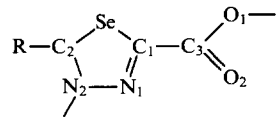
The classical conformational analysis[67–69] has recently undergone some far-reaching developments, and is now usually called 'molecular mechanics'.[70] It is based on the postulate that the conformation of a molecule is a compromise between the tendency for covalent bonds and bond angles to optimise their value (in the additive approximation corresponding to a minimum energy) and the tendency to minimise the resulting

‡ Here and elsewhere we shall use the term H-bond to denote the d value of the H···Y contact.

steric stresses, which create a repulsion between excessively close atoms which are not covalently bound and make a positive contribution to the energy of the molecule; at the same time the fragments of the molecule can rotate round ordinary bonds and thus lower the energy of the non-covalent interactions.

This model relies on the use of isotropic atom–atom potentials and, for approximate calculations based on the same idealogy, it can call upon the WR system. However, in practice isotropic atom–atom potentials are often inadequate. This situation is very well seen, for example, in the presence of both intermolecular and intramolecular SI. Intermolecular SI have been discussed in the previous section. Here we shall be concerned with intramolecular SI, and we shall examine some examples of their effect on the conformation of molecules.

The cation of 4,6,4′,6′,tetra-*tert*-butyl-substituted thiopyrylo-2-monomethenecyanine perchlorate adopts a *Z,Z* conformation.[71,72]



Under these conditions we find a strongly contracted S···S intramolecular contact (ClC) of 3.1 Å (taking 3.68 Å as double the WR of the sulfur atom). Obviously, this close approach of the sulfur atoms is due to their attractive interaction, which exceeds the repulsion between the residual charges of the same sign (+0.053 electronic units).[72] A closer approach is also favoured by the tendency towards conjugation in the carbon skeleton of the cations and symmetrical localisation of the ClO_4^- anions in the cavities between the heterocyclic rings. The stress in the cation is revealed by the increase (to 133.8° as compared with the ideal value of 120°) of the bond angle at the carbon atom which connects the heterocycles, and also by the increase to 122.1° in the exocyclic SCC and S′C′C angles (see Tolmachev et al.[71]).

An even shorter intramolecular S···S contact of 2.960 Å (i.e. a shortening of 0.72 Å) has been found in *Z*-4-methyltetrafluoroethyl-2-(tetrafluorothioacetylmethylene)-2*H*-thiopyran.[73] The sulfur atom lies in the plane of the thiopyran ring on the extension of the C–S bond of this ring; the CS···S angle is 174.7°. As reported,[73] this geometry of the –S···S= fragment is the most favourable to the formation of a CIC. As was pointed out above, SI of the S···S type are often met in intermolecular contacts: as we have seen, they are quite common also within molecules.

Replacing one of the sulfur atoms by oxygen in the cation studied by Tolmachev et al.[71] also produces a *Z,Z* configuration.[72] This creates a contracted intramolecular S···O contact of 2.74 Å ($2\sqrt{R_S R_O}$ = 3.08 Å, $\Delta r = r - 2\sqrt{R_S R_O}$ = −0.34 Å). The spatially unfavourable *Z,Z* conformation of this dye can be stabilised by the electrostatic attraction between the oppositely charged oxygen (−0.147) and sulfur atoms (+0.063). Furthermore, according to Sereda et al.[72] the length of the S···O contact (2.74 Å) allows specific interaction due to electronic factors which also stabilises the *Z,Z* conformation. A similar effect has been observed in the cyclohexane fragment 2,8-disulfonate-5,7-bis(dimethylsulfonium)bicyclo-[4,2,0]-oct-3-ene,[74] in which we find a *cis* configuration of the substituents stabilised by the CIC of the S′ atom with the oxygen of the sulfonate group; the S′···O distance is 2.854 Å.

Attractive interaction of nitrogen and oxygen atoms has been detected in one of the *O*-tosylhydroxylamines.[75] This interaction produces a strongly contracted intramolecular contact of 2.526 Å (as compared with the sum of WR of nitrogen and oxygen atoms of 2.79 Å). The attractive nature of the interaction of the nitrogen and oxygen atoms in this contact was confirmed by an analysis of the bond angles in the molecule. In 3,4-difluoro-8-*exo*-fluoro-12-*syn*-(2′-nitrophenylthio)-tetracyclo-[4.4.0.1^{2,5}.1^{7,10}]-dodec-3-ene the S···F distance (2.942 Å) was shorter[76] by 0.27 Å than the normal noncovalent S···F contact[5] of 3.21 Å. This shows that specific attractive interaction can exist between sulfur and fluorine atoms.[76]

Various examples in which the CIC denote conjugation of the bonds in various fragments of the molecule were quoted in our previous review.[1] Similar observations were made in more recent X-ray structural studies. Thus, in the 2-(*p*-ethoxybenzylidene)-3-phenyl-5-ethoxycarbonyl-1,3,4-selenadiazoline molecule[77]

in spite of the short Se···O distance (2.87 Å) as compared with the sum of the WR, the $C_1C_3O_1O_2$ plane makes an angle of 5° with the $SeC_1N_1C_2$ plane (the $N_1C_1C_3O_2$ torsion angle is −6°). This suggests[77] the presence of conjugation in the $N_1=C_1-C_3=O_2$ system. Similar examples are given in papers[71,72] on the structure of monomethinecyanines.

By analogy with the halogen···halogen contacts, in which the SI increase from chlorine to iodine, it may be assumed that similar effects take place in a contact between Group VI atoms and that the shortened Se···Se contacts denote the presence of SI in these materials. An analysis[78] of the complex bis-(1-isopropyl-3-methyl-4-cyclohexylaldimino-5-selenopyrazolato)nickel(II) supports this assumption. For steric reasons the *cis* compression of the NiN_2Se_2 observed in this complex is less favourable than the *trans* compression. The evidence for this conclusion is the intramolecular Se···Se′ distance (3.667 Å), which is less than double the WR of selenium (4.00 Å).[7] Nevertheless a *cis*-compressed NiN_2Se_2 tetrahedron is observed: as suggested,[78] this effect may be attributed to a Se···Se′ attractive interaction between not covalently bound atoms.

Specific interactions identified by using WR in crystals containing the cluster groups $M_3X_7^{4+}$ and $M_3X_4^{4+}$ (M = Mo, W; X = O, S, Se) are discussed in a recent paper.[79] It was noted that the $M_3X_7^{4+}$ derivatives form interionic contacts substantially shorter than the sum of the van der Waals or ionic radii of the X atoms, which occupy axial positions with respect to the M_3 plane, and the nitrogen, chalcogen, or halogen atoms of the counter ion or of the ion of the same sign. In some derivatives of $M_3X_4^{4+}$ these workers observed the formation of centrosymmetric dimers with the participation of (μ_2-X_2) ligands, in which the X···X distances were also markedly lower than the sum of the WR. These SI are often realised in spite of the coulombic repulsion between particles carrying charges of the same sign. These workers[79] consider that the criterion of the sum of WR[3,4,6] is also applicable to ionic radii in calculations of the degree of 'shortening' of a noncovalent contact.

In the crystal structure of 3-methyl-2-azoniafluorene tetrachloroaurate(III) a short Au···Cl distance (3.510 Å) was detected (for a sum of WR of 4.1 Å), corresponding to a noncovalent contact.[80] Allowing for this contact we can consider the coordination of the gold atom to be tetragonal–pyramidal.

The conformation of the molecules can also be strongly influenced by hydrogen bonds. We shall choose some examples from recently published work in which the presence of contracted intramolecular contacts is confirmed by the presence of an intramolecular H-bond. In the structure of diaqua-bis(nitroaminoguanidine)nickel(II) perchlorate stable N–H···O hydrogen bonds have been observed within the cations between the oxygen atoms of the nitro groups and the coordinated amino

groups; these bonds have N···O distances of 2.56–2.68 Å.[81] In the central fragment of the *N,N'*-di-(2,2,6,6-tetramethyl-1-oxyl-4-piperidyl)-*N*-diethylphosphorylurea molecule[82] we find a six-membered ring (···HNCNPO···) formed by an intramolecular H···O hydrogen bond 1.96 Å long (the Zefirov criterion[83] is $d_{O\cdots H} < 2.1$ Å). This hydrogen bond is retained in solution at moderately high temperatures, as shown by the IR spectrum of the substance.[82] A geometrical modelling of the reaction of ammonia with perfluoro-2-methyl-2-pentene-3-thiocyanate showed that in one of the intermediate products of this reaction (the carbanion A^1) an N–H···F intramolecular hydrogen bond is formed (H···F 1.71 Å for $d_{H\cdots F} = 2.2$ Å,[5] N···F 2.59 Å, NHF 141°).[84]

There can be no doubt (according to the geometrical criteria established for intermolecular hydrogen bonds) that an unusual intramolecular O–H···P H-bond is present in the ···PC=CBOH··· six-membered ring of the $C_{39}H_{56}N_2OBP$ structure (see Ref. 53). In this molecule the OH group has a short contact with the phosphorus atom (O···P 3.103, O–H 0.93, H···P 2.30 Å, OHP 145°). As reported,[53] this contact can be taken as a proof of the formation of an intramolecular O–H···P hydrogen bond, since the quoted distances correspond to the H-bond criterion (sum of the WR of the phosphorus and oxygen atoms 3.3, of the phosphorus and hydrogen atoms 3.0 Å),[7] and furthermore the OH group is positioned in the direction of the phosphorus atom. However, in the IR spectrum of this compound the stretching vibrations band of the OH group (3560 cm^{-1}) is not significantly shifted and is not broadened.[53] Therefore the existence of an O–H···P hydrogen bond in this compound remains an open problem.[53] Doubts have also been expressed concerning the presence of an N–H···N H-bond in the thiosemicarbazone of methylglyoxal.[85] In the five-membered $\cdots N_2N_1CN_3H_2\cdots$ ring of this molecule the presence of an $N_3\cdots N_2$ CIC of 2.637 Å suggests an intramolecular hydrogen bond. However, the $N_3H_2N_2$ angle of 104.9° is said by these workers to be 'unfavourable to bonding'.

Unusual C–H···F–C intramolecular hydrogen bonds have been reported[86] in *exo-cis*-2,3-dichloro-5,5-dicyano-6,6-bis(trifluoromethyl)-norbornane. This structure contains two intramolecular H···F contacts (2.16 and 2.30 Å) which are markedly shorter than the sum of the WR of the hydrogen and fluorine atoms (2.56 Å). One of these contacts is less than 2.2 Å long (the parameter corresponding to the criterion of 'guaranteed' existence of an F···H hydrogen bond).[5] These workers have suggested[86] that the short C–H···F–C contacts in this substance "should probably be interpreted as intramolecular H-bonds". A similar state of affairs was encountered[87] in 2-methyl-5α,6β-7,8-tetrakis(trifluoromethyl)-5,6-dihydro-Δ^2-1,3,4-oxadiazolino-[2,3-*a*]-azepine. This structure contains four short intramolecular H···F contacts, of length much smaller than the sum of the WR of the H and F atoms, and one as short as 2.13 Å. It is again suggested[87] that these contacts should be interpreted as intramolecular C–H···F–C H-bonds. Some doubt arises from the fact that in the five-membered HCCCF 'rings' of these compounds the free motion of the atoms within the molecule is limited, and the C–H···F angles are small; 114° in the first structure and 111° in the second. In relation to this work[86,87] it should be noted that according to the criteria formulated by Zefirov and Porai-Koshits[5,83] a hydrogen bond can be confidently identified only in intermolecular contacts, or for intramolecular interactions in which the contacts are not imposed by the rigid conformation of the molecule.

Thus doubts concerning the presence of SI (and in particular of H-bonds) in the system usually arise because a contracted intramolecular contact can denote either an attractive interaction or an imposed steric stress. For example, in 10-bromo-2,4,8-trinitro-6(5H)-phenanthridinone a Br···H intramolecular contact of 2.43 Å has been discovered; it is strongly contracted as compared with the value $2\sqrt{R_H R_{Br}} = 3.02$ Å as a result of substantial steric hindrances.[88] These effects increase the out-of-plane angles of the carbon atoms in the six-membered ···BrCCCCH··· ring. By relying on the geometrical characteristics of the C–H···Br contact (C···Br 3.161, C–H 0.90, H···Br 2.43 Å, CHBr 138°) it could be thought that a bond of the C–H···Br type is present. However, the shortening of the distance may also be induced by the resulting decrease in the steric stress. Often correct conclusions on the shortening of a contact can be reached by allowing for 'subsidiary' factors. However, if even additional information fails to produce a fully definite conclusion we can only assume that the existence of SI is a possibility.

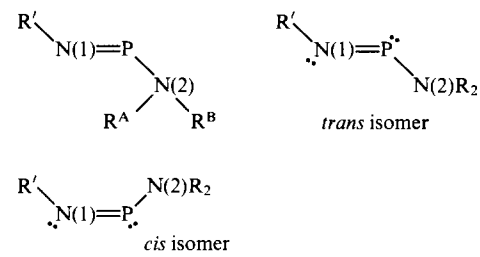
A comparison of the interatomic distances with the sums of the WR is often used to prove the absence of a hydrogen bond. For example, in the 4,4',6,6'-tetranitro-2,2'-dicarboxybiphenyl and 6,6'-dinitro-2,2'-dicarboxybiphenyl molecules the intramolecular distances 3.434 and 3.933 Å (between the oxygen atoms of the carboxylic acid and of the nitro groups respectively) are so much greater than double the WR of oxygen that the presence of any significant hydrogen bond can be excluded.[89]

It was pointed out above that the use of the statistically averaged value (1.29 Å)[3] for the WR of oxygen offers reliable conclusions on the presence of shortened and contracted O···X contacts in the structure, from which reliable deductions can be made. However, the large positive charges on the oxygen atoms usually prevent the formation not only of short intermolecular bonds but also of short intramolecular O···O contacts, even when the conformational conditions appear to be satisfied. The cation of 4,6,4',6'-tetra-*tert*-butyl-substituted pyrylo-2-monomethinecyanine (I) exists in the *Z,E* form,[72] and not in the *Z,Z* form (see above), though the latter is sterically advantageous, since the WR of oxygen is much smaller than the WR of the carbon atom. One possible reason for the existence of the cation (I) in the *Z,E* form is the repulsion between the similarly charged oxygen atoms.[72] According to quantum-mechanical calculations (CNDO/2 method) negative charges are collected on the oxygen heteroatoms (O −0.083, O' −0.137 electronic units), the charge on the O' atom being 0.035 electronic units greater in absolute value than the charge on the C'_1 atom (−0.102 electronic units). In the *Z,E* form of the cation (I) we find the shortened contacts C'···O (2.94) and H'···O (2.29 Å) for WR sums of 3.00 and 2.45 Å respectively. Since the molecule is flat, and the H···O contact closes a six-membered ring, one could conclude that this ring contains a weak intramolecular C–H···O hydrogen bond. However, Sereda et al.[72] reach a different conclusion. In this case the C–H···O contact is constrained, and is created not by an H-bond but by its accommodation in the carbon skeleton of the molecule between the heterocyclic rings. The steric stress within this contact is made evident by the large increase in the exocyclic bond angles at the C_2 and C'_2 atoms (attached to the C_7 atom, which connects the heterocyclic rings) to 129.0°, and the bond angle of the C_7 atom to 128.2°. Nevertheless the shortenings detected in the C···O and H···O contacts do not reach the lower limits expected from the van der Waals interaction (2.82 and 2.15 Å respectively).

To establish the cause of the appearance of a *Z,E* conformation in the above example of 4,6,4',6'-tetra-*tert*-butyl-substituted pyrylo-2-monomethinecyanine a calculation of the effective charges on the atoms of the cation was required.[72] In many other cases of nonrigid molecules the existence of a particular conformation can be explained simply by a geometrical analysis. In the bis-(5,5-dimethyl-1,3-dioxan-2-yl) molecule ($C_{12}O_4H_{22}$) the H···H and O···H contacts (which determine the degree of steric stress) are 2.335 and 2.646 Å long, and exceed the normal van der Waals contacts (2.31 and 2.45 Å), i.e. we observe[90] an unstressed *E*(⊥) conformation § with $\varphi = 90°$.

§ φ is the angle between the plane of symmetry of one dioxan ring and the orientation (averaged atomic plane) of the other. For a parallel orientation of the two rings $\varphi = 90°$.

A geometrical analysis was carried out in order to identify the steric stress in other conformations of the $C_{12}O_4H_{22}$ molecule, i.e. the shortest noncovalent contacts were calculated on the assumption that the conformation of the rings remains unchanged. It was found that the intramolecular contacts are always shortened except in bisequatorial conformers with φ between 90° and 45°.[90] It was suggested that the advantage of the parallel orientation of the dioxan molecules ($\varphi = 90°$) over the crossed orientation ($\varphi = 45°$) is due mainly to the effect of the crystal field (the tendency for the molecule to retain its centre of symmetry in the crystal). In *P*-methoxy-*C*,*C*-bis(trimethylsilyl)methylen-*N*-(2,4,6-tri-*tert*-butylphenyl)-imino-σ^3,λ^5-phosphorane we find a *cis* orientation (torsion angle 5.1°),[91] whereas the characteristic orientation for the original iminophosphines is the *trans* (torsion angle 180°). This orientation is due to steric causes: the difficulty of bringing the methyl group bound to the oxygen atom close to the bulky $SiMe_3$ substituent. The geometrical analysis showed that the rotation of this group round the P–O bond by 180° relative to the position found in the molecule leads to impossibly short C···C contacts (2.152 and 2.614 Å).



In four biphenylcarboxylic acids (4,4′-dinitro-2-carboxybiphenyl, 2′,4-dinitro-2-carboxybiphenyl, 2′-nitro-2-carboxybiphenyl, and 2′,4,4′-trinitro-2-carboxybiphenyl) the dihedral angle between the aromatic rings takes the values[92] −57.9°, −67.3°, +78.6°, and +89.4° because of the repulsion between the substituents. As a result of internal rotation round a single bond the intramolecular distances between not covalently bonded atoms and atomic groupings in all these molecules exceed the distances corresponding to normal van der Waals contacts.

Furthermore, steric hindrances often produce a distortion of the bond angles and an extension of the valence bonds. The distortion increases the probability of bond breaking, and therefore many workers place special emphasis on these sources of instability. Shortened contacts resulting from the distortion of the bond angles have been observed recently[93–98] in various structures by using statistically averaged values of the WR. In some cases inflections in the heterocycles of the molecule are accompanied by repulsion of the atoms which are not covalently bonded, as shown by the WR values,[99] and in other cases the CIC is accompanied by the loss of coplanarity of various fragments of the heterocycle.[100] In the [*N*,*N*,*N*′-tris-(trimethylsilyl)-diamido-*N*″-trimethylsilyl-*P*-phenyl-phosphon-imidato]phenylzinc molecule the presence of bulky trimethylsilyl substituents produces marked steric overloading with CIC (Si···C 3.274, P···C 3.352, C···C 3.166 Å), which leads to substantial nonequivalence of some covalent bonds of the same type on the nitrogen atoms and to a strong distortion of the tetrahedral coordination of the silicon atoms.[101] In the 2-methylphenyl ester of *N*-[2,4,6-tri(*tert*-butyl)phenyl]imidophosphenous acid we find a whole group of contracted intramolecular C···C contacts (2.801–2.882 Å) and N···C contacts (2.942–3.035 Å), which lead to an increase of the CCC bond angles in the 2,4,6-$(Bu^t)_3C_6H_2N$ fragments by ~3° with respect to the ideal values.[102]

The stress generated by steric hindrances in any part of the molecule becomes distributed (if possible) more or less uniformly over the whole of the molecule. A clear example of this behaviour is seen in 3,4′-difluoro-8-*exo*-fluoro-12-*syn*-(2′-nitrophenylthio)-tetracyclo[4.4.0.$1^{2,5}$.$1^{7,10}$]dodec-3-ene, in which the stress due to C···C intramolecular contacts (3.118 Å) and magnified by the H···H contacts (1.88 Å) leads to a fairly uniform distribution of the distortion of the six bond angles in the polycyclic framework of the molecule.[76]

As we know, the deformation of the bond angles is associated with much smaller energy losses than the extension of bonds in the molecule. Therefore bond stretching effects produced by steric hindrance in overloaded molecules are met more rarely than the distortion of bond angles produced by the same effects. Recent X-ray structural studies produced new examples of this behaviour. In 2-amino-5-methyl-3-(1-methylisopropoxyallyl)-1-formyl-3,4,4-tricyanocyclopentene[103] we observe a whole group of CIC with C···C values 3.022, 3.037, 3.048, and 3.057 Å and C···H values of 2.66 Å. The C_2-C_3 and C_3-C_{11} bonds, 1.542 and 1.571 Å long, are elongated by 0.03 Å with respect to the corresponding standard values of the $C(sp^3)-C(sp^2)$ and $C(sp^3)-C(sp^3)$ distances. According to the authors[103] this is probably due to steric overloading. In bicyclic iminoester molecules we find a group of intramolecular contacts shorter by 0.6 (C···C) and 0.4 Å (C···H) than the sum of the corresponding WR. These steric effects lengthen some of the covalent C–C bonds to 1.56–1.59 Å,[104] which increases the reactivity of these compounds (see also Section VI).

An analysis of the influence of steric and electronic factors on the conformation of three sterically overloaded λ^3-aminoiminophosphines [2,4,6-$(Bu^t)_3C_6H_2N{=}P-NR_2$, where R = Me (I), (Pr^i) (II),[105] and $SiMe_3$ (III) [106]] showed that the realisation of *cis* and *trans* forms in these materials is determined by a fine balance between these factors, and that the steric factors revealed by WR calculations have a strong effect on the length of the covalent bonds.

The predominant influence of the R···R′ repulsion following an increase in the volume of the R substituent favours the *trans* isomers. In the *trans* isomers of II and III the N(1)···C(19) (2.934 Å) and N(1)···Si(2) distances (3.227 Å) are greatly shortened with respect to the sums of WR (3.20 and ~3.60 Å); the stronger repulsion between the N(1) atom and the closely accommodated substituent R produced by replacing isopropyl by the bulkier substituent $SiMe_3$ is accompanied by an increase in the N(1)PN(2) bond angle from 105.6° to 109.3° and by an elongation of the P=N(1) bonds from 1.555 to 1.566 Å and of the P–N(2) bonds from 1.656 to 1.668 Å [though the lengthening of the P–N(2) bond may be due at least partially to the effect of the $SiMe_3$ acceptor groups], and also by an increase in the distortion of the configuration of bonds at the N(2) atom.

Steric effects in overloaded molecules can produce not only an elongation but also a shortening of the covalent bonds. The *cis* isomers of λ^3-aminoiminophosphine is energetically more favoured when the volume of the R substituent is small (i.e. for R = Me), when the electronic factors become predominant.[105,106] Nevertheless in the *cis* isomer I the N(1)PN(2) bond angle increases (for steric reasons) to 115.9° as compared with 105.6° in II and 109.3° in III, and the PN(1)C(1) angle increases to 140.7° as compared with 117.6° in III and 129.6° in II. This increase in the bond angles ultimately leads to a shortening of the P=N bond to 1.539 Å as compared with 1.555 Å in II and 1.566 Å in III. The shortening of the P=N bond is due to electronic factors: an increase in the *s*-character of the hybrid atomic orbitals which form this bond and an increase in the *p*-character of the unshared electron pairs in the nitrogen and phosphorus atoms, which favours the $n-\sigma^*$ interactions.

An even stronger shortening of the P=N covalent bond (by 0.04–0.08 Å, i.e. to 1.500 Å) is stimulated (for steric reasons) by the marked increase in the CNP angle in molecules of derivatives of two-coordinated phosphorus in which the –N=P–N< group is replaced by –N=P–O–. This is observed in molecules of 2,4,6-$(Bu^t)_3-C_6H_2N{=}P-OR$, where R = 2-MeC_6H_4 (IV)[102] and 2,6-$(Bu^t)_2$-4-MeC_6H_2 (V).[107] A geometric analysis has shown that the main cause of the increase in the CNP bond angle to 164.1° in IV and to 170.9° in V is the repulsion between the aryl

substituents on the nitrogen and the oxygen atoms; the decrease in the angle at the nitrogen atom to 140° reveals the formation of a strongly contracted C···C intramolecular contact (3.048 Å).[102] The CPN bond angles are increased by steric hindrances to 164.1° in IV and 173.7° in V, i.e. they go beyond the limits of 107.7° – 140.7° previously established for these iminophosphines. The increased bond angles also induce a shortening of the P=N bond to 1.497 Å in IV and to 1.500 Å in V (the P – N distance in the previously studied iminophosphines lay in the 1.539 – 1.575 Å range).

The influence of the steric factor on the electronic factor has been demonstrated[108] for the so-called aroylotropy of 2-substituted carboxylic acids. Here the steric effect of the F, Cl, Br substituents produces a rotation of the carboxy group round the C – C single bond and destroys its conjugation with the benzene ring: this group experiences only the inductive electronic effect of the substituent.

The contracted intramolecular contacts in overloaded molecules are often the cause, and sometimes also the consequence, of the stress in the intramolecular contacts in other parts of the molecule, and are also used to explain some anomalies in the geometric characteristics of these parts. These anomalies, in their turn, account for some of the physicochemical or chemical properties of the substance (see Section VI). Therefore the CIC in nonrigid molecules, offering the possibility of rotation round single bonds, have claimed the widest interest of research workers.

In the *N*-trimethylsilyl-2,4,6-tri-*tert*-butylphenylamidochlorophosphite molecule [$Me_3Si(Ar)N-PClOR$, where Ar = 2,4,6-$(Bu^t)_3C_6H_2$ and R = 2,6-$(Bu^t)_2$-4-MeC_6H_2] the Si and Cl atoms in the planar SiNPCl group are drawn together to within 3.330 Å by steric effects.[109] This is much shorter than the normal distance, since the normal van der Waals Si···Cl contact should be substantially longer (3.60 Å is observed in the normal C···Cl contact, and the WR of the atoms of the third-period elements, P, S, and Cl are 0.4 – 0.5 Å longer than the WR of the corresponding second-period element atoms N, O, F). The formation of the strongly contracted Si···Cl contact in this molecule is due to the presence (near the oxygen atom) of the bulky 2,6-$(Bu^t)_2$-4-MeC_6H_2 substituent, which prevents the perturbation of the planarity of the SiNPCl group. Indeed, as was shown by a geometric analysis,[109] the rotation of this substituent round the P – N bond by +30° relative to the position found in the molecule produces the unacceptably short C···Cl 2.711 and C···C 3.044 Å contacts, and the rotation through −30° produces the short C···C 2.841, 3.294, and 3.299 Å contacts. In two other phosphites of this type, where the 2,6-$(Bu^t)_2$-4-MeC_6H_2 radical is replaced by the phenyl (Ph) and by the adamantyl (Ad) radical, there are no spatial effects opposing the mutual repulsion of the Si and Cl atoms, and therefore the SiNPCl torsion angle in these materials is 68.6° and 67.7° respectively, and the Si and Cl atoms are 3.932 and 3.916 Å apart.[109] A similar case has also been described.[110] In the *N*-(2,4,6-trinitrophenyl)-*N,N'*-di-*p*-anisylbenzamidine structure the intramolecular N···C distance (2.66 Å) between the amidine nitrogen atom and the carbon atom of the picryl group is strongly shortened as compared with the normal van der Waals distance, which could be taken as evidence of both SI and of a strong steric stress. However, as was shown by a detailed analysis of noncovalent contacts carried out during an X-ray structural investigation, this shortening is due to the steric overloading of the molecule, produced by the presence of four benzene rings in the molecule. In both the structures described above the CIC directly affect the chemical properties (reactivity) of the molecules which contain them: this important problem is examined in Section VI.

V. Physicochemical properties of substances

The interpretation of the physicochemical properties of crystalline substances is often treated as the ultimate goal of crystal chemistry. Therefore the possibility of using WR to solve these problems undoubtedly confirms their effectiveness. The WR are most often used in discussions of the structural properties of crystals and molecules, but sometimes these features are directly related to the properties being discussed. In these cases we can directly attempt the interpretation, and even the predictive calculation, of the physical and physicochemical properties. Examples of this kind are discussed below.

Statistically averaged values of the WR were used as Onsager radii of the hydrogen atoms (1.16 Å) and of the CH_3 radicals (2.0 Å) in calculations of the band structure on the surface and in the bulk of polyethylene.[111] The band structure of the polyethylene molecule was calculated by semiempirical CNDO method on the surface of and within a polyethylene mass, treated as a uniform dielectric medium. The energy of the interaction of the polymeric molecule with the medium is expressed through the Onsager radii of the atoms, their average charges, valences, and bond indices. It was established that the immersion into a polyethylene mass lowers the ionisation potential of the polyethylene molecule by 0.87 eV, narrows the band gap by up to 1.9 eV, and raises the bottom of the valence band by 1.2 eV (see Semenov[111]).

As was pointed out above, the use of WR allows the detection in molecular crystals of associations of the molecules which are most tightly interconnected as a result of SI effects. The presence of these true associations must, of course, affect the physicochemical properties of the crystals. Thus, in the 3,5-dichloro-1*H*-1,2,4-triazole structure contracted intermolecular N···Cl contacts (3.149 Å for $d = 3.23$ Å) unite the cyclic trimers formed by hydrogen bonds into layers parallel to the XY plane.[55] The distance between these layers is 3.33 Å. The layer character of this crystal structure accounts for the sharp anisotropy of its thermal deformations,[55] the thermal expansion coefficient being greater in the direction perpendicular to the layers [$\alpha_3 = (161 + 0.29t) \times 10^{-6}\ K^{-1}$] than it is within the layer [$\alpha_1 = (34 + 0.19t) \times 10^{-6}\ K^{-1}$].

An analysis[112] of the intra- and intermolecular interactions in $(CCl_3)_2PCl_3$ and $Cl_3P{=}N-C(CF_3)_3$ crystals led to an interpretation of the differences in the character of the thermal motion of the PCl_3, CCl_3, and CF_3 groups. The rotation of the CCl_3 group in the $(CCl_3)_2PCl_3$ crystal is obstructed by strong intramolecular $CCl_3\cdots Cl_3P$ interactions which limit the mobility of these groups to small librations about the long axis of the molecule; the lengths of the intramolecular Cl···Cl contacts between the CCl_3 and the PCl_3 groups are 3.21 and 3.22 Å (for $d_{Cl\cdots Cl} = 3.65$ Å and $2R_{Cl} = 3.80$ Å). Furthermore the intermolecular contacts formed by the two groups $C(1)Cl_3$ and $C(2)Cl_3$ in the molecule are substantially different, the chlorine atoms of the $C(2)Cl_3$ group [unlike those of the $C(1)Cl_3$ group] having no contracted contacts. As a result of 300 K the mean square amplitude of the libration $\langle\varphi^2\rangle$ is 32 deg^2 for the $C(2)Cl_3$ group and only 3 deg^2 for the $C(1)Cl_2$ group. A decrease in temperature freezes out the enhanced libration of the $C(2)Cl_3$ group, and at 153 K the parameter $\langle\varphi^2\rangle$ for both groups is 0.5 deg^2, i.e. the molecule behaves effectively as a rigid body. A similar state of affairs exists in a $Cl_3P{=}N-C(CF_3)_3$ crystal, where we find an intermolecular Cl···F contact (3.07 Å) and three shortened Cl···F contacts (two intermolecular and one intramolecular). The $\langle\varphi^2\rangle$ values are 41 deg^2 at 208 K and 0.4 deg^2 at 153 K, i.e. the libration of the PCl_3 group is frozen by the decrease in temperature.

Great interest has been stimulated by shortened and by contracted contacts in organic conductor structures, as was pointed out in several reviews.[113–115] A large group of workers[40–45,57,59–62,116,117] attempted to interpret these contacts as factors determining the conductivity.

The organic metal $(ET)_4Cl_2 \cdot 4H_2O$ contains cation–radical layers alternating along the Z axis with layers of the complex anions $Cl_2 \cdot 4H_2O$ (see Shibaeva et al.[117]). The cation–radical layer is formed from ET stacks stretched along the Y axis, and the intermolecular S···S contacts contracted between stacks (3.451, 3.475, 3.489, and 3.541 Å) are aligned with the X axis: the maximum conduction is observed along this axis. A calculation of the conduction anisotropy (from the band structure) gives the ratio $\sigma_a/\sigma_b \approx 7$ (the anisotropy could not be determined experimentally because of the small size of the crystals). The conductivity of $(ET)_4Cl_2 \cdot 4H_2O$ crystals at room temperature is $10-50\ \Omega^{-1}\ cm^{-1}$; at ~ 20 K the material passes into the dielectric state. In the $(ET)_3Cl_2 \cdot 2H_2O$ structure the cation–radical layers along the Z axis alternate with layers of $Cl_2 \cdot 2H_2O$ complex anions, and the cation–radical layer is formed of ET stacks stretched along the X axis.[61] The anisotropy of the conductivity in these crystals is characterised by the ratio of the specific conductances $R_b : R_a : R_c = 1 : 7 : 1000$. The authors[61] suggest that the crystals should have a maximum conductivity along the Y axis; strongly contracted S···S contacts between the stacks (3.343–3.431 Å long) are stretched in this direction, and are complemented by less strongly contracted contacts (less than 3.53 Å). The average conductivity ($\sim 40\ \Omega^{-1}\ cm^{-1}$) should correspond to the X axis, i.e. to the direction of the cation–radical stacks, and the minimum conductivity to the Z axis. The anisotropy of the conductivity in crystals of $(ET)_3CuCl_4 \cdot H_2O$ (see Shibaeva et al.[42]) and of $(BEDOTTF)_2ReO_4 \cdot H_2O$, where BEDOTTF is the symmetrical bis(ethylenedioxy)tetrathiafulvalene,[44] can also be explained in terms of the length of the S···S contacts.

However, as could have been expected, the electric conductivity of these cation–radical salts does not show a direct relationship to the length of the S···S contacts. Thus, in crystals of the cation–radical salt $(ET)_4ZnCl_4 \cdot C_6H_5CN$ we find a whole series of short S···S lengths, including contracted ones,[40] but the complex internal structure of the conducting cation–radical layer gives a conductivity of only $\sim 0.9\ \Omega^{-1}\ cm^{-1}$ at room temperature; the substance is a semiconductor. But in $(BT)_2 \cdot 2Cl \cdot H_5O_2$ crystals the S···S contacts were found to be not contracted but merely shortened (lying between limits of 3.68 and 3.53 Å). Nevertheless the substance has a conductivity of $\sigma \approx 100\ \Omega^{-1}\ cm^{-1}$ and is a quasiunidimensional organic conductor.[57]

Some features of the IR spectra of chemical compounds are sometimes attributed to specific interactions. Thus, Br···Br contacts 3.55 and 3.75 Å long ($2R_{Br} = 3.94$ Å) are found in the $[(Me_2S)AuBr_3]$ structure. The authors suggest[118] that these interactions are responsible for the broadening of some bands in the IR spectrum of the complex.

By using the WR we can study the size and form of the cavities and channels in crystal structures, and in particular in zeolites. The volume and shape of the free space in zeolites strongly affect the diffusion processes in these materials and their adsorption and catalytic properties. The geometry of the free space in the pentasil ZSM-5 has been determined[119] by using the WR: the composition of this material (not allowing for the water) is described by the formula $M_xAl_{1.1}Si_{94.9}O_{192}$, where M_x is a mixture of sodium and tetraalkylammonium cations. The van der Waals radii were taken to be 1.80 Å for the Al and Si atoms and 1.29 Å for oxygen. A calculation showed[119] that all the free space in the pentasil forms an interconnected region with channels and connecting bridges of various sizes. The most favourable sites for the adsorption and diffusion of molecules are the infinite channels with a radius of 2.70–3.30 Å separated by bridges having radii of 2.64 and 2.68 Å.

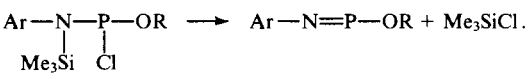
Very different physicochemical properties directly related to the effective volume, size, and shape of the molecule are often found in substances.[1] Special attention is devoted to the volume of the molecules in this context. In particular, by inserting into the formulae the volumes of the self-repeating units of the polymer a large number of physical characteristics were calculated: density, coefficient of volume expansion, melting point, and many others.[120] By using the volume of the molecules of compounds to be separated a model was made of the chromatographic separation of cyclopentadienylcarbonyl complexes of the transition metals.[121] It has been reported[122] that in the similar structures $Cu(C_9H_{13}N_2O_2CH_3)_2$ and $Cu(C_9H_{13}N_2O_2CF_3)_2$ which differ only by the replacement of the CH_3 by the CF_3 radicals, the difference in the volume ascribed to one formula unit is completely explained by the difference in WR of the F (1.40 Å) and the H atom (1.16 Å).

By combining previous X-ray structural studies[124] with an allowance for the WR of the atoms the shape of several mesogenic molecules containing metal atoms with a square coordination has been described:[123] it can be adequately approximated by an anisometric prism $30 \times 10 \times 6$ Å in size. WR have been used[125] to study the structure of aqueous solutions of electrolytes, and in the analysis of structural solvation effects.

Sets of volume increments for the atoms and atomic groups present in molecules had been proposed to facilitate the calculation of molecular volumes.[120,126] The common foundation of all these calculations were the WR. More recently new methods of calculating the volumes and surface areas of molecules from the WR (as well as the density of substances) have been published.[127–131] A paper by Gavezzotti[128] (like the earlier publications of the same author) discusses the correlation between the volumes and surfaces of molecules and the energy of sublimation of the crystal. The method of calculating the atomic volume increments described by Shil'nikov et al.[129] is carried out in three steps: an analysis of the intersection of interpenetrating spheres whose size is determined (fixed) by the WR, a calculation of the increments for atoms with surroundings compatible with the use of analytical expressions, and a Monte Carlo calculation of the increments for the other atoms. Kuz'min and Katser[130] obtained the statistically averaged volume increments of individual atoms and molecular fragments by least squares. Koch and Fischer[131] used the method of constructing Dirichlet regions for the same purpose.

An empirical model which allows the density of a substance to be predicted from approximate data on the geometric structure of the molecule has been proposed.[132,133] The model is based on the concept of the WR, but in this model a special modelling function allows for the effect of the immediate surroundings of an atom on its WR. Furthermore in the calculation of the molecular volume the WR of the end atoms are artifically increased; in liquid substances this produces a more correct allowance for the vibrational motions of the molecules.

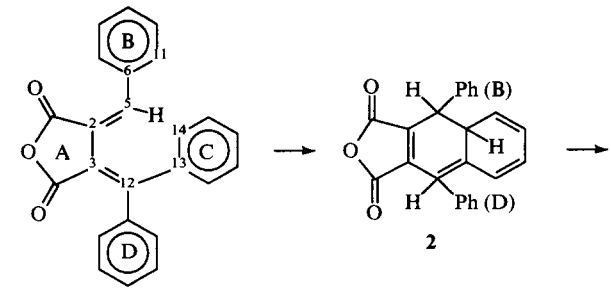
It should be noted that the dependence of the effective WR of an atom on the individual properties of the molecule which includes that atom has been discussed previously. Kitaigorodskii suggested[126] distinguishing between the WR of carbon atoms in aliphatic and in aromatic compounds (1.80 and 1.72 Å), but in subsequent publications he did not adopt this differentiation. It was postulated[134] that sterically overloaded molecules are more loosely packed in a crystal, i.e. that the atoms in these molecules have effectively larger WR (the authors called this effect the 'saturability of van der Waals bonds'). This concept was tested[135] by calculating the energies of noncovalent interactions and the packing density coefficients (K) for 159 substances. The van der Waals volumes of the molecules were calculated by using the Pauling WR.[7] This study revealed a tendency for K to decrease with increasing 'density of the molecule' (which is generally consistent with the model proposed by Atovmyan et al.[134]). However, it was concluded[135] that the straight line giving the average dependence of K on ρ_{mol} (the mass of the molecule related to its volume) cannot be used directly to determine the density of the crystal.



It should be noted that conclusions on the looseness of packing are sometimes reached too hastily. The fact that some intermolecular bearing contacts in the crystal exceed the conventional values is not sufficient to justify such a conclusion.

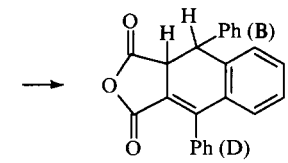
Thus, in a crystal of 2-methylthio-3-phenyl-5-methylthiocarbonyl-1,3-thiazolium-4-olate the molecules are located at a distance generally exceeding the sum of the statistically averaged WR of the atoms in contact, and this (as suggested[136]) accounts for the loose packing. However, these conclusions need to be reconsidered if they were made without allowance for the natural dispersion of the bearing contacts.

VI. Chemical reactions



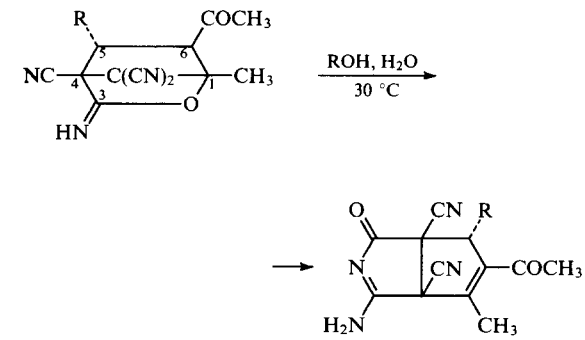
We have previously discussed[1] the steric effects of various types (discovered by using WR) which influence the reactivity of a substance: (1) steric hindrances, leading to the extension of covalent bonds or to the distortion of bond angles; (2) the shielding or complete blocking of the active centre of the molecule; (3) steric factors, which determine the angle of nucleophilic or electrophilic attack, and some other variants of the effect of steric factors on chemical processes. In the present review we shall examine, in addition to recently reported new studies in some of the directions mentioned above, examples of the use of WR in one direction not discussed in Ref. 1.

In some cases the steric effects in overloaded molecules force closer together the not covalently bound atoms: as a result the activation energy of the chemical reaction leading to the establishment of covalent bonds between these atoms is substantially lowered. Thus, in the amidochlorophosphite molecule $Me_3Si(Ar)N-P(Cl)OR$, where $Ar = 2,4,6\text{-}(Bu^t)_3C_6H_2$ and $R = 2,6\text{-}(Bu^t)_2\text{-}4\text{-}MeC_6H_2$ (I), the Si and Cl atoms are drawn together to a distance of 3.330 Å, whereas in other phosphites, where R = Ph (II) or R = Ad (III), there are no obstacles such as those found in (I), and the silicon and chlorine atoms lie at distances of 3.932 and 3.916 Å from each other respectively.[109] The covalent Si–Cl bond is 2.03 (±0.03) Å long.[137] In order to reach this value in the case of the molecule I we must contract the distance between the atoms by ~1.3 Å, and in the case of molecules II and III by ~1.9 Å, i.e. by a much greater amount. Not surprisingly the amidochlorophosphite I easily splits off trimethylchlorosilane (even at 20 °C) in a solution of tetrahydrofuran: this converts it into the λ^3-iminophosphine



Conversely, the compounds II and III are stable up to 180 °C, and they cannot be converted into iminophosphines even by lengthy heating.[109] Similarly, in the *N*-(2,4,6-trinitrophenyl)-*N*,*N*′-di-*p*-anisylbenzamidine molecule[110] the distance between the amidine nitrogen atom and the ipso carbon atom of the picryl group (N···C 2.66 Å) is shortened by 0.54 Å in comparison with the normal van der Waals contact. This close approach of the atoms assists the migration of the picryl group towards the amidine nitrogen atom in solution.

An X-ray structural study has shown[138] that the direction of the photo- and thermochromic cyclisation reactions of *E*-benzylidene-(diphenylmethylene)succinic anhydride **1** is controlled by steric factors. The molecule of this compound is sterically overloaded (especially its diphenylmethylene fragment). In this fragment the C(3)=C(12) double bond (1.37 Å) is 0.02 Å longer, as a result of steric hindrances, than the C(2)=C(5) double bond (1.35 Å) in the benzylidene fragment. For the same reason the C(12)–C(13) bond (1.48 Å) is 0.02 Å longer than the corresponding C(5)–C(6) bond in the benzylidene fragment (1.46 Å). Furthermore the C(3)=C(12) double bond is twisted by 9.4° more strongly than the C(2)=C(5) bond (the torsion angles are 24.4° and 15.0° respectively). As a result the noncovalent distance between the C(5) and C(14) atoms, which are potential reaction centres, is 3.30 Å, which is 0.12 Å less than double the WR of carbon and 0.16 Å shorter than the distance between the atoms C(11) and C(12), (3.46 Å). Thus in the



1 2

3

sterically more overloaded diphenyldimethylene fragment the benzene ring C is more closely connected to the methylene centre C(5), and because of the lower barriers to rotation round the extended C(3)=C(12) and C(12)–C(13) bonds it should be more mobile than the benzene ring B in the benzylidene fragment. It was pointed out[138] that in the molecule I the noncovalent distance between the atoms H(14) and C(2) (2.76 Å) is much shorter than the H(11)···C(12) distance (3.00 Å), which can account for the fast migration of the H(14) atom (in the intermediate **2** formed by cyclisation) towards the C(2) atom, and to the formation of the stable product **3**.

In the 3-imino-4,7,7-tricyano-2-oxabicyclo[2,2,1]-heptanes,[104] which belong to the series of bicyclic iminoesters, we find several CIC between the substituent in position 5, the *gem*-dicyano group, and the C(3) atom. These CIC are 0.6 Å (C···C) and 0.4 Å (C···H) shorter than the sum of the statistically average WR of the corresponding atoms. Steric strain lengthens the C(4)–C(5) bonds to 1.58–1.59 Å and the C–$C(CN)_2$ bonds to 1.56–1.57 Å, which increases the reactivity. When kept in aqueous ethanol (or in ethanol) this compound is converted into a mixture of 3-azabicyclo-[3,3,0]octadienes even at slightly elevated temperatures:[104]

The site of the initial nucleophilic attack on one of the carbon atoms of the cyano group in the 3-(*N*′,*N*′-dimethyl-*N*-acetylhydrazino)-1,1,2,2-tetracyano-5-methylcyclopentane was investigated by a calculation[139] of the role of the steric factor based on a geometrical modelling relying on published values[3] of the WR. It was established that only the *trans* C≡N group (in the β position with respect to methyl) is accessible to nucleophilic attack: large steric hindrances are met in other positions. This conclusion was confirmed experimentally: nucleophiles are added selectively to this cyano group.

A geometrical modelling of one of the Ugi reactions for an N···C=S angle of attack of 90° in the initial stage of the nucleophilic addition for $R' = CH_3$ and $R' = CH_2R$ to 1-methyl-2-thio-4-benzylimino-5-spirocyclohexanehydantoin was carried out[140] by using statistically averaged values[3] of the WR. It was found that for $R' = CH_3$ contacts much shorter than the sum of the corresponding WR are not formed in the initial stage of the nucleophilic addition, whereas for $R' = CH_2R$ the system is highly stressed and a closer approach of the atoms is unlikely. The stereochemical features of the reaction of ammonia with perfluoro-2-methyl-2-pentene-3-thiocyanate have been analysed by the same procedure.[84] The parameter δ, defined as $R_A+R_B-d_{AB}$, where R_A and R_B are the WR of the A and B atoms and d_{AB} is the distance between them (in this case, contracted), was used as a criterion of the possible existence of various stages in the reaction. The geometrical modelling demonstrated the dominant role of the lower steric factor and led to the prediction of the following conformational consequences: for $\delta > 0.35$ Å the stresses are removed by the distortion of valence and torsional angles and of bond lengths, for $0.55 < \delta < 0.65$ Å the stresses are partially relieved by the same factor, but the system remains stressed and the probability of encountering this conformation is small, and for $\delta < 0.85$ Å the system cannot exist in this conformation. Thus the stereospecificity of the reaction indicated by the formation of only one *E*-stereoisomer (2-aminoperfluoro-4,4-dimethyl-4,5-dihydro-5-ethylidene-1,3-thiazole) is due to the lower steric stress in the anion leading to the *E*-isomer than in the anion leading to the *Z*-isomer. Strong steric stresses prevent the cyclisation on heating of *E*-3,4-diaminoperfluoro-4-methyl-2-pentene-3-thiocyanate (through the amino group of the double bond) with formation of a thiazole ring.

In a special program assembled[141] for calculating the steric shielding of the metal atom in complexonates the complex is modelled as a coordination centre with its surrounding ligands (consisting of atoms with known WR). Another program[142] for calculating the shielding of the metal atom in compounds of the MR_n type in terms of WR has been discussed.[1]

The WR method is often used to account for the spatial conditions consistent with various solid-state reactions. Let us examine a new example of this application. An X-ray structural analysis of 4,4'-methylene-bis(phenyl isocyanate) has shown[143] that N···C intermolecular contacts (3.146 Å) are formed in the packing of molecules in a crystal between pairs of isocyanate groups connected by the centre of symmetry. Though this distance is only 0.05 Å shorter than the sum of the WR of the nitrogen and carbon atoms the optimum orientation of the NCO group in the structure is compatible (as suggested[143]) with dimerisation reactions between these groups in the solid phase. This assumption agrees with the conclusion by Shklover et al.[144] that solid-phase polymerisation which produces a bond between the A and B atoms of neighbouring molecules is possible if the r_{AB} distance is not greater than $R_A + R_B + 0.5$ Å, where R_A and R_B are the van der Waals radii of the A and B atoms.

An updated method[146] of calculating the rate constants and the heats of some gas-phase reactions over a wide temperature range by using internuclear distances, WR, and the vibrational energies of molecules has been proposed in a development of a previous method.[145]

The van der Waals radii have been used also for mapping chemical reactions from X-ray diffraction data. We have already discussed[1] in depth the mapping of the tautomeric transition[147] of tropolone derivatives in terms of four aryl-substituted tropolones. A more recent study[148] of five other compounds of this series allowed the geometrical changes in the molecules to be monitored more thoroughly.

* * *

The data discussed in the present review show that the van der Waals atomic radii are still finding extensive and varied applications in chemistry. We note that the WR are much more generally used than the covalent radii, since in order to discuss the geometrical aspects of chemical bonds we need a more exact estimate of the interatomic distances, and tabulations of averaged bond lengths are most frequently used. The pathways available for these transformations were the object of both our previous review[1] and of the present work.

However, we must stress that van der Waals radii will 'work' reliably and give useful results only if used correctly.

In conclusion we should remind the reader that the concept of van der Waals radii was formulated in the 1930s and 1940s, and is the central attribute of the classical organic crystal chemistry, based on the postulate of molecular close packing. However, in recent years there has been a rapid production of data indicating the limitations of this postulate. Our increasing understanding of specific (strongly nonisotropic) atom–atom interactions has led to new views on the structure of organic crystals.[149] The results of nonempirical quantum-chemical calculations are playing an increasingly important role in discussions of molecular structures: they are now carried out systematically not only for the simplest but also for relatively complex polyatomic organic molecules. Strictly speaking these concepts leave no room for the van der Waals radii. However, van der Waals radii are a very convenient and correct means of calculating the possible lengths of noncovalent interatomic contacts: they have become an integral part of modern chemistry, and we believe that they will so remain for a long time.

Abstract. The Brønsted acids formed as a result of the interaction of aluminium chlorides with Group I and II metal chlorides in the presence of proton-donating compounds are promising polyfunctional catalysts for electrophilic processes (polymerisation, depolymerisation and degradation of macromolecules, alkylation, desulfurisation, and hydrogenation). The factor determining the electrophilic activity and selectivity of the action of the catalysts is their acidity. This makes it possible to predict the direction of the changes in the activity and selectivity of the catalyst in specific chemical processes in conformity with the opposite variation rule: with increase in the acidity of the electrophilic catalyst, their activity increases but the selectivity of their action diminishes. The bibliography includes 72 references.

I. Introduction

The importance of catalysis in modern chemistry, characterised by the diversity of reactions, the enormous number of compounds, and the possibility of their modification, is very great. Naturally, the search for readily available active and selective combined-action catalysts, which make it possible to achieve under mild conditions many chemical reactions of practical importance and to investigate their properties, is of special interest.

The classical catalysts based on metal chlorides, used in numerous electrophilic reactions, are $AlCl_3$, $FeCl_3$, $SnCl_4$, etc. However, their high relative acidity also when they are combined with cocatalysts (H_2O, CH_3Cl, HCl, etc.) (Table 1, see over) is responsible in many instances for the occurrence simultaneously with the main process of undesirable chemical reactions (side and secondary reactions), such as the decomposition of the catalytic system, tar and coke formation, degradation of molecules, cross-linking of macrochains, etc. On the other hand, for catalysts characterised by a low acidity the very manifestation by the latter of catalytic properties is doubtful. It is therefore useful to consider the catalytic properties of metal chloride complexes with an acidity lower than that of $AlCl_3$, $SnCl_4$, etc. In particular, a relation between the acidity of electrophilic catalysts and their catalytic activity[6–16] and also the selectivity of their action[13–17] has been noted. The acidity of electrophilic catalysts has therefore attracted attention as a possible criterion for the preliminary assessment of their postulated activity and selectivity.

II. Cationic polymerisation of alkenes

The complexes of aluminium chlorides with proton-donating compounds, i.e. $H[AlCl_3OH]$, $H[Al(C_2H_5)Cl_2OH]$, etc., are catalysts for electrophilic oligo-, poly-, and co-polymerisation reactions of alkenes.[10–13,18,19] By varying the chemical nature of the Lewis acid and the proton donor (H_2O, ROH, HCl, etc.) and in essence the parameters of the acid strength of the catalyst, it is possible to form complexes with a wide range of activities and selectivities † of their action (Table 2, see over).[2,17,20,21]

The ability of electrophilic catalysts to initiate the process is determined by their acid properties, since cationic polymerisation constitutes an unusual sequence of steps occurring in accordance with the principle of the neutralisation of an acid (the active centre) by a base (the monomer),[22,23] and one has to bear in mind that, in the initiation of polymerisation by H acids, the highly acid protons abolish to some extent the differences between the basicities of the alkene monomers and, conversely, weakly acid centres are distinguished by enhanced selectivity in relation to them. The cause of the low selectivity of strongly acid (hard) centres ($H^{\delta+}$), of 'superstrong' acids is that they can interact with single C–C bonds, inducing their dissociation.[24]

The data presented below[10,25] confirm the conclusion that the activity of 'Lewis acid–cocatalyst' complex systems in the electrophilic polymerisation of alkenes depends on their acidity. For clarity, the 'Lewis acid–electron-donating

† Here and henceforth, the degree of conversion of the reactant (%) has been adopted as a measure of the activity of the catalyst.

Note. Reaction conditions: T = 253 K, concentration of hydrocarbons 1.3 M, [Cat] = 5.6×10^{-2} M, solvent — heptane.
[a] [Cat] = 7.3×10^{-3} M, solvent — CH_2Cl_2.

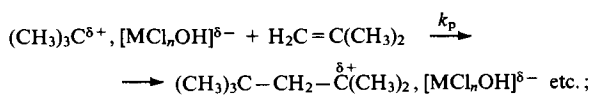
additive' complexes are arranged in series in conformity with their electrophilic activity (the region of active systems is indicated).

$BF_3\cdot R_2O$	$\underline{AlCl_3\cdot R_2O}$	$RAlCl_2\cdot R_2O$	$R_2AlCl\cdot R_2O$	$R_3Al\cdot R_2O$
$BF_3\cdot ROH$	$AlCl_3\cdot ROH$	$\underline{RAlCl_2\cdot ROH}$	$R_2AlCl\cdot ROH$	$R_3Al\cdot ROH$
$BF_3\cdot H_2O$	$AlCl_3\cdot H_2O$	$RAlCl_2\cdot H_2O$	$\underline{R_2AlCl\cdot H_2O}$	$\underline{R_3Al\cdot H_2O}$
$BF_3\cdot HHal$	$AlCl_3\cdot HHal$	$RAlCl_2\cdot HHal$	$R_2AlCl\cdot HHal$	$R_3Al\cdot HHal$

The substituents R in the Lewis acid and in the electron-donating additive can be both the same and different.

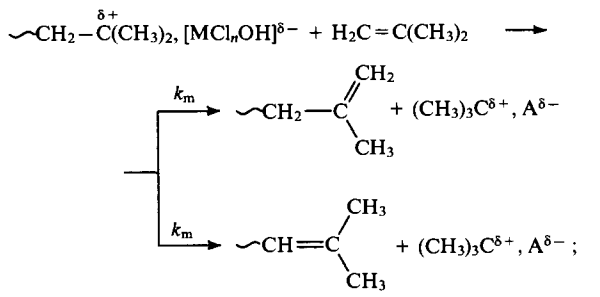
With decrease in the strength of the Lewis acids from left to right, the set of activators from isotypical series promoting the formation of the active centres becomes narrower. The strongest acid (BF_3) induces the ionisation of all the activating bases.[26] Owing to their weak electron-accepting properties, weak Lewis acids show a low activity or are inactive. Evidently, the majority of the effective electrophilic catalysts occupy an intermediate position between the two cases examined as regards their activity.

Formal considerations[10,19] show that the mechanism of the cationic polymerisation of alkenes, in particular isobutene (IB), is fairly simple and includes the following elementary stages with participation of carbonium ions:



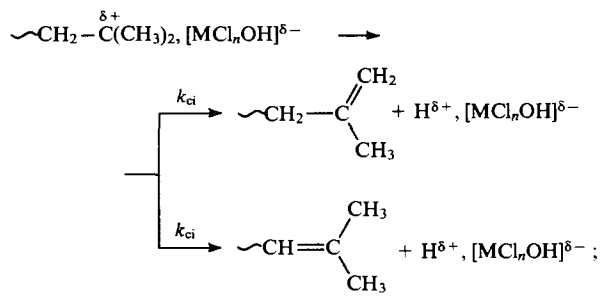
(a) the formation of the catalytic complex:

$$MCl_n + H_2O \longrightarrow [MCl_n\cdot H_2O] \longrightarrow H^{\delta+}, [MCl_nOH]^{\delta-} \text{ (or } H^+, A^-);$$

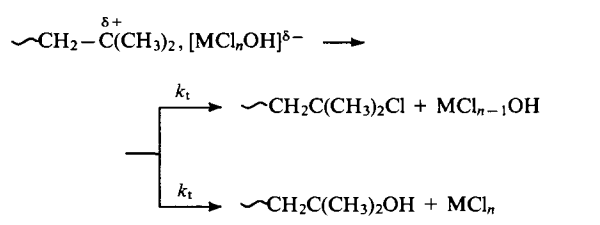


(b) initiation:

$$H^{\delta+}, [MCl_nOH]^{\delta-} + H_2C{=}C(CH_3)_2 \xrightarrow{k_i} (CH_3)_3C^{\delta+}, [MCl_nOH]^{\delta-};$$



(c) chain propagation:



(d) chain transfer to the monomer:

(e) proton transfer to the counterion (probable reaction):

(f) chain termination with capture of a fragment of the counterion.

Like the polymerisation of other alkenes, the polymerisation of isobutene has a series of characteristic features associated with the occurrence of reactions involving the formation and growth of polymeric carbonium ions. The slight internal stabilisation of the growing carbonium ions having the isobutene structure (owing to the absence of strong electron-donating substituents at the cationic centre) is responsible for the significant role of the solvating (electrostatic) function of the monomer despite its low relative permittivities ($\varepsilon = 2-3$). The low degree of solvation of carbonium ions by virtue of their size does not rule out but actually presupposes the effective external stabilisation of the cationic active centre by means of the monomer, associated with its nucleophilicity. This is the reason for the extremely rapid growth of carbonium ions, characteristic of the electrophilic polymerisation of isobutenes, such growth determining in its turn the characteristic features of the isobutene polymerisation reaction in the presence of metal chloride complexes with proton-donating compounds. As a consequence of the high rates of polymerisation and at the same time a fairly pronounced exothermicity of the process (71.9 kJ mol^{-1}), a situation arises such that, even for very slow addition of the initiator and rapid stirring, it is not possible to remove the heat evolved during the reaction in the liquid phase. In this case, the kinetic constants (in particular, $k_p > 10^6$ litre $mol\ s^{-1}$), especially under the conditions involving the formation of a viscous product, may prove to be higher than the diffusion constant (k_D) and the reaction begins almost immediately after the addition of drops of the initiator solution to the liquid monomer, i.e. long before the monomer and initiator drops have been mixed.[19] Hence it follows that, in the cationic polymerisation of isobutene in the presence of metal chloride complexes with proton-donating compounds and a series of other electrophilic catalysts, the principle of a steady-state process cannot be maintained. This means that in reality the molecular masses of the polymer are lower and the molecular distribution (MMD) is broader than expected for an isothermal process (this is in fact observed experimentally[27,28] under industrial conditions). Calculation for the nonstationary polymerisation of isobutene in turbulent streams and modelling of this process have been described in detail in a number of studies[29-35] and will not be discussed in the present review.

III. Degradation of polyalkenes (depolymerisation and degradation of macrochains)

Certain complexes of metal chlorides with a reduced acidity compared with $AlCl_3$, especially catalytic systems such as Brønsted acids based on double salts of aluminium chlorides with Group I and II metal chlorides and proton-donating compounds {H[MAlCl$_4$OH], H[MAlCl$_5$OH], H[MAl(R)Cl$_3$OH], etc.}, are extremely active in processes involving the selective thermocatalytic degradation of polyalkenes, butyl rubber (BR),[8-10,36-46] and petroleum raw material.[47-49] The main gaseous products are then C_4 hydrocarbons (Table 3, see over).

The purely thermal decomposition of polyalkenes is accompanied by the formation of a large set of reaction products (ranging from C_1 to C_6 hydrocarbons), characteristic of the pyrolysis of hydrocarbons. Therefore the concept of selectivity loses its significance when applied to the thermal degradation of polyalkenes.

The electrophilic catalytic degradation of polyalkenes in the presence of H[AlCl$_3$OH] proceeds with a higher yield of low-molecular-mass gaseous products than in the purely thermal decomposition and at lower temperatures. However, this reaction too is insufficiently selective judging from the yield of the monomer (Table 3), because the decomposition of polymeric carbonium ions in the presence of a relatively hard acid involves the formation of a series of gaseous products: ranging from CH_4 (abstraction of methyl substituents) to C_4H_{10} and C_4H_8 (skeletal isomerisation of the macroion with subsequent β-decomposition of the carbonium ion) and also of liquid and wax-like substances, in particular C_5 and other higher hydrocarbons. A major role is attributed in this case to reactions involving random chain transfer to the polymer. Thus the high acidity of the electrophilic polymerisation catalysts promotes an increase in their activity, but reduces the process selectivity. A moderate decrease in the acidity of catalysts of the type H[MAlCl$_4$OH] and H[MAlCl$_5$OH] (compared with $AlCl_3$, etc.) (Table 1) has a favourable effect on the relative contributions of the chain propagation and chain transfer reactions.[37,40] As a result, the process selectivity as regards the yield of C_4 hydrocarbons, in particular iso-C_4 hydrocarbons, increases appreciably (Table 3).

The mechanism of the thermocatalytic degradation of polyalkenes in the presence of catalysts with reduced acidity compared with $AlCl_3$—complexes of metal chlorides with proton donors—differs from the mechanism of the purely thermal decomposition reactions of the alkenes.

The thermolysis of polyalkenes proceeds via a free-radical mechanism,[50] whereas the degradation of polyalkenes in the presence of electrophilic catalysts, in particular Brønsted acids, takes place with participation of carbonium ions.[8,9,51-54]

It has been demonstrated experimentally and theoretically (the LCAO-MO method in the CNDO/2 approximation[8,9,46]) that proton-donating compounds participate in the formation of

Note. Reaction conditions: $T = 573$ K, process time 1 h, [Cat] = 1×10^{-3} mol g^{-1}, the values of $\bar{M}_n$ for high pressure polyethylene (HPPE), polyisobutylene (PIB), and butyl rubber (isobutene–isoprene copolymer, 1.7 mol.% of BR) are 2200, 1100, and 257 000 respectively. [a] Molecular hydrogen was identified among the gaseous products; [b] T = 673 K; [c] T = 653 K.

the electrophilic catalysts. The influence of H_2O and ROH in the activation of electrophiles is determined by the dissociative adsorption of such a proton-donating cocatalyst on the catalyst surface. Therefore the structure of the electrophilic centres corresponds to the structure of the Brønsted acid: $H^+[AlCl_3OH]^-$, $H^+[AlCl_3OR]^-$, $H^+[MAlCl_4OH]^-$, $H^+[MAl.(C_2H_5)Cl_3OH]^-$, etc. The series of changes in the activity of such catalysts is consistent with the increase in their acidity (Table 1). They are capable of initiating both the random decomposition of macromolecules (degradation of polymer chains) and their decomposition in accordance with the end group route (depolymerisation of polymer chains).[37,40] Depending on the type of process, particular reaction products predominate, the selectivity in the action of the catalyst increasing with increase in the contribution of the reaction initiating process in accordance with the end group route.

It has been suggested that the equation for the rate of degradation of polyalkenes with allowance for the stationary nature of the concentration of the active centres for the depolymerisation of macromolecules and the rapid chain propagation in depolymerisation be used to estimate the rate constants for both random initiation (k_{ic}) and initiation in accordance with the end group route (k_{it}), as well as the corresponding lengths of the kinetic chains (z_c and z_t).[8,9,42]

$$\frac{d[P]}{dt} = z_t k_{it} c + z_c k_{ic} [P], \quad (1)$$

where [P] is the concentration of the polymer and c the concentration of the terminal double bonds varying in accordance with the exponential law

$$c = c_0 \exp(-k_{it} t).$$

Here c_0 is the initial content of the double bonds.

The solution of Eqn (1) yields

$$[P] = \exp(-k_{it} z_t t) + \frac{k_{it} z_t c_0}{k_{it} - k_{ic} z_c} [\exp(-k_{it} t) - \exp(-k_{ic} z_c t)]. \quad (2)$$

The quantities k_{it}, k_{ic}, z_t, and z_c may be determined in the initial stages of the degradation process where $[P] \ll 1$ and $t \ll 1/k_{it}$. In this case, it is permissible to disregard the change in the concentration of the terminal double bonds. The decrease in the amount of the polymer (expressed as fractions of the initial amount) is then described by the equation

$$[P] = 1 - k_{ic} z_c t - k_{it} z_t c_0 t. \quad (3)$$

The kinetic parameters obtained for to the thermocatalytic degradation of polyisobutylene[9] in the presence of a catalyst with a moderate relative acidity (from 1.4 to 2.3 mequiv. per gramme of the catalyst) are presented in Table 4. Regardless of the chemical structure of the catalyst, the numerical values of both k_{it} and k_{ic} hardly change (within the limits of error). This confirms (taking into account the overall yield of the gaseous products and also the content of iso-C_4 hydrocarbons) the conclusion that the activity and the selectivity of electrophilic

catalysts, in particular complexes based on metal chlorides, are related to their relative acidity index. The ratio of k_{it} and k_{ic} (Table 4) indicates the preferential initiation of the depolymerisation of the macromolecules in accordance with the end group route at relatively low temperatures of the degradation of the polymeric product. With increase in the process temperature, the contribution of random reactions increases, but the decrease under these conditions in the length of the kinetic chain in the decomposition of polyalkenes for random process initiation (z_c) compared with the length of the kinetic chain for initiation in accordance with the end group route (z_t) may be only apparent. The actual increase in the number of monomer units formed for the random initiation of the process also occurs, since the energy of the β-decomposition of the carbonium ion diminishes under these conditions, but, against the background of the sharp increase in the number of breaks in the macrochains, the degradation of the macromolecules is not manifested.

For low degrees of polymerisation ($\bar{P}_n^0$), the values of z_t are actually equal to the chain length in the depolymerisation of macromolecules. For high values of $\bar{P}_n^0$, z_t becomes constant, which is evidently determined by the relative contributions of the chain propagation and destruction reactions on the carbonium ion active centres formed from the end groups.[8,9]

The presence of a tertiary carbon atom and especially of the C=C double bonds (both terminal and internal) in the macromolecules exerts a signficant influence on the thermocatalytic degradation of polyalkenes. In particular, process initiation predominantly in accordance with the end group route is characteristic of low-molecular-mass PIB specimens with a high relative content of C=C double bonds (Fig. 1), because in the course of the thermocatalytic decomposition of the polymer a slight change in the molecular masses of the polymeric products is observed (in the initial stages of the process, $\bar{P}_n/\bar{P}_n^0 \approx 1$). The ratio $\bar{P}_n/\bar{P}_n^0$ diminishes only for high degrees of conversion. For high-molecular-mass PIB specimens, isobutene–isoprene copolymers containing labile bonds at the junctions between the isobutene clusters and the isoprenyl unit with a C=C bond, and polyethylene (PE) (regardless of its molecular mass) containing internal vinylidene and *trans*-vinylidene C=C bonds, the overall degradation of the macromolecules proceeds simultaneously both as a random process and

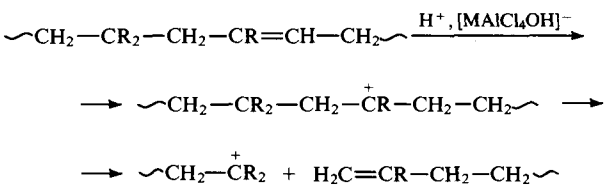
Dependence of the relative degree of polymerisation on the extent of reaction (α) of low pressure polyethylene (LPPE) during thermocatalytic degradation at 633 K in the presence of $H[NaAlCl_4OH]$. Catalyst concentration 1×10^{-3} mol(g LPPE)$^{-1}$. Initial degree of polymerisation of LPPE: (*1*) 2×10^4; (*2*) 6×10^4; (*3*) 1.45×10^5; (*4*) 2.5×10^5; (*5*) 2.7×10^5; (*6*) 8.7×10^5.

in accordance with the end group route, but with different contributions of these mechanisms to the overall process (Fig. 2). The possibility of the initiation of the degradation of macromolecules also via the vinyl end groups cannot be ruled out.

In the general case, the thermocatalytic degradation reactions of polyalkenes are initiated as follows:

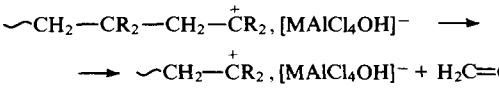
(a) the end group route:

(b) the random route:



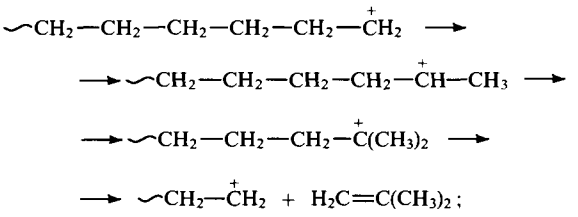
$$\sim CH{=}CR_2 \xrightarrow{H^+,[MAlCl_4OH]^-} \sim CH_2{-}\overset{+}{C}R_2,$$

R = CH_3 (PIB, BR), H (PE);

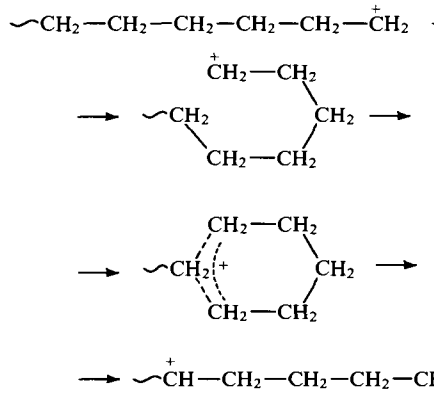


(b) the random route:

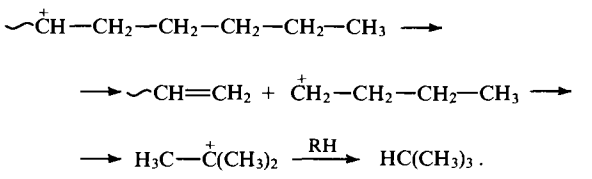
The random route in relation to BR and PE:



The modes of the chain propagation reactions in the course of the decomposition of macrocations may differ significantly depending on the structure of the selected polymer. For example, in the thermocatalytic degradation of PIB and BR, the carbonium ions formed decompose by β-elimination of the monomer—in the given instance isobutene (Table 3):

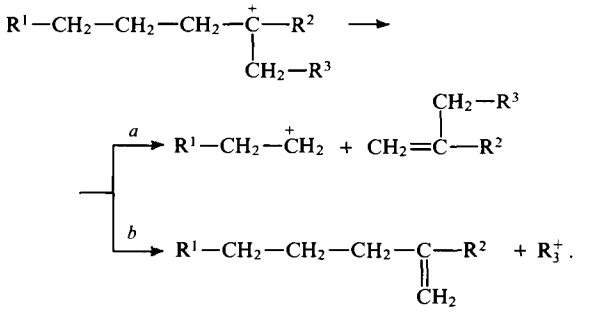


In the thermocatalytic degradation of PE, the linear carbonium ion $R-{}^{+}CH_2$ formed in the reaction can react via two main paths:



(1) as a result of skeletal isomerisation with formation of a tertiary carbonium ion, which decomposes further into a new carbonium ion and isobutene:

(2) as a result of the isomerisation of the macrocation accompanied by the transfer of the excess positive charge to the sixth carbon atom via an intermediate reaction involving the cyclisation of 'flexible' sequences made up of methylene groups:



The β-decomposition of the carbonium ion formed and subsequent isomerisation reaction and the reaction involving the abstraction of a proton from the neutral polymer molecule lead to the formation of isobutane (Table 3):

We may note that this reaction does not correspond to the classical mechanism of the PE depolymerisation process, but can be regarded as a coupled reaction involving the degradation of macromolecules and chain transfer.

In the thermocatalytic decomposition of PE, the macromolecules of which contain branches, for example, high pressure polyethylene (HPPE), the carbonium ions may be formed not only from the C=C double bonds but also from a tertiary carbon atom. The subsequent degradation of the polymeric carbonium ions proceeds via two paths: degradation of the main chain (*a*) and decomposition of the polymeric carbonium ion with elimination of the surrounding group (chain branching) (*b*):

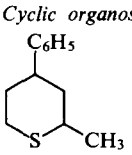
A new carbonium ion, undergoing further decomposition, as well as 'dead' polymer, the macromolecule of which contains a vinylidene bond, are formed in both cases.

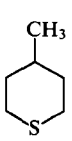
Thus the presence of a tertiary carbon atom and especially of C=C double bonds in the polymer chains plays an important role in the initiation of the degradation of the macromolecules and in the propagation of the thermocatalytic electrophilic degradation of polyalkenes. The stability of polyalkenes in their thermocatalytic electrophilic degradation diminishes in the following sequence: high pressure polyethylene > low pressure polyethylene > polypropylene > poly-isobutylene > butyl rubber,[42] i.e. an increase in the degree of substitution of the carbon atoms in the macromolecules leads to a decrease in the stability of the latter.

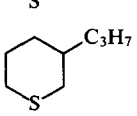
IV. Hydrogenolysis (dehydrosulfurisation) of organosulfur compounds

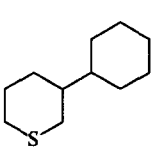
The complexes of metal chlorides having an acidity lower than $AlCl_3$, in particular $H[MAlCl_4OH]$ (M = Li, Na, K) and other compounds of this type, formed as a result of the interaction of $AlCl_3$ with Group I and II metal chlorides (with H_2O as the cocatalyst),[55] exhibit a fairly high activity and selectivity in the reactions involving the hydrogenolysis of organosulfur compounds of different classes (mercaptans, sulfides, disulfides, thiophene) and accompanied by the elimination of H_2S.[56–61] The process proceeds under mild conditions (450–625 K, atmospheric pressure) and does not require the introduction of molecular hydrogen into the reaction zone (Tables 5 and 6).

The nature and structure of the molecules of the hydrocarbon solvent, which behaves as a hydrogen donor, exert an appreciable influence on the extent of the reaction. The most suitable solvents are naphthene hydrocarbons, which is due to their high proton-donating capacity compared with paraffins having the normal structure and especially arenes.









On the basis of experimental data for the hydrodesulfurisation of the naphthene fractions of hydrocarbons[57] and also

Note. Reaction conditions: T = 523 K, catalyst — H[NaAlCl$_4$OH], [Cat] = 1 M, solvent — dodecane.
[a] Catalyst — H[LiAlCl$_4$OH]; [b] catalyst — H[KAlCl$_4$OH].

certain individual organosulfur compounds in hydrocarbon solvents,[58] the catalytic systems H[MAlCl$_4$OH] can be arranged in the following sequence in terms of their activity and the selectivity of their action: H[LiAlCl$_4$OH] > H[NaAlCl$_4$OH] > H[KAlCl$_4$OH]. This sequence agrees with the variation of their acid strength (pK_a, q_{H^+}, RAI) (Table 1).

In all cases, the desulfurisation of organosulfur compounds is accompanied by the formation of gaseous and liquid products (Tables 5 and 7), the main gaseous reaction product at 450–475 K being H_2S (96–98 mass %) under these conditions.

The heterophase, i.e. in the presence of H[MAlCl$_4$OH], hydrogenolysis of organosulfur compounds is complex in view of the occurrence of a series of consecutive-parallel chemical reactions with participation of the hydrocarbon solvent as a proton donor — as a consequence of the polyfunctionality of the action of the catalyst. The process is described by the kinetic equations for topochemical reactions of the Avrami–Erofeev type:[62]

$$c(\tau) = c(\tau_0)\exp[-k(\tau)^n],$$

where $c(\tau_0)$ and $c(\tau)$ are the initial and current concentrations of the reactants respectively, k is the observed rate constant for the reaction of the organosulfur compounds, and n is the reaction order. At the same time, the rate constants for the hydrogenolysis of the organosulfur compounds were estimated from the initial sections of the kinetic curves for low degrees of conversion assuming that the process obeys first-order reaction conditions. The molecular structure of the organic sulfur-containing compounds exerts an appreciable influence on the rate of hydrogenolysis and they can be arranged in the following sequence in terms of their reactivities: hexanethiol > dihexyl sulfide > thiophene. This follows with the strength of the C–S bond in these molecules.[63]

In the desulfurisation of sulfides (Table 6), the reactivity of the compounds investigated varies in the following sequence:
(a) acyclic sulfides:

$$C_6H_5(CH_2)_2-S-(CH_2)_2C_6H_5 > C_6H_5-S-C_{10}H_{21} > \text{iso-}C_5H_{11}-S-C_3H_7\text{-n} > C_6H_5-S-C_3H_7 > \textit{tert}\text{-}C_6H_{13}-S-C_6H_{13}\text{-n} > \text{n-}C_6H_{13}-S-C_6H_{13}\text{-n};$$

(b) cyclic sulfides:

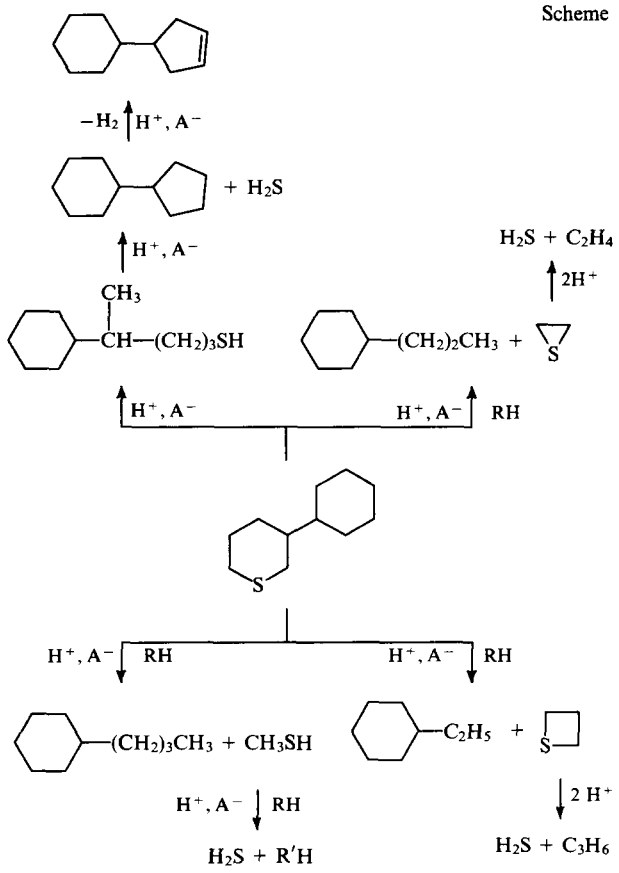
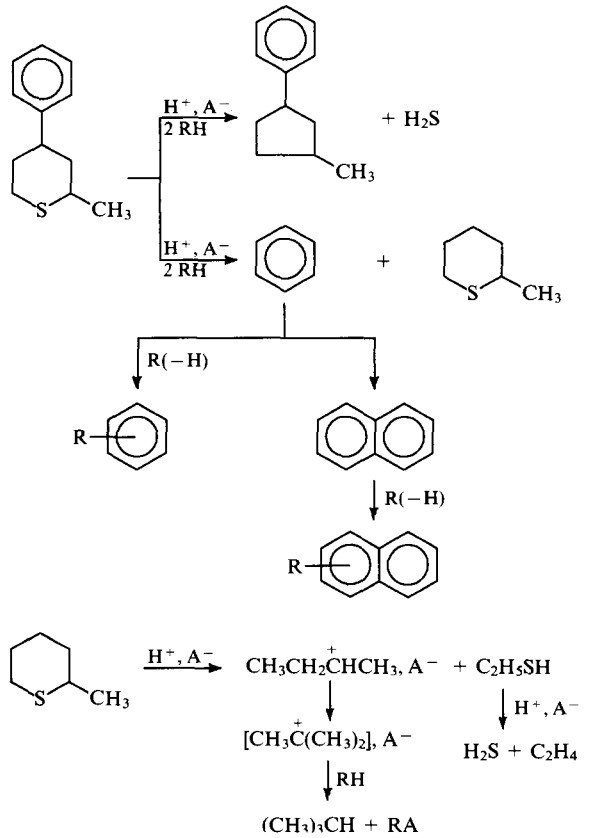
Note. Reaction conditions: T = 523 K, catalyst — $H[NaAlCl_4OH]$, [Cat] = 1 M, solvent — dodecane (t = reaction time).

Evidently, enhancement of the electron-donating properties of the substituent (taking into account its position relative to the S atom in the cyclic sulfides) weakens the C–S bond. The reactivity of cyclic sulfides diminishes in the presence of bulky substituents capable of giving rise to steric hindrance in the hydrogenolysis of organic thiacycloalkanes. The desulfurisation of organic sulfides is favoured by an increase in the degree of branching in the hydrocarbon fragment, which is also due to the enhancement of the electron-donating functions of the substituent.



The molecular structure of organic sulfur-containing compounds (both isotypical and belonging to different classes) does not affect the mode and course of the hydrogenolysis. This is seen, in particular, from the comparison of the compositions of the liquid products formed in the desulfurisation of 3-cyclohexylthiacyclohexane and 2-methyl-4-phenylthiacyclohexane in the presence of $H[NaAlCl_4OH]$ (Table 7). The dissociation of the C–S bond in the thiacyclohexane ring and its further reactions, as well as the dissociation of the C–C bond between the thiacyclohexane ring and the surrounding groups with their subsequent reactions are characteristic of the desulfurisation process. The process proceeds as a series of parallel-consecutive electrophilic reactions.

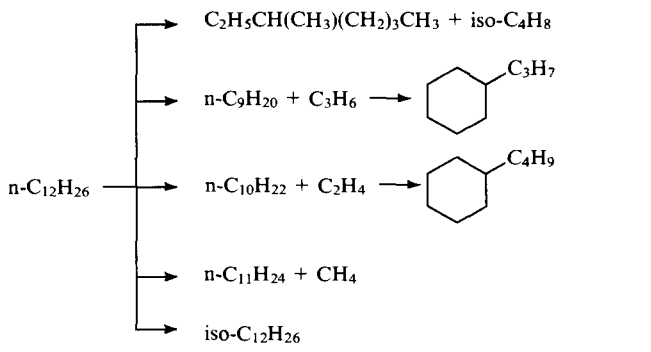
The principal types of the hydrogenolysis of 3-cyclohexylthiacyclohexane in the presence of $H[NaAlCl_4OH]$ (or H^+A^-) in dodecane are presented in Scheme 1.



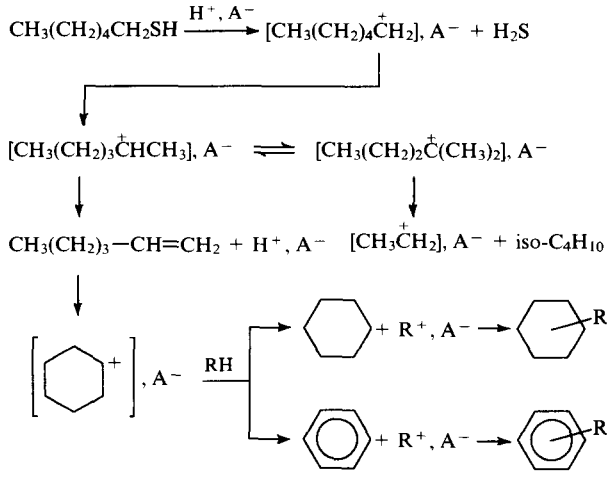
The virtual absence of sulfur-containing compounds 0.5–1 h after the start of the reaction (at 523 K) and the complete absence of mercaptans from the reaction products even in the early stages of the hydrogenolysis of cyclic sulfides (5–10 min) are striking. Furthermore, in the purely thermal decomposition and also in the presence of oxide catalysts, for example alumina–cobalt oxide–molybdenum oxide catalysts, the thiacyclanes react via a stage involving the formation of mercaptans.[64]

The possible types of the hydrogenolysis of 2-methyl-4-phenylthiacyclohexane under the same conditions are illustrated in Scheme 2.

Scheme 1



Scheme 2



On the basis of these experimental data and also the fact that the rate of hydrogenolysis of mercaptans is 1–2 orders of magnitude higher than that of thiacyclanes (Table 6), one may postulate that mercaptans as well as thiirane, thiacyclopropane, 2-ethylthiacyclohexane, and dimethylthiacyclohexane (Table 7) participate in the process as intermediates. This is reflected in Schemes 1 and 2. Saturated aliphatic C_8-C_{11} hydrocarbons and iso-$C_{12}H_{26}$ are formed as a result of the reactions of the solvent (dodecane). Some of the alkanes are transformed into naphthene derivatives (Scheme 3).

Scheme 3

Thus, in the presence of complexes of metal chlorides with proton-donating compounds, the desulfurisation of cyclic sulfides proceeds via a single mechanism: the hydrogenolysis of the C–S bond with formation of H_2S and the heterolytic dissociation of the C–C bonds between the thiacyclane ring and the surrounding groups and also directly in the ring. The process takes place with participation of ions. The C–S bond and subsequently the C–C bonds of the hydrocarbon fragment dissociate also in the hydrogenolysis of mercaptans.

Thus electrophilic catalysts based on H[MAlCl$_4$OH] exhibit a fairly high activity and selectivity in the catalytic hydrogenolysis reactions of various sulfur-containing organic compounds proceeding via the carbonium ion mechanism at relatively low temperatures (470 ± 50 K). An important factor is that the reaction proceeds at the normal pressure and does not require the additional introduction of molecular hydrogen; the higher the acidity of the electrophilic catalyst, the more active but less selective the catalytic system under these conditions.

V. Dehydrogenation and hydrogenation of hydrocarbons

The complexes of metal chlorides with proton-donating compounds are capable of initiating both dehydrogenation[65] and hydrogenation reactions of hydrocarbons. The study of the hydrogenolysis reactions of sulfur-containing compounds (Table 5) and degradation reactions of hydrocarbons (Table 8) in the presence of Brønsted acids based on $AlCl_3$ and Group I and II metal chlorides showed that the mixture of gaseous reaction products contains as a rule molecular hydrogen. In particular, the thermocatalytic degradation of butyl rubber in the presence of $H[MAlCl_4OH]$ (M = Li, Na, K) is accompanied by the evolution of H_2 (up to 0.7 mass%). At the same time, in many instances anomalously high amounts of isobutane and other saturated hydrocarbons have been detected in the gaseous products (Tables 3, 5, and 8). The foregoing indicates the activity of catalysts of this type in both dehydrogenation and hydrogenation reactions of hydrocarbons under comparatively mild conditions (423 ± 40 K, atmospheric pressure).

The thermocatalytic dehydrogenation of hydrocarbons in the presence of $H[MAlCl_4OH]$ has been studied in fair detail in relation to low-molecular-mass model compounds — dodecane, decene, and cyclohexane (Table 8).[65] It is striking that the yield of molecular hydrogen in the dehydrogenation reactions of saturated and alicyclic hydrocarbons is always higher than in the dehydrogenation of alkenes. A similar conclusion can be reached also as regards saturated C_3-C_4 hydrocarbons (propane, isobutane) (Table 8), which evidently indicates a large contribution of the coupled reaction involving the hydrogenation of unsaturated hydrocarbons formed in situ on decomposition of the initial alkanes in the presence of $H[MAlCl_4OH]$.

Typical H_2 elimination curves for the model dehydrogenation reaction of dodecane in the presence of $H[NaAlCl_4OH]$ are presented in Fig. 3*a*. The extrema on the curves indicate the simultaneous dehydrogenation of dodecane and the hydrogenation of the unsaturated hydrocarbon products catalysed by electrophilic catalysts with reduced acidity compared with $AlCl_3$, i.e. $H[NaAlCl_4OH]$, etc. The curves characterising the variation of the content of unsaturated hydrocarbons in the liquid products formed on decomposition of dodecane in the presence of $H[NaAlCl_4OH]$ (Figs. 3*a* and 3*b*) have a similar shape.

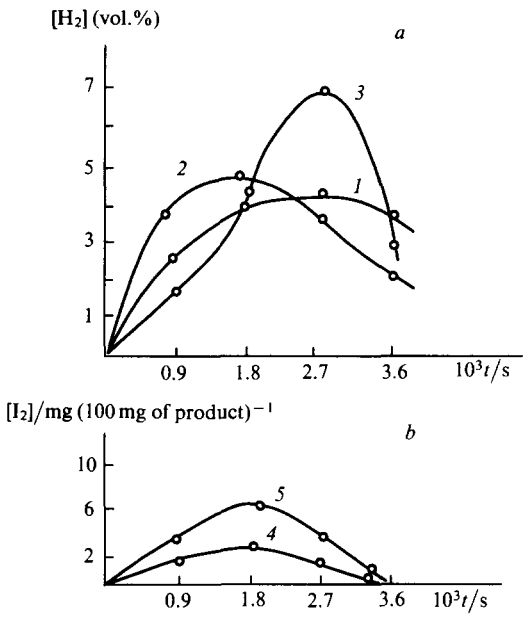


Figure 3. The hydrogen content in the gaseous products (*a*) and variation of the iodine number in the liquid products (*b*) during the catalytic conversion of dodecane in the presence of $H[NaAlCl_4OH]$ as a function of time at different process temperatures (T/K): (*1*) and (*4*) 473; (*2*) 500; (*3*) and (*5*) 525.

The compositions of the liquid products of the thermocatalytic degradation of dodecane, decene, and cyclohexane are presented in Table 9.

Experimental data show that two paths for the formation of molecular hydrogen in the thermal decomposition of hydrocarbons in the presence of $H[MAlCl_4OH]$ are possible: (1) degradation of the hydrocarbon molecules (decomposition via the C–C bonds); (2) cyclisation of unsaturated hydrocarbons with subsequent dehydrogenation of the resulting cyclic compounds. In both cases, the reactions proceed via the carbonium ion mechanism (Scheme 4):

Table 8. Gaseous products of the thermocatalytic decomposition of individual hydrocarbons in the presence of $H[NaAlCl_4OH]$.

Hydrocarbon	Content of gaseous products (vol.%)								
	H_2	CH_4	ΣC_2	C_3H_6	C_3H_8	iso-C_4H_8	iso-C_4H_{10}	ΣC_4	C_5 and above

Note. Reaction conditions: T = 523 K, reaction time 30 min, catalyst : hydrocarbon = 1 : 4.

Table 9. Liquid products of the thermocatalytic decomposition of individual hydrocarbons in the presence of $H[NaAlCl_4OH]$.

Hydrocarbon	Content of liquid products (mass%)									
	C_6H_{14}	C_6H_{12}	cyclo-C_6H_{12}	C_6H_6	$C_6H_5C_2H_5$	$C_6H_5CH_3$	$C_6H_4(CH_3)_2$	other products	iso-$C_{10}H_{22}$	iso-$C_{12}H_{26}$
Dodecane	5.0	—	2.3	2.4	0.8	7.9	15.0	36.3	—	30.3
Dec-1-ene	9.5	8.5	7.1	5.5	—	4.1	—	—	65.3	—
Cyclohexane	2.6	—	—	76.3	—	—	21.1	—	—	—

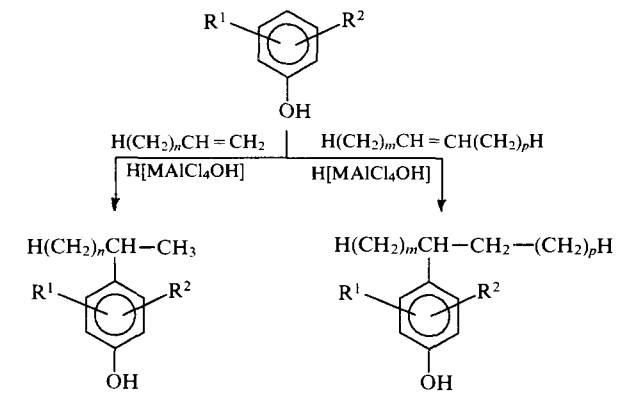
Note. The reaction conditions are indicated in Table 8.

Scheme 4

The formation of anomalously large amounts of unsaturated hydrocarbons in the thermooxidative decomposition of polyalkenes and also of individual saturated and unsaturated compounds in the presence of catalysts — Brønsted acids based on complexes of $AlCl_3$ and Group I and II metal chlorides (Tables 3, 5, 8, and 9) — can be explained by the fact that electrophilic chemical reactions of two types can occur under the given conditions: (1) the interaction of alkenes with alkanes (alkylation); (2) dehydrogenation of the resulting unsaturated hydrocarbons in the presence of H[MAlCl$_4$OH]:

$$CH_2{=}C(CH_3)_2 \xrightarrow{H^+, A^-} (CH_3)_3\overset{+}{C}, A^-$$

$$(CH_3)_3\overset{+}{C}, A^- + \sim CH_2{-}C(CH_3)_2H \longrightarrow$$



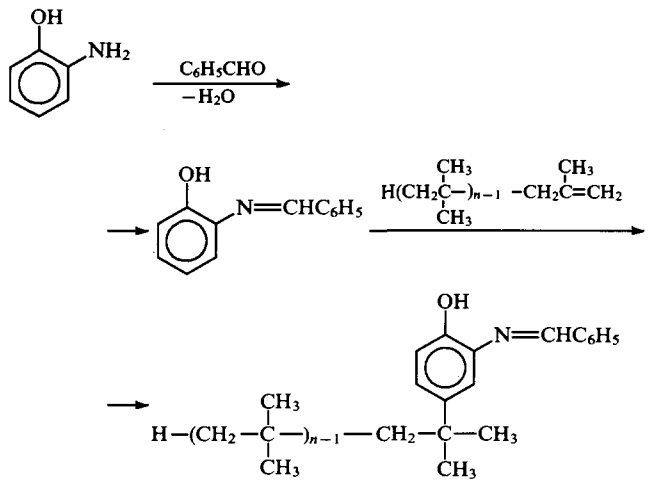
$$\longrightarrow (CH_3)_3CH + \sim CH_2{-}\overset{+}{C}(CH_3)_2, A^-, \text{ etc.}$$

Thus electrophilic catalysts with an acidity reduced compared with $AlCl_3$ are capable of initiating the dehydrogenation and hydrogenation reactions of hydrocarbons proceeding via the carbonium ion mechanism. The active forms of the catalyst are the corresponding Brønsted acids.

VI. Alkylation of phenols by polyalkenes

The Friedel–Crafts alkylation of phenols by alkenes (Scheme 5) belongs to the group of fairly complex reactions involving electrophilic substitution in aromatic hydrocarbons. As a rule the substitution is accompanied by the formation of very appreciable amounts of secondary products, especially when electrophilic reaction catalysts with high relative acidity indices, in particular $AlCl_3$, BF_3, $SnCl_4$, $ZnCl_2$, H_2SO_4, etc., are employed (Table 10). For example, in the reactions of higher α-alkenes with phenols in the presence of $AlCl_3$, the products of the decomposition the phenols (butylphenols, etc.)[66] as well as the products of the interactions of the phenols with $AlCl_3$ (the corresponding salts of HCl)[67] are formed together with alkylphenols.

Scheme 5



$m + p = n - 1$;
$R^1 = R^2 = H$;
$R^1 = H$, $R^2 = o$-, m-CH_3; $R^1 = H$, R^2 = iso-C_3H_7;
$R^1 = R^2 = tert$-C_4H_9; $R^1 = H$, $R^2 = o$-, m-, p-OH.

The ease of the alkylation of phenols by polyalkenes increases after the introduction of electron-donating substituents (HO, H_2N) into monohydric phenols, but diminishes in the presence of two and more bulky substituents in the aromatic ring, which give rise to steric hindrance.

The kinetics of the alkylation of phenols by alkenes have been investigated in relation to the model reaction of phenol with hept-1-ene — $T = 343$ K, identical concentrations of phenol and the alkene (2.4 M), and H[NaAlCl$_4$OH] concentration 0.24 M. The process follows second-order kinetics and the observed rate constant is $(2.2 \pm 0.2) \times 10^{-5}$ litre mol^{-1} s^{-1}.

The interaction of aminophenols with polyalkenes in the presence of H[MAlCl$_4$OH] and other similar Brønsted acids with a reduced acidity compared with $AlCl_3$ involves the amino-groups and not the aromatic ring. Nevertheless, the possibility of the ring-alkylation of aminophenol derivatives (in particular Schiff bases) by polymers under these conditions has been demonstrated (Scheme 6).

Scheme 6

The alkylation of phenols by unsaturated polymeric hydrocarbons proceeds in an even more complex manner because there is a sharp increase in the number of probable secondary reactions such as isomerisation, depolymerisation, and degradation of the polymeric fragments in the initial (polyalkenes) and final (polyalkenylphenols) products. This had been demonstrated earlier in relation to the interaction of polyalkenes with phenol in the presence of benzenesulfonic acid (Table 10).[68]

Systems of the type H[MAlCl$_4$OH], with a reduced relative acidity (Table 1), proved to be more convenient and effective catalysts of the selective alkylation of phenols by polyalkenes than AlCl$_3$. They exhibit a high activity and selectivity in the reactions of phenols with polyalkenes[69,70] occurring under mild conditions (378 ± 15 K, reaction time 3 ± 1 h), which lead to polyalkenylphenols in nearly quantitative yields (90 mass% and above) (Table 10).

Thus the decrease in the acidity of the metal chloride-based catalytic systems (evidently up to a certain limit) lowers (as in the cases examined above) the contributions of the secondary and

[a] Signal due to the carbon atom bound to the oligomeric radical; [b] T = 393 K; [c] T = 373 K; [d] [Cat] = 0.10 mol(mol polyalkene)$^{-1}$, T = 393 K.

side reactions, characteristic, for example, of catalytic processes involving the use of $AlCl_3$ or benzenesulfonic acid.[66,67] As a consequence of this, the selectivity of the action of these catalytic systems in these processes also increases.

Depending on the positions of the C=C bonds in the molecule of the initial polyalkene (terminal or internal), the corresponding polyalkenylphenols are formed; the reaction then proceeds via the classical electrophilic addition mechanism and the catalyst is a Brønsted acid: H^+, $[MAlCl_4OH]^-$.

Further reactions involving polyalkenylphenols and their derivatives may be carried out. In particular, polymeric ethers of (4-methyl-5,6-dihydro-2*H*-pyranyl)phenols have been obtained in this way.[69,71] In addition, polyalkenylphenols are of interest as stabiliser-antioxidants and also as additives to oils.

The presence of the benzylideneamino-group in the phenol ring hinders the electrophilic addition of polyalkenes to aminophenols owing to the depletion of the electron density of the aromatic ring. Benzylideneaminophenols therefore interact with polyalkenes under more several conditions than aminophenols or dihydric phenols.

VII. Dependence of the effectiveness of electrophilic catalysts on their acid–base properties

Experimental results obtained for a fairly large number of electrophilic reactions occurring in the presence of Brønsted acids indicate that the degree of conversion and the yield of the target products may vary within extremely wide limits in specific reactions depending on the nature and structure of the metal chlorides, the nature of the cocatalyst, the position of the corresponding metal in the Periodic System, and in essence (and evidently primarily) the acidity of the catalytic system. In particular, a relation has been traced between the acid–base properties of metal chloride complexes (taking into account the electronic configuration of the metal atom and also its position in the Periodic System) and their effectiveness and the selectivity of their action as catalysts for electrophilic processes. This can be seen in relation to the polymerisation reactions of isobutene from the C_4 hydrocarbon fractions[7,21,24] (Table 2), the degradation of hydrocarbons[3–5,36–49] (Table 3), the alkylation of phenols by polyalkenes[69,70] (Table 10), hydrogenolysis,[56–61] etc. Fig. 4 demonstrates to a first approximation the conventional boundary between the acid (electrophilicity and basic (nucleophilicity) properties of individual metal chlorides (straight line *AB*).

The metal chlorides located above the *AB* line or directly on it ($MgCl_2$, $BaCl_2$, $CaCl_2$, $SrCl_2$, $MnCl_2$, $CoCl_2$, $ZnCl_2$, $InCl_3$, $BiCl_3$, $SnCl_2$, $FeCl_2$) are characterised by a lower acidity than $AlCl_3$, $TiCl_4$, $SnCl_4$, and $FeCl_3$ and hence by a relatively mild catalytic activity. This is responsible for their fairly high activity and selectivity as catalysts of electrophilic processes. The metal chlorides located underneath the *AB* line, including $AlCl_3$, $SnCl_4$, $FeCl_3$, $TiCl_4$, etc., are 'hard' (strong) or 'superstrong' Lewis acids. Therefore their employment as catalysts for certain electrophilic reactions (for example, selective alkene polymerisation processes, degradation of polyalkenes and polydienes, desulfurisation of organosulfur compounds, alkylation of phenols and aminophenols by alkenes, polyalkenes, and polydienes, etc.) is not always effective, since undesirable side reactions may occur.

The results of theoretical calculations of the charges on the hydrogen atoms of the proton donors q_{H^+} in metal chloride-based complexes and other electrophilic compounds of the type of Brønsted acids[16] and also of the universal acidity index pK_a[14,15] in combination with experimental data on the relation between the acidity parameters of chemical compounds and the activity and selectivity of electrophilic catalysts in relation to the cationic polymerisation of alkenes[6–11] have led to a similar conclusion. An alternative measure of the acid strength of electrophilic catalysts is the relative acidity index [RAI/mequiv. (g. cat.)$^{-1}$, see

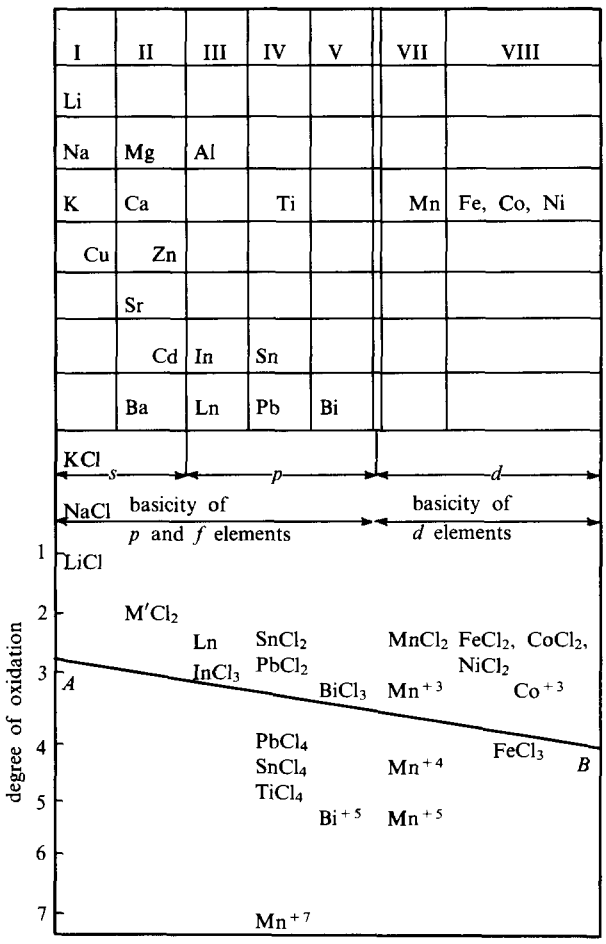

Figure 4. Variation of the acid–base properties of MCl_n as a function of the position of the metal in the Periodic System. M′ = Ba, Sr, Ca, Cd, Mg, or Zn.

Table 1],[13] which can be readily determined experimentally by differential nonaqueous titration [acetophenone (solvent)] and which does not require cumbersome theoretical calculations.

The data presented in Table 1 and also theoretical calculations,[6–11,14,15,21] have led to the discovery of a clear linear relation between the calculated (q_{H^+}, pK_a) and experimentally estimated (RAI) parameters of the acidity of the metal chloride-based complexes (in the form of Brønsted acids) (Fig. 5):

$$pK_a = 27.3 - 109.2\ q_{H^+},$$

(with a correlation coefficient of 0.98 and a standard error of 0.19);

$$RAI = 2.3 - 0.122\ pK_a,$$

and

$$RAI = 13.33\ q_{H^+} - 1.03,$$

(with a correlation coefficient of 0.99 and standard error of 0.085). The correlations between q_{H^+}, pK_a, and RAI are valid for an extremely large number of electrophilic catalytic systems based on metal chlorides and alkyl(aryl)metal chlorides involving Group IIA–VA and IIB–VIIIB metals, as well as relatively new catalytic systems based on metal chlorides and alkyl(aryl)metal chlorides involving Group IIIA metals with Group IA and IIA,B metal chlorides. Similar correlations have been observed for the complexes of boron fluorides and alkyl(aryl)boron fluorides with proton-donating compounds (H_2O, HF, ROH),[6–11] which in all probability makes it possible to reach a conclusion concerning the general

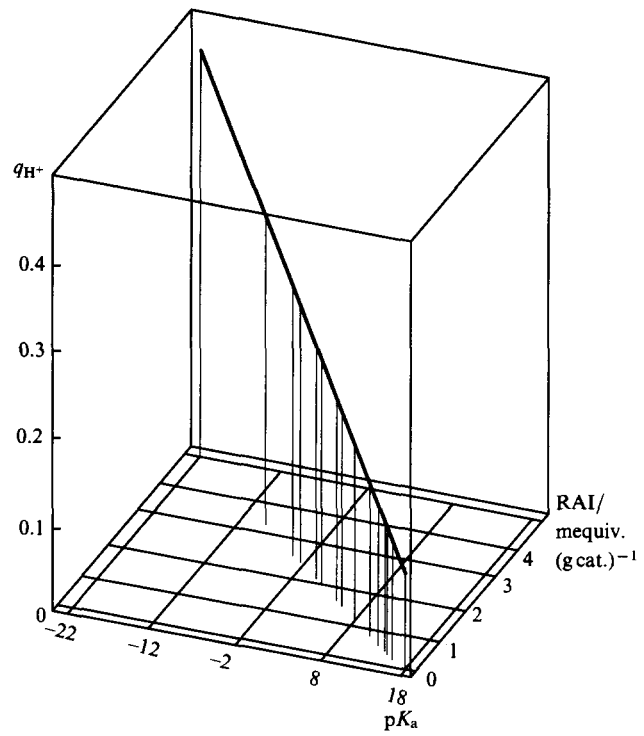

Figure 5. Relation between the parameters characterising the acidity of electrophilic catalysts (pK_a, RAI, q_{H^+}) (according to the data in Table 1).

character of both the methods for the estimation of the parameters of the acid strength of electrophilic chemical compounds and of the rather simple relation between them.

Analysis of the literature data and the results obtained[1-13, 17, 21, 25, 37, 40-49, 56-61, 69, 70] (Tables 1-4, 9, and 10) shows that the numerical values of the parameters characterising the acidity of electrophilic catalysts based on metal chloride complexes (q_{H^+}, pK_a, RAI) are a measure of their effectiveness and activity and of the selectivity of their action in various types of reactions occurring with participation of carbonium ions. The following rule is fairly strictly obeyed: the higher the relative acidity of the electrophilic systems formed in the interaction of Lewis acids with proton donors, the higher the activity but the lower the selectivity of the catalyst for processes occurring with participation of carbonium ions. Under these conditions (Fig. 6), there exist both an upper limit (the catalyst is extremely active, the contribution of side and secondary reactions is large) and a lower limit (extremely low activity of the catalyst) to the effectiveness of the action of catalytic systems (Fig. 6):

(a) $pK_a \gg 11$ [RAI $\leqslant$ 0.9 mequiv. (g cat.)$^{-1}$]—low acidity parameters; such catalytic systems are inactive in many electrophilic processes or their activity is low {ROH, H_2O, $H[R_3AlOH]$, $H[R_3AlOR]$, etc.};

(b) $-10 \ll pK_a \ll +11$ [RAI in the range from 0.9 to 3.0 mequiv. (g cat.)$^{-1}$]—optimum acidity parameters: the catalytic systems exhibit a fairly high activity and selectivity:

(c) $pK_a \leqslant -10$ [RAI $\geqslant$ 3.0 mequiv. (g cat.)$^{-1}$]—high acidity parameters. In this case an extremely high activity but as a rule a low selectivity are characteristic of the catalytic systems {$H[AlCl_3OH]$, $H[BF_4]$, etc.}.

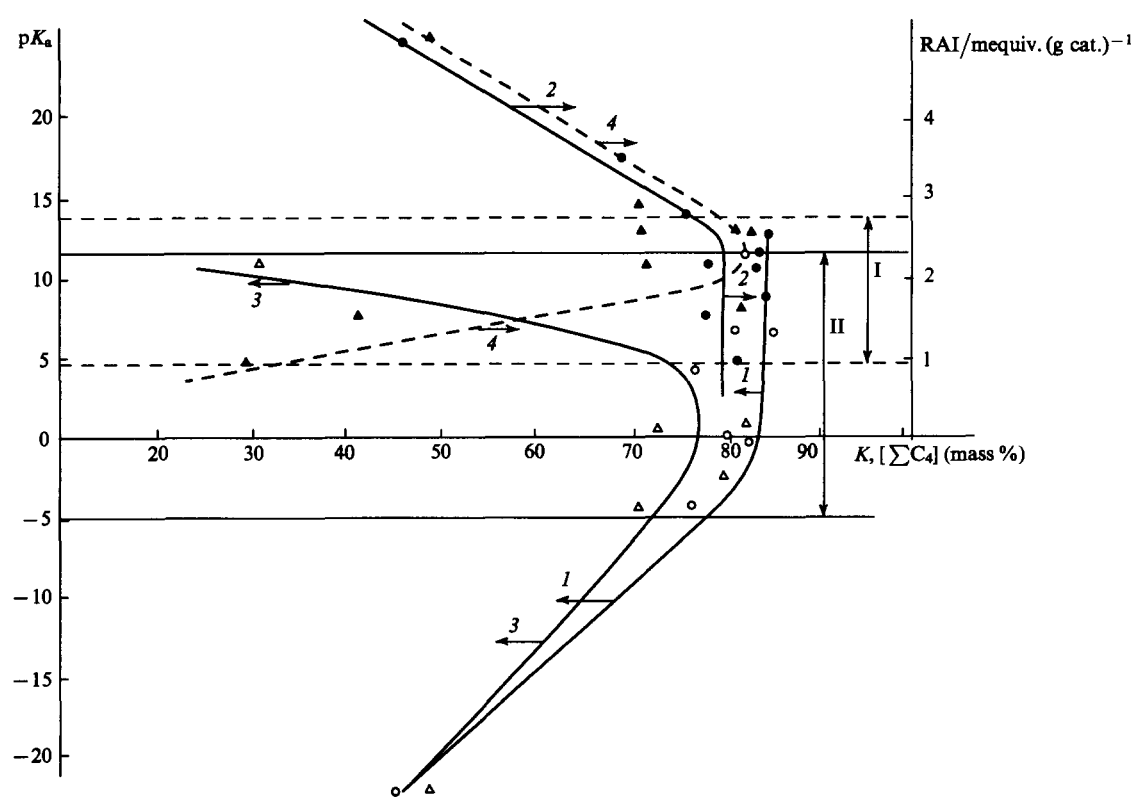

Figure 6. Conventional regions of the optimum values of pK_a (continuous lines) and RAI (dashed line) corresponding to the activity indices [K (mass %)] and selectivity indices {[$\sum C_4$], (mass %)} of the electrophilic catalysts $MCl_n \cdot H_2O$ and $[M'MCl_n] \cdot H_2O$ in relation to the thermocatalytic degradation of high pressure polyethylene ($\overline{M}_n = 22\,000$), [Cat] = 1 × 10^{-3} mol g^{-1}; T = 623 K, 1 h. Curves: (*1*) [$\sum C_4$] = $f(pK_a)$; (*2*) [$\sum C_4$] = f(RAI); (*3*) K = $f(pK_a)$; (*4*) K = f(RAI).

We may note, however, that in all probability the boundary values of the acidity parameters quoted may shift in the general case in one direction or another depending on the nature of the chemical process, the molecular structure, the solvent employed, etc. evidently mainly in view of the change in situ of the parameters of the acid strength of the electrophilic catalytic system employed.

The acidity of the classical catalysts for electrophilic processes, in particular $AlCl_3$ and BF_3, can be reduced by combining them with moderately basic chlorides of *s* or *d* elements. The class of the relatively new electrophilic catalysts, formed as a result of the interaction of halogen-containing compounds of aluminium with alkali or alkaline earth metal chlorides having the general formula $H[MAlR_nCl_mOH]$, where $n = 0$ or 1 and $m = 4$ or 3 for Na, Li, and K and 5 or 4 for Ca, Ba, Mg, Sr, Zn, Co. etc., is of interest in this connection.

VIII. Conclusion

The Brønsted acids comprising the complexes of Group II – VIII metal chlorides, which have a reduced acidity compared with $AlCl_3$ and are formed, in particular, as a result of the interaction of aluminium chlorides with Group I and II metal chlorides in the presence of proton-donating compounds (H_2O, ROH, etc.), are promising polyfunctional catalysts for many electrophilic reactions, in particular cationic polymerisation processes, the depolymerisation of oligo- and poly-alkenes, the degradation of macromolecules, the alkylation, hydrogenation and dehydrogenation of unsaturated hydrocarbons, the dehydrogenation of alkanes and alicyclic compounds, the desulfurisation (hydrogenolysis) of organosulfur compounds, etc. In the presence of such systems, such reactions proceed fairly selectively with a relatively high degree of conversion and under extremely mild experimental conditions (atmospheric pressure, $T = 270 - 650$ K).

An important factor is that the acidity of the chemical compounds may serve as the criterion determining the electrophilic activity of the catalysts and the selectivity of their action, i.e. their effectiveness. In all probability, by estimating the acidity indices of the catalysts of electrophilic processes, one may predict to a first approximation their effectiveness. The construction of characteristic relations (Figs. 5 and 6) for the series of electrophilic reactions occurring via the carbonium ion mechanism is of extremely great interest in this connection. The observed relations make it possible to estimate the postulated catalytic activity and selectivity of the action of potential electrophilic catalysts, to predict the direction of the changes in the activity and selectivity of the electrophilic catalysts, and to seek on this basis new catalysts for specific electrophilic chemical processes.

This review has been written with the financial support of the Academy of Sciences of the Bashkortostan Republic (Grant No. 166).

Advances in the synthesis of polyoxometalates and in the study of heteropolyacids

G M Maksimov

Contents

I. Introduction 445
II. Polyoxometalates with known structures 446
III. Polyoxometalates known in the form of protic acids 447

Abstract. The review surveys data on the known structures of polyoxometalates. The changes in this field which have occurred in the last ten years are traced. Heteropolyacids are considered in detail as a special case of polyoxometalates: their composition and structure, methods of synthesis, stability, and acidity. The bibliography includes 309 references.

I. Introduction

Polyoxometalates are an extensive class of polyoxoanions formed by Group V and VI metals.[1-3] They can be represented by the general formulae $(M_mO_y)^{x-}$ [isopolyanions (IPA)] and $(X_nM_mO_y)^{x-}$ [heteropolyanions (HPA)], where M = Mo, W, and V and, more rarely, Nb, Ta, or a mixture of these elements in the highest oxidation states, while X is a heteroatom. Iso- and hetero-polyanions are historic terms assigned at the time to families of typical representatives of these classes. As the chemistry of these compounds developed (particularly vigorously during the last 25 years), the boundary between IPA and HPA began to blur, which led to a more general name — polyoxometalates.[1] It has recently been suggested[2] that a still more general name be employed — metal–oxygen clusters. However, careful examination shows that IPA and HPA constitute merely an island (although a substantial one) in the vast sea of metal–oxygen clusters. We shall therefore employ for the time being the term polyoxometalates or polyoxoanions. The term heteropolyanions has been firmly retained for the special case involving the presence of one or several heteroatoms X within the ligand sphere of a polyoxometalate with X–O bonds. This applies also to the free protic acids corresponding to the HPA — they are unambiguously referred to as heteropolyacids (HPAC).

The set of elements M incorporated in polyoxometalates is restricted to atoms having a suitable combination of ionic radius and charge and capable of forming element — oxygen $d\pi-p\pi$ bonds. For the heteroatoms X, there is no such limitation. Bearing in mind that the heteroatoms can exist not only within but also outside the polyoxometalate sphere, it is clear that virtually all the elements of the Periodic System can serve as the heteroatoms X with the exception of the noble gas subgroup. The diversity of the X and M atoms and of their proportions is responsible for the existence of an enormous number of polyoxometalates.

The range of applications of these compounds is fairly wide and includes fields such as catalysis, analytical chemistry, medicine, electronics, protective coatings, and many others. The continuously growing interest of investigators in HPA and IPA is indicated by the extensive review literature. During the 10 years which have elapsed since the publication of Pope's monograph in 1983,[1] about 100 reviews have been published in English, German, Russian, Japanese, Chinese, Polish, Czech, and Spanish on the synthesis, structure, properties, and applications of HPA and IPA. We shall mention some of the most complete and interesting reviews. Thus the structures of polyoxometalates have been examined in Refs 2 and 4–7, and their spectra in Refs 8 and 9. The application of polyoxometalates in catalysis,[10-14] in analytical chemistry,[15-19] for the preparation of photochromic coatings,[20] and in pharmacology[17] has been described in fair detail. There are reviews on the use of polyoxometalates in electrocatalysis[21] and photocatalysis.[22] More than half of all the reviews are devoted to the use of polyoxometalates in catalysis, which indicates their effectiveness as catalysts. One may say that to a large extent the studies on IPA and HPA (especially HPA and HPAC) have been associated with their use in catalysis. The frequency of the publication of reviews concerning the structure, chemistry, and applications of polyoxometalates in catalysis and analytical chemistry is sufficient to trace the rapid changes in these branches of knowledge. At the same time, for a long time (20 years) there have been no reviews on the chemistry of defective HPA and their complexes, whilst a detailed review on the chemistry of HPAC[3] was published more than 30 years ago.

The elaborate chemistry of IPA and HPA has led to the existence of an enormous amount of spectroscopic data, the reviews and catalogues of which are extremely useful but their number is small. A review on nontraditional applications of IPA and HPA, including nontraditional catalytic reactions, has also been useful.

The question of the industrial application of polyoxometalates has been dealt with to a very slight extent indeed. Apart from the wide scale general application of HPA for analytical purposes on an industrial scale and in research laboratories, only the employment of HPA and HPAC as catalysts has been described.[11,20,23-25]

The aims of the present review are as follows: to trace the changes in the structural chemistry of polyoxometalates which have taken place after the publication of Pope's monograph[1] and to represent their entire diversity. Particular emphasis is laid on

the study of the present state of the chemistry of HPAC in connection with properties which are important for their employment in acid catalysis.

II. Polyoxometalates with known structures

After the publication of Pope's classical work,[1] an enormous number of communications concerning the determination of the structures of polyoxometalates by X-ray diffraction (XRD) appeared. In the course of only ten years, the number of new structures trebled. The extensive introduction of high-resolution NMR spectroscopy into practical research made it possible also to obtain in many instances data the information content of which was close to that of XRD results. This contributed significantly to progress in the chemistry of polyoxometalates. It is nowadays impossible to make any kind of reliable judgments about the structure of a new polyoxoanion without resorting to XRD or NMR spectroscopic data.

The principles governing the construction of polyoxometalates have been examined in detail[1,2,4,5] and we shall therefore not deal with this question. The empirical formulae of all the known IPA and HPA, which exist in solution in the form of discrete anions, polymeric anions, and anions detected only in the solid state and whose structures have been established,[26-93] are presented below. Their common feature is their synthesis in solution or from solution. The structures, differing in the construction of the inorganic framework of the anion, are indicated for organic IPA and HPA derivatives. The inorganic framework is understood as a three-dimensional lattice consisting mainly of Mo, W, V, and Nb (sometimes Ta and Cr) atoms to which the atoms of any elements other than C, N, and H are attached. The criteria for the differentiation of the structures are as follows: the number of atoms in the inorganic framework, the disposition of the atoms relative to one another without taking into account the type of atoms, the way in which the atoms are joined together, and isomerism. The structural distortions associated with changes in the type of atoms (for example, when W is replaced by Mo, P by As, etc.) are not taken into account and the fine details in the secondary structure (the disposition of the anions and countercations in the crystal lattice) are also disregarded, apart from the instances where the cations are linked directly to the framework of the anion (for example, in lanthanum decavanadate). When a homologous series exists, the general structural formula is indicated (R is the organic residue). If a single representative of the given structure is known, the complete composition of its anion is indicated.

For each structure, the literature references are given to one source (for an homologous series, as a rule the first source) in which the structure has been adequately described or to the only source available (so far as possible, references are given to reviews in which the structures are described). The IPA and HPA whose structures have been determined by X-ray diffraction are listed.

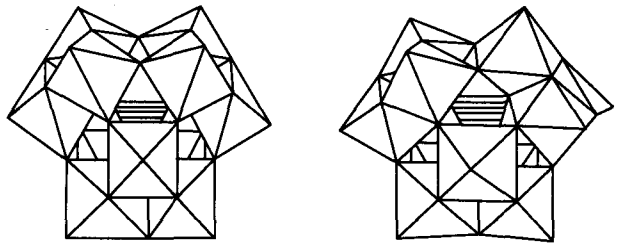
The $Mg_8SiW_9O_{37}$ isomers have been described insufficiently clearly[75] which gives rise to doubts concerning their genuine existence.

Polyoxometalates with a degree of condensation of the atoms M in the polyanion not less than 4 are listed above. One cannot fail to recognise that such subdivision appears somewhat artificial because species with degrees of condensation of 2 and 3 actually belong to the class of polyoxoanions. Pope[1] began his consideration of polyoxometalates with the lowest polyoxoanions (with a degree of condensation of 2 but without organic derivatives), while Chen and Zubieta [6] considered polyoxoanions with a degree of condensation of 3. The remaining reviews on IPA and HPA are frequently restricted to the description of the structures of polyoxoanions beginning with degrees of condensation of 5 or 6 without an explanation of such restriction. Thus by the time the present review was written, the structures of 176 polyoxometalates had been determined by X-ray diffraction. The existence of a further 36 structures has been postulated on the basis of some kind of spectroscopic data. In addition, there exist polyoxometalates (several tens) the structural formulas of which are based solely on the results of elemental analysis.

III. Polyoxometalates known in the form of protic acids



As already mentioned above, the interest in HPAC and their salts has been induced to a large extent by their use in catalysis and in the first place in acid catalysis. A large number of a wide variety of HPAC are known, but only some of them are used in laboratory practice, such as $H_3PMo_{12}O_{40}$, $H_3PW_{12}O_{40}$, $H_4SiW_{12}O_{40}$ and, much more rarely, $H_6P_2Mo_{18}O_{62}$ and $H_6P_2W_{18}O_{62}$. In our view, this is a consequence of the insufficient amount of information as to which HPAC exist. Experience gained in the use of HPAC in acid catalysis has shown that the effect of the HPAC does not always reduce solely to their action as strong acids. The properties of HPAC (including catalytic properties) differ significantly and sometimes also fundamentally depending on their structure and composition. In this sense, there still remains much to be done by investigators. In contrast to polyoxometalates as a whole, the number of new HPAC obtained during the last ten years has changed little. Only a few new HPAC with the Keggin structure and one HPAC of a new structural type have been synthesised. Apparently, the main types of HPAC have already been dis-covered, but the possibilities for the variation of the composition within the structural types are still great.

This section presents data on HPAC which exist in the solid state or at least in the form of a concentrated (not less than 0.1 M) solution. The properties of HPAC important for their employment in acid catalysis are listed briefly below: composition and structure, stability, acidity, and availability.

For the sake of brevity, henceforth abbreviated designations of HPAC will be used in the text (without H and O atoms), indicating the composition of the inorganic framework.

1. Heteropolyacids with the Keggin structure

In terms of a number of known compounds, HPAC with the Keggin structure constitute the most extensive and important class of polyoxometalates. It has been named after Keggin, the English investigator who first determined accurately the structure of the HPA anion of this class (Fig. 1).[1] Table 1 presents the compositions and temperatures of the onset of decomposition of the known HPAC with the Keggin structure, the existence of which is not open to doubt.

a *b*

Figure 1. The structures of the α- (*a*) and β-isomers (*b*) of Keggin HPAC: 12 MO_6 octahedra surround the XO_4 tetrahedron.

There is no doubt about the existence of the following HPAC with the Keggin structure:

$\alpha\text{-}H_3PW_{12}O_{40-n}(O_2)_n$, $n=1-4$ (not isolated in the solid state) [113]
$\beta\text{-}H_4SiW_{12}O_{40}$ [114]; $\beta\text{-}H_4GeW_{12}O_{40}$ [114]
$\alpha\text{-}H_6CoW_{12}O_{40}$ [3,123–125]
$\alpha\text{-}H_{6-n}H_2W_{12}F_nO_{40-n}$, $n=1-3$ [126]
$\beta\text{-}H_3PMo_{12}O_{40}$ [127]; $\beta\text{-}H_4SiMo_{12}O_{40}$ [110,129]
$\alpha\text{-}H_4GeMo_{12}O_{40}$ [3,129]; $\beta\text{-}H_4GeMo_{12}O_{40}$ [129]
$\alpha\text{-}H_4TiMo_{12}O_{40}$ [3,130,131]; $\alpha\text{-}H_3AsMo_{12}O_{40}$ [1,132]
$\beta\text{-}H_8AsMo_{12}O_{40}$ [1]; $H_7PV_{12}O_{36}$ [133]
$H_{3+n}PV_nW_{3-n}Mo_9O_{40}$, $n=1-3$ [136]
$H_5PV_2W_{10-n}Mo_nO_{40}$ [3]; $H_5PNb_2W_nMo_{10-n}O_{40}$ [137,138]
$\alpha\text{-}H_4PW_{11}NbO_{40}$ [141,142]; $H_4VW_{11}VO_{40}$ [144]
$H_5PW_{10}Nb_2O_{40}$ [142]
$H_5VW_{10}V_2O_{40}$ (not isolated in the solid state) [144]
$H_6SiW_{10}Nb_2O_{40}$ [147]; $H_7BW_{10}V_2O_{40}$ [3,148]
$H_{4+n}SiW_{12-n}V_nO_{40}$ ($n=2-4$) [3,146]
$H_4SiMo_nW_{12-n}O_{40}$ [3,145]; $H_6GeW_{10}V_2O_{40}$ [3]
$H_5BW_6Mo_6O_{40}$ [148]; $H_5GeW_{11}VO_{40}$ [150]
$H_4PMo_{11}NbO_{40}$ [152,153]; $H_5PMo_{10}Nb_2O_{40}$ [110]
$H_5SiMo_{11}NbO_{40}$ [157]; $H_6GeMo_{10}V_2O_{40}$ [3]
$H_7H_2W_{11}CrO_{39}$ (not isolated in the solid state) [158,159]

The existence of the following HPAC requires further confirmation (the temperatures of the onset of decomposition in the solid state in °C are given in brackets):

$H_6H_2W_{11}MnO_{39}$ [159]; $H_6CuW_{12}O_{40}$ [160]
$H_5AsW_{10}V_2O_{40}$ [161]; $H_5AsMo_{10}V_2O_{40}$ [161]
$H_6AsMo_9V_3O_{40}$ [161]; $H_7AsMo_8V_4O_{40}$ [162]
$H_3SbMo_{12}O_{40}$ [163]; $H_4CW_{12}O_{33}(O_2)_7$ [164]
$H_6H_2W_{12}O_{33}(O_2)_7$ [164]; $H_4SiW_{11}CrO_{40}$ (~300) [165]
$H_4SiW_{11}AlO_{39}$ [166]; $H_5GeW_{11}SnCo(CO)_3^-$
$P(C_6H_5)_3O_{39}$ [167]

The following are the heteropolyanions the existence of which is not open to doubt:

$H_4ZrW_{12}O_{40}$ [168]; $H_4TeW_{12}O_{40}$ (200) [169,170]
$H_4SeW_{12}O_{40}$ (47) [168,171]; $H_8SeW_8V_4O_{40}$ (187) [171]

[a] The temperature of the onset of decomposition in the solid state.
[b] At a heating rate of 300 K per hour.

The diversity of the HPAC is due to the variation of the central heteroatom X and of the composition of the ligand sphere. The available information about certain HPC, listed above (mainly with different X), has not been confirmed by reliable spectroscopic data and is based solely on the results of chemical analysis. The existence of these compounds requires further confirmation. For example, As^{5+} tends to form HPA of the type As_2W_{21} and As_2Mo_{18}, while HPA of the Keggin type are not characteristic of this anion. However, the introduction of vanadium into the ligand sphere sometimes stabilises the particular HPA structure (instances of stabilisation for $X = V^{5+}$ or S^{6+} have been accurately established) and the formation of stable HPAC having the composition $H_{3+n}As.(W, Mo)_{12-n}V_nO_{40}$ is therefore possible.

The existence of zirconium-containing HPAC is doubtful because Zr^{4+} is too large to be accommodated in the central cavity of the Keggin HPA. Furthermore, it does not form compounds with a coordination number of 4. ZrW_{12} was synthesised from the fluoride complex. Bearing in mind that fluorine forms a very stable complex with Zr^{4+},[168] one can postulate that this compound is in fact a fluorine-containing HPAC with an unknown structure.

As stated correctly by Pope,[1] in the study of HPAC with $X = Se^{4+}$, Te^{4+}, or As^{3+} 'one cannot ignore the influence of the lone pair of the heteroatom'. The compounds $PMo_{12-n}V_n$ are stable for $n = 1-3$.[179] In the synthesis of compounds with $n > 3$ by known methods, the latter undergo partial decomposition with loss of vanadium, the loss being greater the higher the value of n. HPAC with $n > 3$ can be scarcely obtained in a pure form.[142,146,179] It has been shown by spectroscopic methods that, on decomposition of $PMo_{12-n}V_n$, a certain amount of vanadium passes to the cationic component with simultaneous ejection of the excess phosphorus in the form of H_3PO_4.[179,180] The chemical composition of the mixture does not then change, or the change is much less than the extent of the synthesis of HPAC. For this reason, the postulated HPAC with $n = 4-7$ are most probably a mixture of HPAC with $n = 1-3$, H_3PO_4, and VO_2^+.

HPAC known not to exist (the corresponding HPA are stable in nearly neutral media) are sometimes mentioned in patents devoted to the application of HPAC in catalysis. Such non-existent HPAC include $H_nPW_9X_{3-n}Z_xO_{37}$ ($n = 6-7$; $x = 0, 1$; $X^{3+} = Fe^{3+}$, Cr^{3+}, $Z^{2+} = Co^{2+}$, Mn^{2+}, Zn^{2+}, Ni^{2+}),[181] $H_6P_2Mo_5O_{23}$, $H_9CoW_6O_{24}$, $H_7AsMo_{11}O_{39}$, $H_9PMo_9O_{34}$,[182] etc. In such cases, it is more correct to speak of catalysts having the corresponding composition and not of the individual HPAC. This also applies to $SiMo_{10}Sn_2$.

A whole series of HPAC with the Keggin structure have been obtained by cation exchange—for example, $H_2W_{11}Mo$,[183] $TlMo_{12}$,[184] $InMo_{12}$,[185] and the complex HPAC having the composition $X(Mo \text{ or } W)_{11}Z$.[1,186–193] They exist in the form of dilute solutions. Virtually nothing is known about the possibility of their existence in the solid state or in the form of concentrated solutions.

The replacement of W or Mo in the ligand sphere of the HPAC by V has an unambiguous effect on the stability of the HPAC. In terms of their stability in aqueous solutions, HPAC can be arranged in the following sequences:

$$PMo_{11}V > PMo_{12} > PMo_{10}V_2 > PMo_9V_3$$ [194]

$$SiMo_{12} > SiMo_{11}V > SiMo_{10}V_2$$ [195]

$$PW_{12},\ PW_{11}V,\ PW_{10}V_2 > PW_9V_3 > PW_9V_4$$ [139]

$$VW_{10}V_2 > VW_{11}V > VW_{12}\ \text{(hypothetical)}.$$[144]

All the vanadium-containing HPAC are in fact mixtures of HPAC with different values of n.[139,144,179,195] Only $PMo_{11}V$ and $PW_{11}V$ have been synthesised relatively easily.

$PMo_{12-n}W_n$,[179] $PW_{12-n}Nb_n$,[142] and apparently all the remaining mixed-ligand HPAC with $n > 1$ are also mixtures.

The stabilities of various HPAC in aqueous solution have been investigated by ^{17}O NMR methods (based on the rate of isotope exchange with $H_2^{17}O$) and by observing the formation of deposits in concentrated solutions (Table 2). The following HPAC stability series have been constructed on the basis of these data:

$$SiW_{12} > PW_{12} \gg PMo_{12} > SiMo_{12} > GeMo_{12}\ .$$

Hence it is seen that the composition of the ligand sphere has a greater influence on the stability of HPAC than X: HPAC with W are much more stable than those with Mo. The products of the hydrolysis of these HPAC have also been investigated. On hydrolysis of $SiMo_{12}$ and $GeMo_{12}$, deposits of MoO_3, SiO_2, and GeO_2 were precipitated from the solutions. $MoO_3(H_2MoO_4)$ was also precipitated from the PMo_{12} solution, the compound P_2Mo_{18} accumulating in the solution in accordance with the postulated reaction

$$PMo_{12} \longrightarrow PMo_9 \longrightarrow P_2Mo_{18}\ .$$

PW_{12} is apparently hydrolysed via a different mechanism:

$$PW_{12} \longrightarrow PW_{11} + WO_4^{2-}\ .$$

The hydrolysis of PW_{11} does not proceed any further.[196] A series of various tungsten-containing HPAC in terms of their resistance to acid hydrolysis in concentrated aqueous solutions has been

Table 2. Hydrolytic properties of HPAC in aqueous solutions.

HPAC	Temperature/ °C				
	70	110	200	250	270
$SiMo_{12}$	x	x	–	–	–
PMo_{12}	o	x	–	–	–
PW_{12}	o	o	o	+	+
P_2W_{18}	o	o	o	o	o
SiW_{12}	o	o	o	o	o
P_2Mo_{18}	o	o	x	–	–

Note. The solutions were kept in sealed tubes for 24 h (c_{HPAC} = 0.45 M (Keggin) and 0.225 M (Dawson).[196] Here and henceforth the following designations have been adopted: o — compound stable (no deposit); + — compound partly stable (solution turbid but a deposit is not precipitated); x — compound unstable (appreciable deposit); * compound almost stable.

constructed on the basis of experiments on ether extraction in the presence of inorganic acids:

$$PW_{12},\ P_2W_{21},\ P_2W_{18} > PW_{11}Ti > (PW_{11})_2Ce^{4+} > PW_{11}Ce^{4+},\ PW_{11}Cr^{3+} > PW_{11}Zr,\ PW_{11}Bi.$$

In these experiments, the compound $PW_{11}Cr^{3+}$ was obtained as a relatively unstable component in a mixture with PW_{12} and P_2W_{21}.[143] In organic and aqueous organic media, the HPAC are most stable than in water.[110]

The hydrolytic transformations in dilute solutions have been investigated only in relation to PMo_{12}. At a concentration of 0.01 M and below, PMo_{12} decomposes in water, affording unsaturated HPA of the type PMo_{11} and PMo_9 apparently via a mechanism involving alkaline hydrolysis as a result of the decrease in the acidity of the solution. At a concentration of 0.001 M, there is virtually no initial HPAC in the solution.[197] On the basis of general data indicating a decrease in the degree of polymerisation of tungsten and molybdenum following dilution of solutions,[198] it is reasonable to suggest that all the HPAC should hydrolyse in dilute solutions although to different extents and at different rates. One should apparently treat with extreme caution all data concerning dilute (less than 0.01 M) solutions of the HPAC.

Numerous published data on the thermal stabilities of HPAC (see above) should also be treated with care. The assignment of the position of the exothermic peak on the differential thermal analysis curve to the HPAC decomposition temperature is a source of numerous errors.[110] Under these conditions, factors such as the dependence of the rate of decomposition of the HPAC on the heating rate and the possibility of structural changes initiated by the supply of heat are frequently ignored. Thus, decomposition temperatures which are clearly too high have been indicated for HPAC such as (the decomposition temperatures are indicated in brackets in °C) PW_{12} (620), SiW_{12} (530), BW_{12} (420), etc.[199] In this connection, the study[112] where the measurements were accompanied by monitoring involving the ^1H NMR method appears accurate. It was stated in the corresponding communication that not all the HPAC can be obtained in the anhydrous state. Thus H_2W_{12}, BW_{12}, $SiMo_{12}$, and $GeMo_{12}$ decompose during dehydration.

Tsigdinos[110] suggested that the thermal stability be estimated by the method involving a check of the solubility of the HPAC after heat treatment under isothermal conditions. This method demonstrated that the HPAC with molybdenum decompose slowly even at room temperature, the decomposition accelerating above a certain temperature (350 °C for PMo_{12} and 200 °C for $SiMo_{12}$). This method was applied also to other HPAC (Table 3). A HPAC thermal stability series was constructed:

$$PW_{12} > PMo_{12} \gg SiW_{12} > GeMo_{12} > SiMo_{12}.$$

Table 3. Thermal stabilities of HPAC estimated by the Tsigdinos method (2 g of the HPAC was heated for 3 h in air and then stirred in 50 ml of water for 30 min).[196]

HPAC	Isothermal heat-treatment temperature/°C						
	180	250	300	350	370	390	400
$SiMo_{12}$	+	x	x	–	–	–	–
$GeMo_{12}$	o	o	+	–	–	–	x
SiW_{12}	o	o	*	*	*	+	x
PMo_{12}	o	o	o	o	o	+	x
PW_{12}	o	o	o	o	o	o	o

It did not agree with the hydrolytic stability series.[196] The Tsigdinos method makes it possible to estimate to some extent the thermal stability of the HPAC but does not take into account the possibility of solid-phase transformations.

The thermal transformations have been investigated in detail in relation to the following compounds: $SiMo_{12-n}V_n$, $PMo_{12-n}V_n$, PW_{12}, $PW_{11}Z$, and PMo_{12}. It has been shown with the aid of the NMR method that a mixture of $SiMo_{11}V$ and $SiMo_{10}V_2$ decomposes smoothly in the temperature range between 110 and 400 °C.[155] $SiMo_{11}V$ decomposes fully at 300 °C,[200] while $SiMo_{10}V_2$ is relatively stable up to 200 °C and its complete decomposition takes place in the temperature range 300 to 400 °C.[156] No structural rearrangements occur under these conditions.

The heteropolyacids $PMo_{12-n}V_n$, (n = 1 – 3) become insoluble after heat treatment at 200 – 400 °C,[201] their thermal stability diminishing with increase in n. The data on the decomposition temperatures, determined with the aid of derivatographic measurements and vibrational spectroscopy, are different in the studies of different authors (Table 4). The observed tendency[151,203] appears correct, but, bearing in mind the decrease in solubility,[201] the values obtained appear too high. Complete dehydration takes place in the temperature range between 380 and 410 °C.[202] The mechanism of the thermal decomposition of the vanadium-containing HPAC has been investigated. It was found that during heat treatment vanadium and phosphorus are ejected, compounds with a smaller vanadium content being stabilised under these conditions.[204]

After heat treatment for 2 – 5 h at 110 – 400 °C, the acid PW_{12} fully retains its solubility and the ^{31}P NMR spectrum also remains unchanged under these conditions (– 15.0 ppm). After heat treatment at 500 °C, the HPAC becomes partly soluble and new lines appear in the ^{31}P NMR spectrum at – 12.5 and – 13 ppm. Above 600 °C, the PW_{12} is fully insoluble.[205] It has been established by X-ray diffraction that the HPAC begins to change at 400 °C.[111] Salt-forming protons begin to be removed at 420 °C without the formation of the WO_3 phase.[206,207] Different investigators apply the same term (anhydride) to the phase formed at 420 °C, but they attribute different structures to it: $PW_{12}O_{38.5}$[208] or $PW_{12}-O-PW_{12}$.[207] The problem of the real structure of PW_{12} in the temperature range 400 – 500 °C remains obscure.

Table 4. Decomposition temperatures of HPAC of the type $PMo_{12-n}V_n$.

HPAC	n	T_{decomp}/°C	Ref.
PMo_{12}	0	433	203
$PMo_{11}V$	1	442	151
$PMo_{10}V_2$	2	412	151
PMo_9V_3	3	396	151
PMo_8V_4	4	293	203
$PMo_{12-n}V_n$	0 – 3	460	202

The thermal stability of complex HPAC of the type $PW_{11}Z$ (Z = Ti, Zr, Bi, Ce) has been investigated by IR and ^{31}P NMR spectroscopy after heat treatment under isothermal conditions. It was found that $PW_{11}Ti$ and $PW_{11}Zr$ are stable up to 450 °C (the decomposition to oxide phases takes place in the temperature range 450–500 °C), while $PW_{11}Bi$ decomposes partially at temperatures above 150 °C and fully at temperatures above 300 °C with formation of the bismuth salt of PW_{12}. The complex $PW_{11}Ce^{4+}$ begins to be converted into $(PW_{11})_2Ce^{4+}$ even at 150 °C and disappears from the thermolysis products in the temperature range 300–400 °C depending on the heat treatment time. After heat treatment, the specimens dissolve incompletely owing to the formation of Ce^{3+} salts. Owing to the subsequent decomposition of $(PW_{11})_2Ce^{4+}$, PW_{12}, H_3PO_4, and $PW_{11}Ce^{3+}$ appear in the thermolysis products. In terms of their thermal stabilities, cerium-containing HPAC can be arranged in the following sequence:[143]

$$PW_{11}Ce^{3+} > (PW_{11})_2Ce^{4+} > PW_{11}Ce^{4+}.$$

Numerous studies have been devoted to the problem of the thermal stability of PMo_{12}. Most information has been obtained by means of a combination of the methods of thermal analysis, X-ray diffraction, and ^{31}P NMR spectroscopy.[197,209] The PMo_{12} specimens retain their complete solubility after heating to 350 °C. At 385 °C, the specimens still dissolve almost completely but more slowly. After heat treatment at 400 °C and above, the specimens dissolve only partially, the Mo : P ratio in the solutions differing from 12 : 1.[197] The following scheme has been proposed for the thermal transformation on the basis of the results:[209]

$$H_3PMo_{12}O_{40}\cdot n\,H_2O \underset{n\,H_2O}{\overset{200-350\,^\circ C}{\rightleftharpoons}} H_3PMo_{12}O_{40} \underset{\sim 1.5\,H_2O}{\overset{385\,^\circ C}{\rightleftharpoons}}$$

$$\rightleftharpoons H_xPMo_{12}O_{38.5+0.5x} \xrightarrow{> 400\,^\circ C}$$

$$\longrightarrow (PMo_{12}O_{38.5})_n + MoO_3 + (MoO_2)_2P_2O_7 \xrightarrow[50\%]{450\,^\circ C}$$

$$\longrightarrow MoO_3 + (MoO_2)_2P_2O_7$$

$x \sim 0.1$

The phase with $x = 0.1 - 1.0$ is readily soluble in air with a humidity of 80%–90% and is converted into PMo_{12} in 2–4 days. It has been suggested[197] that the $(PMo_{12}O_{38.5})_n$ phase is the cationic-anionic complex $[PMo_{12}O_{39}^{-}][PMo_{12}O_{38}]^{+}$. The anionic part of the complex readily interacts with water, while the cationic component reacts with difficulty but also with regeneration of the initial HPAC.

The formation of the anhydride (or anhydride phases) is apparently a common feature of those HPAC which can exist in the anhydrous state. A partial loss (5%–10%) of protons occurs even on simple dehydration of the HPAC.[112] A gradual loss of protons in the temperature range 300–450 °C has also been noted for ZnW_6Mo_6.[149]

The decomposition temperatures of the mixed HPAC $SiMo_{12-n}W_n$ depend directly on n and have intermediate values between those for $SiMo_{12}$ and SiW_{12}.[210]

The Keggin heteropolyanions are capable of combining with electrons reversibly.[1] The corresponding HPAC also retain this property. Thus it has been possible to reduce PW_{12},[1] SiW_{12}, BW_{12}, H_2W_{12}[211] (by the addition of 6 $\bar{e}$), $SiMo_{12}$,[128] and PMo_{12}[212] (by the addition of 4 $\bar{e}$), fluorine-containing metatungstic acids[213] (by the addition of 6–24 $\bar{e}$), and many other HPAC (by the addition of 1–2 $\bar{e}$). The reduction has different effects on the properties of the HPAC. Thus the compound $AsMo_{10}V_2$ (provided that it exists) loses vanadium after the addition of two electrons.[161] The tungsten-containing compounds do not undergo a change in composition and structure on reduction (at least after the addition of 6 $\bar{e}$). The molybdenum-containing HPAC frequently undergo the isomerisation $\alpha \rightarrow \beta$.[1,110,212] For example, the following reactions take place on reduction in solution:

$$\alpha\text{-}PMo_{12} \xrightarrow{2^-} \alpha\text{-}PMo_{12}(2^-) \longrightarrow$$

$$\longrightarrow \beta\text{-}PMo_{12}(2^-) \longrightarrow \beta\text{-}PMo_{12}(4^-) + \beta\text{-}PMo_{12}$$

$$\downarrow 2^-$$

$$\beta\text{-}PMo_{12}(4^-)$$

The stable form β-PMo_{12} (4 $\bar{e}$) is rapidly reconverted into α-PMo_{12} on oxidation in water. In aqueous dioxane, this process is slower.[212] It is believed that α-$SiMo_{12}$ behaves similarly.[1,110] However, it has been found by X-ray diffraction that the reduced $SiMo_{12}$ (4 $\bar{e}$) has the structure of the α-isomer.[214]

The thermal stability of the reduced HPAC has been investigated in relation to $SiMo_{12}$. It was found that the specimens of the reduced HPAC are more stable than the initial $SiMo_{12}$. The reduced HPAC β-PMo_{12} (4 $\bar{e}$) is stable in aqueous solution up to 180 °C and is much superior in this respect to α-PMo_{12}.[215]

A high acidity is a most important property of the HPAC, which makes it possible to devise effective acid catalysts based on

Table 5. Acid dissociation constants of the HPAC in various solvents at 25 °C.[217]

HPAC	Acetone			Ethanol			Acetic acid
	pK_1	pK_2	pK_3	pK_1	pK_2	pK_3	pK_1

HCl	4.0	–	–	–	–	–	8.4
HNO_3	–	–	–	3.57	–	–	10.1

them. A lot of space is always devoted to this property in reviews concerning the applications of the HPAC. The acidity of the Keggin HPAC has been investigated by various methods, which include the indicator method, the measurement of the diffusion coefficients and ionic conductivities, ion exchange, thermal desorption of bases, ^1H NMR spectroscopy,[20] kinetic methods,[10,13,125,216] and measurement of dissociation constants in solutions (Table 5).

It has been shown that all the HPAC investigated are strong multibasic Brønsted acids. In solutions, they are stronger than inorganic acids such as H_2SO_4, HBr, HCl, HNO_3, and even $HClO_4$. This is due to the large size of the HPA (diameter 10–12 Å) combined with a relatively low charge. In water, the Keggin HPAC are fully dissociated and it is impossible to determine the first three dissociation constants. However, this can be done in polar organic solvents (see Table 5). The weak dependence of the strength of the HPAC on their composition is striking, although here too one can differentiate certain characteristic features: (1) the tungsten-containing HPAC are stronger than the molybdenum-containing HPAC; (2) with increase in the basicity of the HPAC, their acidity diminishes; (3) the acidity of the HPAC diminishes after reduction.

Some doubts about the measurements of the dissociation constants arise from the fact that they were made for highly dilute solutions ($\sim 10^{-5}$ M) and the individuality of the HPAC in them had not been confirmed. However, there are grounds for the assumption that the correction for the hydrolysis of the HPA may influence at the same time the dissociation constants of the HPAC without affecting the general trends observed.

After the introduction of vanadium atoms into the HPAC, their basicity increases whilst their acidity falls. At the same time, HPAC such as PMo_9V_3 and PW_9V_3 are protonated even in their solutions.[218,219] Not all the protons are equivalent in the pentabasic GaW_{12}.[220] The reduced PMo_{12} and $SiMo_{12}$ (4 $\bar{e}$) contain protons bound to the heteropolyanion, but they are all equally strong acids as regards the first 3–4 protons.[221,222] Even the highly reduced $H_2W_{12}F$ (12 $\bar{e}$) affords an amorphous brown powder, having the general composition $H_{19}W_{12}O_{39}F$, which retains its acid character.[213]

The acidity of concentrated solutions of HPAC in water is greater than the acidity of solutions of sulfuric and perchloric acids at the same concentration by 1–1.5 units of the Hammett acidity function H_0.[13,217] The acidity of concentrated solutions of HPAC diminishes in the sequence

$$SiMo_{12} > PMo_{12} > SiW_{12} \sim PW_{12} .$$

This sequence does not agree with that of the dissociation constants possibly owing to the salt effects or the influence of hydrolysis.

The acidities of HPAC in nitrobenzene have been estimated from the formation constants of complexes with chloral hydrate. The following series was obtained:[13]

$$PW_{12} > PMo_{12} > SiW_{12} \approx GeW_{12} > SiMo_{12} > GeMo_{12} .$$

It follows from the data presented that the acidities of different HPAC in solutions vary in different ways with concentration and the solvent.

The mixed HPAC of the type $XMo_{12-n}W_n$ also exhibit a high acidity in solution, the latter increasing with increase in n.[135,223] A high acidity is apparently a common feature of all the Keggin type HPAC.

It has been shown by conductimetric, IR spectroscopic, and thermal desorption methods that the HPAC retain a high acidity also in the solid state (higher than that of aluminosilicate). In anhydrous HPAC, the protons are localised, but their mobility increases at temperatures above 150 °C for PW_{12} and SiW_{12} and above 250 °C for PMo_{12} and $SiMo_{12}$. The catalytic activities of the solid HPAC in acid-catalysed reactions usually decrease in the sequence

$$PW_{12} > SiW_{12} \approx PMo_{12} > SiMo_{12} ,$$

which agrees fully with the acidity series in solutions.[13]

According to adsorption calorimetric data, the proton centres of PW_{12} are fairly uniform and have strengths similar to those in H-mordenite; PW_{12}, which is believed to be the strongest acid among the HPAC, has acid centres with $H_0 < -8.2$.[20] Superacids with $H_0 = -14.52$ and even less can be obtained by combining the HPAC with $SbCl_5$.[224]

The distribution of the acid centres of PW_{12} and SiW_{12} in terms of strength has been investigated in detail by the indicator method combined with titration by n-butylamine (Fig. 2). The largest number of strong acid centres with $H_0 \leqslant -5.6$ have been observed in the HPAC after heat treatment in the temperature range 300–400 °C, their number diminishing sharply above 400 °C. The compound PW_{12} has a larger number of acid centres than SiW_{12}.[225] Such behaviour of the HPAC agrees well with their thermal stability data.

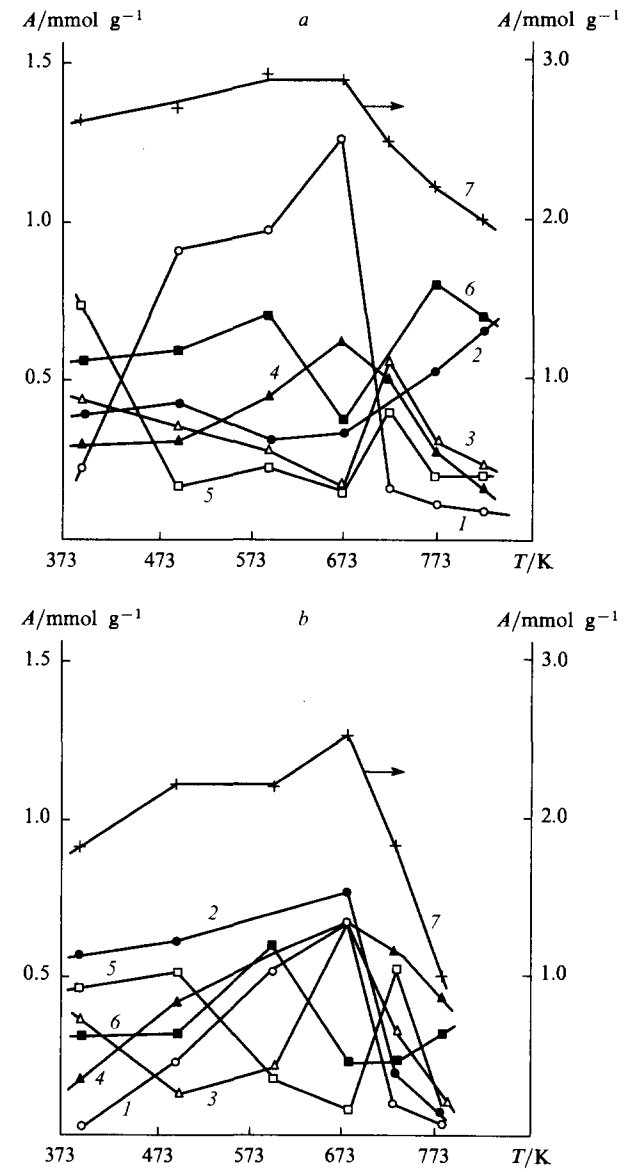

Figure 2. Distribution of the acid centres (A) in PW_{12} (a) and SiW_{12} (b) as a function of temperature.[225] Theoretical numbers of proton centres: 1.04 for PW_{12} and 1.39 for SiW_{12}. Hammett acidity functions: (*1*) $H_0 \leqslant -5.6$; (*2*) $-5.6 < H_0 < -3.0$; (*3*) $-3.0 < H_0 < 1.5$; (*4*) $1.5 < H_0 < 3.3$; (*5*) $3.3 < H_0 < 5.0$; (*6*) $5.0 < H_0 < 6.8$; (*7*) $H_0 \leqslant 6.8$.

The acidity of the HPAC $PMo_{12-n}V_n$ ($n = 0 - 3$) has been investigated by the method involving the thermal desorption of bases. After the introduction of vanadium into the PMo_{12} molecule, the acid centres become nonuniform and their strength and number decrease with increase in n.[226] After evacuation at 350 °C, such HPAC acquire the Mo^{5+} and V^{4+} centres and the Lewis acidity associated with them.[227]

HPAC with $X = P^{5+}$, in particular PW_{12}, PMo_{12}, and $PMo_{12-n}V_n$, are most important in practice because of their relatively high stability and availability. It is not fortuitous that all the examples of the industrial use of HPAC as catalysts known hitherto are based on the application of precisely these HPAC. The HPAC PW_{12} became exceptionally important for acid catalysis, since it has the highest thermal stability and acidity and the methods for its synthesis have been developed in fair detail. In Russia, PMo_{12} is cheaper but has poorer technological properties (lower resistance to hydrolysis and to the reduction of the anion by the organic medium).

2. Heteropolyacids with the Dawson structure

The structure of compounds of this type was first determined by Dawson in 1953 (Fig. 3). The compositions of the known HPAC with the Dawson structure are presented below (the temperatures of the onset of decomposition in the solid state are indicated in brackets):

α-$H_6P_2W_{18}O_{62}$ (210) [1,3,110,228]	α-$H_6As_2W_{18}O_{62}$ [1,3,110]
α-$H_6P_2Mo_{18}O_{62}$ (>120) [1,3,110,229]	α-$H_6As_2Mo_{18}O_{62}$ [1,3,110]
α-$H_6P_2W_{13}Mo_5O_{62}$ [3]	α-$H_6P_2W_{14}Mo_4O_{62}$ [3]
α_1-$H_6P_2W_{17}MoO_{62}$ [230]	α_2-$H_6P_2W_{17}MoO_{62}$ [230]

The existence of certain HPAC with the Dawson structure requires confirmation. These include $H_6PAsW_{18}O_{62}$[231] and $H_{6+n}P_2Mo_{18-n}V_nO_{62}$.[232] There are comparatively few compounds of this type. There is also little information about them.

Investigators have not been very active in the synthesis and study of the HPAC with the Dawson structure. Apart from those indicated above, $X_2W_{17}Z$, where $X = As^{5+}$ or P^{5+} and $Z = Sn^{4+}$, Ge^{4+}, Mn^{3+}, Co^{3+}, Fe^{3+}, or Cr^{3+}, have been obtained by cation exchange in the form of dilute aqueous solutions.[190,233-235] Nothing is known about the possibility of their existence in the solid state or in the form of concentrated solutions. The heteropolyacid $P_2W_{17}Ce^{4+}$ has not been obtained, while $P_2W_{17}Ti$ exists in a concentrated solution (with a content of 43%) only in a mixture with other HPAC.[142] Dawson β-heteropolyacids have not been obtained. The synthesis of β-P_2W_{18} in a concentrated solution has been reported,[231] but it was subsequently found that, when the solution of the salt is acidified, the HPAC decomposes to PW_{12} and α-P_2W_{18}.[142]

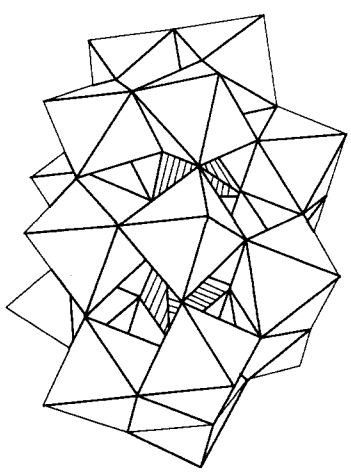

Figure 3. The structure of the Dawson HPAC (α-isomer). The two XM_9 fragments of the Keggin HPA are joined together to form a dimer.

In highly acid solutions, the HPAC α-P_2W_{18}, α-As_2W_{18}, and α-P_2Mo_{18} are entirely stable and are actually more stable than the corresponding Keggin HPAC (α-P_2W_{18} is very stable on hydrolysis in water, although α-P_2Mo_{18} is less stable) (Table 2). In contrast to these compounds, α-As_2Mo_{18} decomposes slowly in the presence of strong acids.[110]

The thermal stability of α-P_2W_{18} has been studied in relative detail. It has been found by differential thermal analysis at a heating rate of 2.5 K min^{-1} that α-P_2W_{18} is dehydrated at 350 °C. Although the DTA curve did not show a distinct exothermic peak, which is usually identified as the HPAC decomposition point, it was concluded that α-P_2W_{18} decomposes at 640 °C.[236] Other workers[207] noted that the behaviour of α-P_2W_{18} on heating is different from that of PW_{12}. They did not detect the anhydride and postulated (without any evidence) that this HPAC decomposes immediately to WO_3, but it was not clear what was the decomposition temperature. It was noted that, after heat treatment at 400 °C for 2 h, the HPAC ceased to dissolve. Subsequently, the same workers[237] recorded the ^{31}P NMR spectra of the heat-treated specimen but these did not throw light on the situation either.

In the most thorough investigation,[228] the thermal transformations of α-P_2W_{18} were investigated by a set of methods: differential thermal analysis (DTA) (heating rate 2.5 K min^{-1}), ^1H NMR, and IR spectroscopy. It was shown that the anhydrous HPAC cannot be obtained and that the last phase retaining the structure of the initial HPAC is $H_6P_2W_{18}O_{62}.2.6H_2O$ and all the protons in this phase are nonhydrated. The phase is formed in the temperature range from 225 to 250 °C and on further increase of temperature the protons are gradually eliminated. The crystallisation of $18WO_3.P_2O_5$ begins at a temperature of about 610 °C (at the selected heating rate), but the deformation of the structure of the initial HPAC was already noted at 210 °C. It remained obscure which phases exist in the temperature range 210-610 °C.

The thermal transformations of α-P_2Mo_{18} were also investigated combining the DTA and IR and ^1H NMR spectroscopic methods. Four endothermic effects due to the dehydration and partial decomposition of the HPAC were observed in the temperature range 120-300 °C. It was discovered that the phase $H_6P_2Mo_{18}O_{62}.3H_2O$ with non-hydrated protons was formed at 270 °C. On further heating, a change in the HPAC structure was observed and the oxide phase crystallised at 530 °C.[229] On thermolysis, α-P_2W_{18} and α-P_2Mo_{18} behave similarly.

The Dawson heteropolyacids can also be reduced without change in structure, at least on addition of 6 $\bar{e}$,[238] the reduction occurring more readily than that of the corresponding Keggin HPAC.[110] It has been found[238] that stable Dawson HPAC have been reduced by the addition of an odd number of electrons.

The direct determination of the acid salts of Dawson HPAC by the indicator method is difficult owing to their colour. It has only been possible to demonstrate[239] that H_0 for P_2W_{18} is less than −3.0. However, according to certain indirect data, it is possible to infer a high acidity of the Dawson HPAC. Thus all the protons of P_2Mo_{18} (2 $\bar{e}$) and P_2Mo_{18} (4 $\bar{e}$) are titrated (8 and 10 respectively), and only in P_2Mo_{18} (6 $\bar{e}$) the last two protons are not titrated.[238] The reduced P_2W_{18} (2 $\bar{e}$) is also a strong acid, all eight of its protons being titrated.[240] It has been noted that the reduced tungsten HPAC are stronger acids than the reduced molybdenum HPAC.[238] In the acid-catalysed conversion of methanol, P_2W_{18} is almost as active as PW_{12} even after preliminary reduction with hydrogen.[239] On the other hand, in the synthesis of *tert*-butyl methyl ether, the Dawson HPAC proved actually more active than the Keggin acids,[13] which indicates not only their very high acidity but also the specificity of their catalytic action. In the decomposition of isobutyl

propionate, P_2W_{18} is less active than the Keggin HPAC,[125] but these data require confirmation, since the question of the thermal stability of α-P_2W_{18} is not clear — the HPAC may change with the conditions of their preparation (evacuation for 8 h at 150 °C).[125]

The methods of synthesis of the Dawson HPAC have been less thoroughly developed and are more difficult than for the Keggin HPAC. This in fact accounts also for the small number of studies in which the HPAC were used as catalysts. Conditions for the synthesis of α-P_2W_{18} and α-P_2Mo_{18} by electrodialysis in almost quantitative yields have been discovered recently.[142] Only the ammonium salt of P_2W_{18} is manufactured in Russia, whilst other Dawson HPAC or their salts are not.

No examples of the practical use of the Dawson HPAC are known. One may mention only a Japanese patent[241] in which it is stated that P_2Mo_{18} may be employed in the industrial hydration of isobutene instead of the unstable PMo_{12}.

3. Other heteropolyacids and isopolyacids

The compositions of other isopolyacids and heteropolyacids, different from the Keggin and Dawson HPAC, the existence of which has been reliably established are presented below (the temperatures of the onset of decomposition in the solid state are indicated in brackets in °C):

$H_6As_2W_{21}O_{69}$ [1,142]
$H_8TeMo_6O_{24}$ (Anderson) [243]
$H_9CrMo_6O_{24}$ [3,110,142,245]
$H_5IMo_6O_{24}$ [3,110]
$H_8ThMo_{12}O_{42}$ (125) [110,246]
$H_8UMo_{12}O_{42}$ (120) [110,247]
$H_2Ln_2XMo_{12}O_{42}$ [249]
$H_9NaF_6W_{18}O_{56}$ [251]
β-$H_4Mo_8O_{26}$ [252]
$H_6P_2W_{21}O_{71}$ (150) [242]
$H_9FeMo_6O_{24}$ [3,110,244,245]
$H_9CoMo_6O_{24}$ [3,110,142,245]
$H_8CeMo_{12}O_{42}$ (Dexter–Silverston) [3,110]
$H_8NpMo_{12}O_{42}$ [248]
$H_6MnMo_9O_{32}$ [110,250]
$H_{10}(PW_{11}O_{39})_2Ce$ (300) [143]
$H_8Mo_{36}O_{112}$ [253].

The existence of certain HPAC requires confirmation:

$H_9AlMo_6O_{24}$ (270) [110,254]
$H_{11}(SiW_{11}SnO_{39})_2Co(CO)_3$ [167]
$H_9GaMo_6V_6O_{24}$ (270) [110,254]
$H_9(PW_{11}SnO_{39})_2PdC_3H_5$ [167].

The structures of many HPAC are unknown:

h-$H_5BW_{12}O_{40}$ [1]
$H_{16}S_2W_{16}V_4O_{72}$ [144]
$H_8VMo_6O_{24}$ [257]
$H_2W_{10}VO_{33}$ [259]
$H_4SW_8V_2O_{34}$ (225–300) [260]
$H_6As_2Mo_2O_{12}$ [3]
$V_2O_5 \cdot I_2O_5$ [3]
$WO_3 \cdot nH_2O_2$ ($n = 0.4-0.7$) [262]
$Te^{4+}W_{18}$ [263]
$Te^{4+}W_8V_4$ (300) [173,174]
$Se^{4+}W_{12}$ (47) [168,171]
$Se^{4+}W_8V_4$ (187) [171]
$Se^{4+}W_7V_3$ [265]
$Sb^{3+}-W$ [266]
$H_{10}NiW_{17}F_4O_{55}$ [255]
$H_6V_2Mo_{12}O_{44}$ [256]
$H_4V_2W_8O_{31}$ [258]
$H_{18}W_{24}VO_{83}$ [259]
$10\,WO_3 \cdot V_2O_5$ [261]
$H_3AsMo_3O_{13}$ [3]
BeW_9 [110]
$Te^{4+}W_{12}$ (200) [169,170]
$Te^{4+}W_9V_3$ [173]
$W:Te^{6+} = 4-18$ [264]
$Se^{4+}W_{10}V_2$ [172]
$Se^{4+}W_8V_3$ [265]
$Se^{4+}W_6V_3$ [265]
$As^{5+}-W$ [266]
M–F–W (M = Nb, V, Fe, Al) [267]
M–F–Mo (M = V, Ti) [267]
$As^{3+}-W$ [268]

Heteropolyacids the existence of which is open to doubt:

$H_8CeMo_{10}O_{36}$ [269]
$H_8CeW_{12}O_{42}$ [270]
$H_4CeW_8O_{28}$ [270,271]
$H_6ThUW_{18}O_{61}$ [272]
$H_8CeMo_8O_{30}$ [269]
$H_6CeW_{10}O_{35}$ [270]
$H_5CeW_8O_{28}$ [271]
$H_8SiW_{11}O_{39}$ [273]

The heteropolyacids β-$H_4Mo_8O_{26}$, $H_8Mo_{26}O_{112}$, BeW_9, $H_{10}NiW_{17}F_4O_{55}$, $H_8CeMo_{10}O_{36}$, $H_8CeMo_8O_{30}$, $H_5CeW_8O_{28}$, and $H_6ThUW_{18}O_{61}$ have not been isolated in the solid state. The HPAC belonging to the series with the Anderson structure are most numerous (Fig. 4). Dilute solutions of GaW_6[274] and $NiMo_{6-n}W_n$ ($n = 0-6$)[275] have been obtained by cation exchange, but nothing is known about the stability of these HPAC.

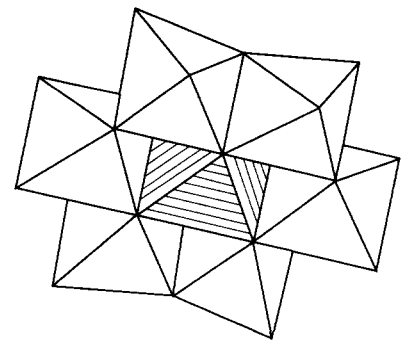

Figure 4. The structure of the Anderson HPAC. Six MO_6 octahedra surround the central XO_6 octahedron.

As a rule, the Anderson HPAC (except the HPAC with $X = I^{7+}$) are tribasic–tetrabasic, whereas the remaining protons are rigidly bound to the HPA. The stability of such HPAC is low. Thus $FeMo_6$ and $CoMo_6$ are stable in aqueous solutions for several weeks,[245] but in the solid state all the Anderson HPAC can be isolated only by evaporation at a low temperature. The strength of their acid centres is unknown. One can only postulate that the titratable protons are fairly weakly bound to the HPA. Examples of the use of such HPAC are also unknown.

The structure of the molybdenum HPAC with heteroatoms having high coordination numbers was first described correctly by Dexter and Silverton in 1968 (Fig. 5).[1] The stability of such HPAC is low. In aqueous solutions, they decompose gradually, but their hydrates can be stored for some time.[246,247] On heating, UMo_{12} loses part of the water of crystallisation in the temperature range from 40 to 120 °C and subsequently the compound begins to decompose. Its analogues behave similarly.[247] The minimum degree of hydration of $ThMo_{12}$ corresponds to ten water molecules. The compound $ThO_2 \cdot 12MoO_3 \cdot 4H_2O$ undergoes rapid dehydration on heating to 200 °C. It dissolves in water, but is not the initial HPAC. Slow heating to 125 °C leads to the same compound, but it has now lost its solubility. In aqueous solutions, these HPAC decompose slowly to complexes of the type X_nMo_{12} ($n = 2-3$).[246] As a result, it becomes possible to obtain HPAC with a ratio $Mo:X < 12$, which are in fact mixtures of the initial HPAC and their complexes. The structure of one of these complexes, namely $H_2Nd_2(H_2O)_{12}UMo_{12}O_{42} \cdot 12H_2O$, has been determined (Fig. 6). This compound is not a salt of a HPAC, since the neodymium atom is bound covalently to the HPA. This is a dibasic

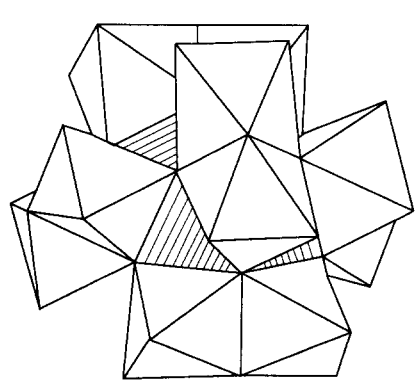

Figure 5. The structure of the Dexter–Silverton HPAC: 12 MoO_6 octahedra surround the central XO_{12} icosahedron.

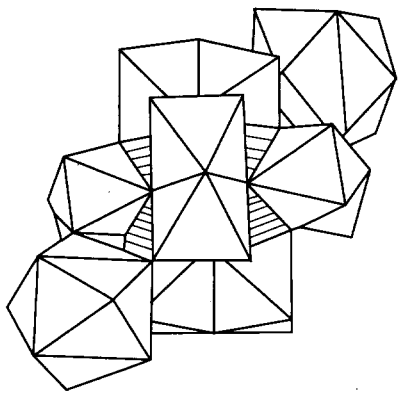

Figure 6. The structure of the HPAC $H_2Ln_2XMoO_{12}O_{42}$: two tri-capped trigonal Ln^{3+} prisms are joined to the Dexter–Silverton anion.

complex HPAC — a strong acid with respect to both protons. It is almost insoluble in water (7×10^{-4} M)[249,276] and is therefore of interest for heterogeneous acid catalysis as the only example of an insoluble HPAC.

Among other similar complex HPAC, dilute aqueous solutions of acids having the compositions $CeMo_{12}Nb$ and $CeMo_{12}Nb_2$ have been obtained. Their structures have not so far been established.[269]

The Dexter–Silverton heteropolyacids are strong acids. Thus five of the eight protons in $NpMo_{12}$ form H_3O^+ ions,[248] while $CeMo_{12}$ is also active in the acid-catalysed synthesis of *tert*-butyl methyl ether, like PMo_{12}.[277] The synthesis of the ether is the only known attempt to employ HPAC of a similar type as a catalyst, probably in view of their low availability and low stability.

The HPAC of the type P_2W_{21} has been investigated in relatively high detail (Fig. 7). It is entirely stable on storage in solution and in the solid state. In their study of the thermal stability of P_2W_{21} by the DTA method alone, French investigators[207] concluded that P_2W_{21} is also stable, like PW_{12}. Later they found[237] that nevertheless P_2W_{21} and PW_{12} behave differently on heating. It was found with the aid of IR and ^{31}P NMR spectroscopy that, on heating in the temperature range 150–300 °C, P_2W_{21} is converted into PW_{12} both in solution and in the solid state. Measurements of the Hammett acidity functions H_0 of concentrated aqueous solutions showed that,

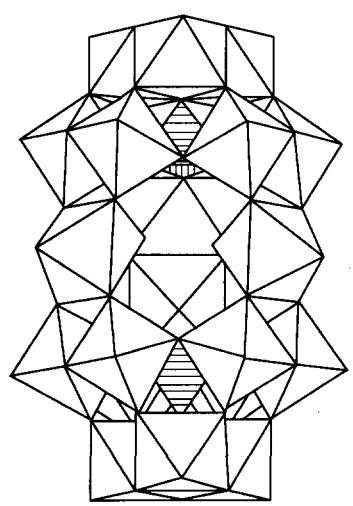

Figure 7. The structure of the HPAC $H_6P_2W_{21}O_{71}$: three $WO_5(H_2O)$ octahedra connect two PW_9 fragments of the Keggin HPA.

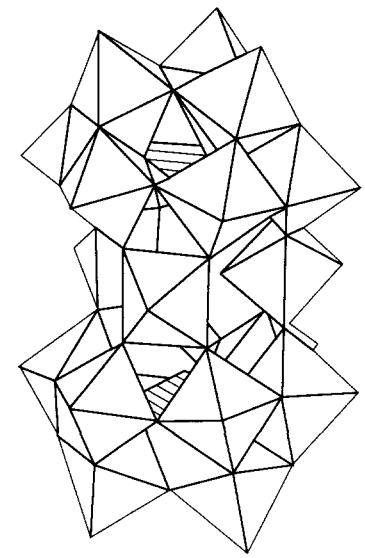

Figure 8. The structure of the HPAC $H_6As_2W_{21}O_{69}$: the $WO_5(H_2O)$ octahedron and two WO_5 pyramids connect two AsW_9 fragments in which the WO_6 octahedra surround the AsO_3 pyramids.

at equal concentrations, P_2W_{21} is actually a stronger acid than PW_{12}, although their acidities are approximately the same when calculated per proton.[242] Examples of the use of P_2W_{21} are unknown. It has been suggested that the HPAC $As_2^{5+}W_{21}$ exists, but it has not been isolated. The HPAC $As_2^{3+}W_{21}$ has a similar structure (Fig. 8) but its properties have not been studied.

NaF_6W_{18} is extremely resistant to the action of acids and alkalis (Fig. 9).[251,278] Apparently complex HPAC based on it exist.[251,255] The properties of similar HPAC have also not been investigated; their study is probably held back by the inconvenient methods of synthesis.

The heteropolyacid $(PW_{11})_2Ce^{4+}$ (Fig. 10) is entirely stable in the solid state at moderate temperatures. Above 300 °C, the following transformations take place:

$$(PW_{11})_2Ce^{4+} \longrightarrow PW_{12} + PW_{11}Ce^{3+} + H_3PO_4.$$

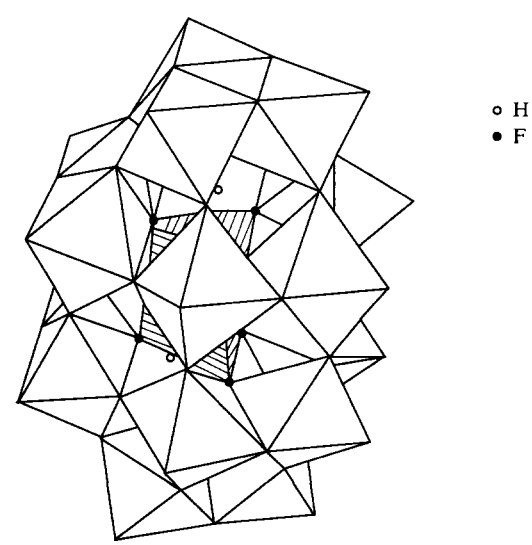

Figure 9. The structure of the HPAC $H_7H_2NaF_6W_{18}O_{56}$: the trigonal Na^+ prism and two protons occupy the central cavity of the HPA having a structure close to that of the Dawson HPA.

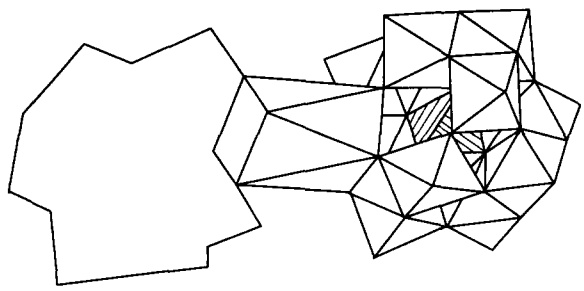

Figure 10. The structure of the HPAC $H_{10}(PW_{11}O_{39})_2Ce$: the square CeO_8 antiprism connects two PW_{11} fragments of the Keggin HPA.

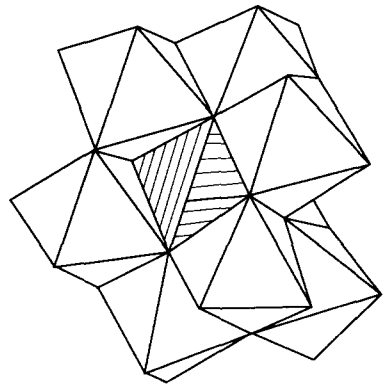

Figure 11. The structure of the HPAC $H_6XMo_9O_{32}$: nine MoO_6 octahedra surround the central XO_6 octahedron.

The mixtures of thermolysis products always contain also the initial HPAC. The decomposition to oxide phases is observed in the temperature range 450–500 °C.[143] Probably other complex HPAC with lanthanide and actinide ions exist.

The heteropolyacid $Mn^{4+}Mo_9$ (Fig. 11) can be obtained in the solid state, but its solutions are relatively unstable.[110,250] The stability of the acid $H_8As_4Mo_{12}O_{50}$, obtained by cation exchange in the form of a dilute aqueous solution, is also low. It is a strong acid: the first four hydrogen atoms dissociate fully and a further four dissociate partially.[279]

Electrodialysis of a solution containing $NaAsO_2$ and Na_2WO_4 in molar proportions of 1:11 afforded a concentrated solution in which 50% of the tungsten was in the form of $H_7AsH_2W_{18}O_{60}$. However, this HPAC was not isolated in the solid state and its properties were not investigated.[142]

The heteropolyanions $XP_5W_{30}O_{110}^{x-}$ are stable in strongly acid (6 M HCl) aqueous solutions,[280] which suggests the existence of the corresponding HPAC. However, such HPAC were not specially isolated and investigated.

As already mentioned above, there are a series of HPAC about which it is only known that they exist. As regards the type of their behaviour, one may postulate that these mixed Mo–V and W–V HPAC have the Keggin structure. However, another structure of these acids is also possible. It has been suggested (but not demonstrated) that the S–W–V HPAC has a structure analogous to that of P_2W_{20}.[144] According to ^1H NMR data, all its protons are hydrated,[260] i.e. it is a fairly strong acid.

Heteropolyacids containing an X heteroatom with a lone pair (Se^{4+}, Te^{4+}, Sb^{3+}, As^{3+}) cannot have the Keggin structure (attributed to them previously) by virtue of the coordination structure of the XO_n polyhedron (usually a trigonal pyramid). HPA with the following structures are known for them: $X_2W_{21}O_{69}^{6-}$, $H_2XW_{18}O_{60}^{7-}$, $X_4W_{40}O_{140}^{29-}$, and $X_9W_{21}O_{86}^{19-}$. Probably the HPAC synthesised with such heteroatoms have one of the structures presented above or they are mixtures of HPAC with similar structures. All these HPAC are strong acids[173,263,281] with moderate thermal stability (up to 200 °C), but some of their protons are retained up to 500 °C.[170]

HPAC containing Te^{6+} are strong acids.[264]

The structures of the corresponding Keggin HPAC have been attributed to the acids synthesised in the presence of HF.[267] However, experience gained in a number of investigations[126,251,255] has shown that it is impossible to ignore the influence of F^- on the structure of the HPA and to reduce the effect of HF to the simple effect of an acid. Two versions of the synthesis of such HPAC are known: from the metatungstate[126] or from NaF_6W_{18}.[251] In terms of the conditions in their synthesis,[267] the second version is more probable, but this naturally requires confirmation.

The existence of certain HPAC, indicated in the literature, may be questioned. Thus the HPAC with a Mo : Ce ratio less than 12 were already mentioned. It is known that the Ce^{4+} ion does not form with tungsten HPA having the Dexter–Silverton structure,[1] so that there is also no corresponding CeW_{12} HPAC. The HPAC containing W^{6+} and Ce^{3+} or Ce^{4+} do not exist in a strongly acid medium.[1,142] This can also be said about the HPAC $UThW_{18}$. The heteropolyanion SiW_{11} is a precursor of the acid SiW_{12} and does not exist in the form of a free acid.[1]

Among the isopolyacids, only the Mo^{6+} acids are known in solutions. When the solutions are acidified, cation exchange or electrodialysis affords solutions which are stable for 24 h.[142] It has been suggested that molybdenum is present in these acids in the form of β-Mo_8[252] or Mo_{36}.[253] Such solutions are suitable for the synthesis of MoO_3 or deposited MoO_3/SiO_2 catalysts.[252]

4. Methods of synthesis of heteropolyacids

Several methods of synthesis of HPAC are known. The most general of these involves the acidification of a solution of a mixture of the initial reactants.[1,3,110,139,250]

$$Na_2WO_4 + H_3PO_4 \xrightarrow{H^+} H_3PW_{12}O_{40}$$

$$Na_2WO_4 \xrightarrow{HF} H_{6-n}H_2W_{12}O_{40-n}F_n$$

$$Na_2MoO_4 + Cr(NO_3)_3 \xrightarrow{H^+} H_9CrMo_6O_{24}$$

$$Na_2MoO_4 + NaVO_3 + H_3PO_4 \xrightarrow{H^+} H_{3+n}PMo_{12-n}V_nO_{40}$$

The reaction by no means takes place smoothly in all cases and in conformity with the stoichiometry. Sometimes an excess of the heteroatom is needed (for example, $X = B^{3+}$ or Si^{4+} in the synthesis of XW_{12} or $X = P^{5+}$ or As^{5+} in the synthesis of X_2W_{18}), or the appropriate temperature must be maintained (low for relatively unstable HPAC or actual refluxing for X_2W_{18}), or a definite order of mixing of the reactants is required. If the component containing X is sparingly soluble, special measures must be adopted to transfer it to the solution.[267]

Acidification can be achieved in several ways. The commonest way involves the use of an inorganic acid (usually HCl or H_2SO_4), after which the HPAC is isolated from the solution of the salts by extraction with ether.[1,3,110,250] However, this method of isolation has numerous disadvantages: a narrow range of extractable HPAC (Keggin and Dawson HPAC and HPAC of the type X_2W_{21} and NaF_6W_{18}), among which compounds with low stabilities may decompose during extraction as a result of the very high acidity of the solution, the nonquantitative yield of the HPAC (for example, not more than 80% for PW_{12}[282] and in reality the yield is even less), fire risk, the need to employ an extraneous reagent, a large amount of waste water produced, corrosion of the equipment, and contamination of the products by the inorganic acid. There is also an advantage: the possibility of removing from the HPAC the impurities which are not

extractable by ether (for example unsaturated HPAC) or of separating mixtures of HPAC extractable under the conditions of different acidities. Despite the disadvantages, the method has been used hitherto in industry to synthesise PW_{12} and SiW_{12} and also in laboratory practice.

In another procedure, acidification is carried out by cation-exchange resins.[3,110,250] Almost all the known HPAC can be obtained with its aid. This method can be regarded as the most universal among all those known. It also has its disadvantages and advantages. The former include the need to regenerate the resins, which leads to waste water, and the need to concentrate dilute solutions of the HPAC; the latter include the absence of corrosion, a very high yield of the HPAC (100% with respect to W or Mo), universality, the 'softness' of the acidification, and a high degree of purification as regards cations. The Dexter–Silverton heteropolyacids can be obtained only in this way, since ion exchange makes it possible to remove the cations even from sparingly soluble HPAC salts. After the cation exchange, dilute solutions of the HPAC are obtained, from which the product is isolated either by evaporation or by salting out with an acid.[283] A combination of two methods is also possible — acidification by an acid and ion-exchange resins.[284,285]

The third acidification procedure, the most progressive one, is electrochemical acidification. It consists in the electrochemical removal of the cations from the initial solution and compensating for them with protons. The process is carried out in flow-type electrodialysers (when all the components are in solution) or dialysers of the nonflow type (solutions with precipitates, as in the synthesis of SiW_{12}).[286] The anodic compartment contains a solution of the initial components, while the cathodic compartment contains a solution of alkali. The compartments are separated by a membrane based on a cation-exchange resin. When a current is passed through the apparatus, the cations pass through the membrane into the cathodic compartment and the anolyte is acidified.

Compounds containing tungsten, molybdenum, and heteroanions are incapable of passing through the membrane. On acidification of the anolyte, they interact, forming the HPAC. The alkali accumulates in the catholyte and can be used again to prepare the initial solution. The only side products of the synthesis are gaseous H_2 and O_2, formed as a result of the decomposition of water at the electrodes. The advantages of this method include a high yield of the HPAC (100% with respect to W and Mo), the absence of solid and liquid waste, and the possibility of doing without extraneous reagents. The disadvantages are the use of special equipment, including dangerous equipment (powerful current sources), the need for the additional removal of impurities from the HPAC (for example the excess of X or impurity HPAC), and the need to follow the concentration of the cation in the anolyte. However, the principal advantages of the method — the high yield of the HPAC and the absence of waste — make up for the above disadvantages and therefore the method is being developed actively at the present time.

Almost all the known most important HPAC such as SiW_{12},[286,287] BW_{12} (with additional purification by extraction with ether),[288] PW_{12},[282,289] P_2W_{21},[242] P_2Mo_{18}, α-P_2W_{18}, PMo_6W_6, $CoMo_6$, $PMo_{12-n}V_n$, $PW_{12-n}V_n$, and $PW_{12-n}Nb_n$ ($n = 1, 2$),[142] as well as new HPAC such as $PW_{11}Ti$, $PW_{11}Zr$, $PW_{11}Bi$, $PW_{11}Ce$, and $(PW_{11})_2Ce$[143] have been obtained by the electrodialysis method. A mixture of HPAC, 90% of which comprised $As_2^{3+}W_{21}$ and $H_2As^{3+}W_{18}$, has been obtained in a system containing As^{3+} and W^{6+}. Assessment of the possibilities of electrodialysis led to the conclusion that this method is suitable for the synthesis of HPAC stable in the form of concentrated aqueous solutions. On the basis of this principle, it proved impossible to obtain HPAC of the type β-P_2W_{18}, NaP_5W_{30}, and many others. The limitations of the methods have also been noted. Thus, owing to the chemical processes on slow electrochemical acidification, it is impossible to obtain PMo_{12}. Solutions of certain HPAC (for example, those containing Cr^{3+}) have a high electrical resistance, which prevents cation exchange through the membrane.[142]

Apart from the synthesis of HPAC, electrodialysis is used to obtain H_2WO_4 with an increased purity[290] and metatungstate salts.[291–295] The creation of an industrial electrodialyser with an output of 50–70 tonnes of tungsten per year and an overall membrane area of 2.5 m^2 has been reported.[297]

We may mention yet another (obsolete) acidification method — the method involving the decomposition of salts,[3,110] for example in accordance with the reactions[3]

$$Ba_3H_2W_{12}O_{40} + 3\,H_2SO_4 \longrightarrow 3\,BaSO_4 + H_6H_2W_{12}O_{40},$$

$$Hg_5BW_{12}O_{40} + 5\,HCl \longrightarrow 5\,HgCl + H_5BW_{12}O_{40}.$$

The initial HPAC salts were obtained in their turn with the aid of inorganic acids. Thus this procedure is a modification of the method involving the acidification of the initial solutions by inorganic acids. Previously this method has a preparative value, but nowadays it has lost it.

The method of synthesis of HPAC next in importance involves the interaction of simple oxides (oxides or acids). Thus phosphomolybdic acids can be obtained from H_3PO_4 and $MoO_3(H_2MoO_4)$.

$$MoO_3 + H_3PO_4 \longrightarrow PMo_{12} \text{ (or } P_2Mo_{18})$$

The composition of the product depends on the reaction conditions: reactant ratio, temperature, and reaction time. For the molar ratio Mo : P = 12, approximately 70% of the molybdenum dissolves in the form of PMo_{12} after refluxing for 3–5 h. After evaporation, the product is isolated in the solid state, but it has to be recrystallised in order to remove the excess H_3PO_4. The best version of the synthesis of PMo_{12} involves the use of a fourfold excess of molybdenum. In this case, the pure acid PMo_{12} is formed immediately, while the excess molybdenum is used for the succeeding cycles of the synthesis. After refluxing with an excess of H_3PO_4 (the optimum ratio is Mo : P = 3) and allowing the mixture to stand for 15–17 days at 20 °C, P_2Mo_{18} is formed. It is best to use MoO_3, since H_2MoO_4 is usually contaminated by ammonia.[3] For the ratio Mo : P = 12, it is possible to attain the complete dissolution of MoO_3 with formation of pure PMo_{12}, provided that one adds to the solution an organic solvent (for example *tert*-butyl alcohol) or a reductant until the attainment of the degree of reduction corresponding to PMo_{12} (4 $\bar{e}$) with subsequent reoxidation.[296] For the ratio Mo : P < 12, mixtures of the HPAC P_2Mo_{18}, PMo_{12}, PMo_{11}, and PMo_9 are obtained[3,197] and the attempt to increase the yield of PMo_{12} by employing an excess of H_3PO_4 (75%–100%) in the synthesis[297] must therefore be recognised as unsuccessful. If the MoO_3 is subjected to preliminary mechanochemical activation, the time required for its dissolution is shortened to several minutes even without using an excess of H_3PO_4 (as happens, for example, in the synthesis of P_2Mo_{18}).[298]

For catalytic purposes it is not always important which of the P–Mo HPAC is present in the solution, since they are all strong acids. Simple dissolution of MoO_3 in a solution with H_3PO_4 (this is achieved using the ratio Mo : Po $\approx$ 6) is sometimes sufficient to obtain an active catalyst.[293,300]

Certain vanadium-containing HPAC can be obtained in the same way. Thus $PMo_{11}V$ is synthesised in a quantitative yield by refluxing a suspension of MoO_3 and V_2O_5 in H_3PO_4 solution with stoichiometric reactant ratios for 5–6 h.[301,302] The heteropolyacid $PMo_{10}V_2$ is more difficult to synthesise: an excess of V_2O_5 and a time of the order of 20 days are required. If hydrothermal conditions are employed, the process is accelerated and in this case it is actually possible to introduce

tungsten into the HPAC.[302] The duration of the synthesis of $PMo_{12-n}V_n$ ($n = 1-6$) is reduced to 1–2 days if V_2O_5 is dissolved beforehand in a dilute solution of H_2O_2 at a low temperature and with the molar ratio $H_2O_2 : V_2O_5 = 1.5-40$.[303]

After a suspension of MoO_3 has been refluxed in a Na_3AsO_4 solution, a solution of the sodium salt of As_2Mo_{18} is formed, from which the HPAC can be isolated by extraction with ether or by cation exchange.[3,250] The heteropolyacids $H_3AsMo_3O_{13}$ and $V_2O_5.I_2O_5$ with hitherto unknown structures have been synthesised by interaction in solutions of oxides or acids.[3]

In the synthesis of tungsten-containing HPAC, the method considered involves considerable difficulties. The reactivities of the initial reactants H_2WO_4 and WO_3 are very low and these compounds hardly dissolve in acid solutions. Only H_2WO_4 freshly precipitated at a temperature below 50 °C reacts with H_3PO_4, affording a yield of the HPAC up to 92%.[3] Apart from PW_{12}, other P–W HPAC are formed under these conditions. These as well as other impurities have to be removed by extraction with ether.[304] The method of synthesis via molybdenum or tungsten halides is a variety of this method. The halides hydrolyse rapidly with formation of molybdenum and tungsten oxy-acids, which immediately react with the heteroatom.[268]

Thus the method of synthesis of HPAC from the initial acids and oxides has limitations associated with the low solubilities or reactivities of the initial compounds. Realistically, one can obtain with its aid only certain HPAC containing molybdenum and vanadium, whereas for the purposes of acid catalysis tungsten-containing HPAC are of greatest interest. In order to facilitate the synthesis or reduce the amount of waste, it is possible to use a combination of methods. For example, WO_3, MoO_3, and V_2O_5 may be dissolved in solutions of Na_2WO_4, Na_2MoO_4, or $NaVO_3$ and the latter can then be acidified by some method.[142] Another application of this procedure involves the synthesis of HPAC/carrier catalysts by forming the HPAC directly on the surface of the carrier.[305,306]

The third method of synthesis of the HPAC, which can be regarded as general, involves their preparation via other HPA or IPA.[1] This method is almost always used in the synthesis of complex HPAC, where the starting materials are unsaturated HPA.[1,142,143]

$$SiW_{11} + Z^{x+} \xrightarrow{H^+} SiW_{11}Z$$

$$PW_{11} + Z^{x+} \xrightarrow{H^+} (PW_{11})_2Z$$

$$P_2W_{17} + Z^{x+} \xrightarrow{H^+} P_2W_{17}Z$$

Bearing in mind the enormous diversity of the ions Z, the unsaturated HPA, and their combinations, there is no doubt that a multiplicity of new HPAC can be obtained by this procedure.

The unsaturated heteropolyanion PW_{11} serves as a source for the synthesis of the acid P_2W_{21}.[242,289] Vanadium-containing HPAC can be conveniently obtained from a simpler HPAC.[307]

$$PMo_{12} + V_2O_5 + H_3PO_4 \longrightarrow H_{3+n}PMo_{12-n}V_nO_{40}$$

$n = 1-3$

Keggin β-heteropolyacids can be readily obtained by reducing (4 $\bar{e}$) Keggin α-HPAC in solutions.[1,110,130,212] HPAC with a definite composition and definite positions of other atoms in the structure can be conveniently constructed from polyunsaturated HPA of the type of PMo_9.[136]

Various HPAC are frequently synthesised from tungsten, molybdenum, and niobium isopolyanions. Almost all the HPAC with Anderson, Dexter–Silverton, and Keggin structures, in which a transition metal ion serves as the heteroatom, have been obtained in this way. In the synthesis, this ion must be retained in solution and, in order to achieve this, the latter must be acid. In such cases, the IPA is the most suitable source of ligands.

$$Mo_4O_{24}^{6-} + Cr^{3+} \xrightarrow{H^+} H_9CrMo_6O_{24}$$

$$H_2W_{12}O_{42}^{10-} + Zn^{2+} \xrightarrow{H^+} H_6ZnW_{12}O_{40}$$

$$H_2W_{12}O_{40}^{6-} + Ga^{3+} \xrightarrow{H^+} H_5GaW_{12}O_{40}$$

Under these conditions, it is also possible to employ isopolyacids as such.[266] In some cases, the use of IPA is particularly preferable. Thus, in order to avoid the formation of P_2W_{21} in the synthesis of PW_{12} by electrodialysis, the PO_4^{3-} anion should be added to the acidified solution only after the complete conversion of the WO_4^{2-} ion into the IPA.[289] The compound $K_7HNb_6O_{19}$ is the only convenient source of niobium in the synthesis of niobium-containing HPAC. The acids $H_2Ln_2XMo_{12}O_{42}$ are obtained from Dexter–Silverton HPAC as such.[249]

Finally, mention should be made of a specific method of synthesis of the HPAC CW_{12} and of its peroxo-analogue by dissolving WC_2 in H_2O_2.[118,119,164]

A method of synthesis of HPAC by the heat treatment of their ammonium or tetraalkylammonium salts may be encountered in certain patents.[181,308,309] However, on thermal elimination of the ammonium cations, the structure of the HPA is disrupted. Such methods may be regarded as methods of synthesis of catalysts whose compositions correspond to those of the initial HPA salts but not the HPAC.

Abstract. Recent studies of adsorption from solutions of mixtures of polymers have been examined. The experimental results reveal an interrelation between the adsorption of polymers from a mixture, the thermodynamic compatibility of the components in solution, the change in the thermodynamic quality of the 'mixed solvent' (polymer + solvent), and the critical crossover concentration for each component (on the one hand) and the averaged critical concentration for the mixture. The influence of the aggregation of macromolecules in solutions of mixtures on the adsorption in the concentration regions above and below the critical concentration for the overlapping of macromolecular globules has been demonstrated. The bibliography includes 30 references.

I. Introduction

According to current views on the properties of solutions of polymers these solutions can be divided into dilute and semidilute.[1] In a dilute solution the macromolecular globules are separated in space, but when the critical concentration c^* (and therefore the critical volume fraction of polymer φ) is reached the globules begin to come into contact and they overlap. The concentration region in which the globules overlap (the cross-over region) corresponds to the local concentration within the globule, giving a solution concentration $\varphi^* < \varphi < 1$. The overlapping is accompanied by a compression of the globules and by a decrease in their size. The critical concentration c^* is determined by the molecular mass of the polymer and by the thermodynamic quality of the solvent. Various theoretical models have been proposed to determine the concentration c^*: according to them this quantity is inversely proportional to the characteristic viscosity $[\eta]$, and the proportionality coefficient depends on the model chosen for the interaction of the globules.[2–6]

Many published data show that macromolecular associations or aggregates with a long average lifetime can be formed in solutions of polymers, depending on their concentration and on the thermodynamic quality of the solvent.[7,8] The size of the aggregates is also determined by the molecular mass and by the nature of the solvent. In solutions of any concentration we find a mobile equilibrium between the aggregated and the free macromolecules. From the standpoint of classifying the solutions into dilute and semidilute it is evident that the aggregation processes should begin in a dilute solution and stop at the transition to a semidilute solution, where all the macromolecules overlap and create a network.

In a series of studies in our laboratory[7,9] the conditions for the formation of aggregates, their size, and number per unit volume have been determined. Comparing these data with the results of adsorption studies (from solutions) led to the formulation of the concept of aggregative adsorption.[10,11] Essentially this concept states that in an appropriate concentration region of the solution, in which macromolecular aggregates are formed, both aggregated and nonaggregated macromolecules are simultaneously transferred to the adsorbent surface during adsorption, but the transfer of the molecular aggregates is energetically more favourable. As a result there are almost no aggregates in the solution over the adsorbent after the adsorption equilibrium has been established, but after some time their equilibrium concentration in the solution is re-established.

The aggregative adsorption mechanism has provided an explanation for several experimental data which did not fit the traditional description of adsorption from dilute solutions,[12,13] such as large adsorptions, well in excess of the calculated monolayer value, with a relatively small proportion of segments bound to the surface, an inversion of the effect of the thermodynamic quality of the solvent on the adsorption following changes in concentration, a dependence of the adsorption on the adsorbent : solution ratio, etc.[7] In the aggregative adsorption mechanism the large difference between the adsorption of polymers and the adsorption of species of low molecular mass is stressed.[10] In the adsorption of polymeric molecules not only the conformation of the adsorbed molecules but also the size and number of the macromolecular aggregates depend on the concentration of the solution, so that at different points of the adsorption isotherm we are dealing with different ratios of these species in the solution. From this point of view it is interesting to consider the adsorption of mixtures of polymers from dilute and from semidilute solutions, in which the aggregation conditions of polymer molecules of each kind should be different. It may be assumed that the adsorption of a mixture of polymers from a common solvent is affected by their thermodynamic compatibility (or noncompatibility) in the solution, defined by the thermodynamic polymer–polymer interaction parameter.

A large group of experimental data on the adsorption of mixtures of polymers is now available.[14-19] In most cases a marked selectivity of the adsorption of one of the components is observed in the adsorption from a mixture. When this effect was first reported[14-16] it seemed reasonable to assume that a noncompatible pair of polymers in solution would also show a more marked segregation of identical macromolecules, i.e. a more marked aggregation. This effect should depend on the overall concentration of the components in solution, on the concentration ratios, and on the concentration of each component (with respect to the remoteness from or closeness to the crossover region for the given polymer).

An analysis of all the available data showed that the adsorption of polymers should be examined from the following standpoints. A solution of a mixture of two polymers in a common solvent can be described as a solution of the polymer A in a solution of the polymer B in the same solvent, and also as a solution of the polymer B in a solution of the polymer A. In this case the thermodynamic quality of the 'mixed' solvent (solvent + polymer) for each polymer will be different from the quality of the pure solvent. The adsorption of each polymer will depend on the influence of the other polymer on the thermodynamic quality of the 'mixed' solvent. Thus the adsorption of each component will be determined not only by the affinity of that component for the surface but also by the ratio of the components. However, this simple and self-evident conclusion introduces serious difficulties in the analysis of the adsorption of mixtures if the analysis is attempted in the classical approach to the determination of the adsorption isotherms.

In the experimental method originally used to study adsorption from mixtures the concentration of the solution was assumed to remain constant, the only variable being the ratio of the dissolved components.[14] This method can give information on the preferential adsorption of the various polymers as a function of the presence of the other. However, it is not a strict method, since each change in the ratio of the components in solution produces a change in the thermodynamic quality of the 'mixed' solvent for each component, i.e. the adsorption conditions were not identical for mixtures of different composition.

There is also a second experimental method in which the concentration of one component only is varied in the solution of the mixture, whereas the concentration of the other component is kept constant. In this case we can construct the adsorption isotherm for the component of variable concentration. This experimental scheme is simply equivalent to studying the adsorption of the given component from solvents of different thermodynamic quality, and therefore it does not readily detect the specific aspects of the adsorption of mixtures if the system displays specific adsorption.

The third method (a continuous increase in the concentration of the solution, as in the classical method of constructing the isotherm) involves adding to the solution the two components in constant relative amounts. However, even this method cannot be called strict, as in this case we have a simultaneous adsorption of the two components in different proportions (depending on their relative adsorbability), and under these conditions each component is adsorbed from a solvent of thermodnamic quality appropriate for that component.

We know of no other method of studying the adsorption of mixtures of polymers. The most important aspect of the adsorption of a mixture of polymers is that it cannot be studied in the classical variant of the construction of adsorption isotherms: the specific features of the adsorption of mixtures are in fact determined by the difference and variability of the thermodynamic quality of the solvent for each component. Thus it is impossible to formulate a 'pure' experiment on the selectivity of the adsorption, since it is impossible to ensure that the solvent has the same thermodynamic quality for each of the polymers. The only way to design a 'pure' experiment is to examine the adsorption of the components from a melt of the two polymers, in the absence of a solvent. We have attempted a study of this type,[20] but even this was not a strictly adsorption-determined experiment.

If the discussion of the adsorption of mixtures is approached from the standpoint of dilute and semidilute solutions it becomes obvious that the aggregation and adsorption conditions should depend on the critical concentration for the overlapping of the macromolecular globules in the mixture, i.e. on the concentration region in which the contact and the overlapping of the globules of different polymers sets in. Obviously, under these conditions we cannot use the c^* values for the different components in the solvent, since in a solution of the mixture the thermodynamic quality of the 'mixed' solvent differs from the quality of the pure solvent and depends on the concentration and on the concentration ratio of the components.

II. Critical concentrations for solutions of polymer mixtures

The theory of solutions of mixed polymers from the point of view of their hydrodynamic properties is still not fully developed. Two approaches to the calculation of the critical concentrations in mixtures are possible.

Table 1. Critical concentrations of polymers in solutions of mixtures, determined by the expression $c^* = 1/[\eta]$.

A. PS–PBMA–CCl_4 system.			B. PC–PCL–$CHCl_3$ system		
c/g (100 ml)$^{-1}$ [a]	$[\eta]$/100 ml g^{-1}	c^*/g (100 ml)$^{-1}$	c/g (100 ml)$^{-1}$ [a]	$[\eta]$/100 ml g^{-1}	c^*/g (100 ml)$^{-1}$

Notes. The following symbols are used: PS polystyrene; PBMA polybutylmethacrylate; PC polycarbonate; PCL polycaprolactone.
[a] Concentration of mixed solvent.

The first uses well known relationships for determining c^*, but the characteristic viscosity of one of the components of the mixture is calculated in the presence of the second polymer, taken in a known proportion. We carried out these calculations for a series of polymer pairs, using their adsorption data given below. The critical concentration for the overlapping of the macromolecular globules was determined by the expression $c^* = 1/[\eta]$, where the characteristic viscosity was found by the standard method using an Ubbelohde viscometer. The special feature of the determination of the critical concentration in a polymer mixture in this approach is the use of a 'mixed' solvent. As can be seen from the data in Table 1 an increase in the concentration of the 'mixed' solvent produces a fall in $[\eta]$, and therefore also an increase in c^* for the given polymer. These data also show a worsening of the thermodynamic quality of the 'mixed' solvent (as compared with the pure solvent) for both the polymers in solution. Therefore the c^* values for the pure solvents cannot be used to study the adsorption of the components of a mixture in the concentration regions below and above the crossover. In all the three experimental methods of determining the adsorption considered above the component ratio in solution is not constant, and therefore the critical concentration of each of the components in the presence of the other determined in this way is also not constant. We consider this approach to be unacceptable also because the c^* values are determined without allowing for the fact that the bulk of the solution is filled with globules of two kinds, and that each kind is 'unaware' of the other. The region of uniform filling of the bulk by globules of two kinds will be in a different concentration region, defined by the size of the globules of each of the components and by their concentration in the solution.

Therefore we shall use an 'averaged' critical concentration for the mixture, determined from the 'averaged' characteristic viscosity. In contrast to the approach previously developed[21,22] we propose the following expression for the 'averaged' characteristic viscosity:

$$[\eta]_m = [\eta]_A\varphi_A + [\eta]_B\varphi_B \ , \qquad (1)$$

where φ_A and φ_B are the volume fractions of the components in their mixture, with $\varphi_A + \varphi_B = 1$.

Thus, for a mixture of the macromolecules A and B (and irrespectively of their thermodynamic compatibility) the crossover region should be reached by each of the polymers at concentrations below c_A^* or c_B^* because the bulk of the solution is already occupied by globules of molecules of kind A and B. We assume that $c_m^* = 1/[\eta]_m$. In that case the averaged crossover concentration is a function of the concentration ratio of dissolved molecules of kinds A and B.

The critical concentrations and the characteristic viscosities for a range of pairs and for their constituent components in a common solvent are shown in Tables 2 and 3. We have studied the adsorption of these same pairs. The PS–PBMA and PS–polydimethylsiloxane (PDMS) system are thermodynamically incompatible in solution, whereas the PC–PCL pair is compatible in the solvents which we have chosen.

An analysis of the data in Tables 2 and 3 shows that in the PS–PBMA system with similar c^* values for the two components

Table 2. Critical concentration and critical viscosity in the polymer–solvent system.

the parameter c_m^* is weakly dependent on the ratio of the components in solution. On the other hand for the PC–PCL system we observe a marked increase in c_m^* with increasing concentration of PCL, due mainly to the only moderately high molecular mass of PCL. In the PS–PDMS system with constant (but different) concentrations of PDMS the critical concentration of the mixture falls with increasing concentration of PS, but with a constant concentration of PS and a variable concentration of PDMS it increases. These results must be included in any analysis of the adsorption from mixtures in dilute and semidilute solutions.

III. Adsorption from solutions of mixtures

The experimental methods of determining the adsorption from mixtures used in our work have already been described.[18,19] In this section we present data on the adsorption on Aerosil of three pairs of polymers: PS–PBMA and PS–PDMS (incompatible in solution) and PC–PCL (compatible). The adsorption of PS–PBMA and PCL–PC mixtures was studied at constant concentrations of the mixture in solution and different component ratios, and the adsorption in the PS–PDMS system was studied at a constant concentration of one of the components and a variable concentration of the other.

1. The polydimethylsiloxane – polystyrene – ethyl acetate system

The dependence of the adsorption of PDMS from a mixture with PS in a common solvent at different constant concentrations of PS (above and below the c^* value for PS) is shown in Fig. 1 in A (adsorption) – c/c_m^* coordinates. As can be seen, in the crossover region and above c_m^* the adsorption decreases after going through a maximum, both in the adsorption of pure PDMS and in the adsorption from its mixtures containing different amounts of PS.

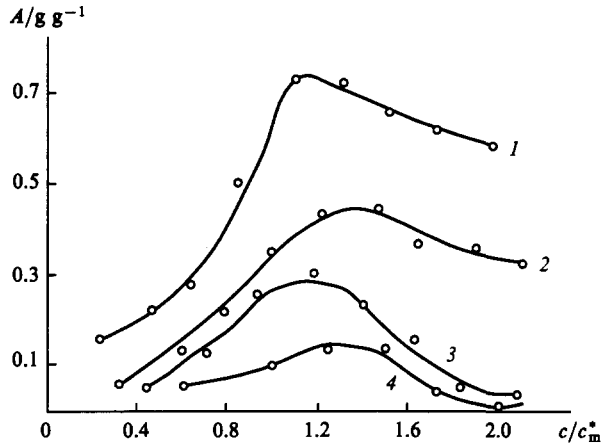

Figure 1. Dependence of the adsorption of PDMS from an individual solution (*1*) and from its mixtures with PS (*2–4*) in ethyl acetate on the concentration of PDMS for PS concentrations of 0.5 (*2*), 1.0 (*3*), and 2.5 (*4*) g(100 ml)$^{-1}$.

The absolute adsorption values are very large, suggesting aggregative adsorption. The same suggestion applies also to the decrease in adsorption at concentrations above c^*_m. As the concentration of PS in the solution is increased (thus worsening the thermodynamic quality of the 'mixed' solvent) the adsorption decreases but the maximum in the region of reduced concentrations greater than 1 is retained (above the crossover region). As has already been mentioned we ascribe this behaviour to the worsening of the quality of the solvent for PDMS, which by decreasing the size of the globules also decreases the size of the aggregates.

In Fig. 2 we show the corresponding data for PS, which indicate that in this case the effects discussed above are less marked (even though the aggregation of PS should be much greater because of its greater molecular mass, see below). The adsorption of PS is much lower, and almost independent of the concentration of PDMS, but an adsorption maximum is observed in the region of concentrations much lower than c^*_m. Obviously, in this case PDMS has a higher affinity for the adsorbent surface, and this produces a higher selectivity of the adsorption, promoted by noncompatibility with the PS.

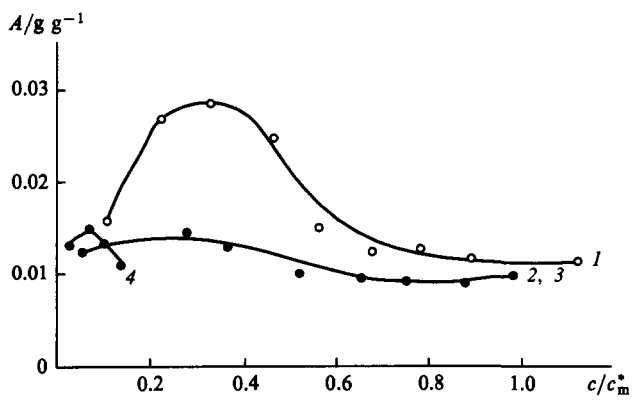

Figure 2. Dependence of the adsorption of PS from an individual solution (*1*) and from its mixtures with PDMS (*2–4*) in ethyl acetate on the concentration of PS for PDMS concentrations of 0.5 (*2*), 1.0 (*3*), and 9.0 (*4*) g (100 ml)$^{-1}$.

2. The polystyrene – polybutylmethacrylate – carbon tetrachloride system

The plots in Fig. 3 show that in the crossover region the adsorption of PS from a mixture with PBMA forms a broad maximum, whereas the adsorption of PBMA increases monotonically (Fig. 4). Under these conditions the adsorption of PS from the mixture is lower, and that of PBMA is higher than for the same adsorptions from a pure solvent. These results denote preferential adsorption from the mixture with PBMA. Evidently, in this case the noncompatibility of the components promotes the preferential adsorptions of one of the components under conditions in which the adsorption of the pure components from the common solvent are approximately equal.

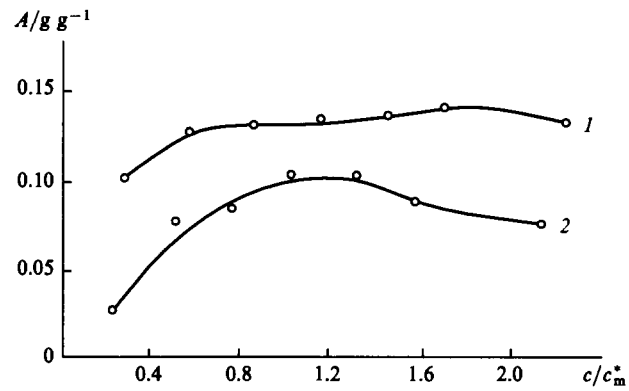

Figure 3. Dependence of the adsorption of PS from an individual solution (*1*) and of its mixture with PBMA (*2*) in carbon tetrachloride on the concentration of PS.

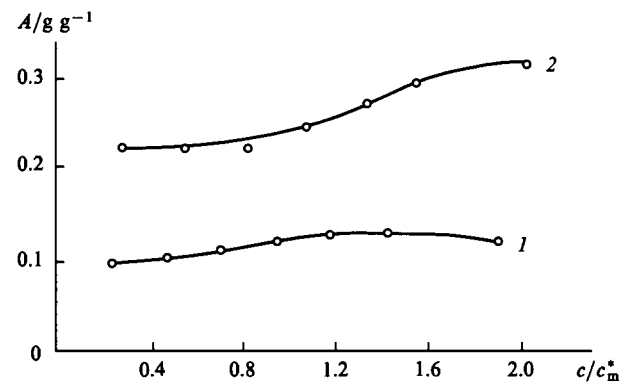

Figure 4. Dependence of the adsorption of PBMA from an individual solution (*1*) and from its mixture with PS (*2*) in carbon tetrachloride on the concentration of PBMA.

In Fig. 5 the data for this system are presented differently: in the form of a plot of the ratio of the adsorptions of the components against the concentration of the mixed solvent (the concentration of PBMA in solution is plotted horizontally) while keeping the overall concentration of the solution constant at 3 g (100 ml)$^{-1}$. It is clear from this figure that the PBMA is adsorbed preferentially at all component ratios in the solution. However, a minimum is found in the plot. A similar minimum occurs (Fig. 6) in the plot (obtained in our laboratory) of the second virial coefficient A_2 for the ternary PS – PBMA – solvent system. The concentration at which the minimum for this pair of polymers is seen coincides with the c^* value of each of the components (we note that these are not very different) and with c^*_m. After passing through c^*_m the ratio of the adsorptions increases again.

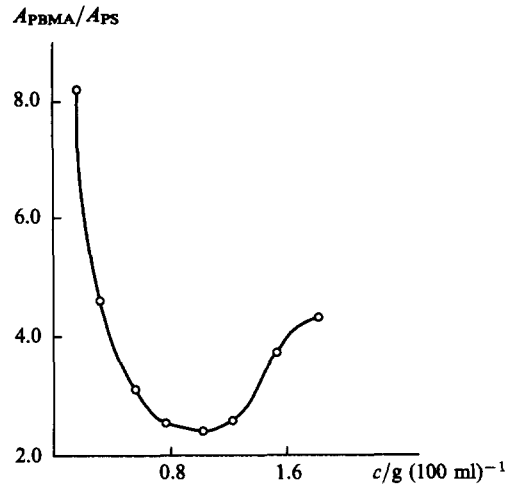

Figure 5. Dependence of the ratio of the adsorptions of PBMA and PS on the concentration of PBMA.

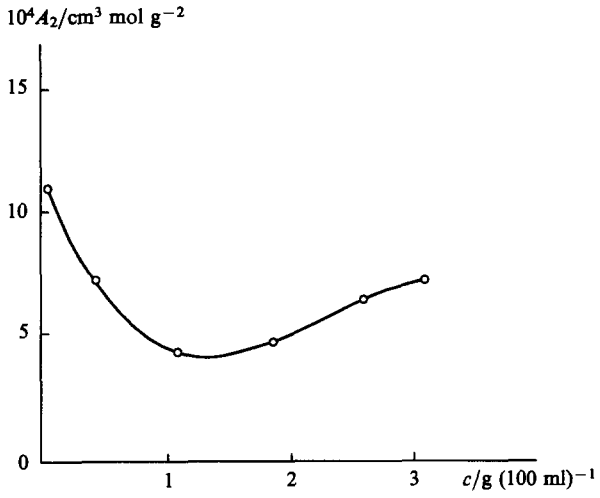

Figure 6. Dependence of the second virial coefficient A_2 on the concentration of the 'mixed' solvent for the PS–'mixed' solvent (PBMA–CCl_4) system.

Comparing Figs 5 and 6 shows the important role of the varying thermodynamic quality of the 'mixed' solvent in the adsorption from mixtures.

3. The polycaprolactone – polycarbonate – chloroform system

The adsorption of a compatible pair of polymers (polycaprolactone and polycarbonate) in a common solvent has been studied from a solution of constant concentration but variable composition. The dependence of the adsorption of PCL on c/c_m^* is shown in Fig. 7. For PCL we see a maximum in the crossover region. The adsorption of PCL is clearly predominant, in spite of its low molecular mass, and therefore the adsorption of PC begins only at high enough concentrations of this polymer in the mixture (Fig. 8), exceeding c^*. However, the adsorption of each of the components from the common solvent is higher than from the mixture: we attribute this effect to the thermodynamic compatibility of the components.

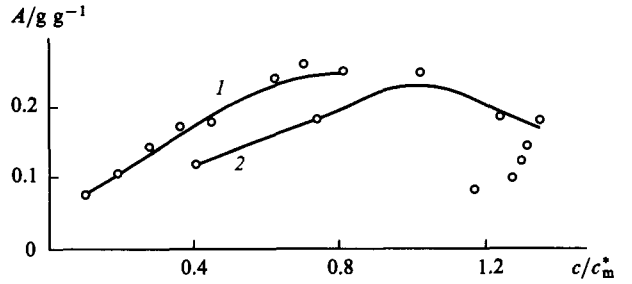

Figure 7. Dependence of the adsorption of PCL from an individual solution (*1*) and from its mixture with PS (*2*) in chloroform on the concentration of PCL.

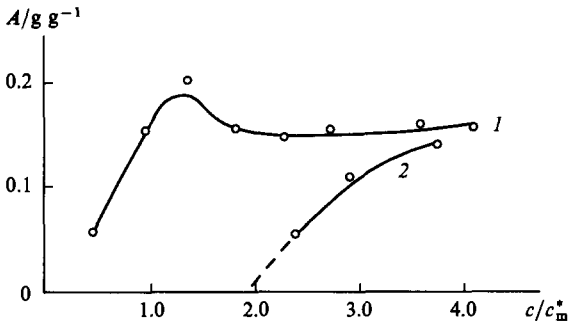

Figure 8. Dependence of the adsorption of PC from an individual solution (*1*) and from its mixture with PCL (*2*) in chloroform on the concentration of PC.

IV. Aggregation in solutions of macromolecules and in their mixtures

We shall now examine some experimental results on the formation of aggregates of these polymers in solution. In order to facilitate the comparison with the data on the adsorption of polymers discussed above these results were obtained by the turbidity spectrum method, which allows the size and number of aggregates to be determined from the spectral dependence of the intensity of light scattering in the visible region. The theoretical foundations of this method were laid by Heler and Pangonic[23] on the basis of the theory of Mie,[24] developed for isotropic spheres. We used a modification of this method.[25]

Data on the formation of aggregates in solutions of PS, PBMA, and PC are shown in Table 4 (see next page). Solutions of PDMS are transparent in the visible region of the spectrum. Aggregates of low-molcular PCL were also not detected, probably because of their small size (the turbidity spectrum method can be used to determine the size of aggregates above 200 Å).

An analysis of the results in Table 4 shows that in this polymer the formation of aggregates begins at concentrations below c^*, and also in the region above crossover. The size of the macromolecular aggregates usually increases with the concentration and depends on the temperature (but the temperature dependence of the adsorption has not been studied yet). However, the dependences on concentration and temperature are not unambiguous, because the quantities of interest are determined both by the change in the quality of the solvent with temperature and by the equilibrium constant of the reaction between aggregated and nonaggregated macromolecules, which is also temperature dependent. In different systems the size and number of the aggregates vary with temperature in different ways in the regions above and below c^*, and therefore it is difficult to identify any well defined trends in their changes.

Table 4. Size r (in Å) and number of macromolecular aggregates per unit volume N (in 10^{-9} cm^{-3}) as a function of the concentration of solution c [in g (100 ml)$^{-1}$] at 25 °C.

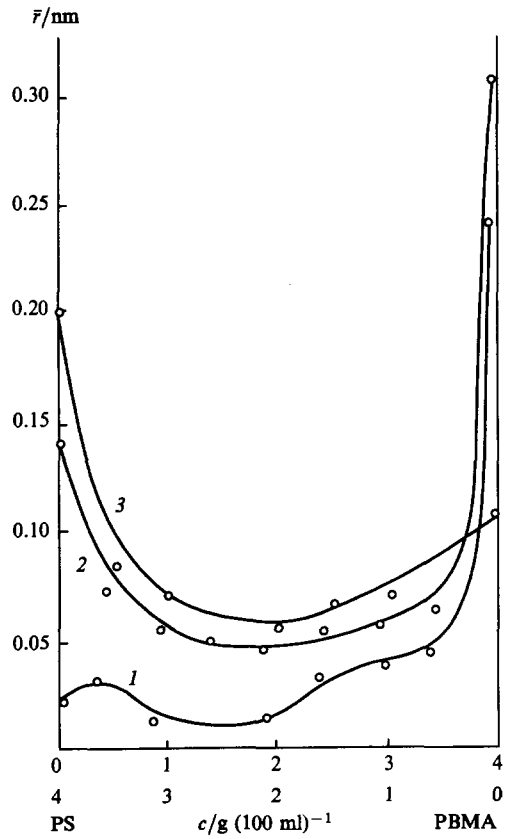

Figure 9. Dependence of the average size of the aggregates of macromolecules in a PS–PBMA–CCl_4 mixture on the composition of the 'mixed' solvent. T, °C: (*1*) 10; (*2*) 25; (*3*) 60.

However, it is obvious that aggregation processes take place also in solutions of mixtures, and that the trend towards aggregation of the molecules of each kind should be most marked when the thermodynamic compatibility of the components is low and the thermodynamic quality of the 'mixed' solvent is poor. In Fig. 9 we also show the averaged size of the aggregates of macromolecules in a PS–PBMA mixture as a function of the composition of the 'mixed' solvent [for an overall solution concentration of 3 g (100 ml)$^{-1}$]. As can be seen the presence of a 'second' polymer (incompatible with the 'first') leads to a marked decrease in the size of the aggregates as a result of the worsening of the thermodynamic quality of the solvent and of the possible collapse of the macromolecules.[26] This is consistent with the data on the characteristic viscosity of one of the components in the presence of the other. The decrease in size of the macromolecules may lead to a decrease in the average size of the aggregates in a solution of the mixture.

V. Conclusion

The experimental data quoted above show the existence of an interdependence between the adsorption of polymers from a mixture, the thermodynamic compatibility of the components in solution, the change in the thermodynamic quality of the 'mixed' solvent, and the critical crossover concentration for each component (on the one hand) and the mean critical concentration for the mixture. The influence of the aggregation of macromolecules in solutions of mixtures of polymers produced by the above factors on the adsorption in the concentration regions above and below c_m^* is also obvious. As a rule the adsorption decreases as the system goes through c_m^*: this may be due (among other reasons) to the fact that the size and number of the macromolecular aggregates which constitute the mixture of components also depend on c^* and are not identical in the regions below and above c^*. Since the formation of aggregates produces a change in the thermodynamic quality of the solvent it is obvious that the presence of a second component must alter the formation conditions of the aggregates by worsening the thermodynamic quality of the 'mixed' solvent (irrespectively of whether the given pair of polymers is compatible in solution).

The high adsorptions of both the individual components and their mixture can be explained only in terms of the aggregative adsorption mechanism: differences in the behaviour of the systems during adsorption in the region above or below the crossover can be attributed to changes in the aggregation conditions of macromolecules of different kind and different concentration regimes under conditions of continuously varying thermodynamic quality of the solvent. The passage through the crossover region produces changes in the structure of the solution as a result of the formation of a network of contacts and of the overlapping of the macromolecular globules. However, in reduced coordinates the passage through the crossover region often does not lead to significant changes in adsorption, i.e. the adsorption is not markedly affected by whether the system is close to or far from the crossover. Therefore the influence of regime of the mixed solution on the adsorption of its components can probably be identified from the dependence of A on c/c_m^*.

Thus the change in the thermodynamic quality of the solvent produced by the introduction of various quantities of a second polymer is mainly responsible for the behaviour of the adsorption from mixtures and for the selectivity of the adsorption of one of the components. Another factor which lack of space prevented us from discussing in the present review is the affinity of the components towards the adsorbent surface. This requires studies on different adsorbents. The simultaneous influence of various factors has so far prevented the development of a theory of adsorption from mixtures.

The theory of adsorption from mixtures is still in its first stage of development, in spite of the fact that the first papers on this topic were published 17 years ago. The number of

experimental data is small, and the number of variables to which the adsorption is sensitive is large: they include the molecular mass of the components,[27] the nature of the adsorbent,[29] and the interaction of the components in solution (the thermodynamic interaction parameter), and also the molecular mass distribution, the formation of aggregates in different regimes, the problems associated with their determination, etc.

However, since the structure of the adsorption layers of mixtures is determined by the conditions of adsorption from the mixtures, and since the adsorption layers play an important role in polymeric composite materials based on multicomponent polymer systems, the further study of the adsorption of mixtures and also the study of the structure of adsorption layers of mixtures[30] are of the greatest importance.

Contents

I. Introduction	471
II. 'Smart' polymers	471
III. Applications of 'smart' polymers	477
IV. Conclusion	486

Abstract. **'Smart' water-soluble polymers and hydrogels are capable of responding reversibly to slight changes in the properties of the medium (pH, temperature, ionic strength, the presence of certain substances, illumination, electric field), the response of the system being readily seen with the naked eye (the formation of a new phase in a hitherto homogeneous solution, sudden swelling or contraction of the hydrogel). The properties of such polymers and hydrogels are examined. The use of 'smart' polymers and hydrogels for the concentration of protein solutions and the dehydration of suspensions, for the creation of membranes with a controllable permeability, for the isolation and purification of biomolecules, for the immobilisation of biocatalysts, and for the creation of sensor systems and systems for the controlled release of medicinal drugs is discussed. The bibliography includes 261 references.**

I. Introduction

In recent years, investigators have devoted much attention to the so called 'smart or intelligent materials'. Materials capable of responding to slight changes in the external medium in a preprogrammed manner are combined under this name.[1] A specialist journal has actually appeared, namely the *Journal of Intelligent Material Systems and Structures* (Technomic Publishing), in which data on this topic are published.

Among the water-soluble polymers and hydrogels, the term 'smart' may be applied to systems which respond reversibly to slight changes in the properties of the medium (pH, temperature, ionic strength, the presence of certain substances, illumination, electric field), the response of the system being readily visible with the naked eye (the formation of a new phase in a hitherto homogeneous solution, sudden swelling or contraction of the hydrogel).

Such systems are evidently attractive for biotechnology and medicine. They place in the hands of investigators a simple method for manipulating the system. Heating/cooling by several degrees or slight changes in the pH can be achieved rapidly and easily and this permits a reversible and repeated transition from a homogeneous to a heterogeneous system and an alteration by a factor of several tens of the degree of swelling of the hydrogels. Such systems have already found practical applications in the isolation and purification of biologically active substances and in the immobilisation of biocatalysts. They can be used for the controlled release of medicinal drugs, in biosensors, and for the modelling of regulation processes in the living cell associated with phase transitions in membranes.

All living organisms move by virtue of the isothermal conversion of chemical energy into mechanical work, expressed, for example, by the contraction of muscles and by the movement of the flagella or cilia of microorganisms. Hydrogels based on 'smart' polymers, capable of markedly swelling (expanding) or, conversely, contracting in response to external stimuli in the form of thermal, chemical, or electrical energy, may be used for the modelling of such systems. The history of the creation of the first systems of this kind in the 1950s is associated with names familiar in polymer chemistry such as those of Kuhn and Katchalsky.[2,3]

A micromotor or a flapping wing, a gel 'beetle' climbing an inclined slope, and a gel 'finger' bending and straightening out in air and not in solution as in most other cases, the motion of all of which was initiated by a gel, were demonstrated in the Section of Polymer Gels of the Congress of the Japanese Polymer Society held in December 1991 in Tsukuba.[4,5]

The aim of the present review was to draw the attention of chemists and biochemists to certain interesting and useful properties of 'smart' polymers and to stimulate, on the one hand, the use of such systems in biochemical and biotechnological research and, on the other, to stimulate the search for and synthesis of new homopolymers and copolymers with such properties.

II. 'Smart' polymers

For a polymer system to become 'smart', i.e. capable of responding strongly to slight changes in the external medium, a first-order phase transition, accompanied by a sharp decrease in the specific volume of the macromolecule, must occur in it. The theoretical foundations of such processes were laid by Flory.[6] One of the main conditions for the manifestation of critical phenomena in swollen polymer networks or linear macromolecules is the presence of a 'poor' solvent. In such a solvent, the forces of attraction between the segments of the polymer chain may overcome the repulsion forces associated with the excluded volume, which leads to the collapse of the polymer chain.

The three-dimensional structure of macromolecules is determined by four fundamental interactions: van der Waals forces, hydrophobic interactions, electrostatic interactions, and

hydrogen bonds. The electrostatic interactions between like charges of the polymer chain constitute the most effective repulsion forces. The osmotic pressure within a hydrogel, arising due to low-molecular-mass counterions, also promotes the swelling of hydrogels. Van der Waals forces, hydrophobic interactions, hydrogen bonds, and the interaction of ions of opposite sign constitute attraction forces and give rise to phase transitions in polymer solutions or to the collapse of hydrogels. The differences in the nature of the interactions inducing the phase transition are manifested to the greatest extent in the temperature dependence of the swelling or collapse of hydrogels.[7] If van der Waals forces (for example, the phase transition in a partly hydrolysed polyacrylamide gel in water–acetone mixtures)[8] or hydrogen bonds (for example, the phase transition in a gel consisting of interpenetrating networks of polyacrylamide and polyacrylic acid)[9] are responsible for the collapse of the hydrogel, then the hydrogel swells following an increase in temperature and contracts when it is reduced. On the other hand, if the collapse of the gel is induced by hydrophobic interactions (for example, the phase transition in the gel of the *N*-isopropylacrylamide–sodium acrylate copolymer)[10] or the interaction of ions of opposite sign [for example, the phase transition in the acrylamide–acrylate–(*N*-acryloyl-3-aminopropyl)trimethylammonium copolymer],[11] then the opposite temperature dependence is observed — the gel swells at a low temperature and contracts when the temperature is raised. In certain hydrophilic gels, for example in the acrylamide–sodium vinylsulfonate copolymer, there is a possibility of two phase transitions. In 65% acetone at low temperatures, the gel is in a state of collapse but begins to swell rapidly at temperatures above −10 °C. Up to 55 °C, the gel remains in its swollen state and then its collapse begins again.[12]

For highly hydrophilic ionogenic polymers, the solvent can become sufficiently poor as a result of the addition of an organic solvent to water. Critical phenomena (precipitation of the polymer from the solution or the collapse of the polymer gel) in the presence of 30%–70% acetone, 1-propanol, or ethanol have been observed for both synthetic polymers (copolymers comprising acrylamide and ionogenic comonomers)[11,13–16] and natural polymers (hyaluronic acid,[17] DNA,[18–20] gelatin,[20] agarose[20]).

For nonionogenic polymers, the solubility of which in water is determined by the formation of hydrogen bonds, water becomes a poorer solvent with increase in temperature. For example, when aqueous solutions of the homopolymers with ethylene oxide and its copolymers with propylene oxide are heated above the lower consolute temperature (LCT), the solution divides into two phases — the phase enriched in the polymer and the aqueous phase which contains hardly any polymers. On neutralisation of ionogenic groups, aqueous solutions of polyelectrolytes also divide into two layers on heating (for example, polymethacrylic acid at pH ~3 and temperatures > 50 °C).[21] As a rule, the LCT for such polymers is 60 °C and above (see, for example, Pandya et al.[22] and Louai et al.[23]), which is relatively unsuitable for biomolecules. However, such polymers can be used successfully to create reversibly soluble catalysts for homogeneous chemical reactions. Thus a homogeneous hydrogenation catalyst, which precipitates on heating to 50–60 °C, has been created on the basis of a block-copolymer of ethylene and propylene oxides (Pluronic) and a rhodium complex. After precipitation, the catalyst can be readily separated from the reaction mixture, dissolved at room temperature, and reused.[24]

For the appearance of critical phenomena in the systems described above, extreme conditions are necessary (a high concentration of the organic solvent, a high temperature, and low pH values), leading to the rapid denaturation of the biomolecules. For this reason, they have not so far found applications in biotechnology. However, the development of enzymology in nonaqueous media and of new methods for the immobilisation and stabilisation of biocatalysts may render such systems promising from the standpoint of biotechnology.

This review deals with polymers and hydrogels in which critical phenomena are observed in aqueous solutions at temperatures not exceeding 40–45 °C and at weakly acid or neutral pH values.

1. Polymers sensitive to changes in pH

Owing to the neutralisation of the charged macromolecule as a result of a change in the pH of the medium, water becomes a poor solvent for the neutral polymer molecule; a possibility of critical phenomena arises. As already mentioned above, for highly charged polyelectrolytes, such as polymethacrylic acid, critical phenomena occur at extreme pH values and temperatures. A decrease in the charge of the macromolecule and an increase in its hydrophobicity as a result of copolymerisation with hydrophobic comonomers make it possible to achieve critical phenomena within an acceptable pH range. For the copolymers of dimethylaminoethyl methacrylate with n-alkyl methacrylates, the collapse of the gels occurs at pH 6.0–6.5 at room temperature. With increase in the content of n-alkyl methacrylate in the gel, the difference between the volumes of the collapsed and swollen gels diminishes and the transition is observed at lower pH values. An increase in the length of the alkyl substituent in n-alkyl methacrylate also diminishes the difference between the volumes of the collapsed and swollen gels but does not exert a systematic influence on the pH of the transition.[25]

Aqueous solutions of methacrylic acid–methyl methacrylate copolymers and derivatives of cellulose which have been rendered hydrophobic [containing carboxy-groups (carboxymethylethylcellulose, cellulose acetate-phthalate, hydroxypropylmethylcellulose phthalate or acetate-succinate)], which are homogeneous at pH > 4 – 5.5, do not separate into aqueous and polymer phases on acidification[26] Such polymers are manufactured on an industrial scale and are widely used in the manufacture of medicinal drugs (Table 1). The shell surrounding a tablet comprising such polymers does not dissolve in the stomach at pH 1.4 and protects the drug against the harmful influence of the contents of the stomach. Having entered the intestine (pH 6.7–7.4), the shell of the tablet dissolves, which enables the drug to be rapidly assimilated into the blood. On the other hand, the copolymer of diethylaminoethyl methacrylate with methyl methacrylate and butyl methacrylate is insoluble at neutral pH values, but dissolves in an acid medium. The shell comprising this polymer protects the tablet against dissolution in the saliva and under these conditions the mouth is not affected by the unpleasant taste of bitter medicines.[27]

Table 2 presents the monomers used in pH-sensitive synthetic polymers and hydrogels. Monomers containing both weak acid or basic groups and strong acids or bases are used to create such systems. The pH-sensitive hydrogels are obtained by radical polymerisation in the presence of a cross-linking agent or by the chemical cross-linking of a water-soluble polymer with the aid of a bifunctional agent. By varying the composition of the monomers and the content of the cross-linking agent, it is possible to obtain hydrogels with various pH-sensitivities and degrees of swelling. The degree of swelling of a hydrogel, i.e. the response of the system to a change in the external conditions, depends mainly on the charge of the monomer, the pK of the ionogenic group, the degree of ionisation, the concentration of the ionic monomer in the polymer network, the degree of cross-linking of the hydrogel, and the pH and the ionic strength of the surrounding medium.[30]

Hydrogels containing acid groups swell in a weakly alkaline medium but collapse in an acid medium. On the other hand, hydrogels with basic groups swell in an acid medium but collapse on raising the pH. Polyampholytic hydrogels, obtained from comonomers one of which is soluble in an alkaline medium but insoluble in an acid medium (for example, methacrylic acid), while the other is actually soluble in an acid medium but insoluble in an alkaline medium [for example, 2-(*N*,*N*-dimethylamino)ethyl methacrylate], swell to the maximum extent at neutral pH values. When such gels are acidified or rendered alkaline, they undergo rapid dehydration.[34]

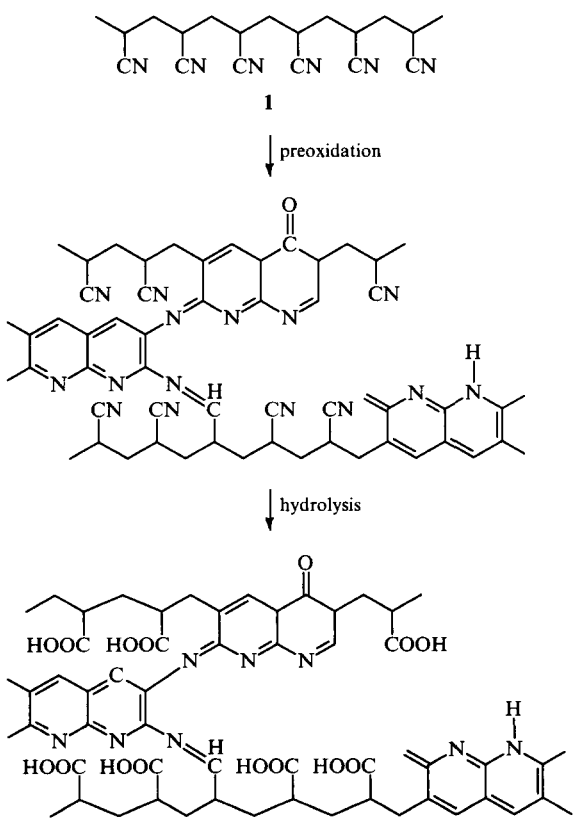
Physicochemical models of the swelling of hydrogels usually take into account the change in the free energy as a result of three factors: (1) the osmotic pressure of the mobile counterions within the gel (the Donnan theory); (2) the mixing of the polymer with the solvent (the Flory–Huggins theory); (3) the stretching of the macromolecules, increasing the free energy, which ultimately actually determines the limiting degree of swelling. Thus the increase in entropy as a result of the mixing of the polymer with an effective solvent increases the swelling of the gel. If the solvent is poor, then the entropy gain is inadequate and the gel does not swell. The extension of the macromolecules during the swelling of the polymer network is described by the elasticity theory, which postulates that the polymer network consists of cross-linked polymer chains in a free Gaussian conformation.[33]

The physicochemical models of the swelling describe satisfactorily only the swelling of weakly charged hydrogels with univalent counterions at high degrees of swelling.[16] For low degrees of swelling or for gels with a high charge density, the theory agrees poorly with experiment. Thus, for a high charge density in the gel, the activities of the ions are no longer equal to their concentrations. In a weakly swollen gel, the effective relative permittivity is lower than in the surrounding solution. This situation is energetically unfavourable for any ion and the latter tends to leave the gel. This tendency intensifies with increase in the hydration radius of the ion. For a low degree of swelling, an appreciable proportion of the water in the gel is in a state where it is bound to the polymer. The ability of such molecules to solvate counterions is much lower. In a highly charged gel at a high degree of swelling, it is no longer permissible to neglect the electrostatic interactions between the fixed charged groups and the mobile counterions, as is done in the Donnan theory. The electric potential in the gel ceases to be uniform, since the counterions tend to be localised in the vicinity of the charged groups. Furthermore, the Donnan theory does not take into account the specific ionic effects, for example, the cross-linking of the polymer chains by polyvalent counterions and complex formation.

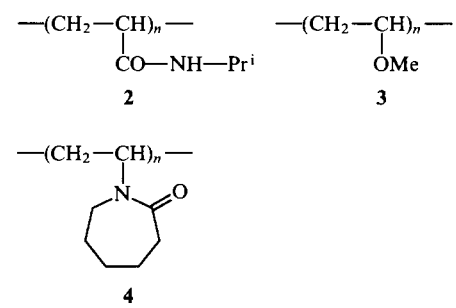


The factors listed above explain the absence of a satisfactory general theoretical model of the swelling of hydrogels.[33]

The change in pH near the electrode is used to create polymer systems responding to the electric potential.[35] Thus a column of a partially hydrolysed (20% of amide groups) polyacrylamide gel 3 cm long in 50% acetone shortens by a factor of 200 under the influence of a potential (> 1.15 V). In the electric field, the protons move to the cathode, while the negatively charged acrylic group of the polymer chain tends to move to the anode. A mechanical stress arises in the bulk of the gel, reaching a maximum in the vicinity of the anode and a minimum near the cathode, which under the conditions of a poor solvent leads ultimately to the collapse of the gel (in a purely aqueous solution, only a gradual decrease in the size of the gel without collapse takes place). The collapse of the gel is reversible and in the absence of an electric field the gel swells again. The response time in such a system is measured in hours. The response can be accelerated by decreasing the size of the gel and by increasing the

electric field strength. The 150–300 μm polyacrylate microparticles undergo a decrease in volume by 90% after 50 s in a 46 V electric field.[36] When the potential of a polypyrrole film is altered from −0.6 to 0.4 V, the pH in its vicinity changes from 4 to 10. The Gaussian polyacrylate gel microparticles on the surface of the film then dissolve in only 15 s. When the initial potential (−0.6 V) is restored, the microgel particles are reformed (in 10 s).[37]

A biodegradable gel, swelling reversibly when the pH is altered, has been obtained from the copolymer of *N,N*-dimethylacrylamide, *N*-*tert*-butylacrylamide, the *p*-nitrophenyl ester of *N*-methacryoylglycylglycine and acrylic acid cross-linked covalently with the aid of *N,N'*-(ω-aminocaproyl)-4,4'-diaminobenzene.[38]



The critical phenomena in highly charged polyelectrolytes, occurring at extreme pH values, are of interest from the standpoint of the possibility of converting chemical energy into mechanical energy and of modelling biomechanical systems. Such systems are nowadays already capable of developing forces sufficient to lift by 0.5 cm a motor-car weighing 800 kg,[39] whilst a composite film consisting of the vinyl alcohol–acrylic acid and vinyl alcohol–acrylic acid–allylamine copolymers is capable of undergoing a change in size in response to a change in the solvent (the replacement of ethanol by 0.01 M NaOH) in only 40 s.[40] The artificial muscle model, created at the Tokyo Technological Institute, is even more striking.[41] Modification by partial oxidation and hydrolysis of the industrially manufactured polyacrylonitrile fibres **1** imparts to the latter the ability to swell strongly in an alkaline medium (1 M NaOH) and to contract in an acid medium (1 M HCl). The elongation reaches 80% in 2 s and the force developed under these conditions is 12 kgf cm^{-2}. For comparison, we may note that skeletal muscles are elongated by 30% in 10^{-2}–10^{-3} s, developing a force of 4–10 kgf cm^{-2}. Thus the effectiveness of artificial muscles almost approaches that of biological muscles.

The mechanical systems capable of converting various types of chemical energy into mechanical work have been examined in an extensive review by Osada,[39] whose coworkers carried out much successful work in this field.

2. Polymers sensitive to changes in temperature

Thermoresponsive polymers and hydrogels with a LCT below 40–45 °C are considered in this section. In their classical work,[42] Taylor and Ceranowski derived a rule according to which there exists a region where the polymer solution has a LCT. One of the most complete lists of polymers having a LCT in aqueous solutions is presented in the review by Galaev and Mattiasson.[43] Polymers with a wide variety of LCT have been synthesised.[44] The possibility of using some of them in biotechnology has been vigorously investigated at the present time. These are mainly poly-*N*-isopropylacrylamide **2** (poly-NIPAA) and other poly-*N*-alkylacrylamides as well as poly-(methyl vinyl ether) **3** (PMVE). Recently poly-*N*-vinylcaprolactam **4** (PVCL) and ethylene oxide–propylene oxide copolymers have attracted the attention of investigators.

The greatest number of publications have been devoted to NIPAA. The NIPAA homo- and copolymers are readily obtained by radical polymerisation in aqueous[45] or organic[46,47] solvents. Poly-NIPAA is soluble in acetone, chloroform, dioxane, tetrahydrofuran, lower alcohols, and cold water; it forms a separate phase at a temperature of about 32 °C, the LCT being almost independent of the molecular mass (*M*) of the polymer.[47] Poly-NIPAA cannot be fractionated into narrow molecular-mass fractions when an aqueous solution of the polymer separates into layers comprising different phases on heating. A carefully dried mixture of acetone and cyclohexane is used for the fractionation.[48]

Narrow molecular mass fractions of poly-*N,N*-diethylacrylamide with a very narrow distribution of molecular masses (polydispersity less than 1.2) have been obtained by polymerising the corresponding monomer with transfer of the group (live polymerisation) in dry tetrahydrofuran, the process being initiated by the methyl(trimethylsilyl)acetal of dimethylketene and catalysed by tetrabutylammonium acetate.[49] However, the molecular mass of the polymer synthesised is low and amounts to only 4700. The lower consolute temperature is 30 °C for the poly-*N,N*-diethylacrylamide synthesised by radical or live polymerisation and 40 °C for that synthesised by anionic polymerisation.[50,51]

The synthesis of copolymers of NIPAA with acryloyloxysuccinimide (used for the covalent immobilisation of proteins),[52] the modification of poly-NIPAA designed to obtain a porous glass[53] and polymer membranes,[44,54,55] and the preparation of block-copolymers of NIPAA with ethylene oxide,[56] the aqueous solutions of which do not separate into two phases on heating, in contrast to the poly-NIPAA homopolymer, but form a gel[57,58] have been described.

The properties of poly-NIPAA in aqueous solutions and the phase transition on heating have been investigated in detail by various methods: turbidimetric,[47,48] viscometric,[48,49] calorimetric,[48,60,61] light scattering,[60,61,63] fluorescence,[63–66] and EPR.[67] The influence of surfactants and of the inclusion of

hydrophobic or ionogenic comonomers on the LCT of poly-NIPAA has been investigated,[59,68-72] while the influence of the phase transition on the sorption of poly-NIPAA on aerosils with various hydrophobic properties has also been studied.[73]

The phase separation of aqueous solutions of poly-NIPAA on raising the temperature is caused by the conformational transition of the macromolecule from a loose globule to a compact coil. Such a transition is accompanied by a sharp decrease in the size of the macromolecule,[62] a decrease in the mobility of the fluorescent dansyl label bound covalently to the polymer,[64] and a fivefold increase in the nonradiative energy transfer between the pyrene and naphthalene labels bound covalently to the macromolecule.[65] The enthalpy of the transition is consistant with the loss of approximately one hydrogen bond per monomer unit.[45] The heat capacity of poly-NIPAA decreases with increase in temperature. The decrease in the heat capacity of poly-NIPAA reflects the collapse of the polymer chain on heating accompanied by a decrease in the number of contacts between the polymer molecule and water molecules similar to that occurring when a protein is renatured after being denatured by cooling.[61]

The formation of multimolecular micelles, consisting of a hydrophobic core surrounded by solvated poly-NIPAA chains, has been observed for the hydrophobically modified NIPAA copolymers at temperatures below the LCT.[63] The exchange of polymer molecules between the micelles is very slow.[66] At the LCT, the collapsed micelles aggregate and effective mixing of the copolymer molecules becomes possible.[63,66] The endothermic enthalpy of the phase separation of the ternary NIPAA–butyl methacrylate–X copolymers, where X is a hydrophilic, hydrophobic, cationic, or ionic comonomer, decreases linearly with increase in the LCT. Thus the hydrophobic interactions between the polymer side groups intensify with increase in temperature owing to the decrease in the structure formation in the water around these groups. It was concluded that the change in the LCT induced by the incorporation of other comonomers is determined by the overall change in the hydrophilicity of the copolymer and not by the direct influence of the hydrophilicity or charge of the comonomer on the water molecules in a structured arrangement around the hydrophobic groups.[71]

Since the hydrophobic interactions are the main driving force inducing the phase separation, the LCT of poly-NIPAA or of its copolymers may be regulated by influencing the effectiveness of these interactions. The introduction of hydrophobic and hydrophilic comonomers respectively decreases and increases the LCT of the polymer.[74] The LCT of poly-NIPAA diminishes with increase in the ionic strength of the solution and increases in the presence of ionic detergents forming stable complexes with the polymer.[57,68-70,75] Organic solvents miscible with water weaken the hydrophobic interactions of the side groups of poly-NIPAA and increase the LCT. However, in the presence of 40–60 vol% of certain solvents (methanol, tetrahydrofuran) the LCT of poly-NIPAA decreases to 0 °C and below.[76]

The gels of poly-NIPAA and other *N*-alkyl-substituted polyacrylamides are obtained by adding cross-linking agents (usually *N,N'*-methylenebisacrylamide) to the initial reaction mixture, by radiation-induced polymerisation,[77] or by cross-linking the copolymer with the aid of a bifunctional agent.[38] The introduction of ionogenic comonomers makes it possible to obtain hydrogels sensitive to changes in both temperature and pH.[78-80] Macroporous gels with high rates of swelling and dehydration have been synthesised at temperatures below the LCT of poly-NIPAA.[81] The poly-NIPAA gel in a granulated form can be obtained by emulsion or suspension polymerisation.[82-84] By employing different *N*-alkyl-substituted polyacrylamides, it is possible to synthesise thermoresponsive hydrogels (TH) with a LCT ranging from 5.5 °C for the poly-*N*-acryloylpiperidine gel to 72 °C for the poly-*N*-ethylacrylamide gel.[85]

The study of the phase transitions in hydrogels of poly-NIPAA[86-97] and other *N*-alkyl-substituted polyacrylamides[93,98-101] was initiated by Ilavsky et al.[98] and Tanaka and coworkers.[10] These investigations are continuing to develop vigorously also at the present time. The dependence of the time required for the phase transition on the size of the gel specimen makes it possible to describe the phase transition approximately as a collective diffusion process.[94] The formation of separate collapsed sections or of a thin film of the collapsed gel on the surface of the specimen plays an important role in this.

The influence of surfactants,[75,102,103] organic solvents,[76,101,104] salts,[105] and poly(ethylene glycols)[106] and of the inclusion of ionogenic comonomers[87,89,98,100,107] on the collapse and swelling of gels has been investigated. The nonradiative energy transfer[108] and mechanical stresses[109] arising on collapse of poly-NIPAA gels have been studied. It is of interest to note that sodium chloride at a concentration of ~1 M induces the collapse of the poly-NIPAA hydrogel at room temperature, whereas other salts exert a typical salting-out effect — the gel is gradually dehydrated with increase in the salt concentration.[105] The strong hydrophobic interaction of the isopropyl groups of poly-NIPAA with the alkyl group of sodium dodecyl sulfate results in the poly-NIPAA gel behaving in the presence of the detergent as a gel of the copolymer of NIPAA with the anionic monomer.[102,103]

A detailed theoretical discussion of the models of the phase transitions in poly-NIPAA gels may be found in recent reviews.[110,111]

Poly(methyl vinyl ether) **3** is obtained by the cationic polymerisation of methyl vinyl ether, this polymer being produced industrially.[85] The LCT for aqueous solutions of PMVE is 34–38 °C.[85,112] The PMVE gel is obtained by the γ-irradiation of polymer solutions.[85] Irradiation at temperatures above the LCT[113] or careful selection of the conditions (irradiation dose, polymer concentration)[114] make it possible to obtain gels with high rates of swelling and dehydration when the temperature is altered. The phase transitions in solutions[45,112,115] and in PMVE gels[85,86,113,116-118] have been studied much less than in poly-NIPAA.

As for poly-NIPAA, hydrophobic interactions apparently play the main role in the phase transition in PMVE.[112] The molar enthalpy of the phase transition is lower for PMVE than for poly-NIPAA,[86] but the phase transition in PMVE is also accompanied by the loss of one hydrogen bond per monomer unit,[118] as in poly-NIPAA.

Polyvinylcaprolactam **4** (PVCL) is obtained by the radical polymerisation of vinylcaprolactam in an organic solvent[120] or in bulk.[121,122] The thermodynamics of the phase transition in aqueous PVCL solutions have been investigated by Tager and coworkers.[123-126] The LCT for aqueous PVCL solutions depends on the molecular mass of the polymer and varies from 31 °C for the polymer with $M = 1\,250\,000$ to 40 °C for the polymer with $M = 15\,500$.[43] The Gibbs free energy, enthalpy, and entropy of mixing of PVCL with water are negative over the entire range of compositions. With increase in temperature, the mixing becomes less exothermic. It has been suggested that hydrophilic and hydrophobic hydration of the polymer takes place in aqueous PVCL solutions. In the ranges of temperatures and compositions close to the binodal curve, the hydrophobic hydration predominates, as a consequence of which the miscibility of the polymer with water diminishes and phase separation takes place.[123]

Cellulose derivatives, in particular hydroxypropylmethylcellulose and ethoxyethylcellulose, are also promising for use in biotechnology. They are distinguished by a high chemical stability and a satisfactory biological compatibility. The LCT for aqueous solutions of these polymers is 50–60 °C, but in the presence of salts and surfactants it diminishes to almost 0 °C.[127-129]

Among epoxyethane derivatives, nonionic detergents, especially Triton X-114 (*p-tert*-octylphenyl ether of polyoxyethylene with a degree of polymerisation of 7–8) have found extensive

application in biotechnology. The copolymers of ethylene and propylene oxides have also attracted the attention of investigators recently. Aqueous solutions of Triton X-114 have a LCT in the region of 18 °C. They are used to extract hydrophobic proteins into the polymer phase (the so called cloud point extraction). However, strictly speaking Triton X-114 ($M = 450 - 500$) and similar compounds are oligomers and not polymers, so that their study is outside the scope of the present review. The theoretical principles and practical aspects of the use of cloud point extraction of detergents have been examined in detail in a brilliant review by Hinze and Pramauro.[130]

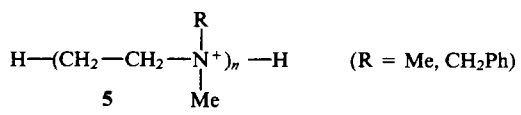
The 50:50 ethylene oxide–propylene oxide copolymer with $M = 4000$ (manufactured by the Union Carbide Company under the trade name UCON 50-HB-5100) has an LCT of 55 °C. However, in the presence of a 0.2 M sodium sulfate solution the LCT diminishes to 40 °C.[131] A more hydrophobic copolymer containing 80 mol.% of propylene oxide ($M = 2000$) has a lower LCT (18 °C).[132]

The methacrylic acid–methacrylate copolymer described above (Eudragit S 100),[27] aqueous solutions of which separate into layers on acidification, forms a separate polymer phase in a neutral medium at 40 °C in the presence of 50 mM Ca^{2+}. The copolymer redissolves when the temperature is reduced.[133,134]

The first communication about reversible gel formation in an inorganic system has appeared recently. The aluminium polyphosphate hydrogel dissolves when the temperature is reduced and reforms at room temperature.[135]

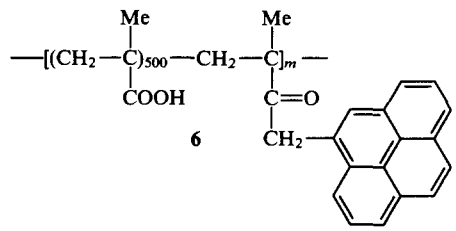
The reversibly flocculating latexes are interesting systems. The minimum NaCl concentration inducing flocculation diminishes with increase in temperature and reaches a constant value at temperatures above the LCT. At a certain NaCl concentration, the latex begins to flocculate after the attainment of a certain temperature, but it can be redispersed on cooling. The formation of such latexes based on poly-NIPAA[136–140] and its copolymers,[77,84,141,142] *N*-acryloylpyrrolidine–*N*-acryloylpiperidine copolymers,[143,144] methacrylic acid esters, and ethylene oxide oligomers with degrees of polymerisation of 1,2,4–5, and 7–8 has been described.[145]

3. Polymeric complexes



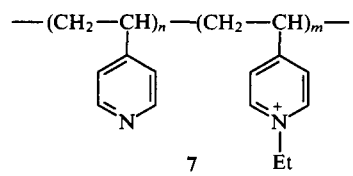
Polymeric complexes, i.e. complexes formed by two different polymers or a polymer and a low-molecular-mass compound, have recently attracted increasing attention by investigators.[146]

The formation of a polyelectrolyte complex is described in a general form by the following scheme:[147]



$$(A^-k^+)_n + (K^+a^-)_m \rightleftharpoons$$
$$\rightleftharpoons [(A^-K^+)_x(A^-k^+)_{n-x}(K^+a^-)_{m-x}] + xa^- + xK^+ ,$$

where A^- and K^+ are the anionic and cationic groups in the polymer and a^- and k^+ are their low-molecular-mass counterions. The degree of conversion Θ is defined as the ratio of the number of interionic bonds formed to its maximum possible value ($\Theta = x/m$ for $n \geqslant m$ or $\Theta = x/n$ for $m \geqslant n$). The solubility of polymeric complexes in water depends on the fraction of the charged ionic group z and on the relative length of the oppositely charged polyions and also on the pH and the ionic strength of the solution. The polymeric complexes formed by polymers with $z = 1$ have minimum solubility at $\Theta \to 1$. Nonstoichiometric polyelectrolyte complexes in which one of the polyions predominates can be represented as an unusual block copolymer consisting of a charged hydrophilic block containing one polymer chain and a neutral hydrophobic block containing two polymer chains.



The cooperative nature of the interaction between the polyions makes such polymeric complexes exceptionally stable even for fairly low degrees of polymerisation of the polyions. For example, the dissociation constant of the polymeric complexes of polymethacrylic acid with quaternised oligoethyleneimines **5** becomes negligibly small even for the octamers.[147]

5

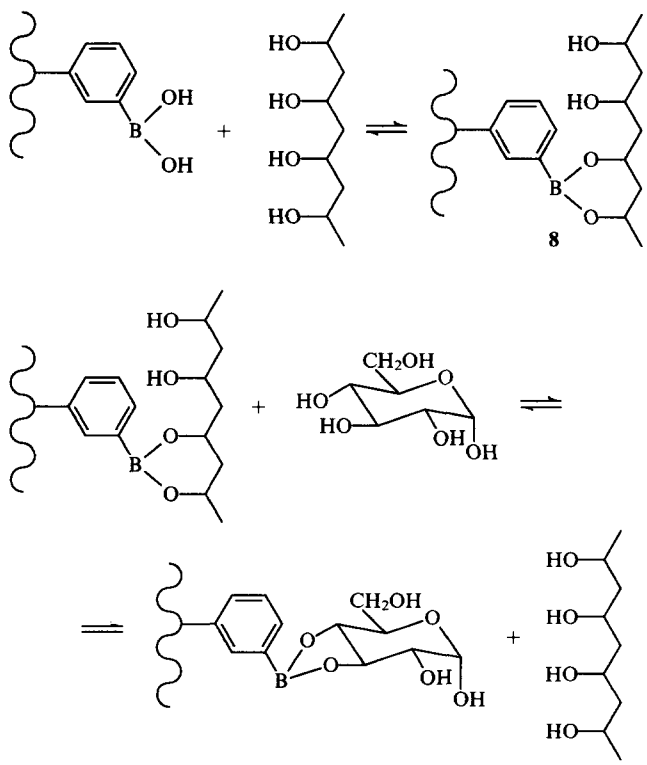
6

7

Despite the high stability of the polymeric complexes, they are capable of exchanging the polyions. The nature and length of the polyion are of fundamental importance in exchange reactions.[148] The polymethacrylate complex **6** (PMA) (degree of polymerisation 4100), containing a fluorescent label (1 label for each 500 monomer units), with partially quaternised poly-4-vinylpyridine **7** (P-4-VP) (degre of polymerisation 170) is capable of exchange with polyphosphates (PP) with different degrees of polymerisation (from 20 to 230):

$$\text{P-4-VP.PMA} + \text{PP} \rightleftharpoons \text{P-4-VP.PP} + \text{PMA} .$$

The equilibrium in this reaction in 0.3 M NaCl is fully displaced to the right for the long polyphosphates and to the left for the shortest polyphosphate. For a fixed degree of polymerisation of the polyphosphates ($n = 70$), the reaction equilibrium is fully displaced to the right in 0.3 M LiCl and to the left in 0.3 M KCl, the equilibrium remaining unchanged in 0.3 M NaCl. Such phenomena have no analogues in nonpolymeric systems and can serve as useful models for the regulation of processes in the living cell with the aid of biopolymers.[148]



Systems capable of undergoing marked but reversible changes in their properties and of responding to slight changes in the medium may be included among 'smart' polymeric complexes. Nonstoichiometric polyelectrolyte complexes (NPC), formed in the interaction of a polycation (for example, poly-*N*-ethyl-4-vinylpyridinium bromide) and an excess of a polyanion (for example that of polymethacrylic acid) are systems promising for biotechnology.[149–151] The ability of such complexes to be precipitated quantitatively from solution when the pH of the latter is altered by only 0.3 of a unit is an attractive feature.[149]

Another interesting group comprises complexes between uncharged polymers, which are obtained as a result of numerous weak interactions, for example via hydrogen bonding between polyacrylic acid and polyacrylamide.[9] The strength of the hydrogen bonds increases with increase in temperature. Thus the gel formed by interpenetrating polyacrylic acid and polyacrylamide polymer networks collapses on cooling to ~20 °C and swells again on heating.[9]

Kabanov and coworkers[152,153] observed complex formation between polymethacrylic acid and polyoxyethylene (POE). Complexes between high-molecular-mass polymethacrylate (or polyacrylate) and POE are formed in this case when the molecular mass of the latter exceeds a certain critical value, which is 2000 for the complex with poly(methyl methacrylate) and 6000 for that with polyacrylate. The complex between POE and polymethacrylate is stabilised by hydrophobic interactions, its stability increasing with increase in temperature, while that of the complex between POE and polyacrylate depends little on temperature.

The important role of hydrophobic interactions (in which the α-methyl group of the polymethacrylate participates) in the stabilisation of the complex between POE and polymethacrylate has been observed also in the study of the influence of the nature of the solvent. Thus the critical molecular mass of POE, necessary for the formation of its complex with polymethacrylate, increases sharply on passing to more hydrophobic water–methanol mixtures, whereas for the polyacrylate complex it remains virtually constant.[154] The marked reversible temperature dependence of the complex formation reaction between polymethacrylate and POE in the range 25–45 °C renders such systems interesting for biotechnological use.[39,155,156]

Boric acid affords stable complexes with polyol compounds. The complex between poly(vinyl alcohol) and the *N*-vinylpyrrolidinone–*N*-acryloylamidophenylboronic acid copolymer is formed as a result of the interaction of boric acid with the hydroxy-groups of the polyol, but in the presence of an excess of another polyol (for example, glucose) the complex decomposes. The removal of glucose (for example, by dialysis) again leads to complex **8**,[157,158] so that the complex formation reaction depends reversibly on the presence of glucose, i.e. the given system can be used as a detector for the presence or absence of glucose.

Among the complexes between polymers and low-molecular-mass compounds investigated, mention should be made of the complex formed by the poly-2-acrylamido-2-methylpropanesulfonic acid with n-dodecylpyridinium chloride. This system responds to changes in the electric potential by a change in the form of the gel.[159]

III. Applications of 'smart' polymers

1. Concentration of protein solutions and dehydration of suspensions

When hydrogels collapse, their volume contracts by a factor of 1000.[86] Their ability to absorb up to several grams of water per gram of the gel and then to give up the absorbed water after a slight change in conditions is used in the dehydration of suspensions and in the concentration of protein solutions. Such processes are based on the cycle presented in Fig. 1.[160]

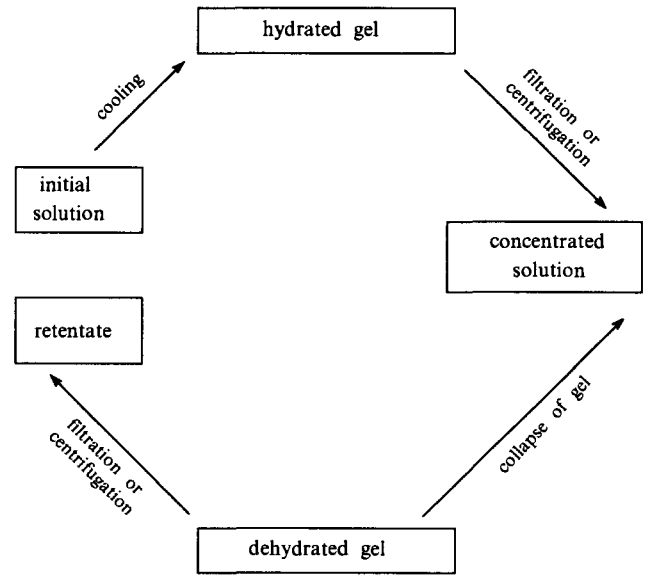


Figure 1. The removal of water from suspensions and concentration of protein solutions.[160]

The gel dehydrated beforehand swells in the initial solution, 'taking up' water. Low-molecular-mass substances, capable of permeating into the gel pores, diffuse within the gel. On the other hand, high-molecular-mass substances, which are incapable of permeating into the pores, remain in solution in a concentrated form. The swollen gel is separated from the solution and regenerated by inducing its collapse (it is heated above the critical temperature or the pH and the ionic strength of the solution are altered). The gel collapses and gives up the previously absorbed water together with the low-molecular-mass substances dissolved in it. After separation by filtration or centrifugation, the dehydrated gel is again ready to concentrate a fresh portion of the initial solution. By regulating the composition and degree of cross-linking of the gel, it is possible to alter its selectivity with respect to the molecular mass and charge of the sorbed solutes.[161–164] When collapsed gels are used for concentration and dehydration (swellex process or gel dewatering process), it is possible to combine the high productivity of liquid extraction with the selectivity of membrane methods.[162]

The idea of concentrating protein solutions by adsorbing water on solid particles had already appeared in the 1960s.[165] However, attention was concentrated only on the stage involving adsorption without the regeneration of the gel, i.e. on the left-hand part of the cycle presented in Fig. 1. Only after the appearance of 'smart' hydrogels has it become possible to carry out economically the entire cycle.

Solutions of casein and bovine serum albumin have been concentrated by a factor of 4.6–4.8 with the aid of a sulfonated polystyrene gel cross-linked by divinylbenzene (the gel was regenerated by means of a concentrated salt solution). The yield of the protein was then 95%–99%.[162]

The appearance of thermoresponsive hydrogels (TH), which collapse on heating, made this type of process even more attractive. The thermoresponsive NIPAA hydrogel has been used to concentrate cellulases from the *Trichoderma reesei* culture liquid.[162]

Cussler and coworkers[166] developed an industrial process for the preparation of soya protein by dehydrating the mother liquor with the aid of poly-NIPAA-TH (Fig. 2).

After the extraction of soya oil, the soya beans are ground up and the proteins are extracted with water at pH 8.5. The mother liquor is separated by centrifugation. In the traditional technology, the proteins are precipitated with acid. The most

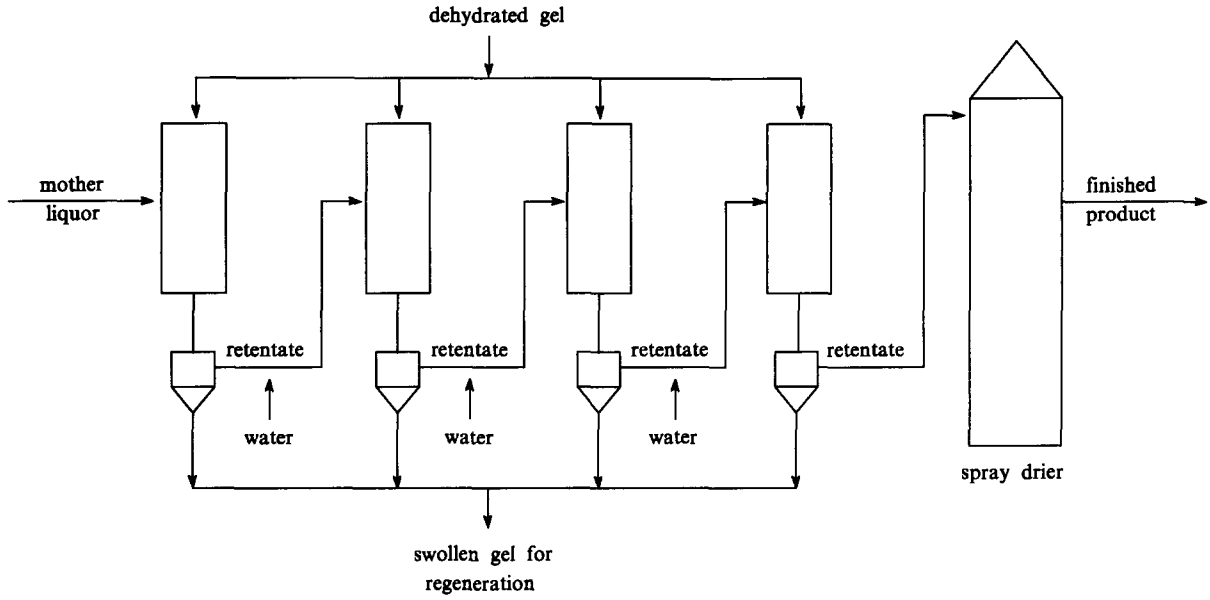

Figure 2. Industrial preparation of soya protein.[160]

valuable among them (the albumin-like proteins) are not precipitated under these conditions and are lost, while the toxic phytins are precipitated. The protein precipitate is dissolved at pH ~7 and dried on a spray dryer. From 100 kg of the initial raw material, 33 kg of the product is obtained.

In the proposed technology, the mother liquor is treated at 5 °C with the collapsed poly-NIPAA-TH, after which the gel swells, adsorbing 40% of water. The swollen gel is separated by centrifugation and the retentate is diluted with water and again treated with the collapsed gel (this procedure is repeated 2–4 times), which makes it possible to separate the protein from low-molecular-mass impurities. After this, the retentate, containing 15% of dry substances, is transferred to the spray dryer. From 100 kg of the initial raw material, one obtains 45 kg of the product. The yield with respect to the protein exceeds 80%.[166]

The new process is not free of disadvantages, one of which is the adsorption of the protein on the surface of the gel particles. However, it does have significant advantages: a high yield of the product as a result of the retention of albumin-like proteins, the absence of the precipitation stage with acidification, which makes it possible to retain a greater amount of the proteins in the native form, and better consumption qualities of the product because of the absence of toxic phytins and a higher protein content. Economic analysis, carried out on industrial apparatus, showed that the capital expenditure on the manufacture of the protein is recovered in 3.2 years.[160]

The PMVE-based thermoresponsive hydrogel is used to remove water from suspensions, in particular the culture liquids of microorganisms.[167,168] This type of process makes it possible to overcome a number of the disadvantages of the traditional filtration. Thus the filtration area may be readily increased by increasing the number of TH particles; the 'pie' comprising the microorganisms, formed on the surface of the particles, is continually disrupted as a result of the increase in the geometrical size of the TH particles on swelling; the path traversed by water from the bulk of the suspension to the filtering surface is greatly shortened.

Engineering calculations have shown that it is necessary to have 7–8 kg of dry PMVE-TH for the preparation of 1 kg of dry substances. In order to compete with the most productive strip filters, the TH particles must withstand at least 2000 cycles, so that an increase in the mechanical strength of the PMVE-TH particles is the primary condition for the successful introduction of the TH into practice.[168]

2. Membranes with a controllable permeability

The ability of 'smart' polymers to undergo a distinct transformation from an uncoiled globule into a compact coil has been used to create membranes with a controllable permeability. The principle of the operation of such a membrane is illustrated in Fig. 3. In the uncoiled conformation, the polymer molecules immobilised on the surface do not prevent the permeation of the solutes into the pores. In the compact conformation, the polymer molecules block or strongly hinder the entry of the solutes into the pores.

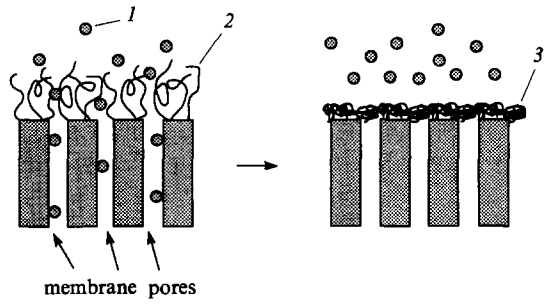

Figure 3. Controllable permeability of a membrane as a function of the conformation of the polymer. (*1*) Solute; (*2*) polymer in the uncoiled conformation; (*3*) polymer in the compact conformation.

Permeability controlled by varying the pH has been achieved when poly-4-vinylpyridine or polyacrylic or polymethacrylic acid were immobilised on the surfaces of the membranes of nylon capsules. In the first case, the permeability increases with decrease in the pH, while in the second it increases with increase in the pH.[169] When the pH is reduced from 6 to 3, the permeability of the polymethacrylate membrane to fluorescence-labelled dextran (M = 10000) changes by a factor of 85.[170]

The regulation of permeability by varying the temperature has been achieved in the immobilisation of poly-NIPAA or other poly-*N*-alkylacrylamides on the pore surface.[44,54,55,171] The change in the effective pore size due to the transition of the immobilised NIPAA molecules from the uncoiled conformation to the compact conformation makes it possible to regulate gel-permeation chromatography by varying the elution temperature.[53]

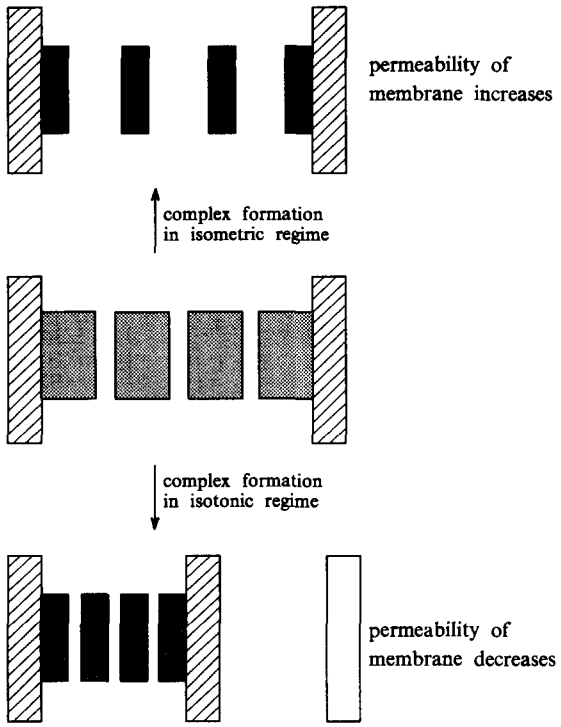

Figure 4. Behaviour of a poly(methyl methacrylate) membrane during the formation of a complex with polyoxyethylene in isometric and isotonic regimes.[39]

If the membrane consists wholly of a polymeric hydrogel, its permeability changes greatly as the degree of swelling of the gel is altered. The permeability of a membrane made from a copolymer comprising 4-acryloylpiperidine (LCT = 5.5 °C), 2-hydroxyethyl methacrylate, and styrene to insulin varies sharply with temperature. Depending on the composition of the copolymer, the permeability either increases or decreases with increase in temperature.[172] A change in the pH or in the electric field alters reversibly the permeability of a poly(methyl methacrylate) membrane by a factor of 50.[173] The complex formation reaction between polyoxyethylene and a poly(methyl methacrylate) membrane can be used both to increase the permeability of the membrane, which has fixed geometrical dimensions (isometric regime), and to decrease the permeability of a freely mounted membrane (isotonic regime) (Fig. 4). In both cases washing of the membrane with a weakly alkaline solution leads to the dissociation of the complex and the restoration of the initial permeability.[39,156]

The acrylamide–acrylic acid copolymer hydrogel, immobilised on porous glass, exists under isometric conditions. Such a membrane allows the passage of aqueous solutions of polyoxyethylene only with $M < 4000$. The collapse of the hydrogel in 50% acetone leads to a sharp increase in the permeability of the membrane: it is now capable of allowing the passage of polyoxyethylene with $M = 80\,000$.[111,174,175]

Thus membranes based on 'smart' polymers can be used to create various systems with feedback.

3. Isolation and purification of biomolecules

The ability of 'smart' polymers in aqueous solutions to form a separate phase after a slight change in conditions has been used to isolate and purify proteins. A general scheme for this process, which has been called affinity precipitation, is illustrated in Fig. 5 (see over).

The conjugate of a 'smart' polymer with a ligand which has an affinity for the given target protein and forms a complex with the latter is added to the initial mixture containing the protein. When the conditions are altered (change in the pH, temperature, and ionic strength, addition of specific complex-forming agents), the polymeric conjugate together with the target protein is segregated as a separate polymeric phase, while the impurities remain in the solution. The polymeric phase is separated from the supernatant. Next the target protein is either eluted from the polymeric phase or the latter is redissolved, altering the conditions in such a way that the complex dissociates, while the polymeric conjugate is reprecipitated but this time without the target protein, which remains in the solution.

This type of approach was first used by Schneider et al.[31] to isolate trypsin. The extract from the pancreas was treated with an acrylamide–*N*-acryloyl-*p*-aminobenzoic acid copolymer containing *m*-aminobenzamidine ligands with a high affinity for trypsin. The trypsin–copolymer complex was precipitated by acidifying the solution to pH 4. The precipitate was separated, washed, and redissolved at pH 8. The polymer was then precipitated but this time at pH 2 (the trypsin–polymer complex is known not to form in an acid medium), whereupon trypsin remained in the solution. After lyophilic drying, the solution contained 90% of trypsin. The copolymer was regenerated (to the extent of 93%) and reused.[31]

Apart from precipitation, reversible flocculation may be used for the purification of biomolecules. The particles of the latex of a copolymer comprising styrene, NIPAA, glycidyl methacrylate, and methacrylic acid are used for this purpose. Thus the antibodies to bovine serum albumin have been isolated from the serum with the aid of the latex containing immobilised bovine serum albumin on its surface.[142]

Examples of the successful employment of the affinity precipitation methods for the isolation and purification of various biomolecules are compiled in Table 3. Mattiasson and coworkers have made a contribution to the development of these methods.[176,179,185–190]

The traditional methods for the purification of proteins by precipitation with ammonium sulfate, polyoxyethylene, or organic solvents are distinguished by simplicity and a high productivity. Their disadvantage is a low specificity. Affinity precipitation makes it possible to combine the simplicity and high productivity of the protein precipitation processes with the high specificity of the affinity chromatographic method. In principle, the same ligands can be used for affinity precipitation as for affinity chromatography. The difference is that affinity precipitation is carried out in a batch regime, which rules out the possibility of the repeated interaction of the protein with the ligand, as in chromatography. Therefore ligands with a high affinity for the protein isolated are preferable for affinity precipitation, which restricts somewhat the choice of the systems employed.[189] Both synthetic and natural polymers are used for affinity precipitation.

The affinity of the target protein for the polymer (for example, the affinity of endo-polygalacturonase for alginate,[187] of agglutinin for chitosan,[176] and of D-lactate dehydrogenase from *Lactobacillus bulgaricus*[186] or xylanase[185] for the methacrylic acid–methyl methacrylate copolymer), is an interesting case, which makes it possible to avoid the complex procedure involving the preparation of the polymer containing the specific ligand.

It is noteworthy that the choice of the polymer is very important for the successful employment of affinity precipitation. The polymeric phase formed should not be too hydrophobic in order not to create an undesirable environment for the protein molecules being isolated.[190] On the other hand, an unduly hydrophilic polymeric phase is difficult to separate from the supernatant, which leads to an appreciable nonspecific trapping of extraneous proteins, i.e. to a decrease in the degree of purification and in the yield of the target protein.[179] The most successful results have been achieved by employing the methacrylic acid–methyl methacrylate copolymer

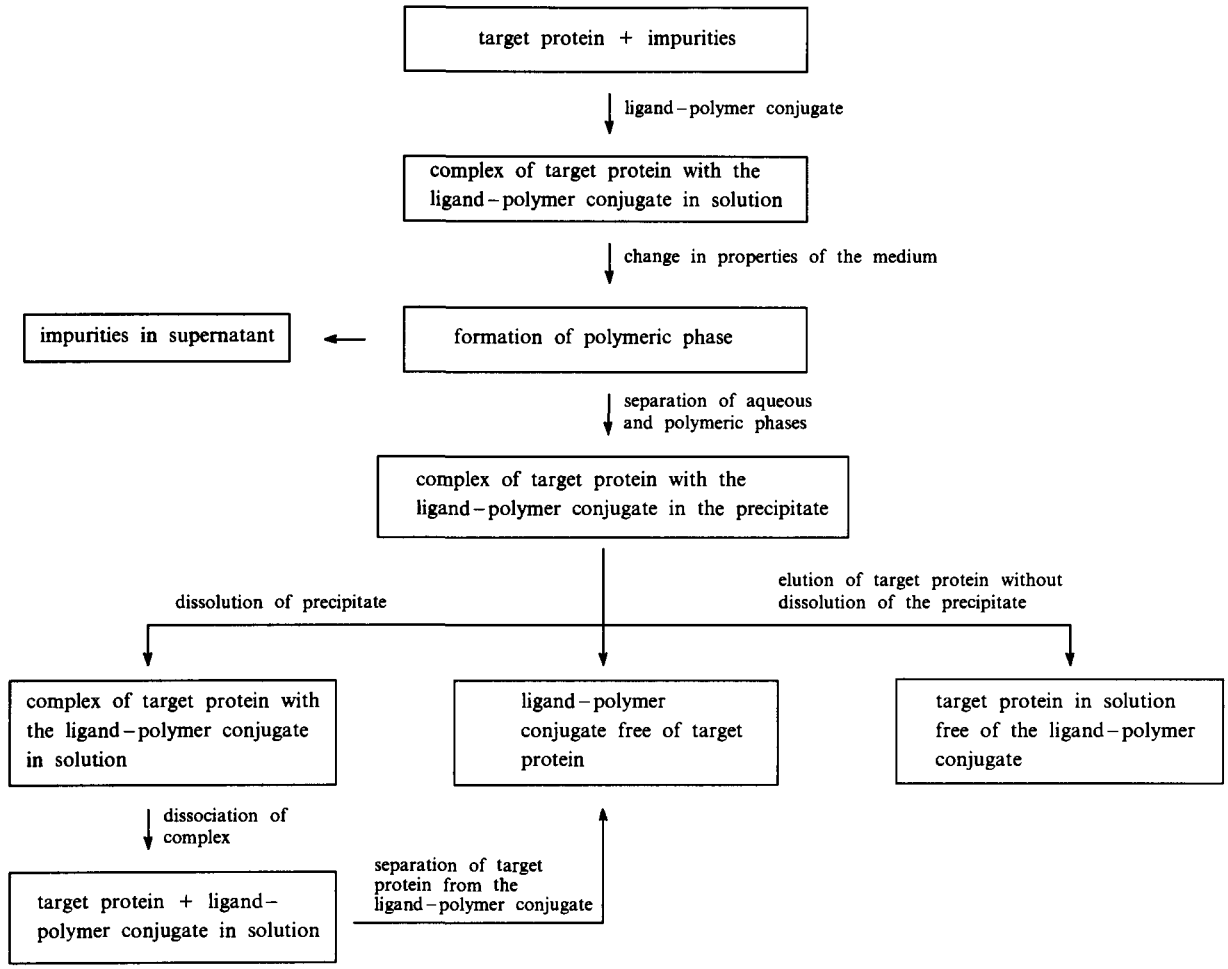

Figure 5. General scheme employed in affinity precipitation methods.

(Eudragit S 100, Table 3). The optimum selection of the conditions makes it possible to attain a tenfold degree of purification of the protein combined with 70%–80% yields.[133,134]

Aqueous solutions of polyoxyethylene and dextran form two immiscible polymeric phases — hydrophilic and hydrophobic — containing more than 80%–95% of water. The hydrophilic and hydrophobic phases consist of dextran and polyoxyethylene respectively. The different distributions of the substances between these two phases are widely used to isolate and purify many biomolecules.[191] One of the problems in this approach is the need to separate the target product from the phase-forming polymer after the mechanical separation of the phases. A convenient way of solving this problem has been proposed by Tjerneld and coworkers.[131,132,192,193]

The principle of the proposed method is illustrated in Fig. 6. A solution of dextran or hydroxyethyl-substituted starch was used as the hydrophilic phase, while the hydrophobic phase consisted of ethylene oxide–propylene oxide copolymers, the aqueous solutions of which separate into aqueous and polymeric phases on heating. When clarified baker's yeast homogenate is added to the two-phase polymer system, enzymes with affinity for the hydrophobic phase (glucose 6-phosphate dehydrogenase, 3-phosphoglycerate kinase, and hexokinase) are extracted into this phase. The extraction of the target product into the hydrophobic phase is facilitated by the addition to the system of the conjugate of the hydrophobic monomer with a ligand having affinity for the target protein (for glucose 6-phosphate dehydrogenase, such a ligand is the dye Procion Yellow).[193] After the mechanical phase separation in the centrifuge, the hydrophobic phase is heated to 24 °C, whereupon the copolymer is segregated in a separate concentrated polymeric phase, whilst the purified enzymes remain in the aqueous phase. The degree of purification and the yield were 5.3% and 50% for glucose 6-phosphate dehydrogenase, 15.3% and 67% for hexokinase, and 15.4% and 72% for 3-phosphoglycerate kinase respectively.[132] The results are entirely comparable with the results of the chromatographic purification of the proteins by traditional methods.

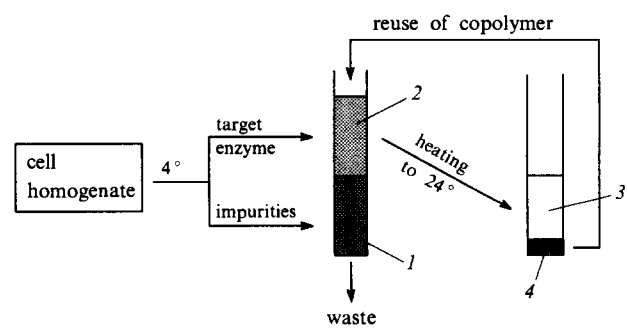

Figure 6. Purification of enzymes in a two-phase system with separation from the phase-forming polymer at a temperature above the LCT.[132] (*1*) Hydrophilic phase — dextran or hydroxypropylstarch; (*2*) hydrophobic phase — copolymer at a temperature below the LCT; (*3*) aqueous phase containing the purified enzyme; (*4*) concentrated polymeric phase — copolymer at a temperature above the LCT.

Table 3. Conditions necessary for the formation of the polymeric phase.

Target product	Ligand	Polymer	Method of formation of polymeric phase	Ref.
Wheatgerm agglutinin	[a]	chitosan	change in pH	176
Trypsin	trypsin inhibitor from soya beans	"	"	177
	p-aminobenzamidine	NIPAA – *N*-acryloyloxy-succinimide copolymer	change in temperature	178
	trypsin inhibitor from soya beans	alginate	addition of Ca^{2+}	179
	"	PVCL	change in temperature	180
Protein A	IgG	hydroxypropylmethylcellulose acetate-succinate	change in pH	181
Human IgG	protein A	galactomannan	addition of tetraborate	182
Alkaline protease	*p*-aminobenzamidine	NIPAA	change in temperature	183
β-Glucosidase	[a]	chitosan	change in pH	184
Hind III restriction endonuclease	λ-phage DNA	NIPAA	change in temperature	183

D-lactate dehydrogenase from *Leuconostock mesenteroides ssp. cremoris*	Cibacron Blue	"	"	188
Lactate dehydrogenase, pyruvate kinase from pig muscle	"	"	change in temperature	133
Alcohol dehydrogenase from baker's yeast	"	"	"	134

[a] The target protein exhibits an affinity for the polymer itself.

Another way of separating the target protein from the phase-forming polymer involves the combination of extraction in a two-phase polymer system with affinity precipitation.[194,195] A conjugate of the Eudragit S 100 copolymer with an affine ligand [human immunoglobulin (IgG) (in the purification of recombinant protein A)[194] or Cibacron Blue (in the purification of lactate dehydrogenase)[195]] is added to the polyoxyethylene–hydroxypropylstarch two-phase polymer system. By virtue of the hydrophobic properties of the polymer, the complex of the target protein with the conjugate is extracted into the hydrophobic phase, which is then separated by centrifugation and the target protein–conjugate complex precipitated by acidification. As a result, the recombinant protein A is purified by a factor of 26 (yield 80%),[194] whilst lactate dehydrogenase is purified by a factor of 12 (yield 50%).[195]

An interesting example of the use of the PVCL-based 'smart' polymer has been demonstrated by Galaev et al.[196] Polyvinylcaprolactam forms stable complexes with dyes, including Cibacron Blue, and is sorbed effectively in a chromatographic carrier containing similar ligands (for example Sepharose Blue). At temperatures above the LCT, the polymer exists in the compact conformation, where each polymer molecule can

interact only with a few ligand molecules, leaving the rest accessible for interaction with enzyme molecules. When the temperature is reduced, the PVCL passes to the uncoiled more flexible conformation. Segments of the polymer molecules acquire the ability to interact with a larger number of dye molecules and begin to compete with the sorbed enzyme for the ligand, ultimately displacing it.

Such a system is the first example of the successful purification of an enzyme by elution solely as a result of changing the temperature without any alteration of the composition of the buffer. The column with Sepharose Blue was treated with a solution of PVCL at room temperature and was washed until traces of the polymer were absent from the eluate. At 45 °C, the unpurified pig muscle extract was deposited on this column and was washed in a buffer until the complete absence of the protein from the eluate, after which the column was cooled to room temperature and the homogeneous lactate dehydrogenase was eluted with the same buffer. A 17-fold purification with a yield of 90% was achieved.[196]

The examples described demonstrate the extensive possibilities of the use of 'smart' polymers for increasing the efficiency of traditional methods for the purification of proteins and for the creation of new ones.

4. Immobilisation of biocatalysts

The ability of polymers to form a separate phase in aqueous solutions following a slight change in external conditions can be used to create reversibly soluble biocatalysts, provided that the enzyme molecule is bound covalently to the polymer. The reversibly soluble biocatalyst acquires the advantages of immobilised enzymes (ease of separation from reaction mixture and the possibility of multiple employment) but at the same time it makes it possible to overcome the disadvantages of immobilised and solid matrix enzymes such as diffusional difficulties in the transport of substrates and products (particularly high-molecular mass ones) and the impossibility of using the enzymes in reactions with insoluble substrates or products.

Catalysts which are reversibly soluble as a function of pH have been obtained by the covalent binding of lysozyme to alginate,[197] of trypsin to the acrolein–acrylic acid copolymer,[29] and of cellulase,[198] amylase,[26] α-chymotrypsin, and papain[119] to methacrylic acid–methyl methacrylate copolymers, carboxymethylcellulose, hydroxypropylmethylcellulose phthalate, and cellulose acetate-phthalate. A reversibly soluble cofactor has been obtained by the covalent binding of NAD to alginate with the aid of diepoxyoctane.[199]

Margolin and coworkers[149,151] studied in detail the behaviour of α-chymotrypsin, penicillinamidase, alcohol dehydrogenase, and urease bound covalently to the polyanion or polycation in the nonstoichiometric polymeric complex of polymethacrylic acid and modified poly(*N*-ethyl-4-vinylpyridinium) bromide. The enzymes in the polymeric complexes are readily precipitated from solution on acidification from pH 6.1 to pH 5.7 and are separated by centrifugation. The polymeric precipitate is redissolved in a buffer solution at pH 6.1 and the immobilised enzyme can be used repeatedly. In the precipitate, the α-chymotrypsin bound covalently to the polyanion is entirely accessible to a high-molecular-mass inhibitor, in contrast to the chymotrypsin bound to the polycation, which is accessible to the extent of only 20%. The enzyme bound to the polycation is present within the hydrophobic core of the complex; it is effectively protected by this environment, which increases its thermal stability.[149]

Enzymes which are reversibly soluble as a function of temperature have been obtained by the covalent binding of α-chymotrypsin and penicillinamidase to PVCL,[200] of trypsin,[74] alkaline phosphatase,[178] and thermolysin[201] to poly-NIPAA, and of lipase and wheat germ to the graft-copolymer comprising NIPAA and the acrylamide–acrylic acid copolymer.[202] The reversible flocculation of latexes has been used to obtain reversibly soluble (more precisely reversibly dispersable) biocatalysts also in affinity precipitation. Trypsin[203] and papain[141] preparations were obtained in this way.

Enzymes which are reversibly soluble as a function of Ca^{2+} concentration are formed on covalent binding of phosphoglyceromutase, enolase, peroxidase, and pyruvate kinase to α_{s1}-casein. The enzyme–casein conjugate is soluble at a Ca^{2+} concentration below 20 mM, but is fully precipitated at a Ca^{2+} concentration in excess of 50 mM. When the Ca^{2+}-binding EDTA is added, the precipitate redissolves.[204]

The use of reversibly soluble biocatalysts in reactions which are difficult or impossible to carry out with the aid of enzymes immobilised on insoluble matrices, for example in the hydrolysis of high-molecular-mass substrates (casein,[141,201] dextrin, and starch[26]), in the hydrolysis of insoluble substrates [cellulose[198] and unpurified starch (corn flour)[26,205–208]], and in the preparation of the insoluble benzyl ester of benzyloxycarbonyl-L-tyrosyl-N^{ω}-nitro-L-arginine[119] and of insoluble phenylglycine[209] is of practical interest.

In the hydrolytic cleavage of corn flour to glucose on treatment with amylase, the reaction product (glucose) inhibits the hydrolysis. The use of a reversibly soluble amylase conjugate increases the efficiency of the hydrolysis. The hydrolysis was carried out at pH 5, at which the amylase conjugate is soluble. After each 24 h, the pH was reduced to 3.5, the unhydrolysed solid residue and the precipitated conjugate were separated by centrifugation, the conjugate was redissolved in a fresh portion of the substrate at pH 5, and the hydrolysis was continued. After five repetitions of the cycle, 101 g of glucose was obtained from 150 g (30 × 5) of the unpurified starch. The activity of the amylase after the fifth cycle ws 96% of the initial value.[205]

The cyclic conversion of the unpurified starch to sugar has been used for the preparation of ethanol by fermentation.[205,207,208] The fermentation by yeast in the presence of a biocatalyst was carried out at pH 5 in a reactor with a conical bottom. The fermentation liquid was periodically acidified to pH 4, whereupon the yeast cells flocculated and the biocatalyst precipitated. The precipitate with the unhydrolysed substrate was separated by allowing it to stand for 10 min, after which it was treated with a fresh portion of the substrate. Ethanol was obtained from the supernatant (80% of the initial volume). After five cycles, 61 g of ethanol was obtained from 150 g of the unpurified starch; the productivity was 0.85 g litre^{-1} h^{-1}.[205,207]

Reversibly soluble amylase has been used also to convert (under continuous fermentation conditions) unpurified starch in ethanol[208] or into lactic acid.[206] In the preparation of ethanol, the fermentation, the separation of the cells and the biocatalyst, and their resuspension were carried out in three separate reactors. The continuous fermentation regime made it possible to increase the productivity to 2 g litre^{-1} h^{-1}.[208] A bioreactor with cells of *Lactobacillus casei* suspended in a κ-carrageenan gel was used in the preparation of lactic acid. The amylase conjugate was separated and resuspended in two other reactors. A productivity of 3.1 g litre^{-1} h^{-1} was attained, which is three times higher than for cyclic batch fermentations.[206]

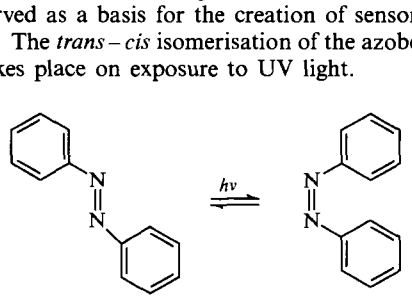
The formation of a water-insoluble polymeric phase by polymers constitutes a convenient method for the immobilisation of enzymes and cells. This process is achieved in the following way: at a temperature below the LCT, the enzyme is dissolved or the cells suspended in a concentrated aqueous solution of the polymer, after which the initial solution is added dropwise to the aqueous solution at a temperature above the LCT. The insoluble polymeric phase formed in the drop 'traps' the enzyme or the cells. After the addition of stabilisers (ovalbumin, egg powder, α-carboxymethylcellulose, tannin) to the initial solution, the polymer particles acquire sufficient stability and do not coagulate on stirring. Trypsin and carboxypeptidase B (stabilised beforehand by covalent binding to the vinylpyrrolidinone–acrolein copolymer),[210] fungal and bacterial cells,[211] and hybridoma cells[212] have been immobilised in a PVCL gel in this way.

The 13:1 NIPAA–vinylferrocene copolymer has been used simultaneously both as a mediator of charge transfer in the enzyme electrode and for the immobilisation of glucose oxidase on the electrode surface.[213–215] At a temperature below 22 °C, the polymer gel film on the surface of the electrode is in a swollen state. The pores in the gel are sufficiently large to allow the permeation of glucose oxidase molecules into their interior and the gel may be 'charged' with the enzyme. At a temperature above 35 °C, the gel collapses, the pores become markedly narrower, and the enzyme is no longer capable of diffusing from the gel, but the gel remains permeable to the low-molecular-mass substrate (glucose). Under these conditions, the glucose concentration is measured with the aid of the electrode. An advantage of such an electrode is the possibility of replacing rapidly and conveniently the inactivated enzyme by fresh enzyme. For this purpose, it is sufficient to wash the electrode below 22 °C in order to remove the inactivated enzyme, charge it with the fresh enzyme, and induce the collapse of the gel by heating it to a temperature above 35 °C.[213]

Thermoresponsive hydrogels were first used for the immobilisation of biocatalysts by Hoffman and coworkers.[216–218] Thus, β-D-galactosidase was immobilised in poly-NIPAA-TH grains (grain size 200–400 μm in the swollen state; critical temperature 37–40 °C). The overall productivity of the bioreactor with the immobilised enzyme at 35 °C differs slightly from its productivity at 30 °C (both temperatures are below the critical temperature). However, cyclic heating and cooling of the reactor between these two temperatures at a rate of 1 °C per minute increases the productivity of the reactor by a large factor. The swelling on cooling and contraction on heating of the TH grains intensify the mass transfer of the substrate and the products into the interior of the grains, the TH operating under these conditions as a pump actuated by a change in temperature and ensuring a more effective supply of the substrate and removal of the products.[217] A similar increase in productivity has been observed also for *Arthrobacter simplex* cells immobilised in poly-NIPAA-TH. The cells catalyse the conversion of hydrocortisone into prednisolone.[218]

Whereas the cyclic heating–cooling between two temperatures below the critical temperature increases the productivity of the bioreactor, heating to a temperature above the critical temperature leads to the complete arrest of the enzymic reaction. The activity of β-D-galactosidase immobilised in poly-NIPAA-TH falls virtually to zero at 50 °C despite the fact that this is the optimum temperature for the soluble enzyme.[219]

exo-1,4-α-Glucosidase has been immobilised in PMVE-TH with a critical temperature of 38 °C. It is noteworthy that the permeability of the TH to the substrate diminishes by five orders of magnitude on heating from 32 to 42 °C, whereupon the reaction stops almost completely. On cooling the TH to 32 °C, the reaction is renewed.[220] A similar effect has been observed also for α-chymotrypsin incorporated in PMVE-TH.[221]



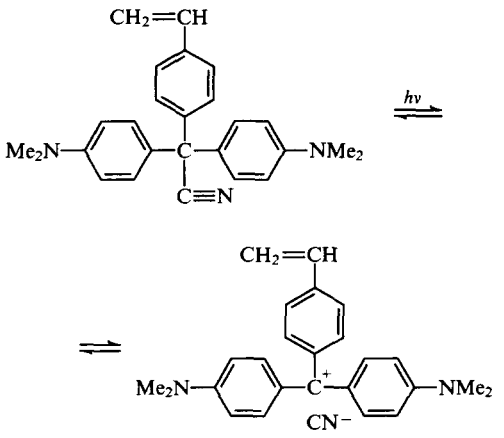
On collapse of the TH, the polymer chains approach one another and the medium within the TH becomes more hydrophobic. Both these factors limit the mobility of the macromolecules incorporated in the gel and hence increase the thermal stability of the immobilised enzyme at temperatures above the critical value.[222] A formal kinetic description of the behaviour of α-chymotrypsin incorporated in a cross-linked poly-NIPAA-TH has been published.[223–225] The temperature dependence of the activity of the immobilised α-chymotrypsin ceases to obey the Arrhenius law at temperatures close to the temperature of the collapse of the NIPAA-TH. This is expressed by the appearance on the Arrhenius plot of a section with an apparent negative activation energy. An increase in the concentration of the cross-linking agent leads to a shift of the break point on the Arrhenius plot towards higher temperatures and to a less marked decrease in the activity of the enzyme.[224]

Thus the biocatalysts obtained by immobilising enzymes and cells with the aid of 'smart' polymers acquire new and unusual properties. They can combine the advantages of homogeneous and heterogeneous catalysts, can serve as convenient 'chemical switches' sensitive to slight changes in external conditions, and are distinguished by a higher productivity as a result of the operation of the 'thermal pump'.

5. Sensor systems

Solutions and hydrogels of 'smart' polymers are sensitive to slight changes in the properties of the external medium, i.e. they function as complete sensors for these properties. For example, a set of solutions of polymers with different LCT can serve as a thermometer. The response of the polymers to changes in the properties of the medium is due to a change in the balance between the hydrophobic and hydrophilic interactions. Covalent binding to the polymer of acceptor molecules capable of undergoing a change in their hydrophobic properties in the presence of the agent to be detected (a definite substance or light) leads to the appearance of two states of the polymer — in the absence of the substance to be detected (characterised by a critical temperature T_1) and in its presence (characterised by a critical temperature T_2). Usually $T_2 > T_1$. If a temperature in the range $T_1 < T < T_2$ is fixed, then the transition from one state of the polymer to the other can be achieved under isothermal conditions with the aid of the agent to be detected. The latter induces a visible change in the solution or hydrogel, which has served as a basis for the creation of sensor systems.[226]

The *trans–cis* isomerisation of the azobenzene chromophore takes place on exposure to UV light.

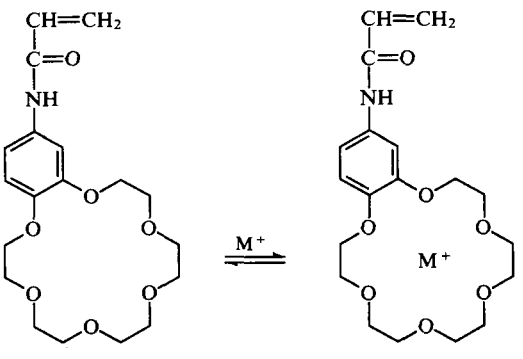


This transition is accompanied by an increase in the dipole moment from 0.5 D (for the *trans*-form) to 3.1 D (for the *cis*-isomer), which indicates an increase in the hydrophilicity of the polymer. The incorporation of a hydrophobic comonomer [*N*-(4-phenylazophenyl)acrylamide] (2.7 mol%) in a copolymer with NIPAA lowers the LCT to 19.4 °C, whilst UV irradiation increases it to 26.0 °C (as a result of the transition of the azobenzene chromophore to the more hydrophilic *cis*-form).[226]

We shall now consider the dimethylacrylamide–4-phenylazophenyl acrylate (7.5 mol%) system.[227] At a temperature slightly above the LCT in the absence of UV irradiation (visible light), the solution is turbid owing to the formation of an insoluble polymeric phase. UV irradiation increases the LCT (from 14 to 21 °C) and the copolymer, which is at a temperature below the LCT, gradually dissolves (the system becomes transparent). When UV irradiation ceases, the LCT is reduced, the copolymer again forms an insoluble polymeric phase, and the system once more becomes turbid. From the foregoing, it is clear that aqueous solutions of most copolymers constitute a sensor responding to UV irradiation.[226]

It is noteworthy that the phase transition in the copolymers becomes sensitive to UV irradiation for a strictly defined content of the acceptor comonomer. This emphasises yet again that the maintenance of a very fine balance between the hydrophobic and hydrophilic interactions is needed for the manifestation of critical phenomena in polymer solutions.

Another molecular acceptor of light quanta is triarylmethyl cyanide (the leuco-derivative of triphenylmethane), which dissociates reversibly on UV irradiation. The NIPAA copolymer containing only 1 mol% of the leuco-nitrile ligands has a LCT of 29.2 °C. After UV irradiation, the copolymer becomes more hydrophilic to such an extent that it loses the capacity for the clearly expressed formation of a polymeric phase following an



increase in temperature.[227] However, when the leuco-nitrile ligands are incorporated in poly-NIPAA-TH, the critical temperature for the collapse increases from 30 °C in the absence of UV irradiation to 32.6 °C (under UV irradiation). At 32 °C, UV irradiation induces the reversible transition of the gel from the collapsed to the swollen state, whereupon the degree of swelling of the gel changes almost by a factor of 10.[228]

On the other hand, the change in the hydrophilicity of the azobenzene chromophore on UV irradiation is insufficient to induce the collapse. The poly-NIPAA gel containing 10.8 mol% of the chromophore does not collapse, but is gradually dehydrated when the temperature is raised. UV irradiation induces an increase in the degree of swelling by only ~25%,[226] but the change in polarity within the hydrogel and the associated change in its permeability to substrates make it possible to regulate the activity of the enzymes immobilised in polyacrylamide gels containing photosensitive ligands.[229-231]

Another approach involves the use of heat derived from the absorbed light to raise the temperature of the TH, which leads to the collapse of the gel. Thus illumination of poly-NIPAA-TH containing Cu-chlorophyllin as the chromophore, with the power of the illumination exceeding 85 mW, at 31.5 °C results in the collapse of the gel.[232]

The change in the hydrophobicity of the acceptor molecule needed for the isothermal transition of the polymer from one state to another may be induced not only by UV irradiation but also by the introduction of various additives.[226,233] Thus the copolymer of NIPAA with the crown-ether **9** (11.6 mol%) has a LCT of 31.5 °C. In the presence of Na^+, the LCT increases to 33.0 °C, whilst in the presence of K^+ it increases to 38.9 °C. Thus the introduction of Na^+ and K^+ cations leads to the dissolution of the copolymer at 32 °C, the copolymer being insoluble in their absence. At 37 °C, this effect is induced only by the addition of K^+ cations. A similar effect has been observed also for poly-NIPAA-TH containing 12 mol% of the crown-ether. The thermoresponsive hydrogel which has collapsed at 33.8 °C swells by a factor of 10 in the presence of 30 mM potassium sulfate.

9

The thermoresponsive hydrogel can be caused to pass from one state to another also under the influence of the products of the reaction catalysed by the enzyme immobilised in the TH. For example, the TH of the NIPAA–acrylic acid copolymer with immobilised urease collapses at 32.4 °C. When urea is added to the collapsed gel (at 33.4 °C), the enzymic reaction results in the formation of ammonia, which increases the pH of the medium. Under these conditions, the LCT of the copolymer increases and the gel swells, its volume increasing by a factor of 7 in 15 min.[234] In a buffer without urea, the TH collapses again.

Rabbit liver esterase hydrolyses the nonpolar ethyl butyrate to more polar products — ethanol and butyric acid. The change in polarity occurring under these conditions is sufficient to induce the swelling of the collapsed poly-NIPAA-TH.[235]

Concanavalin A (a lectin) immobilised in poly-NIPAA-TH can bind various carbohydrates, including the negatively charged dextran sulfate and the neutral methyl α-D-mannopyranoside. Dextran sulfate bound to concanavalin A increases the swelling of the collapsed gel by a factor of 5 as a result of the mutual repulsion of the negative charges on dextran sulfate. The displacement of dextran sulfate by the neutral methyl α-D-mannopyranoside again induces the collapse of the gel. The swelling–contraction cycle can be repeated many times with excellent reproducibility.[235]

The examples quoted above demonstrate the extensive possibilities of the employment of 'smart' polymers for the creation of exceptionally simple, reliable, and fairly sensitive sensor systems. However, this does not exhaust all the possibilities. The phase transition in solutions of such polymers has been used by Hoffman and coworkers[237-239] to devise a new method of precipitation immunoassay (PRECIPIA). The essential features of this method are explained in Fig. 7. *N*-Isopropylacrylamide was copolymerised with monoclonal antibodies to the κ-chain of human immunoglobulin G (IgG) modified by *N*-hydroxysuccinimidylacrylamide. The polymeric conjugate was incubated for 1 h at room temperature with the IgG solution being analysed, poly-NIPAA (to facilitate the thermoprecipitation of the conjugate), and monoclonal antibodies to the γ-chain of human IgG labelled with fluorescein or phycoerythrin. The temperature was raised to 45 °C, the resulting polymeric phase was separated by centrifugation and dissolved in a cold buffer solution, and the fluorescence was measured.

This system is not inferior as regards sensitivity to the traditional heterogeneous immunoassay methods, but makes it possible to overcome their significant disadvantage — the need for incubation in the course of many hours due to the diffusional hindrance to the interaction of the antigen with the antibody immobilised on an insoluble matrix. Since the antigen–antibody interaction during precipitation immunosassay takes place in solution, the incubation time can be shortened to only 1 h.[237-239]

6. Controlled delivery of medicinal drugs

An effective medicinal preparation is not simply a chemical substance but one which is supplied at an appropriate time and at an appropriate place in the organism. The creation of systems for the directed transport and controllable delivery of medicinal substances is one of the hot spots in modern pharmacochemistry. A significant role is assigned to polymers in this process.[68,240,241] Above we have already spoken of the industrial employment of reversibly soluble polymers for the formation of a protecting shell around peroral medicines.

The use of hydrogels for the controllable delivery of medicines is based on their ability to undergo a sharp change in the degree of their swelling and hence in their permeability in response to changes in the medium. The pathological processes occurring in the organism are as a rule associated with changes in the pH, temperature, and concentrations of specific substances. Thus it becomes possible to create systems with feedback, where the pathological process initiates the release of the medicinal drug.

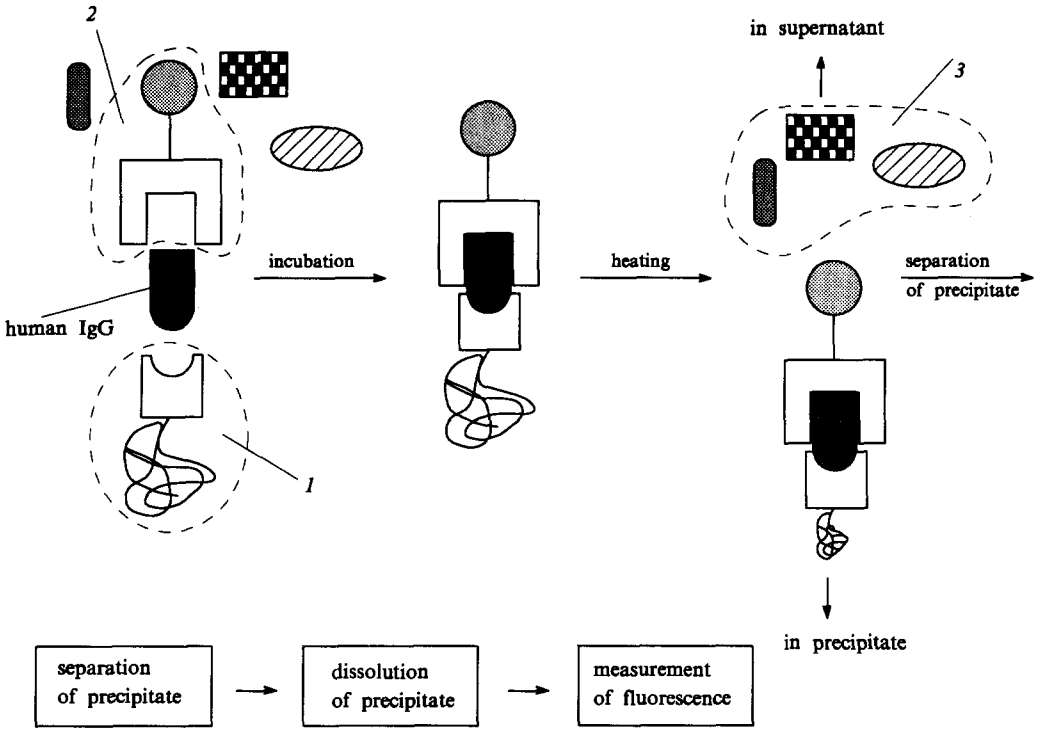


Figure 7. The precipitation immunoassay method.[237] (*1*) Conjugate of poly-NIPAA with monoclonal antibodies to the κ-chain of human IgG; (*2*) monoclonal antibodies to the γ-chain of human IgG with a fluorescent label; (*3*) extraneous proteins.

The gel in the swollen state is 'charged' with the medicinal drug. In the collapsed state, the gel does not give up the drug, diffusion becoming possible only after the swelling of the gel. The transition of the gel from the collapsed to the swollen state may be induced by various factors. Thus the change in the pH of the medium from 5 to 7 leads to the virtually complete arrest of the liberation of caffeine from the gel based on the copolymer of ketyl methacrylate and 2-(*N*,*N*-dimethylamino)ethyl methacrylate.[33] On the other hand, UV irradiation accelerates the diffusion of *p*-aminobenzoate from the poly(2-hydroxyethyl methacrylate) gel containing the azobenzene chromophore.[242] The formation of a charge-transfer complex between triethylamine and the copolymer of 2-hydroxyethyl methacrylate and methacryloyl-β-hydroxyethyl 3,5-dinitrobenzoate increases the swelling of the polymer membrane in water and hence the liberation of Methyl Orange from it.[243] An electric potential of 3–6 V initiates the liberation of edrophonium chloride from the gel based on the butyl methacrylate–2-acrylamido-2-methylpropanesulfonic acid copolymer. In the absence of an electric field, the positively charged medicinal drug is not liberated owing to its interaction with the negatively charged polymer.[244]

The liberation of glucose, insulin, or indomethacin from TH based on the copolymers of NIPAA and alkyl methacrylates ceases completely when the temperature is raised from 20 to 30 °C and is renewed on subsequent cooling to 20 °C. The thin film of the collapsed polymer, formed on the surface of the TH grains when the temperature is raised above the critical value, plays a critical role in the regulation of the diffusion process.[92,244–250] A similar sharp retardation of diffusion as a result of the formation of a collapsed gel film on the surface has been observed also for TH based on interpenetrating polymer networks comprising polyacrylic acid and the acrylamide–butyl methacrylate copolymer.[251] The kinetics of the release of the medicinal drug can be regulated (changing the reaction order from zeroth to first) by altering the nature of the TH, for example by employing interpenetrating polymer networks of poly-NIPAA and poly(methylene glycol ether) of different compositions.[252,253] When the TH collapses rapidly, there is a possibility of the formation of solution-filled cavities, the contents of which are not involved in the exchange with the surrounding medium.[92]

The reversible sorption on the surface of latex particles may be used for the temperature-controlled release of substances. Up to 65% of fluorescence-labelled dextran (M = 70 000), sorbed by the poly-NIPAA latex, is released into the solution on heating. When the temperature is reduced, the entire desorbed dextran is again bound to the latex.[138]

The most interesting approach has been developed by Hoffman and coworkers.[254,255] The authors used hydrogels sensitive to changes both in the pH and temperature. At 37 °C and pH 1.4 (the conditions within the stomach), the TH based on copolymers of NIPAA with acrylic acid and polydimethylsiloxane are in the collapsed state. Indomethacin or amylase, incorporated in the TH grains, hardly diffuse to the outside. At 37 °C and pH 7.4 (the conditions within the intestine), the TH swells markedly and the substances incorporated in it are rapidly released to the surrounding medium: more than 90% of indomethacin is released after 5 h. Thus a system has been created with directional transport and a prolonged release of the medicinal drug.

The creation of an artificial pancreas, i.e. a device releasing insulin in response to changes in the concentration of glucose, makes it possible to solve serious problems in the treatment of the numerous patients suffering from sugar diabetes. The development of such systems is therefore arousing unflagging interest.[256] Definite advances on these lines have been achieved by employing 'smart' polymers. The enzyme glucose oxidase, which oxidises glucose to gluconic acid, is usually employed as the glucose sensor. This reaction is accompanied by a decrease in pH, which in fact initiates the release of insulin. Technically this is achieved in different ways, for example by employing a membrane consisting of the 60:20:20 2-hydroxyethyl acrylate–*N*,*N*-diethylaminomethacrylate–4-trimethylsilylstyrene copolymer. In the swollen state, such a membrane contains 30% of water at pH 6.3 and 53% at pH 6.15, its permeability to insulin increasing in this case by a

factor of 42. Capsules made of this copolymer and containing glucose oxidase and insulin released insulin approximately five times faster in the course of 2–3 h in the presence of 0.2 M glucose. After the removal of glucose, the rate of release of insulin fell to the initial value.[257]

The swelling of the gel in the presence of glucose has been used in a mechanical device consisting of two compartments. The first compartment contained a glucose-sensitive gel and the second a solution of insulin. The solution of insulin was simply forced out by the swollen gel from the device through a valve.[33]

The complex of poly(vinyl alcohol) with the vinylpyrrolidinone–*m*-acrylamidophenylboronic acid may be used as the glucose sensor instead of glucose oxidase.[157] In this case, the hydroxy-groups of glucose displace the hydroxy-groups of poly(vinyl alcohol), as a result of which the polymeric complex decomposes. When glucose has been removed, the complex is reformed. A communication concerning the creation of an artificial pancreas operating in accordance with a similar principle has appeared recently.[258]

An interesting approach to the employment of 'smart' polymers for the controllable delivery of medicinal drugs has been proposed by Tirrell.[259] Among the numerous polyelectrolytes, polyethylacrylic acid possesses the fairly unique ability to undergo a change in conformation in the physiological pH range 7.4–6.5. The transition from the uncoiled to the compact conformation is accompanied by intensification of the interaction of the polymer with lipid membranes.[260] Poly-ethylacrylic acid, immobilised covalently on the surfaces of the vesicles formed by phosphatidylcholine, induces a reorganisation of the large vesicles on transition to the compact conformation, converting them into more compact micelles. The contents of the vesicles are then released into the external medium.

IV. Conclusion

The author hopes that he has succeeded in demonstrating the extensive possibilities for the employment of 'smart' polymers in various branches of biotechnology and medicine. There is no doubt that the examples presented do not exhaust all the possibilities. This field is developing dynamically judging from the constantly growing number of publications. For example, a communication has appeared quite recently[261] stating that the graft-copolymerisation of NIPAA makes it possible to convert a hydrophilic surface (at a temperature below the LCT) into a hydrophobic one (at a temperature above the LCT). This may be used for the directed transport of microparticles with a medicinal drug in the organism or for the segregation and purification of biomolecules (hydrophobic chromatography). The cells of microorganisms also interact in different ways with hydrophilic and hydrophobic surfaces.

Abstract. The characteristic features of the reactivity of the principal classes of organic compounds of tellurium(II) and tellurium(IV) are examined and compared with the analogous compounds of sulfur and selenium. The factors determining the specific features of the chemical behaviour of organotellurium compounds are characterised. It is shown that the possibility of the convenient introduction of tellurium-containing functional groups, their structural modification, elimination, the low-temperature elimination of the tellurium atom as a result of the low energy of the C – Te bond, and the high nucleophilicity of the tellurolate anions and diorganyl tellurides together with other properties create preconditions for the development of a new methodology in organic synthesis. The bibliography includes 446 references.

I. Introduction

The first representative of organotellurium compounds — diethyl telluride — was obtained by Woehler[1] more than 150 years ago, but the principal data concerning the method of synthesis, reactivity, and structure of organic derivatives of tellurium have been obtained during the last 20 – 25 years. These compounds have been considered in monographs,[2–5] while individual classes of acyclic and cyclic tellurium-containing compounds have been the subject of review articles.[6–22] Together with profound analogies between the structure and reactivity of organic compounds of tellurium and [other] higher chalcogens, the studies which have been carried out have revealed significant characteristic features of the chemical behaviour of organotellurium compounds compared with their sulfur and selenium analogues. The present authors' previous review was devoted to the structure of the latter.[23] The present, more complete review takes into account new data which have accumulated during recent years. All the research results analysed are classified in terms of the specific features of organotellurium compounds which distinguish them from those of the other chalcogens and not in terms of the individual classes of such compounds, as was done in previous reviews.[23]

The specific structure and chemical behaviour of organic derivatives of tellurium are determined mainly by the following factors.

1. The increased nucleophilicity and halophilicity of the RTe^- and Te^{2-} anions compared with those of the other organochalcogen derivatives.

2. The reduced thermodynamic and kinetic stability of the tellanyl derivatives RTeX.

3. The ability of the tellurium atom in various coordination states to form extremely stable (compared with sulfur and selenium atoms) intramolecular coordinate bonds with electron-excess centres (oxygen, nitrogen), which play an important role in the stabilisation of the corresponding organotellurium compounds and which influence the stereochemistry of their reactions.

4. The unusual tendency of derivatives of dicoordinate tellurium — diorganyl tellurides R_2Te and diorganyl ditellurides R_2Te_2 — to enter into oxidative addition reactions with formation of structures containing tellurium in the Te(IV) and Te(VI) oxidation states.

5. The fact that the nucleophilicity of diorganyl tellurides is the highest in the series of diorganyl chalcogenides R_2M (M = O, S, Se, Te).

6. The high polarisation of the $Te=X \rightleftarrows Te^+ - X^-$ bonds (X = CR_2, NR, O) which is responsible for the specific reactions of π-telluranes.

7. The sharply increased stability of derivatives of tetracoordinate tellurium — σ-tellanes R_2TeX_2 and $RTeX_3$ as well as tetraorganyltellanes R_4Te — compared with the analogous selenium and sulfur derivatives.

8. The low energy of the C – Te bond (compared with those of the C – S and C – Se bonds).

These specific properties are responsible for the increasing application of organotellurium compounds in preparative organic chemistry (see the relevant reviews[24–31]).

II. Nucleophilic and halophilic properties of tellurolate and telluride anions

The usual methods of synthesis of organic anions RM^- containing Group VIA elements (M = O, S, Se) from the corresponding hydride derivatives RMH are virtually impossible to apply in the case of their tellurium analogues. Until recently, only a few alkanetellurols had been described. These are thermally unstable and are extremely readily oxidised to ditellurides not only by atmospheric oxygen[2,3] but even by dilute H_2SO_4;[32] tellophenols have not been isolated in a pure form. (Trimethylsilyl)silanetellurol[33] $(Me_3Si)_3SiTeH$ and 2,4,6-trialkyltellurophenols[34] 2,4,6-$R_3C_6H_2TeH$ (R = Me, Pr^i, Bu^t), obtained by protonating the lithium salts of tellurols, are relatively stable by virtue of the presence of bulky organic groups. The organyltellurolate anions **1** are therefore usually obtained by reducing diorganyl ditellurides with alkali metal tetrahydroborates in alcohol or a benzene–alcohol mixture[2,3] and with alkali metals in liquid ammonia,[2,3,32,35–38] ether,[39] tetrahydrofuran (THF),[40,41] THF–dimethylformamide (DMF),[42] and hexamethylphosphoramide (HMPA)[43] or by the reactions of organolithium derivatives with elemental tellurium in ether or THF.[2,3] The tellurolate anions are oxidised extremely readily even by atmospheric oxygen and are therefore employed only in situ. These anions exhibit the highest nucleophilicity in the series of analogous derivatives of Group VIA elements. Although there are hitherto virtually no quantitative literature data on the nucleophilicity parameters of the tellurolate anions (such as the Swain–Scott parameter n[44] or the Ritchie parameter N_+[45]), the high basicity and polarisability of RTe^- guarantee that their nucleophilicity is even higher than the current record holders on these scales — the RS^- and RSe^- anions.

Quantitative kinetic data on the relative reactivities of the benzenechalcogenolate anions PhM^- (M = S, Se, Te) have been obtained only for $S_{RN}1$ reactions. In the interaction of 2-quinolinyl radicals, the relative rate constants increase in the sequence PhS^- (1.0) < $PhSe^-$ (5.8) < $PhTe^-$ (28.0),[46] while in the case of the 9-anthranyl radicals the increase is in the sequence PhS^- (1.0) < $PhSe^-$ (1.4) < $PhTe^-$ (3.2).[47]

By virtue of their high nucleophilicity, the tellurolate anions **1** readily add both to activated (α-ethynylcarbonyl compounds[43,48–55]) and nonactivated triple bonds,[43,50,52,53,55–58] which leads to the vinyl tellurides **2** and **3** in high yields.

$$R^1C{\equiv}CCOR^2 + ArTe^- \longrightarrow \underset{\mathbf{1}}{} \underset{TeAr}{R^1C{=}CHCOR^2} \quad \mathbf{2}$$

R^1 = Alk, Ar; R^2 = H, Alk, Ar, OR.

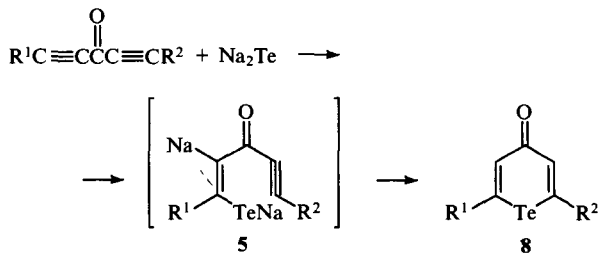
$$R^1C{\equiv}CH + R^2Te^- \longrightarrow \underset{\mathbf{3}}{R^1CH{=}CHTeR^2}, \quad \underset{TeR^2}{R^1C{=}CH_2} \quad \mathbf{3a}$$

R^1 = Alk, Ar, CH_2OH; R^2 = Ar, Me.

The addition of the tellurolate anions to activated triple bonds is regiospecific and is always accompanied by the formation of only type **2** compounds. In the case of the esters of ethyne-1-carboxylic acids, only the (*Z*)-isomers or mixtures of (*Z*)- and (*E*)-isomers with the former greatly predominating (more than 90%) are formed.[51] The preferential formation of (*Z*)-isomers was observed also in the reactions of activated ethynes, but these reactions are less regiospecific and, together with compounds **3**, the formation of the isomeric alkenes **3a** is observed.[53,55,58]

The addition of potassium telluride, generated from tellurium in a superbasic medium [KOH/HMPA(DMSO)/H_2O], first investigated by Trofimov et al.,[59] leads to vinyl telluride as the main product. (For further details about this and similar reactions, see the review of Gusarova et al.[12]) (*Z*)-Divinyl tellurides **4** have been synthesised in high yields by the reaction of Na_2Te (obtained by the reduction of tellurium with sodium tetrahydroborate in an aqueous alcoholic solution of NaOH) with monosubstituted ethynes.[58] In certain cases, the 1,1-disubstituted isomers **4a** are formed in yields up to 10% together with the tellurides **4**.[58]

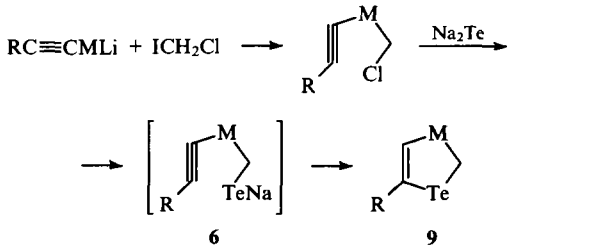
$$RC{\equiv}CH + Na_2Te \longrightarrow \underset{\mathbf{4}}{(RCH{=}CH)_2Te}, \quad \underset{\mathbf{4a}}{(H_2C{=}CR)_2Te}$$



R = Ph, 4-ClC_6H_4, 4-BrC_6H_4, 4-MeC_6H_4, 4-$MeOC_6H_4$,

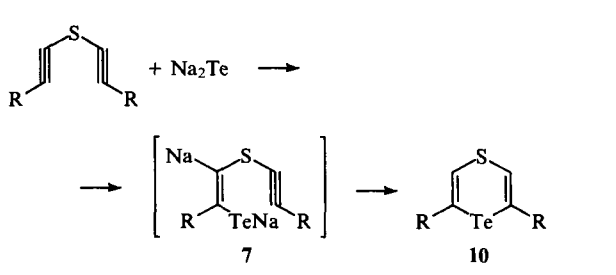
$HOCH_2CH{=}CMe$, $\overline{CH_2CH_2OCH_2CH_2NCH_2}$,

$\overline{CH_2(CH_2)_4CH{=}C}$, $\overline{CH_2(CH_2)_3OCHOCH_2}$.



The intramolecular nucleophilic addition reactions of the tellurolate anions **5**–**7**, formed as intermediates in the interaction of Na_2Te with the corresponding ethynes, have been used for the synthesis of certain tellurium-containing heterocycles which are difficult to obtain by other methods. 2,6-Diorganyltellurapyran-4-ones **8**,[60–64] 2-*H*-1,3-thiatellurols **9** (M = S),[65] 2*H*-1,3-ditellurols **9** (M = Te),[66] and 1-thia-4-telluracyclohexa-2,5-dienes **10**[67] have been obtained by this procedure (Scheme 1).

Scheme 1



$R^1 = R^2$ = $SiMe_3$, Me, Bu^t, Ph; R^1 = Ph,

R^2 = $SiMe_3$, H, $(CH_2)_3OH$, 2-C_4H_3S, $(CH_2)_3OSiMe_2Bu^t$, 4-FC_6H_4, 2,5-$F_2C_6H_3$, 4-$MeOC_6H_4$.

M = S, R = Me, Et, Bu^t, Ph; M = Te, R = H, Me, Et, Ph.

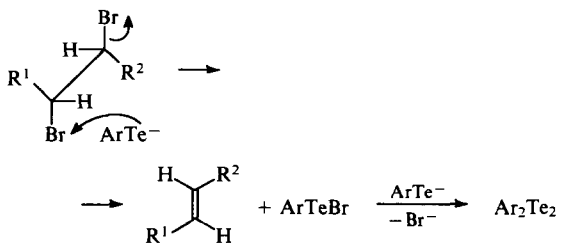
R = H, Me, Bu^t.

In the last case, sodium telluride reacted much faster than sodium selenide and especially sodium sulfide.

The reactions involving nucleophilic addition of arenetellurolate anions to an activated double bond have been much less investigated.[57,68] A series of β-aryltellurapropionic

acids,[68] their esters,[57] and β-phenyltellurapropionitriles[57] have been synthesised with their aid in 31%–62% yield.

$$R^1CH{=}CHCOOR^2 + ArTe^- \longrightarrow ArTeCHCH_2COOR^2 \quad (R^1)$$



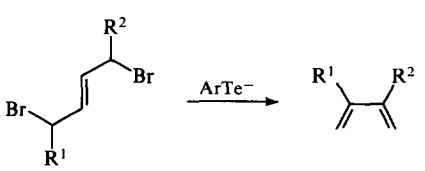
R^1 = H; R^2 = Na; Ar = Ph, 4-MeC_6H_4, 4-$EtOC_6H_4$;

R^1 = H, Me; R^2 = Et; Ar = Ph.

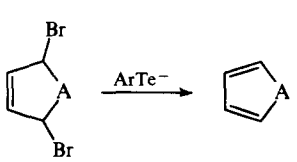
$$RCH{=}CHCN + PhTe^- \longrightarrow PhTeCHCH_2CN \quad (R)$$

R = H, Me.

Organyltellurolate anions are not only more nucleophilic than other chalcogenolate anions but also exhibit more clearly expressed X-philic properties[69] (especially halophilic properties). As a result of this, sodium thiophenetellurolate debrominates vicinal dibromides, affording alkenes in 75%–100% yields.[70] This reaction, which proceeds with high *anti*-stereospecificity, is of definite preparative value, since it can be carried out catalytically in the presence of small amounts of ditelluride (1 mmol per 10 mmol of the halogen-containing substrate) and $NaBH_4$, which reduces the ditelluride obtained back to the tellurolate anion.

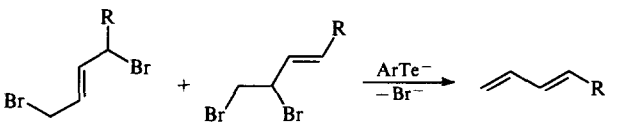


Ar = 2-C_4H_3S; R^1 = R^2 = Me, Ph, CO_2Et; R^1 = H; R^2 = C_8H_{17};



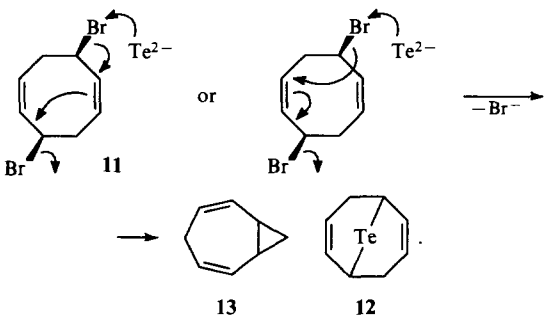
R^1 = CO_2H; R_2 = Me, Ph; R^1+R^2 = —$(CH_2)_4$—.

It is noteworthy that substituted 1,2-dibromocyclohexanes undergo similar debrominations also on treatment with sodium thiophenoxides.[71,72] However, in the case of 1,2-dihaloethanes only the products of the nucleophilic substitution of the halogen atoms by phenylthio-groups are formed.[73]



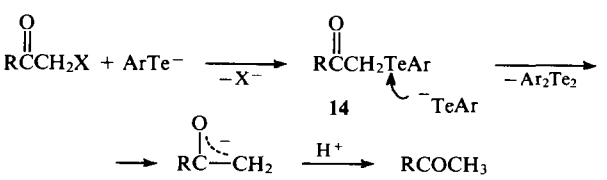
On the other hand, just as the debromination of the vicinal dibromo-derivatives described above is an example of β-halophilic elimination, the synthesis of 1,3-dienes from 1,4-dibromoalk-2-enes or their mixtures with 1,2-dibromoalk-3-enes on treatment with di(2-thienyl)ditelluride, used in catalytic amounts, and $NaBH_4$ is a δ-halophilic elimination reaction.[74] The reactions take place with high yields (60%–100%) and lead to mixtures of the (*E*)- and (*Z*)-isomers in proportions of ~9 : 1.

R^1 = R^2 = Me, Ph.



A = —$(CH_2)_2$— , —$(CH_2)_3$— , —$CH(CO_2Me)$—.

R = Et, Bu, C_6H_{13}, $(CH_2)_7OAc$, $(CH_2)_8OAc$, $C_{12}H_{25}$.

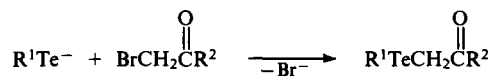


Examples of elimination of a similar kind are not known for the sulfur and selenium nucleophiles.[69]

An instance of ε-halophilic elimination is also known for the telluride anion.[75] Thus, when 3,7-dibromocycloocta-1,5-diene **11** reacts with Na_2Te, bicyclo[5.1.0]octa-2,5-diene **13** is formed together with the expected 9-tellurabicyclo[3.3.1]nona-2,6-diene **12** (yield 18%) in accordance with the following scheme:

An analogous reaction is not observed when Na_2S is employed.

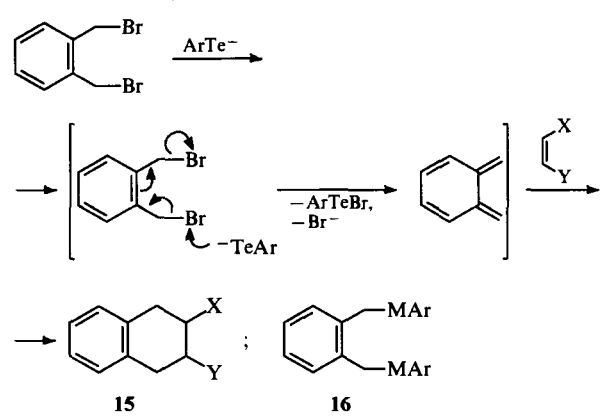
Another possible type of X-philic reaction — the reduction of C–Hal bonds — occurs when sodium (lithium) 2-thiophenetellurolate interacts with α-halocarbonyl compounds. For stoichiometric amounts of the reactants, the final reaction products are the corresponding ketones (or carboxylic acids) and ditellurides and not the products of the nucleophilic substitution, i.e. (2-thienyltelluro)carbonyl derivatives.[76] This is the result of the attack by the tellurolate anion on the tellurium atom of the intermediate tellurides **14**, which leads to the ditellurides and the corresponding enolates. This mechanism has been confirmed both by the isolation in certain cases of type **14** tellurides (R = $CH_2CONHPh$) and by the formation of the benzaldehyde chalcone (yield 48%) when the enolate (R = Ph) is used as the trapping agent.



X = Cl, Br, I; R = Ph, 4-BrC_6H_4.

X = Cl, Br; R^1 = H, R^2 = Ph, 1-$C_{10}H_7$; R^1 = R^2 = Ph.

Similar results had been obtained earlier for the thiolate[77,78] and selenolate[78] anions. However, for these species the preferred mode of reaction (reduction or nucleophilic substitution) is determined primarily by the nature of the halogen. For stoichiometric amounts of the reactants and at reduced temperatures, α-chloro- and α-bromoketones afford mainly the products of nucleophilic substitution, while α-iodoketones give rise to the products of the reduction reactions. Tellurolate anions reduce all α-haloketones to ketones at room temperature.[76] However, at a very low temperature (−78 °C)

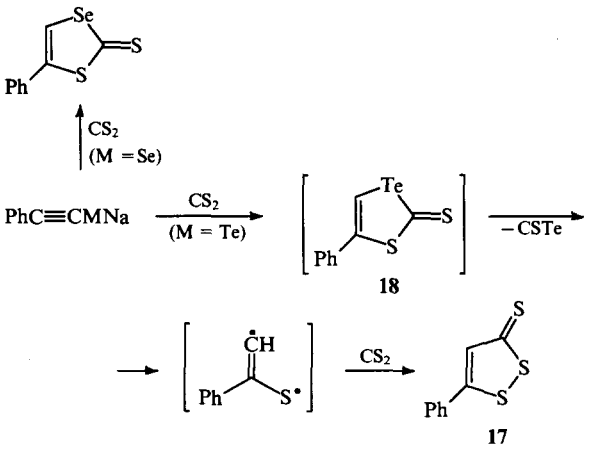


α-bromocarbonyl compounds afford the α-organyltellura-carbonyl compounds **14a** in fairly high yields (55%–92%) on interaction with tellurolate anions.[79] On the other hand, α-chloroketones are reduced even at −78 °C.

R^1 = Bu, Ph, CH_2=CH, BuC≡C, Me_3SiC≡C;

R^2 = OR^3 (R^3 = Li, Et, 4-$NO_2C_6H_4$).

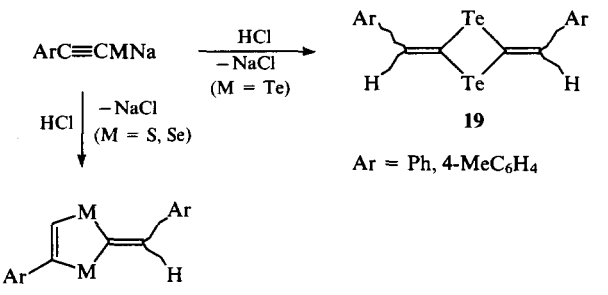
The available data do not permit the quantitative characterisation of the halophilicities of S, Se, and Te organyl-chalcogenolate anions. However, bearing in mind the higher halophilicity of the methaneselenolate anion compared with the sulfur analogue (in the reaction with benzyl halides[80]) and the easy reduction of phenacyl phenyl sulfide by the thiophene-2-tellurolate anion,[76] one could postulate that the halophilicity increases from S to Te. The higher halophilicity of the tellurolate anions compared with the structurally related selenolate anions is indicated also by the result of the reactions of α,α′-dihalo-*o*-xylenes with these anions.[81] In the presence of an excess of the dienophile, the reactions of α,α′-dibromo(iodo)-*o*-xylenes with arenetellurolate anions (generated by the reduction of the corresponding diaryl ditellurides with $NaBH_4$) in boiling xylene, which proceed via the intermediate formation of *o*-quinodimethane, lead to the Diels–Alder adducts **15** in 20%–53% yields. The most probable mechanism of these reactions[81] is presented below.



15 **16**

Ar = Ph, 3-MeC_6H_4, 3-ClC_6H_4, 4-$MeOC_6H_4$;

X = Y = CO_2Et; X = H, Y = CO_2Et, CN, Me.

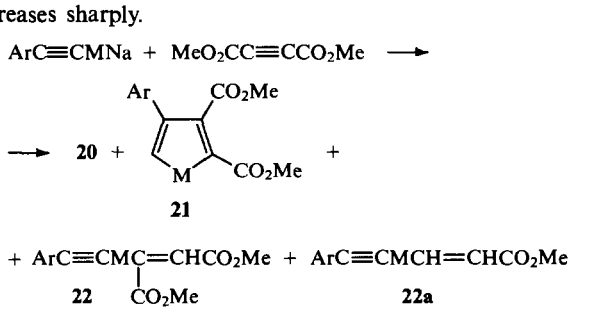


Under the same conditions, sodium benzeneselenolate gives rise to only the product of nucleophilic substitution at the C(sp^3) atoms — α,α′-bis(phenylseleno)-*o*-xylene **16** (M = Se) in 75% yield together with the product of nucleophilic addition to the double bond — ethyl phenylselenopropionate — when ethyl acrylate is employed as the dienophile.[81] Incidentally, the α,α′-bis(aryltello)-*o*-xylenes **16** (M = Te) are also formed in the reaction of arene-tellurolate anions, since the product of the oxidation of compounds **16** — *o*-phthalic aldehyde — has been isolated in ~30% yield in all cases. The preferential formation of the telluride **16** (M = Te, Ar = 4-$EtOC_6H_4$) (yield 50%) has also been observed when the reaction was carried out at room temperature.[82]

The reactions examined below, the mechanisms of which are frequently obscure, are evidently not associated with the nucleophilic or halophilic properties of the organyltellurolate anions. However, the diversity of these reactions compared with the other RM^- (M = S, Se) anions makes it possible to consider them in the present section. In particular, a specific behaviour compared with ethynethiolate(selenolate) anions and geminal dithiolate (diselenolate) dianions, has been observed in certain reactions of their tellurium analogues. Thus, in contrast to sodium phenylethyneselenolate, which affords 5-phenyl-1,3-thia-selenole-2-thione on interaction with CS_2,[83] the product obtained in the similar reaction of sodium phenylethynetellurolate was 5-phenyl-1,2-dithiole-3-thione **17**.[84] The possible process mechanism, involving the dissociation of the C–Te bond in the intermediate 1,3-thiatellurole **18**, is presented below.[84]

18 **17**

Another example of the specific behaviour of the phenyl-ethynetellurolate anion is its protonation (in solution in DMSO) by an ethereal solution of HCl. The only products of this reaction are the *cis*- and *trans*-1,3-ditelluretanes **19**[84–86] and not their isomers — benzylidene-4-aryl-2*H*-1,3-ditelluroles, which was suggested[87] when the reaction was first described. A mixture of the same compounds **19** is also formed in the reaction of phenyl-ethyne with powdered tellurium under highly basic conditions.[88] On the other hand, the protonation of structurally similar thiolate and selenolate anions leads to the benzylidene-4-aryl-2*H*-1,3-dichalcogenoles **20**.[89]



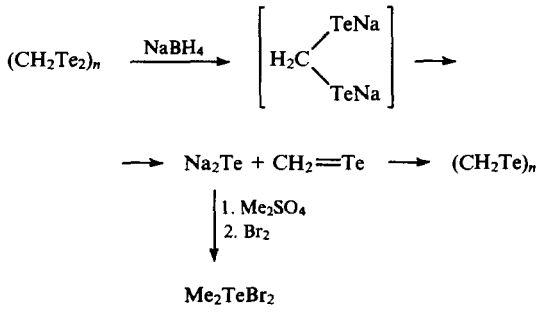
19

Ar = Ph, 4-MeC_6H_4

20

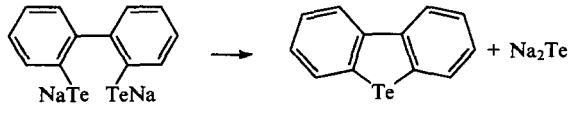
Ar = Ph

The interaction of phenylethynechalcogenolate anions with dimethyl ethynedicarboxylate results in the formation of a mixture of the corresponding chalcogenophenes **21**, the 1,3-dichalcogenoles **20**, and the products **22** and **22a** of the nucleophilic addition of the anions to the triple bond.[84,90] On passing from sulfur to tellurium, the yield of such adducts increases sharply.



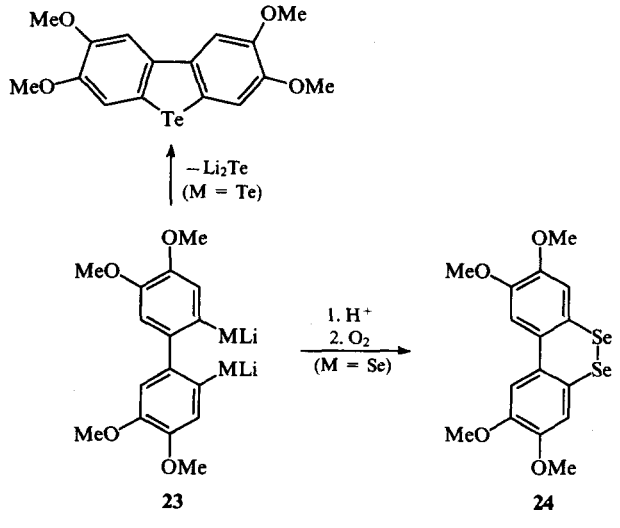
21

22 **22a**



M = S, Se, Te

Significant differences have been observed also in the behaviour of geminal dichalcogenolate anions. Whereas the disodium salt of methanediselenol[91] is fairly resistant to heating and undergoes in solution the usual chemical reactions, its tellurium analogue, obtained by reducing poly(methylene ditelluride)[92] with $NaBH_4$ in ethanol, readily disproportionates to sodium telluride and telluromethanol, which polymerises subsequently to poly(methylene telluride).[93]



The mechanism of the formation of poly(methylene telluride) involving the reduction of poly(methylene ditelluride) with $NaBH_4$ in methanol and the subsequent alkylation of the ditellurolate dianion by methylene bromide (iodide) therefore appears erroneous.[94] Evidently, poly(methylene telluride) is formed via the disproportionation of the dianion, as described above, and not as a result of the alkylation reaction.

The sodium salt of bipyridyl-2,2'-ditellurol also undergoes a similar disproportionation with elimination of sodium telluride.[95] The second reaction product, isolated in a yield exceeding 90%, is dibenzotellurophene.

With the aid of this reaction, it is possible to account for the formation of various final products in the reactions of 2,2'-dilithio-4,4',5,5'-tetramethoxybiphenyl with tellurium and selenium.[96] In the former case, the product is the corresponding dibenzotellurophene, while the dilithio-derivative of the diselenole **23** (M = Se), which is incapable of undergoing the disproportionation reaction described above, is converted into the heterocyclic diselenide **24**, albeit in a very low yield.

23 **24**

III. Kinetic lability of organotellanyl halides

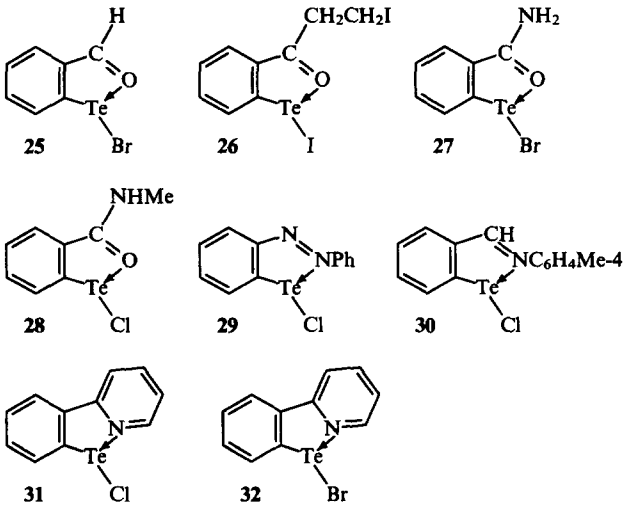
In contrast to the selenium and especially sulfur analogues, the tellanyl derivatives RTeX (X = Hal, OCOMe, SCN, N_3) are relatively unstable compounds, which readily decompose at room temperature both in the crystalline state and in solution.

Tellanyl halides, which are mainly aromatic derivatives, have been most thoroughly investigated among the tellanyl derivatives. The stability of arenetellanyl halides ArTeX increases in the sequence Cl < Br < I as the electronegativities of the atoms in the Te–X bonds approach equality. Thus the bromo-derivatives decompose fully at room temperature in 24 h, while arenetellanyl iodides in the crystalline state can be stored without decomposition for several weeks.[97] In the case of alkanetellanyl halides, the chloro-derivatives are more stable, while alkanetellanyl iodides decompose in several minutes.[98] The overall mechanism of the decomposition of aryltellanyl halides involves the formation of diorganyltellurium dihalides and elemental tellurium.[26,99]

$$2\,RTeX \longrightarrow R_2TeX_2 + Te$$

Such instability is predominantly kinetic in nature and is induced both by the relative ease (compared with other chalcogenyl halides) of dissociation of the chalcogen–halogen bond in solvating solvents and by the increased capacity of compounds of dicoordinate tellurium for associative oxidative addition reactions. Individual decomposition reactions of organyltellanyl halides are also facilitated by the comparative ease of elimination of the tellurium atom.

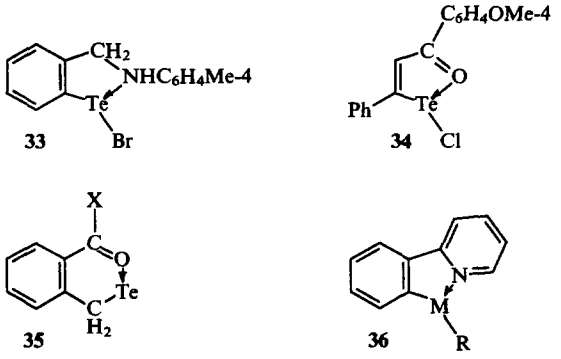
The principal methods for the stabilisation of organyltellanyl halides are associated either with the generation in their molecules of significant steric hindrance to the access of the reactants to the TeX groups or with the coordination of the Te(II) centre, which results in its transition to a more stable higher oxidation state. Thus the increased stability of biphenyl-2-tellanyl[100] and naphthalene-2-tellanyl[101] iodides, compared with other aryltellanyl halides, can be accounted for by the steric shielding of the TeI groups. The naphthalene derivative is thus the first arenetellurenyl iodide isolated in an analytically pure form. On the other hand, the first stable alkanetellanyl halides were tris(trimethylsilyl)methanetellanyl halides $(Me_3Si)_3CTeX$ (X = Cl, Br, I), obtained by oxidising the corresponding ditellurides with the halogen or SO_2Cl_2.[102] The stability of these compounds is undoubtedly associated with the bulky tris(trimethylsilyl)methyl group. However, the high stability of tris(trimethylsilyl)methanetellanyl pseudohalides $(Me_3Si)_3CTeX$ (X = CN, NCO, NCS, NCSe, N_3), obtained by the exchange reaction between tris(trimethylsilyl)methanetellanyl iodide and the corresponding AgX, is also noteworthy.[103]



A second way of stabilising tellanyl halides involves the formation of complexes with neutral ligands,[2,3] the tellurium atom playing the role of the coordination centre.

IV. Intramolecular Te←O(N) coordination as a factor stabilising derivatives of dicoordinate tellurium

The most effective procedure for increasing the stability of tellanyl halides and other tellanyl derivatives involves the introduction in the *o*-position relative to the Te–Hal functional group of substituents capable of forming stable intramolecular Te←O(N) coordinate bonds involving their O or N atoms.[104–106] Compounds of this kind are also useful synthons in preparative organic chemistry and in the first place in the chemistry of tellurium-containing heterocycles.

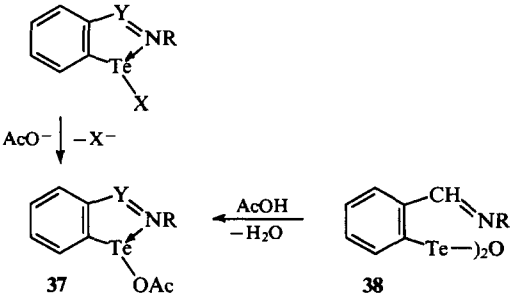


1. Tellanyl halides

Tellanyl halides are stabilised by substituents such as CHO,[107,108] COR,[51,109–118] $CONR_2$,[119,120] NO_2,[121] N=N,[122] CH=N [104,123–127] (this bond can also be part of the pyridine ring [128–130]), and CH_2NR_2.[127,131,132] The lengths *d* of the intramolecular Te←O and Te←N coordinate bonds, which belong to the class of three-centre four-electron (hypervalent) bonds, are in the range 2.21–2.37 Å (compounds **25**–**32**) and are much smaller than the sums of the van der Waals radii of the elements (3.60 Å for Te and O and 3.70 Å for Te and N),[133] approaching the lengths of the usual covalent bonds. The replacement of the sp^2-hybridised by the sp^3-hybridised nitrogen atom weakens somewhat the intramolecular coordination, which lengthens the Te–N bond (of the bond lengths in compounds **30** and **33**).

Compound	*d*(Te–O)/Å	Ref.	Compound	*d*(Te–N)/Å	Ref.
25	2.31	108	**29**	2.21	122
26	2.368	118	**30**	2.239	104, 124
27	2.237	119	**31**	2.236	130
28	2.25	119	**32**	2.236	130
34	2.19	51	**33**	2.375	129

The intramolecular Te←O coordinate bonds stabilise not only arenetellanyl halides but also vinyltellanyl (compound **34**)[51] and alkanetellanyl (compounds **35**)[134] halides.

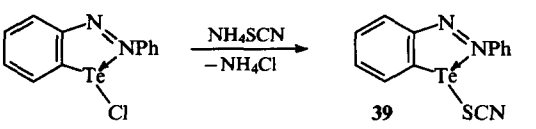


Comparison of the properties of compounds with the same structure of the organic ligand and of the chalcogen-containing groups is desirable for the quantitative characterisation of the relative strengths of the intramolecular O(N)→M coordinate bonds in the series M = S, Se, Te, the measure of which may be either the difference (Σ) between the van der Waals radii of M and O(N) [M···O(N)] or the Pauling bond order (*n*). Although there are comparatively few data, they make it possible to infer that the strength of bonds of this kind increases on passing from sulfur to tellurium. Thus comparison of the Se←N (2.813 Å) [135] and Te←N (2.695 Å) [129] bond lengths in *p*-ethoxyphenyl 2-(2-pyridyl)phenyl chalcogenides **36** with the sums of the van der Waals radii of selenium and nitrogen (3.55 Å) [133] and of tellurium and nitrogen (3.70 Å) [133] indicates the greater strength of the coordinate bonds involving a tellurium atom.

X-Ray diffraction data for benzoisotellurazole [136] and 1,2,5-telluradiazole [137] and their selenium analogues may serve as indirect evidence for the greater strength of the coordinate bonds with participation of tellurium atoms. Strong intermolecular Te···N bonds have been noted for tellurium-containing heterocycles in crystals. Their lengths are 2.40 Å for benzoisotellurazole and 2.764 Å for 1,2,5-telluradiazole (the sum of the van der Waals radii of Te and N is 3.70 Å).[133] The Se···N bonds have not been found in benzoisoselenazole, while in 3,4-diphenyl-1,2,5-selenazole they are much weaker than in telluradiazole. The anomalous physical properties of benzoisotellurazole and 1,2,5-telluradiazole compared with other chalcogen-containing heterocycles, namely the high melting points and sparing solubility in the usual organic solvents, are also explained by the presence of these intermolecular bonds.

2. Aryltellanyl acetates

Aryltellanyl acetates without intramolecular Te←O(N) coordinate bonds have not been obtained. However, stable tellanyl acetates **37** containing an azo-group or an azomethine group in the *o*-position relative to TeOAc group have been synthesised by the exchange reactions of the corresponding telluranyl halides with AcONa [138] or AgOAc [104,126] and also by the interaction of aryltellanic acids **38** with acetic acid.[126]

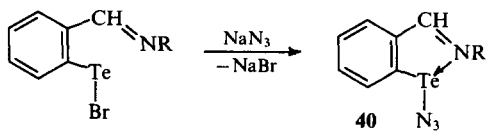


Y = N, R = Ph;

Y = CH; R = 4-MeC_6H_4, 4-$MeOC_6H_4$, 2,4,6-$Me_3C_6H_2$.

The lengths of the coordinate bonds in compounds **37** (Y = N, R = Ph) and **37** (Y = CH, R = 4-MeC_6H_4) are 2.26 Å [138] and 2.297 Å [104] respectively.

3. Aryltellanyl thiocyanates

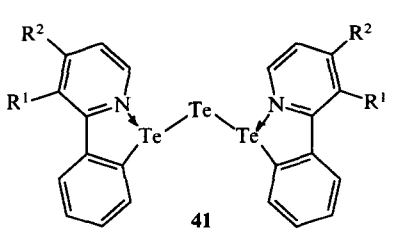


The interaction of equimolar amounts of diaryl ditellurides and thiocyanogen leads to unstable alkyltellanyl thiocyanates, which have been isolated in the form of complexes with thiourea, 2-picoline, and other nitrogen heterocycles.[139] However, the tellanyl thiocyanate **39**, containing the intramolecular Te←N coordinate bond (2.243 Å),[138] is extremely stable in the crystalline state.

It is noteworthy that the lengths of the intramolecular Te←O(N) coordinate bonds in the tellanyl derivatives ArTeX are in the range 2.130–2.375 Å (depending on the nature of X).[104–106] An increase in bond length for different X in the following sequence is then observed: Cl < Br < I < S_2CNMe_2, which agrees with the sequence based on decreasing electronegativity of the substituents X.

4. Arenetellanyl azides

The intramolecular Te←N coordination also ensures a high stability of the arenetellanyl azide **40**, obtained by the reactions of the corresponding arenetellanyl bromides with NaN_3.[126] The attempts to obtain the selenium analogues of these compounds from benzeneselanyl chloride and Me_3SiN_3 led actually only to diphenyl diselenide as a result of the rapid decomposition of the benzeneselanyl azide formed initially.[140] (By virtue of the steric hindrance due to the methyl groups, mesityleneselanyl azide is more stable and can be isolated on a preparative scale).[140] Bearing in mind that the selenyl derivatives ArSeX are in general always more stable than the analogous tellurium compounds, one must rule out the possibility of obtaining arenetellanyl azides from compounds in which the tellurium atom is not involved in intramolecular coordination.

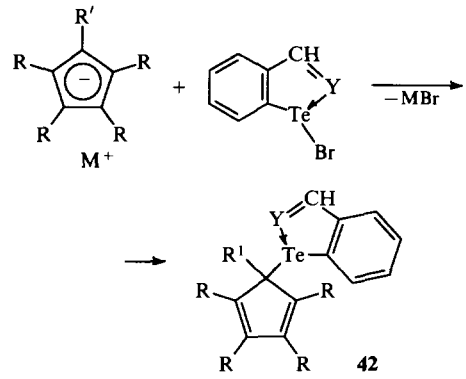


40

R = Ph, 4-MeC_6H_4.

5. Other derivatives of dicoordinate tellurium

Intramolecular Te←O(N) coordinate bonds increase the stability not only of the tellanyl derivatives RTeX but also certain other derivatives of dicoordinate tellurium: tritellurides, aryl cyclopentadienyl tellurides, and bis(organylthio)tellurides.

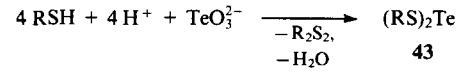


The first representative of tritellurides isolated in a pure form was bis[tris(trimethylsilyl)methyl] tritelluride $[(Me_3Si)_3C]_2Te_3$.[141] The stability of this compound is due to the presence of the bulky tris(trimethylsilyl)methyl group, which gives rise to steric hindrance to attack on the tritelluride bridge. On the other hand, the kinetic and thermal stabilities of type **41** tritellurides are associated with the intramolecular Te←N coordination in these compounds.[128,129] The Te←N bond length in bis[2-(2-pyridyl)phenyl]tritelluride **41** ($R^1 = R^2 = H$) is 2.554 Å.[128]

41

$R^1 = R^2 = H$; $R^1 + R^2$ = —(CH=CH)$_2$—.

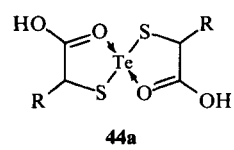
Although aryl cyclopentadienyl sulfides and selenides are thermally stable, the attempts to obtain aryl cyclopentadienyl tellurides by the reaction of metal cyclopentadienides with benzenetellanyl bromide were unsuccessful.[142] However, the stable tellurides **42** have been obtained by the reactions of arenetellanyl bromides containing the *o*-formyl or *o*-aldimine groups, capable of forming strong intramolecular Te←O(N) coordinate bonds.



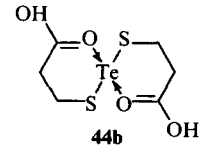
42

R = CO_2Me; R′ = CO_2Me; Y = O, NPh, 2-MeC_6H_4N;

R = CO_2Me; R′ = Me; Y = NPh, 4-$MeOC_6H_4N$.



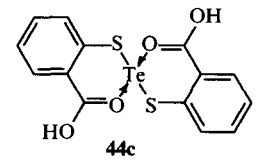
Yet another class of derivatives of dicoordinate tellurium, the stability of which is a consequence of the presence of the Te←O coordinate bonds comprises the bis(organylthiyl) tellurides **43**. Bis(benzenethiyl) telluride **43** (R = Ph) and bis(naphthalene-2-thiyl) telluride **43** (R = 2-$C_{10}H_7$), obtained by the interaction of the corresponding thiols with Na_2TeO_3, decompose very rapidly into diaryl disulfides and tellurium when they are kept in the crystalline state and especially in solutions.[143]



43

R = Ph, 2-$C_{10}H_7$.

Compounds **44a–c**, the carboxy-groups of which are capable of forming Te←O coordinate bonds, are much more stable.[143] According to the authors, two coordinate O←Te bonds are formed in their molecules.



44a

44b

R = H, Me.

44c

According to IR spectroscopic data, a stronger Te←O bond and hence a more powerful stabilisation effect are manifested for five-membered chelates compared with six-membered ones.

V. Oxidative addition reactions of dicoordinate tellurium derivatives

One of the characteristic features of dicoordinate tellurium derivatives — diorganyl tellurides R_2Te and diorganyl ditellurides R_2Te_2 — is their ability to enter into oxidative addition reactions. Derivatives of dicoordinate sulfur and selenium undergo similar reactions. However, whereas in the case of tellurides (ditellurides) the reaction products are the stable σ-tellanes R_2TeX_2 or $RTeX_3$ with covalent Te–X bonds, the oxidation of the sulfides and selenides R_2M (M = S, Se) by the halogens X_2 results in the formation (depending on the nature of the chalcogens M and the halogens X) of either the charge-transfer complexes $R_2M\cdots X_2$

(M = S, Se, X = I; M = S, X = Br) or of σ-chalcogenanes R_2MX_2 (M = S, Se, X = F, Cl; M = Se, X = Br) (for a more detailed description see Section VIII).

Data on the most typical oxidation-reduction addition reactions of various types of organic derivatives of tellurium(II) are presented below.

1. Diorganyl tellurides

Diorganyl tellurides having different structures — dialkyl, aryl alkyl, and diaryl tellurides — readily combine with chlorine,[2,3] bromine,[2,3] iodine,[2,3] and fluorine (diluted with an inert gas)[144,145] under mild conditions (room or reduced temperatures), forming the corresponding σ-tellanes $R^1TeX_2R^2$. The latter are stable crystalline compounds which can be effectively purified by the usual recrystallisation. They are readily reduced to diorganyl tellurides in yields which are in many cases close to quantitative. Various reductants are employed: Na_2S, $K_2S_2O_5$ ($Na_2S_2O_5$), Na_2SO_3, $NaHSO_3$, $Na_2S_2O_3$, $Na_2S_2O_4$, $LiAlH_4$, $NaBH_4$, $N_2H_4 \cdot H_2O$,[2,3] thiourea dioxides,[146,147] zinc powder in benzene or acetic acid, $SnCl_2$, methyl (ethyl)magnesium iodide,[2,3] and lithium diethylamide.[148] The conversion of diorganyl tellurides into σ-tellanes with subsequent reduction of the latter is therefore employed for the isolation of diorganyl tellurides from reaction mixtures and for their purification.

One of the few compounds incapable of undergoing some of the reactions indicated above is $(CF_3)_2Te$.[149] Whereas the reactions of chlorine and bromine lead to the corresponding σ-tellanes, on interaction with iodine, a weaker oxidant, tellurium diiodide is not formed.

Thionyl chloride and sulfuryl chloride are used as oxidants instead of gaseous chlorine in the synthesis of tellurium dichloride.[2,3] Diorganyl tellurides may be oxidised also by certain metal salts: $FeCl_3$,[150] $HgCl_2$,[150] $CuCl_2$,[150–152] and $CuBr_2$.[152] It is noteworthy that, whereas diaryl tellurides are converted only into diaryltellurium dichlorides on treatment with $CuCl_2$,[150–152] the reaction of diethyl telluride with the same oxidant proceeds in a different manner:[153]

$$Et_2Te + CuCl_2 \longrightarrow Et_2TeCl_2 + Et_2Te \cdot CuCl.$$

Diorganyl tellurides are converted into the corresponding tellurium difluorides not only on treatment with fluorine[144,145] but also on reaction with SF_4,[154] XeF_2,[145,155,156] ClF,[156] Ph_2SF_2,[144] and $(4\text{-}MeC_6H_4)_3BiF_2$.[157–159]

$$Ar_2Te + XY \longrightarrow Ar_2Te\begin{matrix}X\\Y\end{matrix}$$

X = Y = NCS; X = Br, Y = I, CN; X = I, Y = Cl.

Diorganyl tellurides also enter into reactions involving the oxidative addition of thiocyanogen,[160–165] the interhalogens (ICl, IBr),[164] and halogen cyanides (BrCN, ICN),[164] forming the corresponding σ-tellanes in high yields.

The oxidation of diorganyl tellurides by lead tetraacetate, which occurs in benzene or toluene solutions at room temperature, leads to diorganyltellurium diacetates in high yields.[166–168]

$$R_2Te + Pb(OAc)_4 \xrightarrow[-Pb(OAc)_2]{} R_2Te(OAc)_2$$

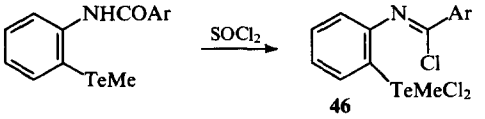
R = Ar, Alk.

The reactions of diorganyl tellurides with certain oxidants, leading to σ-tellanes, proceed via the intermediate formation of telluroxides. Thus the interaction of diorganyl tellurides with benzoyl peroxide affords low yields of diorganyltellurium dibenzoates.[169,170] This mechanism is confirmed by the formation of diaryltellurium dicarboxylates in the reactions of diaryl telluroxides with percarboxylic acids[171,172] and their anhydrides.[171,173]

$$R_2Te + (PhCOO)_2 \xrightarrow[-(PhCO)_2O]{} [R_2TeO] \xrightarrow{(PhCO)_2O} R_2Te(OCOPh)_2$$

The results of the reactions of tellurides with dilute HNO_3, leading to diorganyltellurium dinitrates, have also been explained in terms of the 'telluroxide' mechanism.[2,3]

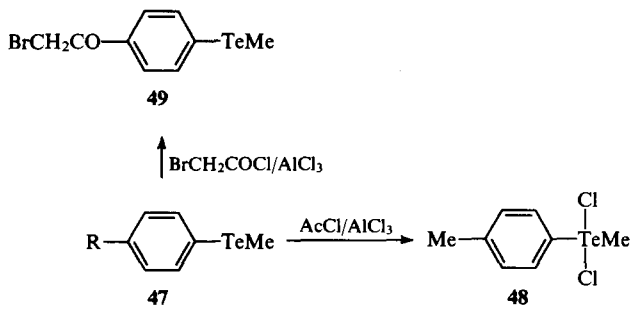
$$R_2Te + HONO_2 \longrightarrow [R_2TeO] \xrightarrow[-H_2O]{HONO_2} R_2Te(ONO_2)_2$$



Finally, the interaction with one equivalent of *m*-chloroperbenzoic acid leads to the mixed σ-tellane **45**.[174] Taking into account the foregoing, the most probable mechanism of the formation of this σ-tellane can be represented as follows:

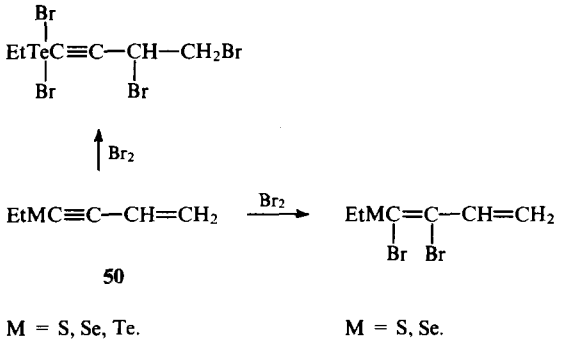
$$R^1R^2Te + ArCO_3H \xrightarrow[-ArCO_2H]{} [R^1R^2TeO] \xrightarrow{ArCO_2H} R^1R^2Te\begin{matrix}OCOAr\\OH\end{matrix}$$

45



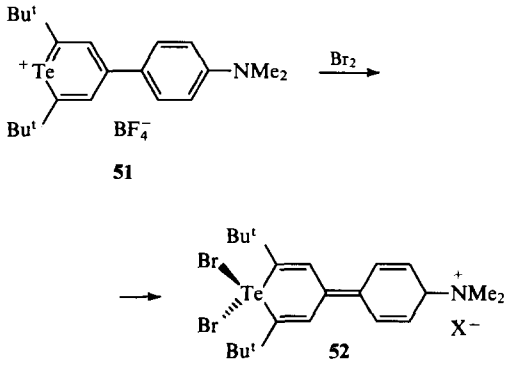
Ar = 3-ClC_6H_4.

The thermodynamic stability of σ-tellanes is the driving force of many of the reactions of diorganyl tellurides leading ultimately to σ-tellanes, while in the similar reactions of diorganyl sulfides, the formation of σ-sulfanes is not observed. Thus the arylation of diaryl ditellurides by arenediazonium salts in the presence of copper(II) halides[151,152] (see Section V) leads to diaryltellurium dihalides in high yields, while the arylation of diaryl disulfides under similar conditions results in the formation of only diaryl sulfides.[175,176] The synthesis of σ-tellanes is achieved by oxidising the diaryl tellurides formed initially with copper(II) salts.[152] Similarly the Sandmeyer reaction of 2-aminophenoxatellurane with CuCl terminates with the formation of 1,1,2-aminophenoxatellurane and not 2-chlorophenoxatellurane.[177] Another example is provided by the interaction of *N*-aroyl derivatives of *o*-methyltelluroaniline with $SOCl_2$.[178] This entails not only the conversion of the amide groups into the –N=C(Ar)Cl groups but also the oxidation of Te(II) to Te(IV), a consequence of which is the formation of the σ-tellanes **46**. These compounds are convenient synthons in the synthesis of 2-arylbenzotellurazoles.[178]



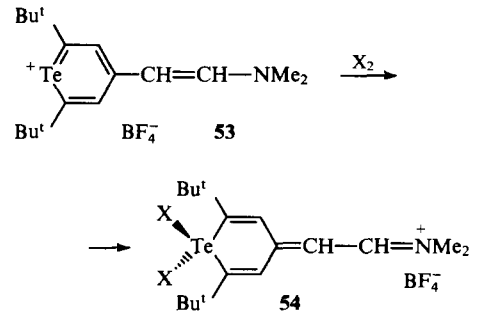
46

It is also of interest to note that the interaction of 4-methylphenyl methyl telluride **47** (R = Me) with acetyl chloride in the presence of $AlCl_3$ involves the oxidation of the initial telluride to the σ-tellane **48**[109] and not acetophenone, as in the case of the analogous selenium derivative.[179] Incidentally, the acylation of the telluroanisole **47** (R = H) by α-bromoacetyl chloride in the presence of $AlCl_3$ proceeds in the usual way, leading to the expected 4-methyltelluro-α-bromoacetophenone **49** in 52% yield.[180]



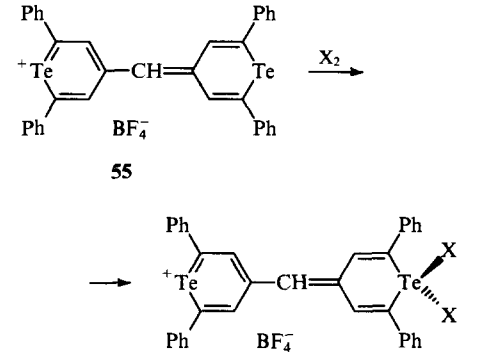
R = H, Me.

The vinylethynyl tellurides **50** behave differently in their reactions with bromine from their selenium and sulfur analogues. Whereas the latter readily combine with bromine only at the triple bond, the tellurides combine with two molecules of bromine: at the double bond and at the tellurium atom.[181]

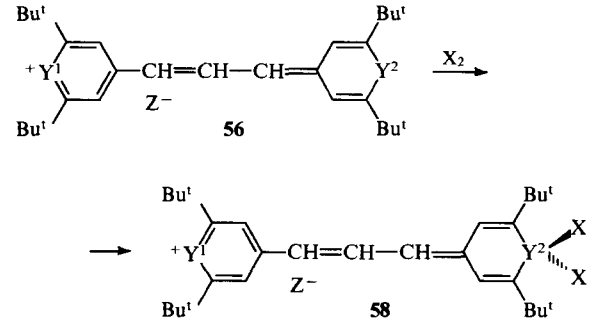


M = S, Se, Te. M = S, Se.

The reactions involving the oxidative addition of the halogens to the tellurium atom of tellurapyrylium salts containing a powerful electron donor (the dimethylamino-group) in the *p*-position relative to the heteroatom are of special interest. Bromine reacts under comparatively mild conditions with 4-(4′-dimethylaminophenyl)tellurapyrylium tetrafluoroborate **51**, which leads to the telluranes **52** in 90%–97% yields.[182] In the presence of an excess of bromine, the BF_4^- anions are exchanged for Br_3^-.



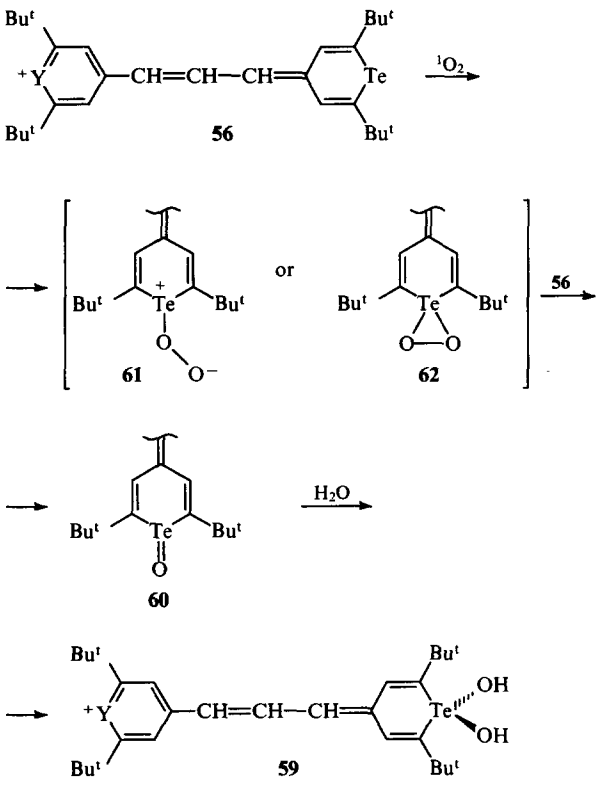
$X^- = BF_4^-, Br_3^-$.



The analogous reactions with the tellurapyrylium dye **53** lead to the dibromo-derivative **54** (X = Br) and the diiodo-derivative **54** (X = I) in 67% and 91% yields respectively.[182]

The symmetrical tellurapyrylium monomethine dyes **55** and trimethine dyes **56** also enter into reactions in which the halogens undergo oxidative addition. The tellurapyrylium fragment is then retained in the σ-tellanes **57** and **58** formed.[182,183]

57, X = Cl, Br, I.



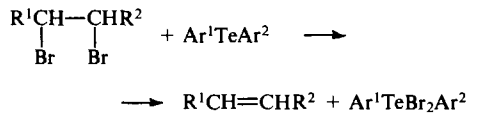
$Y^1 = Y^2 = Te$; X = Cl, Br, I;

$Z = BF_4^-, CF_3SO_3^-, PF_6^-$.

It is noteworthy that the trimethine pyrylium dyes of type **56** ($Y^1 = Y^2 = O$, S, Se) also enter into reactions with chlorine and bromine.[183,184] However, these are much slower than those involving the tellurapyrylium analogues and, which is most important, the trimethine bridges and not the heteroatoms are attacked.

Other examples of oxidative addition reactions, which take place only for the tellurapyrylium trimethine dyes **56** ($Y^1 = O$, S, Se, Te, $Y^2 = Te$) and are not characteristic of other structurally similar compounds without a tellurium atom, involve the oxidative addition of H_2O_2 or singlet oxygen in the presence of water, which results in the formation of the dihydroxytellanes **59**.[185–188] The latter reaction is carried out by the UV irradiation of solutions of the tellurium-containing dyes **56**, whereupon singlet oxygen is formed (the dyes **56** with Y = O, S, Se, or Te and $Y^2 = Te$ serve as effective photosensitisers for the singlet O_2 generation process) and oxidises compounds **56** to the tellur-oxides **60**. It has been suggested[185] that the latter are formed via the pertelluroxides **61** or telluradioxiranes **62**. The subsequent

hydration of the telluroxides **60** leads to the dihydroxytellanes **59**. Such hydration reactions are characteristic of dialkyl and alkyl aryl telluroxides.[2,3,189]

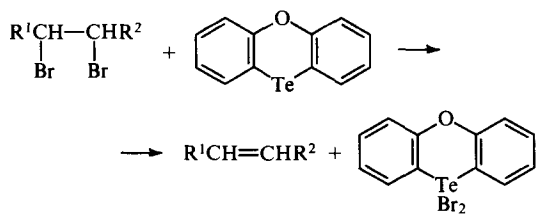


The interaction of other type **56** pyrylium cations, not containing tellurium atoms, with singlet oxygen is slower and the molecular π-skeletons are then involved in the reactions and not the heteroatoms.[186]

One of the characteristic properties of the dihydroxytellanes **59** is the relatively slow thermal reductive elimination of H_2O_2 in aqueous methanol solutions, which leads to the reformation of the initial compounds **56**. This can be used for the photochemical conversion of water and oxygen into H_2O_2.[187,188] Another possible application of the above reaction is photodynamic therapy: tellurapyrylium dyes function under these conditions as photosensitisers of the formation of singlet oxygen or the superoxide radical-anion, which are cytotoxic agents. A useful property of tellurapyrylium dyes is their ability to absorb in the near IR region, where biological tissues are transparent.

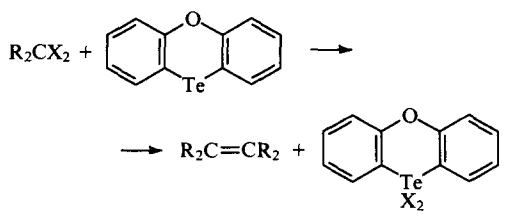
The ability of diorganyl tellurides to be converted by various oxidants into derivatives of tetracoordinate tellurium prevents in a number of instances the employment of reagents which are normally used for the conversion of the functional groups. Thus, in contrast to the sulfur and selenium derivatives, carboxylic acids containing telluride functional groups are converted into the corresponding acid chlorides on treatment with alkyl dichloromethyl ethers in the presence of anhydrous $ZnCl_2$,[51,54,56,111,113,117,190–192] whilst the use of PCl_5 or $SOCl_2$ for these purposes leads merely to the oxidation of tellurium(II) to tellurium(IV).

The appreciable 'affinity' of diorganyl tellurides for the halogens permitted the employment of these compounds as dehalogenating agents in the synthesis of alkanes from organic dihalides. Vicinal[193–195] and geminal[196] dibromo-derivatives are converted, with fairly high yields, into the corresponding alkenes on treatment with diaryl tellurides[193,195] or their cyclic analogue — phenoxatellurane.[194,196]



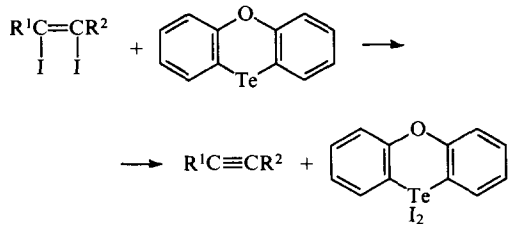
$R^1 = Ph$; $R^2 = CO_2H, CO_2Et, COPh$, 2-pyridyl;

$R^1 = R^2 = Ph$; $R^1 + R^2$ = cholesteryl,



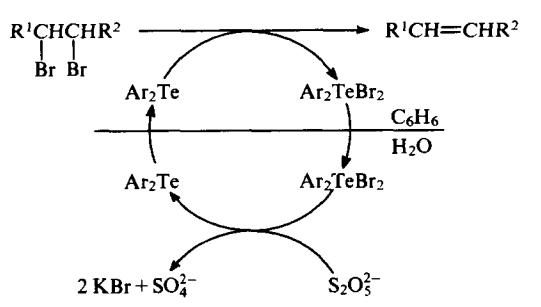
$Ar^1 = Ar^2 = Ph, 4\text{-}MeOC_6H_4$; $Ar^1 = 4\text{-}MeOC_6H_4$;

$Ar^2 = 1\text{-}C_{10}H_7, 2\text{-}C_{10}H_7$.



$R^1 + R^2 = -(CH_2)_3-$, $-(CH_2)_4-$, 1,8-naphthylidene;

$R^1 = Ph$; $R^2 = H, CO_2H, CO_2Et$; $R^1 = Me$; $R^2 = CO_2H$.



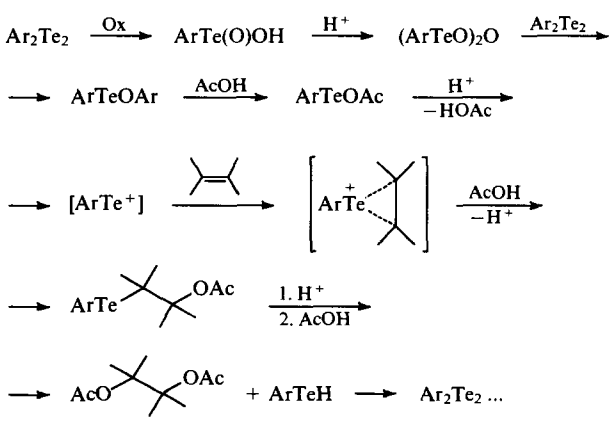
$R = Ph, CO_2Et$; $R + R = C_{12}H_8$, X = Cl, Br.

In terms of its dehalogenating capacity, phenoxatellurane is superior to diaryl tellurides, since it reduces not only 1,2-dibromoalkanes but also 1,2-diiodoalkenes, which leads to ethynes in yields exceeding 80%.[194]

$R^1 = Ph$, $R^2 = H, CO_2H$.

An important advantage of diaryl tellurides over other dehalogenating agents is the possibility of using them in catalytic amounts (the optimum amount is 5% of the mass of the halogen-containing substrates).[195] The reactions lead in this case to a two-phase system (benzene–water) and the tellurium dibromides formed are reconverted into the tellurides on treatment with potassium metabisulfite, which by itself does not reduce the vicinal dibromo-derivatives. The foregoing considerations can be illustrated by the following scheme:

2. Diorganyl ditellurides



Like diorganyl tellurides, diorganyl ditellurides R_2Te_2 undergo oxidative addition reactions under mild conditions (at room or reduced temperature in the absence of catalysts). When solutions of these compounds are treated with the halogens [$Cl_2(SOCl_2$, SO_2Cl_2), Br_2, I_2,[2-4] F_2, XeF_2,[197] or ClF [198]], the Te–Te bonds are ruptured and organyltellurium trihalides $RTeHal_3$ are formed in high yields. On treatment with various reductants, the latter can be reconverted into the corresponding ditellurides. The ease of the interconversions $R_2Te_2 \rightleftarrows RTeX_3$ is used (depending on the relative availability of these compounds) for their synthesis and purification. It has been shown in relation to aryltellurium triiodides that the halogen oxidative addition reactions proceed in stages.[199] The first stage of this process is the rapid formation of arenetelluranyl iodides, which are then converted into complexes **63** and finally into the triiodides **64**.

$$R_2Te_2 + I_2 \longrightarrow RTeI \rightleftharpoons \underset{\mathbf{63}}{RTeI \cdot I_2} \longrightarrow \underset{\mathbf{64}}{RTeI_3}$$

The reactions with other oxidants have been less thoroughly investigated. Thus, according to Pant's data,[166,167] the oxidation of diaryl ditellurides with lead tetraacetate affords, judging from the ^1H NMR spectra of the reaction mixture, aryltellurium triacetates. However, as a consequence of the ready hydrolysis of the latter, the attempts to isolate them from solutions were unsuccessful.

Diaryl ditellurides are catalysts of the oxidation of aromatic alkenes by various oxidants (O_2, Bu^tO_2H, H_2O_2, *m*-$ClC_6H_4CO_3H$) in methanol or acetic acid in the presence of H_2SO_4 to the vicinal dimethoxy- and diacetoxy-derivatives.[200] It has been suggested[200] that these reactions proceed via the intermediate formation of arenetellurinic acids ArTe(O)OH or their derivatives. This has been confirmed by the fact that, when the anhydrides of arenetellurinic acids $[ArTe(O)]_2O$[201] are refluxed with alkenes in acetic acid, they convert the latter into vicinal diacetates; the second reaction product is the corresponding ditelluride. The possible mechanism of these reactions[200,201] is presented in Scheme 2.

Scheme 2

Thus the intermediate formation of arenetellurinic acids or their anhydrides in the oxidation of diaryl ditellurides with Bu^tO_2H, H_2O_2, etc. under the conditions described above is evident; however, these reactions have not been investigated separately.

The ionisation potentials of the chalcogens (in eV) decrease in the sequence S(10.36) > Se(9.75) > Te(9.01).[202] As a result of this, diorganyl ditellurides are much stronger reductants than their sulfur and selenium anaogues and are capable of undergoing certain reactions which are not characteristic of the latter two classes of organochalcogen compounds.

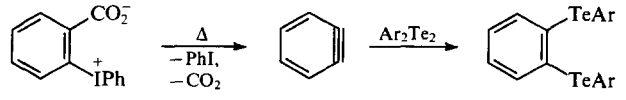
The reducing properties of diaryl ditellurides have been used in preparative organic chemistry for the synthesis of alkenes from vicinal dibromo-derivatives.[203] Organic dibromo-derivatives convert diaryl ditellurides into arenetelluranyl bromides: under the reaction conditions (refluxing in toluene or acetic acid), the latter disproportionate to diaryltellurium dibromides and tellurium. Alkenes are obtained predominantly in the (*E*)-form in 68%–100% yields.

$$R^1\underset{Br}{CH}\!-\!\underset{Br}{CHR^2} + Ar_2Te_2 \longrightarrow$$

$$\longrightarrow R^1CH{=}CHR^2 + ArTeBr \longrightarrow Ar_2TeBr_2 + Te$$

Ar = 4-$MeOC_6H_4$, 4-$EtOC_6H_4$; $R^1 = R^2 = H$, Ph, CO_2H; R^1 = Ph, $R^2 = CO_2H$.

Being strong one-electron reductants, diaryl ditellurides enter into reactions which cannot be carried out with the analogous sulfur derivatives. Thus the interaction of diaryl ditellurides with arenediazonium halides leads to a mixture of equimolar amounts of diaryltellurium dihalides and diaryl tellurides in accordance with the mechanism presented below:[152]



$$Ar^1_2Te_2 + Ar^2N_2X \xrightarrow[-N_2]{} Ar^1Te^{\cdot} + (Ar^2)^{\cdot} + Ar^1TeX,$$

$$Ar^1Te^{\cdot} + (Ar^2)^{\cdot} \longrightarrow Ar^1TeAr^2,$$

$$Ar^1TeX + Ar^2N_2X \xrightarrow[-N_2]{} Ar^1TeX_2Ar^2.$$

On the other hand, diaryl disulfides are arylated by arenediazonium halides only in the presence of copper(II) halides, which promote the formation of free aryl radicals.[175,176]

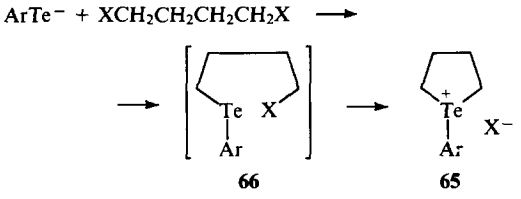
The M–M bond energy (kJ mol^{-1}) in the diorganyl dichalcogenides R_2M_2 decreases in the sequence S(264.0) > Se(202.0) > Te(149.8).[203] This is the reason for the strikingly manifested ability of diorganyl ditellurides to undergo other reactions (other than the reactions with the halogens) involving the dissociation of these bonds. Thus diaryl ditellurides containing electron-donating substituents in the *p*-positions in the arene rings add readily to dehydrobenzene, obtained by the thermal decomposition of 2-phenyliodonium benzoate, forming *o*-bis-(aryltelluro)benzenes in 50%–64% yields.[205-206] Diphenyl disulfide does not enter into this kind of reaction.

Ar = 4-MeC_6H_4, 4-$MeOC_6H_4$, 4-$TeOC_6H_4$.

Mercury tellurophenoxides, which are stable under the usual conditions, are formed under extremely mild conditions—shaking of solutions of diaryl ditellurides with mercury at room temperature.[207-209] On heating, these compounds decompose into diaryl tellurides and HgTe.[209]

$$Ar_2Te_2 + Hg \longrightarrow (ArTe)_2Hg \xrightarrow{\Delta} Ar_2Te + HgTe$$

Ar = Ph, 4-$MeOC_6H_4$, 4-$EtOC_6H_4$.

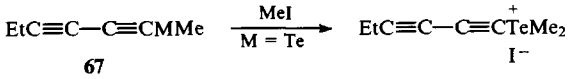


It is probable that the interaction of diaryl ditellurides with powdered copper in boiling dioxane, leading to high yields of diaryl tellurides, also proceeds via the intermediate formation of copper(II) tellurophenoxides.[210-215] This reaction is frequently used as a preparative method of synthesis of diaryl tellurides and for the elimination of traces of diaryl ditellurides from the latter. In contrast to diaryl ditellurides, diaryl disulfides give rise to stable copper(I) thiophenoxides on heating with copper powder in *N,N*-dimethylacetamide.[216]

$$ArSCu \xleftarrow[M = S]{Cu/\Delta} Ar_2M_2 \xrightarrow[M = Te]{Cu/\Delta} Ar_2Te + CuTe$$

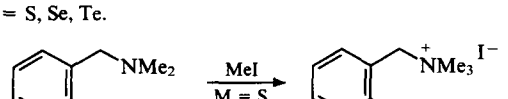
VI. Nucleophilic properties of dicoordinate tellurium derivatives

1. Diorganyl tellurides



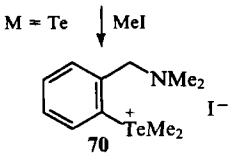
Diorganyl tellurides of various types readily give rise to telluronium salts on interaction both with compounds containing activated neighbouring electron-accepting groups [esters of carboxylic α-bromoacids, α-bromoacetophenones, α-bromoacetone, chloro(bromo)acetonitriles] and with nonactivated alkyl halides.[2,3] The increased nucleophilicity of the tellurium atom, compared with the other chalcogens, in diorganyl tellurides results in the formation of telluronium salts on interaction of not only dialkyl and alkyl aryl tellurides but also diaryl tellurides with haloalkanes.[2,3] Furthermore, iodobenzene can be used as the halogen-containing substrate in relation to dimethyl telluride.[217] The interaction between these compounds leads to dimethylphenyltelluronium iodide in ~50% yield. In contrast to diaryl tellurides, diphenyl sulfide[218] and diphenyl selenide[219] form salts on treatment with haloalkanes only in the presence of Ag^+ cations. A similar difference between the reactivities has been observed also in the alkylation of chalcogen-containing heterocycles. Thus whereas benzo[*b*]tellurophene is alkylated by methyl bromide,[220] benzo[*b*]thiophenium and dibenzo[*b*]thiophenium salts have been obtained by the alkylation of the corresponding heterocycles only in the presence of $AgClO_4$ or $AgBF_4$.[221] The high nucleophilicity of the tellurium atom in diorganyl tellurides is also indicated by data[222] on the interaction of arenetellurolate anions with 1,4-dihalobutanes. 1-Aryl-1-telluroniacyclopentane halides **65** were obtained instead of the expected 1,4-bis(aryltelluro)butanes. These compounds are probably formed as a result of the intramolecular alkylation of the intermediate 1-aryltelluro-4-halobutanes **66**.

Ar = Ph, 4-TeOC$_6$H$_4$; X = Cl, Br.



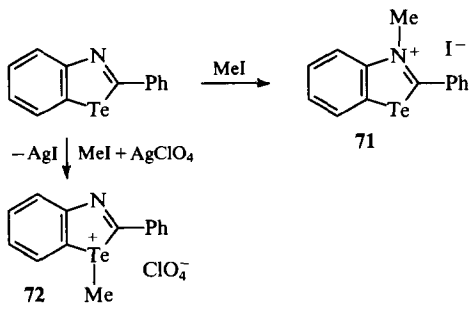
However, one should note that, according to the data of Hope et al.,[223] the main products of the reactions of lithium benzene- and methane-tellurolates with 1,4-dihalobutane are the corresponding tellurides and 1-telluracyclopentane.

Significant differences between the reactivities, determined by the nature of the chalcogen atoms, are observed also in the alkylation of alkylchalcogeno-1,3-diynes **67**[224] and 2-dimethylaminobenzyl methyl chalcogenides **68**.[116]



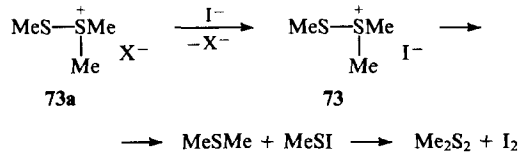
67

M = S, Se, Te.



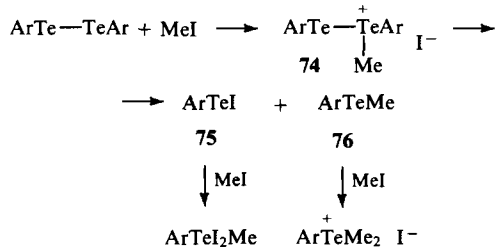
68 **69**

70



Among the methyl chalcogenides **67**, only the telluride is alkylated by methyl iodide, the telluronium salt being formed in this reaction in an almost quantitative yield.[224] More interesting data have been obtained on the alkylation of compound **68**. In the case of 2-dimethylaminobenzyl methyl selenide **68** (M = Se), the object of attack is the nitrogen atom; the iodide of methyl 2-*N*,*N*,*N*-trimethylammoniabenzyl selenide **69** is formed in an almost quantitative yield. On the other hand, the tellurium analogue is alkylated exclusively at the tellurium atom, which leads to the telluronium salt **70** in a high yield.[116]

In relation to 2-phenylbenzotellurazole, it has been shown for the first time that the alkylation of N,Te-containing organic compounds can be achieved at different nucleophilic centres depending on the nature of the alkylating agents.[225,226] Refluxing of 2-phenylbenzotellurazole in an excess of MeI leads to the immonium salt **71** (yield 90%), while treatment of the same heterocycle with methyl iodide in the presence of an equivalent amount of $AgClO_4$ results in the formation of the telluronium salt **72** in an almost quantitative yield. Compound **72** is the first example of benzochalcogenazoles for which alkylation at the chalcogen atom has been achieved.



2. Diorganyl ditellurides

The alkylation of dialkyl disulfides by alkyl halides proceeds fairly effectively in the presence of HgI_2 or on treatment with trimethyloxonium 2,4,6-trinitrobenzenesulfonate.[227] We may note that methylthio(dimethyl)sulfonium iodide **73**, obtained by treating the sulfonate **73a** with the I^- ion, decomposes in accordance with the mechanism presented below:

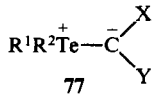
X = 2,4,6-(NO$_2$)$_3$C$_6$H$_2$SO$_3$.

On the other hand, the alkylation of diaryl ditellurides evidently takes place under milder conditions in the presence of compounds similar to HgI_2 or the oxonium cation. Thus refluxing of di(*p*-anisyl) ditelluride in an excess of MeI leads to a mixture of *p*-anisylmethyltellurium diiodide and *p*-anisyl-(dimethyl)telluronium iodide.[228,229] Evidently the intermediate *p*-anisyltelluro(methyl)*p*-anisyltelluronium iodide **74** decomposes, like the iodide **73**, to *p*-anisyltellanyl iodide **75** and *p*-anisyl methyl telluride **76**. The latter products react with the excess MeI, affording the observed products.

The formation of type **74** telluronium salts is not ruled out also in the reactions of dialkyl ditellurides with phenylethyne and MeI under the conditions of phase transfer catalysis (PTC).[230,231]

VII. Reactions determined by the polarisation of the Te=X bonds (X = CR_2, NR, O)

π-Telluranes include telluronium ylides, tellurimides, and telluroxides:

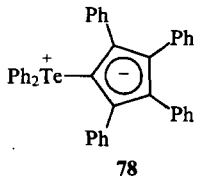


$$R_2Te{=}CR'_2 \longleftrightarrow R_2\overset{+}{T}e{-}\overset{-}{C}R'_2, \quad R_2Te{=}NR' \longleftrightarrow R_2\overset{+}{T}e{-}\overset{-}{N}R',$$

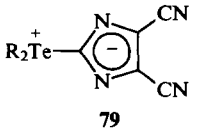
$$R_2T{=}O \longleftrightarrow R_2\overset{+}{T}e{-}\overset{-}{O}.$$

The reactivities and methods of synthesis of these compounds differ significantly from those of their sulfur (and to a lesser extent selenium) analogues. The principal factors responsible for the specific behaviour of π-telluranes compared with other π-chalcogenanes are the more intense polarisation of Te=X bonds (a greater contribution of the polar resonance structures Te^+-X^-) and hence the increased basicity of derivatives of tricoordinate tellurium. A characteristic feature of all π-telluranes without exception is their ability to be converted under the influence of different electrophiles into derivatives of tetracoordinate tellurium — the σ-telluranes R_2TeX_2.

The complete analogy of the electronic structures of organic derivatives of I(III) and Te(IV) should also be reflected in the similarity of the chemical properties of these compounds. The hypothesis[232] that organic derivatives of Te(IV), in particular π-telluranes, can be used in organic synthesis for the same purpose as organic derivatives of I(III) is therefore valid.[233]

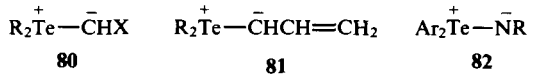


The number of telluronium ylides and imides described hitherto[7,10] is relatively small compared with their sulfur analogues. The doubly stabilised telluronium ylides **77**,[234–238] the diphenyltelluroniacyclopentadiene **78**,[239–241] and the diaryltelluronia-4,5-dicyanoimidazolylylidenes **79**[242] have been isolated on a preparative scale and characterised. The monostabilised and unstabilised telluronium ylides, compounds **80**[243–246] and **81**[247–249] respectively, have been used only in situ. Among tellurimides, only those which contain strongly electron-accepting groups at the nitrogen atom have been described.[250–256]



77

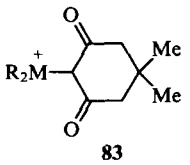
X+Y = $COCH_2CMe_2CH_2CO$, *o*-COC_6H_4CO;



X = CO_2R; Y = CO_2R, CN, NO_2; X = Y = CN

78

79



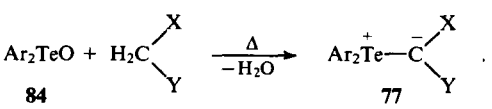
80 **81** **82**

X = CO_2R, CN, COR, $CONHBu^t$

X = SO_2R, COR (R = CCl_3, *m*-$O_2NC_6H_4$, *p*-$O_2NC_6H_4$).

We shall consider initially the properties and reactions common to all π-telluranes.

1. In contrast to dialkyl and alkyl aryl sulfoxides, the corresponding telluroxides are always isolated, by virtue of their high basicity, in the form of hydrates having the structure of σ-telluranes — diorganyltellurium dihydroxides $R_2Te(OH)_2$.[2,3,10,189] The basicity constants of the chalcogenoxides R_2MO[171,257–259] increase, like those of the telluronium ylides **83** (M = Te),[235] in the sequence M = S, Se, or Te. Thus the basicity constants of di(4-methoxyphenyl)chalcogenoxides $(4\text{-}MeOC_6H_4)_2MO$ have the following values in acetonitrile (the constants for the compounds with M = S or Se have been recalculated in relation to this solvent): S (4.2),[257] (5.4),[258] Se (9.1),[259] Te (14.9).[171] The telluroniadimedone ylides **77** (X+Y = $-COCH_2CMe_2CH_2CO-$) are somewhat weaker bases, comparable in strength to aromatic amines.[260] Indeed, $pK_a = 10.59$[235] for diphenyltelluroniadimedone ylide **83** (M = Te, $R^1 = R^2 = Ph$) is virtually identical with pK_a for aniline determined under identical conditions.[260] It follows from the pK_a for the diorganylchalcogenoniadimedone ylides **83**[235] that the basicity of the ylides increases sharply in the sequence S, Se, Te.

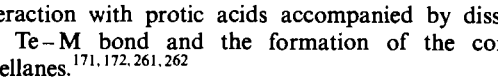


83

R = Me, M = S ($pK_a = 9.67$), Te ($pK_a = 12.07$);

R = Ph, M = Se ($pK_a = 9.59$), Te ($pK_a = 10.59$).

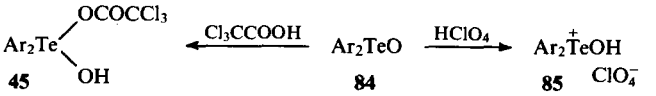
By virtue of the high basicity of the oxygen atom in the diaryl telluroxides **84**, their reactions with reactive methylene compounds, leading to the telluronium ylides **77**,[236,237] do not require, in contrast to the synthesis of the corresponding sulfonium ylides, the use of any kind of dehydrating agents of the type of Ac_2O, PCl_5, $SOCl_2$, dicyclohexylcarbodiimide, etc.[7,10] The reactions are carried out by refluxing a mixture of equimolar amounts of the components in C_6H_6 or $CHCl_3$, the water formed in the reaction being simultaneously distilled away.



84 **77**

The syntheses of the tellurimides **82** from the diaryl telluroxides **84** and amides also take place under similar conditions.[251–253]

84 **82**



2. A characteristic feature of all π-telluranes is their interaction with protic acids accompanied by dissociation of the Te–M bond and the formation of the corresponding σ-tellanes.[171,172,261,262]

77, 82, 84

R^1 = Alk, Z = C(X)Y (**77**), NR^2 (**82**), O (**84**); X = F, Cl, Br, I, $OCOR^3$.

The reactions of diaryl telluroxides with acids proceed stepwise. For the equimolar reactant ratio, either type **45** hydroxytelluranes[171] (see above) or type **85** telluronium salts[171] are formed depending on the nature of the acids.

45 **84** **85**

In contrast to diaryl telluroxides, their sulfur analogues do not react with acids. On the other hand, the interaction of the doubly stabilised sulfonium ylides (dinitromethylides) with solutions of halides in organic solvents afford sulfides and not σ-sulfuranes.[263] Selenonium dinitromethylides occupy an intermediate position: depending on the nature of the hydrogen halides and the reaction conditions, either σ-selenanes or selenides are

formed.[264] The characteristic features of the reactions of the doubly stabilised chalcogenonium ylides with HHal noted above can be evidently attributed to the sharp increase in stability of the tetracoordinate derivatives of the chalcogens in the series S, Se, Te (for further details see Section VIII).

3. The diaryl telluroxides **84** [171-173] and tellurimides **82** [262] readily react with carboxylic acid anhydrides, affording the corresponding σ-tellanes, i.e. diaryltellurium dicarboxylates **86** and diacylamides (in the case of tellurimides).

$$\underset{\textbf{82, 84}}{Ar_2\overset{+}{T}e-\overset{-}{Z}} + (R^1CO)_2O \longrightarrow \underset{\textbf{86}}{Ar_2Te(OCOR^1)_2} + \underset{Z = NR^2}{Z(COR^1)_2}$$

Z = O (**84**), NR^2 (**82**); R^1 = Alk.

Diaryl sulfoxides do not react with anhydrides, while diaryl selenoxides behave similarly to diaryl telluroxides, giving rise to diarylselenium dicarboxylates.[171]

The reactions of π-telluranes and, in particular, of diaryl telluroxides with carboxylic acids and their anhydrides are important for the following two reasons.

a. They are convenient preparative methods of synthesis of diaryltellurium dicarboxylates, which make it possible to obtain virtually any compounds **86** in nearly quantitative yields. The methods for the formation of these compounds described earlier, namely the exchange reactions of diaryltellurium dihalides with silver salts of acids,[167,265] or the oxidation of diaryl tellurides by lead tetraacetate [166,167] require either the use of expensive silver salts or make it possible to obtain only diacetates. The interaction of diaryl tellurides and of the corresponding carboxylic acids with hydrogen peroxide (molar ratios 1:2:1) (yields 82%-92%) is a convenient preparative modification, which makes it possible to avoid the preliminary synthesis of diaryl telluroxides.[266]

$$Ar_2Te + H_2O_2 \xrightarrow[-H_2O]{} \underset{\textbf{84}}{[Ar_2TeO]} \xrightarrow[-H_2O]{RCOOH} \underset{\textbf{86}}{Ar_2Te(OCOR)_2}$$

b. In view of the ease of the interaction of acids with diaryl telluroxides, one cannot use for the synthesis of the latter the acid reagents widely employed in the preparation of sulfoxides from sulfides: HNO_3, H_2O_2 in acetic anhydride, peracids, etc.[267]

We may also note the ability of diaryl telluroxides to interact with acyl chlorides[171] (diaryl sulfoxides do not interact with the latter). For equimolar reactant ratios, a 1:1 mixture of diaryltellurium dichlorides and diaryl tellurium dicarboxylates **86** is formed.

$$\underset{\textbf{84}}{Ar_2TeO} + RCOCl \longrightarrow Ar_2TeCl_2 + \underset{\textbf{86}}{Ar_2Te(OCOR)_2}$$

However, in the presence of an excess of acyl chlorides, diaryltellurium dichlorides and carboxylic acid anhydrides are obtained in high yields.[171]

$$\underset{\textbf{86}}{Ar_2Te(OCOR)_2} + 2\,RCOCl \longrightarrow Ar_2TeCl_2 + 2\,(RCO)_2O$$

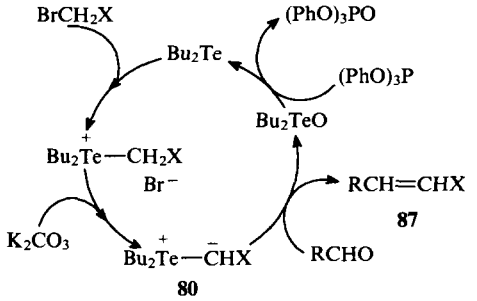
Later[268] this reaction was used as a preparative method of synthesis of acid anhydrides with different structures.

4. The telluronium ylides **77** [261] and imides **82** [262] react under mild conditions with the halogens, the reaction involving the cleavage of the Te-M bonds in the formation of σ-telluranes.

$$\underset{\textbf{77, 82}}{Ar_2\overset{+}{T}e-\overset{-}{Z}} + X_2 \longrightarrow Ar_2TeX_2 + X_2Z$$

Z = C(X)Y (**77**), NR′(**82**); X = Cl, Br, I.

Sulfonium dinitromethylides give rise to dicoordinate sulfur derivatives, i.e. diorganyl sulfides, under analogous conditions.[263]



5. The monostabilised telluronium ylides **80**, generated by treating the corresponding telluronium salts with bases (Bu^tOK [243-245]) or NaH [244] and used in situ, are smoothly condensed with aldehydes and ketones, forming α,β-unsaturated esters (nitriles, ketones) **87** in fairly high yields. The (*E*)-isomers are formed preferentially in these reactions.

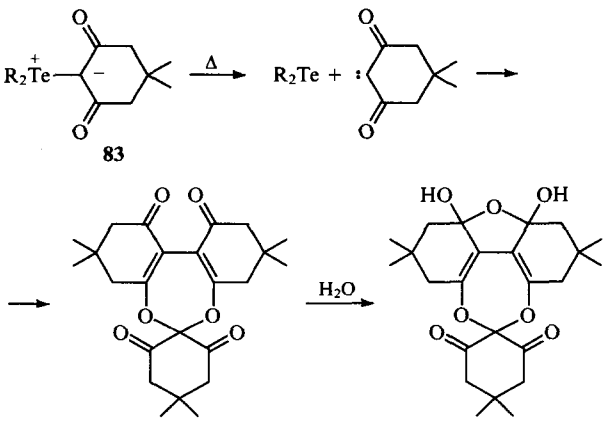
$$\underset{Y^-}{Bu_2\overset{+}{T}eCH_2X} \xrightarrow[-HY]{HB} \underset{\textbf{80}}{\left[Bu_2\overset{+}{T}e-\overset{-}{C}HX\right]} \xrightarrow[-Bu_2TeO]{R^1R^2C=O} \underset{\textbf{87}}{R^1R^2C=CHX}$$

X = CO_2Et, COPh, CN; Y = Cl, Br; R^1,R^2 = H, Alk, Ar.

On the other hand, the structurally similar sulfonium ylides do not react with aldehydes and ketones,[269,270] although they do react with α,β-unsaturated carbonyl compounds to form cyclopropanes.[269,270]

The ease of the synthesis of telluronium salts from dibutyl telluride and the ability of dibutyl telluroxide (or the corresponding dihydroxide), obtained as a result of the reaction, to be reduced back to the telluride by various reductants [$(PhO)_3P$, Na_2SO_3, $NaHSO_3$, $Na_2S_2O_3$] made it possible to carry out the latter reaction, as well as a series of other reactions involving organotellurium reagents described previously (see the reactions of arenetellurolate anions and diaryl tellurides) under catalytic conditions.[246] The alkenes **87** are formed stereoselectively in high yields when aldehydes and α-bromocarbonyl compounds are treated with catalytic amounts of dibutyl telluride in the presence of K_2CO_3 (as a base) and $(PhO)_3P$ (as a reductant) in accordance with the following mechanism:

X = CO_2Me, COPh, $COPr^i$.

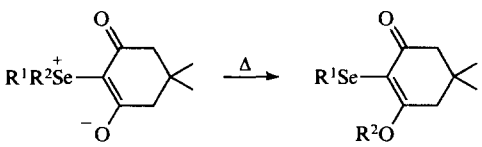


The fact that the alkenes **87** are obtained in high yields in the form of the (*E*)-isomers when aldehydes are condensed with telluronium salts in boiling THF in the absence of bases, i.e. under conditions which rule out the formation of ylides, is of special interest.[245,271]

$$ArCHO + \underset{Y^-}{Bu_2\overset{+}{T}e-CH_2X} \xrightarrow{\Delta} \underset{\textbf{87}}{ArCH=CHX}$$

X = CO_2Me, CN, COPh; Y = Cl, Br.

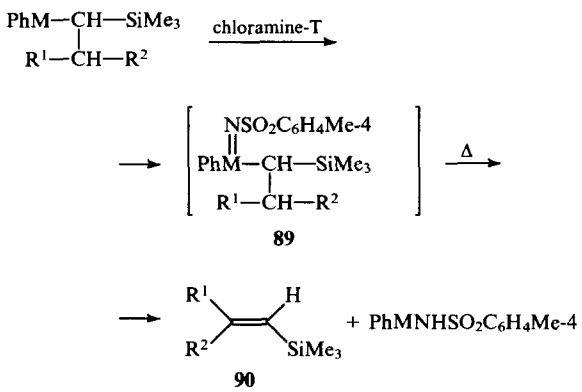
However, the mechanism of these reactions remains unelucidated.



6. The thermolysis of the telluroniadimedone ylides **83** (M = Te) and their selenium analogues **83** (M = Se) proceeds in completely different ways. On heating in inert solvents, the former decompose with formation of tellurides and the product of trimerisation of the carbanionic fragment of compound **88**.[272]

83

88

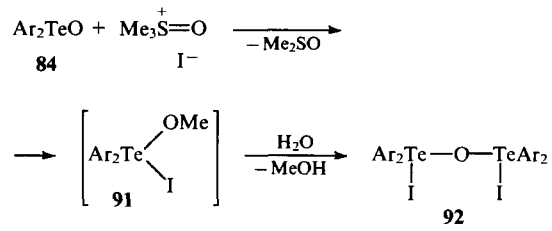


On the other hand, the selenoniadimedone ylides **83** undergo the Stevens thermal rearrangement under the same conditions.[273]

83a

The different results of the thermolytic reactions can be accounted for by the smaller Te^+-C^- bond energy compared with that of Se^+-C^-. This is also confirmed by mass-spectrometric data for the type **83** telluronium[274] and selenonium[275] ylides. In the case of the telluronium ylides, the intensities of the M^+ molecular peaks are extremely low (0.1%–0.3% of the total ionic current), whereas for the selenonium ylides they are fairly intense.

The thermolysis of the chalcogenonium imides **89**, containing S, Se, or Te, takes place in the same way and leads to the vinylsilanes **90** predominantly in the (*E*)-form.[276] The nature of the chalcogen affects only the reaction conditions: sulfur derivatives decompose at 100 °C, those of selenium decompose at room temperature, and those of tellurium decompose in boiling THF.

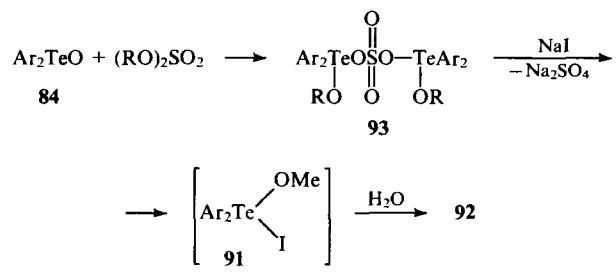


89

90

M = S, Se, Te; $R^1 = C_9H_{19}, C_{11}H_{23}, C_{13}H_{27}, C_{15}H_{31}$; R^2 = H.

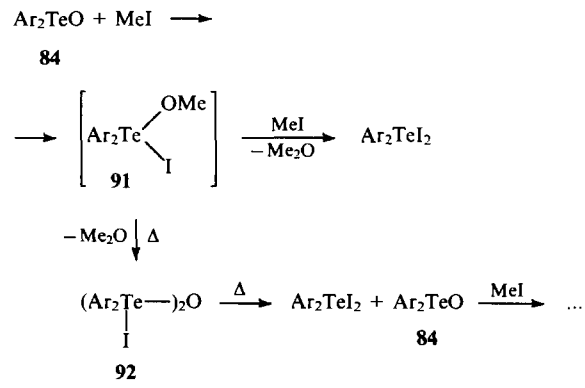
7. Extremely significant differences are observed in the reactions of diaryl telluroxides and sulfoxides with alkylating agents. Depending on the nature of the alkylating agents, the sulfoxides undergo both *O*- and *S*-alkylation.[277] On the other hand, the interaction of diaryl telluroxides with various alkylating agents (trimethylsulfoxonium iodide,[278,279] dialkyl sulfates,[279,280] and methyl iodide[279,281]) leads evidently to *O*-alkylation only (it has been suggested that the structure of the intermediates corresponds to the σ-tellanes **91**). However, in most cases the compounds isolated were formed as a result of further reactions of these intermediates, the structure and composition of which are determined by the nature of the groups linked to the tellurium atom and the reaction conditions.



The interaction of the diaryl telluroxides **84** with trimethylsulfoxonium iodide leads ultimately to the bis(diaryliodotellurium) oxides **92**, probably via the intermediate *O*-alkylation product **91**.[278,279]

91

92



Treatment of diaryl telluroxides with dialkyl sulfates involves the formation of the σ-tellanes **93**,[279,282] which are converted into the oxides **92** on treatment with NaI $2H_2O$.

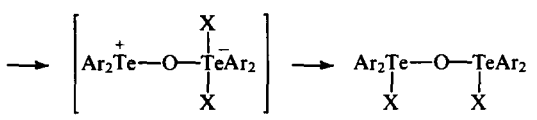
93

91

Telluroxides and sulfoxides behave quite differently in their reactions with methyl iodide. While dimethyl sulfoxide affords the *S*-alkylation product — trimethylsulfoxonium iodide — on refluxing in an excess of MeI,[277] diaryl telluroxides give rise to diaryltellurium diiodides in high yields under the same conditions.[279,281] The formation of the latter can be explained by the mechanism presented below,[279] which indicates two alternative paths leading to the conversion of diaryl telluroxides into diaryltellurium diiodides.

91

92



84

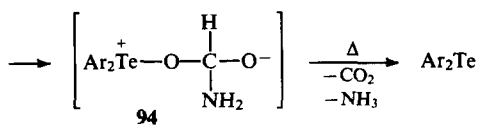
The possibility of the formation of tellurium diiodides via the bis(diaryliodotellurium) oxides **92** has been confirmed by the fact that the oxides **92** obtained by independent methods[282] decompose into diaryltellurium diiodides and diaryltelluroxides on heating in solution.

8. The diaryl telluroxides **84** react readily with the σ-tellanes Ar_2TeX_2, forming bis[diarylhalo(acetoxy)tellurium oxides **92** in high yields.[282]

$Ar_2TeO + Ar_2TeX_2 \longrightarrow$

84

92



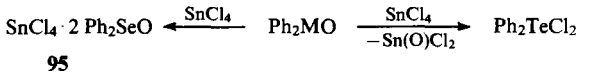
X = F, Cl, Br, I, OCOMe.

Such a reaction is evidently impossible for organosulfur compounds because of the instability of σ-sulfanes — analogues of Ar_2TeX_2.

9. The high nucleophilicity of the diaryl telluroxides **84**, which promotes the formation of the intermediate **94**, results in the ready reduction of compounds **84** to tellurides on heating in an excess of formamide at 120–140 °C. The yields of the tellurides are almost quantitative.[283]

$Ar_2TeO + HCONH_2 \longrightarrow$

84



94

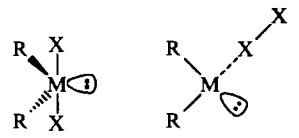
The same reagent has been used for the reduction of diaryl selenoxides,[283] whereas diaryl sulfoxides, which are the least basic among the chalcogenoxides, do not react with formamide.

Evidently formamide has significant advantages as a reductant over bis(trimethylsilyl) chalcogenides[284] and phenylselenotrimethylsilane.[285] Indeed, the above reagents, which are in addition synthesised only in moderate yields, have an unpleasant smell and are extremely sensitive to moisture and air. Furthermore, their employment entails the formation of side products [the chalcogens, $(Me_3Si)_2O$, or Ph_2Se_2 and $(Me_3Si)_2O$], which hinders the isolation and purification of diaryl tellurides.

10. The striking tendency of various organotellurium compounds to be converted into tetracoordinate tellurium derivatives is probably responsible for the different results of the reactions of diphenyl telluroxide and diphenyl selenoxide with $SnCl_4$. Whereas Ph_2TeO gives rise to the corresponding σ-tellane, i.e. Ph_2TeCl_2,[286] diphenyl selenoxide affords complex **95** under the same conditions.[287]

95

M = Se, Te.



VIII. The increased stability of tetracoordinate tellurium derivatives

The most thoroughly investigated derivatives of tetracoordinate tellurium are σ-tellanes: diorganyltellurium dihalides R_2TeX_2 and organyltellurium trihalides $RTeX_3$. These compounds are at the same time important synthons for the preparation of various derivatives of di-, tri-, penta-, and hexa-coordinate tellurium.[2–5] Tetraorganyltellanes R_4Te have been less thoroughly investigated and the first tellurone reliably described (and so far the only one) is di(4-methoxyphenyl) tellurone.[288]

σ-Tellanes and tetraorganyltellanes exhibit an increased stability compared with the analogous sulfur and selenium derivatives. These compounds have a trigonal-bipyramidal structure; the equatorial and axial bonds, even those with identical substituents, have different lengths. The axial bonds are hypervalent,[289,290] their three-centre orbitals being occupied by four electrons: two from the *p*-orbitals of the chalcogen atoms and one each from the axial substituents. As a result of this, the axial bonds are appreciably lengthened compared with the usual two-centre two-electron covalent bonds. Thus the average lengths of the $Te-C_{eq}$ bonds are 2.127 Å for tetramethyltellane Me_4Te[291] and 2.13 Å for the tetraphenyltellane solvate $Ph_4Te \cdot 0.125C_6H_6$;[292] on the other hand, the $Te-C_{ax}$ bond lengths are 2.292 and 2.29 Å respectively. In the case of nonequivalent substituents, the axial positions are always occupied by the more electronegative ligands in which there is a possibility of delocalisation of the electrons from the nonbonding L^1-M-L^2 orbital (L is the substituent and M the chalcogen). The increased stability of σ-tellanes compared with other σ-chalcogenanes can be explained by the higher energy level of the *p* orbital of tellurium, which favours bonding.[289,290]

1. The σ-tellanes R_2TeX_2 and $RTeX_3$

Depending on the nature of the chalcogen and halogen atoms, the compounds R_2MHal_2 (M = S, Se, Te; Hal = F, Cl, Br, I) have either a covalent structure with a trigonal-bipyramidal configuration of the bond (TBP) at the central atom (compounds **96**) or are charge-transfer complexes (CTC) of type **97**.[293–297] In the latter, the chalcogen atom is coordinated to only one halogen atom and the M···X–X angle is close to 180°.

96 **97**

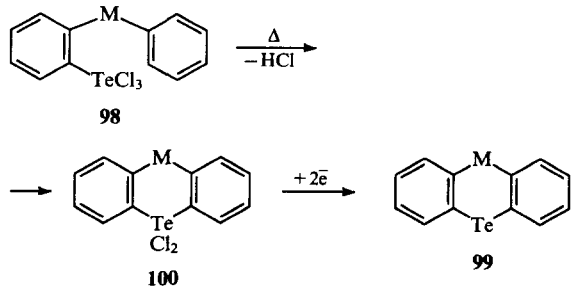
The formation of compounds of one type or another is determined primarily by the effective electronegativities (EO) of the chalcogen and halogen atoms. In general, if the electronegativity of the halogens is much higher than that of the chalcogens, covalent type **96** TBP structures are formed. Otherwise, the formation of type **97** CTC is to be expected. This rule agrees well with results of X-ray diffraction in other studies on R_2MX_2, the results of which for the structures of the compounds R_2MHal_2 are presented below:

M	F	Cl	Br	I
S	TBP	TBP	CTC	CTC
Se	TBP	TBP	TBP	CTC
Te	TBP	TBP	TBP	TBP

However, one should note that variation of the electronic nature of the groups R linked to the chalcogen atoms can alter the effective electronegativity of the latter, which may affect in its turn the structure of the R_2MHal_2. Thus diorganylselenium dibromides are usually σ-selenanes,[293–296] whereas, judging from the ^{13}C NMR spectra, dibromoselenoxanone[295,296] as well as the diarylselenium dibromides Ar_2SeBr_2 (Ar = 4-NCC_6H_4, 4-$O_2NC_6H_4$, 3,5-$Cl_2C_6H_3$, 2-ClC_6H_4) and $Ar^1Ar^2SeBr_2$ (Ar^1 = 2,6-$Cl_2C_6H_3$, Ar^2 = Ph)[298] are molecular complexes. This is due to the increase in the effective electronegativity of the selenium atom as a consequence of its conjugation with strongly electron-accepting groups.

It follows from the data presented that, regardless of the nature of the chalcogens, the true σ-chalcogenanes are the difluorides and dichlorides. The former are thermally stable for any M, while the stability of the dichlorides increases sharply in the sequence S, Se, Te. Some data on the thermal stabilities of the σ-chalcogenanes R_2MCl_2 as well as $RMCl_3$ and MCl_4 are presented below.

The σ-tellanes R_2TeX_2 are readily reduced to diorganyl tellurides R_2Te by various reductants (see above) and can be converted into telluronium salts, telluroxides, telluronium ylides,

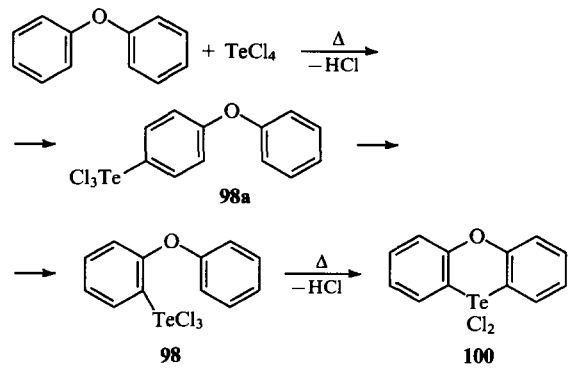


SCl_4 decomposes at −31 °C [299]	$SeCl_4$ melts without decomposition at 305 °C [299]	$TeCl_4$ melts without decomposition at 224 °C [299]
The compounds $RSCl_3$ decompose even at temperatures in the range 5–25 °C [300,301]	The compounds $RSeCl_3$ are stable at room temperature; on heating, they decompose readily into RSeCl and Cl_2 [302–305]	The compounds $RTeCl_3$ are stable up to their melting points [2–5]
The compounds R_2SCl_2 decompose at temperatures below 0 °C; at room temperature, they exist only under a dry chlorine atmosphere [306–310]	The compounds R_2SeCl_2 are stable up to their melting points [299,305]	The compounds R_2TeCl_2 are stable up to their melting points [2–5]

and tetraorganyltellanes.[2–5] On interaction with $TeCl_4$, diaryltellurium dichlorides are converted into aryltellurium trichlorides.[311]

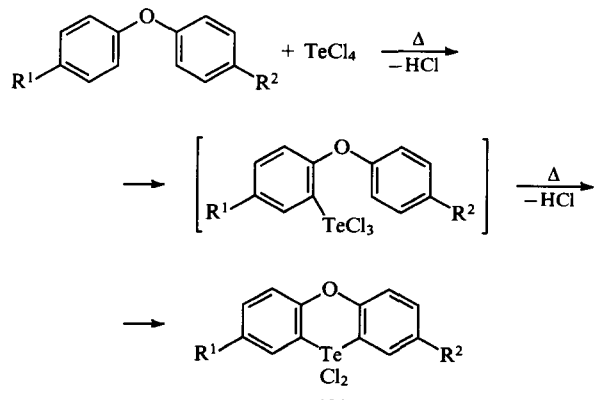
Like other organyltellurium trihalides $RTeX_3$, aryltellurium trichlorides (the most thoroughly investigated representatives of σ-tellanes of this type) are readily reduced to diorganyl ditellurides, hydrolysed to aryltellurium oxide halides, and are converted into diaryltellurium dichlorides (symmetrisation reaction).[311] They also readily form the pertelluranes $[RTeX_4]^-$ and $[RTeX_3Y]^-$ containing a pentacoordinate tellurium atom.[2–5]

Aryl(organyl)tellurium trihalides $RTeHal_3$ are electrophiles, but their reactivity is inferior to that of the corresponding tellurium tetrahalides. The electrophilicity of the aryltellurium trihalides $ArTeHal_3$ (Hal = Cl, Br, I) decreases in the sequence Cl, Br, I.[312] Aryltellurium trichlorides therefore add comparatively readily to double and triple bonds and undergo electrophilic substitution reactions with activated strong electron donors, aromatic substrates, and aliphatic compounds containing activated methyl or methylene groups (ketones, acetic anhydride, etc.).[2–5] The method of synthesis specific to tellurium-containing heterocycles, involving the intramolecular electrophilic cyclisation of the aryltellurium trichlorides **98** having the appropriate structure, is in fact based on the electrophilic nature of the trichlorotelluro-groups.



This reaction has been most often employed to synthesise tricyclic tellurium-containing systems **99** with two heteroatoms. The reaction leads to the formation of the corresponding tellurium dichlorides **100**, which are smoothly converted into the heterocycles **99** on treatment with various reductants.

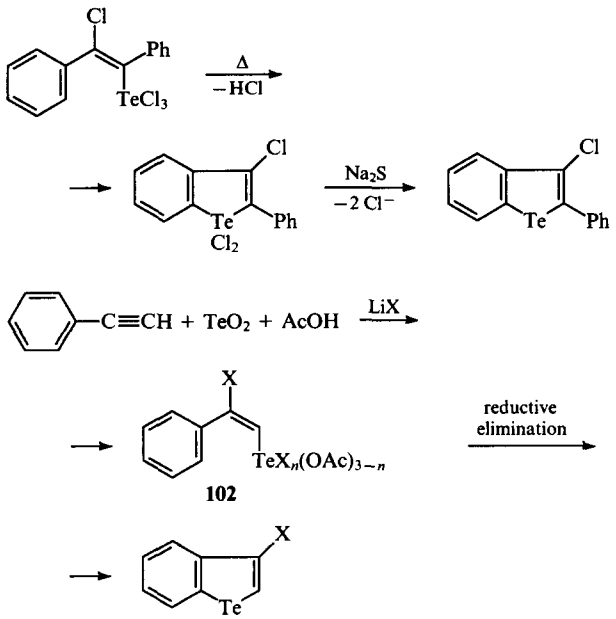
M = CH_2, NH, O, S.



The synthesis is usually carried out by heating the trichloride **98** in suitable solvents or without them. The cyclisation temperatures are determined primarily by the electronic nature of the heteroatoms. As the electron-donating properties of these atoms become more pronounced, the temperature at which the process takes place is reduced. Thus the cyclisation of 2-(phenylamino)phenyltellurium trichloride **98** (M = NH) takes place on refluxing in acetic acid,[313] whereas the cyclisation of the diphenyl ether **98** (M = O) and diphenyl sulfide **98** (M = S) requires heating to 200 °C [314] and 240–250 °C [315] respectively. The weak electron-donating properties of the methylene bridge are evidently the reason why 10,10-dichlorotelluraxanthene **100** (M = CH_2) could not be obtained by heating 2-benzylphenyltellurium trichlorides **98** (M = CH_2).[316] The synthesis of this heterocycle was found to be possible only by carrying out the reaction in the presence of $AlCl_3$, which increases the electrophilicity of the trichlorotelluro group as a result of the formation of the complex $[ArTeCl_2]^+[AlCl_4]^-$.[316,317]

It is of interest to note that 10,10-dichlorophenoxatellurane **100** (M = O) can be obtained in approximately 50% yield by the prolonged heating of equimolar amounts of $TeCl_4$ and diphenyl ether.[314] The primary product of this reaction, isolated in an analytically pure form, is *p*-phenoxyphenyltellurium trichloride **98a**, because, like other electron releasing groups,[2,3,318,319] the OPh group directs the electrophile to the *para*-position. However, on further heating of this compound, the $TeCl_3$ group migrates to the *ortho*-position and the *o*-phenoxyphenyltellurium trichloride thus obtained is converted further into the heterocycle **100** (M = O).

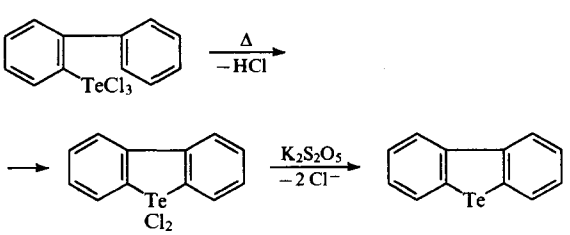
A similar migration of the $TeCl_3$ groups with subsequent cyclisation occurs on heating *p*-(phenylamino)phenyltellurium trichloride (obtained from *p*-chloromercuriodiphenylamine and $TeCl_4$ [313]) in acetic acid and by heating $TeCl_4$ in an excess of Ph_2S at 190–200 °C.[196] The yields of the heterocycles **99** (M = NH, S) are, however, extremely low and amount to 7% and 6% respectively.



Similar reactions have been used also to synthesise 2,8-disubstituted 10,10-dichlorophenoxatelluranes **101**. The latter are obtained in 14%–50% yields on heating melts of mixtures of 4,4′-disubstituted diphenyl ethers and $TeCl_4$.[177,320–324]

$R^1 = R^2$ = Me,[321] Cl,[322] F;[323]

R^1 = Me, R^2 = H,[320] Cl,[320] F,[324] CO_2H;[320] R^1 = F, R^2 = Cl.[177]



The synthesis of five-membered tellurium-containing heterocycles — substituted benzo[*b*]tellurophenes and dibenzotellurophenes — has also been achieved with the aid of cyclisation reactions of the corresponding aryltellurium trichlorides. Thus the first representative of benzo[*b*]telluro-phenes — 1,1,3-trichloro-2-phenylbenzo[*b*]tellurophene — has been obtained in a yield exceeding 50% by heating 2-chloro-1,2-diphenylvinyltellurium trichloride[325] (the product of the electrophilic addition of $TeCl_4$ to diphenylethyne[326]). A series of 3-halobenzo[*b*]tellurophenes have been synthesised in 21%–92% yields by treating phenylethyne with tellurium dioxide in acetic acid in the presence of LiX.[327,328] The latter reaction evidently proceeds via the intermediate formation of the σ-tellanes **102**, the cyclisation of which leads to the required heterocycles.

102

X = Cl, Br, I.

Brief heating at 210 °C of 2-trichlorotelluriobiphenyl (obtained from 2-chloromercuriobiphenyl and $TeCl_4$) leads to 1,1-dichlorodibenzotellurophene in almost quantitative yield.[329]

Evidently, these reactions, like those examined above, could not be used to obtain the sulfur and selenium heterocycles because the corresponding arylsulfur trichlorides and arylselenium trichlorides are thermally unstable. However, benzo[*b*]thiophene[330] and benzo[*b*]selenophenes[331] as well as dibenzothiophene[332] and dibenzoselenophene[333] have been obtained by the thermal cyclisation of arylchalcogen monohalides ArMX (M = S, Se; X = Cl, Br, I).

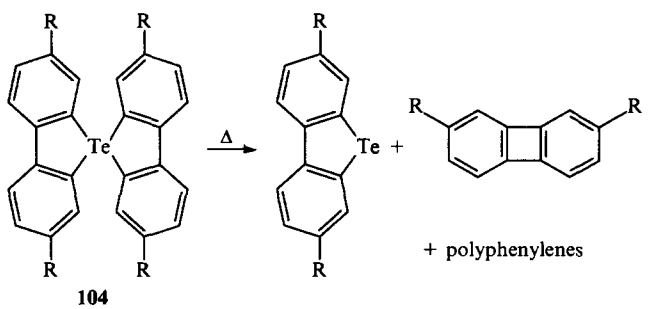
2. Tetraorganyltellanes R_4Te and tetraalkoxytellanes $(RO)_4Te$

As in the case of the σ-tellanes R_2TeX_2 and $RTeX_3$ as well as their sulfur and selenium analogues, significant differences between the thermal stabilities of tetraaryltellanes Ar_4Te **103** and other tetraarylchalcogenanes Ar_4M (M = S, Se) are observed. The latter exist only in solutions at very low temperatures [thus the formation of tetrakis(pentafluorophenyl)sulfane in solution on reaction between SF_4 and C_6F_5Li has been detected by the ^{19}F NMR method at −80 °C[334]], decomposing to biaryls and diaryl chalcogenides on raising the temperature. In contrast to them, the tetraaryltellanes **103** are stable crystalline compounds under the usual conditions, melting above 100 °C.[335–338] It is noteworthy that the tetraalkyltellanes **103**, which have been obtained comparatively recently, are thermally stable but are extremely sensitive to air and light.[339–341] The most general method of synthesis of compounds **103** involves the interaction of organolithium or organomagnesium derivatives with $TeCl_4$[335–338,340,341] [Ph_4Te has also been obtained from PhLi, Ph_2TeCl_2, and Ph_3TeCl,[335] whilst $(CF_3)_4Te$ has been synthesised by the reaction of $(CF_3)_2TeCl_2$ with $(CF_3)_2Cd$.[339]]

$$RM + TeCl_4 \xrightarrow[-MCl]{} R_4Te$$

103

M = Li, MgX; R = Ph,[335,337,338] C_6D_5,[338] 4-MeC_6H_4,[337,338] C_6F_5,[336] Me,[340,341] Bu,[341] Me_3SiCH_2,[341] $CH_2{=}CH$,[340] $CH_2{=}CHCH_2$.[341]



Tetraaryltellanes, which are stable under the usual conditions, decompose smoothly to diaryl tellurides and biaryls on heating.

$$Ar_4Te \xrightarrow{\Delta} Ar_2Te + Ar{-}Ar$$

103

The decomposition of tetraalkyltellanes, especially $(CF_3)_4Te$, proceeds in a more complex manner, considerable amounts of secondary reaction products being formed in addition to dialkyl tellurides and the corresponding hydrocarbons.

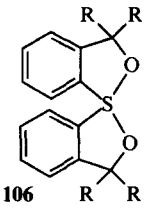
The highly stable cyclic tetraaryltellanes **104**[250,255,342,343] (with melting points above 200 °C) decompose on thermolysis similarly to the acyclic tetraaryltellanes **103**: the principal decomposition products are dibenzotellophene and biphenylene.

104

R = H, Me.

The high thermal stability of the recently synthesised hexamethyltellurium Me_6Te is also noteworthy;[344] this compound does not decompose on heating in solution in C_6D_6 in a sealed tube at 140 °C in the course of 4.5 h (for comparison, we may note that tetramethyltellane Me_4Te decomposes fully in 4 h at 120 °C).[344]

The thermal stabilities of tetraalkoxychalcogenanes $(OR)_4M$ (M = S, Se, Te) are also very different. Among the sulfur derivatives, only those which contain perfluorinated alcohol residues are stable.[345] Tetraalkoxyselenanes are stable only below 0 °C,[346,347] decomposing rapidly to dialkyl selenites and dialkyl ethers when the temperature is raised.[346,347]



$$(RO)_4Se \xrightarrow{\Delta} (RO)_2Se{=}O + R_2O$$

105

The tetraalkoxytellanes $(RO)_4Te$ (R = Me, Et, Pr^i, Bu)[347–349] are thermally more stable than their sulfur and selenium analogues and can be vacuum distilled without decomposition. Their thermolysis proceeds in a different way from that of

the selenium derivatives. Thus tetraethoxytellane decomposes on heating to ethanol, acetaldehyde, and tellurium.[350]

We may also note that dialkoxydiorganyltellanes $R^1_2Te(OR^2)_2$, obtained by means of exchange reactions of diorganyltellurium dihalides with sodium alkoxides, are thermally stable regardless of the nature of the alkoxy-groups.[351] On the other hand, only those sulfur analogues which contain perfluoroalkoxy-groups, for example $Ph_2S[OC(CF_3)_2Ph]_2$,[306,352] or have the cyclic structure **106**[306] are stable under the usual conditions.

R = H, Me, CF_3.

106

IX. Reactions involving the dissociation of C–Te bonds

The C–Te bonds have the lowest energy among carbon–chalcogen bonds. The bond energies of the latter as well as the M–M bond energies (kJ mol^{-1}) in diorganyl dihalides RM–MR[204] are presented below.

	S	Se	Te
C_{prim}–M	287.0	246.9	213.4
C_{sec}–M	285.8	245.6	302.0
M–M	264.0	202.0	149.8

As a result of the significant decrease in the carbon–chalcogen bond energies in the sequence S, Se, Te, certain reactions, which in the case of organosulfur and organoselenium compounds take place with retention of the C–M bonds, in the case of organotellurium compounds are accompanied by the dissociation of the C–Te bonds. Because of this, certain reactions leading to particular types of acyclic and cyclic sulfur and selenium compounds are inapplicable to the synthesis of the structurally similar tellurium-containing derivatives. On the other hand, the application of organotellurium compounds in preparative organic chemistry is based precisely on the ease of dissociation of the C–Te bond accompanied by elimination of the Te atom. This section deals with the reactions of derivatives of dicoordinate tellurium, principally of diorganyl tellurides of various types, which proceed with dissociation of one or two C–Te bonds (elimination of the Te atom). (Analogous reactions of certain derivatives of tricoordinate tellurium were examined in Section VII, while those of derivatives of tetracoordinate tellurium and the telluroxide elimination reactions have been considered in other reviews.[10,26,27,29,30])

The dissociation of the C–Te bonds in organotellurium compounds in general and in diorganyl tellurides in particular takes place as a result of pyrolysis or photolysis and also on treatment with Raney nickel, transition metals (primarily palladium and its compounds), nontransition metal salts, Group IV element hydrides, as well as a series of oxidants, electrophiles, and nucleophiles.

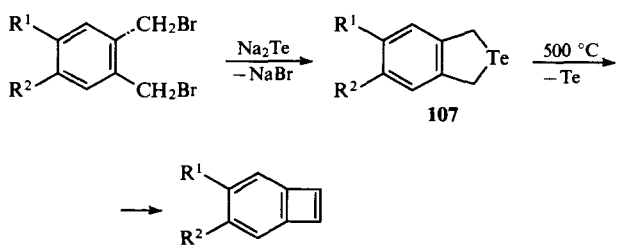
The gas-phase pyrolysis of dialkyl tellurides[2,3,353,354] is accompanied by the dissociation of both C–Te bonds and makes it possible to obtain ultrapure tellurium. It is believed[2,3,355] that these reactions take place via a radical mechanism. The pyrolysis of dimethyl telluride (330–380 °C) is four times faster than that of Me_2Se.[353] The decomposition in the gas phase of mixtures of volatile dialkyl tellurides and alkyl derivatives of metals (Zn, Cd, Hg, etc.)[356,357] is used for the synthesis of the tellurides of these metals, which have found an application as semiconductors, in the preparation of opto- and acousto-electronic systems, etc.

The synthesis of benzo[*b*]thiophene and of its selenium analogue (in yields of 85% and 40% respectively),[358] as well as selenophene, mixed with benzo[*b*]selenophene,[359] can be achieved by means of the high-temperature reactions of diphenyl disulfide and diselenide with ethyne and propargyl alcohol respectively. On the other hand, diphenyl ditelluride decomposes in similar reactions with liberation of metallic tellurium; for example, benzo[*b*]tellurophene is detected in only trace amounts (1%–2%).[358] The different compositions of the final products of the reactions of 2-iodothiophene with dimethyl selenide and telluride and the formation of considerable amounts of metallic tellurium[360] are also a result of the decrease in the carbon–chalcogen bond energy on passing from selenium to tellurium.

Reactions involving the pyrolytic dissociation of the C–Te bonds have been used in a number of instances for the preparative synthesis of various hydrocarbons. Allyl and benzyl halides interact with lithium telluride, affording 1,5-dienes (yield 60%–93%)[361] and bibenzyl (yield 37%)[24,361] as the main products. These hydrocarbons are the products of the coupling of the allyl(benzyl) radicals arising following the elimination of the tellurium atom from the intermediate diallyl(benzyl) tellurides.

$$R^1CH{=}CHCHX + Li_2Te \xrightarrow[-LiX]{110\ ^\circ C} \left[\left(R^1CH{=}\underset{R^2}{\underset{|}{C}}H\right)_2Te\right] \xrightarrow[-Te]{\Delta} R^1CH{=}\underset{R^2}{\underset{|}{C}}H^{\bullet}$$

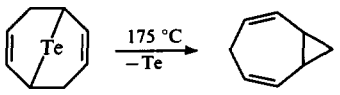
$$\longrightarrow R^1CH{=}\underset{R^2}{\underset{|}{C}}H{-}\underset{R^2}{\underset{|}{C}}H{-}CH{=}CHR^1$$



$R^1 + R^2 = -(CH_2)_4-$, $-(CH_2)_5-$, $-(CH_2)_6-$;

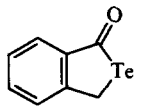
$R^1 = R^2 = Me$; R^1 = Ph, $CH_2{=}CH$, Pr, R^2 = H; X = Cl, Br.

$$PhCH_2Br + Li_2Te \xrightarrow[-LiBr]{110\ ^\circ C} [(PhCH_2)_2Te] \xrightarrow[-Te]{\Delta} \longrightarrow PhCH_2^{\bullet} \longrightarrow PhCH_2CH_2Ph.$$



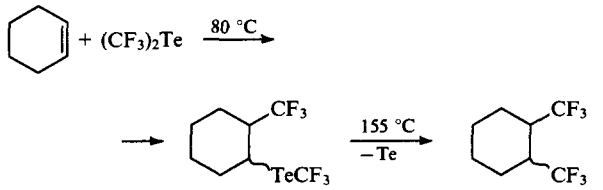
Such reactions, which constitute a new method of synthesis of 1,5-dienes are characteristic of tellurium derivatives only. Indeed, whereas treatment of 3-bromocyclohexene with lithium telluride gives 2,2′-bicyclohexenyl in 81%–86% yield, only the corresponding selenide is formed in the analogous reaction with Li_2Se.[361] However, one should note that the interaction of allyl and benzyl halides with sodium and lithium tellurides at room temperature makes it possible to obtain symmetrical diallyl or dibenzyl tellurides in 50%–100% yields.[341,355,362–366]

The pyrolysis of the cyclic tellurides **107** (the mechanism of their synthesis is presented below) and **12** (see over; the synthesis of this compound was described in Section II) is also accompanied by the elimination of the tellurium atom and the formation of derivatives of cyclobutene[367] and bicyclo[5.1.0]octa-2,5-diene respectively.[75]



107

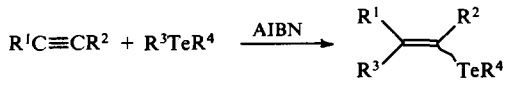
$R^1 = R^2 = H$; $R^1 + R^2 = (-CH{=}CH-)$.



12 13

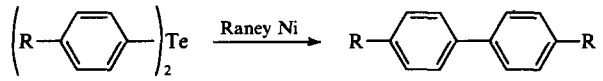
On the other hand, the attempts to obtain benzocyclobutenone by the vacuum flash photolysis of tellurophthalide **108** were unsuccessful;[134] the elimination of the tellurium atom was not observed under these conditions.

108



As the electron-accepting properties of the groups linked to the tellurium atom are enhanced, the temperature at which the tellurium atom is eliminated probably decreases. Thus at 80 °C bis(trifluoromethyl) telluride adds to cyclohexene, forming a mixture of *cis*- and *trans*-1-trifluoromethyltelluro-2-trifluoroethylcyclohexanes **109**; the tellurium atoms are eliminated from these compounds at 155 °C.[368]

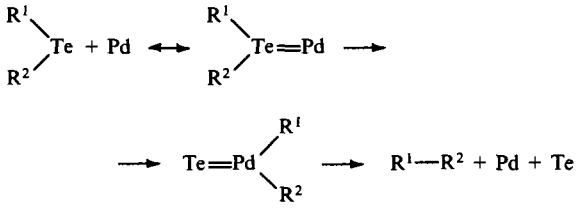
109



According to the data of Naumann and Wilkes,[368] bis(trifluoromethyl) telluride is superior to CF_3I and $(CF_3)_2Hg$ in terms of its trifluoromethylating capacity in both thermal and photochemical reactions.

Whereas the carbotelluration of cyclohexene (preceding reaction) takes place at 80 °C, the carbotelluration of alkynes is achieved when benzene solutions of equimolar mixtures of alkynes and diorganyl tellurides are refluxed in the presence of catalytic amounts of 2,2′-azobisisobutyronitrile (AIBN).[369,370]

The reaction proceeds via a radical mechanism and leads to a mixture of (*E*)- and (*Z*)-vinyl tellurides in yields ranging from 40% to 100%. The $C(sp^3)$–Te bonds are dissociated exclusively in alkyl phenyl tellurides; the C_{tert}–Te bonds are cleaved more readily than the C_{prim}–Te bonds.[370]



The synthesis of symmetrical biaryls from diaryl tellurides catalysed by Raney nickel is of definite interest for preparative organic chemistry.[371] The reactions are carried out by refluxing diaryl tellurides with a 20-fold molar excess of freshly prepared Raney nickel in 2-methoxyethyl ether for many hours and make it possible to obtain biaryls in 72%–90% yields.

R = OEt, OMe, Me, H, Br.

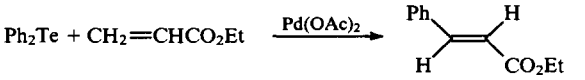
However, one should note that, according to Horner and Doms,[372] Ph_2Te is reduced under the influence of Rany nickel to benzene. Tellurium is then evidently converted into nickel telluride because on treatment with inorganic acid after the reaction H_2Te is evolved.

A more general method of synthesis of hydrocarbons of different composition (yield 76%–100%), based on the elimination of tellurium atoms from diorganyl tellurides, involves treatment of the tellurides R^1TeR^2 with palladium generated in situ from $Pd(OAc)_2$ and Et_3N.[373]

R^1 = 4-$MeOC_6H_4$; R^2 = 4-$MeOC_6H_4$, Ad^t, $C_{15}H_{31}$;

$R^1 = R^2 = PhCH_2CH_2$; $R^1 = PhCH_2CH_2$, $R^2 = CH_2Ph$.

Palladium(II) salts promote the insertion of carbon monoxide in the Te–C bonds of diorganyl tellurides, which leads to either carboxylic acids[43,374] or their methyl esters[53] depending on the conditions. The most convenient procedure for carrying out these reactions involves treatment of solutions of diorganyl tellurides in MeOH/Et_3N at room temperature with carbon monoxide in the presence of stoichiometric amounts of palladium(II) salts.[53] The reactions can also be carried out in the presence of catalytic amounts of $PdCl_2$ when the reaction mixtures contain oxidants, the most effective of which is $CuCl_2$.[53] It is believed[43,53] that the reactions proceed via the intermediate formation of the monomeric complexes $(R_2Te)_2PdCl_2$ or dimeric complexes $[R_2TePdCl_2]_2$ with subsequent migration of the organic groups from Te to Pd, the insertion of CO in the Pd–C bond, and the hydrolysis of the acylpalladium intermediates.



$R^1 = Ph$;

R^2 = PhCH=CH, EtO_2CCH=CH, PhC≡C, $C_6H_{13}C$≡C, Ph, $C_{12}C_{25}$.

It is noteworthy that, when the salts of other transition metals capable of forming complexes with diorganyl tellurides [Rh(III), Ru(III), Ir(III)] are used, the carbonylation reactions have very low yields (for $RhCl_3 \cdot 3H_2O$) or do not occur at all. The ability of triorganyl chalcogenides R_2M to enter into the reactions considered above increases sharply in the following sequence of the elements M: S ≪ Se < Te.[43,53] Thus Ph_2S does not enter into the reaction, Ph_2Se forms methyl benzoate in 14% yield, whereas in the reaction involving Ph_2Te the yield of the ester increases to 86%.

The arylation of alkenes by diorganyl tellurides also proceeds via arylpalladium intermediates formed when phenyl groups migrate from Te to Pd.[375] Thus the interaction of diphenyl telluride with ethyl acrylate in the presence of $Pd(OAc)_2$ leads to the formation of (2*E*)-phenyl acrylate in a yield exceeding 90% (biphenyl is a side product of the reaction).

It is noteworthy that Ph_2Se undergoes a similar reaction, but its rate is much slower than that of the reaction with Ph_2Te.

Under comparatively mild conditions, one or both C–Te bonds in diorganyl tellurides are cleaved by the triorganyl-substituted hydrides of Group IVA elements R_3XH (X = Si, Ge, Sn; R = Et, Bu, Ph).[376–382] The composition of the final reaction product (dissociation of one or two bonds) then depends on the nature of the hydride. Thus Et_3SiH and Et_2Te afforded compounds **110** and **111** in comparable yields at 200 °C,

Et_3GeH gave rise to the analogous compounds at 140 °C, but the reaction of Et_3SnH (even at 20 °C) led to the formation of only bis(triethylstannyl) telluride **111** (X = Sn).[376,377]

$$R_3XH + Et_2Te \xrightarrow[-C_2H_6]{} \underset{\mathbf{110}}{R_3X{-}TeEt} + \underset{\mathbf{111}}{R_3X{-}Te{-}XR_3}$$

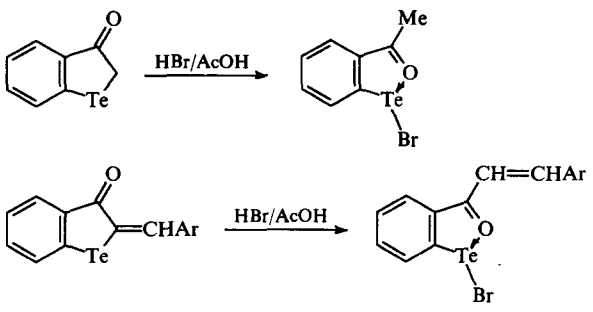
The mild conditions in the reactions of diorganyl tellurides with triorganyltin hydrides and the high yields of the hydrocarbons makes it possible to employ diorganyl tellurides in the synthesis of the latter.[378–382] Ph_3SnH or Bu_3SnH are usually employed in these reactions. Diorganyl selenides are reduced to hydrocarbons in high yields (heating with Ph_3SnH at 120 °C).[378] However, organic sulfides are inert to Ph_3SnH.[378] The reduction of tellurides and selenides by tin hydrides probably proceeds via a S_H2 mechanism;[378,383] the rate of reduction of tellurides is then higher than that of selenides.

$$R_3SnH \longrightarrow R_3Sn^{\bullet} + H^{\bullet}$$

$$R_3Sn^{\bullet} + R^1_2Te \longrightarrow R_3Sn{-}TeR^1 + R^{1\bullet}$$

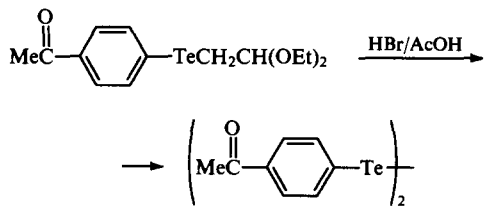
$$R^{1\bullet} + R_3SnH \longrightarrow R^1H + R_3Sn^{\bullet}$$

The dissociation of one (more rarely two) C–Te bond is observed in the protodetelluration and halodetelluration reactions of diorganyl tellurides. These reactions are most characteristic of alkyl aryl tellurides containing in the *ortho*-position functional groups capable of being coordinated to the Te atom; the weaker of the two C–Te bonds, namely $C(sp^3)$–Te, is then cleaved. Thus treatment of alkyl *o*-carbonylaryl tellurides by hydrogen halides (usually HBr) affords high yields of the *o*-halotellurocarbonyl compounds **112** stabilised by strong intramolecular O→Te coordinate bonds.[107,114,116,384]



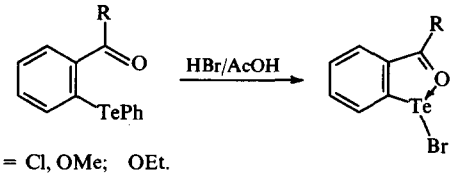
112

X = Cl, Br, I; $R^1 = R^3 = H$; $R^2 = CH_2CO_2Et, CH_2CH(OEt)_2$;[107]



$R^1 = R^2 = Me$; R^3 = H, 4-Cl, 4-Me, 5-Me;[116]

R^1 = Me,[384] Ph;[114] R^2 = Bu; R^3 = H; X = Br.



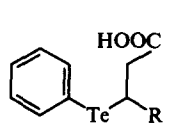
The $C(sp^3)$–Te bonds in telluroindoxyl[112] and telluroaurones[110] dissociate under similar conditions.

The presence of the COR groups in the *ortho*-positions relative to the TeR groups is a necessary condition for the formation of arenetellurenyl halides. Indeed, in the case of the diethyl acetal of *p*-acetylphenyltelluraacetaldehyde the hydrolysis leads only to the corresponding ditelluride.

It is of interest to note that not only the $C(sp^3)$–Te bond but also the C_{Ar}–Te bonds are cleaved by HBr when coordinating groups are present in the *ortho*-position in the molecules. Treatment of derivatives of 2-carboxyphenyl phenyl telluride (but not the acid itself) with HBr in acetic acid leads to tellanyl bromides in high yields.[113] Bearing in mind the ease of the reduction of the tellanyl bromides obtained to ditellurosalicylic acid, this reaction can be regarded as a convenient preparative method of synthesis of the latter.

R = Cl, OMe; OEt.

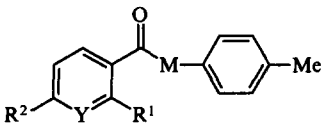
The $C(sp)$–Te bonds in the ethynes **113**[385,386] and **114**[387] and in alkylchalcogenovinylethynes **50a**[386,388] are very readily cleaved by acids in the presence (or absence) of Hg^{2+} salts.



$RC{\equiv}CMMe$	$MeMC{\equiv}CMMe$	$CH_2{=}CHC{\equiv}CMMe$
113	**114**	**50a**

R = Me, Ph.

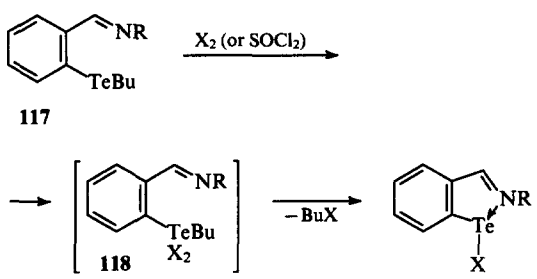
Whereas phenyl(methyl)thio- and phenyl(methyl)seleno-ethynes are hydrated with formation of the methyl esters of phenyl(methyl)thio(seleno)acetic acids, their tellurium analogues afford only the products of the cleavage of the $C(sp)$–Te bonds ($PhC{\equiv}CH$) and the product of partial dehydration — PhCOMe in the case of compound **113** (R = Ph, M = Te).[385] Whereas bis(methylseleno)ethyne **114** (M = Se) gives rise to a small yield of the addition product of the triple bond in its reaction with acetic acid in the presence of Hg^{2+} salts, its tellurium analogue undergoes only protodetelluration.[387] The product of the addition of acetic acid to the triple bond can be obtained under mild conditions from 1-methyltellurobut-3-en-1-yne **50a** (M = Te) in a low yield.[388] However, under more severe conditions this telluride is protodetellurated,[388] although the sulfur and selenium compounds having analogous structures are entirely stable under these conditions.[388]



The ease with which protodetelluration takes place prevents in many instances the application in the synthesis of tellurium-containing compounds of reactions such as those employed in the chemistry of their sulfur and selenium analogues. Thus 3-phenyltelluropropionic acid **115** (R = H)[191] and its phenyl analogue **115** (R = Ph)[109] do not cyclise on treatment with perfluoroacetic acid (PFA) under the conditions employed to obtain selenachromanones,[389] but decompose with liberation of metallic tellurium. Similarly the attempts to synthesise telluro-chromanone by the pyrolysis of β-(*o*-carboxyphenyltelluro)-propionic acid or by the Dieckmann condensation of its diester were unsuccessful: the reactions occurred with cleavage of the $C(sp^3)$–Te bonds and led to ditellurosalicylic acid.[191]

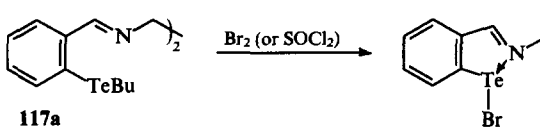
Here it is appropriate to mention that one of the methods of synthesis of thia- and selena-xanthones — the photocyclisation of the esters **116** (M = S, Se) is inapplicable to the synthesis of telluraxanthones. UV irradiation of solutions of the telluroesters **116** (M = Te) leads to a complex mixture of products as a consequence of the cleavage of the C–Te bonds.[114,390,391]

115



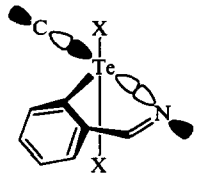
R = H, Ph

116



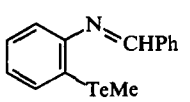
M = S, Se, Te; $R^1 = R^2 = H$; R^1 = H, R^2 = OMe; R^1 = Cl, SMe, OMe, SO_2Me; R^2 = H, Y = N, CH.

Reactions involving the oxidative addition of the halogens to alkyl aryl tellurides (see Section V and also Refs. 2–4) usually lead to stable alkylaryltellurium dihalides. However, when the *o*-tellurated azomethines **117**[104,123,124,126] and **117a**[125] react with the halogens or SO_2Cl_2, the C(sp^3)–Te bonds are cleaved, which leads to the formation of the corresponding tellanyl halides in high yields. The reactions evidently proceed via the σ-tellane intermediates **118**, the existence of which in solutions at a low temperature has been demonstrated with the aid of ^{1}H NMR spectra.[104] When the temperature is raised to room temperature, butyl halide molecules are eliminated.



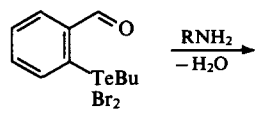
117

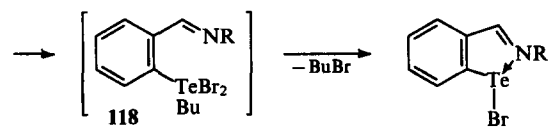
118



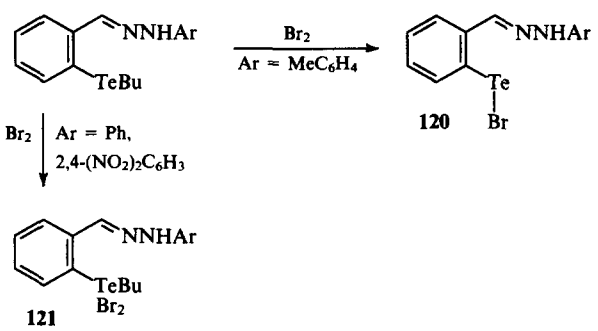
117a

The driving force of these reactions is, as in the protodetelluration reactions examined above, the marked stabilisation of tellanyl halides (which are 10-Te-3-telluranes according to the N–X–L nomenclature[392]) as a result of the coordination of the N(O) atoms to the tellurium atoms. In addition, there are favourable steric conditions for the N–Te and n(N) → σ*(Te–Bu) electron delocalisations in the intermediates **118**. As can be seen from the orbital interaction model **118a**, such delocalisation weakens the Te–C bond, which forms an angle of approximately 180° with the Te←N bond.



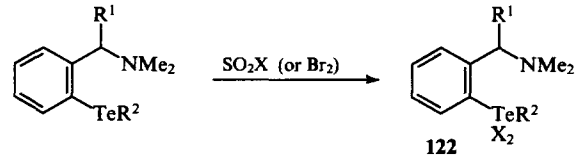


118a

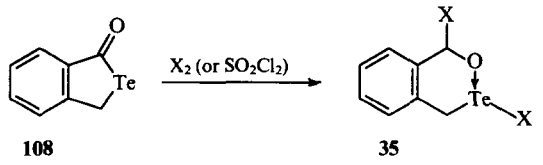


119

There are many examples of reactions facilitating the dissociation of the C–X bonds, which occurs when the interacting fragments are arranged in such a way that appreciable overlap of the n(O)–σ*(X–C) or n(N)–σ*(X–C) orbitals and hence partial population of the antibonding σ*(X–C) orbitals are ensured. In fact, benzylidene-2-methyltelluroaniline **119**, in which there is no N→Te coordination, gives rise to stable tellurium dihalides. The interaction of *o*-dibromo(butyl)tellurobenzaldehyde with primary amines gives rise to *o*-halotellurobenzylideneamines and not the σ-tellanes **118**.[104,124]



Thus, regardless of the nature of the substituents in the *N*-aryl rings of the azomethines **118**, their halogenation always leads to arenetellanyl halides. On the other hand, similar reactions with the arylhydrazones of 2-butyltellurobenzaldehyde proceed differently.[393] Electron-donating substituents in the arylhydrazone rings (Ar = MeC_6H_4) favour the cleavage of the C(sp^3)–Te bond on bromination, which leads to the formation of the tellanyl bromide **120**; when Ar = Ph or 2,4-$(NO_2)_2C_6H_3$, the arylhydrazones of 2-dibromo(butyl)tellurobenzaldehyde **121** are formed.



The reactions examined above, involving the halogenolysis of *o*-butyltellurobenzylideneamines and the arylhydrazones of 2-butyltellurobenzaldehyde are excellent illustrations of the influence of intramolecular N→Te coordinate bonds on the reactivity of organotellurium compounds (for other examples, see Section X).

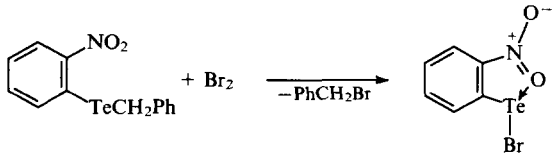
It is noteworthy that, when 2-alkyltellurobenzyldimethylamines are treated with SO_2Cl_2[131] or Br_2,[131,132] the stable σ-tellanes **122** are formed. This is evidence that the coordinate bonds involving an sp^3-hybridised nitrogen atom are weaker than those involving an sp^2-hybridised nitrogen atom.

R^1 = H; R^2 = Me, Et, Bu; $R^1 = R^2$ = Me; X = Cl, Br.

The cleavage of the C(sp^3)–Te bond at low temperatures takes place also in the halogenolysis of tellurophthalide **108**.[134] The tellanyl halides **35** formed in this reaction are the first examples of stable alkanetellanyl halides, their stability being due to the presence of the O→Te coordinate bonds.

108 35

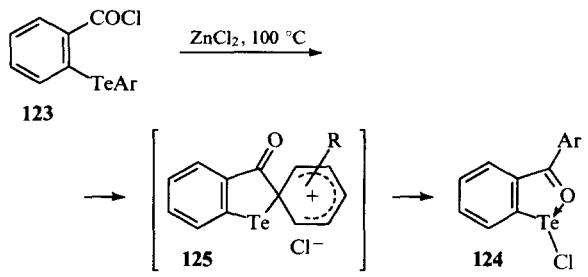
X = Cl, Br, I.



The halogenolysis of aryl benzyl tellurides, accompanied both by the dissociation of the C(sp^3)–Te bonds and by an increase in the coordination number of the tellurium atom, proceeds fairly specifically under the influence of $SOCl_2$ or SO_2Cl_2.[364,394]

$$RTeCH_2Ph \xrightarrow{X} RTeCl_3 + PhCH_2Cl$$

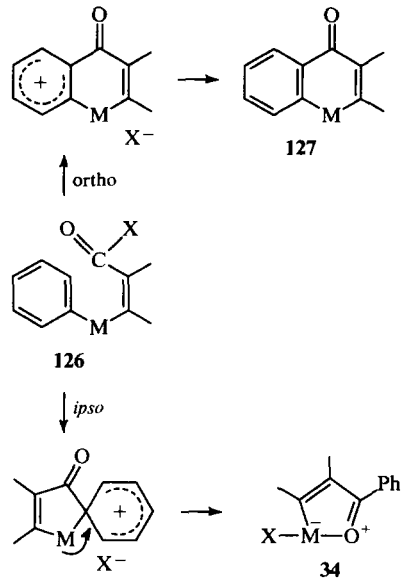
R = 4-MeOC$_6$H$_4$, 2-C$_{10}$H$_7$; X = $SOCl_2$, SO_2Cl_2.



$$(PhCH_2)_2Te \xrightarrow{Br_2} PhCH_2Br + TeBr_4$$

Treatment of benzyl 2-nitrophenyl telluride with bromine entails the formation not of a tribromotelluro-derivative but of a tellanyl bromide stabilised by the O→Te coordinate bond.[121]

The C–Te bond dissociates also on interaction of bis(pentafluorophenyl)telluride with an excess of ClF, which results in the formation of considerable amounts of $C_6F_5TeF_4Cl$ and TeF_5Cl together with $(C_6F_5)_2TeF_4$.[156]

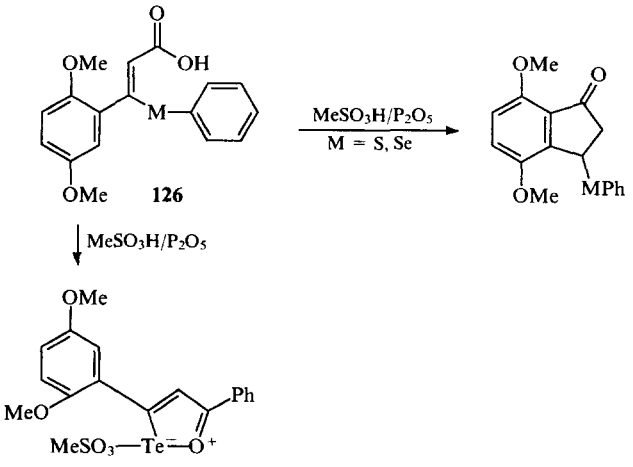


The cleavage of the C–Te bonds with simultaneous rearrangement has been achieved by treatment with certain Lewis acids. Thus heating of aryl 2-chlorocarbonylphenyl tellurides **123** in the presence of $ZnCl_2$ results in their rearrangement to 2-aroylbenzenetellanyl chlorides **124**,[111,113] which are probably stabilised by the formation of the intermediates **125**.

Ar = Ph, 4-MeC$_6$H$_4$, 2-C$_4$H$_3$S.

The selenium analogues of compound **123** undero a similar rearrangement, whilst the corresponding sulfur and oxygen analogues cyclise the thioxanthones and xanthones.

Another similar example illustrating the influence of the nature of the chalcogen atoms on the mode of reaction is the cyclisation of β-arylchalcogenopropenoyl chlorides **126** [51,54,115] or the corresponding acids.[115] The electrophilic cyclisation of these compounds can be achieved either by *ortho*-acylation, which leads to six-membered heterocycles — chalcogenochromones (flavones) **127**, or via *ipso*-acylation accompanied by the formation of five-membered heterocycles — 1,2-oxachalcogenolium chlorides **34**.

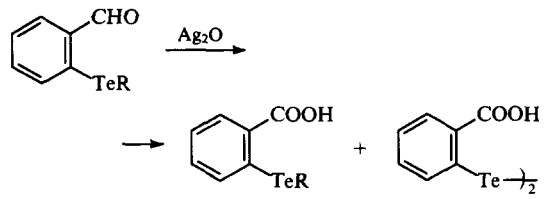


X = Cl, OH; M = S, Se, Te.

Regardless of the nature of substituents in the arene ring, the sulfur derivatives **126** (M = S) are only *o*-acylated, which leads to the thiochromones **127** (M = S).[115,395–398] Only *ipso*-acylation and the formation of the heterocycles **34** (M = Te) is characteristic of the *para*-substituted β-aryltelluropropenoyl chlorides **126** (M = Te).[51,54,115] This is probably due to both the increased polarisability of the tellurium atom and to its relatively low electronegativity compared with other chalcogenes. Depending on the nature of the substituents in the selenoaryl rings, the selenium compounds **126** (M = Se) can cyclise either to the heterocycles **127** (M = Se)[399–401] or to 1,2-oxaselenolium chlorides **34** (M = Se).[115] Mixtures of the two heterocycles are formed in some cases.

However, one should note that, by varying the nature and positions of the substituents in telluroaryl rings of compound **126** (M = Te), it is possible to activate the *ortho*-positions in these rings to electrophilic attack, i.e. to drive the interaction towards the preferential formation of tellurochromones (flavones).[54,115]

Furthermore, whereas the cyclisation of β-thio(seleno)arylcinnamic acids **126** (M = S, Se) on treatment with the $MeSO_3H-P_2O_5$ system leads to benzocyclopentenones,[401] the analogous reaction with the tellurium analogues affords 1,2-oxatellurolium methanesulfonates[54] (Scheme 3).

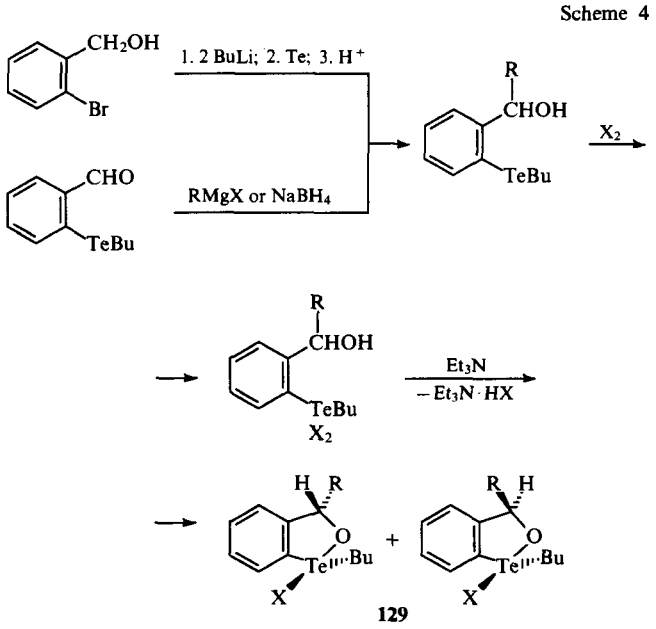


Scheme 3

The dissociation of the C–Te bond in diorganyl tellurides can also take place in the presence of other than halogen-containing ($SOCl_2$, SO_2Cl_2) oxidants. Thus, according to Balfe and coworkers,[169,170] on reaction with O_2 or H_2O_2 dialkyl tellurides

are converted into complexes of different compositions, one of the components of which is tellurinic acids RTe(O)OH. These old data probably require additional confirmation. Incidentally, the formation of alkanetellurinic acids, the structure of which has been established by spectroscopic methods, has also been noted in the oxidation of 1-alkyltellurobut-3-en-1-ynes of type **50**.[402] The C(*sp*)–Te bonds are dissociated during the reaction and vinylethyne is formed together with the trimers.

The oxidation of 2-alkyltellurobenzaldehydes by Ag_2O in an alkaline medium affords, apart from the expected 2-alkyltellurobenzoic acid **128**, the product of the cleavage of the C(sp^3)–Te bond — ditellurosalicylic acid.[190] In the case of *o*-methyltellurobenzaldehyde, the acid **128** is obtained in a yield of about 60%.



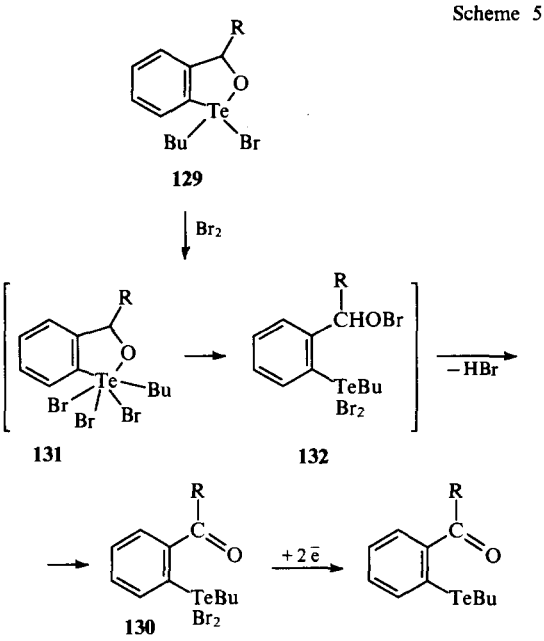
128

R = Me, Bu.

On the other hand, the oxidation of aryl benzyl tellurides by atmospheric oxygen gives rise to the corresponding benzaldehydes.[81,364,366,394]

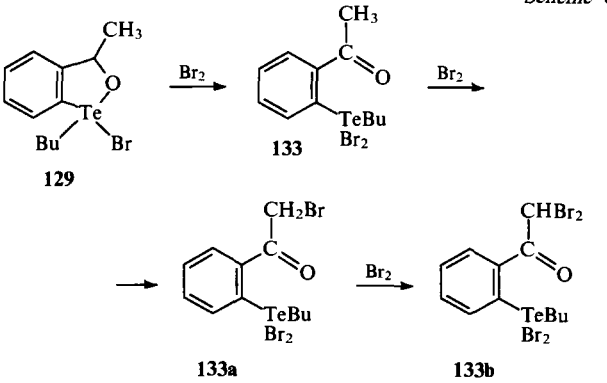
The ready dissociation of the C–Te bonds under the influence of oxidants is the reason why some of the usual oxidation reactions in organic chemistry cannot be employed for the synthesis of organotellurium compounds. Thus the oxidation of the secondary alcohol 1-(2-methyltellurophenyl)ethanol (in order to obtain 2-methyltelluroacetophenone) by DMSO in acetic acid [109] or of the methyl group in 2-methyltellurotoluene (in order to synthesis 2-methyltellurobenzaldehyde) [190] is accompanied by the elimination of the tellurium atom. The recently developed method of synthesis of tellurium-containing carbonyl compounds from 3*H*-2,1-benzoxatelluroles **129**, the synthesis of which is illustrated in Scheme 4, is of definite interest in the chemistry of such tellurium-containing carbonyl compounds.[403,404]

Scheme 4



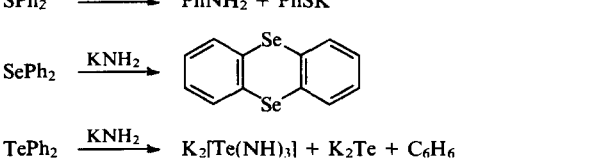
129

X = Cl, Br, I; R = H, Me, Ph, 4-MeC$_6$H$_4$.



On treatment with bromine, the O–Te bond in the heterocycles **129** is cleaved, giving rise to aldehydes or ketones **130**, depending on the nature of the substituents in the 3-position in the heterocycle, with the Te(Bu)Br_2 group in the *o*-position. The reaction probably proceeds via intermediate **131** with a hexacoordinate tellurium atom, which rearranges to compound **132**. Yields of the carbonyl derivatives **130** are 70%–90% (Scheme 5).

Scheme 5



Bearing in mind that 3-R benzoxatelluroles **129** can be obtained from 2-butyltellurobenzaldehyde, the above sequence of reactions can be regarded as a new method for the conversion of *o*-alkyltellurobenzaldehyde into ketones and of *o*-alkyltellurobenzyl alcohols into aldehydes, which is specific to organotellurium compounds. In the case of the 3-methyl derivative **129** (R = Me), the acetophenone derivative **133** formed initially is brominated at the methyl group with formation of compounds **133a** and **133b** (Scheme 6).[404]

Scheme 6

Finally, the cleavage of the Te–C bonds by various nucleophiles is possible. Thus the nature of the chalcogen atoms in diphenyl chalcogenides determines the different results of their reactions with potassium amide in liquid ammonia presented below.[405] The reaction with Ph_2Te is accompanied by the complete dissociation of the C_{Ar}–Te bonds.

On treatment with lithium in liquid NH_3 or with $LiNH_2$, the bonds between the chalcogens and the unsaturated groups in the alkylseleno(telluro)alkenynes of type **50** are ruptured, whereas in their thio-analogues both these bonds and the C(sp^3)–S bonds are cleaved.[406]

$$CH_2{=}CHC{\equiv}CLi + RMLi$$

$LiNH_2$; M = S, Se, Te; R = Me, Bu

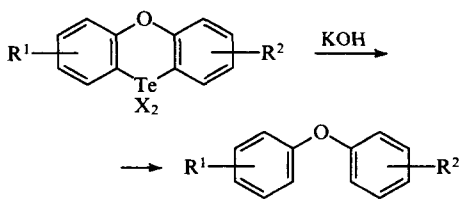
$$CH_2{=}CHC{\equiv}CMR \xrightarrow[M = S,\ R = Me]{LiNH_2} CH_2{=}CHC{\equiv}CSLi + RLi$$

50

On the other hand, in contrast to the sulfur and selenium derivatives **50**, which combine with RMgX at the triple bond[407] with formation of chalcogen-containing allenes, their tellurium analogues react with dissociation of the C(sp)–Te bond and the formation of dialkyl tellurides. The cleavage of the C–Te bonds in compound **50** (M = Te) is also observed in the reaction with EtSH.[408]

Lithium in liquid NH_3 also ruptures the C(sp^2)–Te bonds; on subsequent alkylation of ethynetellurolate by alkyl halides, alkyl vinyl tellurides are formed.[409]

$$(CH_2{=}CH)_2Te \xrightarrow[2.\ RX]{1.\ Li/NH_3} CH_2{=}CHTeR$$



R = Me, Et, Pr.

On the other hand, the cleavage of the Te–C bonds in bis(perfluoroalkyl)tellurides by aqueous solutions of alkalies takes place at room temperature and leads to perfluoroalkanes.[410]

$$(R_F)_2Te \xrightarrow{KOH} R_FH$$

$R_F = CF_3, C_2F_5$.

Eimination of the tellurium atom is also observed on heating phenoxatelluranes, 10,10-dichlorophenoxatelluranes, and 10,10-dinitratophenoxatelluranes in aqueous K_2CO_3 or KOH solutions;[18,21] diaryl ethers are then formed in high yields. These reactions have been used to identify the products of electrophilic substitution of phenoxatellurane (nitration, bromination).

X = Cl, ONO_2.

Much attention has been devoted in recent years to the reactions of diorganyl tellurides with organolithium compounds. Like the Grignard reagents, these compounds cleave the C–Te bond in dialkyl,[411–413] alkyl aryl,[411,413–416] and even diaryl tellurides.[411,417–420] The reactions of butyllithium with organyl vinyl and divinyl telluride are accompanied by the dissociation of the C(sp^2)–Te bonds and lead to vinyllithium derivatives,[58,411,413,421] the latter being formed with retention of the configuration. The C(sp)–Te bonds are ruptured just as readily by organolithium and organomagnesium compounds [the C(sp)–Te bonds[411,413,422,423] are also cleaved by $NaBH_4$].[422,424] It has been shown by ^{13}C NMR spectroscopy that the reactions of organolithium compounds with diorganyl tellurides proceed via the intermediate formation of complexes **134** containing a tricoordinate Te atom. The latter decompose with formation of the thermodynamically more stable organolithium derivative (for example, R^1Li) and a new diorganyl telluride.

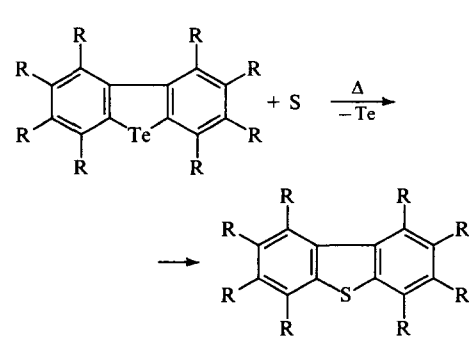
$$R^1TeR^2 + R^3Li \longrightarrow \left[R^1{-}\underset{\displaystyle R^3}{\overset{|}{Te}}{-}R^2\right]^- Li^+ \longrightarrow$$

134

$$\longrightarrow R^1Li + R^2TeR^3$$

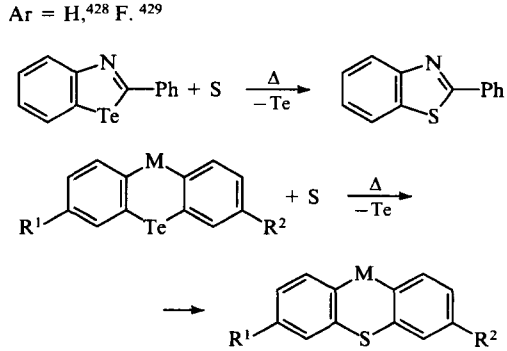
The comparatively readily available diorganyl tellurides have therefore been used as effective sources of alkyl-, alkenyl-, alkynyl-, aryl-, acyl(aroyl)-,[425] and carbamoyl-lithium compounds.[426] They can be synthesised from organyl halides without the preliminary isolation of the telluride, in accordance with the following scheme:

$$R^1X + R^2TeLi \xrightarrow[-LiX]{} R^1TeR^2 \xrightarrow[-R^2TeR^3]{R^3Li} R^1Li$$



The interaction of diaryl and alkyl aryl tellurides with Grignard reagents (for alkyl aryltellurides the group R in RMgX must be the same as one of the groups in ArTeR) in the presence of catalytic amounts of nickel or cobalt compounds [$NiCl_2(PPh_3)_2$, $NiCl_2(Ph_2PCH_2CH_2PPh_2)_2$, $CoCl_2(PPh_3)_2$] also takes place with dissociation of the C–Te bonds. This leads to the formation of a mixture of cross- and homo-coupling products.[50,52]

$$ArTeR + RMgBr \xrightarrow{Cat} Ar{-}R + Ar{-}Ar + R{-}R$$

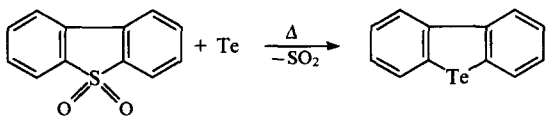


On heating with elemental sulfur, the tellurium atom in certain organotellurium compounds is substituted by a sulfur atom. These reactions are undergone both by diaryl tellurides[336,427] and by tellurium-containing heterocycles: dibenzotellurophenes,[428,429] 2-phenylbenzotellurazole,[178] phenoxatelluranes,[177,321–324,430] phenothiatellurane,[196] and phenotellurazines.[431] The only example of the substitution of the tellurium atom by selenium involves the formation of phenoxaselenane on heating phenoxatellurane with powdered selenium.[430]

$$Ar_2Te + S \xrightarrow[-Te]{\Delta} Ar_2S$$

Ar = Ph,[427] C_6F_5.[336]

Ar = H,[428] F.[429]



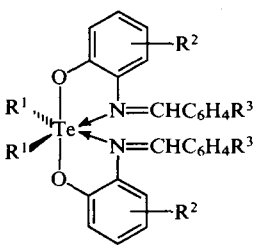
M = O; $R^1 = R^2$ = H,[430] Me,[321] Cl,[322] F;[323]

R^1 = F, R^2 = Me,[177] Cl;[324]

M = S; $R^1 = R^2$ = H;[196] M = NEt; $R^1 = R^2$ = H, Me[431].

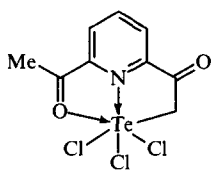
This property of organic tellurium derivatives is evidently due both to the higher C–S bond energy compared with that of C–Te and the more pronounced aromaticity of the sulfur heterocycles compared with their tellurium analogues.[15] On the other hand, the greater aromaticity of tellurium-containing heterocycles compared with heterocyclic sulfones leads to the possibility of the substitution of the SO_2 group by a Te atom.[432]

X. Intramolecular Te←N(O) coordination and the reactivity of organotellurium compounds



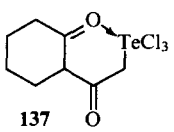
Intramolecular Te←N and Te←O coordinate bonds are one of the principal factors ensuring the stability of certain classes of organotellurium compounds (see Section IV) and exerting a significant influence on the reactivity and structure of organic tellurium derivatives.[104–106] Data concerning the influence of intramolecular coordination on reactivity are qualitative; one of the examples of the influence of the N→Te coordination on the halogenolysis of 2-butyltellurobenzylideneanilines was examined previously (see Section IX).

1. Reduction of C=N bonds

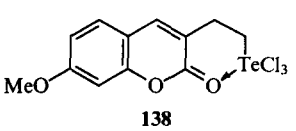


In contrast to the C=N bonds of the tellurium-free aromatic azomethines, which are readily reduced by $NaBH_4$ in ethanol, 2-butyltellurobenzylidene-4′-methylaniline does not change even after prolonged refluxing with this reductant.[126] On the other hand, both the C=N bond and the $TeBr_3$ group are reduced (the latter to TeBr) in 2-tribromotellurobenzylidene-4′-methylaniline on treatment with $NaBH_4$, leading to a secondary amine.[127] Replacement of the 4-methyl group by the more bulky *tert*-butyl groups in the 2-, 4-, and 6-positions inhibits both these reactions.

2. Reactions of σ-telluranes

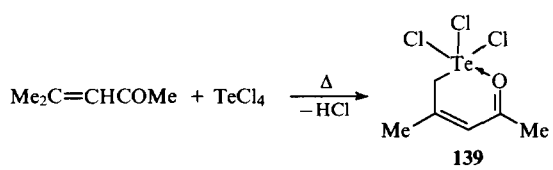


The presence of the Te←N and Te←O coordinate bonds in the molecules of σ-telluranes increases significantly their hydrolytic stability. The diorganyl (diaryloxy)telluranes **135** with Te←N bonds are not hydrolysed on prolonged contact with water,[433,434] whereas diaryl(dialkoxy)telluranes which do not contain such bonds are rapidly hydrolysed even by atmospheric moisture.[351] A similar behaviour is characteristic also of the tellurium trichlorides **136–138**,[435] which are inert to water [the usual trichlorides are rapidly hydrolysed by water with formation of the tellurium oxide chlorides RTe(O)Cl].[2,3]



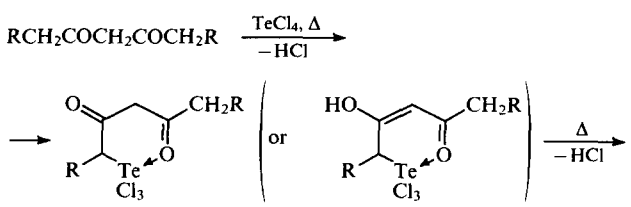
135

136



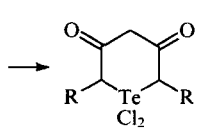
137

138



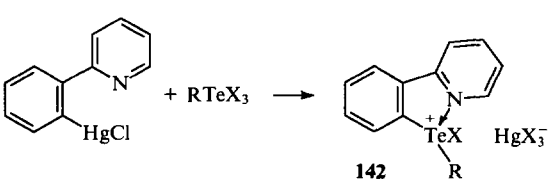
The electrophilic nature of the $TeCl_3$ groups coordinated to N and O atoms is less pronounced than that of noncoordinated trichlorotelluro-groups. Thus, whereas acetophenone and its derivatives afford σ-telluranes of the type $(ArCOCH_2)_2TeCl_2$ on interaction with $TeCl_4$,[436–439] the reactions of 2,6-diacetylpyridine, 2-acetylcyclohexanone, and 3-acetyl-7-methoxycoumarin with $TeCl_4$ give rise to only σ-telluranes of the type $RTeCl_3$ (compounds **136–138**) even in the presence of a twofold molar excess of the carbonyl component.[435]

The reaction of mesityl oxide with $TeCl_4$ in $CHCl_3$ is also instructive. It leads to 2-methylpent-2-en-4-onetellurium trichloride **139**,[440,441] i.e. involves the methyl group adjoining the double bond and not that linked to the carbonyl group, as happens in the analogous reactions of acetophenones and other methyl ketones.[436–439] The possible reaction mechanism involves the initial electrophilic attack by $TeCl_4$ on the COMe group with the subsequent rearrangement of the resulting tellurium trichloride to compound **139**. The driving force of the reaction is the marked stabilisation of the trichloride **139** with the Te←O coordinate bond (the bond length is 2.44 Å).[441]



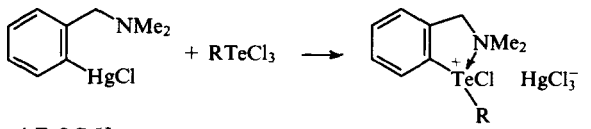
139

This is probably the reason[440] why in the reactions of 1,3-diketones with $TeCl_4$ the latter attacks the terminal carbon atom, which results in the formation of 1-telluracyclohexane-3,5-dione 1,1-dichlorides **140**.[18,21] When the hydrogen atoms at the terminal carbon atoms are substituted, there is a possibility of the formation of the tellurium trichlorides **141**, which are stabilised by the Te←O coordination.



141

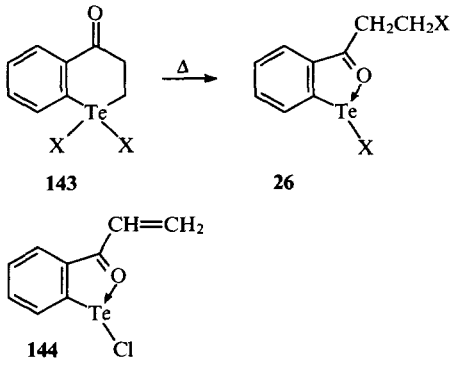
140



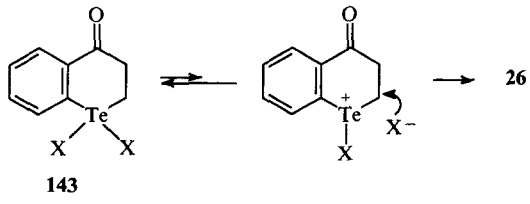
The interaction of organyltellurium dichlorides and tribromides $RTeHal_3$ with RHgHal leads readily to diorganyltellurium dihalides R_2TeHal_2 and $HgHal_2$.[2,3] However, when the formation of coordinate bonds involving the Te atom becomes possible in the final product, the reactions of $RTeHal_3$ with ArHgCl lead to 2-(2-pyridyl)phenylhalo-tellurium trihalomercurates **142**.[129,442]

142

X = Cl, Br; R = 4-$EtOC_6H_4$.



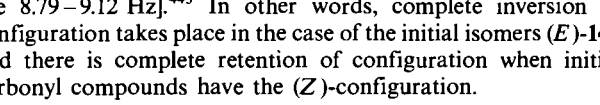
The products of the interaction of 2-chloromercuriobenzyldimethylamine with $ArTeCl_3$ have an analogous structure.[131]



R = 4-EtOC$_6$H$_4$.

3. Rearrangement of dihalotellurochromanones

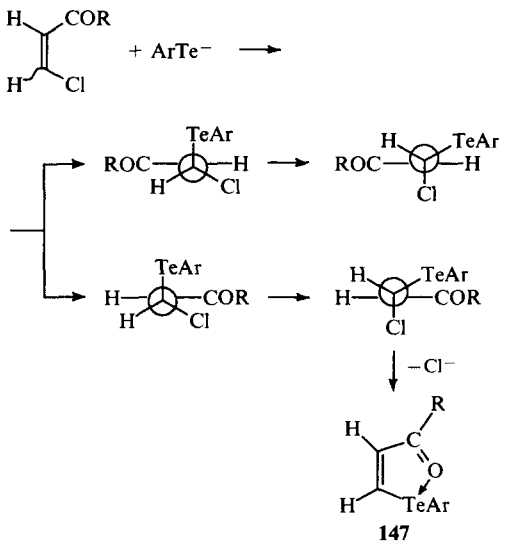
Dihalotellurochromanones **143** undergo on heating a rearrangement, not described previously, which involves the dissociation of the C(sp^3)–Te bond and the formation of 2-(β-halopropionyl)benzenetellurenyl halides **26**.[118] In the case of the chloro-derivative **143** (X = Cl), the ketone **144** was isolated as the final product, evidently as a consequence of the elimination of HCl from compound **26** (X = Cl) formed initially. The rearrangement is achieved by heating solutions of dihalotellurochromanones in $CHCl_3$, C_6H_5Br, or $C_6H_5NO_2$ for 20–30 h.



As in the series of reactions considered above, the driving force of the rearrangement is the marked stabilisation of the tellanyl halides **26** with the Te←O coordinate bonds [the length of the bond in 2-(β-iodopropionyl)benzenetellanyl iodide **26** (X = I) is 2.368 Å][118] and the possible mechanism involves the predissociation of the Te–X bond with subsequent attack by the halide anion on the β-carbon atom.

4. Stereochemistry of reactions involving the substitution of chlorine atoms in β-chlorovinylcarbonyl compounds by arenetellurolate anions

The reactions involving the nucleophilic substitution of chlorine atoms in β-chlorovinylcarbonyl compounds **145** by arenetellurolate anions leads in all cases to the formation of only (*Z*)-isomers by β-aryltellurovinylcarbonyl compounds **146** [the spin–spin coupling constants for the ketones **146** ($R^1 = R^2 = H$) are 8.79–9.12 Hz].[443] In other words, complete inversion of configuration takes place in the case of the initial isomers (*E*)-**145** and there is complete retention of configuration when initial carbonyl compounds have the (*Z*)-configuration.



$R^1 = R^2 = H$; R^3 = Ph, 4-MeC$_6$H$_4$, 4-MeOC$_6$H$_4$, 4-BrC$_6$H$_4$;

R^1 = Ph, $R^2 = R^3 = H$; $R^1 + R^2 = -(CH_2)_4-$, $R^3 = H$;

Ar = Ph, 4-MeC$_6$H$_4$, 4-EtOC$_6$H$_4$.

The stereochemical result obtained may be interpreted in terms of a 2-stage nucleophilic substitution mechanism (addition–elimination).[444] The first stage of the process is the addition of the arenetellurolate anions to the double bond activated by the strongly electron-accepting carbonyl group. Among the possible conformers arising on rotation of the C–C single bond in the carbanion formed, the most stable is evidently the conformer stabilised by the intramolecular Te←O coordinate bond. In the second stage, the elimination of the chloride ions from this conformer leads to the formation of the (*Z*)-isomers **147** which are additionally stabilised by the formation of the Te←O coordinate bonds.[443]

Apparently 2-(4′-ethoxyphenyltelluro)-1-formylcyclohexene **146** [Ar = Ph; $R^1 + R^2 = -(CH_2)_4-$, $R^3 = H$], which is a cyclohexene derivative, is also a (*Z*)-isomer with an intramolecular Te←O coordination bond. Judging from the ^{1}H NMR spectrum, the aldehyde **146** (Ar = R^1 = Ph, $R^2 = R^3 = H$) exists in solution in only one form. On the basis of the mechanism proposed above and the marked stabilisation of tellurium(II) derivatives by intramolecular coordinate bonds, the hypothesis that this form has the (*Z*)-structure in which the Te and O atoms are coordinated is evident.

* * *

The specific features of the chemical behaviour of organotellurium compounds considered in the present review give rise to interesting additional possibilities for a rapidly developing aspect of organic synthesis — the methodology of the use of organoelement synthons incorporating heavy elements of the main groups of the Periodic Table. The organoiodine[233] and organoselenium[445] methodologies, based on the extensive possibilities for the introduction, modification, and elimination of the corresponding groups accompanied by the formation of new carbon–carbon bonds, have come to be widely used.

The possible employment of phenyl derivatives of bismuth(V) for the *C*- and *O*-phenylation of various organic compounds is being developed.[446] It is so far too early to speak of an organotellurium methodology, but the foundations for its establishment have already been laid in the specific reactions of organotellurium compounds which have been presented.

The present review is one of a series of communications written with the financial support of the Russian Fundamental Research Fund (code 93-03-5000, 93-03-18692) and the Soros Fund (grant ML-4000).

The vinyl ethers of aminoalcohols and their derivatives

B F Kukharev, V K Stankevich, G R Klimenko

Contents

I. Introduction 523
II. Methods of synthesis of the vinyl ethers of aminoalcohols 523
III. Chemical properties of the vinyl ethers of aminoalcohols 526
IV. Practical applications 535

Abstract. The results of studies on the methods of synthesis and properties of the vinyl ethers of aminoalcohols are surveyed and described systematically. Their practical applications are considered. The bibliography includes 265 references.

I. Introduction

The vinyl ethers of aminoalcohols (VE AA) occupy a notable place among the vinyl derivatives of nitrogen- and oxygen-containing compounds which are widely used in organic synthesis.

By virtue of the presence of amino- and vinyloxy-groups, these compounds combine the very extensive synthetic possibilities of both amines and vinyl ethers. Here one should note that, although these groups do not exert a mutual influence on one another in the classical sense of this concept, nevertheless in many reactions the VE AA behave differently from both amines and the vinyl ethers of alcohols. This difference is manifested primarily by the competition between the amino- and vinyloxy-groups in reactions with electrophiles and also by the occurrence of secondary processes with participation of the group which is not involved in the main reaction.

As a result of the lower dissociation energy of the C – N bond compared with the C – O and C – C bonds, the conditions in the main method for synthesis of vinyl ethers — vinylation of alcohols by ethyne — frequently prove to be somewhat too severe for the vinylation of aminoalcohols and leads to the elimination of the amino-group. Furthermore, the reaction is complicated by *N*-vinylation and cyclisation processes.

Thus specific methods, differing significantly from those known for aliphatic amines and vinyl ethers, are frequently needed to increase the selectivity and yields both in the synthesis of the VE AA and in their chemical reactions.

Individual questions associated with the synthesis and chemical properties of the VE AA have been considered hitherto in monographs[1–5] and reviews[6–8] devoted to the chemistry of ethyne and its derivatives. However, the range of problems discussed there is extremely narrow because of the specific nature of the publications and, furthermore, these compounds are considered mainly as a special case of the vinyl ethers of alcohols.

In the present review, an attempt is made to represent as fully as possible the available literature data on the synthesis and chemical properties of the VE AA, the aim being also to demonstrate and assess the position occupied by these compounds in organic synthesis. The prospects for their practical application are also considered.

II. Methods of synthesis of the vinyl ethers of aminoalcohols

1. Interaction of aminoalcohols with ethyne

Among the methods of synthesis of the VE AA known hitherto, the commonest and most universal is the base-catalysed addition of aminoalcohols to ethyne.

$$RR^1NCR^2R^3(CH_2)_nCR^4R^5OH \xrightarrow{CH\equiv CH} RR^1NCR^2R^3(CH_2)_nCR^4R^5OCH{=}CH_2$$

$n = 0–8$; $R–R^5$ = H, Alk, Ar, Het;

R = $Me_3Si(CH_2)_3$, CH_2CH_2OH, $CH_2CH_2NH_2$;

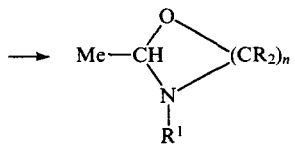
$R + R^1 = -CH_2CH_2OCH_2CH_2-$;

$R + R^1$, $R + R^2$, $R + R^4$, $R^2 + R^4 = -(CH_2)_{2-5}-$.

Since the 1930's, this reaction has been used to obtain a wide range of VE AA with various structures.[9–50]

The potassium or sodium alkoxides derived from the aminoalcohols to be vinylated[9–29] or the hydroxides of the corresponding metals were used (in an amount corresponding to 5% – 20% of the weight of the aminoalcohol) as the catalyst.

Lithium, sodium, potassium, rubidium, and caesium oxides, hydroxides, alkoxides, phenoxides, naphthoxides, cyanides, zincates, and sulfides have been proposed as the catalysts in a series of patents.[30–32]



The interaction of the aminoalcohols **1** with ethyne in the absence of catalysts[9,51,52] and also in the reaction catalysed by cadmium acetate[33,53] results in the formation either of polymerisation products[9,53] or of 2-methyl-1,3-oxazacycloalkanes **2**.[33,51,52]

It has been suggested that the formation of the cyclic product **2** is associated with the occurrence under these conditions of the *N*-vinylation and subsequent cyclisation of the unstable intermediate enamines.[51] It is noteworthy that the *N*-vinylation, especially in the case of aminoalcohols with a secondary

hydroxy-group which is difficult to vinylate, is possible also under the conditions of base catalysis. Thus it has been reported that only 3-aryl-5-aryloxymethyl-2-methyl-1,3-oxazolidines were obtained from 3-arylamino-1-aryloxypropan-2-ols and ethyne.[54]

$$HO(CR_2)_nNHR^1 \xrightarrow[100-200\,^\circ C]{CH\equiv CH,\ 2-4\ MPa}$$

1 (conversion 10% – 30%)

2 5% – 75%

n = 2, 3; R = H, Me, Et;

R^1 = H, Me, Ph, CHMePh, CH_2CH_2OH, $CH_2CH_2NH_2$.

The vinylation of aminoalcohols at atmospheric pressure of ethyne is usually carried out without solvents.[10-17,34-36] On the other hand, when the reaction is carried out in autoclaves, solvents are usually employed, for example benzene,[9,18-26,37] dioxane,[21,38,39] *tert*-butyl alcohol,[27] n-butyl alcohol,[33] ethers and polyethers,[30] and dimethyl sulfoxide.[40] This greatly increases the amount of ethyne introduced into the reaction, accelerates the process, and makes it possible to raise the yield of the products. The use of water as the solvent lowers the yield of the products and hinders their isolation.[9,22]

The reaction temperature and ethyne pressure are varied within wide limits depending on the structure of the aminoalcohol and the method used for carrying out the reaction. Thus the vinylation of ethanolamines in the vapour phase,[31,32,41] (temperature 250 – 300 °C) and in a gas – liquid emulsion[10,12-14,16,17] in flow-type[11,36] and bubble-type[34,35] reactors has been carried out at atmospheric pressure (temperature 100 – 150 °C, yield of the VE AA 54% – 86%), while the reaction in the liquid phase[30] has been performed at 11.2 MPa and a temperature of 120 – 180 °C with a yield of 75% – 95%. In the vinylation in periodic-action autoclaves, which is commonest, the initial ethyne pressure is usually 1 – 2.5 MPa and the temperature is 100 – 180 °C.

A detailed analysis of various methods for the vinylation of ethanolamines and an assessment of the prospects for their industrial application on the basis of literature data published up to 1972 have been presented in a monograph.[2] The monograph deals with problems concerning the optimisation of the process and its kinetics and discusses the ways in which the side products of the reaction are formed and the methods for the analytical monitoring, isolation, and purification of the vinyl ethers.

From the standpoint of practical application, the vinyl ether of monoethanolamine **3** is undoubtedly of greatest interest. However, in the series of ethanolamines the vinylation of monoethanolamine actually involves the greatest difficulties.[9,11,23] It has been shown recently that the main reason for this is the ready decomposition at a temperature above 100 °C of the ether **3** by alkali.[55,56] In the presence of potassium hydroxide at 110 – 115 °C, it decomposed to the extent of 70% after 5 h, affording a 45% yield of the azomethine **4** and other extensive degradation products. Under the same conditions but in the presence of sodium hydroxide, the degree of decomposition of the ether **3** did not exceed 2%.

In this connection, it is clear that, in the synthesis of the vinyl ether **3**, its continuous removal from the reaction zone is necessary and that preference should be given to sodium hydroxide as the catalyst. Taking into account these refinements, a method has been developed for the vinylation of monoethanolamine at atmospheric pressure in which the yield of the ether **3** is 93% – 96%.[53,57]

$$\underset{\mathbf{3}}{CH_2{=}CHOCH_2CH_2NH_2} \xrightarrow{MOH}$$

$$\longrightarrow \underset{\mathbf{4}}{CH_2{=}CHOCH_2CH_2N{=}CHCH_3} + NH_3$$

$$+ H_2 + H_2O + EtOH + MeCOOM + M_2CO_3$$

M = K, Na.

2. Interaction of aminoalcohols with substituted ethynes

There are very few literature data on the synthesis of VE AA having substituents in the vinyl group by the addition of aminoalcohols to substituted ethynes.

It has been shown that the addition of one molecule of 2-diethylaminoethanol to diethyne in the 1,2-positions with formation of the *cis*-isomer **5** takes place exothermically without catalysts. The addition of a second molecule requires a catalyst (potassium alkoxide or hydroxide) and heating. This results in the formation of both regioisomers **6** and **7** in an overall yield of 55% – 60%.[25,58-60]

$$CH{\equiv}C{-}C{\equiv}CH \xrightarrow{Et_2N(CH_2)_2OH}$$

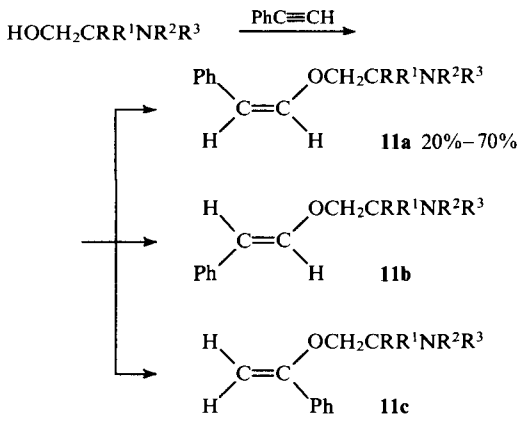
$$\longrightarrow \underset{\mathbf{5}\ 80\%-90\%}{Et_2N(CH_2)_2OCH{=}CH{-}C{\equiv}CH} \xrightarrow{Et_2N(CH_2)_2OH}$$

$$\longrightarrow \underset{\mathbf{6}}{Et_2N(CH_2)_2OCH{=}CH{-}\overset{\displaystyle O(CH_2)_2NEt_2}{\overset{|}{C}}{=}CH_2} +$$

$$+ \underset{\mathbf{7}}{Et_2N(CH_2)_2OCH{=}CH{-}CH{=}CHO(CH_2)_2NEt_2}$$

The study of the reactions of diethyne alcohols **8** with aminoalcohols established that, at 105 – 110 °C in the presence of potassium hydroxide, acetone is split off from the alcohols **8** and the resulting diethynes **9** combine with aminoalcohols, affording the vinylethyne derivatives **10** in yields up to 52%.[61]

$$\underset{\mathbf{8}}{R{-}C{\equiv}C{-}C{\equiv}C{-}CMe_2OH} \xrightarrow[-Me_2CO]{}$$



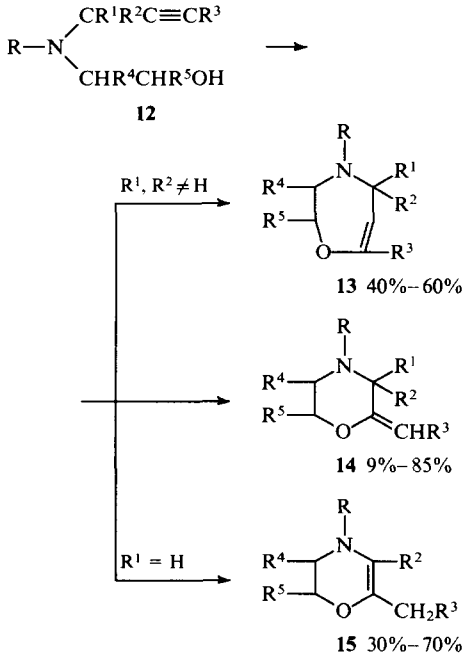
$$\longrightarrow \underset{\mathbf{9}}{R{-}C{\equiv}C{-}C{\equiv}CH} \xrightarrow{HO(CH_2)_2NR^1_2}$$

$$\longrightarrow \underset{\mathbf{10}}{R{-}C{\equiv}C{-}CH{=}CHO(CH_2)_2NR^1_2}$$

R = Me, Ph; R^1 = Et, Bu.

The use of diethyne as well as other substituted ethynes with an activated triple bond is probably limited to the synthesis of vinyl ethers with a tertiary amino-group, since aminoalcohols with primary or secondary amino-groups add to such ethynes as typical amines with formation of enamines.[62-64]

The study of the reactions of aminoalcohols with phenylethyne showed that, at 120 – 130 °C in the absence of solvents, the products **11a** of the *trans*-addition to the β-carbon atom in phenylethyne are formed preferentially on treatment with alkali metal hydroxides. The amount of the products **11b** of the *cis*-addition is between 3% and 15%, while that of the products **11c** of the addition to the α-carbon atom in phenylethyne is 2% – 5% relative to the amount of the *trans*-isomer **11a**. When the reaction is carried out in dimethyl sulfoxide (DMSO), its stereoselectivity diminishes (the ratio of the *trans*- and *cis*-adducts **11a** and **11b** is 1 : 0.6), but their regiospecificity is unaffected.[65,66]

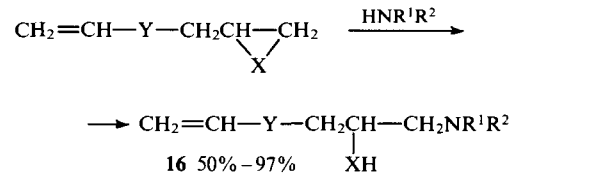


R, R^1 = H, Me, Et; $R^2+R^3 = -CH_2CH_2OCH_2CH_2-$;

R^2, R^3 = H, Me, Et, CH_2Ph, Ph, 2-MeC_6H_4, 4-MeC_6H_4, Ac.

The base (KOH, $NaNH_2$)-catalysed intramolecular cyclisation of *N*-propargylethanolamines **12** to the oxazepines **13**[67,68] or the morpholine derivatives **14** and **15** (Scheme 1)[1,39,69–72] is a special case of the reaction under consideration.

Scheme 1



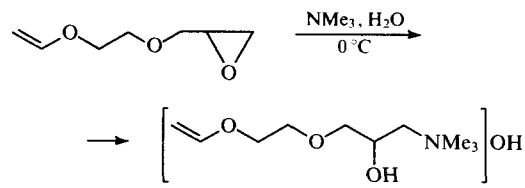
R = H, Me, Et, Bu^t, CH_2CH_2OH; $R^1 = R^2 = H$, Me;

$R^1+R^2 = -(CH_2)_5-$;

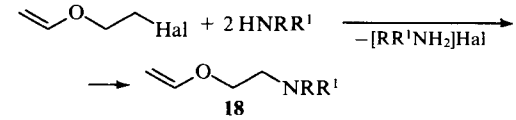
R^3, R^4, R^5 = H, Me, $CH_2CH=CH_2$, Ph, $PhCH_2CH_2$, 2-$MeOC_6H_4$, 4-$MeOC_6H_4$, CH_2OMe, $CH_2OCH=CH_2$, CH_2NEt_2.

3. Other methods of synthesis of the vinyl ethers of aminoalcohols

A series of procedures for the synthesis of VE AA based on the reactions of amines with reactants containing the vinyl group have been described. For example, the vinyl ethers **16** have been obtained by the reaction of amines with the vinyl derivatives of oxiranes[73–79] and thiiranes.[80]



X = O, S; Y = O, $O(CH_2)_2O$, $O(CH_2)_3O$, $OCHMeCH_2CH_2O$, $O(CH_2)_2O(CH_2)_2O$, $O(CH_2)_2O(CH_2)_2O(CH_2)_2O$;

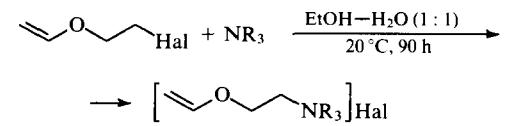


R^1, R^2 = H, Et, Pr, Bu, Bu^t, $CH_2CH=CH_2$, CH_2Ph, CH_2CH_2OH, $CH_2CH(OH)CH_2OCH_2CH_2OCH=CH_2$;

$R^1+R^2 = -(CH_2)_5-$, $-CH_2CH_2OCH_2CH_2-$.

The quaternary base **17** has been obtained from trimethylamine and the glycidyl vinyl ether of ethylene glycol.[75]

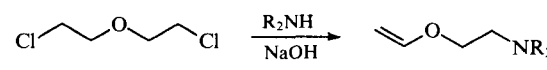
Methods have been developed for the synthesis of the vinyl ethers of the aminoethanols **18**[18,81–84] and their quaternary salts **19**[85] by the nucleophilic substitution of the halogen in 2-haloethyl vinyl ethers by amines.



Hal = Cl, Br;

R = R^1 = Bu (30%), $CH_2CH=CH_2$ (26%), $CH_2=C(Me)CH_2$ (29%);

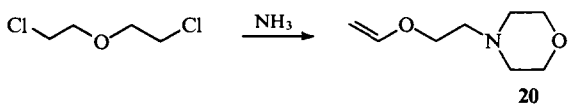
R = H, R^1 = CH_2Ph (61%); R = H, R^1 = $Me_3Si(CH_2)_3$ (70%);



R = Bu, R^1 = $CH_2CH=CH_2$ (57%);

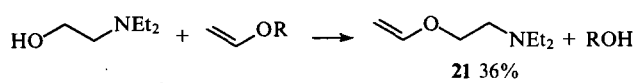
$R+R^1 = -(CH_2)_5-$ (55%), $-CH_2CH_2OCH_2CH_2-$ (90%).

Hal = Br, R = Me (82%); Hal = I, R = Me (67%).



The vinyl ethers of aminoalcohols have also been obtained by the reaction of secondary aliphatic and aromatic amines with di(2-chloroethyl) ether at 50–200 °C with subsequent treatment of the reaction mixture with an aqueous solution of sodium hydroxide.[86]

R = Et, Bu, C_6H_{13};

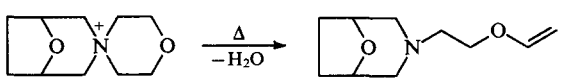


R_2 = $-(CH_2)_5-$, $-CH_2CH_2OCH_2CH_2-$, $-CH=CH-CH=CH-$

The vinyl ether of 2-morpholinylethanol **20** has been obtained from an aqueous solution of ammonia and di(2-chloroethyl)ether under similar conditions.[87]

20

Attempts have been made to synthesise VE AA by the mercury acetate-catalysed transvinylation reaction. It was then possible to obtain only the vinyl ether of 2-diethylaminoethanol **21**.[88]



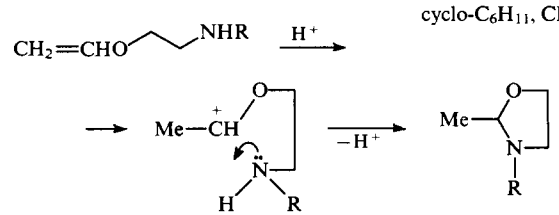
21 36%

R = Et, CH_2CH_2OBu.

Only 2-methyl-1,3-oxazacycloalkanes **2** have been obtained from the amino-alcohols **1** with primary and secondary aminogroups under the conditions of this reaction.[89,90]

The addition of amines,[91–94] alcohols,[93,95] thioalcohols,[93,96] urea,[97] and carboxylic acids[98] to 2-vinyloxyalkyl isocyanates[94,97] and to 2-vinyloxyethyl isothiocyanate (Scheme 2) may be regarded as a method of synthesis of the vinyl ethers of *N*-acyl- and *N*-thioacyl-ethanolamines.

The Hofmann degradation of the morpholine bases can also lead to vinyl ethers. However, the only example is the synthesis of the vinyl ether **23** from the spirocyclic morpholine base **22**.[99]

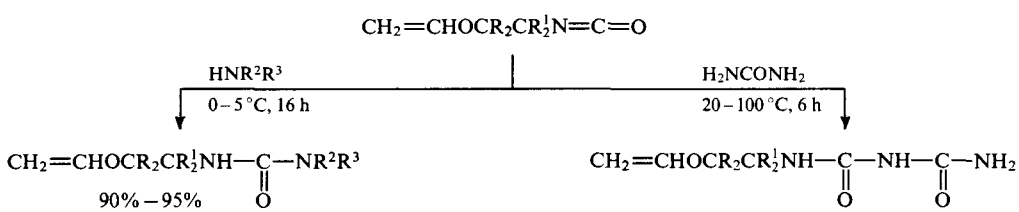


22 **23** 57%

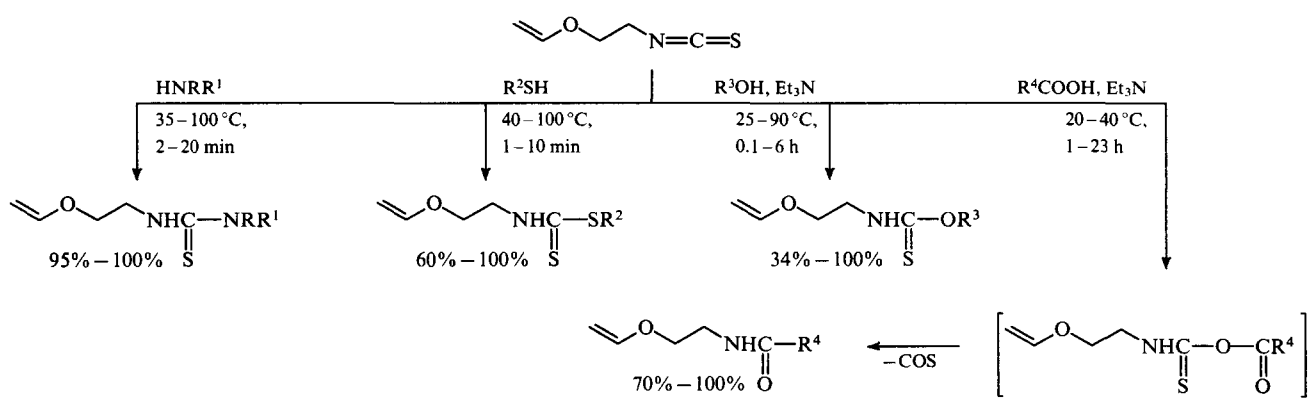
III. Chemical properties of the vinyl ethers of aminoalcohols

1. Reactions of the vinyl ethers of aminoalcohols with acids

In contrast to aliphatic amines, the VE AA contain several basicity centres of different nature: hard centres (nitrogen and oxygen atoms) and a soft centre (the sp^2-carbon atom). This is the reason for their more complex, compared with aliphatic amines, behaviour in relation to acids. Thus, there is only isolated evidence that the salts of vinyloxyethylamines and protic acids, for example the substituted benzoates[100] and the oleate[101] of the amine **3**, as well as the picrates of *N*,*N*-bis(2-vinyloxyethyl)-amines[102] and vinyloxyethylmorpholine **23**[99] can be obtained in solution in benzene.



As a result of the reduction of the basicity of the nitrogen atom due to the electronic effect of the substituents, the protonation of the soft basicity centre becomes competitive. Thus the vinyl ether of *N*-phenylethanolamine is cleaved by traces of hydrochloric acid to phenylaminoethanol and products of unknown structure. At the same time, it cyclises to 2-methyl-3-phenyloxazolidine in 13% yield.[22] The even more weakly basic vinyl ethers of *N*-acylethanolamines cyclise quantitatively[91,103–107] in the presence of catalytic amounts of protic acids.



R = Ph (13%), Ac (100%), C(S)SAlk (100%),

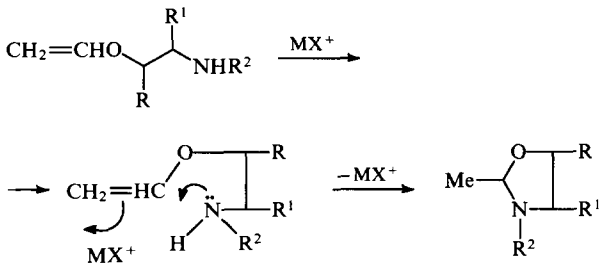
Alk = Me, Et, Pr, Bu, Bu^i, Bu^t, $CH_2CH{=}CH_2$, cyclo-C_6H_{11}, CH_2Ph

Scheme 2

R, R^1, R^2, R^3 = H, Me, Et, C_8H_{17}, $C_{12}H_{25}$.

R, R^1 = H, Me, Et, Bu, Bu^i, $CH_2CH{=}CH_2$, cyclo-C_6H_{11}, CH_2CH_2OH, CH_2CH_2SH, $CH_2CH_2OCH_2CH_2SBu$, Ph, 2,4-$Me_2C_6H_3$, 3,4-$Cl_2C_6H_3$, 3-ClC_6H_4, 2-$MeCOC_6H_4$, 2-$C_{10}H_7$, 3-Me-2-C_5H_3N;

R+R^1 = $-(CH_2)_5-$, $-CH_2CH_2OCH_2CH_2-$; R^2 = Et, Pr, Bu, C_5H_{11}, C_6H_{13}, C_7H_{15}, CH_2Ph;



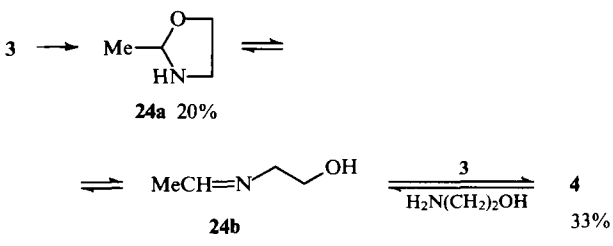
R^3 = $CH_2(CF_2)_nH$, n = 2, 4, 6, 8, 10; R^4 = Me, Et, Pr^i, Bu, Bu^i, C_7H_{15}, Ph, (3-Ind)CH_2 (Ind = indolyl).

When cyclisation is impossible due to structural factors, as happens, for example, in the case of the weakly basic vinyl ether of *N,N*-diphenylethanolamine[19] or quaternary vinyloxyethylammonium salts,[83] polymerisation involving the vinyl group, catalysed by strong acids (H^+, Fe^{3+}, BF_3), takes place readily.

The highly basic vinyl ethers, for example the vinyl ethers of *N*-monoalkylethanolamines and *N,N*-dialkylethanolamines, as well as the vinyl ethers **16** (X = O) neither cyclise nor polymerise on treatment with catalytic amounts of HCl, $FeCl_3$, and $BF_3.Et_2O$.[19,22,26,75]

However, on treatment with more than an equimolar amount of BF_3 [108,109] or $BF_3.Et_2O$, [40] the VE AA polymerise regardless of the structure of the amino-group, since in this case the complex of the vinyl ether with BF_3 actually polymerises and not the ether itself.

Soft acids (for example, Hg^{2+} and Pd^{2+}) coordinating to the soft π-basic centre induce the cyclisation of the VE AA regardless of the basicity of their amino-group.[110–112]



76%–99%

R, R^1 = H, Me, $MeOCH_2$;

R^2 = H, Me, Et, CH_2Ph, Ph, Ac, CH_2CH_2OH, CH_2CH_2CN, $CH_2CH_2OCH{=}CH_2$;

M = Hg, Pd; X = Cl, AcO.

The reaction is complicated by the occurrence of an exchange process with formation of the azomethine **4** only in the case of the simplest vinyl ether **3** owing to the ability of the oxazolidine **24a** to undergo a tautomeric transformation into the azomethine alcohol **24b**.

24a 20%

24b 33%

The available data on the interaction of VE AA with acids belonging to the class intermediate between hard and soft acids are limited to only one example of the formation of a chelate complex of the vinyl ether of monoethanolamine $[(CH_2{=}CHO(CH_2)_2NH_2)_2Cu]Cl_2$, in which the copper atom is coordinated simultaneously to the ether oxygen and the amino-group.[113]

2. Alkylation

The alkylation of VE AA with a tertiary amino-group usually leads to the formation of monomeric quaternary salts.[25,83,85,114–177] As in the quaternisation of aliphatic amines, in this case the yields of the salts and the reaction time depend greatly on the structure of the amino-group and of the alkylating agent and also on the reaction conditions. For example, in the interaction of the vinyl ether of diethylaminoethanol with ethyl bromide in the absence of a solvent at 20 °C, the yield of the quaternary salt is only 15% after 21 days.[116] The alkylation of 4-(2-vinyloxyethyl)-1,4-perhydrotriazine 1-oxide by benzyl chloride, allyl bromide, or methyl iodide at 20 °C in nitromethane is completed by the formation of the corresponding salts in 93%–97% yields after only 10–12 h.[115]

$$CH_2{=}CHO(CH_2)_nNRR^1 + R^2X \longrightarrow [CH_2{=}CHO(CH_2)_nNRR^1R^2]X$$

R = Bu, R^1 = $CH_2CH{=}CH_2$;

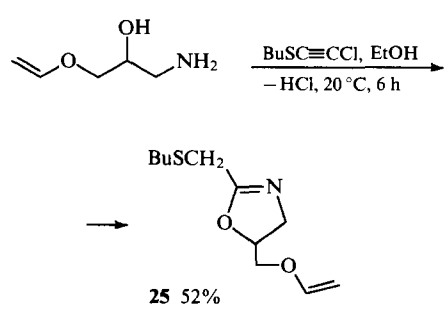
R = R^1 = Et, Bu, $CH_2CH{=}CH_2$, $CH_2C(Me){=}CH_2$;

R + R^1 = $-(CH_2)_5-$, $-CH_2CH_2OCH_2CH_2-$, $-CH_2CH_2S(O)CH_2CH_2-$;

R^2 = Me, Et, $CH_2CH{=}CH_2$, $CH_2C{\equiv}CH$, CH_2Ph, CH^2COCH_3, CH_2COPh; X = Cl, Br, I, $MeSO_4$, 4-$MeC_6H_4SO_3$.

Only polymeric quaternary salts have been obtained in the alkylation of the trivinyl ether of triethanolamine[19] and also of the vinyl ether **16** (X = O)[75] by methyl iodide. Partial polymerisation is observed when amines of the type $(CH_2{=}CHOCH_2CH_2)_2NCH_2XAlk$ (where X = O, S) are treated with alkyl halides.[102]

The alkylation of the vinyl ethers of aminoalcohols with primary[84,118] and secondary amino-groups by alkyl halides, methyl monochloroacetate,[19] and chloro- or bromo-cyanogen[119] in the presence of KOH,[38,69,84,118,120,121] NaOH,[19] Na_2CO_3,[117] and K_2CO_3,[40,119] leads to the formation of the corresponding secondary and tertiary amines in 50%–95% yields without any complications.



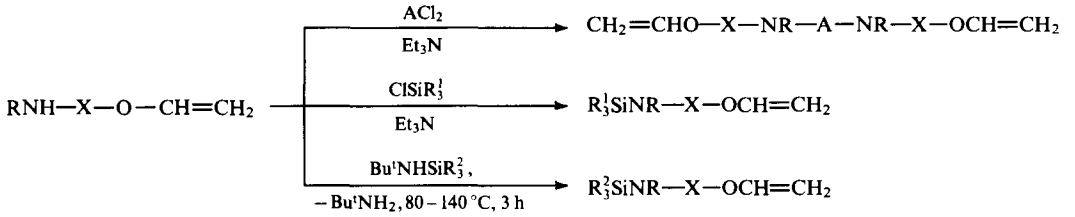
$$RNHCR^1_2CHR^2OCH{=}CH_2 + R^3Hal \longrightarrow RR^3NCR^1_2CHR^2OCH{=}CH_2$$

R = H, Me, Et, Ph, CH_2Ph, $CH_2C{\equiv}CH$, CH_2CH_2OH, $CH_2CH_2OCH{=}CH_2$

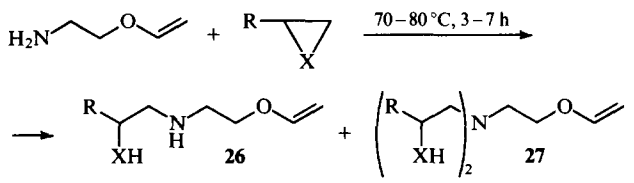
R^1, R^2 = H, Me; $RNHCR^1_2CHR^2 = \overline{CH_2CMe_2NHCMe_2CH_2CH}$;

R^3 = Me, $CH_2CH{=}CH_2$, $CH_2C{\equiv}CH$, CH_2Ph, CH_2COOMe, CH_2COOEt, CN; Hal = Cl, Br, I.

In the interaction of the monovinyl ether of 3-aminopropane-1,2-diol with butylthiochloroethyne, the hydroxyl adds to the triple bond with formation of the oxazoline **25** in addition to the chlorine-substitution reaction.[122]

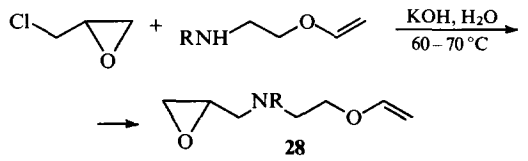


25 52%



Both the products **26** and **27** with alkoxy- and alkylthio-substituents and the vinyl ethers of epoxyaminoalcohols **28** have been obtained[123] by the interaction of VE AA with epoxy-compounds[76] and thiiranes.[80]

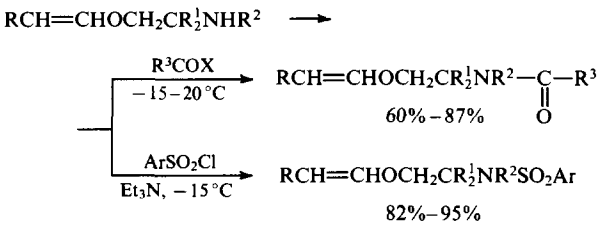
Together with alkylation, also the silylation of VE AA, for example by α-ω-dichloropolysiloxanes,[124] alkyl(aryl)chlorosilanes, and silylamines, has been described (Scheme 3).[125]



Scheme 3

X = $(CH_2)_2$, CMe_2CH_2, $CMe_2(CH_2)_3CHMeCH_2CH_2$; A = $(SiMe_2O)_nSiMe_2$; R = H, Alk; R^1 = Alk, Ph, Cl; R^2 = Alk, Ph.

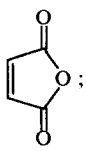
X = O, S; R = $CH_2OCH_2CH_2OCH{=}CH_2$,



R = $CH_2CH{=}CH_2$ (82%); $CH_2CH_2OCH{=}CH_2$ (75%)

3. Acylation

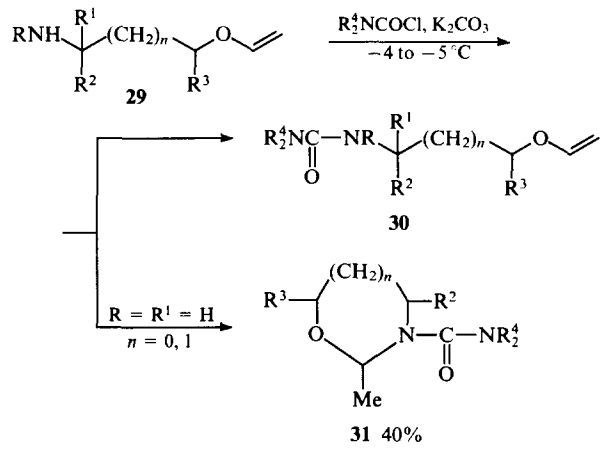
The acylation of VE AA by the anhydrides[65,126,127] and chlorides of carboxylic acids[128–130] and sulfonic acids[84] usually takes place without complications of any kind.



The reaction is carried out in the presence of organic bases

R = H, Ph; R^1 = H, Me;

R^2 = H, CH_2Ph, 4-$Me_2NC_6H_4CH_2$, 4-$MeOC_6H_4CH_2$, $CH_2CH_2OCH{=}CH_2$, $\overline{OCH{=}CH{-}CH{=}CCH_2}$, CH_2CH_2COOBu, $CH_2CHMeCOOMe$;



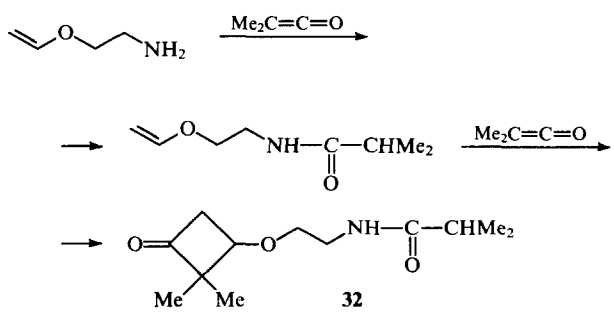
R^3 = Me, Ph, 2,4-$Cl_2C_6H_3OCH_2$, EtO; X = Cl, AcO;

R^3COX =  ; Ar = Ph, 4-MeC_6H_4.

(pyridine,[128] triethylamine[84,129]) or inorganic bases[65] as acid acceptors. An excess of the vinyloxyalkylamine is more rarely employed.[127,130]

Both linear carbamides **30**[94] and cyclic carbamides **31**[131] have been obtained as a result of the acylation of the VE AA **29** by *N,N*-dialkylcarbamoyl chlorides.

The carbamides **30** are formed from the amines **29** with a secondary amino-group and also from the same amines with a primary amino-group, for which there is steric hindrance to cyclisation ($n > 2$ or the amino-group is attached to a tertiary carbon atom). Only the carbamides **31** have been obtained in all other cases.



n = 0–3, 4, 8;

R, R^1, R^2, R^3 = H, Me, Bu, $C_{12}H_{25}$, $C_{18}H_{37}$, CH_2Ph, cyclo-C_6H_{11};

R^4 = Me, Et, Bu, $C_{12}H_{25}$, $C_{18}H_{37}$, cyclo-C_6H_{11};

R^4_2 = $-(CH_2)_5-$, $-CH_2CH_2OCH_2CH_2-$.

In the interaction of diethylketene with the vinyl ether of monoethanolamine, the latter is initially acylated, after which cycloaddition takes place and leads to the formation of the cyclobutanone **32** in 80% yield.[132]

The acylation of VE AA by esters is carried out by keeping the reactant mixture for 2–7 days at room temperature or for 5–40 h at 60–95 °C.[18,97,133,134]

$$RNH(CH_2)_nOCH{=}CH_2 \xrightarrow[-R^2OH]{R^1COOR^2} \rightarrow R^1CONR(CH_2)_nOCH{=}CH_2$$

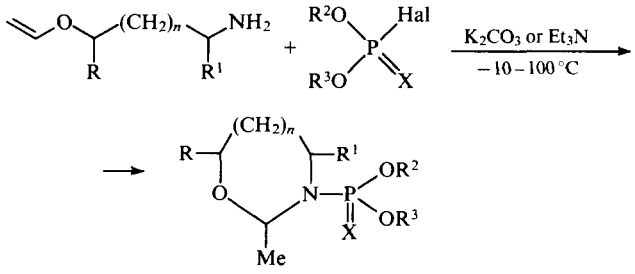
R^2 = Me, $CH{=}CH_2$; n = 2, 3.

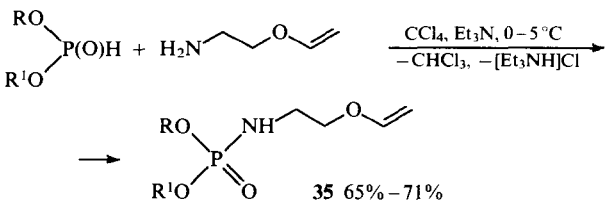


Cyclic carbonates interact with vinyloxyethylamine much more readily, affording high yields of the carbamates **33**.[135–138]

33

R = H (70%), CH_2Cl (100%).

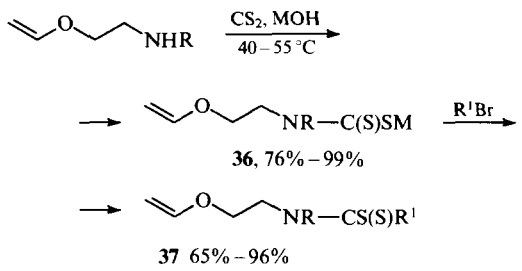
The reactions of dialkyl phosphorothiohalidates or phosphorohalidates with the vinyl ethers of ethanol- and propanolamines lead to the cyclic phosphoramidate derivatives **34**.[139]



34 70%–80%

n = 0, 1; R = H, Me, $C_{16}H_{33}$, Ph; R^1 = H; X = O, S;

$R^2 = R^3$ = Et, $C_{12}H_{25}$, Ph; $R^2 + R^3 = -(CH_2)_2-$; Hal = F, Cl, Br.



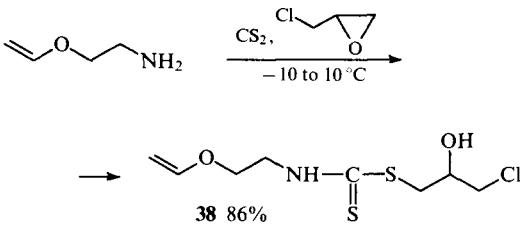
The acyclic phosphoramidates **35** have been obtained by the reaction of dialkyl phosphites with the vinyl ether of monoethanolamine in the presence of carbon tetrachloride and triethylamine.[140]

35 65%–71%

R, R^1 = Et, Pr, Pr^i, Bu, Bu^i, C_5H_{11}.

The dithiocarbamic acid salts **36** have been obtained by the reaction of the vinyl ethers of mono- and di-ethanolamines with carbon disulfide in the presence of alkali metal hydroxides.[141–143] Subsequent alkylation of the salts gave rise to the dithiocarbamates **37**.[141,144]

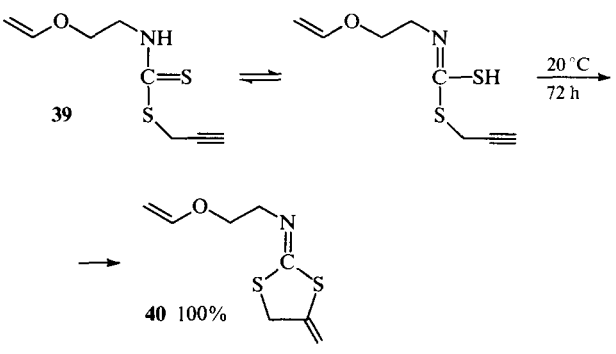
36, 76%–99%



37 65%–96%

R = H, $CH_2CH_2OCH{=}CH_2$;

R^1 = Me, Et, Bu, Bu^i, CH_2Ph, $CH_2CH{=}CH_2$, $CH_2C{\equiv}CH$;



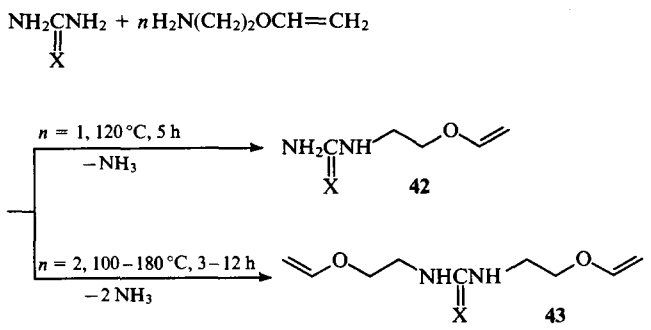
M = Na, K.

The joint treatment of 2-vinyloxyethylamine with carbon disulfide and epichlorohydrin leads to the dithiocarbamate **38**.[145]

38 86%

The thione–thiol tautomerism of dithiocarbamates leads to the possibility of the existence of derivatives of the isomeric dithiocarbamic acid. This type of cyclic derivative **40** has been obtained from the dithiocarbamate **39** at room temperature in a quantitative yield.[144]

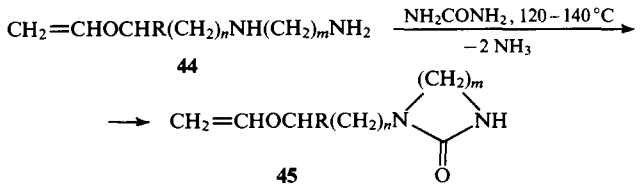
40 100%



Carbon dioxide and carbon disulfide react readily with VE AA, but the stable carbamic acid salts **41** have been obtained only for the vinyl ethers of 2-amino-ethanol and 3-aminopropanol.[146]

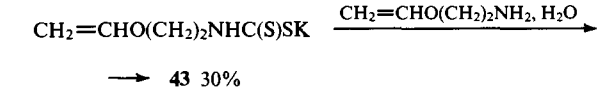
$$2\,CH_2{=}CHO(CH_2)_nNH_2 \xrightarrow{CO_2} [CH_2{=}CHO(CH_2)_nNHC(O)O]NH_3(CH_2)_nOCH{=}CH_2$$

41 99%



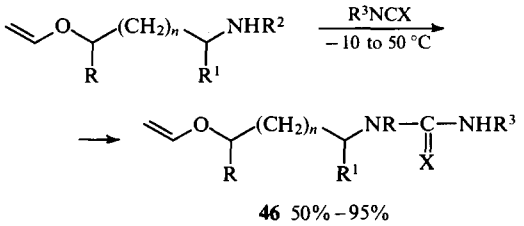
n = 2, 3.

The amide exchange reaction has also been used to acylate vinyloxyalkylamines. For example, when urea or thiourea is fused together with the vinyl ether of ethanolamine high yields of *N*-mono(2-vinyloxyethyl)urea and *N*,*N*-bis(2-vinyloxyethyl)-urea, as well as the corresponding thiourea derivatives (compounds **42** and **43**) were obtained depending on the reactant ratio.[42,147]



X = O, S.

The cyclic ureas **45** have been obtained from the vinyl ethers **44** and urea under similar conditions.[43]

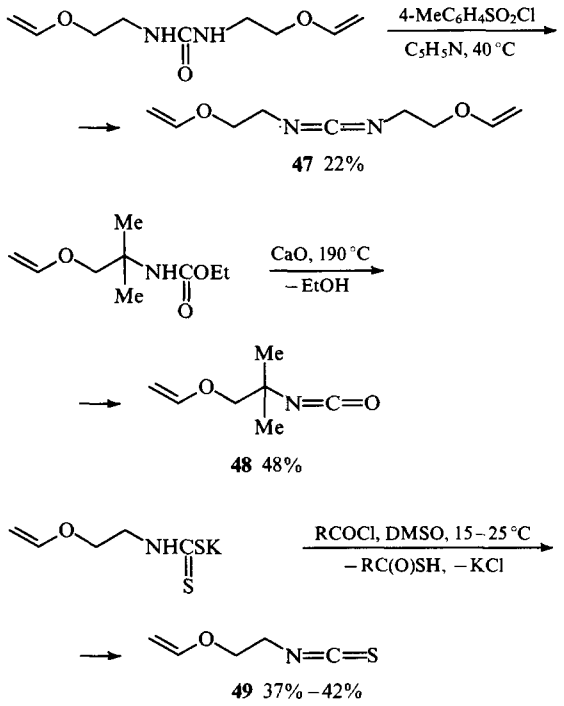


n = 1, 2; m = 2, 3; R = H, cyclo-C_6H_{11}, Ph.

The substituted thiourea **43** has also been synthesised by the interaction of an aqueous solution of a potassium carbamate derivative with vinyloxyethylamine.[148]

Isocyanates,[84,94,129,149,150] isothiocyanates,[91,150–152] and isocyanic acid, obtained in situ from KOCN and inorganic acids at pH 6.8,[153,154] readily combine with vinyloxyalkylamines, giving rise to the corresponding urea and thiourea derivatives **46** (Scheme 4).

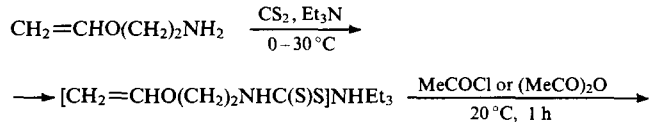
Scheme 4



n = 2–5; R, R^1 = Me, Et, $C_{16}H_{33}$, Ph;

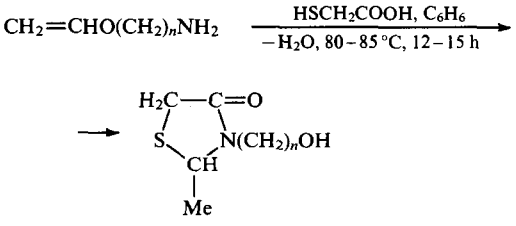
R^2 = H, Me, Et, Bu, cyclo-C_6H_{11}, CH_2Ph, $CH_2CH_2OCH{=}CH_2$, CH_2CH_2CN, 4-$Me_2NC_6H_3CH_2$, 4-$MeOC_6H_4CH_2$, $\overline{OCH{=}CH{-}CH{=}CCH_2}$, CMe=CHC(O)Me, $\overline{CH_2CH_2OCHMeCH}$, $\overline{CH_2(CH_2)_3CHMeCH}$;

R^3 = H, Me, Et, Bu, $MeOCH_2$, $BuOCH_2$, Ph, 2-ClC_6H_4; X = O, S.



Some of the vinyl derivatives of urea and carbamic and dithiocarbamic acids described above have been used to synthesise vinyl-containing carbodiimide (compound **47**),[155] isocyanate (compound **48**),[130] and isothiocyanate (compound **49**)[104,106,156] derivatives (Scheme 5).

Scheme 5

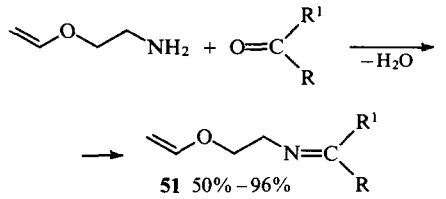


R = Me, Ph.

It was shown that the method of synthesis of the isothiocyanates **49** can be greatly improved by combining the synthesis of the carbamic acid salt from vinyloxyethylamine and carbon disulfide with the subsequent treatment with acid anhydrides. This single-reactor synthesis makes it possible to raise the yield of the isothiocyanate **49** to 95%.[157,158]

The replacement of carboxylic acid anhydrides by $POCl_3$ lowers the yield of compound **49** to 21%.[159]

Carboxylic acids are unsuitable for the acylation of VE AA owing to the instability of the latter in an acid medium already mentioned. The not altogether unusual result of the reactions of vinyloxyethyl- and vinyloxypropyl-amines with thioglycolic acid may serve as confirmation of this.[160]

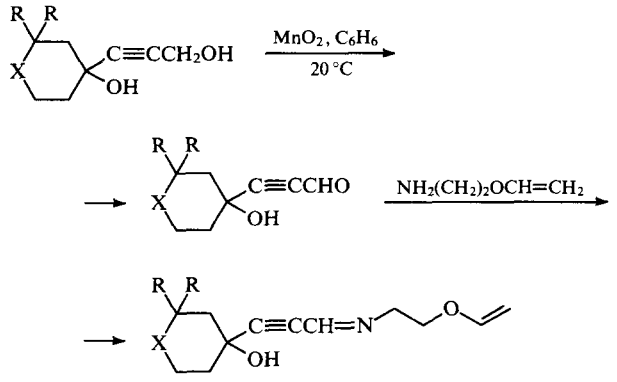


n = 2, 3.

Here there is also a possibility of the intermediate formation of the azomethine alcohol **24b**, which subsequently reacts with thioglycolic acid, affording the thiazolidinone **50**.[161]

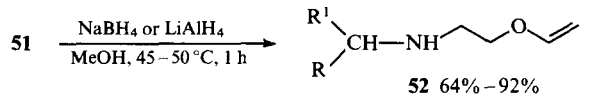
4. Reactions with carbonyl compounds

As a typical primary amine, the vinyl ether of monoethanolamine readily condenses with aldehydes[162–164] and ketones,[165–169] giving rise to the Schiff bases **51**.



51 50%–96%

R, R^1 = H, Me, Ph, 2-HOC$_6$H$_4$, 4-MeOC$_6$H$_4$, 4-NO$_2$C$_6$H$_4$, 3-NO$_2$C$_6$H$_4$, 4-ClC$_6$H$_4$, 3-CF$_3$C$_6$H$_4$, 4-Me$_2$NC$_6$H$_4$, 3,4-(MeO)$_2$C$_6$H$_3$, OCH=CH—CH=C;

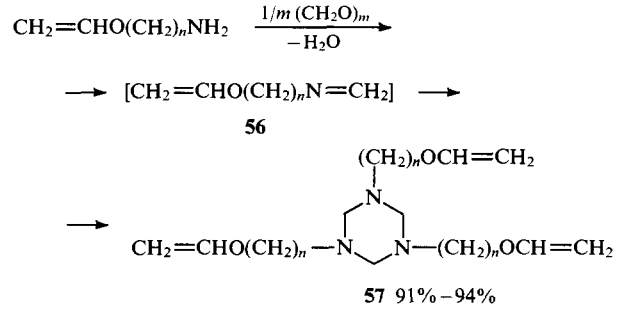


R + R^1 = –(CH$_2$)$_{4-5}$–, –CHMe(CH$_2$)$_4$–, –CHMeCH$_2$NMeCHMeCH$_2$–, –CH$_2$CH$_2$OCMe$_2$CH$_2$–.

The condensation of the vinyl ether of monoethanolamine with aldehydes proceeds so smoothly that it is possible to obtain the Schiff bases of unstable ethynealdehydes by oxidising ethyne glycols with active manganese dioxide in the presence of the above amine.[170,171]

X = O, R = Me (49%); X = CH$_2$, R = H (61%).

The hydrogenation of the vinyl derivatives of Schiff bases by hydrogen on Raney nickel even at room temperature and atmospheric pressure proceeds with reduction of the C=N and C=C bonds.[162] The selective reduction of the C=N bond alone with formation of the ether **52** is achieved with the aid of metal hydrides.[84,121,166–169]

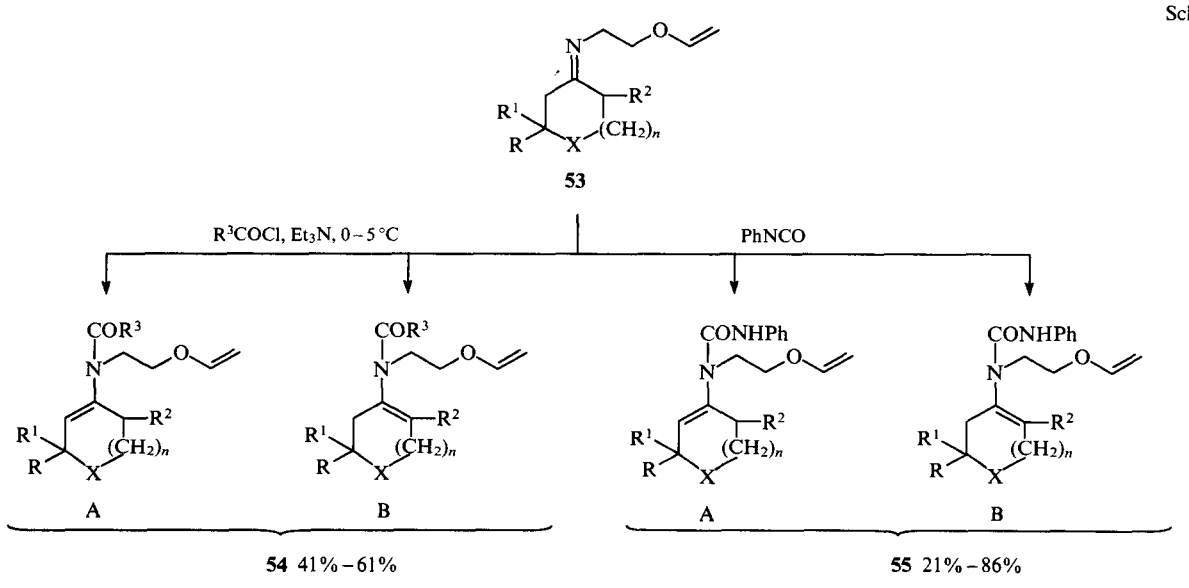


52 64%–92%

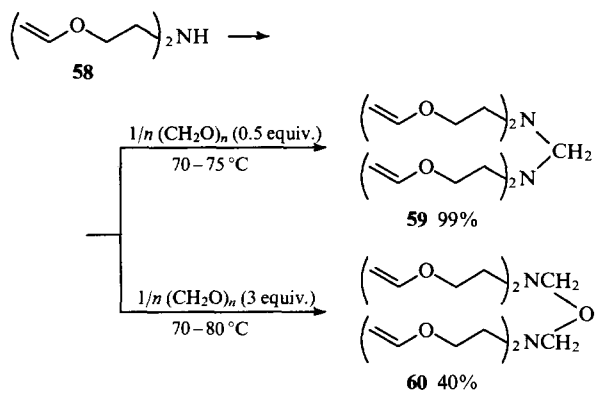
The amides **54** have been obtained by acylating the Schiff bases **53**,[166,167,172,173] while the urea derivatives **55** have been synthesised by condensing the bases **53** with phenyl isocyanate (Scheme 6).[149]

The reaction proceeds selectively with formation of the type A enamine structure only for X = CH$_2$, whilst in all the remaining cases equal amounts of the isomers A and B are obtained.

The condensation of the vinyl ethers of ethanolamine and propanolamine with paraformaldehyde leads to the products of the trimerisation of the azomethines **56** — the trivinyl ethers of 1,3,5-tris(2-hydroxyalkyl)hexahydrotriazine **57**.[162,174]

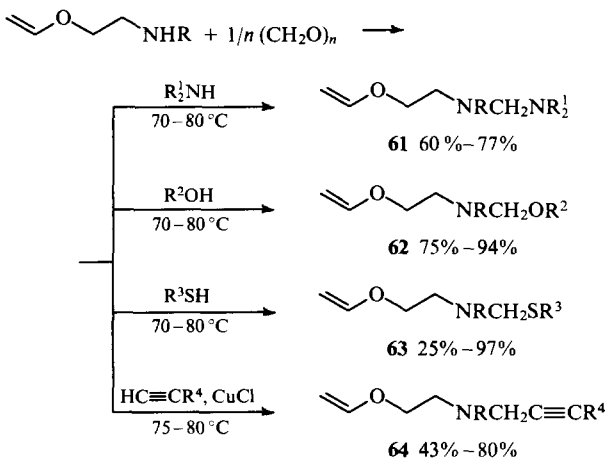


57 91%–94%



n = 2, 3.

N,N,N',N'-(2-Vinyloxyethyl)methylenediamine **59** has been obtained by the reaction of the divinyl ether of diethanolamine **58** with a stoichiometric amount of paraformaldehyde,[128,175] while in the presence of an excess of paraformaldehyde the product was the tetravinyl ether **60**.[102]

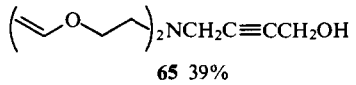


Scheme 6

n = 0, 1; R, R^1, R^2 = H, Me; R^3 = Me, Et, Pr, Ph; X = O, NMe, CH$_2$.

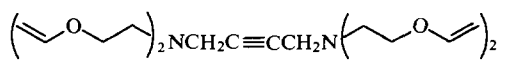
The vinyl ethers of aminoalcohols with a secondary amino-group and paraformaldehyde have been used for the amino-methylation of amines,[102] alcohols,[102,128] thioalcohols,[102] and ethynes[38,121,176-178] in the synthesis of the vinyl ethers of *N,N*-disubstituted aminoethanols **61**–**64**.

R = $CH_2CH_2OCH{=}CH_2$, CH_2CH_2COOEt, CH_2CH_2COOBu, $CH_2CHMeCOOMe$; R^1 = Et, $CH_2CH{=}CH_2$;



R_2^1 = $-CH_2CH_2OCH_2CH_2-$;

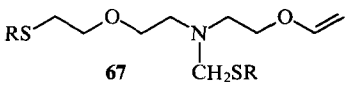
R^2 = Bu, $CH_2CH{=}CH_2$, $CH_2C{\equiv}CH$, $CMe_2C{\equiv}CCH{=}CH_2$, $CH_2CH_2OCH{=}CH_2$; R^3 = Bu, $CH_2CH{=}CH_2$, Ph;



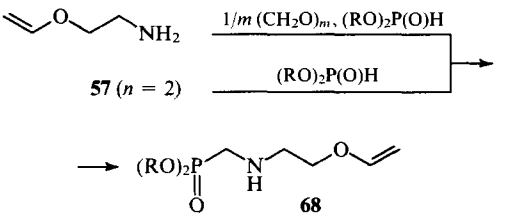
R^4 = H, Ph, $C{\equiv}CCH_2OH$, $C{\equiv}CCMe_2OH$

In the absence of catalysts, ethynyl alcohols are amino-methylated only at the hydroxy-group,[102] but in the presence of copper monochloride the aminomethylation takes place exclusively at the ethynyl group.[177]

The aminomethylation of ethyne by paraformaldehyde and the amine **58** gives rise to the formation of the aminoalcohol **65** and the diaminobutyne **66** together with propargylamine **64** (yield 18%).[177]

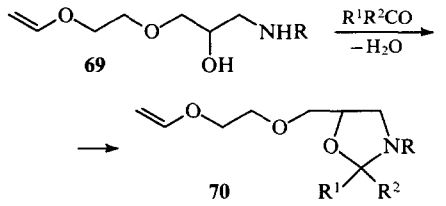


65 39%



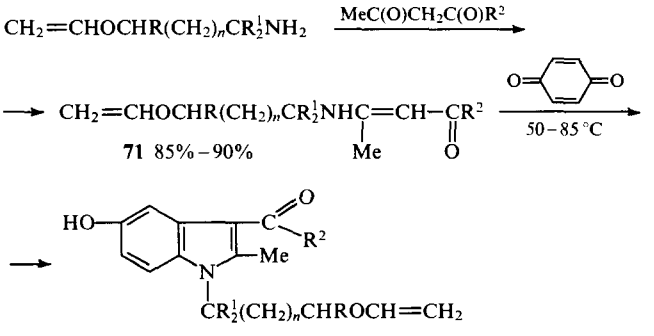
66 24%

The aminomethylation of thioalcohols is complicated by the side reaction involving the addition of the thioalcohols to the vinyl-oxy-group, as a result of which the sulfides **67** are obtained in yields up to 20% from the amine **58**, in addition to the sulfides **63**.[102]



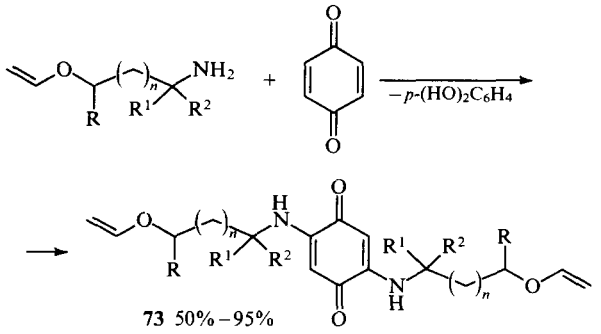
R = Bu, $CH_2CH{=}CH_2$.

When the vinyl ether of monoethanolamine and para-formaldehyde are used for the aminomethylation of dialkyl phosphites, the yields of the phosphonates **68** is significantly reduced. These compounds are obtained in satisfactory yields by the interaction of dialkyl phosphites with the triazine **57** (n = 2).[179]



R = Et (43%), R = Bu (36%).

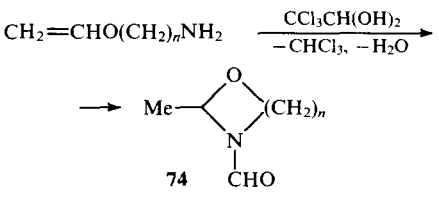
The vinyl ethers **69**, containing a hydroxy-group, condense with carbonyl compounds, affording the oxazolidines **70** in yields up to 91%.[180]



R, R^1, R^2 = H, Me, Et, Pr, Bu; $R^1 + R^2 = -(CH_2)_5-$.

Dicarbonyl compounds such as acetylacetone and aceto-acetic ester condense with VE AA, forming the enamines **71**,[149,167,181-183] the subsequent reaction of which with 1,4-benzoquinone leads to the indoles **72**.[182,183]

R, R^1 = H, Me, Et; R^2 = Me, OEt; n = 0–2.

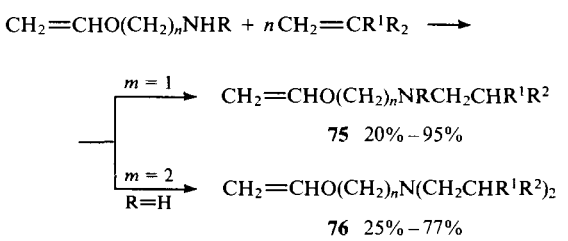


The interaction of 1,4-benzoquinone with VE AA, like that with primary amines,[184] involves an oxidation–reduction process, which results in the formation of the diaminobenzo-quinones **73**.[185,186]

73 50%–95%

R = R¹ = R² = H, Me, Et; *n* = 0–2.

The reaction of chloral hydrate with aliphatic amines is known to be accompanied by the formylation of the latter.[187] In the case of VE AA, not only their formylation but also their cyclisation to the 1,3-oxazacycloalkanes **74** take place.[188]

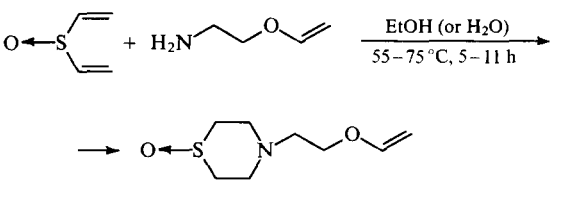


74

n = 2 (69%), *n* = 3 (56%).

5. Addition to carbon – carbon multiple bonds

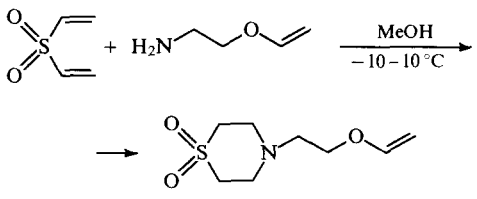
Like the usual aliphatic amines, the vinyl ethers of aminoalcohols add to the activated C=C and C≡C bonds. For example, their addition to acrylonitrile,[189] acrylamide,[190] and the esters of acrylic[19,117,127] and methacrylic[127,191] acids has been described. Depending on the reactant ratio, the vinyl ethers with a primary amino-group can give rise to both the monoadducts **75** and the diadducts **76**.[117,127]



75 20%–95%

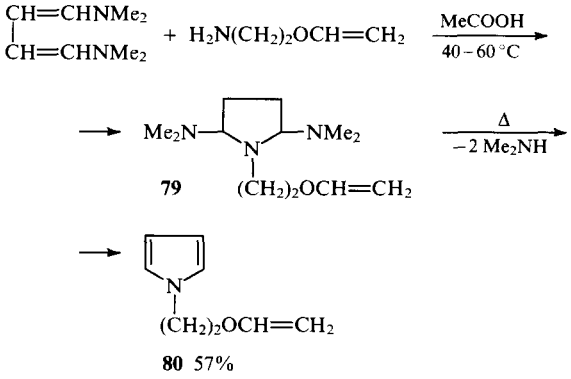
76 25%–77%

n = 2, 3; R = H, Me, $CH_2CH_2OCH{=}CH_2$; R^1 = H, Me;



R^2 = CN, $CONH_2$, COOMe, COOEt, COOBu.

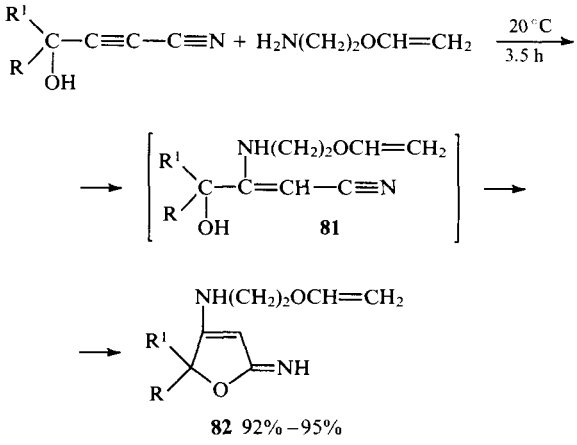
At a temperature above 50 °C, divinyl sulfoxide readily combines with the vinyl ether of monoethanolamine, affording 4-(2-vinyloxyethyl)-1,4-perhydrothiazine 1-oxide **77**.[114,115,192,193]



77 75%–85%

The reaction with divinyl sulfone takes place even on cooling, whereupon the sulfone **78** is formed.[194]

78 82%

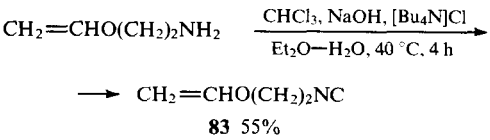


The interaction of the vinyl ether of monoethanolamine with 1,4-bis(dimethylamino)buta-1,3-diene is exothermic in the presence of catalytic amounts of acetic acid. The pyrrolidine **79** formed is converted into 1-(2-vinyloxyethyl)pyrrole **80** during distillation.[195]

79

80 57%

When the vinyl ether of monoethanolamine is added to the triple bonds of tertiary cyanoethynyl alcohols, the intermediate unstable nitriles **81** are formed initially and then cyclise to the furan derivatives **82**.[196]

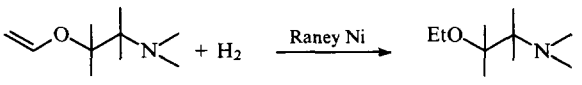


81

82 92%–95%

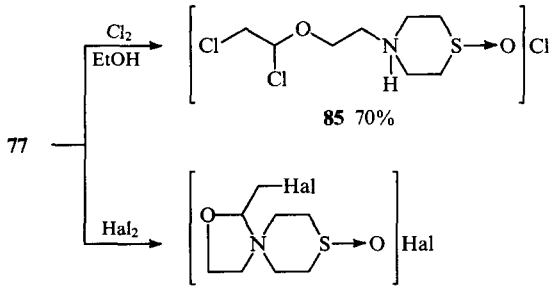
R = R¹ = Me; R + R¹ = –$(CH_2)_4$–.

Under the conditions of phase transfer catalysis by tetrabutylammonium chloride, the interaction of the vinyl ether of monoethanolamine and the dichlorocarbene generated from chloroform results in the formation of 2-vinyloxyethyl isocyanide **83**.[197]



83 55%

6. Reactions involving addition to the vinyl group

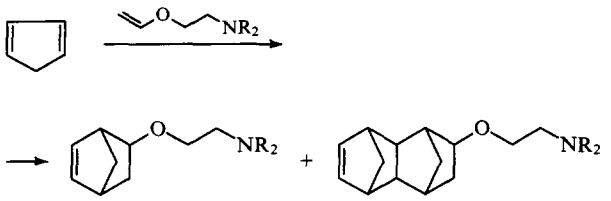


One of the reactions involving only the vinyl group is the hydrogenation of VE AA. The reaction is carried out on Raney nickel at temperatures in the range 20–150 °C and hydrogen pressures from atmospheric to 5 MPa. The yields of the ethyl ethers of aminoalcohols **84** are 65%–100%.[20,21,26,44,162,191,194,198–200]

The study of the hydrogenation of the vinyl ether of monoethanolamine on Raney nickel showed that the reaction is of zero order with respect to the vinyl ether and that its rate diminishes in the series of solvents ethanol > 1:1 ethanol–water > 1:1 dioxane–water > water.[199]

84

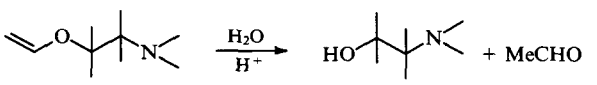
When chlorine adds to the vinyl ether **77** in ethanol, the hydrochloride of the dichloroether **85** is formed, whereas in aprotic solvents the product is the spiro-cyclic salt **86**. Regardless of the type of solvent, the interaction of iodine with compound **44** leads to the salt **86**.[114,201]



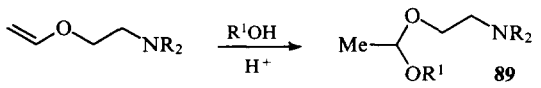
85 70%

86 95%–98%

Hal = Cl, I.



When the vinyl ethers of ethanolamines are used as dienophiles in the reaction with cyclopentadiene, the mono- and di-adducts **87** and **88** are formed in low yields.[202]



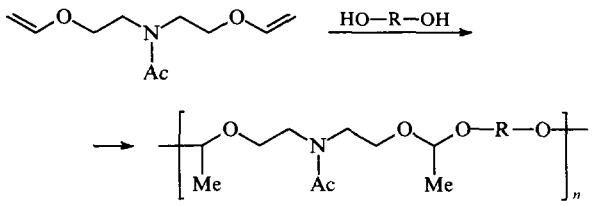
87 10%–17% **88** 6%–28%

R = H, Me, Et.

In acid aqueous solutions, VE AA are quantitatively hydrolysed to the aminoalcohols and acetaldehyde, but detailed studies of the hydrolysis have not been carried out. In the main, this reaction has been used to demonstrate the structure of the vinyl ethers.[18,20,21,26,44,99,191]

The vinyl ethers of aminoalcohols, which are stable in the presence of protic acids, are capable of combining with alcohols with formation of the acetals **89** when the reaction is catalysed by these acids.[20,21,24,203]

89



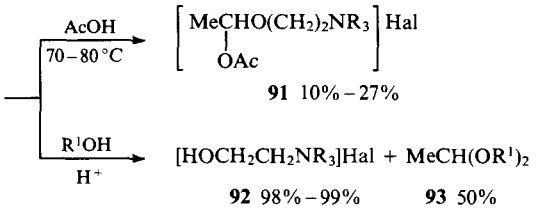
R = Et, R^1 = Bu (13%); R = Me, R^1 = $CH_2CH_2NMe_2$ (5%),

R = Et, R^1 = $CH_2CH_2NEt_2$ (6%); R = Ph,

R^1 = CH_2CH_2NHPh (62%); R = H, R^1 = $(AlkO)_2P(O)CH_2$ (70–82%).

Alk = Et, Pr^i, Bu.

When glycols are used as the alcohols, the reaction affords the oligoacetals **90**.[204]



90 98%–99%

n = 4–7; R = $(CH_2)_2$, $(CH_2)_2O(CH_2)_2$, $(CH_2)_2O(CH_2)_2O(CH_2)_2$.

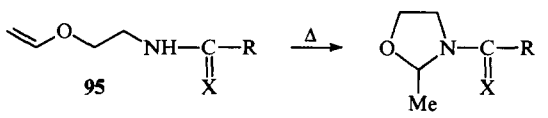
Quaternary vinyloxyethylammonium salts give rise to the adducts **91** with acetic acid, but are cleaved by alcohols when the reaction is catalysed by hydrochloric or sulfuric acids to the aminoalcohol salts **92** and the acetals **93**.[116]

$[CH_2{=}CHO(CH_2)_2NR_3]Hal$ ⟶

91 10%–27%

92 98%–99% **93** 50%

R = Me, Et; R^1 = Me, Et, Bu; Hal = Br, I.



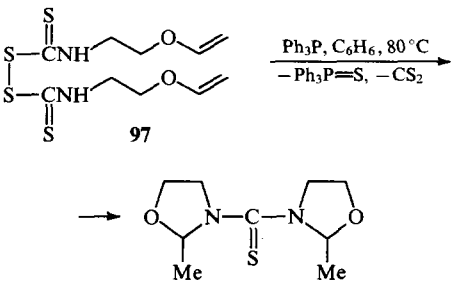
The addition of thioalcohols to the vinyloxy-group in VE AA proceeds, as in the case of alkyl vinyl ethers,[205] contrary to the Markovnikov rule with formation of the sulfides **94**.[67,102,124,141]

$CH_2{=}CHO(CH_2)_2NH_2 + EtSH \xrightarrow{100\,^\circ C,\ 6\ h}$

⟶ $EtS(CH_2)_2O(CH_2)_2NH_2$

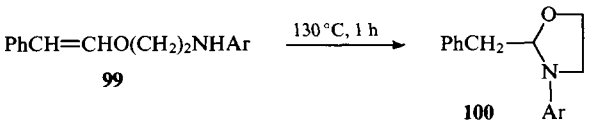
94 20%–32%

Apart from the acid-catalysed cyclisation of vinyloxyalkylamines and vinyloxyalkylamides discussed above, it has been frequently noted that the cyclisation of certain amides **95** to the oxazolidines **96** can take place in the absence of acid catalysts. Thermal cyclisation has been observed at a temperature higher by 80–120 °C than in the acid-catalysed process.[95,96,104,105,137,138,156,206,207]



95 **96** 70%–100%

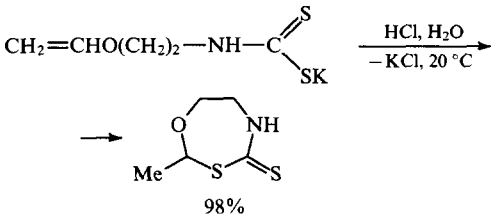
X = S, R = SBu, SCH_2Ph, $O(CF_2)_{6-10}H$;



X = O, R = $OCH_2CH(OH)CH_2Cl$.

The unusual, not acid-catalysed, cyclisation of thiuram disulfide **97** to the thione **98** takes place when compound **97** interacts with triphenylphosphine.[208]

97 **98** 39%



It has been shown recently[209] that the interaction of an aromatic substituent in the 2-position in the vinyloxy-group imparts to the ethers **99** the capacity for cyclisation to the oxazolidines **100** on treatment with bases. The thermal cyclisation of compound **99** does not occur.[65]

99 **100**

Ar = Ph (87%), 4-MeC_6H_4 (91%).

In the case of *N*-(2-vinyloxyethyl)dithiocarbamic acid, formed in situ from an aqueous solution of potassium carbamate and hydrochloric acid, the cyclisation takes place at the more acid SH group and not the amide group.[210]

98%

7. Polymerisation

In contrast to alkyl vinyl ethers for which cationic polymerisation is the main polymerisation reaction,[205] the vinyl ethers of aminoalcohols polymerise as a rule via a radical mechanism. This is associated with the deactivation of the cationic catalyst by the reaction forming a complex with the amino-group. Rare examples of the successful cationic polymerisation were examined above in the discussion of the reactions of vinyl ethers with acids.

2,2'-Azobisisobutyronitrile[19,21,26,211–225] or other azo-compounds[42,108,124,125] are usually employed to initiate the radical polymerisation. In the case of homopolymerisation, the reaction is carried out at 60–80 °C with 2%–5% of the initiator for 20–100 h. The yield of the polymers, which are viscous liquids with a low molecular mass (1000–2000), is usually low and ranges from 5% to 20%. Solid polymers with a three-dimensional structure are obtained under analogous conditions from certain divinyl ethers of diethanolamines and the trivinyl ether of triethanolamine in 40%–70% yields.[19,26,133,211,213]

The attempts to initiate the homopolymerisation of the vinyl ethers of ethanolamines by benzoyl peroxide were unsuccessful.[19,108,219] On the other hand, this initiator induces the polymerisation of quaternary vinyloxyalkylammonium salts.[83]

There are data on the initiation of the polymerisation of the vinyl ether **3** by γ-radiation.[226–229] It has been noted that in this case the degree of conversion of compound **3** into water-soluble polymers with quantitative retention of the amino-groups does not exceed 30%. For higher degrees of conversion of compound **3**, water-insoluble products are formed.

The use of elemental sulfur as the initiator of the polymerisation of the ether **3** has been described.[224,230] The polymer formed under these conditions contains up to 4.4% of sulfur and has a molecular mass of about 1000.

In order to investigate the reactivities of VE AA, they were copolymerised with other vinyl monomers, for example with methyl methacrylate,[125,191,212–214,219,231,232] acrylamide,[225,233,234] hexamethylenedimethacrylamide,[223] acrylonitrile,[42,225,231,232] divinylbenzene,[42] styrene,[150,225,232] vinyl chloride[150,153,231] *N*-vinylpyrrolidinone,[215,216,221,227,233–235] 4-vinylpyridine and 2-methyl-5-vinylpyridine,[216,235] 1-vinyl-4,5,6,7-tetrahydroindole,[236] the glycidyl vinyl diether of ethylene glycol,[217,218] the monovinyl ether of ethylene glycol,[154,237] and other vinyl ethers.[42,150,225,232,234,238]

The presence of the highly reactive amino-groups in the VE AA homopolymers makes it possible to achieve readily polymer-analogue reactions and to obtain in this way graft copolymers which are difficult to obtain by other procedures. For this purpose, the homopolymers were alkylated by alkyl halides and alkyl sulfates,[225,239–244] acylated by acid halides,[245] hydroxyalkylated by oxiranes,[243] and cyanoethylated by acrylonitrile.[246,247] The homopolymers were modified by condensing them with formaldehyde and acetylacetone,[97,243,248,249] by making them undergo the amide exchange reaction with urea,[250,251] and by their addition to isocyanates.[42,245]

IV. Practical applications

Although it is at present still impossible to say that the VE AA are employed as widely as, for example, vinyl ethers and esters, nevertheless the available literature data indicate considerable prospects for their use in industry, agriculture, and medicine.

In the study of their physiological activity, it was established that the vinyl ethers **16** (X = O) and the quaternary salts **19** exhibit hypotensive and spasmolytic activities.[75,85] Compound **77** and its salts may be used to correct the haemostasis in antithrombic therapy.[114,115,193] 2-Aryl-1-methyl-*N*-(2-vinyloxyethyl)-ethylamines reduce the appetite and are recommended for the treatment of obesity.[168,169] *N*,*N*-Bis(2-vinyloxyethyl)-*S*-(acylvinyl)dithiocarbamate and its salts possess a tuberculostatic activity.[252]

Effective fungicides,[42,119,150,152,238] insecticides[42,119,130,142,150,232] acaricides,[143,152] bactericides,[152] and bacteriostatic agents[94,152] have been found among VE AA derivatives.

The technical applications of VE AA are frequently associated with the solution of ecological problems. Thus they are employed for the detoxication of industrial waste by the elimination of heavy metals[163] and cyanides,[174,253] for the flotation purification of water by the elimination of organic suspensions (silt,[190] lignin[101,254]), and also for combating ore dust.[126] The employment of these compounds for the enrichment of muscovite[255,256] and polymetallic ores[146,257] not only increases efficiency but also makes it possible to reduce the amount of highly toxic reagents employed in these processes.

VE AA are used as intermediates in the synthesis of substances with analgesic, psychotropic,[258,259] and radio-protecting[141] properties. They are also employed to obtain corrosion

inhibitors,[42,139,152,154] plasticisers,[42,97,139,154] photostabilisers for plastics,[154] antioxidants for lubricating oils,[42,139] as fire-proofing reagents,[139] and as reagents imparting hydrophobic properties to materials of plant and animal origin.[97,231]

The polymers and copolymers obtained from VE AA are used as anion-exchange resins,[42,125,211] water-soluble complex-forming agents,[233,260] sorbents for transition and polyvalent metals,[42,223,233–235,243,248,261] flotation agents for the enrichment of polymetallic ores,[237,247,249,251,262,263] reagents for the removal of aldehydes, epoxides, and isocyanates,[42] as well as organic and mineral suspensions[239–243,246,250,264,265] from water, hardening agents for epoxide resins,[222,230] self-hardening epoxide resins,[217,218] adhesives,[109,130,150,217,218,238] plasticising[97,109,231,245] and antistatic[42,225] additives to plastics, coatings, and films,[42,97,125,150,152] auxiliary materials in the textile and cellulose-paper industries,[94,97,117,130,134,150,153,154,244,245] lubricating and hydraulic liquids or additives to them,[42,124] and fungicides and bactericides.[220,225]

Ozonolysis of unsaturated compounds in the synthesis of insect pheromones and juvenoids

G Yu Ishmuratov, R Ya Kharisov, V N Odinokov, G A Tolstikov

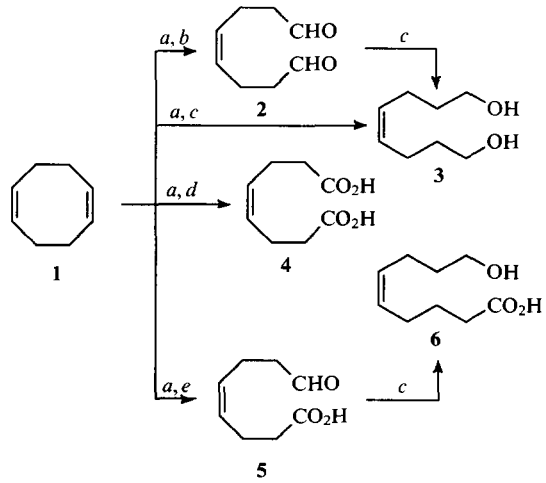
Contents

I. Introduction 541
II. Use of selective ozonolysis of cyclic and acyclic dienes and trienes in the synthesis of pheromones and juvenoids 541
III. Synthesis of pheromones and juvenoids from the ozonolysis products of cyclic and acyclic alkenes 551

Abstract. The review surveys data on the use of the ozonolysis of cyclic and acyclic monoenes, dienes, and trienes in various stages of the total synthesis of insect pheromones and juvenoids. The bibliography includes 178 references.

I. Introduction

In a review published in 1981,[1] we presented the results of studies on the structures of peroxide ozonolysis products and the path followed in their transformation into the final oxygen-containing compounds without a peroxide fragment. As a result of progress in this field, the ozonolysis of alkenes has become not only a recognised analytical method for the determination of the structures of the initial unsaturated compounds but also a procedure for the highly selective introduction of oxygen-containing functional groups into organic molecules. The development of the ozone generation technique and of the control over ozonolysis have reached a level such that this reaction has advanced sufficiently to be included in the class of modern methods which are not only of preparative value but also of interest for industry.



During the last decade, a considerable number of studies have been published on the use of ozonolysis of unsaturated compounds in the synthesis of insect pheromones and juvenoids. The present review is devoted to a survey of the results of these investigations.

II. Use of selective ozonolysis of cyclic and acyclic dienes and trienes in the synthesis of pheromones and juvenoids

The problems arising in the intensification of agricultural production and in the expansion and improvement of measures for the protection of nature and human health may be solved only with the aid of integrated systems for the protection of cultivated plants, forests, and agricultural and forestry produce. An indissoluble component of these measures in the fight against insect pests is the partial or complete replacement of the traditional chemical poisons by ecologically clean new generation insecticides, which include pheromones and juvenile hormones regulating arthropod behaviour and development.

The primary tasks in the synthesis of insect pheromones, juvenile hormones, and their analogues include the development of preparatively convenient methods of synthesis of the key intermediates, such as the α,ω-bifunctional compounds capable of undergoing selective chemical transformations. One of the promising ways of synthesising such compounds is the ozonolysis of alkenes.[1-57] The study of the oxidative cleavage of alkenes has become especially timely in connection with advances in metal complex catalysis, by virtue of which cyclic and acyclic oligomers and cooligomers of 1,3-dienes have become available.

The products of ring opening of cyclic butadiene oligomers are widely used in the synthesis of pheromones and other natural products. Thus the partial ozonolysis of one of the most readily available butadiene oligomers — (1*Z*, 5*Z*)-cyclo-octadiene **1** — as well as other cyclic butadiene oligomers and cooligomers provides a simple and effective path to bifunctional unsaturated compounds containing terminal functional groups which are of the same or different nature depending on the procedure used in the treatment of the peroxide ozonolysis product.[1,58-64]

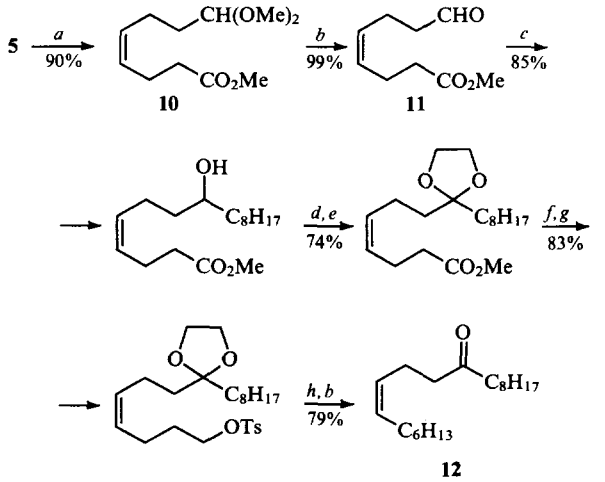
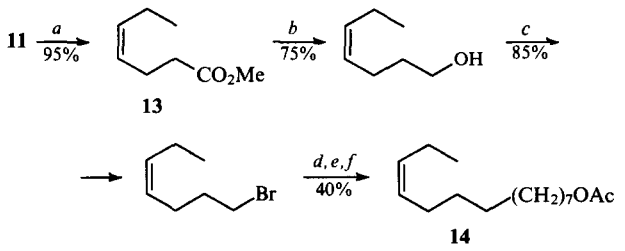
Received 8 February 1995
Uspekhi Khimii **64**(6) 580–608 (1995); translated by A K Grzybowski

A whole series of Lepidoptera pheromones have been obtained from α,ω-bifunctional alkenes **2–6**. Disparlure **8**—the pheromone of the gypsy moth (*Porthetria dispar*)—has been synthesised from (*Z*)-oct-4-ene-1,8-dioic acid **4**. The Kolbe condensation was used in two stages of this process (*c*, *d*).[65,66]



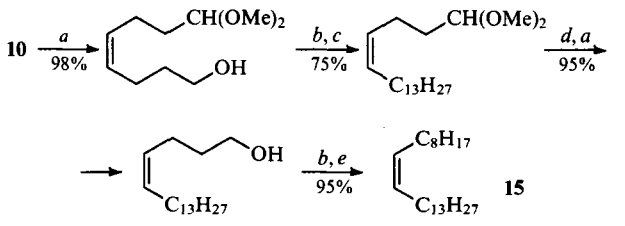
(*a*) MeOH–H$^+$; (*b*) KOH–MeOH;
(*c*) $Me(CH_2)_7CO_2H$–Pt/anode–MeOH;
(*d*) $Me_2CHCH_2CH_2CO_2H$–Pt/anode–MeOH;
(*e*) MCPBA (*m*-chloroperbenzoic acid)–CH_2Cl_2.

The simpler synthesis of disparlure from (*Z*)-oct-4-ene-1,8-diol **3** involves its transformation into the dibromo-derivative **9** and two successive stages in which it is coupled with n-heptyl- and isobutyl-magnesium bromides.[67–69]



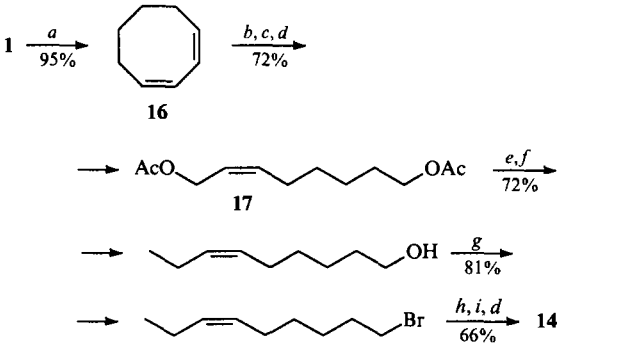
(*a*) PBr_3–Py; (*b*) n-$C_7H_{15}MgBr$; (*c*) Bu^iMgBr; (*d*) $ArCO_3H$ (Ar = 3-ClC_6H_4, 2-$HO_2CC_6H_4$).

The aldehydoacid **5** can be converted into the acetal-ester **10**, which has served as a convenient reagent for the synthesis of certain insect pheromones. For example, the synthesis of the sex pheromone **12** of the peach fruit moth (*Carposina niponensis Walsingham*) is based on the selective hydrolysis of the acetal **10** to the aldehydoester **11** and its interaction with n-octylmagnesium bromide.[70]



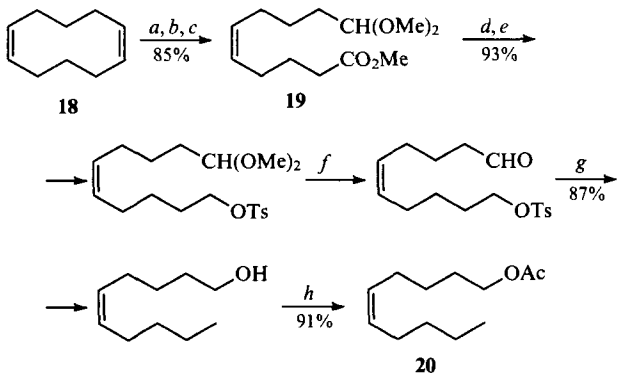
(*a*) MeOH–H$^+$; (*b*) H_3O^+; (*c*) n-$C_8H_{17}MgBr$; (*d*) PCC (Py·$HCrO_3Cl$, pyridinium chlorochromate); (*e*) $(CH_2OH)_2$–TsOH; (*f*) DIBALH (Bu^i_2AlH); (*g*) TsCl–Py; (*h*) PrMgBr–Li_2CuCl_4.

Yet another variant of the transformation of the aldehydoester **11** leads to the sex pheromone **14** of the oak moth (*Tortrix viridana*). The decarbonylation of compound **11** by treatment with tris(triphenylphosphine)rhodium chloride takes place under mild conditions, affording a high yield of the methyl ester of the (4*Z*)-heptenoic acid **13**, which determines the subsequent success of the entire synthesis.[71]



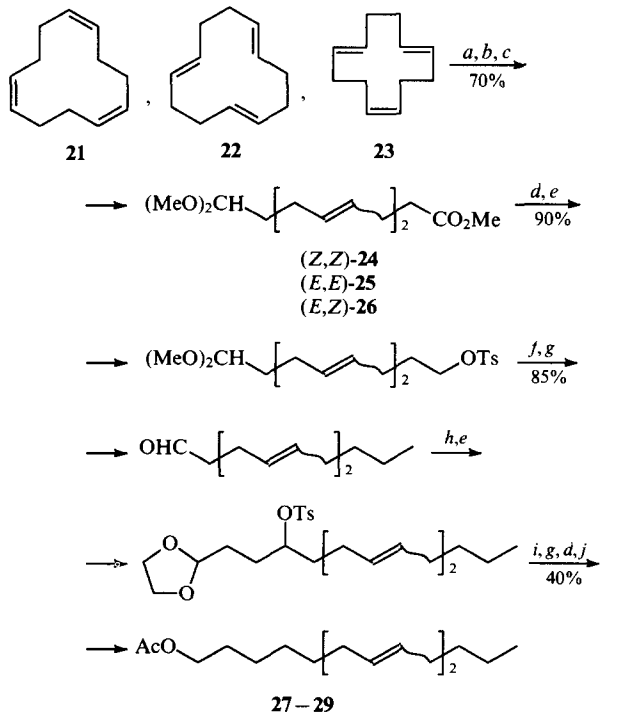
(*a*) $(Ph_3P)_3RhCl$; (*b*) DIBALH; (*c*) $Br_2·PPh_3$;
(*d*) $EtOCH(Me)O(CH_2)_7MgBr$–CuI–2,2′-Bipy;
(*e*) TsOH–MeOH–H_2O; (*f*) Ac_2O–Py.

The stereospecific syntheses of (9*Z*)-tricosene **15** [a component of the sex pheromone of the housefly (*Musca domestica*)[72,73]] and of (9*Z*)-tetradec-1-enyl acetate and (9*Z*)-hexadecenal[74] [the components of the sex pheromones of the pine moth (*Panolis flammea*) and the cotton bollworm (*Heliothis armigera*) respectively] have been achieved by the successive transformations of the acetal-ester **10** involving the ester and acetal groups and two cross-couplings with the corresponding organomagnesium and organolithium reagents catalysed by copper salts.

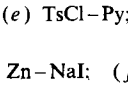


(*a*) DIBALH; (*b*) TsCl–Py; (*c*) n-$C_{10}H_{21}MgBr$–Li_2CuCl_4;
(*d*) H_3O^+; (*e*) n-$C_5H_{11}MgBr$–Li_2CuCl_4.

After reduction and acetylation, the product of the partial ozonolysis of cycloocta-1,3-diene **16** gave rise to (2*Z*)-1,8-diacetoxyoct-2-ene **17**, capable of regio- and stereo-selective coupling with Grignard reagents via the allylacetoxy-groups, which has been used in the regio- and stereo-selective synthesis of the oak moth pheromone **14**.[71]

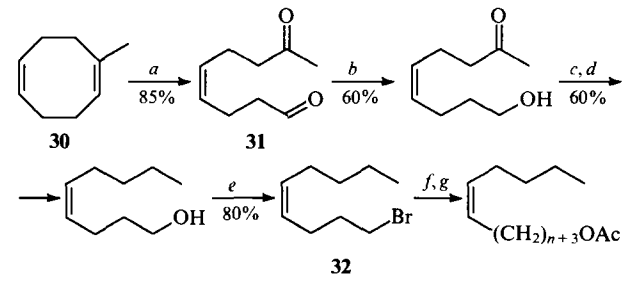


(*a*) Bu^tOK–DMSO; (*b*) O_3–cyclo-C_6H_{12}–MeOH;
(*c*) $NaBH_4$–MeOH; (*d*) Ac_2O–Py; (*e*) MeMgI–Li_2CuCl_4;
(*f*) DIBALH; (*g*) $Br_2·PPh_3$;
(*h*) $EtOCH(Me)O(CH_2)_5MgBr$–CuI–2,2′-Bipy;
(*i*) TsOH–MeOH–H_2O.



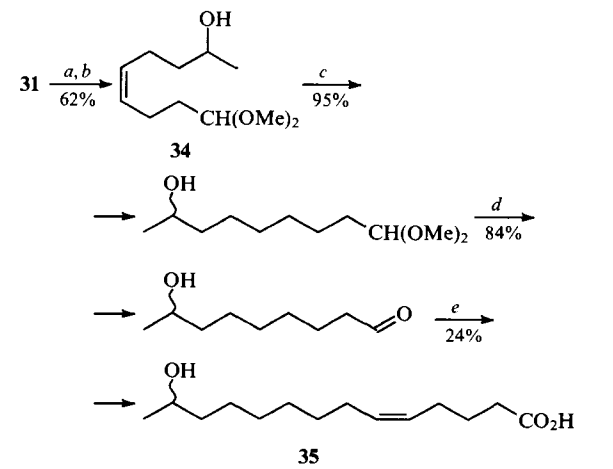
The carbon skeleton of the (*Z*)-C_{10} block **19**, obtained from the products of the selective ozonolysis of (1*Z*,6*Z*)-cyclodecadiene **18**, is identical to the skeleton of the component of the pheromone of the turnip moth (*Agrotis segetum*)—(5*Z*)-dec-1-enyl acetate **20**; the latter was therefore synthesised via chemoselective transformations of the functional groups.[75,76]

(*a*) O_3–cyclo-C_6H_{12}–AcOH; (*b*) AcONa–AcOH–Ac_2O; (*c*) TsOH–MeOH; (*d*) DIBALH; (*e*) TsCl–Py; (*f*) H_2O–PPTS (Py·HOTs, pyridinium *p*-toluenesulfonate); (*g*) $LiAlH_4$; (*h*) Ac_2O–Py.



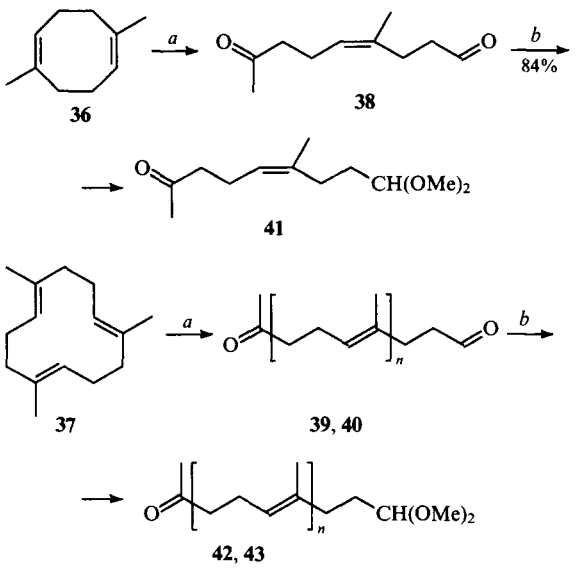
The C_{12} α,ω-bifunctional compounds **24**–**26**, obtained by the selective ozonolysis of (1*Z*,5*Z*,9*Z*)-cyclododecatriene **21**, (1*E*,5*E*,9*E*)-cyclododecatriene **22**, and (1*E*,5*E*,9*Z*)-cyclododecatriene **23**, are of evident interest for the synthesis of the diene components **27**–**29** of the pheromone of the pink bollworm (*Pectinophora gossypiella*).[77,78]

(*a*) O_3–cyclo-C_6H_{12}–AcOH; (*b*) AcONa–AcOH–Ac_2O; (*c*) TsOH–MeOH; (*d*) DIBALH; (*e*) TsCl–Py; (*f*) Me_2CuLi; (*g*) HCl; (*h*)  ; (*i*) Zn–NaI; (*j*) Ac_2O–Py.



One of the approaches to the solution of the problem of the synthesis of pheromones with a terpenoid structure and a trisubstituted double bond involves the use as the starting compounds of regularly constructed oligomers, cooligomers, and telomers of isoprene, the methods of synthesis of which have now been thoroughly worked out, as well as natural terpenoids with trisubstituted double bonds. When this approach is employed, the task reduces to the choice of selective methods for the necessary transformation of the initial compound for the subsequent construction from the resulting functional block-synthon of the required carbon skeleton of the pheromone. The transformation of the initial cyclic isoprenoid into the α,ω-bifunctional synthon is achieved by opening its ring[79–81] and, in the case of an acyclic initial compound with a specified geometry of the double bond, a suitable method is chosen for its conversion into an intermediate which is suitable for subsequent employment in the formation of the target pheromone.[82–86]

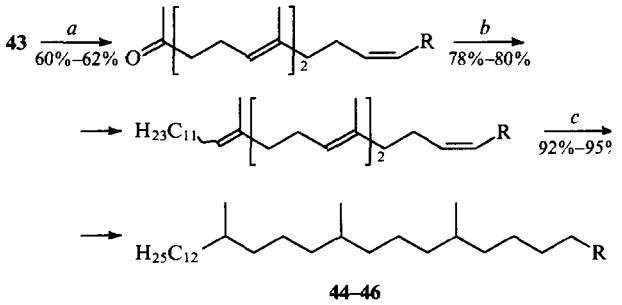
A series of pheromones have been synthesised from 1-methyl-(1*Z*,5*Z*)-cyclooctadiene **30**. The partial ozonolysis of this isoprene—butadiene codimer proceeds selectively via the trisubstituted double bond, which makes it possible to obtain (*Z*)-alk-1-enyl acetates—the pheromones of the order Lepidoptera.[87,88] (*Z*)-Non-4-enyl bromide **32** was obtained by successive transformations of the functional groups of the ozonolysis products of compound **31**. Compound **32** was converted into the corresponding Grignard reagent and the latter was subsequently coupled with the acetoxybromo-derivatives **33**.



(*a*) O_3–cyclo-C_6H_{12}–MeOH; H_2–Pd–$CaCO_3$–PbO; (*b*) $KBH(OAc)_3$; (*c*) $TsNHNH_2$; (*d*) $NaBH_3CN$; (*e*) PBr_3–Py; (*f*) Mg; (*g*) $AcO(CH_2)_nBr$ (**33**).

After a two-stage reaction (selective protection of the aldehyde functional group and subsequent reduction of the keto-group to give the hydroxyacetal **34**), the ketoaldehyde **31** affords the key intermediate for the synthesis of (13*RS*)-hydroxy-(*Z*)-tetradec-5-enoic acid **35**—the acyclic precursor of the racemic form of the macrolide component of the aggregation pheromone of the flat grain beetle (*Cryptolestes pusillus*).[89]

(*a*) MeOH–NH_4Cl; (*b*) $NaBH_4$–MeOH; (*c*) H_2–Raney Ni; (*d*) PPTS–H_2O; (*e*) $HO_2C(CH_2)_4PPh_3Br$, $NaN(SiMe_3)_2$.

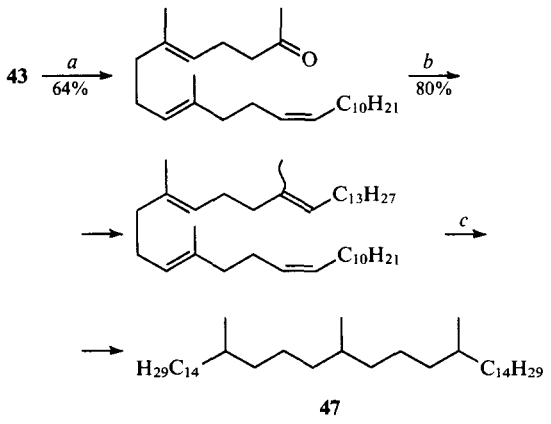


The most readily available cyclooligomers of isoprene are its (1*Z*,5*Z*)-dimer **36** and the (1*E*,5*E*,9*E*)-trimer **37**. The products of their selective ozonolysis have been used widely in the synthesis of pheromones.[59,60,79–81] The ozonolysis of (1*Z*,5*Z*)-1,5-dimethylcycloocta-1,5-diene **36** gives the monoterpene ketoaldehyde **38** with the (*Z*)-configuration, while ozonolysis of (1*E*,5*E*,9*E*)-1,5,9-trimethylcyclododeca-1,5,9-triene **37** affords the ketoaldehydes **39** and **40** with the (*E*)-configuration. The easily achieved selective protection of the aldehyde group in the ketoaldehydes **38**–**40** led to the corresponding monoacetals **41**–**43**, from which the target pheromones were synthesised.

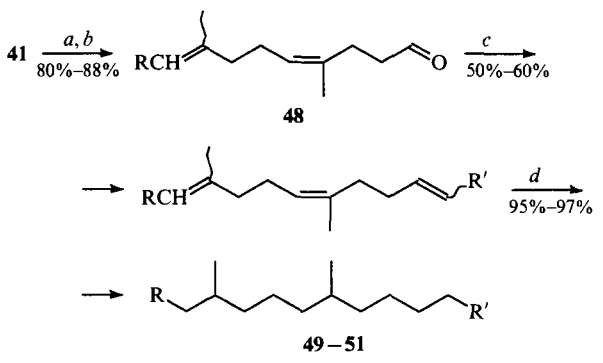
n = 1 (**39**, **42**), 2 (**40**, **43**)

(*a*) O_3–cyclo-C_6H_{12}–MeOH, H_2–Pd–$CaCO_3$–PbO; (*b*) MeOH–NH_4Cl.

The subsequent conversion of compound **43** into an alkene via the aldehyde group and then the keto-group and subsequent hydrogenation led to the diastereoisomeric (±)-13,17,21-trimethyltriacontane and its homologues **44**–**46**.[90,91]



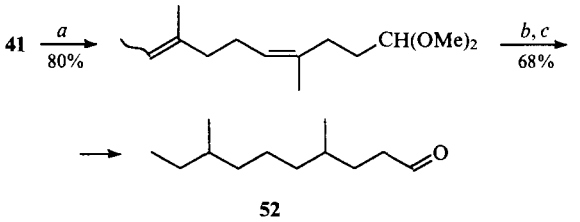
R = n-C_8H_{17} (**44**), n-$C_{10}H_{21}$ (**45**), n-$C_{12}H_{25}$ (**46**)



(*a*) RCH=PPh_3; (*b*) n-$C_{11}H_{23}CH$=PPh_3; (*c*) H_2–Pd/C.

A similar approach has been used in the synthesis of 15,19,23-trimethylheptatriacontane **47** — a component of the pheromone of the tsetse fly (*Glossina morsitans morsitans*).[92]

The carbon skeletons of the diastereoisomeric (±)-7,11-dimethyloctadecane **49**, (±)-15,19-dimethyltritriacontane **50**, and (±)-17,21-dimethylheptatriacontane **51** — the components of the egg-laying pheromones of the yellow-fever mosquito (*Aedes aegypti*), the stable fly (*Stomoxys calcitrans*), and the tsetse fly respectively, have been constructed by the introduction of double bonds into the unsaturated ketoacetal **41** with the (*Z*)-configuration via the keto-group and then the aldehyde-group (in compound **48**).[93–95]



(*a*) n-$C_{10}H_{21}CH$=PPh_3; (*b*) n-$C_{13}H_{27}CH$=PPh_3; (*c*) H_2–Pd/C.

49: R = n-C_5H_{11}, R′ = n-C_3H_7;

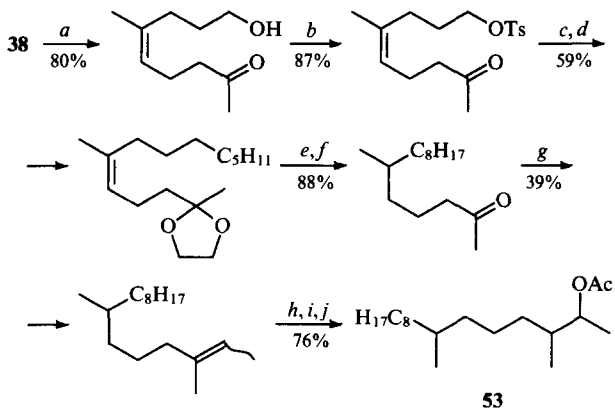
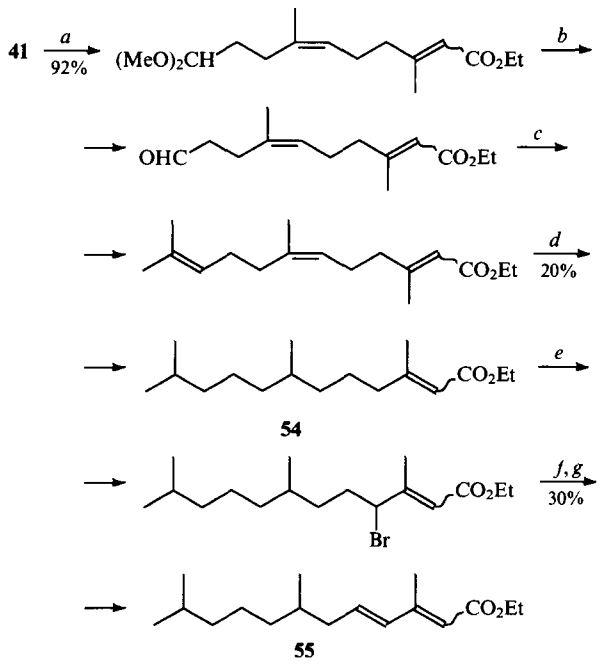
51: R = n-$C_{15}H_{31}$, R′ = n-$C_{12}H_{25}$.

(*a*) RCH=PPh_3; (*b*) H_3O^+; (*c*) R′CH=PPh_3; (*d*) H_2–Pd/C.

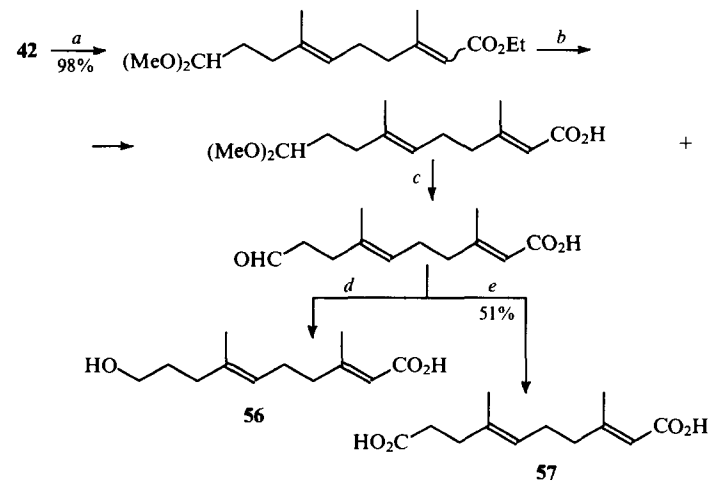


4,8-Dimethyldecanal **52** — the aggregation pheromone of the flour beetles (*Tribolium confusum* and *Tribolium castaneum*) — has been conveniently synthesised from the ketoacetal **41** by increasing its carbon chain length by two atoms via the keto-group with subsequent hydrogenation and hydrolysis.[96]



(*a*) MeCH=PPh_3; (*b*) H_2–Pd/C; (*c*) H_3O^+.

By use of the difference between the reactivities of the carbonyl groups of the ketoaldehyde **38**, it proved possible to achieve selective transformations leading to the racemic 3,7-dimethylpentadec-2-yl acetate **53** — the sex pheromone of the pine sawflies of the genera *Diprion* and *Neodiprion*.[97]



The synthesis of the ethyl ester of (2*E*,4*E*)-3,7,11-trimethyldodeca-2,4-dienoic acid (hydroprene) **55**, which has found extensive application as a juvenoid, is based on selective transformations of the unsaturated ketoacetal **41**, involving ethoxycarbonylmethylenation of the keto-group, conversion of the formyl group into an alkene by treatment with isopropylidenetriphenylphosphorane, ionic hydrogenation to the α,β-unsaturated ester **54**, and then transformation (via allylic bromination–dehydrobromination) into the target hydroprene.[98]

(*a*) $NaBH(OAc)_3$; (*b*) TsCl–Py; (*c*) $(CH_2OH)_2$–TsOH; (*d*) n-$C_5H_{11}MgBr$–Li_2CuCl_4; (*e*) H_2–Pd/C; (*f*) H_3O^+; (*g*) $MeCH{=}PPh_3$; (*h*) B_2H_6; (*i*) H_2O_2–NaOH; (*j*) Ac_2O–Py.

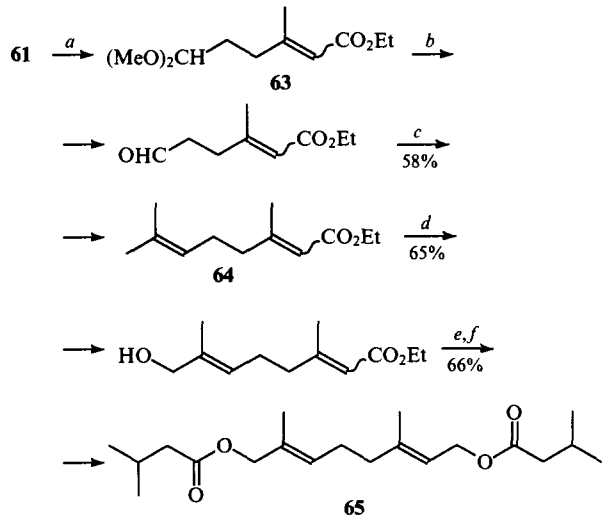
The ketoacetal **42** proved to be a convenient starting compound in the stereospecific synthesis of (2*E*,6*E*)-3,7-dimethyldeca-10-hydroxy-2,6-dienoic acid **56** and (2*E*,6*E*)-3,7-dimethyldeca-2,6-diene-1,10-dioic acid **57**, as well as the diol **58** — the terpenoid components of the pheromone of the danaid butterflies (*Danaus plexippus* and *Danaus chrysippus*) (Scheme 1).[99]

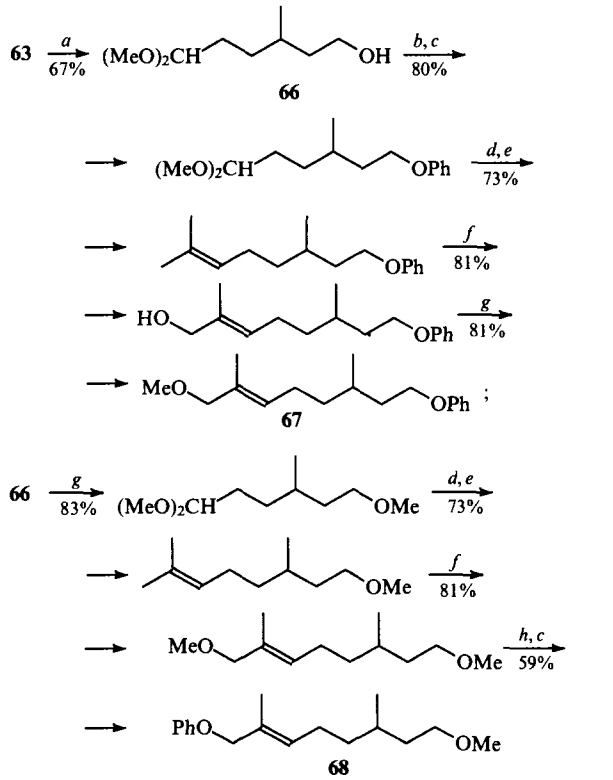
The racemic juvenile hormone YuG-III **60** has been synthesised stereospecifically from the ketoacetal **42** by means of its successive Petersen methoxycarbonylmethylenation, hydrolysis, coupling of the resulting aldehyde to isopropylidene-triphenylphosphorane, and the selective epoxidation of the intermediate triene ester **59** at the terminal double bond.[100]

(*a*) $Me_3SiCH_2CO_2Et$–LDA; (*b*) PPTS–H_2O; (*c*) $Me_2C{=}PPh_3$; (*d*) SiO_2–$AgNO_3$; (*e*) NBS; (*f*) K_2CO_3.



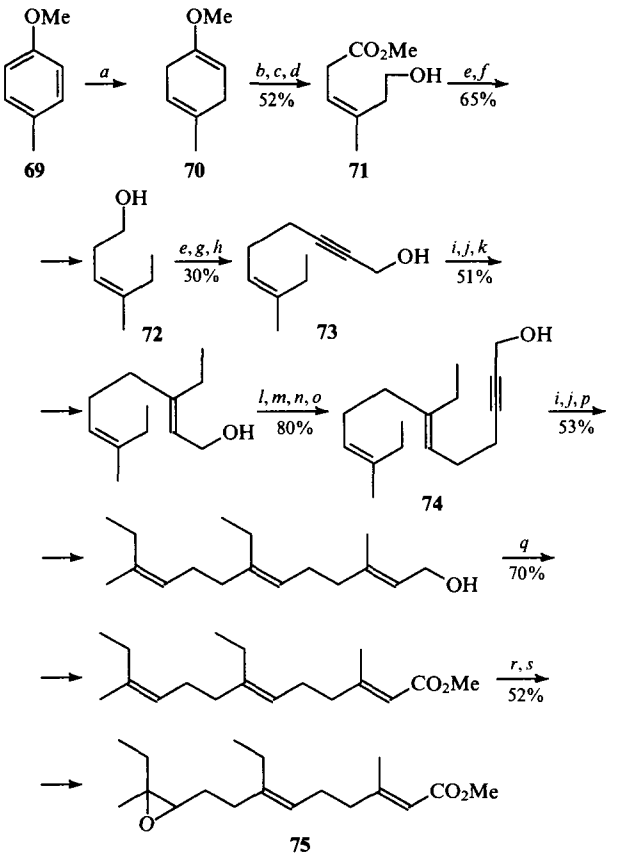
1,1-Dimethoxy-4-oxopentane **61**, obtained by the exhaustive ozonolysis of the isoprene oligomers **36** and **37** and the selective formation of acetal groups, has been used in the synthesis of 2,6-dimethylhepta-1,6-diene-3-yl acetate **62** — the attractant of the Comstock mealybug (*Pseudococcus comstoki*).[101]

(*a*) O_3–cyclo-C_6H_{12}–MeOH, H_2–Pd/$CaCO_3$–PbO; (*b*) MeOH–NH_4Cl; (*c*) $CH_2{=}PPh_3$; (*d*) H_3O^+; (*e*) $H_2C{=}C(Me)MgBr$; (*f*) AcCl.



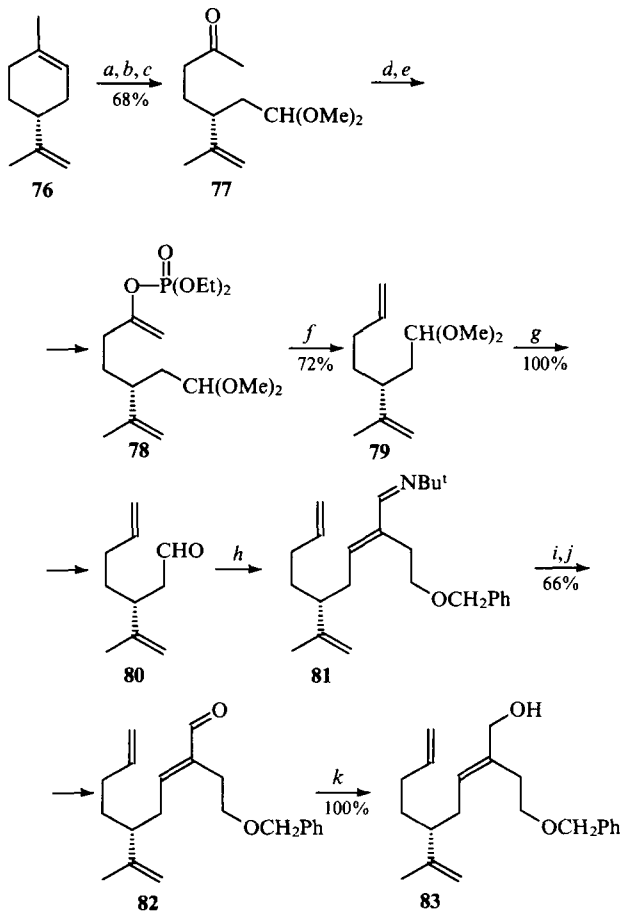
Scheme 1

(2*E*,6*E*)-2,6-Dimethylocta-2,6-diene-1,8-diyl diisovalerate **65**—the sex pheromone of the Crimean click beetle (*Agriotes tauricus*)—has been synthesised from the dimethyl acetal of levulinic aldehyde **61**.[102] The synthesis includes, among others, stages involving the epoxycarbonylmethylenation of the product and the introduction of double bonds into the latter to give the α,β-unsaturated ester **64** and subsequent allylic oxidation with a mixture of *tert*-butyl hydroperoxide and selenium dioxide.



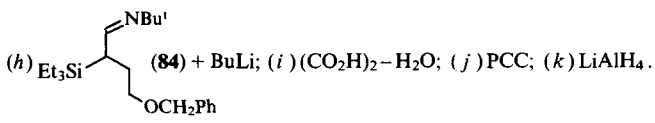
(*a*) $Me_3SiCH_2CO_2Et$–LDA; (*b*) H_3O^+; (*c*) $Me_2C{=}PPh_3$; (*d*) Bu^tOOH–SeO_2; (*e*) $LiAl(OBu^i)H_3$; (*f*) Me_2CHCH_2COCl–Et_3N.

The product of the Petersen ethoxycarbonylmethylenation of the ketoacetal **61**, namely the ester **63**, served as a convenient intermediate in the synthesis of (2*E*)-1-methoxy-8-phenoxy- and (2*E*)-1-phenoxy-8-methoxy-2,6-dimethyloct-2-enes **67** and **68**, which exhibit a juvenoid activity.[103]



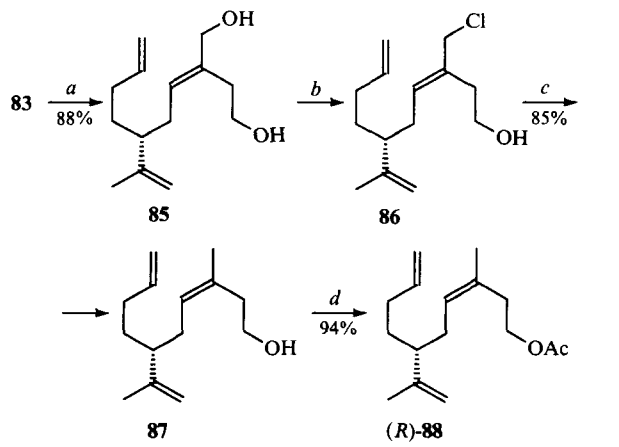
(*a*) Li–NH_3; (*b*) TsCl–Py; (*c*) PhONa; (*d*) PPTS–H_2O; (*e*) $Me_2C{=}PPh_3$; (*f*) Bu^tOOH–SeO_2; (*g*) NaH, MeI; (*h*) PBr_3–Py.

Ozonisation proved to be very effective in the conversion of the vinyl ether **70**—the readily available product of the Birch reduction of the methyl ether of *p*-cresol **69**—into the precursor for the synthesis of the juvenile hormone YuG-I **75**—the alcohol **72**.[104] The selectivity of the ozonolysis of compound **70** to give compound **71** is due to the significantly higher reactivity of the methoxy-substituted double bond. The illustrated sequence of stages in the conversion of compound **70** into compound **72** ensured automatically the required (*Z*)-configuration of the terminal unit of the chain of the juvenile hormone **75**. The transition from the C_7 block **72** to the target compound **75** is achieved by increasing the length of the carbon chain by means of the regio- and stereo-selective alkylation of the propargyl alcohols **73** and **74** via the corresponding vinyl iodides.

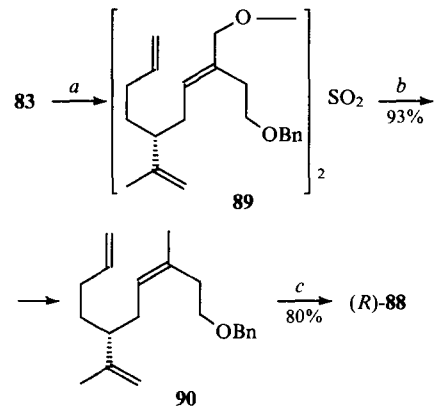


(*a*) Li–NH_3–$EtCMe_2OH$–THF; (*b*) O_3–MeOH; (*c*) Me_2S; (*d*) $NaBH_4$; (*e*) TsCl–Py; (*f*) $LiAlH_4$; (*g*) $LiC{\equiv}CCH_2OTHP$ (THP = tetrahydropyran-2-yl); (*h*) HCl; (*i*) $LiAlH_4$–NaOMe; (*j*) I_2; (*k*) Et_2CuLi; (*l*) PBr_3; (*m*) $LiCH_2C{\equiv}CSiMe_3$; (*n*) Ag^+, CN^-; (*o*) BuLi, CH_2O; (*p*) Me_2CuLi; (*q*) MnO_2, NaCN–MeOH; (*r*) HOBr; (*s*) Pr^iONa.

Limonene proved to be a convenient starting material for the synthesis of pheromones containing a chiral centre. (6*R*)-3-methyl-6-(2-propenyl)deca-3,9-dien-1-yl acetate (*R*)-**88**—the sex pheromone of the California red scale (*Aonidiella aurantii*)—has been synthesised from (*R*)-limonene **76**.[105] This was possible as a result of partial ozonolysis of limonene **76**, which takes place selectively and involves the endocyclic double bond. This gave ketoaldehyde **77**, in which the aldehyde group was protected selectively. The enolisation of the ketone **77** by a strong base and the fixation of the enolic form as the diethyl phosphate **78** followed by treatment with lithium in ammonia gave the diene acetal **79**. The deblocking and Petersen condensation of the aldehyde **80** with the silane **84** led to the imine **81**, from which the allyl alcohol **83** was obtained by successive hydrolysis and reduction.

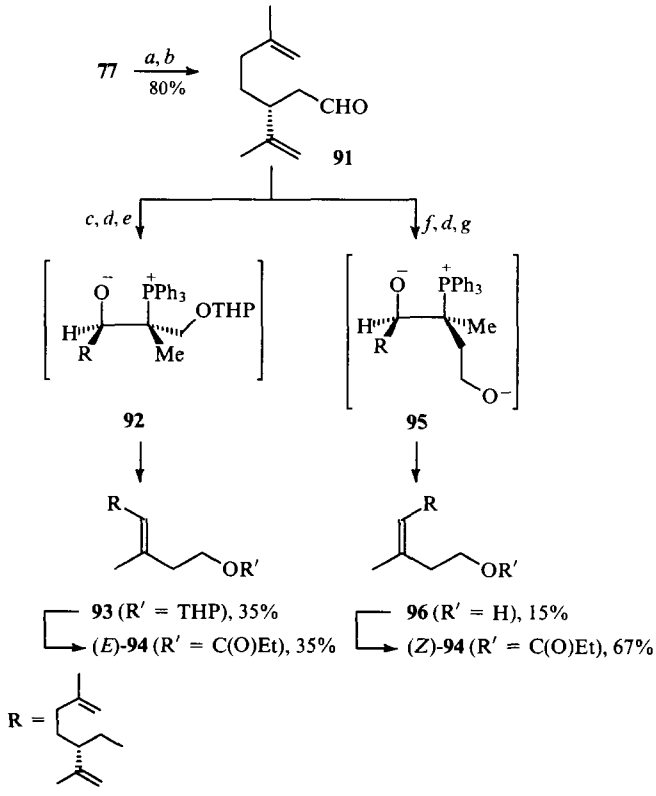


(*a*) O_3–MeOH; (*b*) $(H_2N)_2CS$; (*c*) $HC(OMe)_3$–$CeCl_3 \cdot 6H_2O$; (*d*) LDA; (*e*) $ClPO(OEt)_2$; (*f*) Li–NH_3; (*g*) $HClO_4$–H_2O–THF;



(*h*) **(84)** + BuLi; (*i*) $(CO_2H)_2$–H_2O; (*j*) PCC; (*k*) $LiAlH_4$.

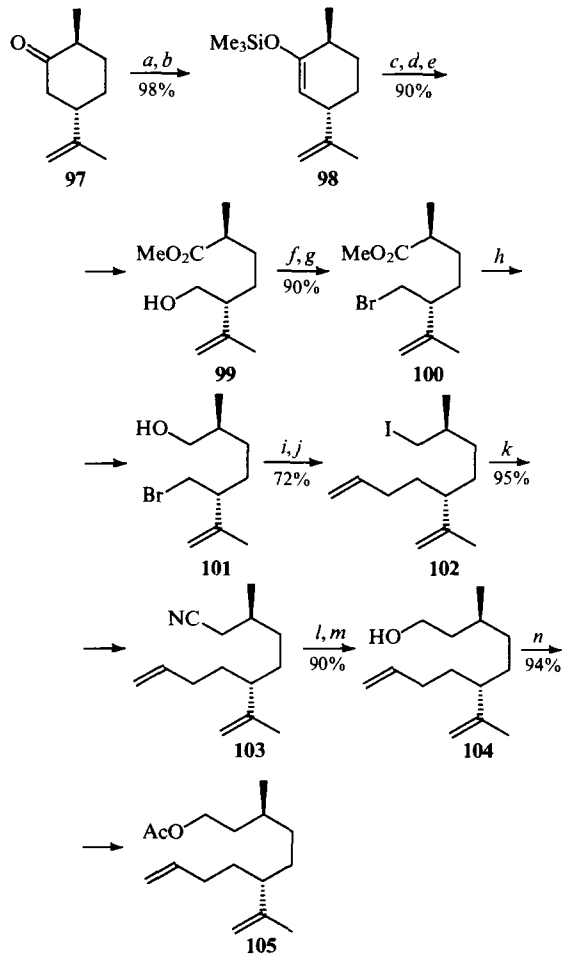
The alcohol **83** was transformed into the target pheromone (*R*)-**88** in two ways. The first involved the removal of the benzyl protecting group under mild conditions (the conditions of the Birch reaction) and the subsequent substitution of the allylic OH group of the resulting diol **85** by chlorine. The hydrogenolysis of the chlorohydrin **86** afforded the pheromone precursor **87**, the acetylation of which completed the synthesis.



(*a*) Li–NH_3; (*b*) NCS (*N*-chlorosuccinimide)–Me_2S; (*c*) $LiAlH_4$; (*d*) Ac_2O–Py.

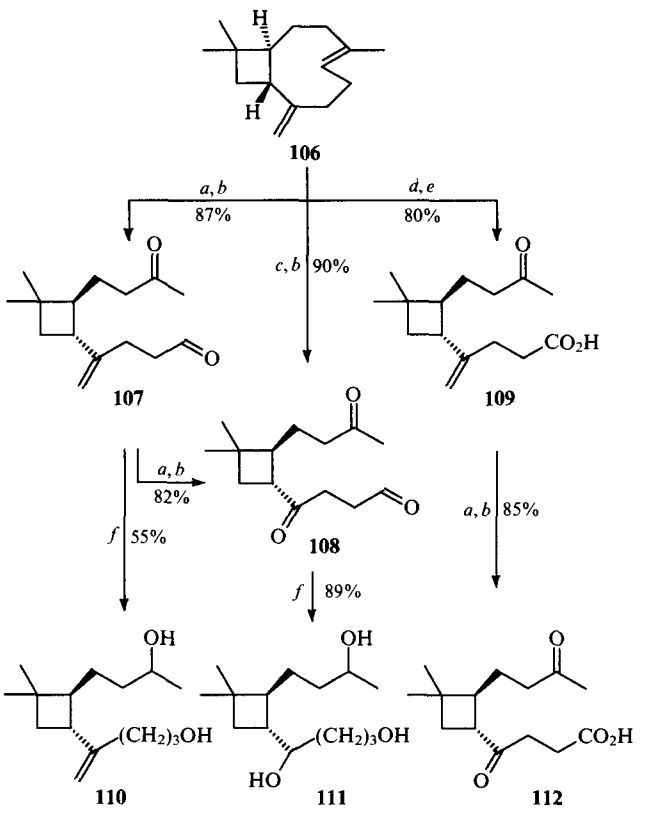
The alternative procedure for the transformation of compound **83** into the acetate **88** included the stage in which the sulfate **89** was formed and was subsequently reduced to the benzyl ether **90** and the benzyl group in the latter was replaced by the acetate group.

(*a*) SO_3–Py; (*b*) $LiAlH_4$; (*c*) Ac_2O–$HClO_4$.



The optically active bifunctional reagent **77** has been used successfully in the stereospecific synthesis of the (*E*)- and (*Z*)-stereoisomers of (6*R*)-3,9-dimethyl-6-(2-propenyl)deca-3,9-dien-1-yl propionate **94** — the components of the sex pheromone of the white peach scale (*Pseudaulacaspis pentagona*).[106] In the synthesis of the pheromone component having the (*E*)-configuration (*E*)-**94**, the product of the methylenation of the ketoacetal **77** and subsequent hydrolysis (the dienal **91**) was converted by means of a modified Wittig reaction via the intermediate betaine **92** into the trisubstituted alkene pheromone precursor **93** (*E* ⩾ 97%). The deprotonation of the betaine **95**, generated from ethylidenetriphenylphosphorane and the chiral

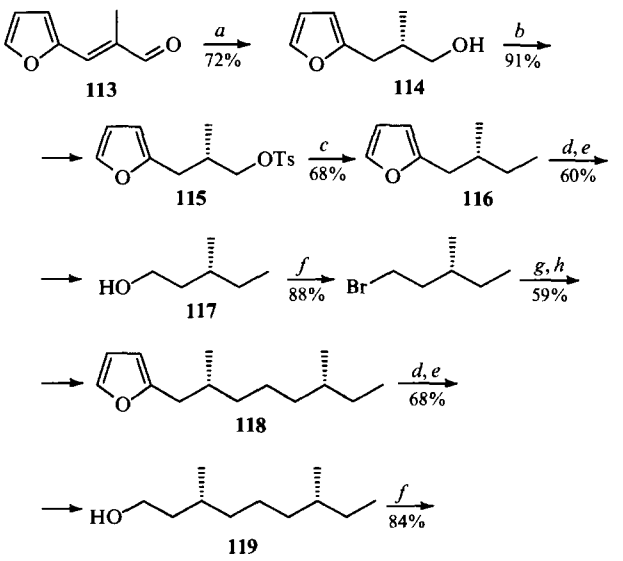
(*a*) $CH_2{=}PPh_3$; (*b*) H_3O^+; (*c*) $THPO(CH_2)_2CH{=}PPh_3$; (*d*) BuLi; (*e*) MeI; (*f*) $MeCH{=}PPh_3$; (*g*)  ; (*h*) EtCOCl–Et_3N.



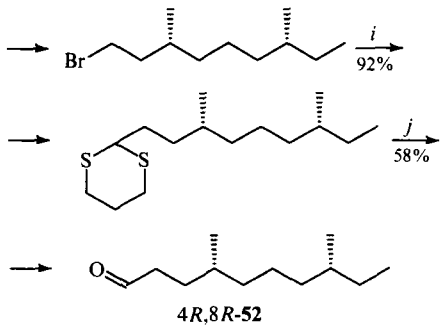
aldehyde **91**, and treatment of the resulting anion with epoxyethane led to the (*Z*)-homoallyl alcohol **96**, which was converted into the target pheromone component with the (*Z*)-configuration (*Z*)-**94**, in which the content of the principal stereoisomer was ⩾98%.

Dihydrocarvone **97** proved convenient for the synthesis of (3*S*,6*R*)-3-methyl-6-(2-propenyl)dec-9-en-1-yl acetate **105** — the sex pheromone of the California red scale (*Aonidiella aurantii*).[107] In order to open the ring in the cyclic ketone **97**, the latter was converted into the silyl enol ether **98**, the ozonolysis of which afforded the hydroxyester **99**. The iodo-derivative **102** was obtained via the bromoester **100** and bromohydrin **101** stages by coupling with allylmagnesium chloride and by the replacement of the alcoholic functional group by the halogen. Conversion into a higher homologue (by reaction with cyanide) and transformation of the functional group led to the target pheromone **105**.

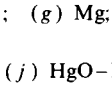
(*a*) LDA; (*b*) Me_3SiCl; (*c*) O_3–MeOH–CH_2Cl_2; (*d*) $NaBH_4$; (*e*) CH_2N_2; (*f*) MsCl–Py; (*g*) Bu_4NBr; (*h*) DIBALH; (*i*) $H_2C{=}CHCH_2MgCl$–CuI; (*j*) $I_2 \cdot PPh_3$; (*k*) NaCN; (*l*) NaOH; (*m*) $LiAlH_4$; (*n*) Ac_2O–Py.



It has been established[108] that the ozonolysis of caryophyllene **106** takes place preferentially at the endocyclic double bond. On treatment with an equimolar amount of ozone and subsequent reduction of the peroxide ozonolysis products, the dicarbonyl derivative **107** was obtained, whereas exhaustive ozonolysis leads to the tricarbonylcyclobutane derivative **108**. The reduction of the keto- and diketoaldehydes **107** and **108** with sodium tetrahydroborate affords the di- and tri-hydroxy-*trans*-alkylcyclobutanes **110** and **111** respectively. The hydrolytic cleavage of the peroxide products of the partial ozonolysis of caryophyllene leads to the ketoacid **109**, the subsequent ozonolysis of which leads to the carboxylic deketoacid **112**.

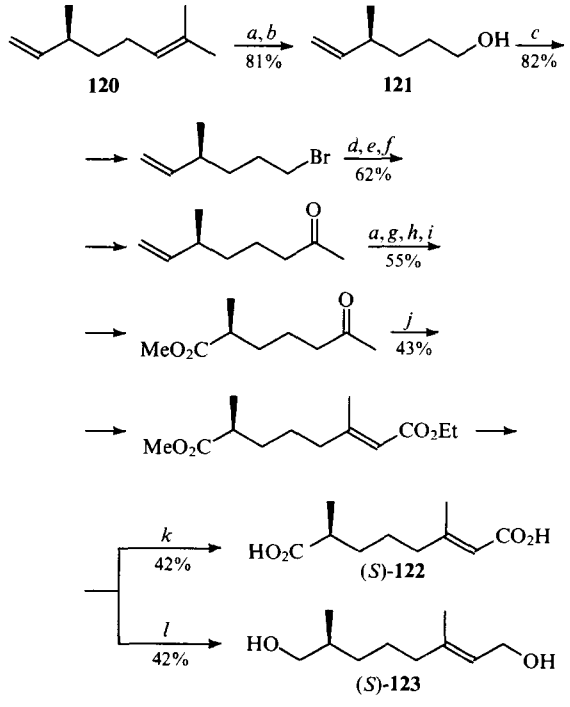


(*a*) O_3–MeOH; (*b*) H_2–Pd–$CaCO_3$–PbO; (*c*) excess O_3–MeOH; (*d*) O_3–cyclo-C_6H_{12}–AcOH; (*e*) AcONa–AcOH–Ac_2O; (*f*) $NaBH_4$.



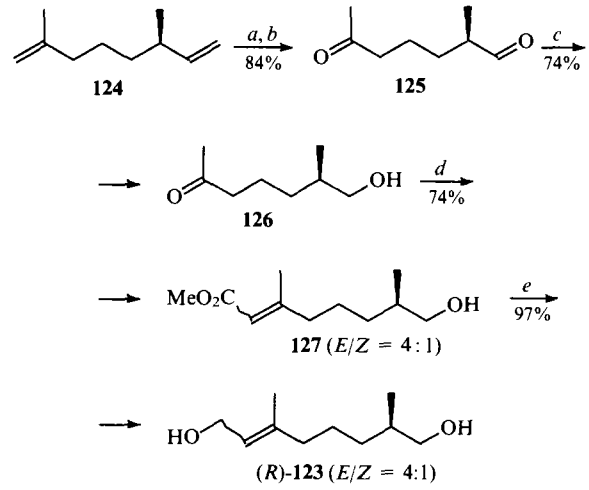
Laboratory biological tests on the cyclobutane derivatives synthesised demonstrated the likely usefulness of the search for analogues of juvenile hormones among compounds of this series.

The natural aggregation pheromone of the confused and red flour beetles (*Tribolium confusum* and *Tribolium castaneum*), namely (4*R*,8*R*)-4,8-dimethyldecanal **52**, has been synthesised from 3-(2-furyl)-2-methylacrolein **113** by means of enzymic reduction.[109] The optical purity of the resulting alcohol **114** was ⩾99%. Other key stages of this synthesis employed the ozonolysis of the 2-substituted furans **116** and **118** (obtained by alkylating the tosylate **115**), which led to the optically active alcohols **117** and **119** respectively.



4*R*,8*R*-**52**

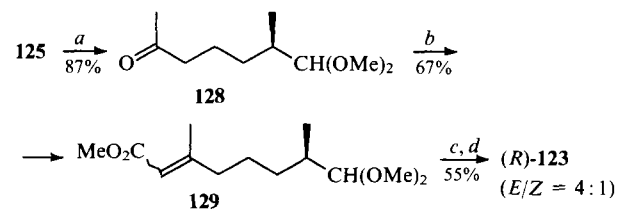
(*a*) baker's yeast; (*b*) TsCl–Py; (*c*) MeMgI–Li_2CuCl_4; (*d*) O_3; (*e*) $LiAlH_4$; (*f*) NBS–PPh_3; (*g*) Mg; (*h*) **115**–Li_2CuCl_4; (*i*)  –BuLi; (*j*) HgO–$BF_3 \cdot OEt_2$.



The enantiomerically enriched alcohol **121** has been synthesised from (*S*)-(+)-dihydromyrcene **120** by means of ozonolysis, which involves preferentially the trisubstituted double bond. The alcohol **121** was subjected to selective transformations leading to the unsaturated dicarboxylic acid **122** and the diol **123**—the pheromone components of the Chinese bean weevil (*Callosobruchus chinesis*) and the monarch butterfly respectively.[110]

120 **121** (*S*)-**122** (*S*)-**123**

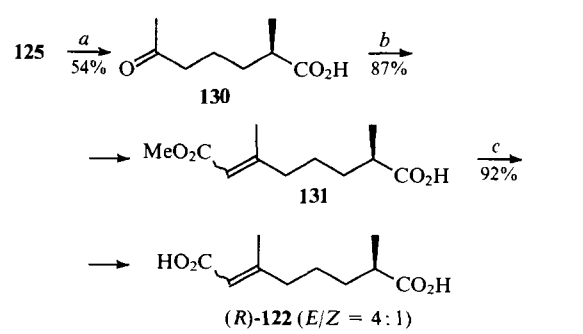
(*a*) O_3–$NaHCO_3$–CH_2Cl_2–MeOH; (*b*) $NaBH_4$; (*c*) PBr_3–Py; (*d*) Mg; (*e*) MeCHO; (*f*) PCC; (*g*) H_2–Pd–$CaCO_3$–PbO; (*h*) Ag_2O; (*i*) CH_2N_2; (*j*) $(MeO)_2P(O)CH_2CO_2Et$–EtONa; (*k*) NaOH; (*l*) DIBALH.



The initial chiral structural block in the syntheses of the (*R*)- and (*S*)-enantiomers of (2*E*)-3,7-dimethyloct-2-ene-1,8-diol **123** (the product secreted by the monarch butterfly) and (2*E*)-3,7-dimethyloct-2-ene-1,8-dicarboxylic acid **122** (the sex pheromone of *Callosobruchus chinesis*) is 2,6-dimethyloctadiene **124** (regioisomeric with respect to dihydromyrcene **120**) with the corresponding (*R*)- or (*S*)-configuration.[111] The schemes presented here indicate the transformations of the (*R*)-enantiomers of the diene **124**, the ozonolysis of which led to the chiral ketoaldehyde **125**. The carbonyl groups in the latter were differentiated (for the subsequent selective conversion into alkene groups) in two ways: by the selective hydride reduction of the aldehyde group, yielding the hydroxyketone **126**, or by blocking the aldehyde group, which leads to the ketoacetal **128**. The involvement of the hydroxyketone **126** in the Wittig–Horner reaction with trimethyl phosphonoacetate gave a mixture of the geometrical isomers of the hydroxyester **127** with respect to the Δ^2-double bond; reduction with lithium tetrahydroaluminate led to the corresponding mixture of the (*E*)- and (*Z*)-diols (*R*)-**123**.

124 **125** **126** **127** (*E*/*Z* = 4:1) (*R*)-**123** (*E*/*Z* = 4:1)

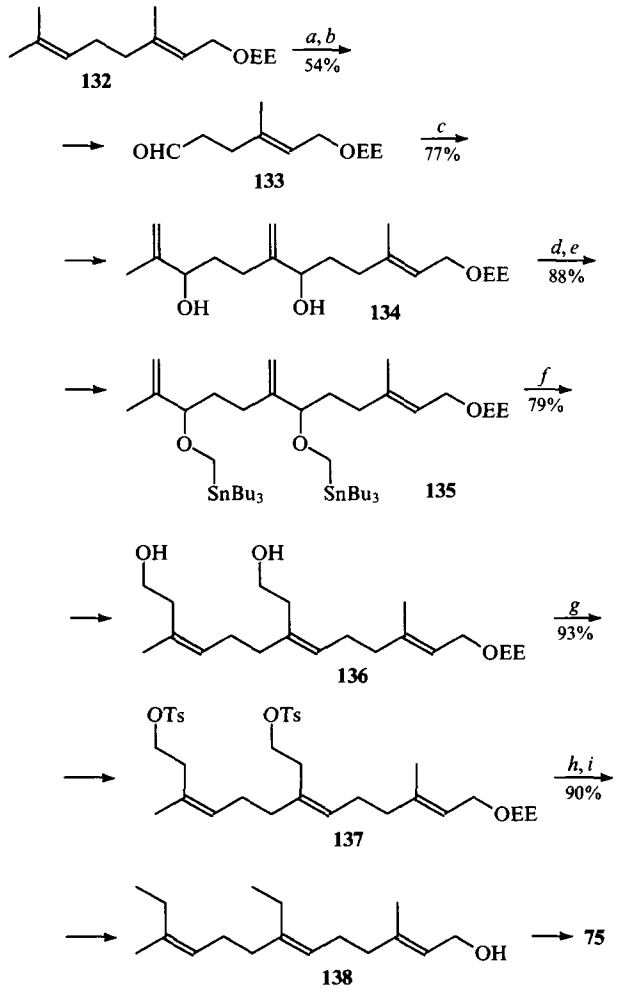
(*a*) O_3; (*b*) Me_2S; (*c*) $NaBH_4$; (*d*) $(MeO)_2P(O)CH_2CO_2Et$–NaH; (*e*) $LiAlH_4$.



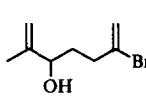
The transformation of the ketoacetal **128** into the diol (*R*)-**123** involved the Wittig–Horner reaction, which led to a mixture of the (*E*)- and (*Z*)-isomeric esters **129**. The deblocking of the aldehyde group and subsequent hydride reduction afforded a mixture of the (*E*)- and (*Z*)-isomers of the diol (*R*)-**123**.

128 **129**

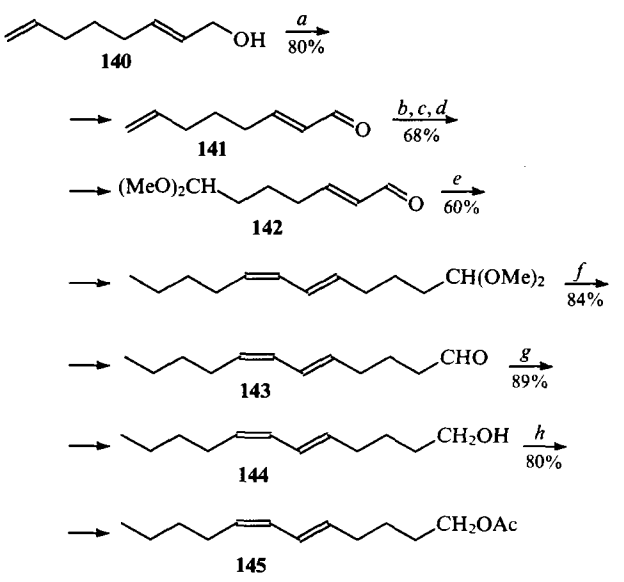
(*a*) MeOH–TsOH; (*b*) $(MeO)_2P(O)CH_2CO_2Me$–NaH; (*c*) HCO_2H–H_2O; (*d*) $LiAlH_4$.



The synthesis of (*Z*,*E*)-(7*R*)-3,7-dimethyloct-2-ene-1,8-dioic acid (*R*)-**122** involves the oxidation of the aldehyde group in the ketoaldehyde **125** and the Wittig–Horner coupling of the ketoacid **130** with trimethyl phosphonoacetate, which leads to the monoester **131** in the form of a mixture of the (*E*)- and (*Z*)-isomers.[111]

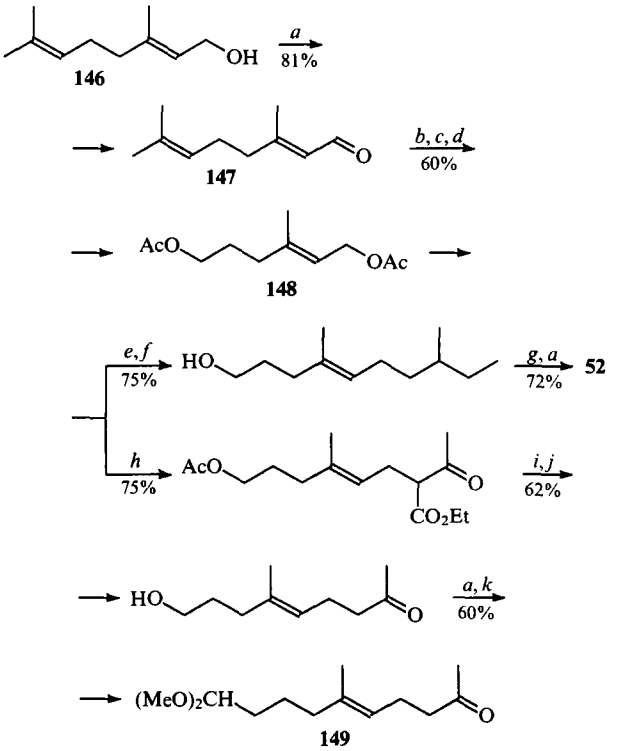


130 **131** (*R*)-**122** (*E*/*Z* = 4:1)



(*a*) $AgNO_3$–EtOH–H_2O; (*b*) $(MeO)_2P(O)CH_2CO_2Et$–NaH; (*c*) NaOH.

A highly stereoselective method of synthesis of bishomofarnesol **138** — an intermediate in the synthesis of the juvenile hormone YuG-1 **75** — has been achieved by means of the partial ozonolysis of the ethoxyethyl (EE) derivative of geraniol **132** at the isopropylidene group. The interaction of the resulting aldehyde **133** with the dianion derived from the diene bromohydrin **139** yields the monosubstituted trisallyl alcohol **134**; its distannyl derivative **135** is converted by means of a 2,3-sigmatropic rearrangement with high (*E*)-stereoselectivity into the bishomoallyl alcohol **136** and further, via the corresponding ditosylate **137**, into the target trienol **138**.[112]

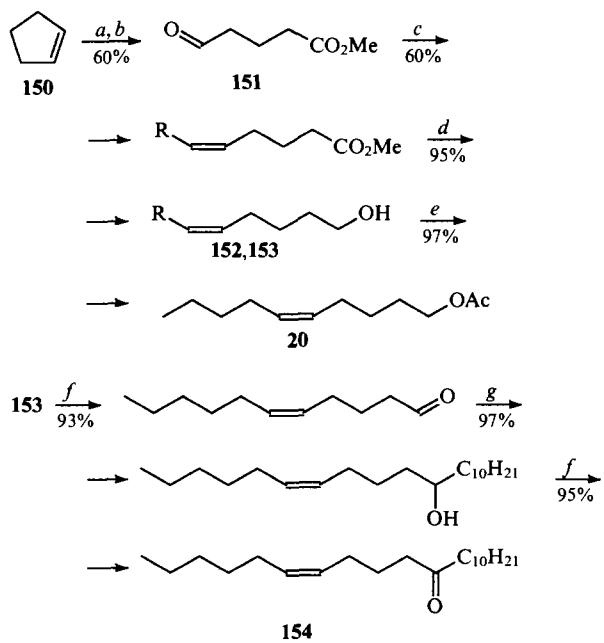


(*a*) O_3–CH_2Cl_2–Py; (*b*) Zn; (*c*)  Br (**139**) + BuLi;
(*d*) KH; (*e*) Bu_3SnCH_2I; (*f*) BuLi; (*g*) TsCl–Py; (*h*) $LiAlH_4$; (*i*) AcOH–H_2O.

An isolated double bond is known to have a reactivity an order of magnitude higher towards ozone than a double bond conjugated with the aldehyde group. This enabled us to expand the possibilities, discovered previously,[113] for the preparative application of the partial ozonolysis of acyclic polyenes as a method of synthesis of bifunctional unsaturated compounds. It was established[114] that (2*E*)-2,7-octadienal **141**, which can be readily obtained from the telomer **140** of butadiene and water, is converted into (2*E*)-7,7-dimethoxyhept-2-enal **142** in a satisfactory yield on interaction with ozone. The target compounds — (5*E*, 7*Z*)-5,7-dodecadienal **143** and the corresponding alcohol **144** and acetate **145** [the components of the sex pheromone of the lackey moth (*Malacosoma neustria* L.)] — were synthesised from compound **142**.

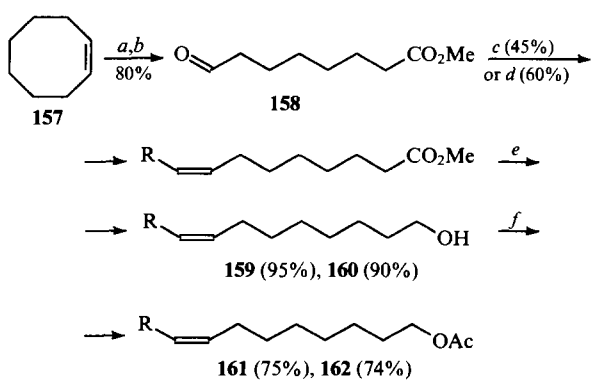
(*a*) PCC; (*b*) O_3–cyclo-C_6H_{12}–MeOH; (*c*) Me_2S; (*d*) MeOH–NH_4Cl; (*e*) $HO_2C(CH_2)_4PPh_3Br$, $NaN(SiMe_3)_2$; (*f*) H_2SO_4–MeOH; (*g*) $LiAlH_4$; (*h*) AcCl–Py.

(2*E*)-1,6-Diacetoxy-3-methylhex-2-ene **148** has been obtained by the partial ozonolysis of (2*E*)-3,7-dimethylocta-2,6-dienal **147** (the product of the oxidation of geraniol **146**) at the isopropylidene group. The aggregation pheromone **52** of the confused and red flour beetles and (4*E*)-1,1-dimethoxy-4-methylnon-4-en-8-one **149** — the intermediate for the synthesis of the components of the sex pheromone of the danaid butterflies (*Danaus plexippus* and *Danaus chrysippus*) — were synthesised from compound **148**.[114]



(*a*) PCC; (*b*) O_3–cyclo-C_6H_{12}–MeOH; (*c*) $NaBH_4$; (*d*) Ac_2O–Py; (*e*) EtCH(Me)CH_2Br–Mg–CuI; (*f*) KOH–MeOH; (*g*) H_2–Pd/C; (*h*) $MeCOCH_2CO_2Et$–NaH–$Pd(OAc)_2$–PPh_3; (*i*) NaOH; (*j*) H_2SO_4; (*k*) MeOH–NH_4Cl.

The decisive stages in these syntheses were the catalytic cross-coupling reactions between the diacetate **148** and the corresponding organomagnesium and organosodium reagents, which take place regio- and stereo-specifically with respect to the allylic acetoxy-group.

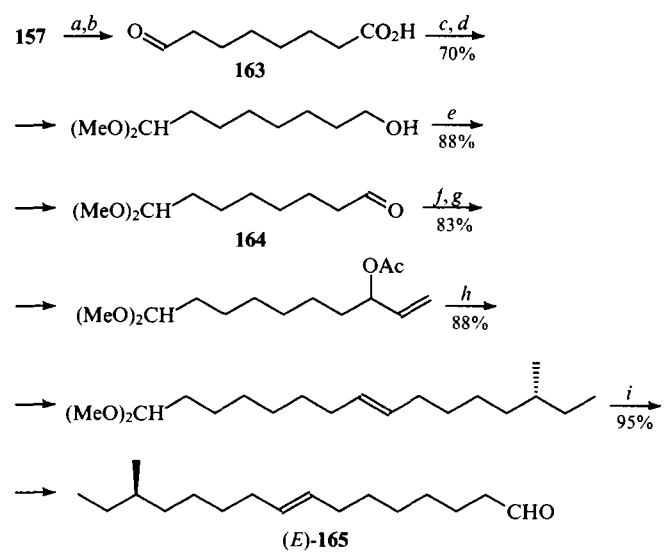


III. Synthesis of pheromones and juvenoids from the ozonolysis products of cyclic and acyclic alkenes

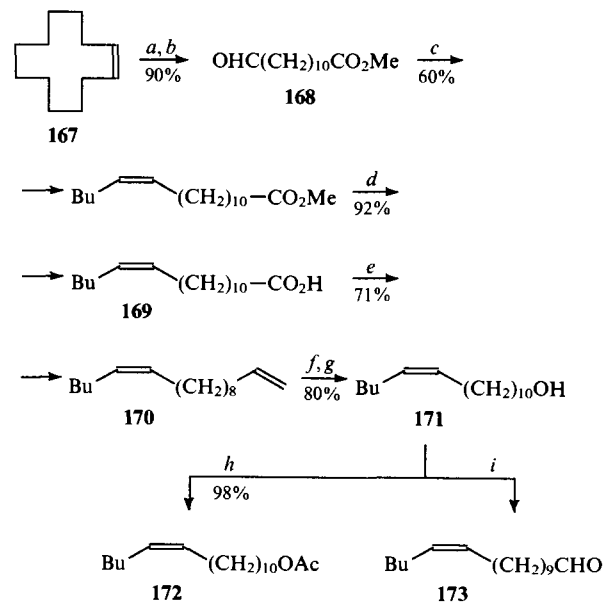
The ozonolysis of monoenes leads to saturated oxygen-containing compounds which are of interest for the synthesis of pheromones and juvenoids. Thus (5*Z*)-dec-5-enol **152** and (5*Z*)-undec-5-enol **153** have been synthesised from methyl 5-oxopentanoate **151** — the product of the functionally differentiated ozonolysis of cyclopentene **150**.[115] The acetate **20** of compound **151** is part of the composition of the pheromones of insects belonging to the genus *Agrotis*. (6*Z*)-Heneicos-6-en-11-one **154** — the sex pheromone of the tussock moth of the genus *Orgyia* which are pests on conifer forests — have been synthesised from compound **153**.

R = Bu (**152**, **155**), n-C_5H_{11} (**153**, **156**).

(*a*) O_3–$NaHCO_3$–CH_2Cl_2–MeOH; (*b*) Ac_2O–Et_3N; (*c*) RCH=PPh_3 (**155**, **156**); (*d*) DIBALH; (*e*) Ac_2O–Py; (*f*) PCC; (*g*) n-$C_{10}H_{21}MgBr$.



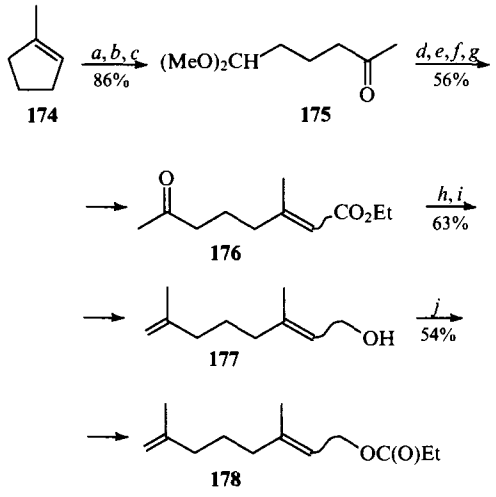
R = Pr (**159**, **161**), n-C_5H_{11} (**160**, **162**).



(*a*) O_3–$NaHCO_3$–CH_2Cl_2–MeOH; (*b*) Ac_2O–Py; (*c*) PrCH=PPh_3; (*d*) n-$C_5H_{11}CH$=PPh_3; (*e*) DIBALH; (*f*) Ac_2O–Py.

The ozonolysis of cyclooctane **157** under the conditions described by Odinokov et al.[115] led to a high yield of methyl 8-oxooctanoate **158**, which was used in the Wittig reaction with n-alkylidenetriphenylphosphoranes. This led to the discovery of a simple path to insect pheromones having the structure of (*Z*)-alk-8-enols **159** and **160** and their acetates **161** and **162**.[116]

In the synthesis of the optically active component (*E*)-**165** of the aggregation pheromone of the khapra beetle (*Trogoderma granarium*), the product of the ozonolysis of cyclooctene **157** and of the hydrolytic cleavage of the peroxide ozonolysis product — the aldehydoacid **163** — was converted in three stages into the monoacetal **164**, which reacted with the chiral bromo-derivative **166** obtained from dihydromyrcene **120**.[117]



(*a*) O_3–cyclo-C_6H_{12}–AcOH; (*b*) AcONa–AcOH–Ac_2O; (*c*) TsOH–MeOH; (*d*) DIBALH; (*e*) PCC; (*f*) H_2C=CHMgBr; (*g*) Ac_2O; (*h*)  (**166**) + Mg + CuI; (*i*) PPTS–H_2O.

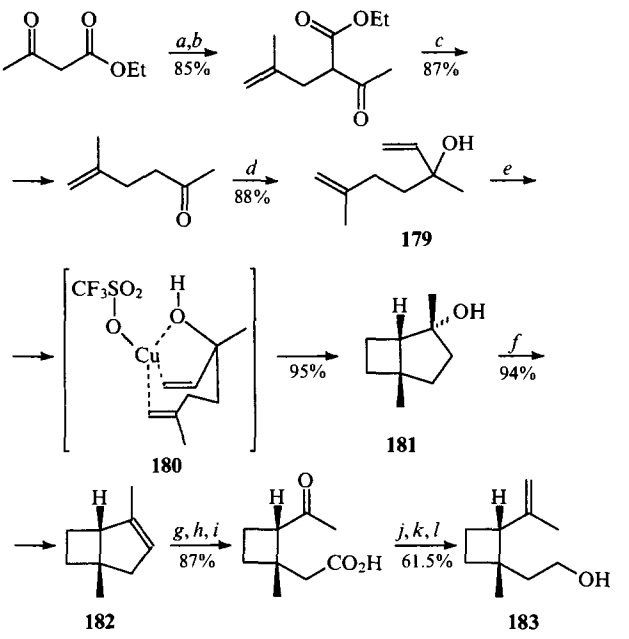
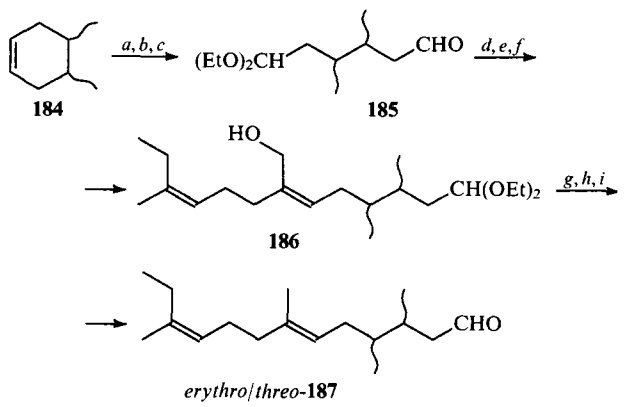
Methyl 12-oxododecanoate **168**, obtained by the ozonolysis of cyclododecene **167**, has been used to synthesise (11*Z*)-hexadec-11-en-1-ol **171**, its acetate **172**, and (11*Z*)-hexadec-11-enal **173** — the components of the sex pheromone of the noctuid moths belonging to the genera *Mamestra* and *Heliothis*. The key stages in this synthesis[118] are the Wittig conversion of the aldehyde **168** into an alkene, oxidative decarboxylation of the acid **169**, and selective hydroboration of the diene **170** at the terminal double bond.



The ketoester **176** has been synthesised by the ozonolysis of 1-methylcyclopent-1-ene **174** and subsequent selective transformations of 1,1-dimethoxy-5-oxo-hexane **175**, including the conversion of the keto-group into an ethoxycarbonylalkene group and the alkylation of the formyl group by methylmagnesium iodide followed by oxidation. Compound **176** was converted in two stages into 3,7-dimethylocta-2,7-dien-1-ol **177** (isomer ratio $E/Z = 85 : 15$), the propionate **178** of which is a component of the sex pheromone of the San Jose scale *Quadraspidiotus perniciosus*.[119]

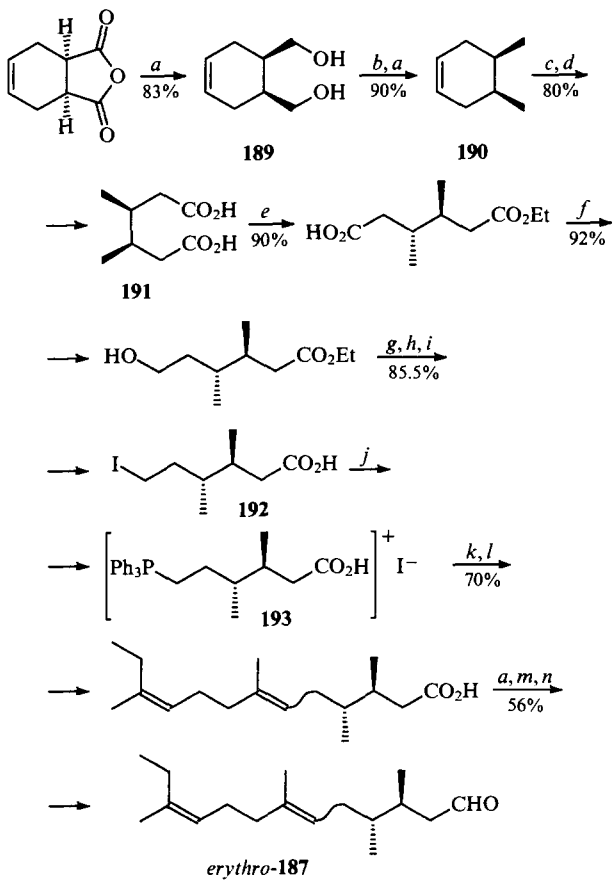


(*a*) O_3–MeOH; (*b*) H_2–Pd–$CaCO_3$–PbO; (*c*) MeOH–NH_4Cl; (*d*) $Me_3SiCH_2CO_2Et$–LDA; (*e*) PPTS–H_2O; (*f*) MeMgI; (*g*) PCC; (*h*) CH_2Br_2–$TiCl_4$–Zn; (*i*) $LiAl(OBu^t)H_3$; (*j*) EtCOCl–Et_3N.

Application of the copper-salt-catalysed 2π + 2π photocycloaddition reaction to terminal 1,6-dienes leads to photobicyclisation products, which has been used in the synthesis of grandisol **183** — the sex pheromone of the cotton-boll weevil (*Anthonomus grandis*).[120] It has been suggested[121] that, in the presence of copper trifluoromethanesulfonate, the dienol **179** gives rise to the tridentate complex **180**, which ensures the stereoselective formation of the bicyclic compound **181**. The latter is readily converted subsequently into the target pheromone **183** by ozonolysis of the product of its regioselective dehydration — the bicyclene **182**.

erythro-(3*S*,4*R*,6*E*,10*Z*)-3,4,7,11-Tetramethyltrideca-6,10-dienal (pharanal) **187** has been identified as the pheromone of the pharaoh ant (*Monomorium pharaonis L.*), which is a carrier of pathogenic bacteria. Several methods have been developed for the synthesis of racemic analogues of pharanal on the basis of the Wittig reaction. Thus 6,6-diethoxy-3,4-dimethylhexanol **185**, obtained by the ozonolysis of a mixture of the *cis*- and *trans*-isomers of dimethylcyclohexene **184**, was converted into an alkene by treatment with the phosphorane **188** and subsequent Cory hydroxymethylation of the intermediate; this led to the hydroxyacetal **186**, which was subsequently converted into the pheromone **187** as a mixture of the *erythro*- and *threo*-isomers.[122]

(*a*) EtONa; (*b*) $H_2C=C(Me)CH_2Cl$; (*c*) NaOH, Δ; (*d*) $H_2C=CHMgBr$; (*e*) *hν*, CuOTf; (*f*) HMPA (hexamethylphosphoramide); (*g*) O_3–AcOH; (*h*) Zn; (*i*) H_2CrO_4; (*j*) Me_3SiCH_2MgCl; (*k*) $SOCl_2$; (*l*) $LiAlH_4$.



erythro/*threo*-**187**

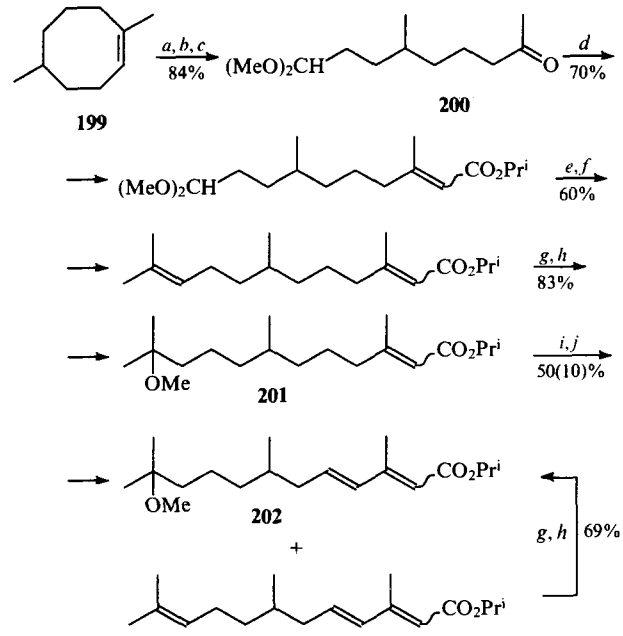
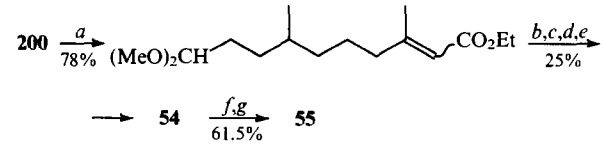
The racemic *erythro*-(3*SR*,4*RS*)-pharanal was synthesised from *cis*-1,2,3,6-tetrahydrophthalic anhydride, which was converted into *cis*-4,5-dimethylcyclohexene **190** via the diol **189**. This cycloalkene was converted by ozonolysis into *erythro*-3,4-dimethyladipic acid **191** and further, via the iodo-derivative **192**, into the phosphonium salt **193**. Coupling of the phosphorane generated from the salt **193** with the ketone **194** yielded an aldehyde with the *erythro*-configuration in the form of a mixture of Δ^6-Z/E-isomers (46 : 54); *erythro*-pharanal **187** was isolated from the latter by preparative gas–liquid chromatography (GLC).[123]

Methods of synthesis of a series of insect pheromones having the structure of unsaturated alcohol acetates have been developed on the basis of the products of reductive ring opening of the ozonides of the alkyl ethers of the enolic form of cycloheptanone.[124,125] Thus the aldehydoester **197**, obtained from 1-methoxycycloheptene **196**, was made to undergo an (*E*)-stereoselective alkene formation reaction (by treatment with formylmethylidenetriphenylphosphorane) and the product was then



(*a*) $LiAlH_4$; (*b*) MsCl–Py; (*c*) O_3; (*d*) H_2CrO_4; (*e*) EtOH–H_2SO_4; (*f*) B_2H_6; (*g*) TsCl–Py; (*h*) NaI; (*i*) KOH; (*j*) PPh_3; (*k*) NaH; (*l*)  (**194**); (*m*) PCC; (*n*) preparative GLC.

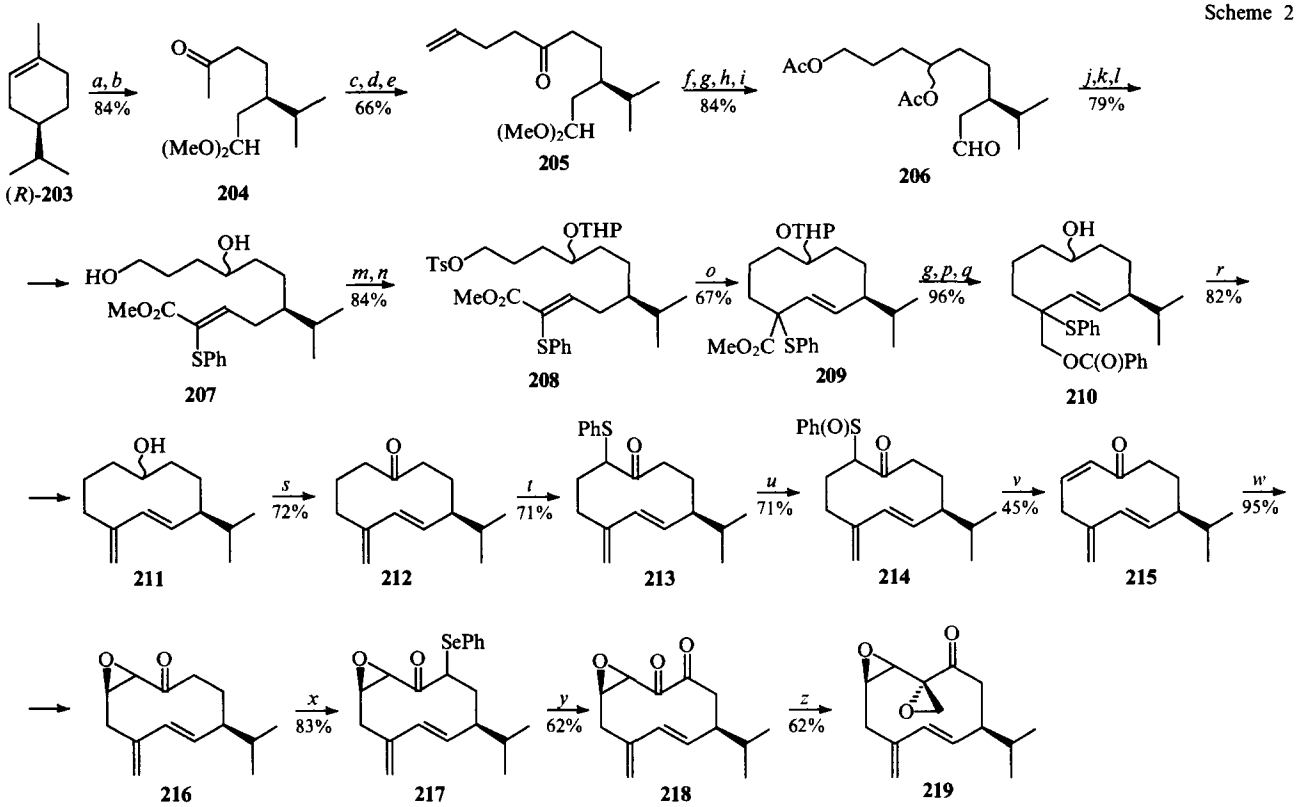
converted by means of a (*Z*)-stereoselective alkene formation reaction (by treatment with propylidenetriphenylphosphorane) into the pheromone **198** of the grape leafcurler (*Lobesia botrana*) containing 92% of the principal stereoisomer.[125]



(*a*) O_3–PPh_3–CH_2Cl_2; (*b*) OHC–CH=PPh_3; (*c*) EtCH=PPh_3; (*d*) $LiAlH_4$; (*e*) Ac_2O–Py.

The isopropyl ester of (2*E*)-11-methoxy-3,7,11-trimethyldodec-2-enoic acid **201** has been obtained by the ozonolysis of 1,5-dimethylcyclooct-1-ene **199** and the subsequent transformations of the ketoacetal **200**, including isopropoxycarbonylmethyleneation at the keto-group and then conversion of the aldehyde group into an alkene component by treatment with isopropylidenetriphenylphosphorane and methoxylation of the isopropylidene group.[126] The allylic bromination of compound **201** and subsequent dehydrobromination led to the familiar juvenoid methoprene **202** in the form of an 82:18 mixture of the (2*E*,4*E*)- and (2*Z*,4*Z*)-isomers.

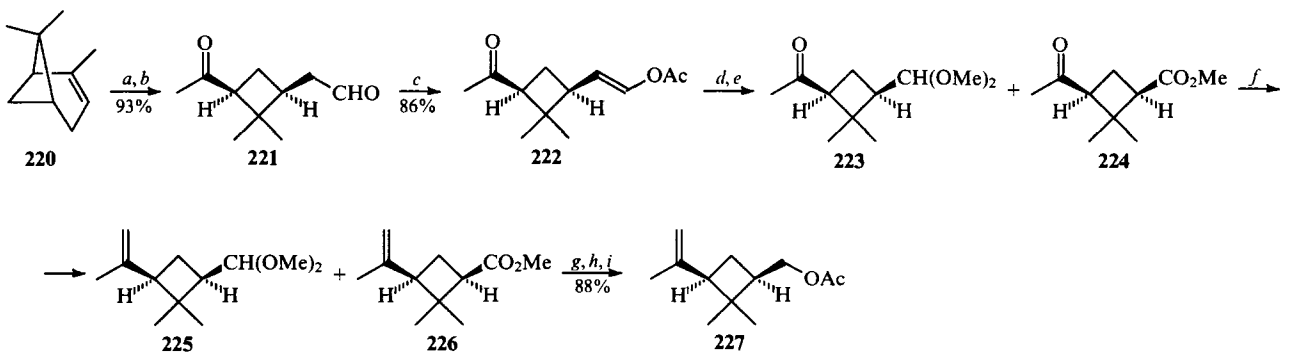
(*a*) O_3–MeOH; (*b*) H_2–Pd/$CaCO_3$–PbO; (*c*) MeOH–NH_4Cl; (*d*) $Me_3SiCH_2CO_2Pr^i$–LDA; (*e*) PPTS–H_2O; (*f*) Me_2C=PPh_3; (*g*) $Hg(OAc)_2$–MeOH; (*h*) $NaBH_4$–NaOH; (*i*) NBS–$(PhCO_2)_2$; (*j*) LiBr–Li_2CO_3.



Hydroprene **55** has been obtained in the form of a 77:23 mixture of the (2*E*,4*E*)- and (2*Z*,4*E*)-isomers by the selective transformations of the ketoacetal **200**, including the ethoxycarbonylmethylenation of the keto-group, alkylation of the formyl group by isopropylmagnesium bromide with subsequent deoxygenation, and allylic bromination-dehydrobromination.[98]

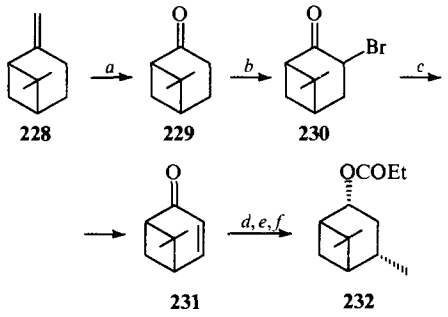
(*a*) $Me_3SiCH_2CO_2Et$–LDA; (*b*) PPTS–H_2O; (*c*) Pr^iMgBr; (*d*) TsCl–Py; (*e*) Zn–NaI; (*f*) NBS–$(PhCO_2)_2$; (*g*) LiBr–Li_2CO_3

(+)-Dihydrolimonene (*R*)-**203** has served as the source of one of the chiral centres in the synthesis of (–)-periplanone B **219**—the sex pheromone of the American cockroach (*Periplaneta americana*).[127–129] The synthesis (Scheme 2) begins with the ozonolysis of the terpene (*R*)-**203** and the subsequent selective protection of the aldehyde group. The interaction of the carbanion generated from the dimethyl acetal of the ketoaldehyde **204** with allyl bromide led to the product **205**. Oxidative cleavage of the double bond in the latter, the subsequent reduction of the intermediate ketoaldehyde, and the acetylation and deblocking of the carbonyl group led to the aldehyde **206**. The latter was converted into the diol **207** by condensation with the carbanion generated from methyl benzenesulfonylacetate and subsequent dehydration and hydrolysis. The tosylation of the primary alcoholic group of the latter, accompanied by the blocking of the secondary hydroxy-group, afforded compound **208**, the deprotonation of which led to cyclisation. The product **209** was converted in several stages into the dienol **211** with endocyclic and exocyclic conjugated double bonds. The oxidation of the dienol **211** to the corresponding ketone **212** and its



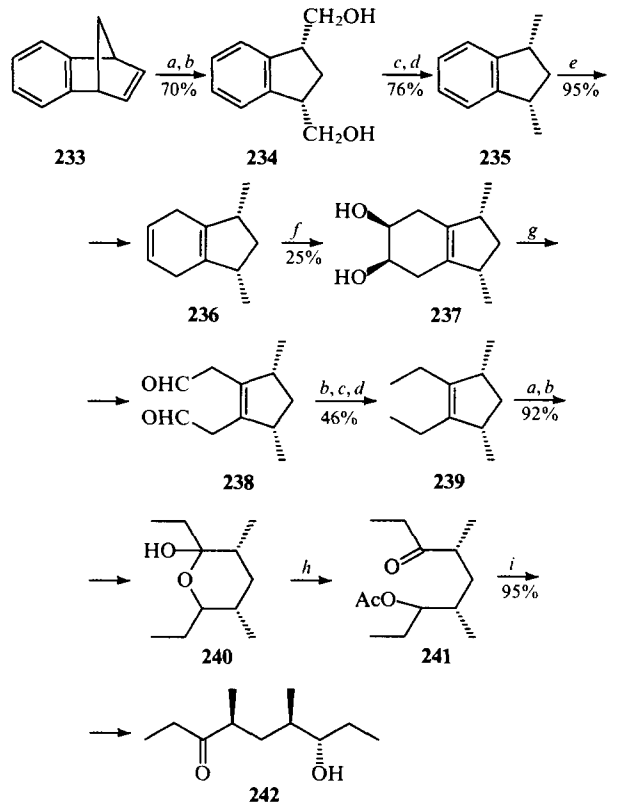
Scheme 2

(*a*) O_3–MeOH; (*b*) Me_2S, TsOH; (*c*) $(MeO)_2CO$, NaH; (*d*) $H_2C{=}CHCH_2Br$; (*e*) KOH–MeOH; (*f*) OsO_4–$NaIO_4$; (*g*) $LiAlH_4$; (*h*) Ac_2O–Py; (*i*) HCl; (*j*) $PhSCH_2CO_2Me$–LDA; (*k*) Ac_2O–AcONa; (*l*) MeONa–MeOH; (*m*) TsCl–DMAP (4-4-dimethylaminopyridine)–Et_3N; (*n*) DHP (dihydropyran)–PPTS; (*o*) $NaN(SiMe_3)_2$; (*p*) PhCOCl–DMAP–Py; (*q*) Dowex 50W (H^+); (*r*) Na–$C_{10}H_8$ (naphthalenesodium); (*s*) PCC–NaOAc; (*t*) $PhSSO_2Ph$–$LiN(SiMe_3)_2$; (*u*) $NaIO_4$; (*v*) $CaCO_3$, 110 °C; (*w*) Bu^tOOH–KH; (*x*) PhSeBr–$LiN(SiMe_3)_2$; (*y*) H_2O_2–Ac_2O–AcONa, K_2CO_3; (*z*) $Me_2S{=}CH_2$.



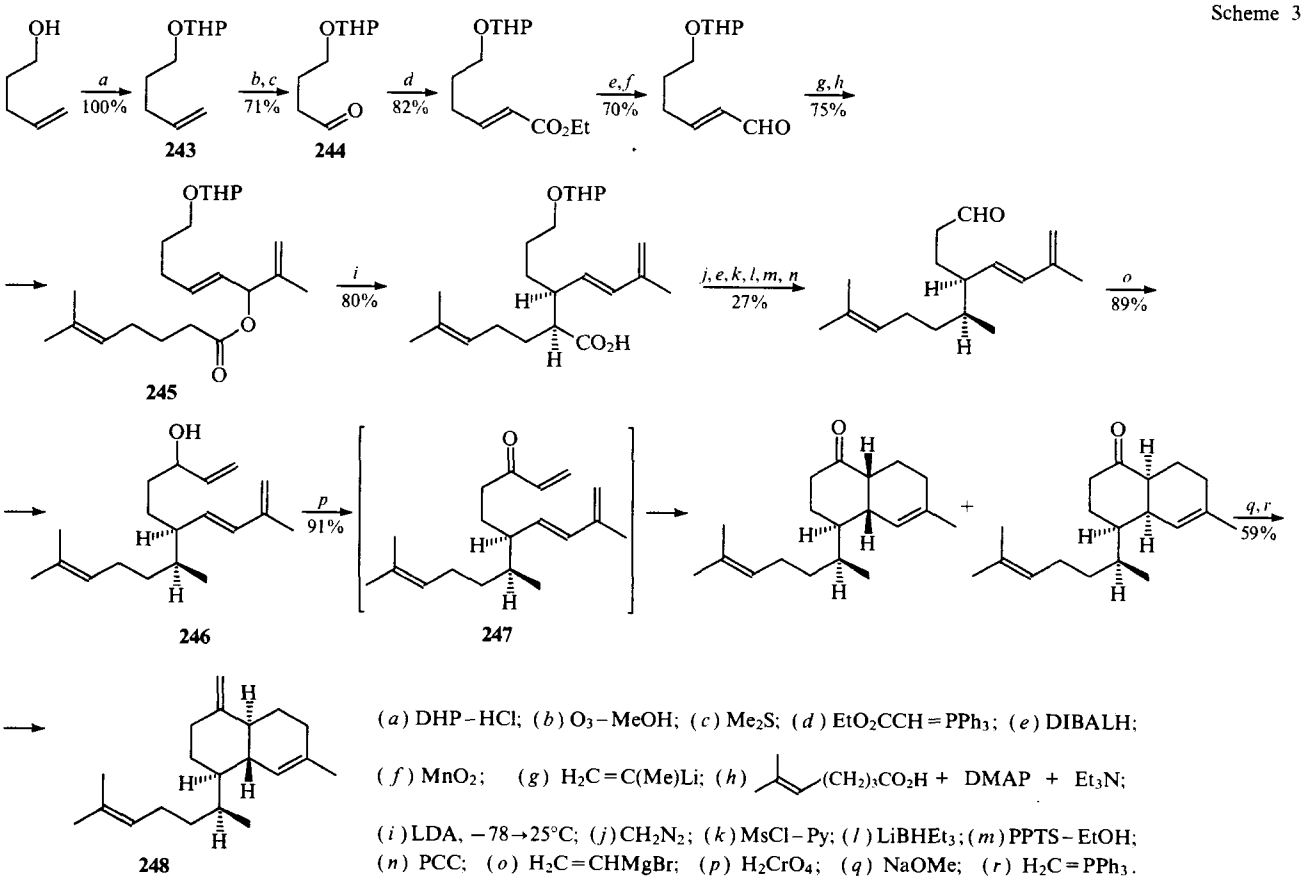
α-phenylsulfanylation afforded the sulfide **213**, which was oxidised to the sulfoxide **214**; the thermal elimination of PhSOH led to the cyclic ketotriene **215**. Its epoxidation by the *tert*-butyl hydroperoxide–base system[130] took place regioselectively with the preferential formation of the epoxide **216**. The latter was oxidised via the phenyl selenide **217** to the diketone **218**, the interaction of which with methylidenedimethyl-λ^4-sulfane took place selectively at one of the keto-groups and led to the target diepoxide **219**.

The readily available (+)-α-pinene **220** served as the initial compound for the synthesis of (+)-*cis*-(1*R*, 3*R*)-1-acetoxymethyl-3-isopropenyl-2,2-dimethylcyclobutane **227** — the sex pheromone of the grape mealybug (*Planococcus citri*).[131] The ozonolysis of compound **220** gives rise to the ketoaldehyde **221** in which the configurations of the asymmetric centres correspond to those of the natural pheromone. The necessary shortening of the side chain was achieved via the enol acetate **222** with its subsequent ozonolysis, which led to a mixture of the acetal **223** and the ester **224**. A mixture of compounds **225** and **226** was obtained by Wittig methylenation and was then converted in three stages into the acetate **227**. The optical isomer of the pheromone was synthesised in accordance with the same scheme from (–)-α-pinene.[132]



(*a*) O_3–MeOH; (*b*) H_2–Pd–$CaCO_3$–PbO; (*c*) Ac_2O–Et_3N; (*d*) O_3–SiO_2; (*e*) MeOH–TsOH; (*f*) $H_2C{=}PPh_3$; (*g*) PPTS–H_2O; (*h*) DIBALH; (*i*) Ac_2O–Py.

The product of the ozonolysis of β-pinene **228** — nopinone **229** — has found extensive application in the synthesis of insect pheromones.[133–135] For example, it is known that the bicyclic propionate **232** possesses sex pheromone activity for cockroaches. Transformation of ketone **229** gives apoverbenone **231**, converted into the sex pheromone **232** by stereoselective coupled addition of the lithium cuprate reagent and subsequent Meerwein – Ponndorf – Verley reduction of the carbonyl group.[133]



(*a*) O_3–MeOH; (*b*) Br_2; (*c*) DBU {1,8-diazabicyclo[5.4.0]undec-7-ene}; (*d*) Me_2CuLi; (*e*) $(Pr^iO)_3Al$–Pr^iOH; (*f*) $(EtCO)_2O$.

A recently developed approach[136] to the synthesis of (±)-serricornine **242** — the sex pheromone of the tobacco beetle (*Lasioderma serricorne*) — is based on the ozonolysis of benzonorbornadiene **233** to the diol **234**, which is converted via the corresponding methanesulfonate into *cis*-1,3-dimethylindane **235**. Its reduction (via the Birch reaction) gives rise to the diene **236**, the *cis*-hydroxylation of which and subsequent oxidative degradation of the resulting 1,2-diol **237** lead to the dialdehyde **238**. The latter is converted by the reduction–methanesulfonation–reduction procedure into the tetrasubstituted cyclopentene **239**. Repeated ozonolysis of compound **239** leads to the lactol **240**, which is converted into the target ketoalcohol **242** via the ketoacetate **241**.

(*a*) O_3–CH_2Cl_2; (*b*) $NaBH_4$; (*c*) MsCl–Et_3N; (*d*) $LiAlH_4$; (*e*) Li–NH_3– EtOH; (*f*) OsO_4–*N*-methylmorpholine *N*-oxide; (*g*) $Pb(OAc)_4$; (*h*) Ac_2O–DMAP; (*i*) DBU.

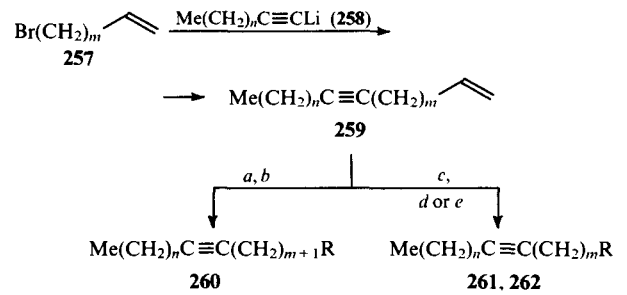
The bicyclic diterpene component of the protective secretion of termites (*Cubitermes umbratus*) (compound **248**) has been synthesised stereoselectively[137] (Scheme 3) from the product of the ozonolysis of the tetrahydropyranyl ether of pent-4-enol **243**. The key stages are the stereoselective Claisen rearrangement of the (*Z*)-enolate of the ether of the 2,8-disubstituted 1,4-dien-3-ol **245** and the spontaneous intramolecular Diels–Alder reaction of the oxidation product of the alcohol **246**.

In the majority of the syntheses of (2*E*)-9-oxodec-2-enoic acid **252** — the 'royal jelly' of honey bees (*Apis mellifera*) — the concluding stage is the condensation of 7-oxooctanal **251** with malonic acid via the Doebner reaction. An effective method has been proposed for the synthesis of the ketoaldehyde **251** on the basis of the coupling of the THP ether of 5-bromopentanol **249** with methylallyl chloride and subsequent ozonolysis of the resulting terminal alkene.[138]

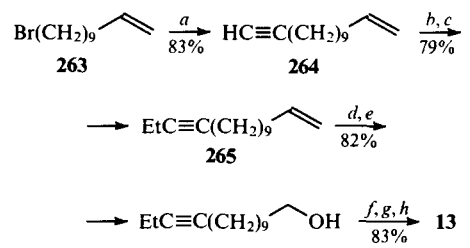
(*a*) Mg; (*b*) $H_2C=C(Me)CH_2Cl$–CuI–2,2′-bipy; (*c*) O_3–MeOH; (*d*) H_2–Pd–$CaCO_3$–PbO; (*e*) TsOH–MeOH–H_2O; (*f*) PCC; (*g*) $H_2C(CO_2H)_2$–Py–piperidine.



The synthesis of the enantiomerically enriched juvenoid hydroprene.[139] (*S*)-**55** in the form of a 7:3 mixture of the (2*E*,4*E*)- and (2*Z*,4*E*)-stereoisomers has been achieved by the selective transformations of the readily available tetrahydrogeraniol **253** [obtained from (*S*)-dihydromyrcene **120**], involving the ozonolysis of the homoallyl alcohol **255**, in the preparation of the key conjugated enone **256**.

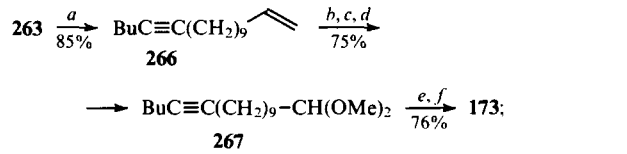
(*a*) Bu^i_3Al; (*b*) O_2; (*c*) H_2–Pd/C; (*d*) PCC; (*e*) $H_2C=C(Me)CH_2MgCl$; (*f*) O_3–CH_2Cl_2–MeOH; (*g*) Me_2S; (*h*) TsOH–Na_2SO_4; (*i*) EtMgBr–$HC\equiv COEt$; (*j*) H_2SO_4.

In the synthesis of Lepidoptera pheromones, which consist as a rule of unsaturated alcohols, acetates, and aldehydes,[35] the so called 'acetylenic' path is usually employed. It consists in the coupling of alkali metal alkynylides with alkyl halides having an oxygen-containing functional group in the ω-position; the subsequent stereoselective reduction of the triple bond affords alkenes with either (*Z*)- or (*E*)-configurations.[34,35]

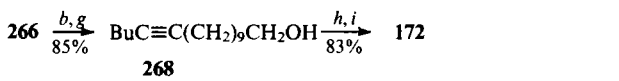


An alternative approach, based on the condensation of lithium alkynylides **258** with ω-bromoalkenes **257** and expanding significantly the synthetic possibilities of the 'acetylenic' path, has been developed recently.[140,141] The terminal double bond in the coupling product **259**, introduced with the aid of the ω-bromoalkene **257**, is smoothly transformed into the required oxygen-containing functional group. This is achieved, for example, by hydration via an organoboron intermediate to the corresponding ethyne alcohol **260** or by ozonolysis with formation (depending on the method of treatment of the peroxide product) of the alkyn-1-ol **261** or the alkynal **262** with a carbon chain shorter by one atom than in the alkenyne precursor **259**.

R = CH_2OH (**260**, **261**), CHO (**262**).

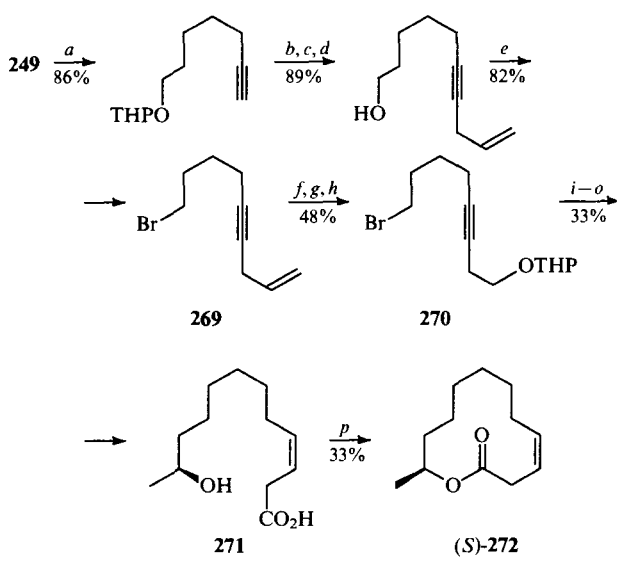


(*a*) BBN; (*b*) H_2O_2–NaOH; (*c*) O_3; (*d*) $NaBH_4$; (*e*) Me_2S.



This approach has been used in the synthesis[141] of the sex pheromone **13** of the green oak moth based on the ozonolytic cleavage of the double bond in pentadec-1-en-12-yne **265**, obtained by the ethynylation of undecenyl bromide **263** with subsequent ethylation of the terminal alkenyne **264**.

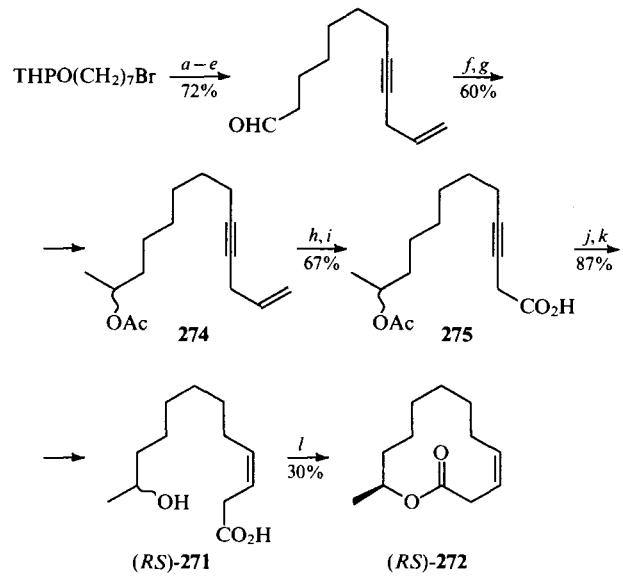
(*a*) $HC\equiv CLi$; (*b*) $LiNH_2$; (*c*) EtBr; (*d*) O_3–cyclo-C_6H_{12}–MeOH; (*e*) $NaBH_4$; (*f*) BBN; (*g*) AcOH; (*h*) Ac_2O–Py.



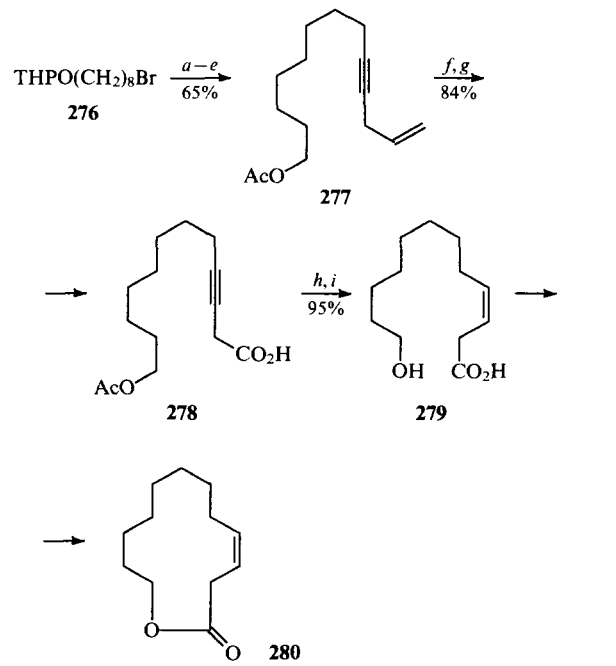
The components of the pheromones of the cabbage moth (*Mamestra brassicae*) and the cotton bollworm (*Heliothis armigera*) (compounds **172** and **173**) have been synthesised[140,141] via heptadec-1-en-12-yne **266**, obtained by the reaction of the bromo-derivative **263** with lithium hex-1-ynylide. The ozonolysis of the enyne **266** led (depending on the reductant employed) either to the alkyne acetal **267** or to the alcohol **268**, which are readily transformable into the target aldehyde **173** or the acetate **172** respectively.

(*a*) $C_4H_9C{\equiv}CLi$; (*b*) O_3–cyclo-C_6H_{12}–MeOH; (*c*) Me_2S; (*d*) MeOH–TsOH; (*e*) H_2–Pd–$CaCO_3$–PbO; (*f*) PPTS–H_2O; (*g*) $NaBH_4$; (*h*) Bu^iMgBr–Cp_2TiCl_2 (Cp = η^5-cyclopentadienyl); (*i*) Ac_2O–Py.

An effective synthesis of the optically pure (*S*)-(3*Z*)-dodec-3-en-11-olide (*S*)-**272** [ferrulactone II—a component of the aggregation pheromone of the rusty grain beetle (*Cryptolestes ferrugineus*)] is based on the macrolactonisation of the acid (*S*)-**271**, obtained by the cross-coupling of the protected bromohydroxy-derivative **270** with the optically active epoxide **273**. The ethyne C_8 block **270** was synthesised by the partial ozonolysis of the 1,4-enynyl bromide **269**—the product of the successive increase in the length of the linear chain of the precursor **249** by reaction with lithium ethynylide and allyl bromide.[142]



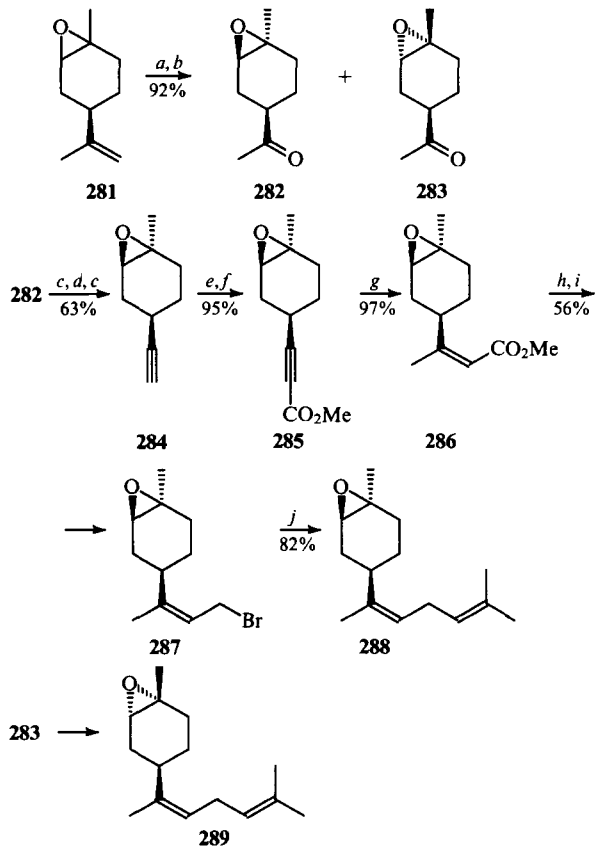
(*a*) HC≡CLi; (*b*) EtMgBr–CuI; (*c*) $H_2C{=}CHCH_2Br$; (*d*) TsOH–MeOH–H_2O; (*e*) $Br_2{\cdot}PPh_3$; (*f*) O_3–cyclo-C_6H_{12}–MeOH; (*g*) $NaBH_4$; (*h*) DHP–TsOH; (*i*) Mg, CuBr–Me_2S; (*j*)  (**273**); (*k*) Ac_2O–Py–DMAP; (*l*) PPTS–EtOH; (*m*) H_2CrO_4; (*n*) K_2CO_3–MeOH; (*o*) H_2–P2-Ni ($NaBH_4$-reduced nickel with ethylenediamine); (*p*) BPDS (2,2′-bipyridyl disulfide)–PPh_3–$AgClO_4$.



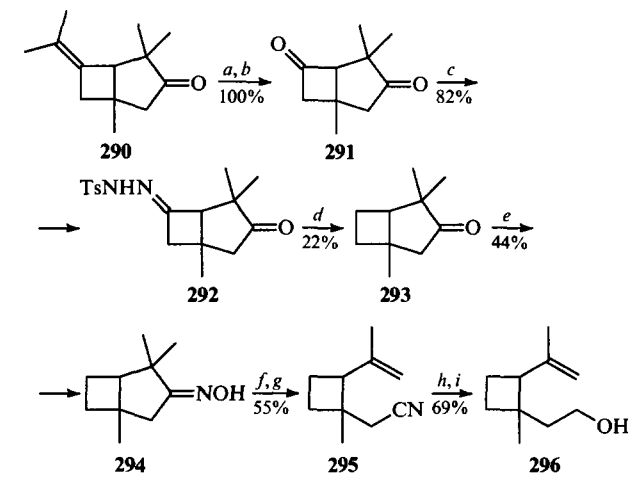
Since the racemic ferrulactone II (*RS*)-**272** is also biologically active, its synthesis is likewise of practical value. A new synthesis has been proposed[143,144] for the acyclic precursor (*RS*)-**271** of the pheromone, in which the acetoxyenyne **274** is used in one of the key stages of the selective ozonolysis. The ozonolysis involves exclusively the double bond and leads (after the oxidation of the peroxide product by the Jones reagent) to the ethyne acetoxyacid **275**, which is converted into the target macrolide (*RS*)-**272** by a standard method.

(3*Z*)-12-Hydroxydodec-3-enoic acid **279**—the acyclic precursor of (3*Z*)-dodec-3-en-12-olide **280** [a component of the aggregation pheromone of the flat grain beetle (*Cryprolestes pusillis)*] has been synthesised, by means of analogous transformations but in a smaller number of stages, from the THP ether of 8-bromooctan-1-ol **276**.

A method proposed for the synthesis of the stereoisomeric components of the sex pheromone of the southern green stink bug (*Nezara viridula*) (compounds **288** and **289**) is based on the

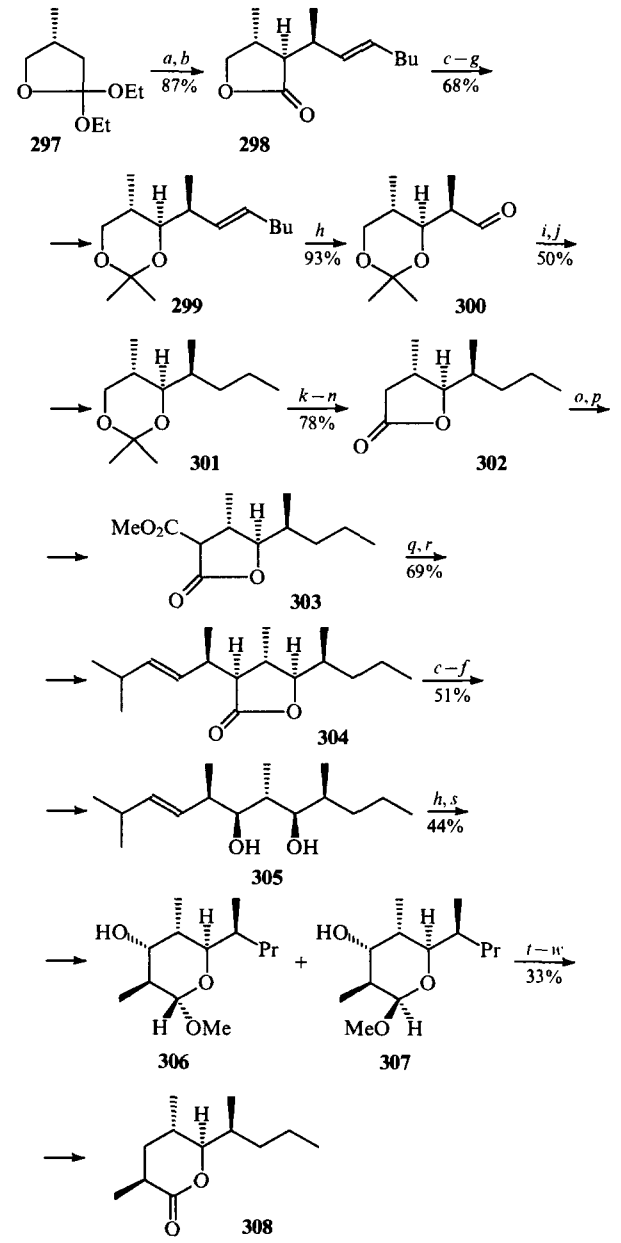


(*a*) HC≡CLi; (*b*) EtMgBr–CuI; (*c*) $H_2C{=}CHCH_2Br$; (*d*) TsOH–MeOH–H_2O; (*e*) PCC; (*f*) MeMgI; (*g*) Ac_2O; (*h*) O_3–cyclo-C_6H_{12}–MeOH; (*i*) H_2CrO_4; (*j*) K_2CO_3–MeOH; (*k*) H_2–P2-Ni; (*l*) DDS–PPh_3–$AgClO_4$.



(*a*) HC≡CLi; (*b*) EtMgBr–CuI; (*c*) $H_2C{=}CHCH_2Br$; (*d*) TsOH–MeOH–H_2O; (*e*) Ac_2O–Py; (*f*) O_3–cyclo-C_6H_{12}–AcOH; (*g*) H_2CrO_4; (*h*) K_2CO_3–MeOH; (*i*) H_2–P2-Ni.

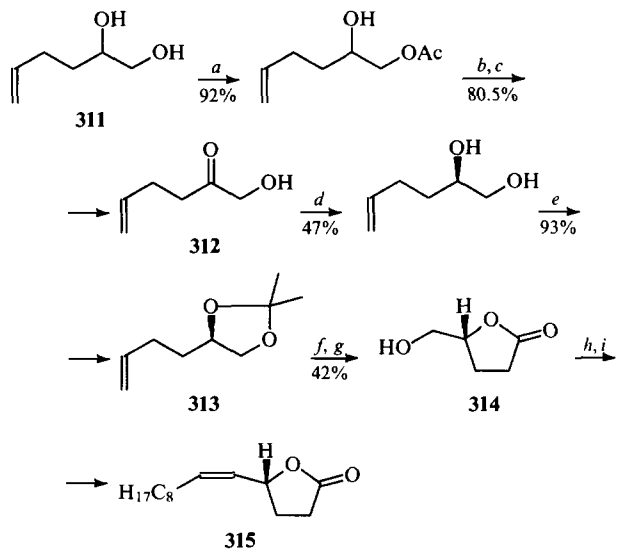
ozonolysis of (*R*)-(+)-limonene oxide **281**, which is available as an equimolar mixture of the α- and β-epoxides. The product of the reduction of the ozonide is the corresponding mixture of the ketones **282** and **283**, which was separated chromatographically. In order to obtain the component **288**, the diastereoisomer **282** was converted via the corresponding vinyl phosphate into the terminal ethyne **284** and further into the ester **285**. The regio- and stereo-specific coupled addition of dimethyllithium cuprate led to the (*Z*)-alkene **286**, which was converted into the bromide **287** via the corresponding alcohol. The target *endo*-epoxide **288** was obtained in the concluding stage—the condensation of the bromide **287** with 1-lithio-2-methylpropene. The component **289** has been synthesised similarly from the diastereoisomer **283**.[145]



(*a*) O_3; (*b*) PPh_3; (*c*) LDA; (*d*) $(EtO)_2P(O)Cl$; (*e*) BuLi; (*f*) $ClCO_2Me$; (*g*) Me_2CuLi; (*h*) DIBALH; (*i*) CBr_4-PPh_3; (*j*) $Me_2C=CHBr-Bu^tLi$.

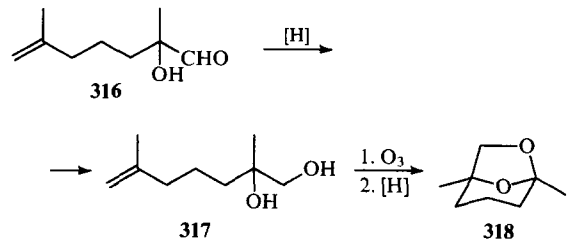
The synthesis of 1,4,4-trimethylbicyclo[3.2.0]heptan-3-one **293** — a key intermediate[146] in the synthesis of grandisol **296** [a component of the sex pheromone of the cotton-boll weevil (*Anthonomus grandis*)] — was based on the ozonolysis of the bicyclic compound **290**, which was converted quantitatively into the diketone **291** with subsequent selective reduction of one of the carbonyl groups via the corresponding tosylhydrazone **292**. The bicyclic ketone **293** was subsequently converted into the oxime **294**, in the tosylate of which regioselective fragmentation occurred on deprotonation of one of the methyl groups with the opening of the five-membered ring and the formation of the unsaturated nitrile **295**.[147] Two-stage reduction (via an intermediate aldehyde) completed the synthesis of grandisol **296**.

(*a*) $O_3-MeOH-CH_2Cl_2$; (*b*) Me_2S; (*c*) $TsNHNH_2$; (*d*) $NaBH_4$; (*e*) $H_2NOH\cdot HCl$, KOH; (*f*) TsCl–2,6-lutidine; (*g*) Py–5% NaOH; (*h*) DIBALH; (*i*) $LiAlH_4$.



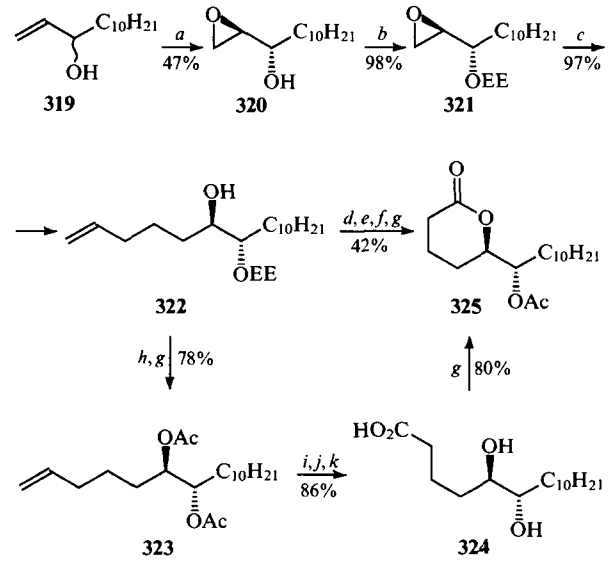
In the synthesis of (+)-invictolide **308** — the optical isomer of the pheromone of the fire ant (*Solenopsis invicta*) [developed on the basis of (*R*)-3-methyl-γ-butyrolactone], the ozonisation was effectively used in three stages.[148] In the first of these, the unsaturated ketal **299** was ozonolysed. Compound **299** was obtained from the diethylortholactone **297** by transesterification with the alcohol **309**, the Claisen rearrangement, epimerisation, the Baeyer–Villiger oxidation of the lactone **298**, and protection of the diol. The ozonolysis product — the aldehyde **300** — was converted into the unsaturated ketal **301** via alkene formation and hydrogenation stages and then into the lactone **302**. The latter was converted into the methoxycarbonyl derivative **303** and was

(*a*)  (**309**)–Me_3CCO_2H; (*b*) Bu^tOK-Bu^tOH; (*c*) MeLi; (*d*) H_2O_2-AcOH; (*e*) $Ac_2O-DMAP-Et_3N$; (*f*) KOH–MeOH; (*g*) $Me_2C(OMe)_2-TsOH$; (*h*) O_3-MeOH, Me_2S; (*i*) $MeCH=PPh_3$; (*j*) H_2–Ra-Ni; (*k*) HCl; (*l*) TsCl–Py; (*m*) NaCN; (*n*) HCl–MeOH; (*o*) LDA; (*p*) $NCCO_2Me$; (*q*) $NaH-Pd(PPh_3)_4-PPh_3$,  (**310**); (*r*) LiCl–DMSO–H_2O; (*s*) $HC(OMe)_3-TsOH$; (*t*) BuLi–PhOSCl; (*u*) Bu_3SnH–AIBN (azobisisobutyronitrile); (*v*) O_3–EtOAc; (*w*) $TsOH-CH_2Cl_2$.



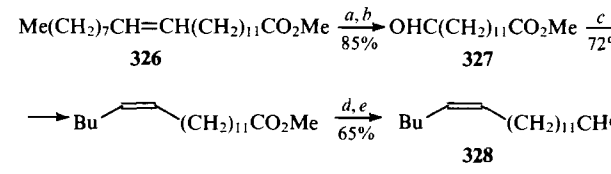
alkylated by the allyl phosphate **310** with subsequent demethoxycarbonylation; this led to the unsaturated lactone **304**, which was oxidised, by a procedure similar to that used for the oxidation of compound **298**, to the diol **305**. Its ozonisation, followed by treatment of the peroxide product with dimethyl sulfate and methyl orthoformate, led to a mixture of the axial (compound **306**) and equatorial (compound **307**) cyclic methoxyacetals, the last of which was oxidised by ozone to the target invictolide **308** after deoxygenation.

An effective procedure has been proposed for the preparation of the key hydroxylactone **314** in the synthesis of the sex pheromone **315** of the Japanese beetle (*Popilia japonica*).[149] It is based on the ozonolysis of the monoene acetal **313**, obtained by enzymic reaction involving the regio-specific acylation of the vicinal diol **311** and the enantioselective reduction of the intermediate ketoalcohol **312**.



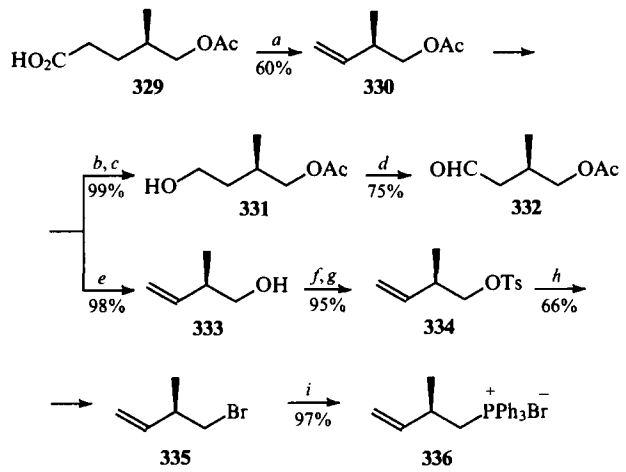
(*a*) Ac_2O–PPL (pig pancreas lipase); (*b*) H_2CrO_4; (*c*) NaOH; (*d*) Baker's yeast; (*e*) $H_2C{=}C(Me)OMe{-}H^+$; (*f*) O_3, Me_2S; (*g*) $Ag_2O{-}OH^-$; (*h*) PCC; (*i*) $C_8H_{17}CH{=}PPh_3$.

Frontaline **318** — the aggregation pheromone of insects of the genus *Dendroctonus* — has been synthesised by ozonising the unsaturated vicinal diol **317** (readily obtainable from the aldehydoalcohol **316**) with subsequent reduction of the peroxide ozonolysis product accompanied by cyclisation.[150]



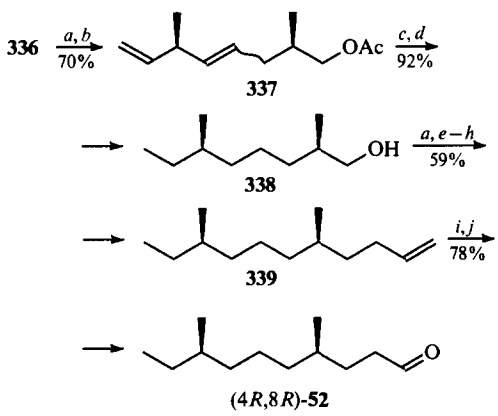
(2*R*,3*S*)-(+)-1,2-Epoxytridecan-3-ol **320** has been obtained by a modified reaction involving the enantioselective epoxidation of tridec-1-en-3-ol **319**. A short path to the conversion of compound **320** into the main component of the egg-laying pheromone **325** of the mosquito *Culex pipiens* has been found. The key stage of this transformation is the ozonolysis of compound **322** — the product of the coupling of the epoxyether **321** with but-3-en-1-ylmagnesium bromide, which proceeds with complete retention of the configuration of the asymmetric centres. The pheromone **325** and its optical isomer have also been synthesised by the ozonolysis of the diacetate **323**.[151–153]

(*a*) $Ti(OPr^i)_4$–(+)-DET (diethyl tartrate)–Bu^tOOH; (*b*) $H_2C{=}CHOEt$–TsOH; (*c*) $H_2C{=}CH(CH_2)_2MgBr$–CuBr; (*d*) O_3–AcOH; (*e*) H_2O_2–SeO_2–Ac_2O; (*f*) TsOH–PhH; (*g*) Ac_2O–Py; (*h*) HCl; (*i*) O_3–MeOH; (*j*) H_2O_2–HCO_2H; (*k*) K_2CO_3.



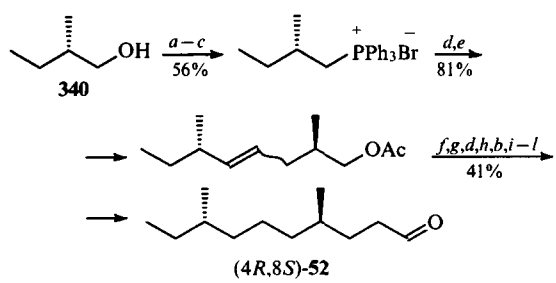
A convenient procedure for the preparation of α,ω-bifunctional reagents used in the synthesis of insect pheromones involves the ozonolysis of derivatives of higher monounsaturated carboxylic acids, for example, oleic and undecenoic.[154–158] Thus, methyl 12-formyldodecanoate **327**, which is necessary for the construction of the carbon skeleton of (*Z*)-octadec-13-enal **328** [a component of the pheromone of the Asiatic rice borer (*Chilo suppressalis*)], has been synthesised by the ozonolysis of the methyl ester of brassidic (or erucic) acid **326**.[154]

(*a*) O_3–CH_2Cl_2; (*b*) PPh_3; (*c*) $BuCH{=}PPh_3$; (*d*) $LiAlH_4$; (*e*) PCC.



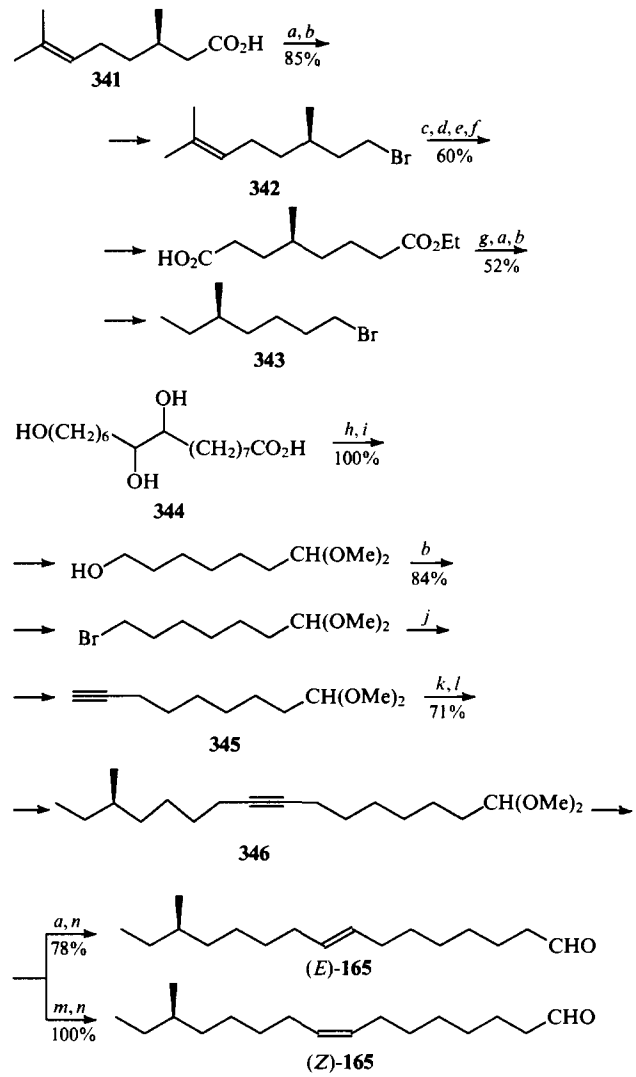
(*R*)-(+)-5-Acetoxy-4-methylpentanoic acid, isolated from the products of the oxidative degradation of the side chain of the (25*R*)-series sapogenins in the manufacture of steroid medicinal preparations, provides extensive possibilities for the synthesis of optically pure chiral pheromones.[159] This bifunctional chiral block has been used to synthesise pheromones with one or several asymmetric carbon atoms. Thus, (*R*)-2-methylbut-3-en-1-yl acetate **330** (the product of the oxidative decarboxylation of the acid **329**) and (*S*)-2-methylbutan-1-ol **340** (a readily available product of the fermentation of sugar) served as a basis[160] for the synthesis of two optically pure stereoisomers of 4,8-dimethyldecanal **52**.

The synthesis of the (4*R*,8*R*)-stereoisomer **52** includes[160] the independent syntheses of the acetoxyaldehyde **332** and the phosphonium salt **336**. The aldehyde **332** was obtained from the alkene **330** via the acetoxyalcohol **331**. The alkene has also been used in the synthesis of the bromo-derivative **335** via the intermediate alcohol **333** and the tosylate **334**. The bromo-derivative **335** was converted into compound **336** by a high-pressure method.



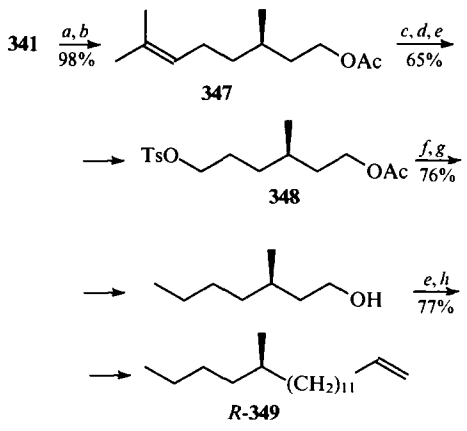
(*a*) $Pb(OAc)_4$, $Cu(OAc)_2 \cdot H_2O$; (*b*) BBN; (*c*) H_2O_2–AcONa; (*d*) PCC; (*e*) KOH; (*f*) BuLi; (*g*) TsCl; (*h*) NaBr; (*i*) PPh_3, 14 kbar.

The Wittig coupling of the aldehyde **332** to the ylide generated from the salt **336** led to the dienyl acetate **337**, which was converted in two stages into the alcohol **338** and further, via the corresponding bromo-derivative, into the alkene **339**. The latter was transformed into the pheromone (4*R*,8*R*)-**52** by ozonisation.



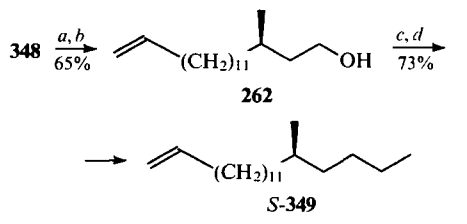
(*a*) BuLi; (*b*) **332**; (*c*) H_2–Pd/C; (*d*) KOH; (*e*) TsCl; (*f*) NaBr; (*g*) Mg; (*h*) $H_2C{=}CHCH_2Br$; (*i*) O_3–CH_2Cl_2; (*j*) Me_2S.

The (4*R*,8*S*)-stereoisomer of compound **52** was synthesised by a procedure in which the chiral alcohol **340** was used in the construction of the (8*S*)-asymmetric centre and this synthesis does not differ fundamentally from that described above.[160]



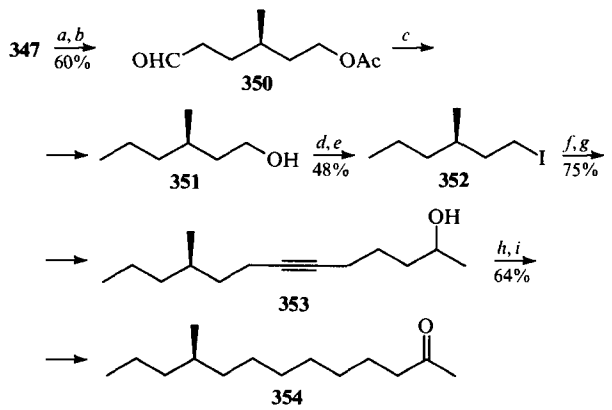
(*a*) Ts–Py; (*b*) NaBr; (*c*) PPh_3; (*d*) BuLi; (*e*) **332**; (*f*) H_2–Pd/C; (*g*) KOH; (*h*) TsCl; (*i*) Mg; (*j*) $H_2C{=}CHCH_2Br$; Me_2S.

(*R*)-(+)-Citronellic acid **341**, obtained by the acid cleavage of the readily available (*R*)-(+)-pulegone, has found extensive application as an optically active unit.[161] (*R*)-5-Methylhept-1-yl bromide **343** has been used as the chiral block in the syntheses of the (*R*)-trogodermals with the (*Z*)- or (*E*)-configuration of the double bond [compound (*Z*)-**165** or (*E*)-**165**]. Compound **343** was obtained by converting the acid **341** in two stages into (*R*)-citronellyl bromide **342**, the subsequent transformations of which included stages involving malonic ester synthesis and ozonolysis with oxidative cleavage of the ozonide. The achiral unit **345** was obtained by the oxidative cleavage of aleuritic acid **344**. Its subsequent alkylation by the bromo-derivative **343** with the (*R*)-configuration afforded the ethyne precursor of the target pheromone **346**.[162,163]



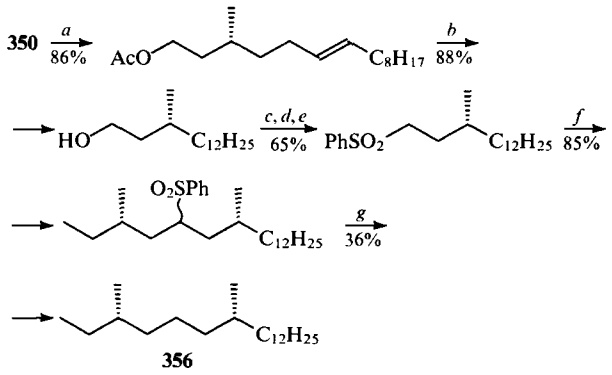
(*a*) $LiAlH_4$; (*b*) Br_2–PPh_3; (*c*) $NaCH(CO_2Et)_2$; (*d*) LiCl–H_2O; (*e*) O_3–MeOH; (*f*) H_2CrO_4; (*g*) $AgNO_3$–$K_2S_2O_8$; (*i*) MeOH–HCl; (*j*) $HC{\equiv}CNa$; (*k*) BuLi; (*l*) **343**; (*m*) H_2–P2-Ni; (*n*) PPTS–H_2O.

The bifunctional nature of (*R*)-citronellic acid **341** made it possible to synthesise from the latter both optical isomers of 14-methyloctadec-1-ene **349** — the sex pheromone of the peach mining moth (*Lyonetia clerckella*).[164] In the synthesis of the (*R*)-enantiomer of compound **349**, citronellyl acetate **347** was converted, after ozonolysis, into the α,ω-acetoxytosylate **348**, the subsequent alkylation of which with dimethyl- and di(undec-10-enyl)-lithium cuprates completed the synthesis of the target pheromone.



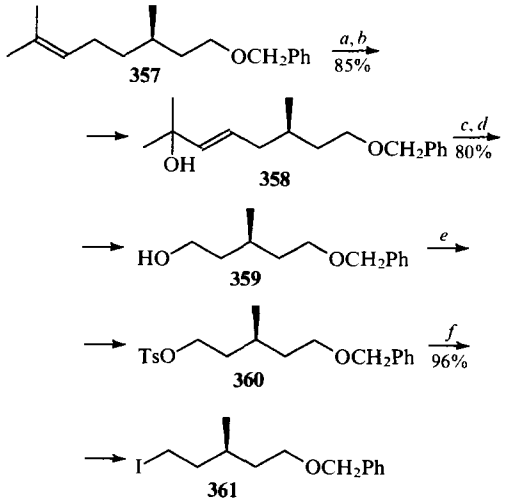
(*a*) $LiAlH_4$; (*b*) Ac_2O–Py; (*c*) O_3–MeOH–CH_2Cl_2; (*d*) $NaBH_4$; (*e*) TsCl–Py; (*f*) Me_2CuLi; (*g*) NaOH; (*h*) $[H_2C{=}CH(CH_2)_9]_2CuLi$.

In order to obtain the (*S*)-optical isomer (*S*)-**349**, the intermediate acetoxytosylate **348** was alkylated in the reverse order. i.e. the alkene component of the target molecule was constructed initially.

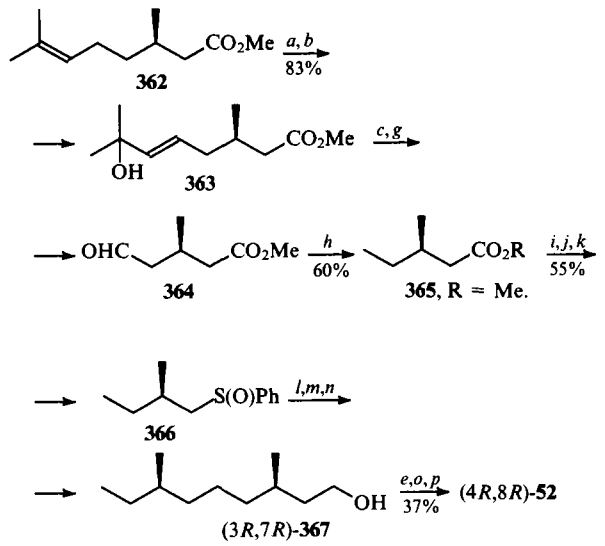


(*a*) $[H_2C{=}CH(CH_2)_8]_2CuLi$; (*b*) NaOH; (*c*) TsCl–Py; (*d*) Et_2CuLi.

10-Methyltridecan-2-one **354**—the optically active pheromone of the spotted cucumber beetle (*Diabrotica undecimpunctata*) with the (*R*)-configuration—has been synthesised from citronellyl acetate **347**, the ozonolytic cleavage of which afforded the acetoxyaldehyde **350**. The Kishner reduction of the latter led to (*R*)-3-methylhexan-1-ol **351**, which was converted into the iodide **352** and the alkynol **353** was obtained by coupling with the ethynylide **355**. Hydrogenation and oxidation of compound **353** led to the target pheromone.[165]

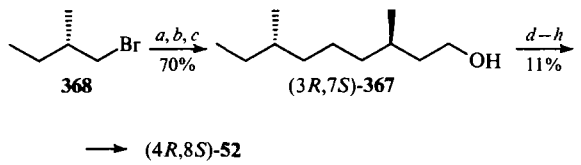


(*a*) O_3–MeOH–CH_2Cl_2; (*b*) Me_2S; (*c*) $N_2H_4 \cdot H_2O$–KOH; (*d*) TsCl–Py; (*e*) NaI; (*f*)  (**355**); (*g*) TsOH–MeOH; (*h*) H_2–Pd/C; (*i*) H_2CrO_4.

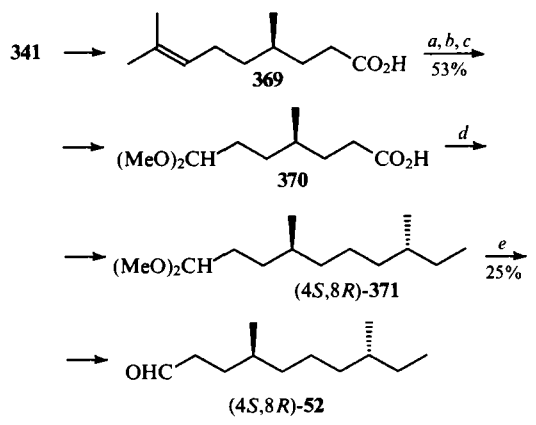


The chiral acetoxyaldehyde **350** has found an application in the synthesis of the sex pheromone **356** of the alfalfa blotch leafminer (*Agromyza frontella Rondarni*) in the construction of the (7*R*)-asymmetric centre.[166]

(*a*) $H_{17}C_8CH{=}PPh_3$; (*b*) $LiAlH_4$–$CoCl_2$; (*c*) TsCl–Py; (*d*) PhSNa; (*e*) MCPBA; (*f*) BuLi,  ; (*g*) Na–Hg–EtOH.

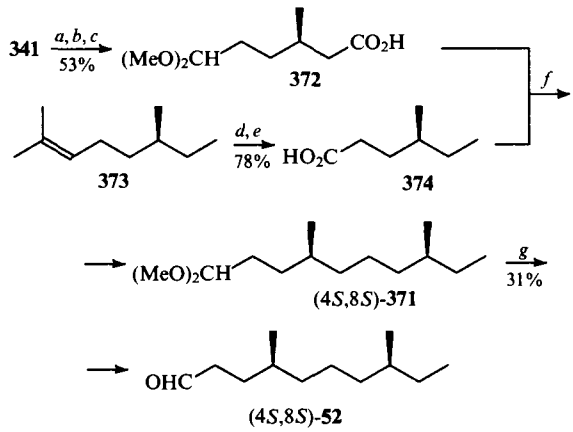


All four stereoisomers of 4,8-dimethyldecanal **52** have been synthesised from the acid **341**.[167] In the synthesis of (4*R*,8*R*)-**52** and (4*R*,8*S*)-**52**, the initial benzyl ether of citronellol **357** was oxidised to the allyl alcohol **358**, the ozonolysis of which (after reductive treatment) afforded the alcohol **359**. Its tosylate **360** and iodide **361** were used to construct the (4*R*)-asymmetric centre in the molecule of compound **52**. The sulfoxide **366**, obtained from the allyl alcohol **363** [the product of the oxidation of (*R*)-methyl citronellate **362**], was used to form the (8*R*)-centre. The ozonolysis of compound **363** yielded the aldehydoester **364**, which was subjected to the Huang-Minlon reduction to the acid **365**. The latter was converted in three stages into the sulfoxide **366**. Its coupling with the iodide **361** and subsequent hydrogenolysis led to the alcohol (3*R*,7*R*)-**367**, the increase in the chain length of which to give the target aldehyde (*R*, *R*)-**52** was carried out via the intermediate nitrile.



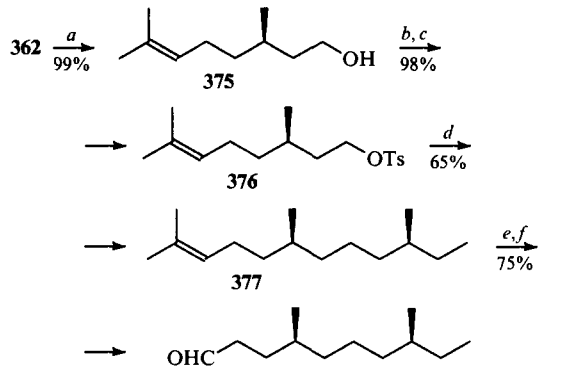
(*a*) $Ph_2Se_2-H_2O_2$; (*b*) Bu^tOOH; (*c*) $O_3-CH_2Cl_2-MeOH-NaHCO_3$; (*d*) $NaBH_4$; (*e*) TsCl–Py; (*f*) NaI; (*g*) Me_2S; (*h*) $N_2H_4 \cdot H_2O-KOH$; (*i*) $Pb(OAc)_4-I_2$; (*j*) PhSNa; (*k*) MCPBA; (*l*) BuLi; (*m*) **361**; (*n*) $Li-EtNH_2$; (*o*) NaCN; (*p*) DIBALH.

The (8*S*)-centre in the (4*R*,8*S*)-stereoisomer of compound **52** was constructed with the aid of the readily available (*S*)-2-methylbutyl bromide **368**, the coupling of which with the tosylate **360** led to the alcohol (3*R*,7*S*)-**367**. It was converted into the pheromone with the (4*R*,8*S*)-configuration via the corresponding nitrile.[167]



(*a*) Mg; (*b*) **360**–Li_2CuCl_4; (*c*) H_2–Pd/C; (*d*) TsCl–Py; (*e*) NaCN; (*f*) NaOH; (*g*) $LiAlH_4$; (*h*) PCC.

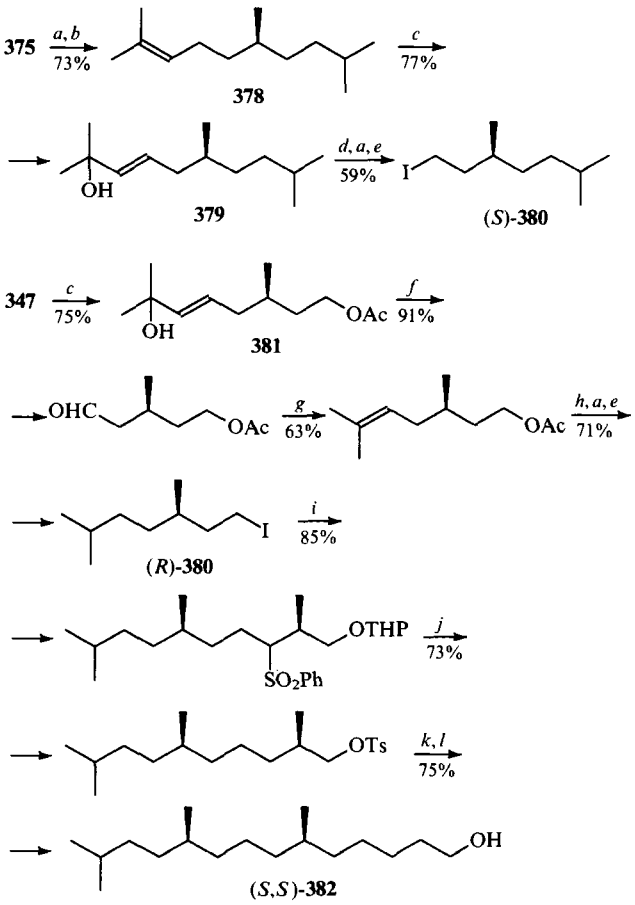
In the synthesis of the (4*S*,8*R*)-isomer, the chiral units for the construction of the skeleton of the sex pheromone were the acids **365** (R = H) and **370**. The latter was obtained by the ozonolysis of homocitronellic acid **369**. The Kolbe condensation of the acid correspondimg to **365** and **370** led to the acetal (4*S*,8*R*)-**371**, the hydrolysis of which afforded the aldehyde **52** with the (4*S*,8*R*)-configuration.[168]



(*a*) O_3–MeOH; (*b*) Me_2S; (*c*) TsOH–MeOH; (*d*) NaOMe–MeOH, **365** (R = H) + e^- (Pt, 24 V, 0.8–1.2 A); (*e*) $HClO_4$.

The (*S*,*S*)-isomer of the pheromone **52** was synthesised in accordance with the same principle. The chiral units were the acids **372** and **374**, obtained by the ozonolysis of citronellic acid **341** and tetrahydromyrcene **373** respectively. The acetal (4*S*,8*S*)-**371**, obtained in the electrolysis of an equimolar mixture of the acids **372** and **374**, was readily converted into the target aldehyde (4*S*,8*S*)-**52**.

(*a*) O_3–MeOH; (*b*) Me_2S; (*c*) TsOH–MeOH; (*d*) O_3-Me_2CO; (*e*) H_2CrO_4; (*f*) NaOMe–MeOH, e^- (Pt, 24 V, 1.5 A); (*g*) 35% $HClO_4$–THF.

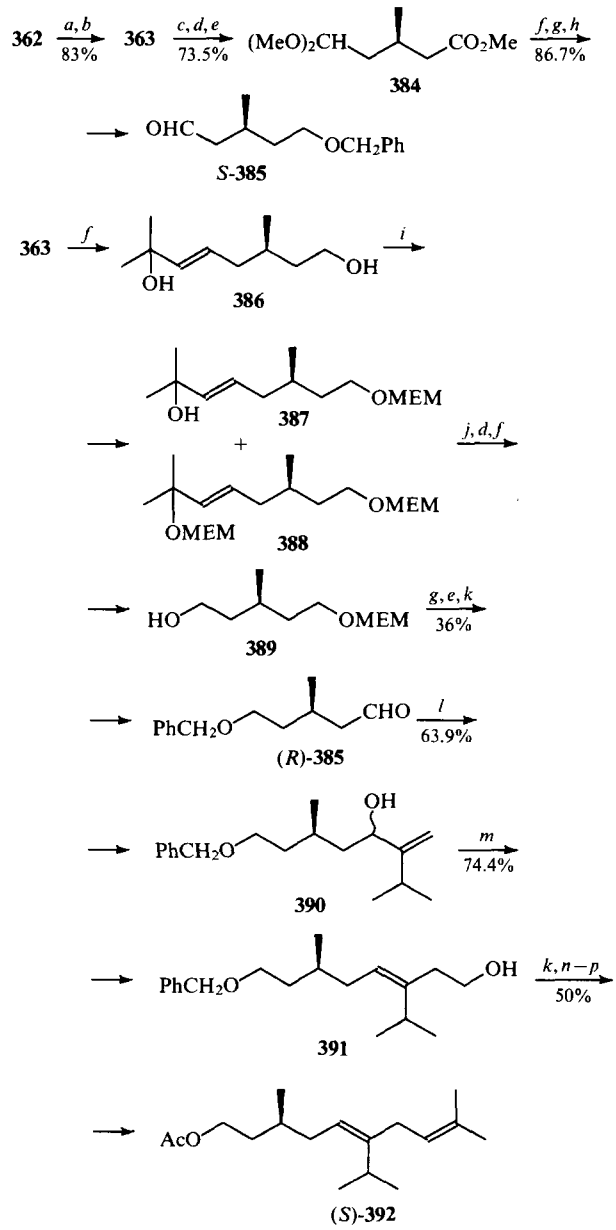


Yet another short path to the synthesis[169] of the enantiomerically pure (4*S*,8*S*)-dimethyldecanal involves the use of readily available chiral units—(*R*)-methyl citronellate **362** and (*S*)-2-methylbutan-1-ol **340**. The former reagent was converted in two stages, via the intermediate (*R*)-citronellol **375**, into the tosylate **376**, while the latter was converted into the bromide **368**, the Wurtz cross-coupling of these precursors afforded 2,6,10-trimethyldodec-2-ene **377**, which was converted by ozonolysis into the aldehyde **52** with the (4*S*,8*S*)-configuration.

(*a*) DIBALH; (*b*) BuLi; (*c*) TsCl; (*d*) **368** + Mg–Li_2CuCl_4; (*e*) O_3–MeOH–CH_2Cl_2; (*f*) Me_2S.

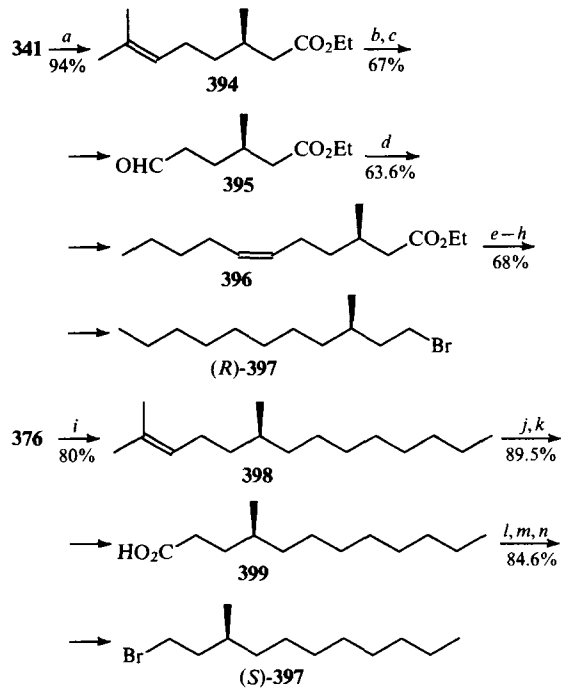
The phenyl sulfone (*S*)-**383** and the iodide **380** with the (*R*)- and (*S*)-configurations were used as the chiral building blocks in the syntheses of all four stereoisomers of 6,10,13-trimethyltetradecan-1-ol **382**—the aggregation pheromone of the predatory stink bug (*Stiretrus anchorago*).[170] [The reactions leading to (6*S*,10*S*)-**382** are shown in the scheme below.]

The carbon skeleton of (*S*)-**380** was constructed by converting (*R*)-citronellol **375** into 2,6,9-trimethyldec-2-ene **378**, its allylic oxidation (with rearrangement), and the subsequent ozonolysis of the product **379**. The iodide **380** with the (*R*)-configuration was synthesised by the ozonolytic cleavage of the allyl alcohol **381**, which can be readily obtained from citronellyl acetate **347** by the method described by Hori and Sharpless.[168]



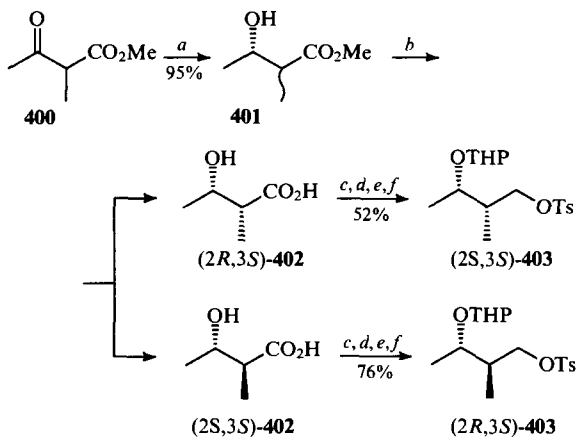
(*a*) TsCl–Py; (*b*) $Me_2CHMgBr–Li_2CuCl_4$; (*c*) $Ph_2Se_2–H_2O_2$, Bu^tOOH; (*d*) O_3, $NaBH_4$; (*e*) NaI; (*f*) O_3, Me_2S; (*g*) $Me_2C=PPh_3$; (*h*) $LiAlH_4–CoCl_2$;

(*i*) THPO–≡–SO_2Ph [(*S*)-**383**]–BuLi; (*j*) Na–Hg–EtOH; (*k*) $Cl(CH_2)_4OTHP–Mg–Li_2CuCl_4$; (*l*) TsOH–MeOH.



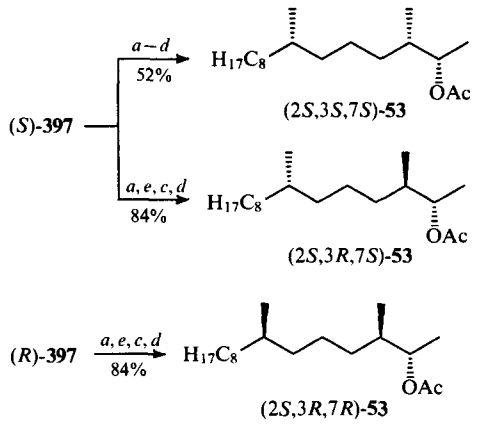
The allyl alcohol **363** — the product of the allylic oxidation of (*R*)-methyl citronellate **362** by a diselenide — has been used to synthesise the (*R*)- and (*S*)-enantiomers of (5*E*)-6-isopropyl-3,9-dimethyldeca-5,8-dienyl acetate **392** — the sex pheromone of the yellow scale (*Aonidiella citrina*).[171] The (3*R*)-centre in the molecule of compound **392** was formed by the conversion of the allyl alcohol **363**, by ozonolysis with reductive cleavage of the ozonide, into the dimethyl acetal **384**, which was converted by means of standard procedures into the key aldehydoester (*S*)-**385**. The optical isomer of the latter — the aldehyde (*R*)-**385** — was obtained from the same allyl alcohol **363** by its transformation via the diol **386** into a mixture of the mono- and di-esters **387** and **388**, the ozonolysis of which and two-stage reduction afforded the monosubstituted diol **389**. The latter was converted via its benzyl ether into the other key aldehydoester (*R*)-**385**. The further transformations of the aldehydes† (*S*)-**385** and (*R*)-**385** included stages involving interaction with the Grignard reagent derived from 2-bromo-3-methylbut-1-ene **393** and the 2,3-sigmatropic rearrangement of the resulting allyl alcohols **390** via their stannyl derivatives to the (*E*)-homoallyl alcohols **391**. The latter were oxidised to the corresponding aldehyde and were converted into the target (*S*)- or (*R*)-**392** by means of the Wittig alkene formation reaction.

† The scheme below indicates the reaction leading to the biologically active (*S*)-enantiomer of compound **392**.



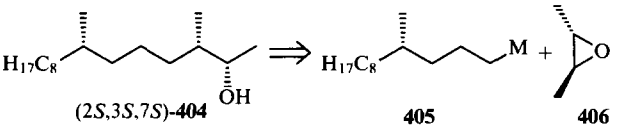
(*a*) $Ph_2Se_2–H_2O_2$; (*b*) Bu^tOOH; (*c*) O_3–MeOH; (*d*) Me_2S; (*e*) TsOH–MeOH; (*f*) $LiAlH_4$; (*g*) $PhCH_2Br–NaH$; (*h*) $HClO_4$; (*i*) NaH–MEMCl ($MeOCH_2CH_2OCH_2Cl$); (*j*) $O_3–CH_2Cl_2–MeOH–NaHCO_3$; (*k*) $CrO_3 \cdot 2Py$; (*l*) $H_2C=C(Pr^i)MgBr$ (**393**); (*m*) $Bu_3SnCH_2I–KH$, BuLi; (*n*) $Me_2C=PPh_3$; (*o*) $Li–NH_3$; (*p*) Ac_2O–Py.

Citronellic acid **341** has also been used in the synthesis of the isomers of 3,7-dimethylpentadec-2-yl acetate **53**, which forms part of the composition of the sex pheromone of the pine sawflies belonging to the genera *Diprion* and *Neodiprion*.[172] The synthesis consists of two stages. In the first of these, the C_{12} and C_5 blocks (**397** and **403** respectively) are formed simultaneously, while in the second they are coupled and the product is subjected to further transformation to give the target compounds. The acid **341** serves as the starting material for the synthesis of the C_{12} block **397** having both the (*R*)- and (*S*)-configurations. Compound (*R*)-**397** was synthesised by the ozonolysis of its ethyl ester **394** to give the aldehydoester **395** and its subsequent conversion into the unsaturated ester **396**. The optical isomer (*S*)-**398** was synthesised by alkylating (*R*)-citronellyl tosylate **376** and by the ozonolysis of the resulting alkene **398** to the acid **399**, which was then subjected to the Hunsdiecker reaction.



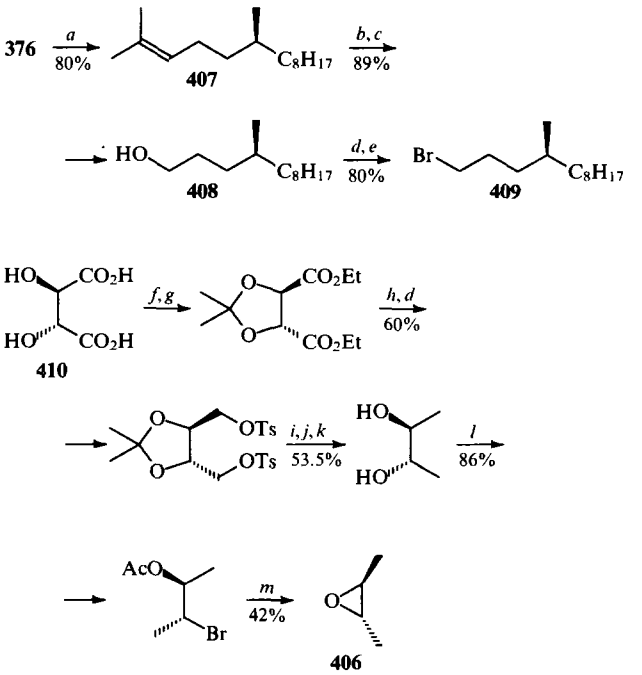
(*a*) EtBr; (*b*) O_3–MeOH; (*c*) H_2–Pd/C; (*d*) $BuCH{=}PPh_3$; (*e*) H_2–PtO_2; (*f*) $LiAlH_4$; (*g*) TsCl–Py; (*h*) LiBr; (*i*) n-$C_6H_{13}MgCl$–CuI; (*j*) O_3–CH_2Cl_2; (*k*) H_2O_2–HCO_2H; (*l*) NaOH; (*m*) $AgNO_3$; (*n*) Br_2.

The synthesis of the C_5 block with two chiral centres requires greater effort. The diastereoselective asymmetric reduction of methyl 2-methyl-3-oxobutyrate **400** led to a 3:1 mixture of the optically active *erythro*- and *threo*-alcohols **401**, which was separated by fractional crystallisation initially of their sodium salts and then of their ammonium salts. The products of such fairly laborious operations — the hydroxyacids (2*R*,3*S*)-**402** and (2*S*,3*S*)-**402** — were converted in four stages into the corresponding differentially protected diols (2*S*,3*S*)-**403** and (2*R*,3*S*)-**403**, which are necessary for the synthesis of the target products.



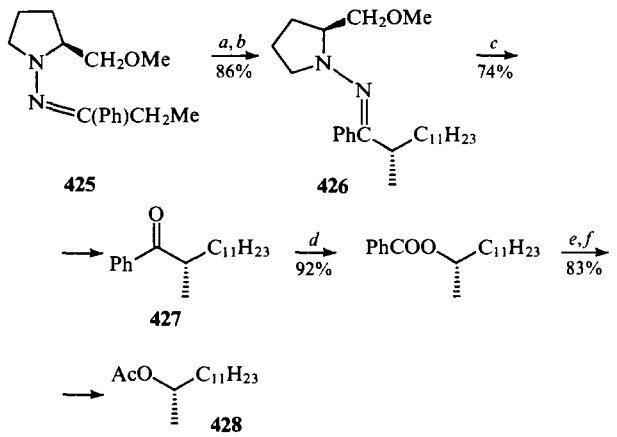
(*a*) H_2–Ni–(*S*,*S*)-$(HO_2CCHOH)_2$; (*b*) crystallisation; (*c*) CH_2N_2; (*d*) DHP–TsOH; (*e*) $LiAlH_4$; (*f*) TsCl–Py.

By combining the stereoisomers of the C_5 and C_{12} blocks in coupling reactions of the organomagnesium derivatives with the tosylates, three optically pure stereoisomers of diprionyl acetate **53** were obtained.



(*a*) Mg; (*b*) (2*S*,3*S*)-**403**–CuI; (*c*) TsOH–MeOH; (*d*) Ac_2O–Py; (*e*) (2*R*,3*S*)-**403**–CuI.

The retrosynthetic analysis of the structure of diprionol (2*S*,3*S*,7*S*)-**404** showed that it can be obtained by the reaction of the organometallic nucleophile **405** with (*S*,*S*)-2,3-epoxybutane **406**.



The real chiral building block corresponding to the fragment **405** — (*S*)-(+)-1-bromo-4-methyldodecane **409** — has been synthesised[173] from (*R*)-(+)-citronellyl tosylate **376** by coupling the latter with dihexyllithium cuprate and subsequent ozonolysis of the alkene **407** to the alcohol **408**. The complementary epoxide **406** was obtained from L-(+)-tartaric acid **410** in nine stages. On reaction with the epoxide **406**, the dialkyllithium cuprate prepared from compound **409** afforded the target diprionol **404** with a high configurational homogeneity of all three chiral centres.

The proposed method of synthesis[177] of the pheromone component **423** of the small wood ant (*Formica polyctena*) and the red wood ant (*Formica rufa*) was based on the Michael addition of the azaenolate generated from the hydrazone (*S*)-**419** to the (2*E*)-methyl pent-2-enoate **424** with the asymmetric induction of two chiral centres. The subsequent ozonolysis of the hydrazone **420** led to the aldehyde **421**, which was converted into the target pheromone **423** via the dithioacetal **422**.

A similar approach has been used in the enantioselective synthesis[178] of a component of the aggregation pheromone **428** of the fruit fly *Drosophila mulleri*, the key stages of which are the asymmetric α-alkylation of the azaenolate derived from the hydrazone **425**, the ozonolysis of the hydrazone **426**, and the Baeyer – Villiger oxidation of the ketone **427** accompanied by the inversion of the configuration.

(*a*) LDA; (*b*) $C_{11}H_{23}Br$; (*c*) $O_3-CH_2Cl_2$; (*d*) MCPBA; (*e*) $LiAlH_4$; (*f*) Ac_2O-Py.

Thus the present review of literature gives grounds for the conclusion that there is a growing interest in the use of the ozonolysis of unsaturated compounds at various stages of the total synthesis of insect pheromones and juvenoids, which frequently determine the success in the application of the chosen procedure.

Abstract. A review of common trends in the development of modern radiation processing is presented. The sources of ionising radiation and the most important processes practically induced under the influence of this radiation are discussed. It is shown that radiation methods can be used successfully for the modification of materials, for the sterilisation of medical articles, for the solution of ecological problems, for the treatment of food products, in radiation engineering, etc. Special attention is paid to processes at the pilot plant and industrial scales. The bibliography includes 548 references.

I. Introduction

The aim of radiation technology is to study, develop, and improve the methods, apparatus, and assemblies used to apply ionising radiations. Radiation methods are used to generate or to improve new properties in materials, new methods of exploiting them, new means of production, etc., and also to solve ecological problems, some problems in nuclear technology, and various other problems. Radiation processing is a relatively new field of study. The first radiation processes (radiation sterilisation of medical items and radiation cross-linking of the polyethylene insulation of wires) were introduced into industrial practice in the mid-1950s,[1] so that the introduction and development of radiation technology as a separate science has now been going on for 35–40 years.

In spite of the shortness of its past history this field of study has already achieved some definite successes. This is shown by the very abundant scientific and technical literature, which includes thousands of original papers and reviews, many patent disclosures and claims, specialised monographs,[1–64] and pamphlets in the 'Radiation-chemical technology' series,[65–87] and representative meetings of specialists held in various countries (in particular, international conferences on radiation technology organised every 2–3 years).[88–96]

Radiation technology still occupies a relatively modest place in the overall volume of industrial and agricultural production. The rate of growth of production by radiation methods is increasing continuously: ~15%–20% per annum. Thus, in foreign countries industrial products worth about 10^{10} US dollars are produced every year by radiation methods. In the not too distant future this could make the industrial production by radiation processes comparable in importance with conventional processes.

Radiation technology can be divided into radiation-chemical, radiation-physical, and radiation-biological processing. Modern radiation-chemical technology is being developed mainly along the following directions: (1) the radiation modification of materials (mainly polymeric); (2) radiation polymerisation, including radiation hardening and radiation graft polymerisation; (3) radiation degradation (mainly of polymeric materials); (4) ecology. The main aims of radiation-biological technology are the radiation sterilisation of medical articles and the radiation treatment of food products. The radiation-physical technology includes the radiation doping of semiconductors, ion implantation, the radiation treatment of articles used in electronic technology, etc. However, the boundary between these divisions of radiation technology is not sharp. A topic common to all these divisions is the construction of radiation apparatus (the production and assembly of sources of ionising radiation and of radiation equipment and the technological dosimetry of ionising radiations).

Regions of radiation-biological technology such as the radiation sterilisation of medical articles and preparations and the radiation treatment of food products are usually classified with the radiation-chemical technology. An important part of these problems is the radiation stability of the polymeric materials from which the medical articles and the medicinal preparations are manufactured, the qualitative and quantitative determination of the composition of the substances formed in the food products during their irradiation, and the identification of the irradiated products. Problems common to radiation-chemical and radiation-physical technology include the increase in the

corrosion resistance of metals and alloys during ion implantation, the radiation doping of semiconductors, etc.

This paper is a review of the current state of radiation processing, with special emphasis on processes realised under pilot plant and under industrial scales. It was written mainly from data published in the last 10–15 years.

II. Sources of ionising radiation

The following sources of ionising radiation are commonly used in radiation processing: ^{60}Co (and more rarely ^{137}Cs) sources of γ radiation, electron accelerators, $^{90}Sr + ^{90}Y$ sources of β radiation, ion implanters, and (very rarely) nuclear reactors.

1. ^{60}Co sources of γ radiation

γ Irradiators are used mainly in the radiation sterilisation of medical equipment and (to a smaller extent) in the radiation treatment of food products. More than 180 industrial γ irradiators based on ^{60}Co are currently operating over the world. The activity of ^{60}Co in one γ irradiator can be as high as 10 MCi. The largest foreign producer and supplier of industrial γ irradiators based on ^{60}Co is the Canadian 'Nordion International Inc.' company. Modern industrial irradiators are housed in specially equipped structures and are usually automated.

2. Electron accelerators

The total number of electron accelerators currently used in radiation processing (including research assemblies) is greater than 1000. The energy of the electron beams generated by electron accelerators is 0.15–10 MeV. Beams with an energy lower than 0.15 MeV are very seldom used because of their unacceptably low penetrating power. At energies greater than 10 MeV the irradiated objects begin to show a significant amount of induced radioactivity.

Industrial electron accelerators can be divided into three groups.[97]

(1) Low-energy accelerators, with an electron energy of 0.15–0.5 MeV and beam powers up to 300–350 kW. The characteristics of accelerators produced in various countries are summarised in Table 1.[1,98] More than 400 of these machines are currently operating over the world: more than 250 of them are used in industry. They are used mainly for hardening coatings, and for treating surfaces and thin-film items.

Low-energy accelerators can themselves be divided into three subgroups:[100] with a scanning beam, with an extended cathode, and with a multiple cathode. The first subgroup includes, for example, accelerators of the 'Aurora' type, the second includes accelerators of the 'Electrocurtain' type, and the third accelerators of the 'Broad Beam' type. We note that in recent years

[a]The stated beam powers are guaranteed: a power of 100 kW can probably be achieved.

multicathode accelerators with powers of up to 400 – 500 kW and beam widths up to 3.2 m have been developed.[100]

(2) Intermediate-energy accelerators, with an electron energy of 0.5 – 5.0 MeV and a beam power of up to 300 – 350 kW. More than 500 of these machines are operating over the world. The parameters of accelerators of this group are shown in Table 2.[1,49,50,101–104]

Accelerators of the 'Dynamitron' type are the most widely used accelerators of this type outside the Russian Federation: about 150 of these machines were functioning in 1990.[105] Among the accelerators produced in Russia the most widely used are those of the ELV type (approximately 70 of these machines having been produced so far)[106] and of the ILU type (23 machines produced so far).[107] The nuclear physics institute of the Siberian Section of the Russian Academy of Sciences has developed an ELV-6M accelerator (electron energy 0.5 – 1.0 MeV and maximum beam power 200 kW) and a 'Torch' accelerator (energy 0.5 – 1.0 MeV, maximum beam power 500 kW).[108] In the USA an electron accelerator of the induction type with a beam energy of up to several megawatts is being developed.[109]

Intermediate-energy accelerators are used in many areas of radiation processing: for cross-linking the polyolefin insulation of cables, for the production of thermally formed articles and of foamed polyethylene, for the vulcanisation of the components of tyres, for the purification of waste water and gas discharges, etc.

(3) High-energy accelerators, with an electron energy of 5 – 10 MeV and a beam power of up to 100 kW. These are mostly linear accelerators: about 30 of these machines are used in

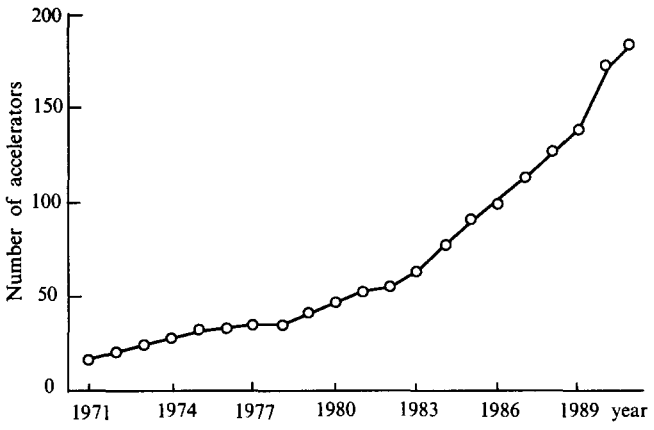

Figure 1. Increase in the production of electron accelerators by the Japanese firm 'Nissin High Voltage Co., Ltd.'

radiation technology. The parameters of some of them are given in Table 3.[1,50,98,110–115] They are used for the radiation sterilisation of medical articles and (to a smaller extent) for the radiation processing of food products.

At the present stage of development of radiation technology electron accelerators are much more generally used than sources of γ radiation. This is because of the greater operational safety and the greater power of the electron accelerators. The rates of development of electron-beam processes are illustrated in Fig. 1, which shows the increase in the number of electron accelerators produced by the Japanese firm 'Nissin High Voltage Co., Ltd.' for radiation technology during the period 1971 – 1991.[104]

3. Other sources

$^{90}Sr + {}^{90}Y$ β sources are used in radiation-physical technology, mainly in the surface treatment of semiconductor devices. Ion beams are also used for the same purpose, and ion implanters are very widespread. For example, about 800 implanters were operating in Japan in 1987.[116] Nuclear reactors were used as sources of ionising radiation only in the radiation doping of semiconductors.[35]

In recent years the possibility of exploiting the breaking (breamsstrahlung) X-radiation with a maximum energy of 5 MeV generated by electron accelerators with a beam power of 200 – 300 kW[113,117–122] is being studied. An electron beam with an energy of 5 MeV and a power of 200 kW can generate a bremsstrahlung X-radiation with a power of ~15 kW when decelerated in a high atomic number metal (for example, tantalum), counting only the radiation in the same direction as the stream of electrons: this is equivalent to the power of γ radiation from a ^{60}Co sample with an activity of ~1 MCi. However, an X-ray beam can be used more effectively (by a factor of approximately 1.5 – 2.5)[118] than γ radiation because ^{60}Co emits its γ quanta isotropically, i.e. in all directions.

Possible applications of the bremsstrahlung X-radiation include the radiation sterilisation of medical items and the radiation treatment of food products. Several equipments based on electron accelerators have already been assembled by using appropriate converters of electron beams into bremsstrahlung X-radiation,[113] and one assembly with an accelerator of the Cockcroft – Walton type (electron energy 5 MeV, beam energy 150 kW) produced by the 'Radia Industry Co., Ltd.' (Japan) has been used on commercial applications[121] since 1992.

III. Radiation modification of materials

The radiation modification of materials is the controlled (and therefore useful) change in their properties produced by using irradiation. The ionising radiation is most often used to modify polymers, because of the high molecular mass of polymers, which allows even relatively small doses to produce marked changes in its properties.

The radiolytic conversion most useful in practice in polyolefins is cross-linking. This is used in various industrial processes, such as the modification of polyolefins [mainly polyethylene and poly(vinyl chloride)], the insulation of cables and wires, the preparation of stronger and heat resistant films, tubes, and manufactured articles, the production of polyethylene foams and (in a much smaller volume) of polypropylene foams, the vulcanisation of elastomers and items made from them (components of tyres, polysiloxane rubbers aimed at the production of thermally stable self-adhesive electrically insulating tapes and rubber-glass cloth, latex from natural raw rubber, rubber gloves, etc.).

1. Production of cables and wires with a radiation-cross-linked insulation

The radiation cross-linking of polyolefins increases their mechanical strength and heat resistance, improves their electrical insulation properties (especially at high temperatures), etc. For these reasons the process discussed in this section is widely used in the production of cables and wires.[1,5,6,10,17,20,50,79,123]

The radiation cross-linking of polyolefin insulation was first achieved in the USA in the 1950s. At present the list of countries in which this process is applied includes Japan, Great Britain, France, Germany, the PRC (China), and several others. In the former Soviet Union 16 industrial lines with electron accelerators of the ELV or ILU type (maximum power ~0.5 MW) were operated.[97,123] Many of these lines were found in the 'Belarus'kabel' plant (Belorussia); their combined maximum annual production was $(160-180)\times10^3$ km of wires with cross-sections between 0.12 and 6.0 mm^2 (see Gofshtein[124]). In Japan ~12% of the insulation produced is radiation-cross-linked.[125]

The radiation method is used to modify mainly polyethylene and poly(vinyl chloride) insulation. Radiation treatment is applied on a smaller scale to insulations of poly(vinylidene fluoride), chlorosulfonated polyethylene, the ethylene – propylene terpolymer, the copolymer of ethylene and tetrafluoroethylene, etc. Radiation-cross-linked polyurethane has recently started to be used as insulation.[126]

The sources of ionising radiation used to irradiate wires and cables are mainly electron accelerators with an energy of 0.3 – 5 MeV and powers of up to 100 – 150 kW. The dose needed to cross-link grades of polyethylene made abroad is 0.2 – 0.4 MGy,[127] whereas the indigenous grade of cable polyethylene requires 0.5 MGy.[123] This dose can be greatly lowered by adding sensitisers to the polyethylene. Typical sensitisers include dipropargyl succinate (which when used as an additive lowers the radiation dose to 0.1 – 0.12 MGy),[128] trimethylolpropane triacrylate and trimethylolpropane trimethylacrylate,[129] alkylamides and some aminoalcohols,[130] etc.

The use of sensitisers is specially valuable with a poly(vinyl chloride) insulation, because when exposed to relatively high doses (60 kGy and above)[131] this polymer undergoes marked structural degradation. Triallyl cyanurate,[132] tetraethyleneglycol dimethacrylate,[133] and other compounds have been proposed as sensitisers for this material.

An important scientific and technical problem, met in conjunction with the use of wires and cables with radiation-cross-linked insulation at high temperatures, is the need to inhibit processes leading to the thermal oxidation of the insulating polymeric material. This thermal oxidation can be suppressed by introducing special substances (antioxidants) into the polymer. In the case of polyethylene effective antioxidants include some phenolic compounds [for example, 1,1,3-tris-(2-methyl-4-hydroxy-5-*tert*-butylphenyl)butane], aromatic amines [for example, *N*,*N*′-diphenyl-*p*-phenylenediamine], and organic substances containing sulfur [for example, 4,4,thio-bis-(6-*tert*-butyl-3-methylphenol)].[134–138]

However, by reacting with the free radicals formed during the irradiation of the polymer the antioxidants increase the dose needed to achieve cross-linking. In this respect organosulfur antioxidants are better than phenolic compounds, since their use induces a much smaller increase in the dose.[137] We note that additives acting simultaneously as sensitisers and as antioxidants have been developed in Russia.[123]

Another important problem is the elimination of fire hazards from cable items having a radiation-cross-linked polymeric insulation. Additives which lower the inflammability (called antipyrenes) include decabromodiphenyl oxide, tetrabromobisphenol, condensed bromacenaphthalene, and aluminium hydroxide.[137,139-141] Condensed bromacenaphthalene (whose molecule contains 1-10 bromacenaphthalene units and 2-4 bromine atoms) is specially effective in the protection of chlorinated polyethylene and of the ethylene-propylene terpolymer.[141,142] Furthermore it is an antioxidant, and ensures radiation stability of the polymer up to 10 MGy. These properties are due to its grafting to the polymer chain during the irradiation.

The radiation cross-linking of polymers has a number of advantages over the chemical reaction, which uses peroxides as initiators.[143] They include better exploitation characteristics of the product, a cheaper process, lower energy losses, and a gain in the working areas. This explains why wires and cables with a radiation-cross-linked polymer insulation are now industrially produced in many countries. They are used in telecommunication systems, in military and in cosmic technology, in electronics and computer instrumentation, in the electric systems of automobiles, in nuclear reactors, etc.[20,131,139-141,144,145]

2. Preparation of densified and thermosetting items

The second radiation-chemical process realised in industry, based on the cross-linking of polymers (mainly polyethylene), is the preparation of densified and thermosetting items. They include thermosetting films, tapes, small bags, small and large tubes, hoses, flaps, and items of a more complex configuration used in the electrical industry, in the automobile and food industries, in electronics, in ship building, and in construction.[79,146-150]

The 'memory' effect (also known as 'shape memorising') provides the basis of the preparation of thermosetting items.[151] Essentially in this effect a polymeric material is irradiated with a dose smaller than the dose corresponding to gel formation, deformed at a temperature higher than the melting point of the crystallites, and then cooled rapidly. After a second heating to the same temperature, it tends to regenerate its initial form (owing to the formation of a three-dimensional network). If this material is stretched over any item it forms a tightly fitting shell after the heating process.

In addition to polyethylene we can use poly(vinyl chloride), poly(vinylidene fluoride), some rubbers, ethylene-ethyl acrylate and ethylene-vinyl acetate copolymers, etc. to prepare thermosetting items. In most cases electron accelerators are used in the production of thermosetting articles. Electron beams with an energy of 1-3 MeV are used to irradiate tubes, and with films and tapes the beams have an energy of 0.5-1.0 MeV.[147] Assemblies based on transformers with an insulated core and dynamitrons have been developed in the USA; in Russia accelerators of the 'Aurora', 'Elektron', ELV, and ILU type are used. In particular, in Russia a special workshop producing thermosetting polyethylene films and tubes[152] has operated 5 electron accelerators since 1978. The operating speed of this assembly is 1600 t a^{-1}. Two industrial lines have recently been mounted in Syzran' for the production of thermosetting polyethylene tapes: both are fitted with an accelerator of the ELV type (beam power 40 kW).[152] The operating speed of each line is 800 t a^{-1}. In foreign countries thermosetting items are produced by 'Raychem' (USA), 'Nitto' (Japan), and other firms.

The technology of the preparation of thermosetting films differs somewhat from the production technology of small pipes, of tubes, and of flaps. The production of thermosetting films[1,79,146] is shown schematically in Fig. 2. The best dose is 0.12 MGy.[79] Thermosetting pipes, tubes, and flaps can be produced by two methods.[147] In the first the tubes are produced by extrusion; they are then electron irradiated, their diameter is increased by orienting them above the melting point, and they are rapidly cooled, producing a new diameter. In the second method (called the tape method) a polyethylene tape is prepared by extrusion, is irradiated, exposed to oriented heating, and rapidly cooled; tubes are then produced from the heated tapes by winding them on a mandrel. It has been stated that the doses needed for the production of tubes and tapes could be 0.2-0.3 MGy[147] or 0.1-0.12 MGy[79-148] Obviously, the difference is due to differences in the state of the polymeric compositions used in the process.

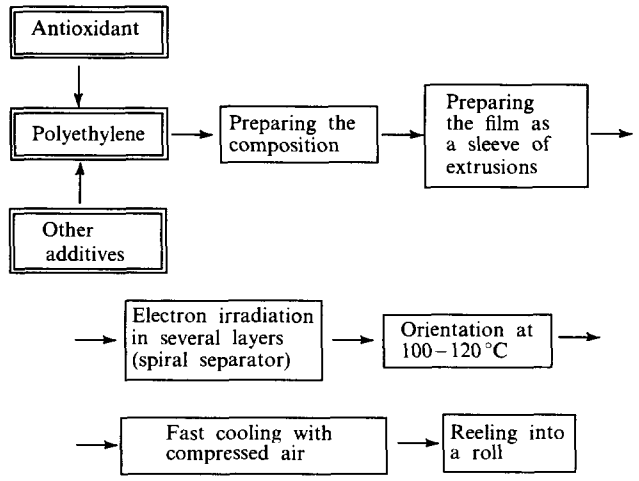

Figure 2. Scheme for the production of thermosetting films.

In the USA thermosetting films are used for packing cooled foodstuffs under vacuum.[146] The 'termoplen' film, produced in Russia, is also a packing material, whereas the 'agroplen' film is used in industrial hothouses to cover the soil before admitting overheated steam in order to eliminate harmful vegetable cultures.[152] Polyethylene tubes made of 'radplast T' are used for the insulation of connected wires and terminals in electric wiring, for the upkeep of damaged insulation, etc. 'Radlen' polyethylene films have been designed to protect gas and petroleum ducts from corrosion.[152]

3. Production of radiation-cross-linked foamed polyethylene

The production technology of radiation-cross-linked polyethylene foams was developed in Japan in the mid-1960s.[153,154] This material is produced in several countries at present.[154-156]

The production of radiation-cross-linked polyethylene foams includes the following main steps: the preparation of the initial composition, the production of the intermediate product (as a sheet) by extrusion at a temperature not above 125-130°C, the irradiation of this sheet by electrons in order to induce cross-linking (dose of 50-70 kGy), the foaming of the cross-linked item at 180-200 °C by the decomposition of a gas former (often known as a porofore) introduced into the composition. A commonly used porofore is diazodicarbonamide $H_2NCON{=}NCONH_2$, which decomposes at ~200 °C (giving 200-250 cm^3 of gaseous products per 1 g of porofore, including CO, CO_2, N_2, and NH_3. Foaming promoters (usually zinc stearate[155]) are added to the composition to lower the decomposition temperature of the porofore. Other additives are also used if necessary: antioxidants, cross-linking sensitisers, dyes, etc. The purpose of the irradiation is to increase the viscosity of the polyethylene melt as a result of cross-linking. An increase in density suppresses the emission of gas from the melt and thus greatly increases the volume of the polymer.

Radiation-cross-linked polyethylene foams have good cushioning and thermal insulation properties, low water absorption, and good elasticity.[154,156,157] In Russia polyethylene foams are produced from low-density polyethylene. It is available as foamed sheets with smooth surfaces (from 0.5 to 1.0 m wide, from 3 to 5 mm thick, up to 50 m in length).[157] These parameters of the radiation-cross-linked polyethylene foams allow them to be used in the building and automobile construction industry, in the production of sporting equipment, as a heating medium and a packing material, etc.

A method of producing cross-linked polyethylene foams with an improved surface was recently reported in Japan.[158] It consists in irradiating polyethylene containing diazodicarbonamide and dicumyl peroxide (initiators of chemical cross-linking) with electrons having an energy of 0.2–0.5 MeV, and then heating it to 220 °C. Cross-linking takes place in the bulk of the polymer as a result of the free radicals formed in the thermal decomposition of the peroxide: because of its low energy the electron beam can induce the radiation cross-linking of polyethylene only in a thin surface layer.

The technology for the preparation of radiation-cross-linked polypropylene foams was developed recently.[144] It is similar to the production technology of polyethylene foams, except for the higher temperature of the process. It was found that the dose should correspond to a gel fraction of 25%–45%. Radiation-cross-linked polypropylene foams have a much higher thermal stability (i.e. a smaller loss in volume when stored at a given temperature) than radiation-cross-linked polyethylene foams. The difficulty in preparing polypropylene foams arises from the rapid decrease in the viscosity of the melt with increase in temperature.[159] This disadvantage can be eliminated by adding polyethylene.[159]

4. Vulcanisation of elastomers and of items made from them

In the case of elastomers we replace the concept of 'cross-linking' by 'vulcanisation'. The radiation-induced vulcanisation of various elastomers and items made from them has found industrial application.

a. Vulcanisation of the components of tyres

It has long been considered (since the late 1950s) that the radiation vulcanisation of automobile tyre casings should be a promising area of application of ionising radiation. However, it was subsequently shown[77] that this process is undesirable because of the complexity of the configuraiton of the tyres, the variety of the chemical nature of tyres, and especially because of the presence of cord, whose strength is degraded by the irradiation. The idea of a combined thermal and radiation vulcanisation of tyres, for example by using ionising radiation for the final vulcanisation of the tyres after a partial thermal vulcanisation,[77] also failed to achieve industrial application because of lack of financial advantage.

A practically more successful approach was a preliminary irradiation of stocks of the individual components of tyres (protectors, carcasses, side walls, etc.) before assembly, formation, and thermal vulcanisation.[160,161] Electron accelerators with energies of 0.8–1.0 MeV were used as the source of radiation. The dose required for the treatment varies from 1 to 200 kGy, depending on the type of radiation. This preliminary treatment allowed the cohesive strength of the raw materials to be increased and some of the natural rubber to be replaced by synthetic rubber while keeping the total time of manufacture of the tyres constant to within ~20%.

The preliminary radiation treatment of the components of tyres has found industrial application in other countries (mainly the USA and Japan). For example, in Japan 9 electron accelerators with a total power of ~0.6 MW were used for this purpose in 1988.[116,162,163]

b. Production of thermally stable self-adhesive electrically insulating materials

In 1971 a radiation method of producing thermally stable self-adhesive electrically insulating tapes and rubber–glass cloths from polyheterosiloxane rubber was developed and introduced into industry.[66,164–166] The production of electrically insulating tape is achieved by using γ radiation from ^{60}Co, and that of rubber–glass cloth by an electron beam generated by an ELV accelerator. Assemblies of this type are now operating in a factory at Kazan'.[66]

The production of electrically insulating tape includes the following steps:[66] the preparation of the initial composition, consisting of polyheterosiloxane rubber with some additives, the addition of pigment to the composition in the rubber mixer at temperatures not above 50 °C, the preparation of stocks of the tape on a polyethylene substrate as rolls 13–15 cm in diameter, their radiation vulcanisation with a ^{60}Co γ source (dose of 0.10–0.13 MGy). Since the preparation of the tape is a batch process, blocks of 25 rolls of the tape are rotated during the irradiation in order to distribute the dose uniformly. The source of γ radiation has a projected activity of 0.75 MCi and an average dose rate of 2.2 Gy s^{-1}.

Siloxane rubber with an additive of a halogenated polymer containing boron is used for the production of the electrically insulating tape.[166] Its vulcanisate has the properties of autohesion and adhesion at room temperature, apparently due to the presence of B–O groups in the polymer chain. Tapes produced by this method are the leading electrically insulating material. They are characterised by a good autohesion, high stability towards water and ice, and long working life (at 250 °C they retain their properties for 200–300 days).[66]

The technological process of preparing self adhesive rubber–glass cloth consists in steeping the glass cloths in a solution of polysilosane, removing the solvent, depositing on the impregnated glass cloth the main layer of rubber mixture, and vulcanising the composite material with an electron beam (using a dose of 50–70 kGy).[66] A ^{60}Co source of γ radiation can also be used for the vulcanisation. In this case the cloth is irradiated in rolls. The operating characteristics of the cloth are approximately the same as in the tapes described above.

c. Other processes based on the vulcanisation of elastomers

Several other processes based on the radiation vulcanisation of elastomers have been described. In Indonesia a pilot plant based on a ^{60}Co γ source (with an activity of 225 kCi) is being operated for the vulcanisation of natural rubber latex.[167] The dose is ~30 kGy (with a dose rate of ~2.8 kGy h^{-1}). The operating speed of the assembly is 1000 t a^{-1}.

The radiation vulcanisation of the latex of natural rubber is one of the stages in the preparation of rubber gloves for handling radioactive preparations.[168] The γ radiation from ^{60}Co is used for this purpose (with a dose of 12 kGy).

It has been reported[169] that the vulcanisation of rubber based on butadiene–styrene copolymer under the influence of electron radiation generated by a linear accelerator can be used in the production of rubber 'cushions' for the tracks of tanks. A technology for the production of medical tubes from siloxane rubber, and roofing and water-repelling material with an atmosphere-resistant layer of ethylene–propylene or butadiene–styrene rubber by using electron radiation to vulcanise these elastomers has been proposed.[170]

5. Other processes based on the cross-linking of polymers

In addition to producing the insulation of wires and cables, thermosetting items, and polyethylene and polypropylene foams the radiation cross-linking of polymers is used to make other products and materials, such as polyethylene tubes for hot water installations,[79,171] matrices of filled polyethylene for concrete and reinforced concrete items,[172] protecting rings of low-pressure polyethylene for rubber packing in water apparatus,[173] insulators of ethylene–vinyl acetate copolymer filled with

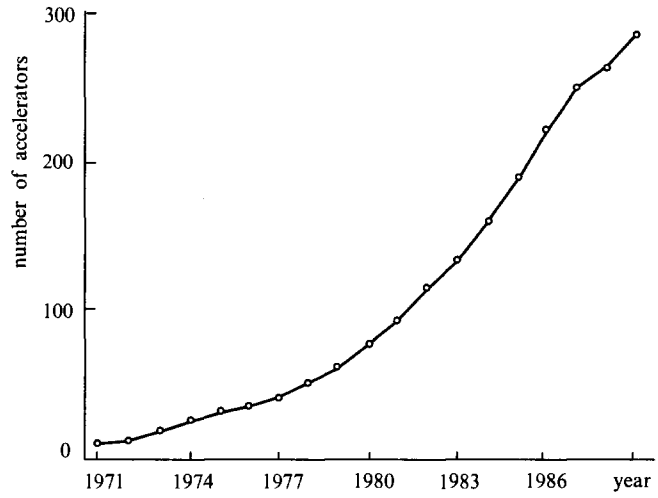

Figure 4. Increase in the number of assemblies with electron accelerators for hardening coatings.

aluminium hydroxide,[174] plastics [for example, of poly(ethylene terephthalate) and nylon] with improved thermal stability for use in modern electronics,[145] etc.

We shall briefly dwell on one new radiation process: the preparation of fibres of silicon carbide SiC.[175–177] This fibre is obtained by heat treatment at 1200 °C of radiation-cross-linked polycarbosilane fibre. It was found that the fibre has a higher thermal stability than the silicon carbide fibre prepared from thermally cross-linked polycarbosilane (see Fig. 3 and Ref. 176). The dose needed to achieve cross-linking is 10 MGy. In Japan a pilot plant is batch operated with an electron accelerator to treat 4.5 kg of polycarbosilane. A project for the commercial establishment of a production rate of 1 tonne of silicon carbide fibre per month in 1996 has been worked out in detail.[176,177]

IV. Radiation polymerisation

Many radiation processes realised on pilot plant and on industrial scales are based on the radiation polymerisation of monomers and their mixtures. These include primarily the radiation hardening of coatings (mainly under the influence of electron beams) and radiation graft polymerisation.

1. Hardening of the coatings

The radiation hardening of coatings has been introduced into industry in many countries.[1,67,98,101,102,116,178–195] In terms of the power of the electron accelerators this process occupies an intermediate place (coming after the radiation cross-linking of the polyolefin insulation of cables and wires). In 1990 ~350 laboratories, pilot plants, and industrial assemblies with electron accelerators for the hardening of coatings were operating throughout the world. Rates of development of this region of radiation technology are illustrated in Fig. 4, which shows the growth of the number of assemblies fitted with an electron accelerator (not including data for the former Soviet Union and for the People's Republic of China).[179]

The wide-ranging interest in radiation hardening was due mainly to its advantages over thermochemical hardening.[1,27,67,196] It was claimed to have a much lower (~85 times) energy consumption,[197] and to offer a gain in working areas, a reasonably high rate, the ability to operate at room temperature, and a lower consumption of reactants. It should specially be stressed that radiation hardening is a cleaner process from an ecological standpoint. Under thermal hardening the organic solvents in the hardened compositions are evaporated into the atmosphere. Industry produces approximately ~20 million tonnes of ordinary compositions every year [177] and, as a result, ~8 million tonnes of organic solvents are introduced into the surrounding medium. Radiation-hardened compositions contain no solvents. Unfortunately, these compositions (together with those obtained by photochemical hardening) account for only 1% of the total production. Obviously, in the interests of the protection of the ecological environment every effort should be made to replace the thermal method of hardening by the radiation (or photochemical) method.

Radiation hardening offers the following advantages over the photochemical hardening under the influence of UV radiation:[179,182] photoinitiators are not required, absence of sensitivity to pigments, uniform hardening even in relatively thick coatings, almost 100% conversion, and the possibility of grafting the monomer to the polymeric substrate. At the same time, the photochemical hardening offers a substantially lower cost (usually by 2–20 times) for the apparatus and instrumentation,[179] less attack on the sample, and lack of an oxygen effect. The high cost of hardening under the influence of electron radiation is often responsible for the preferential application of thermal or photochemical methods. For example, in Japan 29 090 photochemical assemblies were operating in 1988, as opposed to only 60 with electron accelerators.[116]

The doses needed to harden coatings depend on the state of the composition to be hardened and on the irradiation conditions, and usually lie between 20 and 200 kGy.[67] A high operating speed for these relatively high doses can be achieved by using sufficiently powerful electron accelerators. Since the thickness of the coatings is usually small mainly low-energy accelerators are used in this region of technology (electron energy between 0.15 and 0.35 MeV).

The most widely used accelerators are of the 'Electrocurtain' type (see Table 1): in 1991 ca. 200 of these machines were used for radiation hardening.

The power of the electron beams is expressed in kW, but the operating speed of the electron-beam assemblies is often measured in MGy m min^{-1}. For the low-energy accelerators made abroad whose parameters are listed in Table 1 the productivity in these units is 8.2, 3.75–15, and 2–12 respectively for EPS,[198] 'Electrocurtain',[199] and 'Broad Beam'.[100] These machines can be constructed with several accelerator tubes in order to increase the operating speed of the assembly. For example, accelerators of the 'Aurora' type are produced with 1–3 tubes, and accelerators of the 'Electrocurtain' type have between 1 and 4 tubes.[200,201] The power of an accelerator of the 'Electrocurtain' type with four accelerator tubes arranged in series is 100 kW m^{-1} (with an energy of 0.175 MeV).

Assemblies based on accelerators which generate electron beams of higher energy are sometimes used. This happens when the hardening of coatings is combined, for example, with the cross-linking of a polymeric substrate. In particular, electron accelerators of the ELV type (1.2–1.5 MeV energy) are used in

Russia for the production of artificial leather, in which the hardening of the decorative and protective coating is combined with the cross-linking of the polymeric material of the leather (see below).

The basis of hardening compositions are mixtures of unsaturated oligomers (oligoester maleates, oligoester-, polyester, polyurethane and epoxyacrylates and acrylates of organosilicon compounds) and vinyl monomers such as styrene, triethyleneglycoldimethacrylate, hexanediol-1,6-diacrylate, 2-ethylhexyl acrylate, tripropyleneglycol diacrylate, trimethylolpropane triacrylate, and pentaerythritol triacrylate.[67,202–205] In addition to oligomers and monomers the compositions may contain pigments, fillers, inhibitors, stabilisers, and other additives.

Irradiation produces copolymerisation of the oligomer and of the monomer with formation of a stable and insoluble three-dimensional cross-linked polymer. In the great majority of cases this 'thin-layer' radiation polymerisation is a free-radical process, strongly inhibited by the presence of oxygen. If the hardening is carried out in air the oxygen reacts with the free radicals in the surface layer of the coating, suppressing the polymerisation and producing an adhesive and insufficiently hard surface.

Several methods of overcoming the oxygen effect have been suggested.

(1) Irradiation in an atmosphere of inert gas (nitrogen, CO_2, combustion products of natural gas).[67]

(2) Closing the layer to be hardened with a polymeric film (for example, polyethylene or nylon), and removing the film after the irradiation.[206]

(3) Sequential irradiation with an electron beam and with UV light: also called the 'double hardening' method. The light dissociates the peroxidic compounds and induces additional polymerisation as a result of the free radicals created by the process.[184,207]

(4) Using additives which inhibit the oxidation (for example, amines) or which sensitise the hardening (for example, salts of transition metals),[208] or also 'floating' additives (for example paraffin wax).[67,209]

(5) Covering the composition to be hardened with a protective layer of water.[209]

(6) Using special compositions containing oligomers modified by phthalic anhydride, dicyclopentadiene, styrene, etc.[47,210]

(7) Irradiating at very high dose rates ($\sim 10^{11}$ Gy s^{-1}), generated by nanosecond pulses of electrons.[211]

(8) Polymerisation by a cationic mechanism (in this case the oxygen has practically no inhibiting effect).[208,209] This type of hardening is only seldom met.

Methods of suppressing the effect of oxygen were discussed in detail in a review by Fomina et al.[212] In practice only the first three methods have been realised (the second only once). The third method began to be used a few years ago. Nitrogen containing not more than 0.05%–0.1% of oxygen as an impurity is usually used as the inert gas.[209,213]

In recent years the technique of radiation hardening of various polymeric coatings has been developed and brought into industrial practice (paints and varnishes, adhesives, magnetics, metallised materials, printing dyes, etc.) on many surfaces (timber, metallic, ceramic, stone, paper, polymeric, on magnetic disks, etc.).[1] Table 4 shows a list of the materials with radiation-hardened coatings produced in Russia and the Ukraine. The list of the corresponding articles produced by the foreign industry is even wider.[1] In particular, it includes timber parquet tiles and massive rocket bodies.

Table 4. Products with radiation-hardened coating produced in Russia and the Ukraine.

Product	Location of equipment	Operating speed	Ref.
Wooden panels for television sets [a]	L'vov, Simferopol, Samara	11 m^2 min^{-1} (L'vov)	67, 214, 215
Wooden panels for furniture	Kiev, [a] Moscow	950 000 m^2 a^{-1}	67, 216
Artificial leather	Kirov [b]	1.3 $t\,h^{-1}$	217, 218
Gypsum–polymer plates with decorative coatings	Kolomna (Moscow region)	200 000 m^2 a^{-1}	219
Asbestos–cement plates with decorative coatings	Near Moscow	200 000 m^2 a^{-1}	67, 218
Ceramic lining plates with decorative coatings	Dnepropetrovsk	2–5 m^2 min^{-1}	220
Plenkosintokarton [c]	Moscow	—	221, 222
Premelts for the production of laminated glass textolite	"	—	221, 222
Polymeric pressure-sensitive thin-film adhesives	"	—	221, 222

2. Grafting polymerisation

Radiation grafting polymerisation is used to improve the properties of materials (mainly polymeric). In practice this process is used for finishing textile items, for grafting acrylic acid to polyethylene (in order to increase its adhesion to aluminium), for producing ion-exchange membrane, etc. The most important region of application is radiation biotechnology.

a. Radiation biotechnology

Studies and technological developments in radiation biotechnology are proceeding in two main directions: the production of biocompatible materials and the immobilisation of bioactive substances in polymeric matrices.

Biocompatible materials. Synthetic polymers are often used as biomaterials.[223,224] However, they have several defects: the most important is the presence of toxic impurities (catalysts, stabilisers, plasticisers, dyes), which can be washed out in an aqueous biological environment. On the other hand if the polymer is produced by the radiation method it does not contain these harmful impurities and furthermore it is sterile. Among the most important radiation methods of preparing biocompatible materials we can include graft polymerisation, polymerisation in the bulk, in solution, in an emulsion, or in the solid state, and cross-linking.[223,224] The most widely used of these methods is the first.

One of the main requirements on biocompatible polymers is that they should be hydrophilic. However, hydrogels become mechanically weak when they adsorb large amounts of water (30%–95%), and therefore hydrophobic polymers are used as substrates in their production [silicone rubber, polyethylene, poly(ethylene terephthalate), polytetrafluoroethylene, polyurethanes].

The compounds mainly used to prepare hydrogels include 2-hydroxyalkyl methacrylates $CH_2=C(CH_3)CO_2ROH$ [where R is $-CH_2CH_2-$, $-CH_2CH(CH_3)-$, or $CH_2CH(OH)CH_2-$]; acrylic acid, acrylamide and their derivatives, the derivatives of aminoethyl methacrylate, *N*-vinyl-2-pyrrolidone, penta-2,4-dien-1-ol, *N*-vinyl-*N*-methylacetamide, sodium styrenesulfonate, etc. are used less often. The radiation grafting of these monomers (or of their mixtures) to various substrates produces neutral, anionic, or cationic hydrogels.[223–230] Let us consider some relevant cases.

The production of polyelectrolyte biomaterials having a good blood compatibility has been reported:[231] it uses the radiation grafting of acrylic acid (from an aqueous solution) to polyethylene, followed by the deposition of polyethyleneimine on the resulting copolymer. As reported,[228,232] the radiation grafting of acrylamide to blood vessel substitutes obtained from poly(ethylene terephthalate) fibres markedly improves their properties. Thromboresistant materials have been prepared by the radiation grafting of *N,N*-dimethylacrylamide on polytetrafluoroethylene and on the copolymer of ethylene with polytetrafluoroethylene. It was found that the biocompatibility depends on the dose rate used for the grafting.[233] An improved blood compatibility was obtained also by using other combinations of polymer and of grafted monomer, for example silicone tubes + *N*-vinyl-2-pyrrolidone,[234] polyurethane films and tubes + acrylamide or 2-hydroxyethyl methacrylate,[235,236] silicone rubber (silastic) + *N*-isopropylacrylamide or its copolymers with acrylamide,[237] poly[bis(trifluoroethoxy)phosphazene] or poly[bis(phenoxy)phosphazene] + *N*-vinyl-2-pyrrolidone,[229] or polyethylene tubes + acrylamide,[238] polyamide + a mixture of vinyl monomers (2-hydroxyethyl methacrylate, acrylamide, etc.),[230] and other combinations.

Polymerisation in the bulk and cross-linking are used much less often. Hydrogels obtained by these methods form solid systems or microspheres (without using polymeric substrates).[224] Studies of this type were carried out with 2-hydroxyethyl methacrylate,[239] poly(ethylene oxide),[240] *trans*-1,4-polyisoprene,[241] poly(vinyl alcohol),[242] poly-*N*-vinyl-2-pyrrolidone,[243–246] etc.

The biomaterials prepared in this way were suggested for use in the production of soft contact lenses,[239] of adsorbents for the separation of biologically important substances by the affinity chromatography method,[230] seamless thermosetting compounds for blood vessels,[241] indicators for bilirubin in the urine,[232] surgical dressing,[243,244,246] etc. (Surgical dressing material prepared by radiation cross-linking have been produced on a commercial scale in Poland since 1990 under the trade names HDR^R and AQUA-GEL^R).[244]

However, it should be stressed that these methods did not find wide application in practice. In particular, the use in medical implantation of any material produced by the radiation method has not so far been reported. According to one report[230] this is because of the loss of biocompatibility during lengthy in vivo trials. The explanation of this disappointing result lies in the monitoring (in most cases) of only one property, associated with the biocompatibility, whereas these materials call for a more complex study.

Immobilisation of bioactive substances. The greatest practical applications were achieved by radiation methods of immobilising bioactive substances (antibiotics, antibodies, antigens, anti-cancer preparations, bacterial cells, contraceptives, enzymes, hormones, immunodiagnostic substances, proteins, and others) in polymeric matrices in order to lower their mobility.[223,224,228,243,244,247–257] The main aims of immobilisation are the following:[247] fixing and lowering the solubility of a bioactive substance in order to extend its effectiveness, giving to a material of correct shape and size an enhanced stability towards heat and chemical reactants, and a controlled slow evolution for moderately high and local action. The main regions of application of radiation-immobilised biological materials can be classified into two groups:[250] (1) biochemical processes (of the fermentation type) with the participation of immobilised enzymes, yeasts, bacterial cells, etc.; (2) biomedical applications (systems with a controlled evolution of medicinal substances, immuno-logical systems, artificial organs, etc.), which involve immobilised medicinal preparations, enzymes, antibodies, and cells.

Two main methods of radiation immobilisation have been proposed: the formation of chemical bonds between a bioactive substance and the substrate, and the capture of the material by the polymeric matrix.[248] In the first method the biomolecules react with the functional groups of the polymer, radiation-grafted or radiation-cross-linked, or obtained by radiation polymerisation. It has been reported that heparin, trypsin, chymotrypsin A, L-aspartamine, papain, asparaginase, glucosooxidase, albumin, antibodies, antigens, etc.[251,252,258–260] can be immobilised by this method.

In the second method radiation polymerisation at room temperature or at low temperatures is used to immobilise the bioactive substance, in conjunction with cross-linking of the polymers.[223,247–249,261] The method has been used to immobilise antibiotics, bacterial cells, hormones, haemoglobin, polypeptides, ureases, and various medicinal preparations (pilocarpine, provital, cancer-fighting preparations, etc.). Let us examine some typical examples.

The radiation polymerisation of aqueous solutions of acrylamide in the presence of provital or pilocarpine hydrochloride yielded preparations with controlled additions of medicinal substances used in the treatment of burns and glaucoma respectively.[228] Polyvinylpyrrolidone rods containing prostalgin, prepared by radiation polymerisation and cross-linking, are useful for inducing births.[244] Thin polymeric membranes with a high enzyme activity were synthesised by the radiation hardening of a mixture of a hydrophilic polymer [for example, poly(ethylene glycol) dimethacrylate] and a solution of an enzyme (for example, glucoamylase).[262] Matrices with the cancer-fighting preparation narcyclazine, from which it can be very slowly evolved, were obtained by γ irradiation at -78 °C of a mixture of 2-hydroxyethyl methacrylate and trimethylolpropane trimethacrylate.[263] A promising application of the

chemotherapeutic treatment of cancer consists in implanting the immobilised anti-cancer agent within the tumour: in this way its effect is local and it does not penetrate into the blood stream, thus minimising undesirable side effects.[248,249]

b. Finishing of textile materials

The properties of natural and of artificial fibres and tissues can be improved by radiation grafting.[264–267] In particular, the grafting of *N*-methylolacrylamide significantly improves the crease resistance of tissues made from a mixture of polyester and cotton fibres.[196,265] At the end of the 1960s the firm 'Deering Milliken Corporation' (USA) demonstrated a combined method of finishing these tissues which included the radiation grafting of *N*-methylolacrylamide.[196] To this end they used several electron accelerators: the operating speed of the assembly was 4.5×10^6 m a^{-1}. Articles which do not need to be ironed for long times were produced from the modified tissue. This production was maintained for 10 years, but in the late 1970s the production of textiles by this method was abandoned because of its low profitability and of the introduction of the more economical photochemical method of grafting.[268,269]

Since 1976 a pilot apparatus including an accelerator of the 'Electron' type (energy 0.7 MeV, beam power 7 kW) has been in use for the finishing of tissues by the radiation grafting method at the Glukhovsk cotton and paper concern in the Moscow region.[270] The operating speed of the assembly was 10–100 m min^{-1} (for a dose of 10–20 kGy). One of the processes (the preparation of cotton and paper tissue with antibacterial properties, is achieved by the grafting of methyl-5-vinylpyridinium methylsulfonate followed by the addition of hexachlorophene.[264] Tissues with grafted acrylic acid, treated with a solution of a copper(II) salt, have similar properties. It was reported[271] that the industrial production of tissues having these properties has been prepared: the assembly is fitted with an electron accelerator of the 'Aurora' type.

Yet another pilot assembly (with an 'Aurora' accelerator) for the local finishing of textile materials (for example, polyamides) has long been operating in Dresden.[272,273] Irradiation simultaneously with grafting was carried out on given areas of the textile (outlined by using aluminium 'masks'); under these conditions the grafted and the nongrafted regions had different properties (in particular, a different depth of colour). The operating speed was 50–60 m min^{-1} (for a dose of 100 kGy).

At present, studies of the radiation finishing of cotton–paper materials by using an electron accelerator are also being carried out in India (see, for example, Ref. 274).

c. Other processes based on radiation grafting

Several other processes based on the radiation grafting of monomers to polymers have been developed. They include the preparation of polyethylene with grafted acrylic acid, which has a high adhesion to aluminium, the production of ion-exchange membranes, etc.

In 1968 an industrial assembly for the radiation grafting of acrylic acid to polyethylene, aimed at the preparation of material with a high adhesion to aluminium, began to operate in France.[275] Powdered polyethylene was irradiated with electrons (dose 7–10 kGy) in the air, and acrylic acid was then grafted to it by heating. The operating speed of the assembly was ~20 t d^{-1}. The material prepared in this way is used as a coating for aluminium foil. A technology for the production of grafted polypropylene has also been worked out.[275] Ion-exchange membranes are being manufactured in Japan on a pilot-plant scale by the radiation grafting of acrylic acid on polyethylene films.[276] These membranes are used as separators in alkaline batteries. An apparatus was constructed on the basis of a 'Dynamitron' accelerator (2 MeV energy). A part of the film (for tapes 100–300 m long) was irradiated in a nitrogen atmosphere: grafting was then carried out by inserting the sample for a prescribed time into a solution of acrylic acid saturated with nitrogen, washing the sample, and drying it.

There are reports[196] that battery separators manufactured from polyethylene films with radiation-grafted acrylic acid have been commercially distributed, but at the moment they are being sold only in the USA. The technology of preparing battery separators on the basis of polyethylene with radiation-grafted acrylic acid or acrylonitrile was developed also in Russia.[277,278] In China γ radiation from ^{60}Co is used for the manufacture of these separators (with an annual production of 10 km^2).[279]

The published literature contains a very large amount of other possible (or already feasible) applications of radiation grafting (see, for example, Refs 1 and 271). In the USA the radiation grafting of acrylamide on starch is used to produce flocculants.[196] In France radiation grafting of *N*-vinylpyrrolidone onto silicone rubber is used to prepare soft contact lenses:[196] this product is sold in China.[279] In Japan a pilot plant has been constructed (operating speed 1 t d^{-1}) with a ^{60}Co source of γ radiation (activity 6.5 kCi) for the gas-phase grafting of butadiene to poly(vinyl chloride); the product is characterised by an enhanced impact resistance.[280]

Pikaev et al.[281] have described the technology of the radiation grafting of acrylic acid, acrylonitrile, and of a series of other monomers to butadiene–styrene thermoelastic plastics and to rubbers based on the ethylene–propylene terpolymer which markedly improves the lubrication properties of the products and their adhesion characteristics. To carry out these processes they constructed a pilot plant assembly with a Cockcroft and Walton electron accelerator as the source of ionising radiation. The operating speed of the assembly was 4.2 t a^{-1} with a dose rate of 2.2 Gy h^{-1}.

Radiation gas-phase grafting polymerisation can be used to encapsulate fertilisers in order to extend their lifetime.[86] This is achieved by grafting acrylamide and then vinylidene chloride on the fertiliser (carbamide). The required dose is ~30 kGy.

Other important products obtained by radiation grafting include effective adsorbents for ammonia and acetaldehyde from the gas phase,[282,283] of uranium from sea water,[283] of metals from waste water,[283] water absorbents,[284,285] etc. A method of creating barrier layers from polysiloxane on polymeric packing materials by radiation grafting has recently been developed.[286] These layers protect the packed material from the penetration of oxygen, oil, etc. The grafting of phenylacetylene to polyethylene increases the thermal stability and improves the electric conduction properties of the polymer.[287] The radiation stability of polyethylene is substantially increased by the grafting of acenaphthene.[288] The ethylene–propylene terpolymer and chlorosulfonated polyethylene with radiation-grafted condensed bromoacenaphthalene have a relatively high radiation stability and fire resistance.[141]

3. Production of modified porous materials

The radiation method of modifying various porous materials (wood, cement, asbestos–cement materials, etc.) is now relatively widespread.[86] The method consists in impregnating these materials with monomers or oligomers and polymerising them under the influence of ionising radiation (usually γ radiation from ^{60}Co). It is most often used with wood and plastic materials.

a. Wood and plastics materials

The polymerisation of monomers impregnated in wood greatly improves the properties of the latter: its mechanical strength is increased, its stability towards decay is also increased, and the water absorption is decreased.[76] Methyl methacrylate is often used as the monomer. The dose required for the polymerisation is 10–20 kGy (depending on the dose rate).[76,289] Styrene, and a mixture of acrylonitrile with methyl methacrylate, butyl methacrylate, etc., are used more seldom.

The dose depends on the nature of the monomer. In the case of styrene it is 250–300 kGy.[76] At these high doses the process is complicated by the decomposition of the wood. For this reason the dose used to prepared wood–plastics materials should not exceed 50 kGy.[76] As a result, when monomers difficult to polymerise are needed (for example, styrene) sensitisers are used

(CCl_4, solutions of metal salts with a variable valency, tributylphosphate, etc.).

A high moisture resistance is achieved in wood by using compositions consisting of a mixture of acrylonitrile and methyl methacrylate with additives of ethylene glycol dimethacrylate and maleic anhydride.[290] The dose needed to polymerise this mixture is ~10 kGy. To polymerise butyl methacrylate with some additives 10–30 kGy are required at a dose rate of 8 kGy h^{-1} (see Khan et al.[291]). Radiation modification is used for both soft and hard timber species.[289,292] In the USA hard species are modified by the radiation method, more than 80% being oak timber.[289]

In many countries wood–plastic composites are prepared by the radiation method.[76] In the USA parquet flooring, sports goods, everyday objects, etc.[289,292] are manufactured. In 1975 a pilot plant with a ^{60}Co source of γ radiation (activity ~100 kCi) was produced in Russia (Solikamsk) and operated for a long time for the production of parquet flooring from birch timber impregnated with methyl methacrylate.[76,293] The operating speed was ~10^5 m^2 a^{-1}. A similar but smaller apparatus was assembled in Hungary (with an operating speed of ~200 t a^{-1}).[290,294]

Wood and plastics materials from wood of tropical origin (bamboo, rubber tree, red liana, etc.) prepared by the radiation method can now find practical application.[290,294–300] The original timber of these woods is not used because of its low stability towards rotting.

b. Other composite materials

Among other porous materials modified by polymers we should discuss the cements.[76,293] Cement–polymer materials prepared by the radiation method have a much higher stability than the initial concretes; they are also characterised by an improved stability towards external interactions. The operating characteristics of wood–textile materials, tufa, gypsum, cardboard, paper, etc. are improved as a result of the modification by polymers.[76,293] According to one report[301] composite materials usable in construction and in the production of ceramic articles can be made from the waste products of the cellulose and paper industry by drying them, introducing mineral additives, unsaturated esters, and vinyl monomers, followed by radiation polymerisation.

Radiation polymerisation has been proposed as a means of producing armoured plastics, consisting of a strength material (for example, glass cloth) and a polymeric binder.[302] Plastics of this type are produced by repeating the sequential electron-beam treatment of the cloth and the binder. The technique of polymerising a thin layer of monomeric composite additive on the surface of a moving polyethylene film under an electron beam was developed for the production of adhesion-active materials.[303]

The radiation polymerisation of polymers in porous materials allows us to preserve and strengthen items made of wood, stone, bone, ceramics, etc. having historical value.[304–308] To this end the eroding items (statues, clay vases, dishes, items of furniture, everyday objects, skeletons, gypsum objects, etc.) are saturated with the monomer in a vacuum (or the monomer introduced separately by diffusion), and the monomer is then polymerised by γ radiation from ^{60}Co. This polymerisation gives the item a high mechanical strength which cannot be achieved by ordinary methods. Methyl methacrylate is used most often, vinyl acetate and unsaturated polyester resins are used least often. When the colour of the article has become bleached, a hydrophilic monomer can be used (for example, 2-hydroxyethyl methacrylate) which 'develops' the colouring as a result of polymerisation. This method was developed in Austria, the former Czechoslovakia, France, Germany, Switzerland, the former USSR, and Turkey, and has found some practical applications.

Another application of the radiation polymerisation of monomers impregnated in porous objects has recently been described:[309] the restoration of old books kept in large libraries (like the British Library). A suitable mixture of monomers is deposited on the page, and irradiated when an appropriate degree of impregnation has been reached. The method has been validated on a pilot plant with a ^{60}Co source of γ radiation. The 'Nordion International Inc.' corporation in cooperation with the British Library has planned to assemble an industrial gamma source with an annual throughput of up to 5×10^5 books.

4. Other processes based on radiation polymerisation

There are reports of the practical use of several other processes based on radiation polymerisation. In the People's Republic of China (PRC) the radiation polymerisation method is used on a pilot plant scale to produce polyacrylamide, used in the petroleum industry.[279] The operating speed is 400 t a^{-1}. According to one report[310] polyacrylamide produced by the radiation polymerisation of acrylamide in an ethanol solution can be used as a coating for medical X-ray films: the product is available in China from many producers of photographic film.

Pilot plants with ^{60}Co sources of γ radiation for carrying out emulsion radiation polymerisation have been described.[68,311,312] In 1989 several types of latex were prepared in China by the radiation emulsion polymerisation method with a ^{60}Co γ source (operating speed up to 2000 t a^{-1}).[313] The products are used as a binder in the textile industry and as a thickener in the printing trade.

Various optical items (Fresnel lenses, contact lenses, prisms, etc.) can be obtained by the low-temperature radiation polymerisation of methyl methacrylate, 2-hydroxyethyl methacrylate, and some other monomers.[314,315] The monomer (or sometimes the prepolymer) is placed in a mold and cooled to a temperature close to its glass transition temperature (between −50 and −78 °C). After γ irradiation the resulting polymer is removed from the mold. Because the process has been carried out at a low temperature the compression of the product is relatively small, and the polymer emerges transparent and free from cracks and bubbles even with relatively large items: the method can be used to prepare Fresnel lenses having an area of 1 m^2 (see Kaetsu et al.[315]). The method has been used by the firm 'Nippon Kogaku Co.' (Japan) to produce lenses used in photolithography.[315] It consists of two stages: the preparation of the prepolymer and the polymerisation in the mold at low temperatures. The operating speed is several hundred lenses per annum.

V. Radiation degradation

Radiation degradation is not so widely used as radiation polymerisation. The most important processes based on the radiation degradation of polymeric materials are the production of fodder and of fodder additives from waste products containing cellulose, the control of the molecular mass of polymers, and the decomposition of PTFE and rubbers from butyl rubber.

1. Preparation of fodder for cattle from waste products containing cellulose

Waste products containing cellulose (sawdust, shavings, chaff, fine splinters, etc.) also contain large quantities of polysaccharides; therefore they can be treated as a potential source of fodder for cattle. Irradiation of these materials produces a marked change in their properties: they are amorphised, the recovery of polysaccharides from lignin is improved, the amount of cellular tissue decreases, and monomeric and oligomeric carbohydrates are formed.[41,85,316] For example, wheat chaff contains 36.8% of carbohydrates in the dry residue after γ irradiation to a dose of 1 MGy and acid hydrolysis.[317] It has been shown experimentally that these materials (in particular sawdust, chaff, or shavings) can replace 3%–10% of the normal fodder for oxen, pigs, sheep, and chickens when irradiated to a dose of 0.2–0.6 MGy.[85,316,318]

The dose needed for a substantial improvement in the quality of the fodder from waste products containing cellulose depends on the type of waste and on the class of cattle.[41,85,316,318] It lies between 0.1 and 1.0 MGy. Of course, this large dose can hardly be used economically. But it can be decreased by simultaneously irradiating and heating the waste products or by heating them after irradiation.[85]

A large-scale series of experiments with these fodders has been planned by building a pilot-plant assembly with an ILU electron accelerator.[85,318] Its operating speed is 0.2–0.3 t h^{-1} (see Ershov[85]). The use of the irradiated product as a 5% addition to the feed in an aviary with an annual production rate of ~7 million hens has been reported.

2. Degradation of PTFE waste products

The radiation degradation of polytetrafluoroethylene (PTFE) waste products converts them into a powder or into products having a low molecular mass which are useful in practice.[269] Relatively high doses are required (0.5 MGy or even higher), and at sufficiently high dose rates the heat evolved within the polymer produces a simultaneous thermal degradation (observed at temperatures above 360 °C).[319,320] Under these conditions the nature of the resulting substances depends on the temperature, the dose, and the presence of oxygen. Irradiation in an inert atmosphere produces perfluoroolefins (up to 60%) and perfluoroparaffins. In the presence of oxygen fluoroanhydrides of perfluorocarboxylic acids are formed. The resulting compounds can be used in the synthesis of other substances containing fluorine.

In Russia and in the former German Democratic Republic (GDR) two pilot plants with electron accelerators have been assembled. The annual production of one of these plants is 12 t a^{-1}.[319,320] The Japanese firm 'Sumitomo Heavy Industries, Ltd.' carries out this process on a commercial scale, using a high-power 'Dynamitron' accelerator. In the People's Republic of China three assemblies have been built for the same purpose:[279] the product is used mainly as a high-quality lubricating material.

3. Regeneration of rubbers based on butylrubber

In most cases items made of rubber based on butylrubber cease to perform satisfactorily after a relatively short period of operation. However, many substances present in their composition remain almost unchanged. Therefore it should be possible to exploit them for a second time after a suitable regeneration. One regeneration method which has been used in practice is a radiation treatment which leads to degradation of the polymer.[321–324]

Butylrubber is a copolymer of isobutylene and isoprene. The process consists in breaking up the degraded vulcanised rubber, irradiation (both ^{60}Co γ radiation and an electron beam can be used), crushing, etc. The optimum dose is 50–100 kGy. The product can be added (in 10%–15% quantities) to various rubber mixtures.

The radiation method of regeneration of rubber made from butylrubber is used in the PRC on a commercial scale. The assembly (including an electron accelerator) has a productivity of 200 tonnes per annum,[279] and more than 400 tonnes of rubber were regenerated up to the middle of 1992 in an apparatus using a ^{60}Co source of γ radiation.[324]

4. Other processes

Among the other processes of this group we should include the control of the molecular mass of polymers. It is difficult to obtain a polymer with a prescribed molecular mass by polymerising the monomer: this aim is much more simply achieved by subjecting the polymer to degradation by radiation. The process was realised in practice with poly(ethylene oxide) in the USA[196] and with cellulose (in Russia).[325] In the latter case a pilot plant with an electron accelerator (energy 0.3–0.6 MeV, power 40 kW) was used to irradiate a cellulose bed (1–5 layers, 0.8–1.0 m in width) with a dose of 50 kGy.

Many workers have reported that a previous irradiation of waste products containing cellulose (wood shavings, paper spoilage, waste material from the production of palm oil, etc.) increases the yield of final products even for relatively low doses. We shall quote some examples.

It was stated[78,196] that the irradiation of wood waste in air with a dose of 5–20 kGy increases its storage life and improves the yield of cellulose when the material is subsequently treated by traditional methods (for example, by boiling in acid). Thus, in the case of Christmas tree residues the yield of final product is increased by 5%–9% even for a dose of 5 kGy.[78] The reason for this large effect is not clear.

Brenner[326] has proposed a combined method of treatment of waste paper and other waste containing cellulose aimed at the production of glucose. The method consists in the preparation of a fibrous mass, irradiating it with a dose of 10 kGy, and subjecting it to a brief high-temperature (232 °C) acid hydrolysis. The yield of glucose is 50% of the amount of cellulose in the initial mass, i.e. 10% higher than the amount obtained in treatment without irradiation. A similar effect was observed in the fermentative hydrolysis of previously irradiated sawdust, fine chaff, and other waste products.[327,328]

Let us also consider the methods of increasing the yield of the final products from waste containing cellulose obtained from the irradiation of food products used in the treatment of this waste. It was shown (see, for example, Refs. 85 and 316) that the irradiation of the hydrolysate produced by thermocatalytic hydrolysis of vegetable stocks increases the yield of nutrient yeasts when grown on this hydrolysate. The yield increases by 8%, 16%, and 20% for γ radiation doses of 1, 5, and 10 kGy respectively. This effect is explained by the radiation-chemical decomposition of furfural and other compounds, known to be inhibitors of the growth of yeasts. According to Kume and coworkers[329–331] the irradiation of fermentation media used in treating the waste from the production of palm oil so as to obtain from them fodder for animals and to use them to grow edible fungi (dose 10 or 25 kGy), gives satisfactory results.

VI. Radiation sterilisation of medical articles

The radiation sterilisation of medical articles (in most cases, used only once) is one of the most important industrial processes which uses ionising radiation. It follows from Brinston's paper[332] that in the late 1980s about 30% of the medical production items for once-only usage were sterilised by the radiation method. We note a tendency for an increase in the amount of medical production sterilised by the radiation method. At present the fraction amounts to 40%–50%.[176,177] It has been forecast[332] that in the year 2000 more than 50% of the production of once-only medical items will be sterilised by this method.

γ-Radiation from ^{60}Co and electron beams are used for the sterilisation. The possible advantages of using bremsstrahlung X-radiation generated by powerful electron accelerators have been pointed out. An apparatus of this type based on an accelerator of the Cockcroft and Walton type (electron energy 5 MeV, beam power 150 kW) has already been built[121] (see also Section II.3). In 1992 about 120 large γ sterilisers using ^{60}Co were functioning throughout the world (see also Woods and Pikaev[1]). These assemblies are located in more than 40 countries. Of course, γ radiation from ^{137}Cs is also used for sterilisation, but only relatively seldom.[50]

About 30 sterilisers based on electron accelerators (mainly linear accelerators and accelerators of the 'Dynamitron' type) are operating throughout the world. The energy of their electron beams, used for the sterilisation, is mainly 5–10 MeV. Beams with a lower energy may find application[333,334] in the sterilisation of the packing of medical items. Of course, an assembly with an accelerator of the ILU-6 type (electron energy up to 2.5 MeV, beam power up to 20 kW) has already been tested.[335] It has been suggested that hypodermic syringes should be located in a vertical plane and irradiated from both sides.

It should be noted that in recent years the use of electron accelerators has been increasing as compared with γ sources. This is because of the greater safety offered by working with accelerators as well as because of the greater powers, resulting in shorter times of treatment. Thus, linear electron accelerators specially designed for radiation sterilisation have recently come onto the market (in particular, from the American firm 'Varian Associates Inc.').[336]

Table 5. Characteristics of industrial radiation sterilisers in Russia and the Ukraine with ^{60}Co sources of γ radiation (A) and with linear electron accelerators (B).

A. ^{60}Co source.

Location of the steriliser	Activity/MCi
St. Petersburg	0.93
Belgorod-Dnestrovskii (Ukraine)	0.36
Moscow region	0.12
Kaluzhsk region	0.67
Kazan'	0.17
Tyumen'	0.47

Kostroma[a]	1, UELV-10-10	10	10
Moscow[a]	1, LEU	10	10
Leningrad region[a]	2, LUE-8-15S	8	Both 15

[a] The steriliser is in the building stage.

[b] Improvements are being carried out on the steriliser. Two LUE-8-15S linear electron accelerators will be brought into operation (energy 8 MeV, power 15 kW, annual production from each machine 1400 t).[337]

In Russia the last ten years have seen a large increase in the number of once-only items (mainly syringes). In 1995 it is planned to produce 6×10^9 syringes for once-only use, 190×10^6 containers for the storage of blood, and 320×10^6 blood transfusion units.[337] At the same time we observe an intense development in the radiation sterilisation of these products. In Table 5 we quote some data on the industrial radiation sterilisers in Russia and the Ukraine.[98] In addition to industrial sterilisers, equipment based on linear electron accelerators is located in research institutes. The total number of assemblies, including those functioning in institutes, is ~ 30 (see Khrushchev et al.[338]).

In addition to medical items for once-only applications (syringes, needles, surgical items, materials and tissues to be implanted, anaesthetic and obstetric kits, equipment for inhalation, dialysis, and blood transfusion, dressings, gloves, Petri dishes, masks, bandages, pipettes, etc.), some pharmaceutical preparations are also subjected to sterilisation by radiation (eye ointments and drops, ointments for burns, salt solutions, veterinary products, etc.), as well as packing materials. In some countries radiation sterilisation is applied to various solid medicinal preparations, ointments, and suspensions of pharmaceutical stock.[339] This method is used also in the sterilisation of tissues and organs of humans and animals needed in implantation surgery.[340,341] The radiation sterilisation of cosmetic materials (bentonite, gelatine, starch, talc, etc.) also offers attractive prospects.[324-344] The sterilising dose adopted in many countries is 25 kGy. In the Scandinavian countries it is much higher (35 kGy for electron radiation and 32 kGy for γ radiation).[57,345] In some countries (in particular the USA and Canada) there is no fixed sterilising dose: it is determined by the initial number of microorganisms in the product to be sterilised, by their nature, and by their sensitivity to the action of the radiation.[346] Therefore it may vary from 10 to ~ 40 kGy. The dose may be decreased by a careful control of the production conditions of the medical items. In Russia the dose used for sterilisation is 15–25 kGy.[337,338,347]

These doses are relatively high, and therefore in parallel with the sterilisation we must solve the problem of the radiation stability of the preparations and materials from which the item is manufactured. It was found (see, for example, Refs 348 and 349) that many polymers used in the preparation of medical articles are stable enough towards radiation to 'endure' the sterilising dose, but the degradation (especially, post-radiational) of polypropylene, which is widely used as a material for syringes, produces a coloration and makes the material brittle.[350-352] Therefore polypropylene stabilised by various additives has now begun to be used for the production of syringes.

Most of the solid medicinal preparations retain their properties after irradiation with sterilisation doses (see, for example, Ref. 341). This is also true of a series of preparations in the form of concentrated aqueous solutions.[353] However, most medicines in the form of aqueous solutions suffer large changes (dissociation with formation of new substances, changes in pH, etc.). These include some new radiopharmaceutical preparations[354-356] vitamin B_{12},[357] insulin,[357] etc. For these preparations the use of protective additives has been suggested (for example, thiosulfate for a solution of ^{131}I sodium iodide),[354,358] or alternatively irradiation in the frozen state,[357,359-362] when as a result of phase separation only a very small fraction of the energy of the ionising radiation is absorbed by the dissolved substance. Neither of these methods has been applied in practice so far.

An analysis of the economics of these processes has shown that the cheapest method of sterilisation is treatment with steam, and the dearest is the use of ethylene oxide: the radiation method occupies an intermediate place.[363,364] However, at high production rates the radiation sterilisation may compete with the steam method.[364] Obviously, in future the sterilisation with ethylene oxide will continue to be applied in the case of medicinal products unstable towards heat and ionising radiation. For many other items intended for once-only application the radiation method will be the predominant method of sterilisation.

VII. Use of radiation for the protection of the environment

The first studies of the use of ionising radiation for the protection of the environment were carried out in the 1950s.[11] At present studies and technological developments in this region of radiation technology are proceeding in the following main directions:[365] the radiation treatment of natural water, the radiation purification of domestic, industrial, and agricultural waste waters, the radiation treatment of deposits from waste waters, the radiation purification of discharge gases, and the radiation treatment of solid refuse.

1. Natural water

Natural water (from rivers, lakes, reservoirs, artesian wells, etc.), which is used to feed the population, may be contaminated by harmful impurities and contain pathogenic microorganisms and parasites. Often the concentration of these impurities and the level of contamination are small, and relatively low doses are needed for the radiation treatment of the water.

It was found (see, for example, Refs 11, 366, 367) that doses of ~ 1 kGy are sufficient for the purification and disinfection of natural water (in particular, for the removal of organic compounds of the humin type, which produce colour, smell, etc.). It was recently shown[368] in studies of water strongly coloured by natural organic compounds and by finely divided particles, taken from a river in northwestern Russia, that doses of the order of several kGy can lower the coloration to the required level. The dose required for decoloration depends on the season in which the sample was taken from the river. For example, the dose for autumnal water is higher than for the winter.

One of the important problems still awaiting solution is the purification of natural water from toxic and carcinogenic organic compounds containing chlorine. These substances are introduced into the water from the contaminated surroundings, and are formed during the chlorination of water containing several

organic compounds. It has been shown[365,369–378] that the irradiation of water contaminated with organic substances containing chlorine (1,2-dichloroethane, 1,1,1-trichloroethane, trichloroethylene, tetrachloroethylene, chlorobenzene, 4-chlorophenol, 2,4-dichlorophenol) leads to their decomposition. On the basis of these data we may conclude that small amounts of these substances (10^{-4} mol dm^{-3} and below) may decompose upon exposure to relatively small doses (1 kGy or less). In these systems the use of radiation methods seems promising.

However, it should not be forgotten that in the radiolysis of chlorinated aromatic compounds the dechlorination may be accompanied by the formation of other toxic substances. For example, in the radiolysis of chlorobenzene solutions isomeric hydroxycyclobenzenes [sic. Ed. of Translation] and phenol compounds are formed. Furthermore we observe a marked dependence of the yield of decomposition products upon the strength of the dose (especially at low concentrations).[378]

The irradiation of contaminated water in conjunction with ozonisation produces a synergistic effect (see below). Thus, ozonisation of water contaminated with trichloroethylene and tetrachloroethylene[376,377] also eliminates almost completely the dependence on dose strength in dilute solutions, and also protects the irradiated water from a second appearance of the microorganisms and parasites during its transport along conduits.[377]

Radiation treatment gives good results also in the treatment of ground waters. Firstly, it can be used successfully to regenerate water boreholes contaminated by the products of biological processes.[379–381] Ionising radiation kills the bacteria responsible for the redox reactions of the ions Fe(II), Mn(II), etc., and for the subsequent precipitation of insoluble hydrolysis products, which lead to 'clogging' of the water separators and 'ageing' of the boreholes. The doses needed for this are 0.25 – 0.4 kGy.[379] This method was widely used in the GDR.[273,379] 372 Boreholes were fitted with ^{60}Co sources of γ radiation (total activity 132 kCi). However, after the union of the German Democratic Republic and the Federal Republic of Germany all sources were removed from the boreholes because in the FRG the irradiation of food products is not allowed, and drinking water is classified as such. Interest in this method has been shown in the Czech state[380] and in the USA.[381]

Secondly, in situ irradiation of contaminated water in underground reservoirs leads to its purification. For example, it has been shown[380] that the concentration of cyanide ions in underground water is much decreased if the reservoir is fitted with a ^{60}Co source of γ radiation and activated carbon is added to it. After a 6 years use of the installation the concentration of cyanide ions in the reservoir had fallen by more than an order of magnitude.[382]

In spite of the promising results of studies and technological developments the purification of natural water to produce drinking water has still not found large-scale application. Of course, in Austria it is planned to build an assembly for the purification of drinking water having a production rate of 1000 m^3 h^{-1} (see Ref. 376). The details of its future operation are being planned with a prototype having an operating rate of 3 m^3 h^{-1}.

2. Sewage

It has been found (see, for example, Refs 369, 383 – 385) that for the radiation treatment of domestic sewage after its biological purification doses from 0.4 – 0.5 kGy to several kGy are required. For example, the doses needed for disinfection and for the decomposition of harmful impurities (detergents, organic sulfides, dyes, etc.) in the sewage of Tokyo amounted to several kGy.[385] The use of radiation treated water for industrial purposes has been recommended. Kurucz et al.[369] give the same doses, and point out that they are higher for nonchlorinated than for chlorinated water. In the latter case the study was carried out in an apparatus based on an IST electron accelerator (operating rate 460 dm^3 h^{-1}).[369,386]

Industrial sewage differs from contaminated natural water in containing more impurities at much higher concentrations. In most cases higher doses are required for the purification of these effluents (some tens of kGy or more). As a result combined methods of purification have been developed in recent years, in which the radiation treatment is carried out in conjunction with a conventional method (chemical, biological, thermal, flotation, etc.). A brief description of the combined methods is given in Table 6.

Table 6. Combined methods of purifying sewage waters.

Method	Basic processes	Removed impurity[a]	Ref.
Radiation – flotation	Flotation, γ irradiation, secondary flotation	Mercury	387, 388
Radiation – biological	Electron irradiation, additional biological purification	Mixture of isobutyl naphthalenesulphonates	389
Radiation – polymerisation	Irradiation of the sewage containing the monomer	Monomers	26
Thermo – radiation	Irradiation of the waste products while heating	Bacteria, parasites, etc.	390
Radiation – electrodialysis	Combination of radiation and electrodialysis	Various organic substances	391
Radiation – coagulation	Irradiation in the presence of a coagulant	Polyoxyethylene-n-nonyl phenyl ether etc.	392, 393
Radiation – adsorption	Irradiation in the presence of activated carbon	Pesticides	394 – 396
Oxyradiation	Irradiation of the waste while passing oxygen through the solution	Parasites, bacteria, etc.	397
Ozonoradiation	Irradiation of the waste saturated with ozone	Various organic substances	392, 393, 398

[a]These impurities are quoted as an example.

A radiation-biological method is used to purify the discharge waters of the Voronezh synthetic rubber factory from the emulsifier. The latter material (Nekal) is a mixture of isomeric butyl naphthalenesulfonates of the general formula $C_{10}H_6(R)SO_3Na$, where $R = (CH_3)_3C-$, $(CH_3)_2CHCH_2-$ or $CH_3CH_2CH(CH_3)-$, predominantly the first two butyl groups;[399] the alkyl and the sulfonate group are in the same ring in a pair of positions relative to each other. Nekal is classified as a 'hard' surface-active substance and does not dissociate biologically. However, it was shown[389,399] that the removal of the alkyl of the sulfonate group (or both) from its molecule produces biodegradable substances. Dealkylation and desulfonation take place at relatively low doses. The dose needed to decompose $\sim 100-150$ mg dm^{-3} of Nekal is 2–3 kGy. A study by pulse radiolysis has shown[400] that OH radicals contribute to these processes, and to a smaller extent the hydrated electrons produced in the radiolysis of water also make a contribution.

An apparatus for purifying waste waters has two ELV electron accelerators (0.7 MeV energy, total power 70 kW). The waste water is irradiated as a foam (density 0.02–0.03 g cm^{-3}). The operating rate of the assembly is $\sim 12\,000$ m^3 d^{-1}. After the electron beam treatment the water passes to the biological purification arrangement. The degree of removal of Nekal can be as high as 99.5%. At present this apparatus is used to purify underground water contaminated with Nekal.

We should briefly mention the problem of the disinfection of manure discharge in connection with the building and operation of large pig farms. Many workers[41,401,402] have shown that this problem can be solved in principle by using radiation methods. Four pilot plants (three with electron accelerators, one with a ^{60}Co source of γ radiation) were developed for the disinfection and purification of waste waters in large amounts in the Minsk, Moscow, and Omsk regions and operated for a long time. However, the process was never used in practice.

In our country several projects for the production of large assemblies including electron accelerators (total power ~0.9 MW) were considered for the purification of domestic and industrial sewage.[403–405] The largest of these projects was aimed at the radiation treatment of the domestic sewage of one of the towns in the Leningrad region. Its designed operating rate was 110 000 m^3 d^{-1}.[405] However, none of these projects has yet been realised.

3. Sedimentation of sewage

When domestic sewage is allowed to settle (the first stage in their normal purification) deposits containing insoluble solid particles (5%–8%) and water (92%–95%) are formed. In the biological treatment deposits of another type, called the excess active silt (which consist mainly of microorganisms) are formed at the aeration stage. The deposits can be used as fertilisers and as additives to animal fodder. However, they are loaded with bacteria, viruses, and parasites, and they may contain harmful substances. Obviously, they should be disinfected before being used. As can be seen from many published reviews (see Refs 28 and 401) this problem can be solved successively by radiation methods.

It was found that disinfection is achieved at doses of 2–10 kGy. Furthermore irradiation often accelerates the filtration and the sedimentation of deposits, and therefore also their dehydration. At present the technology of the radiation treatment of deposits from sewage waters is being applied in many countries on pilot plant or on industrial scales. The corresponding equipments are based on sources of γ radiation or on electron accelerators. Some data on these assemblies are listed in Table 7. It is intended to build similar apparatus in Canada, Poland, and the Argentine. The system proposed in Canada is based on a ^{60}Co source of γ radiation (with a planned production rate of 80 t d^{-1}).[416,417] The planned production of the Polish system with a linear electron accelerator (energy 10 MeV) is 50–70 t d^{-1} (for a dose of 5 kGy).[418]

4. Gaseous emissions

At present the most intensively studied area in radiation technology includes the work on one of the most important ecological problems: the purification of gaseous emissions from harmful substances (mainly SO_2 and the nitrogen oxides NO_x, where $x = 1, 2$). Many workers have demonstrated the promise of using electron beams for the purification of these gases. It was clearly shown that the electron-beam treatment of gases containing SO_2 and NO_x removes both impurities at the same time.

A pioneering contribution to this problem was made by Japanese research workers and engineers in the early 1970s.[419,420] It was subsequently found[420–423] that the addition of ammonia to the irradiated gas results in the formation of a powdery product of composition $(NH_4)_2SO_4$ and NH_4NO_3 which can be used as an agricultural fertiliser. At present the process goes under the name of the 'Ebara process', after the Japanese organisation 'Ebara Co.' which built and operated the first pilot plant for the purification of gases.

At present studies and technological developments in this area of work are being carried out in Japan, the USA, Germany, Poland, Russia, Italy, China, Belorussia, and South Korea. The method is realised on a large pilot plant scale. Table 8 shows some information on the pilot and demonstration assemblies. Furthermore, in some countries large experimental plants with electron accelerators are being operated for the development of new methods of radiation purification of gas discharges from various sources.[436]

From the results obtained during studies, technological developments, and extended trials it may be concluded that effectiveness of removing SO_2 exceeds 95%, and in the case of NO_x it can reach 80%–85%.[436] The doses needed for purification are between ~10 and 20 kGy (depending on the concentrations of SO_2 and NO_x); the energy of the electorn beam should lie between 0.3 and 0.8 MeV.

The mechanism of the reactions proceeding during the irradiation of gas discharges containing SO_2 and NO_x has been studied by several workers (see, for example, Ref. 371). The electron beam, interacting with the main components of the gas discharges, produces secondary electrons, ions, free radicals, atoms, and excited particles, which react with SO_2, NO_x, and other possible constituents, as well as taking part in dimerisation, neutralisation, and other reactions. The extent of these processes is not large. For example, in one reported computer modelling[437] 181 reactions of this type were considered. Not only are the nitrogen oxides in these processes oxidised, but they can also be reduced (25%–30%) to N_2O and N_2. Whereas the NO_x is removed entirely by radiation-chemical reactions, the SO_2 is oxidised both in radiation-chemical processes and in thermal reactions involving oxygen and ammonia.[438–440] Up to 70%–90% of the SO_2 can be removed by thermal reactions.[440]

Electron-beam treatment is used also in the purification of exhaust gases from thermal electric power stations operating with coal, fuel oil, etc. and also for the removal of harmful impurities from the exhaust gases from furnaces for the heat treatment of sweepings (SO_2, NO_x, and HCl), from tin treatment plants, (SO_2), and from automobile subways (NO_x). Recently a mobile apparatus with an electron accelerator (0.15–0.3 MeV energy) was constructed in the FRG for the removal of harmful volatile organic compounds from the gases of industrial undertakings, and of nitrogen oxides and benzene from the gases of automobile subways.[441] It was mounted on a trailer, and its operating speed was 1000 $m^3\ h^{-1}$. Sometimes the purification technology differs

Table 8. Large pilot and demonstration scale apparatus with electron accelerators for the purification.

[a] Apparatus designed for the removal of SO_2, NO_x and HCl. [b] The accelerator has three irradiators. [c] The accelerator has two irradiators.

from the Ebara process. Thus, in the purification of gases from the furnace for the heat treatment of sweepings the additive $Ca(OH)_2$ is used; in general this additive is not used in the gases from tin treatment plants (where the SO_2 is removed as sulfuric acid).

In Russia the studies in this area of radiation technology are carried out in several scientific and technological development centres.[442,443] In addition to the equipment already functioning in Novosibirsk (see Table 8) pilot plants are also planned for Moscow, Lipetsk, and Orenburg.[403,430,443] It has been suggested[443] that one of the installations should be fitted with a many-aperture electron accelerator of the 'Finval' type (see Table 1).

However, even the largest of the assemblies built so far allow the removal of the gases produced by only one relatively small generating block (with an electric power of 5–8 MW) of a thermal power station. This limitation is due first of all to the inadequate power of currently available electron accelerators. Accelerators with beam powers of 0.5 MW (in Russia[108]) and even 0.8–1.8 MW (in the USA[109,436]) are now being built. We should stress the importance of a Polish project aimed to build an assembly with a productivity of 270 000 $m^3 h^{-1}$ (for a total electron beam power of 1.2 MW).[444,445]

A lowering of the dose required for the removal of harmful impurities (i.e. an increase in the radiation-chemical yield of the decomposition) should accompany the large-scale applications of the radiation methods of purifying exhaust gases. Different methods of solving this problem have been reported. The effectiveness of the removal of NO_x increases if the technique of repeated (or band) irradiation is used.[434,446,447] As can be seen from Ref. 442 the introduction of an aqueous aerosol into the gas to be purified (in the absence of ammonia) produced a marked lowering of the dose.

Another possible path is to use catalysts as additives. Injecting a solution containing (for example) Mn^{2+} ions into the gas before the electron-beam treatment stage can increase the efficiency of the process. The evidence for this statement[72] is that gases are very effectively purified from SO_2 (oxidation yield up to 10^4 molecules for 100 eV) when passed through a dilute sulphuric acid solution of Mn(II).

Increased efficiency can be achieved also by combining the irradiation with other methods of treatment. It has been reported[448,449] that combining γ irradiation with the application of an electric field produces a marked increase in the radiation-chemical yields of the oxidation of SO_2 in the gas phase (up to 100–150 molecules per 100 eV). According to Zimek et al.[450] the purification efficiency is increased by the simultaneous application of an electron beam and of a stream of microwave energy.

From the economic point of view the Ebara process can compete with the conventional methods of purifying discharge gases.[436,438,451] Its cost effectiveness increases with the SO_2 content of the gases to be purified.

5. Solid waste

There are published reports that radiation methods can find practical applications in the decontamination of waste from hospitals and from airports, in the regeneration of active carbons, and in the purification of contaminated soils. The importance of using γ radiation for the disinfection of hospital waste has been pointed out.[452] At present only one assembly with a ^{60}Co source of γ radiation is being operated (in the state of Arkansas, USA),[453] to treat infected hospital waste. As reported,[452] one relatively small source can disinfect this waste for all the hospitals in a town with a population of 1 million, and a large source can provide for the needs of the hospitals in a town with a population of 5 millions.

The technology of the radiation treatment of hospital wastes has been developed also in Russia.[454] It consists of four stages: (1) the separation of the liquid and the solid phase, (2) the radiation disinfection of the liquid wastes, (3) the radiation disinfection of the solid wastes, (4) the purification of the emitted gases. A suitable assembly with a ^{60}Co source of γ radiation was constructed ('Gammatok-100'); its productivity is 65 $m^3 d^{-1}$. However, the method has not yet been used on a commercial scale.

Another promising application of γ radiation is the treatment of wastes for international airports.[452] 20–30 t (or even more) of waste are produced annually in large international airports. This amount of waste can be treated by a gamma-apparatus of intermediate size. The Canadian company 'Nordion International Inc.' plans to construct an irradiator of this type.[452]

The next possible application is the regeneration of the activated carbon used in the purification of natural and of waste waters by using electron irradiation.[455] Samples of carbon with adsorbed sodium lauryl sulfonate were subjected to radiation treatment. The dose required for regeneration was 1 MGy. An economic assessment showed that the radiation method is ~8–10 times cheaper than the usual high-temperature steam method.

Radiation methods can be used to purify contaminated soil.[456–458] Two methods have been developed. The first consists in mixing the contaminated soil with water and a nonionic surface-actant substance and treating the mixture with γ radiation.[456] This method was used to purify soil contaminated with chlorinated dioxins. In particular it was shown that 2,3,7,8-tetrachlorodibenzo-*p*-dioxin is converted by successive oxidative dechlorination into the nonchlorinated dibenzo-*p*-dioxin, characterised by a negligibly small toxicity. The radiation-chemical yield of the decomposition is $\sim 10^{-6}$ molecules per 100 eV. This means that the breakdown takes place mainly as a result of the 'direct action' of the ionising radiation on the dioxin molecule.

The second method was developed for soil contaminated with volatile organic substances (for example, trichloroethylene).[457,458] It consists in the vacuum extraction of impurities from the soil followed by their electron-beam treatment in the gas phase.

VIII. Radiation treatment of food products

The history of the radiation treatment of food products spans an interval of about 50 years. Many important data on the useful effects of ionising radiation on these products have been obtained. These effects include the suppression of the growth of potatoes and onions during storage, the extension of the storage time of meat and fish in the frozen state, the disinfestation of grain and fruit, the sterilisation of meat products in order to achieve long lifetimes in the non-frozen state, etc.[1] Up to 1994 the irradiation of food products was permitted in 38 countries, and pilot and production plants were operating in 27 countries for the radiation treatment of food products:[459] potatoes, onions, garlic, tomatoes, beans, seasonal vegetables, spices, strawberries, citrus fruit, apples, mangoes, dried fruit, grains, rice, poultry, fermented sausages, shrimps, dried fish, frozen frog's legs, etc. Data for spices and seasonal vegetables (Fig. 5) show that the quantity of products treated by ionising radiation increases from year to year.[459]

Careful chemical and biological studies and also tests on the nourishing properties of the irradiated products reported from specialists in many countries have shown that the radiation treatment has no harmful effect on the products. International organisation have stressed[1] that the irradiation of any foodstuff is safe up to doses of 10 kGy: under these conditions higher doses can be used for food products which account for a small part of the human diet (for example, spices). It has been decided that the following types of ionising radiation can be used: γ radiation from ^{60}Co and ^{137}Cs, bremsstrahlung X-rays generated by electron accelerators with an energy not greater than 5 MeV, and electron radiation with an energy not greater than 10 MeV. The setting of an upper energy level for electrons and X-rays aims to avoid any substantial induced radioactivity. This has been confirmed by many theoretical and experimental studies (see, for example, Refs 460–462).

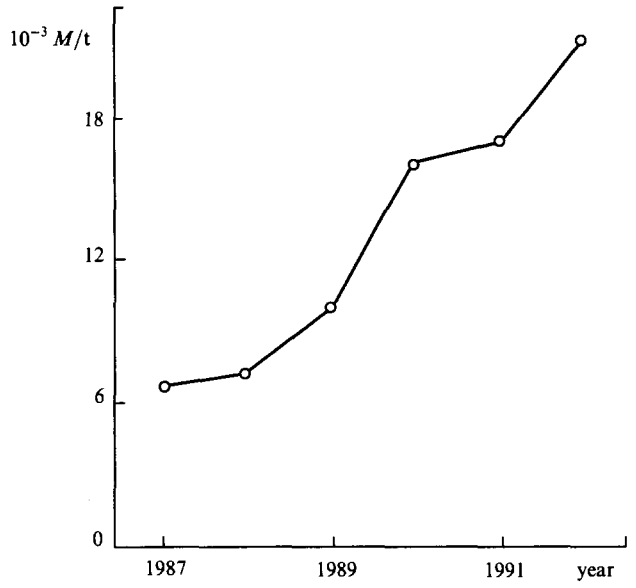

Figure 5. Increase in the number of species and seasonal vegetables (M) treated by radiation.

At present both γ radiation and electron beams are used for the treatment of food products. The possibility of using bremsstrahlung radiation is being considered. The suggested doses are relatively small:[1] 0.05–0.15 kGy (for inhibiting the growth of potatoes, onions, etc.), 0.15–0.50 kGy (for the disinfestation of grain, fruit, etc.), 0.5–1.0 kGy (to slow the ripening of fruit, vegetables, etc.), 1.5–3.0 kGy (for increasing the lifetime of strawberries and other fruit), 2.0–5.0 kGy (for the destruction of pathogenic parasites and microorganisms in fresh and in frozen poultry, shrimps, frog's legs, etc.), 2.0–10 kGy (to improve the technological properties of several food products), 10–50 kGy (for the decontamination of food additives and ingredients, especially spices), 30–50 kGy (for the sterilisation of meat, meat products, dietary products for the sick, etc.). Some establishments have a relatively high operating speed. let us consider some examples.

In 1973 an apparatus with a ^{60}Co source of γ radiation (activity 0.3 MCi) began to function for the treatment of potatoes (productivity 15 000–20 000 tonnes per season).[463] In 1986 a pilot plant with a ^{60}Co activity of 0.24 MCi was constructed in the GDR for the irradiation of onions (operating speed 18 t h^{-1}).[464] The largest apparatus ever used in this region of radiation technology, with two electron accelerators, was assembled in Odessa in the early 1980s for the disinfestation of imported grain (operating speed 400 000 t a^{-1}).[465] It was planned to build an apparatus of this type in the Rostov region, but the project could not be realised. From 1986 until 1990 the French firm 'Société des Protéines Industrielles' used an electron accelerator (energy 7 MeV, power 5 kW) to treat chicken's fillets (operating speed ~3 t h^{-1}). A more powerful accelerator (energy 10 MeV, power 10 kW) has been in use since 1990: this change has made a 2-fold improvement in the operating speed.[466–467] Since the end of 1991 the 'Vindicator Inc.' company (USA) has treated strawberries and citrus fruit with γ radiation from ^{60}Co.[468,469] In the USA two demonstration equipments with linear electron accelerators were built (energy 5 MeV, power 20 kW, or energy 10 MeV, power 10 kW) to irradiate strawberries, fruit, poultry, and other products.[470] In Poland an apparatus based on a linear electron accelerator of the 'Elektronika' type (energy 10 MeV, power 10 kW) was built for the treatment of spice, mushrooms, etc.[471] In the late 1980s the radiation treatment of spices had been established in 17 countries (for example, in Belgium, France, the Netherlands, the UAR, and the USA).[472] Garden strawberries are another product now being treated in large quantities. This is specially true of France, the Netherlands, the USA, and several other countries. For example, in the UAR 4–8 tonnes of strawberries were irradiated per annum.[473] In the early 1990s the total amount of food products treated by radiation methods was 500 000 t a^{-1}.[468]

An important problem in this field of radiation technology is the identification of food products which have undergone radiation treatment. The identification of irradiated products is essential for the information of the buyer and for proper sales control. This is a difficult problem, because the effects produced by the ionising radiation are usually small; furthermore they lead

Table 9. Chemical changes used to identify irradiated food products.

Change	Product	Ref.
Formation of volatile compounds from lipids	Fish, meat	474–476
Changes in DNA (for example, formation of thymidineglycols)	Meat	474,475
Changes in proteins (for example, formation of *o*-tyrosine)	Meat, prawns	474–477
Formation of hydrocarbons from fatty acids	Meat, prawns, frogs' legs	476,478
Formation of 2-alkylcyclobutanones from fatty acids	Poulty, eggs	476,479
Formation of CO from fatty acids	Meat	476,480
Formation of 2,3-butanediol	Alcoholic drinks	481
Hydroxylation of aromatic compounds	Fruit, vegetables	482
Decomposition of starch	Spices	483,484
Formation of free radicals	Strawberries, fruit, meat with bones, fish and sea foods containing bones, shells, etc., spices	474–477, 485,486

to changes similar to those produced by storage. Useful results have nevertheless been obtained.

A universal method for the detection of irradiated food products has still not been developed, though all types of radiation effects have been examined (chemical, physical, and biological). They include changes in the histological and morphological characteristics, in the physical properties (electric impedance, viscosity, wetting properties, etc.), in the chemical changes in the components of the food products (carbohydrates, lipids, proteins, nucleic acids, vitamins, etc.), and in the formation of free radicals, detected by chemiluminescence, thermoluminescence, and ESR methods.[474-476] Some chemical changes used to identify irradiated food products are shown in Table 9.

Clearly, the most promising are the methods based on the formation of free radicals. These species are retained in bones, shells, membranes, grains, skins, etc.; they can exist for relatively long times, and therefore they can be detected by luminescence methods and by ESR. It has been claimed[476] that routine analyses can already be done by the ESR method (for the analysis of meat including poultry, with bones), by the thermoluminescence method (for spices and herbs), by the gas chromatography method (for meat, including poultry), and by the determination of long-chain hydrocarbons.

The level of industrial application of radiation treatment is strongly dependent on the ratio of consumers to the number of irradiated food items. Many questionnaires have shown that this ratio is usually large (see, for example, Refs 459 and 472).

IX. Radiation-physical processing

The changes in the physical properties of materials (mainly solids) after irradiation have been used as a basis for several practical applications. They include ion implantation, the doping of semiconductors, the modification of semiconductor materials and articles, the preparation of polymeric membranes and resists for photolithography, changes in the colour of glass and of precious stones, the thermal effect of powerful electron beams, etc.

Ion implantation is the introduction of additional atoms into the surface of a solid by bombardment with accelerated ions. Ion energies greater than 1 keV are often used.

Ion implantation is used for the doping of semiconductors, for modifying solid surfaces (to generate anticorrosion coatings on metals and alloys, to clean surfaces, to improve optical surfaces, to deposit films, etc.)[14,29,30,43] We note that for high ion fluxes (greater than $10^{17} - 10^{18}$ cm^{-2}), when the concentration of implanted ions is comparable with the concentration of atoms in the surface layer of the target, new compounds are formed (or, in the conventional language, ion synthesis takes place). For example, when silicon is bombarded with nitrogen, carbon, and oxygen ions the compounds Si_3N_4, SiC, and SiO_2 are formed respectively.[43] This process is used to form protective films and insulating layers in integrated circuits. Ion implantation is also used to produce alloys and solid solutions, including metastable alloys: the process is often called ion metallurgy.

The next region of radiation-physical processing is the radiation doping of semiconductors with the help of nuclear reactions.[35] The reactions can be initiated by thermal neutrons, which are characterised by large ranges, so that by using this method semiconductors can be doped evenly over their entire volume. The most important application of the method is the doping of silicon by phosphorus, based on the $^{30}Si(n,\gamma)^{31}Si$ reaction in a nuclear reactor.[35,487] Silicon-31 has half-life of 2.62 h: by undergoing a β decay it is converted into phosphorus-31.

The first large-scale production of radiation-doped silicon was set up in 1983 in the RBMK-1000 reactors of the Chernobyl atomic power station;[488] 54.5 t of this material were prepared (including 12.8 t in 1991). Methods of producing it in other atomic power stations with reactors of the RBMK type are being examined.[488] The doping of silicon is carried out also in an experimental reactor in Obninsk (with a production rate of several tonnes per annum). In foreign countries radiation-doped silicon is almost wholly produced in research reactors.[488]

Attempts are also being made to dope GaAs, InAs, InP, InSb, etc. by using n,γ reactions.[488] The most widely used of the materials prepared in this way is doped gallium arsenide. We note that doping can be carried out also by using other nuclear reactions. Thus the irradiation of silicon with protons of 20–25 MeV energy in order to dope it with aluminium has been suggested.[489]

X-Radiation, and electron and ion beams, are used in photolithography. The first two forms of radiation offer a high resolution (up to $\sim$0.1 μm) in the preparation of silicon integrated circuits.[490,491] The separation of the device from the SiO_2 in these circuits (as one of the stages in the lithographic process) can be achieved by ion beam etching.[43] Polymers having high radiation-chemical yields in their cross-linking or degradation reactions can be used as resists when ionising radiation is used. For example, chloromethylated polystyrene and poly-α-methylstyrene,[492] and also poly(glycidyl methacrylate),[493] are cross-linked by irradiation and act as negative resists. Poly(methyl methacrylate) and its derivatives, poly-1-butenesulfones, and some polysilanes are decomposing polymers: they behave as positive resists.[491] Polymers usually undergo cross-linking and decomposition simultaneously. It has been suggested[491] that a polymer acts as a negative resist if G (decomposition) $< 4G$ (cross-linking), where G is the radiation-chemical yield, measured as the number of molecules, atoms, bonds, etc. formed (or dissociated) by the absorption of 100 eV of energy of ionising radiation.

The irradiation of high-power semiconductor devices (for example, power diodes and thyristors) with electrons in relatively high doses improves their high-speed performance and some other operational characteristics.[30,494-498] This irradiation is practiced in several countries (Italy, the Czech republic, China, Japan etc.).[279,494,499] For example, in China and in Italy up to 100–150 thousand semiconductor devices are subjected every year to electron-beam treatment.[279,494]

Low-energy focussed electron beams (0.25 eV and below) can be used to heat the irradiated objects to high temperatures. These beams can be used for melting, evaporating, cutting, and welding various materials.[43,500,501] According to several workers (see, for example, Refs 502–504) electron irradiation can be used for the high-temperature synthesis of materials such as portland cement, sodium aluminate, barium and strontium ferrites, lead molybdate, etc. Simultaneous radiation and thermal treatment can lead to reactions with a higher rate, a higher yield, and at a lower temperature. A project has been reported[505] for the construction of an apparatus with an electron accelerator of the ELV type (energy 1.5 MeV, power 20 kW), aimed to treat cement so as to improve its performance. An apparatus has been built in Novosibirsk on the basis of an ELV electron accelerator (energy 1.5 MeV, power up to 100 kW) with the aim of creating a radiation-thermal technology for the production of cement and other similar materials.[506]

The formation of cylindrical tracks in materials (usually in polymeric films) irradiated with beams of heavy ions has been used for the production of membrane filters.[43,507] In most cases poly(ethylene terephthalate) films 1–10 μm thick are used, with ion beam energies (argon, nitrogen, xenon, etc.) above 100 MeV. The damaged parts of the irradiated film are removed by etching with a suitable solvent. This treatment produces pores with a diameter dependent on the mass, charge, and energy of the ions and on the time and temperature of the etching.[507-509] By controlling these parameters pores of a diameter dependent on the mass and charge (from a few nanometers to tens of micrometers) can be prepared. Filters prepared by this method are used in medicine, biology, and in the food industry.[43,507]

The ability of ionising radiation to form colour centres in solids is used in practice. It is used to change the colour of some

glass items, precious stones (for example topaz, diamond, and others), and pearls.[499] One of the metro stations in Prague is decorated with γ-irradiated glass tiles (in which a brownish tint was produced by irradiation).[499] This project required the irradiation of about 10 000 tiles with γ radiation (dose 2.7 kGy).

X. Other applications

Other applications of ionising radiation are known. First we should mention radiation synthesis. This has long been thought to be one of the most promising sections of radiation-chemical technology. Thus it was widely believed that ionising radiation (in particular, the radiation from a nuclear reactor) can be successfully used also for large-scale synthesis. Only a few processes using γ radiation and electron beams have been realised in practice (see Table 10). At present these studies have been almost completely discontinued, and they are carried out only in a few centres on a laboratory scale. For example the preparation of 2,3-dimethyltartaric acid by the γ irradiation of aqueous solutions of pyruvic acid,[515] of 1,2,3,4-butanetetracarboxylic acid by the γ radiolysis of aqueous solutions of succinic acid,[516] and of hexafluoropropylene oxide by the low-temperature liquid-phase oxidation of hexafluoropropylene,[517] etc. have been described.

As reported,[518,519] high-temperature electron-beam treatment can be used to regenerate catalysts and sorbents used in the oil and gas industry. Tests with large samples (up to 2 t) of irradiated catalysts showed that this treatment leads to almost 100% regeneration of the initial catalytic activity.

The possibility of using electron beams for the treatment of mineral deposits[520] and for the gasification of coal[521] has been studied, but these processes are still far from practical realisation. Paths towards the use of radiation from a nuclear reactor for the synthesis of hydrogen from water and CO_2 (through the formation of carbon monoxide and its subsequent conversion) were studied in the 1970s and 1980s, and considered to be an important problem in hydrogen energetics.[522,523] However, studies in this direction were subsequently abandoned.

Some problems in atomic energetics and in radiochemical production are directly related to applied radiation chemistry. They include accounting for special features of radiolytic transformations in aqueous solutions of actinide and of trace elements, establishing the features of the radiolysis of extractants and diluents, studying the radiation-chemical processes in highly radioactive waste, the radiation capacity of heat-transfer agents (in particular, water) and other reactor materials, the radiation corrosion of construction materials, etc. A discussion of these problems goes beyond the scope of the present work. Relevant information can be found in published monographs[1,47,53,60,71,524–528] and reviews.[529–533]

XI. Technological dosimetry of ionising radiations

In the development of the technology of a radiation process the best control of the operation of the assembly and of the creation of a high-quality product requires carrying out various dosimetric measurements, including the determination of the dose and of its strength, establishing the distribution of the dose in the irradiated sample, etc. The absorbed doses used in radiation technology cover a wide range (from ~50 Gy for the inhibition of the growth of potatoes and onions to >1 MGy for experiments with the radiation); the same is true of the strength of the dose. The irradiated samples include gases, liquids, and solids; they can be homogeneous or heterogeneous. It follow that dosimetry in radiation technology is required to solve many complex problems.

A large set of parameters needing to be measured can be 'overlapped' by using a relatively large number of dosimeters. Obviously, for each range of doses characterising the various processes there should be a particular dosimeter. To a large extent

Table 10. Radiation syntheses realised on pilot plant and on production scales.

Country and period of functioning of the apparatus	Process	Type of radiation	Product	Operating rate/t a^{-1}	Ref.
USA, 1962–1970s	$CH_2=CH_2 + HBr$	^{60}Co γ radiation	C_2H_5Br	~450	510

Table 11. Dosimeters for different dose ranges.

Type of dosimeter	Method of measurement	Range of dose/Gy
Alanine	ESR	$1 \times 10^0 - 2 \times 10^5$
Solution of ferrous sulphate (Fricke dosimeter)	Spectrophotometric	$2 \times 10^1 - 2 \times 10^2$
Solution of dichromate	"	$5 \times 10^2 - 1 \times 10^5$
Solution of Ce(IV) sulfate	"	$1 \times 10^2 - 1 \times 10^5$
Solution of chlorobenzene in aqueous ethanol	Titration of H^+ or Cl^- (potentiometric, or high-frequency conductimetric)	$5 \times 10^1 - 1 \times 10^6$
Thermoluminescent, based on LiF	Measurement of the luminescence on heating to 195 °C	$< 1 \times 10^0 - 1 \times 10^3$
Crystalline LiF	Spectrophotometric	$2 \times 10^2 - 2 \times 10^6$
Solutions of dyes	"	$2 \times 10^0 - 2 \times 10^5$
Coloured polymer films and plates	"	$2 \times 10^0 - 2 \times 10^5$
Colourless polymer films and plates	"	$1 \times 10^4 - 4 \times 10^5$
Glucose solution	Polarimetric	$5 \times 10^4 - 2 \times 10^6$
Glass (silicate, activated with nickel)	Spectrophotometric	$1 \times 10^2 - 1 \times 10^4$
Glass (metaphosphate, activated with manganese)	"	$3 \times 10^3 - 1 \times 10^5$
Quartz	"	$1 \times 10^5 - 5 \times 10^7$
Nitrous oxide	Change in pressure, gas chromatographic, mass spectrometric	$5 \times 10^2 - 2 \times 10^4$

this problem is already solved. Table 11 shows the chemical dosimeters available for different ranges of doses.[19,33,50,57,97,534]

Among the recent developments we may quote the dosimetric systems based on aqueous solutions of rhodamine dyes with additions of selenate[535] and of solutions of tetrazolium salts.[536,537] The former system is suitable for dosimetric measurements in the radiation treatment of food products. The latter system can be used, depending on the composition, to determine doses over a wide range of compositions.

In Russia several dosimetric systems have been developed, including practically the whole range of doses used in radiation technology.[33,81,538] They include glucose solutions, plates of poly(methyl methacrylate), polymer films containing a dye, glasses with various additives, etc.

In several radiation processes (for example, the radiation sterilisation of medical products) we use light indicators of the dose in the form of labels attached to the item being irradiated. The labels contain a radiation-sensitive dye or the leuco-base of a dye. The irradiation produces a change in the colour of the indicator. This indicates that the item has been irradiated. Some data on these dose indicators can be found in various publications.[538-545]

A direct determination of the dose can be made with a calorimeter. Several forms of calorimeter, differing in the simplicity of their design and used in routine measurements and for the calibration of chemical dosimeters, have been developed in recent years.[1,545-548] They include water, graphite, and polystyrene calorimeters. The first two consist of Petri dishes filled with water or containing a graphite disk; changes in temperature are measured with thermistors. They can be used to determine doses in the ranges of 1 – 50 and 0.1 – 20 kGy respectively. The polystyrene calorimeter is designed to measure the power of the dose of γ radiation.

In Russia a special equipment including precision calorimeters has been produced for the accurate preliminary testing and calibration of dosimeters.[33,538]

Another important problem is the international comparison of dosimetric mesurements. It is essential, so as to ensure that radiation processes are carried out on a single world dosimetric basis. The International Atomic Energy Agency plays a leading role in this international effort.

XII. Conclusion

This discussion of the present state of radiation technology leads to the following conclusions. In addition to the expanded use of some well known processes, new processes have been developed (for example, the production of silicon carbide fibre). The use of electron accelerators as a source of ionising radiation safer and more power-ful than sources of γ radiation has been greatly developed. Bremsstrahlung X-radiation has begun to be used in radiation technology. It should be noted that the use of ^{137}Cs as a source of γ radiation has almost completely ceased because it is less safe than ^{60}Co. Interest in ion beam problems has increased considerably, especially in Japan, where ion beams are now used in studies of their influence on semiconductors and on constructional materials for cosmic technology, on the radiation defects in materials for thermonuclear reactors, in radiation biotechnology, etc.[176]

At present radiation technology is finding increasing applications in ecology. This is specially seen in radiation methods of purification of rejected gases from SO_2, NO_x, and other harmful impurities. Evidently, a substantial outbreak in the radiation treatment of food products can be expected in the near future. This will be assisted by the recent commissioning of the first appropriate commercial assembly in the USA.[468,469]

In spite of the general commercial recession we find (in Russia) an increase in the production of medical items sterilised by the radiation method. This is accompanied by an extension in the use of electron accelerators. Ecological applications of radiation technology are also being successfully developed. Definite improvements were made also in the region of the radiation hardening of coatings.

More and more countries are now using radiation technology, which is being transferred from the developed to the developing countries. The International Atomic Energy Agency maintains both a financial and a scientific and technical support of the various programmes, and as a result of this support radiation assemblies have been constructed in Bangladesh, Vietnam, Syria, Iran, Peru, Ecuador, Ghana, and other countries. The main field of application of these assemblies is the radiation sterilisation of medical items and the treatment of food products.

One of the main advantages of radiation technology is the lowering in the level of contamination of the environment produced by its use. In particular, no harmful gases (of the ethylene oxide type) are used in radiation sterilisation. As has already been pointed out, the compositions used in radiation hardening, unlike the compositions used for ordinary, thermal hardening, do not contain organic solvents. Undoubtedly, all this will stimulate further developments in radiation technology.

Abstract. The modelling of a surface as an assembly of moving atoms interacting with one another and with an incident particle is examined. Both dynamic methods for the modelling of a surface (for short times) and probability methods (for long times) are analysed. The Massey adiabaticity criterion has been used to determine the regions of applicability of the methods of molecular dynamics. Within the framework of probability methods, the chemical bond is described with the aid of Harrison's generalised periodic system of the elements. Together with the general modelling problems, the reconstruction of the surface, physical and chemical sorption, as well as the modification of the surface and of its morphology as a result of the multiple repetition of elementary processes (precipitation, etching, corrosion) are discussed. The bibliography includes 169 references.

I. Introduction

The molecular modelling of the chemical interaction of atoms and molecules with a surface is based on the concept of the surface as an assembly of moving individual atoms or molecules interacting with one another and with the incident particle.[1–6] The central problem is that of the description of the chemical bonds, including the situation where the incident particle interacts with the surface, at a level ensuring the reconstruction of the surface, the generation of electronic surface states, etc. Problems involving the selection of the laws of motion arise: the Newton and Schrödinger equations, the stochastic approximations of the type of Langevin equations, and the specification of the interactions between the particles. The next problem is that of the selection of the number of atoms, the geometry of their arrangement in the cell, and the boundary conditions representing the interaction of these atoms with the surrounding medium.

In the classical method of molecular dynamics (MMD), Newton's equations are solved numerically. The principal problem is that of selecting the interaction potential. In the quantum MMD, the interaction energy for each configuration of the heavy particles is found in the course of the calculation by solution of the Schrödinger equation. The observed forces acting on the ions are used to determine the classical trajectories of the latter.

Both the classical and the quantum MMD are valid only for a particular electronic state (the adiabatic approximation). Such approaches are suitable for the determination of equilibrium characteristics of different states and for modelling the dynamics within the framework of only one electronic state.

The adiabatic approximation is inapplicable in the region of the intersection of the potential surfaces of different electronic states. In these regions, the motion of the heavy particles may induce electronic transitions and their trajectories permit branching. The main problem involves the search for an effective solution of the nonstationary Schrödinger equation.[5] Modern computers permit calculations for times many orders of magnitude shorter than those required for the description of the dynamics of the modification of the surface in terms of real length and time scales. However, such problems generally require the consideration of nonadiabatic chemical reactions. This inevitably introduces a probability element into the dynamics. Furthermore, the dynamic memory of the initial conditions is retained only over periods of the order of magnitude of several relaxation times, after which the trajectories become stochastic, as happens in nature.[7–11]

For this reason, it is necessary to resort to probability modelling methods as well as dynamic methods, particularly since in many cases the result of a specific dynamic process and not the process itself is important. Discrete probability

approaches and the Monte Carlo method† are based on lattice models of the surface. The simpler studies are limited to the geometrical modelling of the morphology (cellular automata). In the continuous models, the surface is assumed to be a continuous function of the spatial coordinates and time. The principal problem in probability methods involves the inclusion in the latter of a universal description of the chemical bond on the surface which could be chosen for modelling the multiple repetition of elementary steps. The use of the method based on Harrison's generalised periodic system of the elements (GPSE) is very promising.[14]

The authors of the present review have confined themselves to the consideration of the simplest systems permitting modelling by the most sophisticated methods, and endeavoured to consider all the fundamental problems which determine the further development of the molecular modelling of chemical processes on the surface.

II. Classical molecular dynamics

The method of molecular dynamics (see, for example Refs 9, 15, and 16)‡ in its traditional formulation consists in the numerical solutions of Newton's classical equations for a system of N particles with a known interparticle interaction potential Φ and with specified initial conditions:

$$\frac{m_i \mathrm{d}^2 r_i}{\mathrm{d}t^2} = \nabla\Phi(r_1,...,r_N), \quad i = 1, 2, ..., N, \tag{1}$$

where m_i and $r_i(t)$ are the mass and the coordinate of the ith particle respectively. The calculated phase trajectories $\{r_i(t), v_i(t)\}$ [here $v_i(t)$ are the velocities] are used to calculate the quantities $X[r_i(t), v_i(t)]$, which depend on microscopic variables. In order to obtain the macroscopic average quantities $< X(t) >$, all these quantities are averaged either with respect to time or with respect to a set of initial states of the system. The method of molecular dynamics makes it possible to calculate the time correlation functions, the relaxation to equilibrium, etc. and also the characteristics of the equilibrium states.

Eqns (1) model a nearly microcanonical assembly (the total energy of the system remains constant on average).[7-9] In other cases, described by assemblies differing from the microcanonical assembly, the MMD equations may contain additional terms. These can represent, for example, the Langevin forces, which model the heat exchange with the external medium, or the reactions of the bonds, imposed on the system and ensuring the constancy of the thermodynamic quantities (kinetic energy, pressure) or of the spatial gradients of the macroscopic parameters (temperature, velocity).[17,18]

Depending on the problem being solved, different boundary conditions are applied to the system (periodic conditions, rigid or 'stochastic' walls, a subsystem of stationary particles, etc.).

The interaction potential Φ is frequently represented approximately by the sum of the interaction potentials of all the pairs of particles and use is made of simple analytical formulae of the Lennard-Jones, Buckingham, etc. types. The necessary number (two-three) of parameters included in them is selected on the basis of empirical data.

However, such an approach is not always applicable even to the description of the properties of condensed inert gases.[13] The situation is even more complex in the case of the atoms of other elements, between which the formation of chemical bonds, for example covalent bonds (like those between Si or Ge atoms), is possible. No pair potential ensures the stability of a tetrahedral structure of such a system because it does not give rise to even a local energy minimum for this configuration.

A somewhat different picture is observed in the case of metals.[19] With the aid of pair potentials, it is possible to describe in this instance the regular structure and energy of the equilibrium crystal. For the modelling of, for example the elastic properties, it is necessary to introduce into the total energy of the system additional terms which clearly depend on the volume of the system (i.e. which take into account the interaction of the lattice site ions through the electron gas). This approach is applicable only to 'regular' structures, where the concept of volume is unambiguously defined. For 'defective' structures (vacancies, microcracks, surfaces), the volume is not defined unambiguously and such a simple model becomes inapplicable because the dependence of the results on the volume is very marked. The problem of the formation of a chemical bond between the metal atoms and the chemically reactive impurity introduced into the metal, for example hydrogen, which was mentioned above, also remains unsolved.

Many attempts have been made to overcome the above difficulties by introducing multiparticle (ie. not reducible to the sum of pair interactions), empirical (or semiempirical) potentials.[19-35] Following the procedure of Baalamane et al.,[36] we shall divide these approaches into three main groups: the cluster potentials, cluster functionals, and inserted atom methods.

The cluster potentials[20,25,28,29,31] include the following terms, after the pair interaction terms, in the expansion of the total energy in terms of the multiplicity of the interaction:

$$\Phi = \sum_{i>j} \Phi_2(r_i, r_j) + \sum_{i>j>k} \Phi_3(r_i, r_j, r_k) + \sum_{i>j>k>l} \Phi_4(r_i, r_j, r_k, r_l) + ... \tag{2}$$

Each term represents the sum of the interaction energies $\Phi_n(r_i, r_j, ..., r_n)$ of a n-particle 'cluster', which do not reduce to a combination of the preceding terms. The series (2) usually terminates at the Φ_3 term.

Such a potential makes it possible to specify around each atom, on a sphere having a radius equal to the distance to the nearest neighbour in the crystal, four potential wells located at the vertices of a tetrahedron. This idea was first applied to the MD modelling of crystalline and liquid silicon by Stillinger and Weber (the SW potential),[20] who represented Φ as the sum of pair and three particle interactions. The pair potential has the usual form with components corresponding to attraction and repulsion and a minimum at a distance equal to the distance to the nearest neighbour in a diamond-like lattice.

$$\Phi_2(r_{ij}) = \begin{cases} A(Br_{ij}^{-p} - r_{ij}^{-q}) f_c, & r_{ij} < a, \\ 0, & r_{ij} > a, \end{cases} \tag{3a}$$

where r_{ij} is the distance between the atoms i and j and $f_c = \exp[(r_{ij} - a)^{-1}]$ is a function which smoothly cuts off the interaction at distances equal to the distance between the first and second nearest neighbours.

The three-particle potential has the form

$$\Phi_3(r_i, r_j, r_k) = h_i + h_j + h_k , \tag{3b}$$

$$h_i = \lambda \exp[\gamma (r_{ij} - a)^{-1} + \gamma (r_{ik} - a)^{-1}] \left(\cos\vartheta_{ijk} + \tfrac{1}{3}\right)^2,$$

and includes a function of the angle ϑ_{ijk} between the ij and ik bonds which in fact ensures its relative rigidity. The parameters p, q, A, B, a, λ, and γ are chosen in order to satisfy the empirical data on the structure, energy, and elastic properties of the silicon crystal.

† The Monte Carlo method, used for the molecular modelling of the structure and thermodynamic properties of equilibrium states,[12,13] has not been included in this review but is mentioned in those cases where it is employed.

‡ The importance of this method for chemical physics has been emphasised in A L Buchachenko's review [*Uspekhi Khimii* **56** 1593 (1987); *Russ. Chem. Rev.* **56** 907 (1987)].

The structure and melting point of the diamond-like silicon,[20] its phonon spectrum,[37] and even the formation of the dimers on the Si (100) surface [(2 × 1) reconstruction][38] are modelled satisfactorily with the aid of the SW potential. However, the other crystalline modifications of silicon and amorphous and liquid silicon at temperatures remote from the melting point as well as more complex reconstructions § of surfaces with different orientations are not described by potential (3).[38,39] This is not surprising, since a potential with a rigidly specified angle between the bonds does not permit the formation of a structure with a coordination of the atoms other than tetrahedral.

Nevertheless, owing to its relative simplicity, the SW potential has been used widely in calculations (see, for example, Refs 40–46). The potentials of the interaction of silicon atoms with oxygen atoms and fluorine (Si–F and Si–O) have been derived from the SW potential. They are used, for example, in the study of the chemical reactions of the silicon surface with fluorine[44,45] or of the structures and vibrational spectra of crystalline and amorphous SiO_2.[46]

The cluster functionals[18–21,23,27,29,30] have the form

$$\Phi = \sum_{i>j} \Phi_n(i,j;k \in a_n) \ . \tag{4}$$

Here each pair of interacting particles i and j in an instantaneous configuration enters into the composition of the cluster a_n comprising n particles, including those selected. The configuration of the cluster depends on the structure of the test substance (crystal, glass, etc.) and on the law governing the interparticle interaction. The energy of the interaction of a pair of particles i and j depends not only on their coordinates but also on the coordinates of all $n-2$ particles k included in the cluster a_n. The more complex form of Eqn (4) arises from the desire to construct a universal potential, i.e. to describe the greatest possible number of structures with different coordinations using a single functional form and as far as possible a single set of parameters.

The most characteristic attempt on these lines has been undertaken by Tersoff.[21–23] The main idea was to incorporate the weakening of the bonds with increase in the number of nearest neighbours of the atom participating in the formation of the bonds. The total energy of the system has the form characteristic of the pair interaction approximation.[22]

$$\Phi = \sum_{i>j} f_c(r_{ij})\left[f_A(r_{ij}) + b_{ij} f_R(r_{ij})\right] \ , \tag{5a}$$

where $f_c(r_{ij})$ is the cut-off function which determines the radius of action of the potential and $f_A(r_{ij})$ and $f_R(r_{ji})$ are the pair attraction and repulsion potentials. The coefficients b_{ij} are functions of the local environment of the particles i and j:

$$b_{ij} = \left\{1 + \beta^m \left[\sum_{k \neq i,j} f(r_{ij}, r_{ik}, \theta_{ijk})\right]^m\right\}^{-1/2m} , \tag{5b}$$

where β and m are adjustable parameters and f is a function of the coordinates of the three particles i, j, and k; the summation was carried out over all the atoms k within the radius of action of the atoms i and j. Thus the depth and position of the potential minimum for the atom i in the vicinity of the atom j depend on the instantaneous positions of all the remaining atoms of the system, which renders potential (5) in essence a multiparticle potential. This imparts to it a fairly high flexibility, which makes it possible to describe structures with different configurations when the adjustable parameters (there are 13 of these altogether) are selected successfully.

§ Reconstruction is defined as the change in the structure (and symmetry) of the near-surface layers of the crystal compared with the bulk-phase structure.

Indeed the Tersoff potential models almost all the crystalline modifications of silicon,[22] its phonon spectrum,[23] and many reconstructions of the surface.[22,37] Liquid and amorphous silicon are less successfully modelled.[23] For an appropriate parametrisation, this potential makes it possible to describe multicomponent systems[24] (which need not contain silicon), including simple chemical reactions occurring on detonation of explosives of the type $A_2 + B \rightarrow A + AB$.[47] Nevertheless, potential (5) is not fully universal, since for the calculation of different properties and structures it requires different parametrisations.[22,23] For example, when the parameters of Eqn (5) are selected for the best description of the dependence of the energy on the specific volumes of different crystalline modifications of silicon, the accuracy of the calculation of the phonon spectrum is lost, and conversely.

The inserted atom method (IAM).[19] The total energy of the system assumes the form

$$\Phi = \sum_{i>j} \Phi_2(r_i, r_j) + \sum_i F(\rho_i) \ , \tag{6}$$

where Φ_2 is the energy of the pair interaction of ionic cores, $F(\rho_i)$ is the energy of the atom i 'inserted' in a medium having at the site of insertion an electron density ρ_i, which is generated by the electrons of all the remaining atoms of the system and is assumed to be additive, i.e.

$$\rho_i = \sum_{j \neq i} \rho(r_{ij}) \ , \tag{7}$$

$\rho(r)$ being the density of the electrons in the atom of the test element at a distance r from the nucleus. The last function is determined either from quantum-mechanical calculations or from empirical data. The functions Φ_{ij} and $F(\rho)$ in the initial formulation of the inserted atom method were selected by adjustment for consistency with empirical data for the crystal (the lattice constant, the elastic constants, the sublimation energies of various crystalline modifications, the formation energy of a vacancy).

It is seen from Eqns (6) and (7) that there is a relation between the IAM and the method of cluster potentials. Thus, if the function $F(\rho)$ is linear, then the IAM is equivalent to the approximation of pair interaction potentials, since the force acting on the atom i is proportional to the sum of functions which depend only on r_{ij}. For a quadratic variation of $F(\rho)$, we arrive at the triple potentials approximation, etc. This approach has been assigned[36] to the method of cluster functionals. We segregated it in a separate group because different physical considerations are employed in constructing the right-hand sides of Eqns (4) and (6). This is associated with the fact that initially these two methods developed in relation to different groups of elements: to Group IV semiconductors and metals respectively.

The relation[34]

$$F(\rho) = -c\rho^{-1/2},$$

which is universal for all metals, has been largely used recently for $F(\rho)$. This is based on the possibility of interpreting $\rho(r)$ in Eqn (7) as the square of the overlap integral of the wave functions of the atoms i and j.

The IAM has been applied successfully to the study of the structures and diverse properties of metals and alloys (including liquid ones): defects, the structures of the surfaces, various reconstructions, the phase structures of alloys, the bulk-phase and surface phonons, the structures of the interfaces, and the hydrogen on the surface (see, for example, Baskes et al.[35] and the references quoted therein).

The attempt to extend the IAM to systems with covalent bonds (Si and Ge)[35] has not been very successful. In particular, it leads to the 'external relaxation' of the surfaces on

reconstruction, i.e. the distance between neighbouring crystalline planes increases near the surface and does not diminish as would be expected from experimental data and which has been confirmed by other theoretical models. The IAM method[35] has been extended[48] to 26 elements (mainly metals). Certain deficiencies of the potentials[35] have been corrected, but a radical improvement could not be achieved for silicon and germanium.

III. The regions of applicability of the adiabatic approximation

As early as 1988, Tersoff,[22] who proposed one of the most successful cluster functionals, expressed doubts concerning the possibility of constructing a fully universal empirical potential. Having compared the results obtained with the aid of six potentials from different groups, the authors of a critical review[36] concluded that they are not universal and that no potential has decisive advantages which would lead to its being preferred to others. It was concluded that a universal potential cannot be constructed.

The causes of the relative failure of the group of methods employing the interaction potentials of the particles in calculations of their motion (the potential approach) have been specified as "...the general inability to model the formation of π-bonds" and "...the inadequacy of the description of angular forces", i.e. there is a direct indication that many quantum-mechanical effects cannot be described with the aid of classical potentials.

We shall now consider the limits of the applicability of approximation (1).

The use of the potential Φ is valid only in terms of the adiabatic approximation. In this case, the potential $\Phi(R_i)$ is a solution of the problem of the determination of the eigenvalue of the equation

$$\left(-\frac{\hbar^2}{2m}\sum_{i=1}^{n}\nabla_i^2 + V(R,r)\right)\varphi_R(r) = \Phi(R)\,\varphi_R(r)\ , \qquad (8)$$

where the summation is carried out over all the electrons. The term ∇_i denotes differentiation with respect to the electronic coordinates r_i and V denotes the interaction of all the charges [R and r are the sets of coordinates of the ions and electrons and $\varphi_R(r)$ is the wave function of the electron subsystem, which depends parametrically on the ionic coordinates R].[99]

The wave function in Eqn (8) refers to a specific state of the electron. For example, the ground state of crystalline silicon corresponds to the diamond lattice and is described by the wave function φ_0, which represents a linear combination of the sp^3 orbitals for each atom. The potential curve *1* in Fig. 1*a* corresponds to this structure. Another wave function and hence another potential curve (curve *2*) correspond to any metastable crystalline modification of silicon (for example, the simple cubic modification). We may note that, depending on the average distances between the ions, the ground states of the lattice may prove to be the states of structures of different symmetries. Strictly speaking, different structures should be modelled by different potentials.

Nevertheless, with the aid of the same empirical classical potential, it is possible to model not only the global but also certain local energy minima in the configuration space. The explanation for this is that the potentials examined in Section II do not follow from Eqn (8). They contain a large number of adjustable parameters, the successful selection of which permits the construction of a potential surface similar to that illustrated by a dashed line in Fig. 1*a*.

In order to understand the possibilities and limitations of this approach, it is necessary to apply Massey's adiabaticity criterion:[5,99]

$$\frac{a\Delta\Phi}{\hbar v} \gg 1, \qquad (9)$$

where a is the characteristic distance over which $\varphi_R(r)$varies, $\Delta\Phi$ the distance between the adiabatic potential surfaces, and v the characteristic velocity of the heavy particles. Thus the adiabatic approximation is valid over the entire range of values of R, except in the regions of the intersections (or the pseudo-intersections) of the adiabatic potential surfaces.

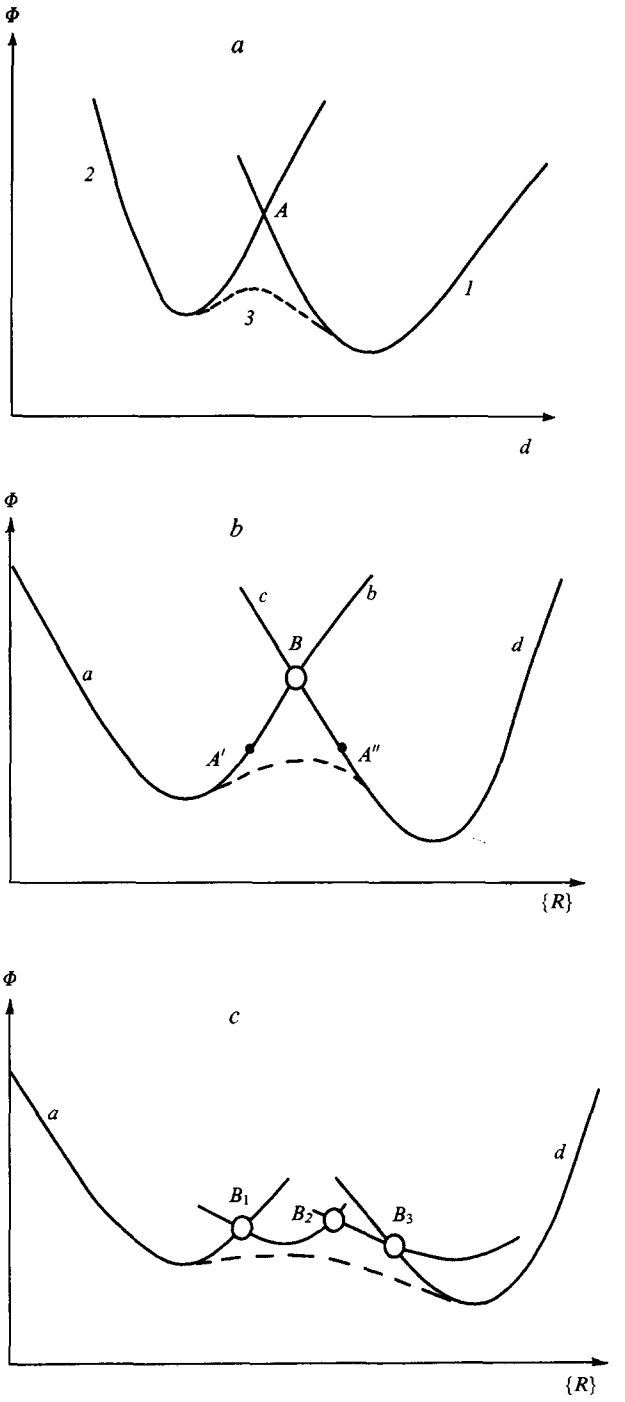

Figure 1. Conventional schematic illustration of adiabatic potential surfaces and nonadiabaticity regions: (*a*) potential curves for different regular crystalline structures as a function of the distance (d) to the nearest neighbour: continuous lines *1* and *2* — exact quantum-mechanical calculation, dashed line *3* — model potentials; (*b*) potential surfaces in the configuration space; the circle B represents the region of nonadiabaticity; (*c*) schematic illustration of numerous potential surfaces.

In the vicinity of such intersections, the motion of ions may induce nonadiabatic electronic transitions, the representation of the wave function for the system in the form of the product of the electronic anionic components becomes impossible, and approximation (8) loses its physical significance. The solution of

the dynamic problem in this (nonadiabatic) case must involve the study of electronic transitions.

In other words, the adiabatic approximation is by no means valid over the entire range of the possible values of R for a polyatomic system and the use of Eqns (1) with $\Phi(R)$ is possible only in the regions of the configuration space R (hypervolumes) separated from one another by hyperlayers, where approximation (1) is in principle impossible. The thickness of such layers may be estimated with the aid of Eqn (9).

Fig 1*a* does not illustrate this situation, since the point A does not correspond to the intersection of the surfaces $\Phi(R)$ in the space $\{R\}$ (Fig. 1*b*). The points A' and A'' in Fig. 1*b* correspond to identical distances to the nearest neighbour, i.e. to the point A in Fig. 1*a*, but they are completely different points in the configuration space. The potential surface for the ground state (the aBd curve) is divided into the adiabatic regions $aA'B$ and $BA''d$ corresponding to different electronic states (which in turn correspond to different symmetries), the adiabatic approximation breaking down in the vicinity of the boundary between them (the region of the point B).

Fig. 1*b* illustrates highly schematically the principal idea, although it does not in fact correspond to reality — the potential surfaces for the diamond and simple cubic lattices in the configuration space cannot intersect anywhere. Any path in this space, connecting the points corresponding to these structures, passes in succession through the points B_i at which there are intersections with the potential surfaces of the excited states (there are only three such points in Fig. 1*c*). The degeneracy of these points can be removed by taking into account any of the interactions disregarded previously, but in this case Massey's criterion necessitates a quantum treatment of the region B_i, although this is not in fact important.

The motion of the atoms within the adiabatic regions (aB and Bd in Fig. 1*b* and aB_1, B_1B_2, B_2B_3, and B_3d in Fig. 1*c*) obeys Eqns (1). On the other hand, when the regions intersect at the points B_i, Eqns (1) lose their significance — the potential $\Phi(R)$ cannot describe the interaction of heavy particles. Electronic transitions may occur in these regions and the trajectories may undergo branching. The choice of the type of extension of the trajectories must be made with the aid of statistical modelling based on the quantum-mechanical calculation of the amplitudes of the transition probabilities. Such an approach is valid if the nonadiabatic regions B_i in the phase space are much smaller than the regions corresponding to classical motion. In this section, we shall confine ourselves to the consideration of the quantum effects associated with the interaction and will not be concerned with cases where the de Broglie wavelength of the heavy particles becomes comparable to a and interference effects appear.

Thus the empirical potentials (the dashed lines in Figs. 1*a* – 1*c*) may describe the properties (including the time correlations) of the stationary state of the system in the vicinity of several (but not all!) local minima. However, the transitions between these states, obtained by the MMD, are not transitions with a real dynamic process occurring in the course of the correct time. For this reason, the processes accompanied by electronic transitions, for example the kinetics and times of the reconstruction of surfaces, are difficult to describe with the aid of the MMD in its classical formulation.

Example. We shall analyse a study[42] in which the temperature dependence of the velocity of the phase transition front (solidification or fusion) in silicon was investigated with the aid of the SW potential. The calculation was performed as follows. A rectangular parallelepiped was examined; 24 crystal planes, containing 18 silicon atoms each, passed through it parallel to its bases. Periodic boundary conditions were applied in the directions parallel to the planes. The atoms in two planes closest to one of the bases are stationary and occupy the crystal lattice sites. The atoms in the third and fourth layers are used to supply or remove heat (a constant temperature is maintained for these atoms with the aid of a scaling recalculation of the velocities). The remaining atoms of the system obey the usual MD [Eqns (1)] and are referred to as MD atoms.

In the initial instant, the MD atoms are either in positions corresponding to a specially prepared melt (in the modelling of crystallisation) or at the crystal lattice sites (in the modelling of fusion). The distribution of the velocities of these atoms corresponds to a certain initial temperature. The required phase transition temperature is then specified for the atoms of the third and fourth layers and is subsequently maintained constant. The heat exchange front gradually spreads towards the MD layers and leads to a structural rearrangement of the atoms (the phase transition).

Any layer is regarded as having become crystallised when its particles have become stably localised in the vicinity of lattice sites. Conversely, a layer is regarded as having fused when the particles have moved away from the vicinity of the lattice sites.

The results of the calculation are compared with experimental data in Fig. 2, which also presents the curves for the classical transition state theory. We may draw attention to a significant scatter, increasing on passing to fusion [$V(T) < 0$], which indicates a less satisfactory description of the fusion process. From our point of view, this scatter does not reduce to a statistical scatter but can be accounted for by the following causes:

On crystallisation, the particles 'roll down' into the potential well, the depth and position of which are determined beforehand by the particles of the preceding, already 'solidified', layers. In this case, the process activation energy is low (if it exists at all) and the results of the classical and quantum calculations may be similar.

On the other hand, on fusion such potential wells are not prepared beforehand. The atoms must 'collectively' seek the energy minimum. Such a process may be accompanied by the overcoming of high potential barriers, as a result of which the system may be fixed at local (metastable) minima, with which the scatter of the results may in fact be associated. In this case, the results of the classical and quantum-mechanical calculations will not agree and the possibility of determining the velocity of the fusion front within the framework of the adiabatic approximation (1) is open to doubt. The discussion of these questions will be continued in Sections IV, V, and VI.

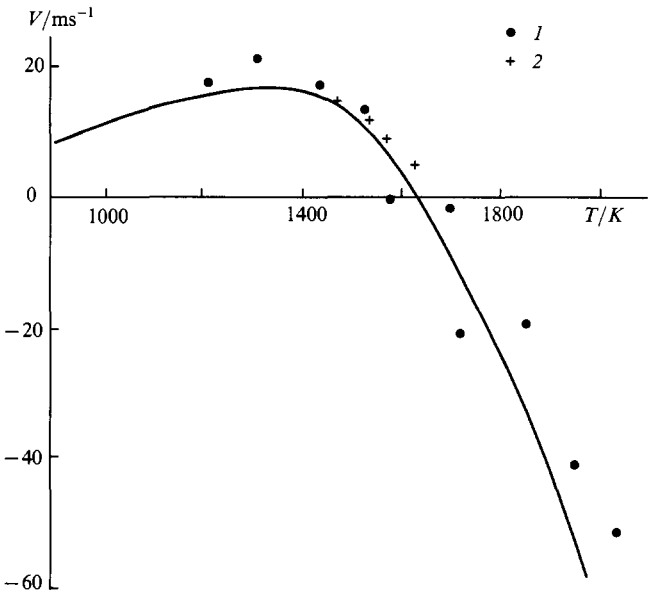

Figure 2. Temperature dependence of the velocity of the phase transition front. The positive velocities correspond to hardening and the negative ones to fusion. The curve was obtained by means of the transition state theory: (*1*) calculation; (*2*) experiment.

IV. Adiabatic quantum molecular dynamics

Approaches, which are frequently referred to as quantum MD, have developed in recent years in parallel with the potential approach. The scheme of Car and Parrinello (CP)[49] and the tight-binding method,[50,51] genetically related to the first procedure, are the most popular and will be briefly discussed in this Section.

1. The method of Car and Parrinello

The CP method involves the simultaneous calculation of the dynamics of valence electrons and ions (ionic cores),[52] the ions being considered in terms of the classical approximation and the electrons in terms of the quantum-mechanical approximation. Suppose we have a system of N ions with a mass M, described by the coordinates R_i ($i = 1, \ldots, N$) and the velocities $\dot{R}_i$, and N_1 electrons in the ground state and characterised by a set of wave functions (orbitals) $\psi_j(t)$ ($j = 1, \ldots N_1$). The latter may be expanded in terms of a set of basis functions $\chi_1, \ldots \chi_m$.

$$\psi_j(t) = \sum_k C_k^j(t)\chi_k .$$

The significance of coordinates and velocities of the electron subsystem is attributed to the amplitudes C_k^j and their derivatives with respect to time $\dot{C}_k^j$. Thus if the dependence of the potential energy E_{tot} of the system on R_i and C_k^j is known, it is possible to construct the pseudo-Lagrangian

$$L = \frac{\mu}{2}\sum_j\sum_k(\dot{C}_k^j)^2 + \frac{M}{2}\sum_k\dot{R}_i^2 - E_{tot}(C_k^j, R_i) .$$

Here the first term is the fictitious kinetic energy of the electronic component and μ the fictitious mass of the electron, the choice of which will be discussed below. Having supplemented the pseudo-Lagrangian by the condition that the functions ψ_j are orthonormalised

$$\sum_k C_k^{j*}C_k^j - \delta_{ij} = 0, \tag{10}$$

it is possible to obtain the equations of motion of the electrons and ions.

$$\mu\ddot{C}_k^j = -\frac{\partial E_{tot}}{\partial C_k^j} - \sum_l \lambda_{jl}C_k^l , \tag{11a}$$

$$M\ddot{R}_i = -\frac{\partial E_{tot}}{\partial R_i} . \tag{11b}$$

The last term in Eqn (11a) represents the response to the 'binding' [Eqn (10)] and λ_{jl} are undefined Lagrange multipliers, which are found simultaneously with the solution of Eqns (11).

The energy of the system E_{tot} is determined by the density functional method (see, for example, Yin and Cohen[53]). A system of planar waves is generally chosen as the basis system. Eqns (11) are solved numerically by methods analogous to those employed for the integration of classical MD equations. The scheme used in the solution, the minimisation of the initial electron energy (the adjustment of the energy of the electron subsystem to the Born–Oppenheimer surface, i.e. to the ground state) for fixed initial positions of the ions, the choice of the number of basis functions, etc. have been discussed in detail in a review.[52]

The theoretical justification of the CP method[49] consists in the fact that the solution of Eqns (11) under conditions where the trajectories reach equilibrium and in the temperature limit $T \to 0$ ('annealing') makes it possible to find the states of the electron and ion system (wave functions and coordinates) which gives rise to a minimum in the density functional. The $T \to 0$ annealing procedure is an important element of the CP method.

The principal difficulty in the application of the CP method (the maintenance of the constancy of the overall kinetic energy of the ions and E_{tot} at finite temperatures) is associated with the presence of the fictitious kinetic energy of the electrons, which depends on the fictitious mass μ. In choosing μ, it is necessary to seek a compromise. On the one hand, in order to diminish the oscillations in the 'real' energy, μ must be reduced. On the other hand, μ determines the minimum permissible time step in the integration and, in order to decrease the computational time, it is desirable to increase μ. This question as well as other procedures for the attainment of adiabatic conditions have been examined in a number of studies.[52,54,55]

The CP method has been applied successfully in the calculation of the structures (including the electronic structure) and properties of systems such as the protons in crystalline silicon,[56] liquid and amorphous silicon[54,57,58] and carbon,[59,60] liquid metals,[61] crystalline ice,[62] and liquid water.[63]

The fundamental limitation of the CP method in its current formulation is that the electrons exists only in the ground state, i.e. are on the Born–Oppenheimer surface, which is different for different characteristic structures (crystalline, liquid, and amorphous). Being capable of describing each of these structures, the CP method is not in principle designed to calculate the transitions between them. In this respect, the CP method is even more limited than the potential approach.

Thus, by resorting to CP quantum dynamics, we cannot solve the problem of the description of transitions between different electronic states.

The CP method proved to be extremely powerful, but it requires an enormous expenditure of computer time. This is associated with the simultaneous numerical integration of the equations of motion of the ions and electrons. The small time step in the integration is determined by the low fictitious mass of the electron, but the overall time is determined by the characteristic times of the dynamics of the ions. The total number of steps proved to be very large. The second cause is the enormous number of planar waves necessary for the calculation (several hundreds for semiconductors and several thousands for metals).

These factors limit the number of atoms involved in the calculation to ~ 100, whereas the number of particles required in calculations for complex reconstructions, dislocations, and real surfaces is much greater.

2. The tight-binding method

The wish to reduce the requirements for computer resources associated with the CP method led to the appearance of its simplified versions — the so called tight-binding methods (TBM). These methods make it possible to accelerate the computations by factors of tens and hundreds at the expense of accuracy.

In the most radical version[50] of the TBM, the following principal simplifications, compared with the CP scheme, are introduced:

(a) The abandonment of the explicit calculation of the electron dynamics.

(b) The choice as basis functions of only a small number of valence electron orbitals in the consideration of the crystal structure (four sp^3 orbitals per atom for diamond-like Si).

(c) The forces F_i acting on the ions from the electrons are calculated in accordance with the Hellmann–Feynman theorem

$$F_i = \sum_j < \psi_j|\frac{\partial\hat{H}}{\partial R_i}|\psi_j > ,$$

where $\hat{H}$ is the Hamiltonian of the electron subsystem (the summation is carried out over all occupied electronic levels).

(d) Interionic pair potentials are introduced in accordance with the equation

$$\Phi_2(R) = E_{tot}(R) - E_{BS}(R) , \tag{12}$$

where E_{tot} is the total potential energy of the system determined by the density functional method[64] and E_{BS} is the energy of the band structure calculated in accordance with the tight-binding empirical scheme.[65] The quantities $E_{tot}(R)$ and $E_{BS}(R)$ are found for a regular crystal structure per atom of the crystal.

Thus the equations of motion of the ions assume the form

$$M\ddot{R}_i = F_i - \nabla_i \sum_j \Phi_{ij}.$$

They are solved according to the following scheme: (1) adjustment of the energy of the electrons to the Born – Oppenheimer surface for the initial positions of the ions; (2) calculation of the forces F_i; (3) calculation of a single time step for the ions; (4) recalculation of the wave functions and return to step 2.

The phonon spectra of diamond-like silicon,[50] the fine anharmonicity effects (thermal expansion, the shift and broadening of the phonon lines with increase in temperature) in diamond-like silicon,[66] the degree of adsorption of hydrogen on the (100) surface of diamond,[67] etc. have been calculated with the aid of the TBM.

The attempts to apply the TBM to the modelling of different Si and Ge surfaces demonstrated its nonuniversality,[68] analogous to the nonuniversality of the classical potential approach. The reason for this is that a system of basis wave functions specific to a tetrahedral structure is employed. This system is unsuitable for the description of electronic structures with symmetries other than tetrahedral, which have other wave functions.

These considerations led Mercer and Chou[68] to the conclusion that the TBM must be parametrised for Si and Ge. Here $E_{BS}(R)$ is again calculated for the sp^3 orbitals, while $E_{tot}(R)$ is calculated separately for each of the large number of crystalline modifications. Thus the interionic pair potential $\Phi_2(R)$ is found to be different for different crystal lattices, i.e. its dependence on the coordination appears. This dependence was in fact parametrised in such a way that $\Phi_2(R)$ was a function of the local environment of the given atom, i.e. of the local coordination number. This procedure is fully analogous to that employed by Tersoff[22] in the classical potential approach. In this approach, $\Phi_2(R)$ is a cluster functional.

The parametrised TBM is extremely flexible, i.e. it makes it possible to describe successfully virtually all reconstructions of the Si or Ge surfaces with the aid of the same (for each element) set of adjustable parameters.[69]

Thus the situation illustrated schematically in Fig. 1 is also repeated in the TBM. By using this method, it is possible to construct a potential surface having local minima close to the real minima for different electronic states (terms). On the other hand, it is clear that the dynamics of the transitions between these states cannot be reproduced by such procedures. The CP and TBM methods operate only with stationary solutions of the Schrödinger equation. On the other hand, the description of the electronic transitions requires the solution of nonstationary quantum-mechanical equations.

V. Reconstruction, adsorption, surface diffusion, clusters

1. Modelling of the surface

The block of mobile particles in the MMD is referred to as the basic cell (BC). For the surface of a crystal, it consists of a certain number of layers of particles and is bounded 'from below' by a layer (or several layers) of stationary particles. When necessary, the deeper layers can be replaced by a continuous medium, which acts on the BC in accordance with the Mie or Steele potentials.[6] We select a cell with a height h and a length and width l [in the horizontal directions, the BC is either also bounded by layers of stationary particles or periodic boundary conditions (PBC) are used in these directions]. The number of particles in the BC is $N = nl^2h$, where n is the average concentration of particles.

The choice of the dimensions of the cell. Modelling a section of the surface, is made in such a way that the motion of individual atoms reproduces characteristics of the phonon spectrum important for the given problem; the reconstruction and relaxation of the cell surface are reproduced.

In the modelling of equilibrium processes (desorption, surface diffusion, incidence of thermal particles) at a certain temperature, the size of the cell is chosen on the basis of the conditions l, $h > k_{min}^{-1}$, where k_{min} is the minimum wave vector of the phonons which still contribute to the energetics of the process investigated.

In the modelling of nonequilibrium processes (incidence of fast particles), the size of the BC must be chosen so that the interaction time t_1 (the computation time) is much shorter than the time t_2 required for the return to the surface of the nonequilibrium excitation reflected from the BC boundary:

$$t_1 \sim \frac{\sigma}{v_{inc}} \ll t_2 \sim \frac{l}{c} \left(\text{or } \frac{h}{c}\right), \tag{13}$$

where σ is the characteristic dimension of the potential, v_{inc} is the velocity of the incident particle, and c the speed of sound.

There exists a procedure for softening condition (13) by introducing the removal of heat into the calculation. The Langevin terms (the δ-correlated random force and friction linked in accordance with the fluctuation-dissipation theorem) are then introduced into the equations of motion (1) for the boundary particles in the BC. They model thermal conduction, quenching the nonequilibrium excitations arriving at the cell boundary. The inequality (13) is replaced by the condition $t_1 < t_2$.

The above conditions are useful for the estimation of the characteristic dimensions, because the quantities involved in them are frequently known only in terms of order of magnitude. It is desirable that the choice of the final BC dimensions (and boundary conditions) should be made on the basis of the results of trial calculations.

Boundary conditions. The reconstruction and relaxation of the surface can be modelled only with the aid of PBC. On the other hand, if the structure of the surface is already known, then the corresponding geometry can be specified for a bounded cell. Nevertheless it appears that an equal degree of uniformity of the BC along the horizontal plane is attained for PBC when the BC size is smaller than for a bounded cell.

The removal of heat is more naturally modelled for a bounded BC, because it can be achieved in all directions, whereas for PBC it is possible only in the 'downward' direction. The reproduction of the removal of heat for PBC requires an increase in the size of the BC compared with the bounded cell.

Averaging. The result of the interaction of an incident particle with the surface depends on the position of the target point relative to the surface atoms. Therefore, if interaction coefficients averaged with respect to the surface are required, the averaging must be carried out with respect to all the positions of the target point within the limits of the projection of the unit cell of the crystal (or the BC for a noncrystalline body) on the surface. Naturally, for a reconstructed surface the averaging region is greater than for a nonreconstructed surface. The statistical error increases owing to the motion of the surface atoms, which in fact never occupy equilibrium positions.

2. Reconstruction

Flat surface. An attempt at the classical modelling of the dynamics of the initial stage of the reconstruction (dimerisation) of the Si(100) and Ge(100) surfaces and of their equilibrium struc-ture has been undertaken[70] with the aid of potentials of the SW type.

In the initial instant, all the atoms occupy the sites of a tetrahedral structure and have velocities with a Maxwellian

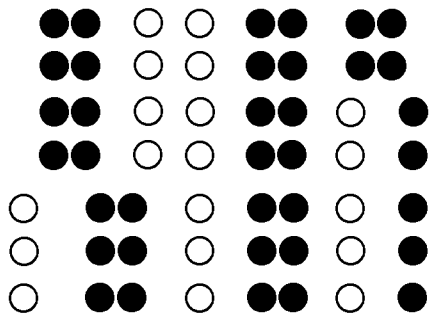

Figure 3. Schematic illustration of the first layer of a reconstructed silicon surface.

distribution at the temperature considered. In the course of the computation, the nonequilibrium initial structure evolves to a reconstructed structure containing ordered rows of dimers (Fig. 3). The reconstruction takes place as follows: the formation of a dimer at any surface site induces the rapid dimerisation of two adjoining atoms, etc., i.e. a growing row of dimers appears. Two rows of dimers, growing in opposite directions, can meet and form a single long row. If the rows are displaced relative to one another when they meet, then 'free' atoms are formed at the meeting point.

The properties of the equilibrium structure obtained correspond to the available experimental data. The average distance between the atoms in the dimer proved to be 2.42 Å (the experimental values range from 2.36 to 2.47 Å). The qualitative explanation of the experimentally observed transition from the $c(4 \times 2)$ structures (inclined asymmetric dimers) and $p(2 \times 2)$ structures (inclined symmetrical dimers) at low temperatures to structures with the (2×1) symmetry (noninclined dimers) at high temperatures is one of the most interesting results.[70] From the standpoint of the MD experiment at finite temperatures, the inclined dimers are always present owing to the thermal shift, i.e. the 'instantaneous photograph' always reveals their presence. However, at low temperatures the slopes of neighbouring dimers are correlated — they exist in the counterphase. This in fact yields an instantaneous picture of type $c(4 \times 2)$ reconstructions. Owing to the intensification of thermal motion, at high temperatures the inclinations of the dimers become noncorrelated, which corresponds (on average) to the (2×1) symmetry.

The attempt to apply the more complex Tersoff potential showed that the latter yields a force of attraction between the atoms in the dimer which is too large (Fig. 4).

Calculations have also been made[70] of the reconstruction times, but these results may be open to doubt (see Section III).

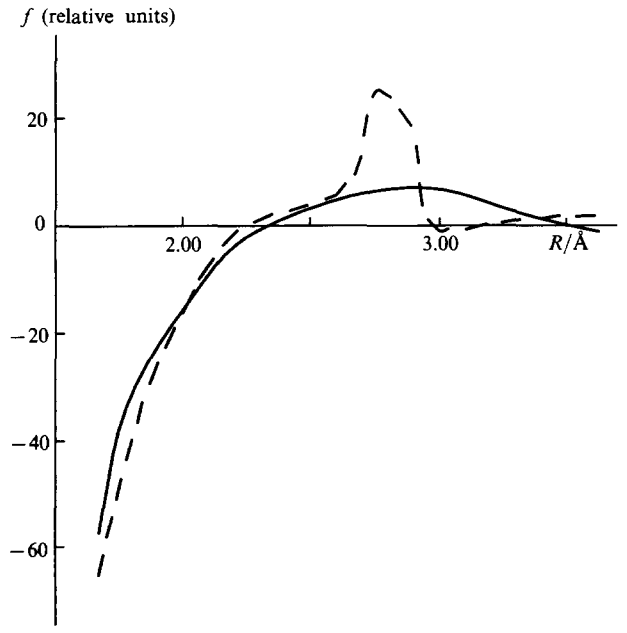

Figure 4. Forces acting in the direction between the atoms in the dimer for different potentials. Continuous line — calculation employing the SW potential; dashed line — calculation employing the Tersoff potential.

Steps. In a study of the atomic and molecular structures of monomolecular steps on the Si(001)−(2 × 1) surface, the Car–Parrinello method was employed.[71] A cell comprising seven layers was considered. The free bonds of the lower layer of silicon atoms were saturated by 48 oxygen atoms.

For a flat surface, it was found that symmetrical dimers, i.e. those in which both atoms have the same coordinate z, are unstable. Compared with $s(2 \times 1)$, the $b(2 \times 1)$ reconstruction (inclined dimers in which the difference between the levels of the atoms is $\Delta z = 0.51$ Å) lowers the overall energy by 0.10 eV dimer^{-1}. The ground state of a flat surface proved to be the $c(2 \times 4)$ reconstruction (the directions of inclination of neighbouring dimers in one row and on passing from one row to another alternate, $\Delta z = 0.72$ Å, and the decrease in energy is 0.24 eV dimer^{-1}). The $p(2 \times 2)$ reconstruction with $\Delta z = 0.72$ Å is inferior to the latter only to the extent of 8 meV dimer^{-1}.

The geometry of a monomolecular step may be extremely varied. Fig. 5 illustrates three configurations: S_A — the upper terrace dimers perpendicular to the edge of the step (Fig. 5*a*), S_B — dimers parallel to the edge of the step whereupon the step may be terminated by the row of atoms of the lower terrace, the corresponding dimer pair which is ahead of the upper terrace (Fig. 5*b*) or under it (Fig. 5*c*) (the nonrebonded and rebonded edges). The combination of the inclinations of the dimers, the

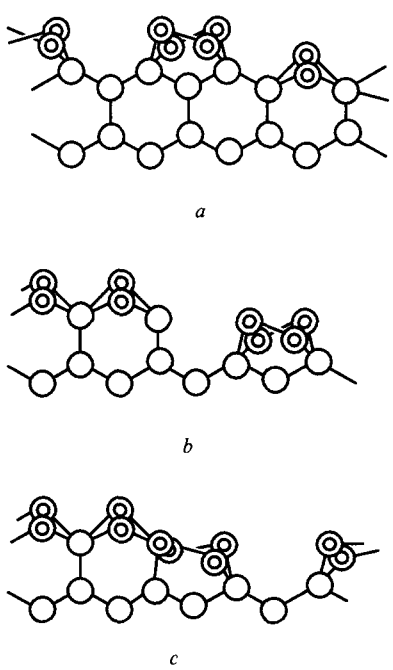

Figure 5. Schematic illustration of a step on the surface of silicon for three configurations: (*a*) S_A; (*b*) S_B (nonrebonded edge); (*c*) S_B (rebonded edge). The double circles denote the atoms of surface dimers. Apart from the atoms of the dimers, which are in the plane of the figure, the atoms in the next plane (in depth) are also shown.

different reconstructions of the upper and lower terraces, and the edges of the step decrease by a large factor the number of possible configurations. Boguslawski et al.[71] modelled only eight principal cases, including those variants of the S_A and S_B steps which had been observed experimentally.

Calculation of the electron dynamics enabled the authors[71] to reproduce the specimens observed in a scanning tunnel microscope and to compare them with the results of measurements. The qualitative features of experimental data could be explained on the basis of the shape of the wave functions of the surface states without additional hypotheses concerning the reconstruction induced by the blade.

3. Sticking, accommodation, adsorption, and scattering

The elementary sticking and accommodation steps have been widely investigated by the MMD, for example in Refs 41 and 72–74. We shall consider the study[41] where the sticking and energy accommodation coefficients for the atoms X (helium, neon, and argon) on falling on the Si(100) surface were calculated in the range of energies of the incident particles from 0.1 to 1 eV and at surface temperatures from 300 to 1000K. The Si–Si interaction was described in terms of the SW potential. The interaction of the X atoms with the Si atoms was described with the aid of the Lennard–Jones potentials.

The X atoms were projected towards the surface and at right angles to it from a certain distance z_0, selected at random, over which the X–Si interaction is virtually nonexistent. The initial position of the atom relative to the region of mobile surface particles was also selected at random. The distribution of the initial velocities of the moving surface particles was of the Maxwellian type at a temperature T_s in the range from 300 to 1200 K. The trajectories of all moving particles were calculated.

A particle was regarded as having been reflected when the condition $z > z_0$ (z being the current distance between the atom and the surface) was fulfilled, i.e. if the particle intersected the plane of projection in the opposite direction. This criterion of reflection leads to prolonged calculations, but it is necessary for the accurate calculation of the energy accommodation coefficient.

The atom is regarded as sticking if the direction of its velocity changes four times. Sometimes the first return of the particle to the surface is regarded in the literature as sticking.[74] However, visualisation of the calculations shows that the particle is in many cases reflected after the second collision with the surface atoms. On the other hand, instances of reflection after the third collision during the residence time of the X particles within the confines of the modelled block have not been observed.

After the completion of the calculation in each attempt, the surface particles return to the initial position with a new Maxwellian velocity distribution. The total number of attempts N for each energy E_i was 100. The sticking coefficient k_{st} is defined as the ratio of the number of attempts with sticking M_{st} to the total number of attempts M.

Fig. 6 presents the results of the MD calculations of the coefficients of sticking to the nonreconstructed Si (100) surface. The sticking coefficients diminish with decrease in the mass of the incident particles, with increase in their energy, and also after an increase in the temperature of the surface. A procedure has been proposed[41] for reconciling the results of the calculation with the analytical rigid cubes model[75] by introducing into the latter an effective angle of incidence ϑ.

A dependence on the mass of the incident particles is manifested also in interaction with the surfaces of polymers; we shall return to this question at the end of this section.

Methods in which the sticking of a gas to the surface is considered within the framework of the approximation where the incident atom is classical (quasi-classical) but the phonons are treated quantum-mechanically have been analysed.[76] A model example of the sticking of He, Ne, and Ar atoms to the surface of copper has been quoted.

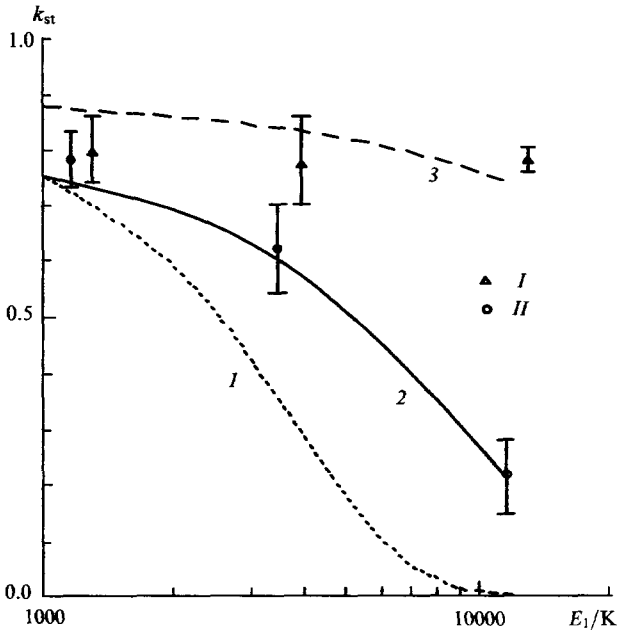

Figure 6. Dependence of the sticking coefficient on the energy of the incident particle. MD calculation: (*I*) Ne, surface temperature $T_s = 640$ K; (*II*) He, $T_s = 1160$ K. Rigid cubes model: (*1*) He (angle of incidence $\vartheta = 0$); (*2*) He ($\vartheta = \pi/6$); (*3*) Ne ($\vartheta = 0$).

The enthalpies of adsorption of 13 hydrocarbons (pentane, cyclohexane, 2-methylbutane, decane, etc.) on a mineral smectic clay have been calculated with the aid of the classical MMD.[77] The significant sensitivity of the results to the choice of the parameters of the Lennard–Jones potential used for the description of the interaction of the nonbonded atoms with one another was elucidated. None of the sets of potentials known in the literature made it possible to achieve agreement with experimental data.

Various equilibrium states of hydrogen adsorbed on the (001) surface of diamond have been considered by the tight binding method.[67] The method of molecular dynamics has been used only in the gradient descent method, i.e. as a procedure for the fastest determination of the location of the energy minimum for a system which was initially close to the configuration of the system under consideration. The structures of the clean C(001) surface and two structures with adsorbed hydrogen — monohydrogenated (001)—(2 × 1):H (phase *1*) and dihydrogenated (001)—(1 × 1):H (phase *2*). The structures of the electron bands and the density of the electronic states were calculated. It was found that there are no electronic states in the forbidden band gap in phase *2*, while in phase *1* they do exist. Yet another qualitatively explained effect is the repulsion of the surface electronic states in phase *2* into the conduction and valence bands. In the latter case, the surface electronic state is in resonance interaction with the electronic level of the C atom, which actually leads to an increase in the conductivity of diamond by several orders of magnitude after its treatment in a hydrogen atmosphere. This effect is apparently of a purely surface type.

For high energies of the incident particles, the treatment is restricted to the simplest interaction potentials. The individual trajectories of the incident Ne^+ ion (2 and 4 keV)[78] were modelled by a sequence of pair collisions with surface atoms. Account was taken of the collective effects when the Ne^+ ion interacts almost simultaneously with a group of atoms arranged in a nearly symmetrical configuration around the trajectory of the ion (chanelling is a typical example).

The scattering of ions on different Ni faces on the reconstructed Pt(110)–(1 × 2) and –(1 × 3) surfaces as well

as the dislodgement of the oxygen atoms adsorbed on Ni were investigated. The results agree satisfactorily with experiment.

4. Surface diffusion

The diffusion of rhodium and nickel adsorbed atoms on the (111) and (001) surfaces of rhodium and nickel respectively has been considered.[79] The Morse and inserted atom potentials were used. The distributions with respect to energies and the relation between the rotational and translational energies in the diffusion of a CO molecule on the Ni(111) surface have been determined in another study.[80] Tully's stochastic dynamics was used. The non-Arrhenius temperature dependence of the calculated diffusion coefficients is noteworthy. A comparison was made with Kramers theory.

Wang et al.[81] carried out calculations for the diffusion of a CO molecule on the Pt(111) surface at temperatures in the range 100 – 500 K. The surface was specified by a potential which depends on the coordinates of the stationary platinum atoms. The CO molecule was oriented mainly at right angles to the surface. The dependence of the diffusion on the rotational and vibrational states of CO was noted. The diffusion coefficients obtained agreed with the available experimental data within the limits of the scatter of the latter. An attempt was made to model the energy exchange between CO and the surface by including the interactions of the molecule with phonons. In view of the increase in the required computation time by a factor of 100, only two trajectories were calculated. They showed that the energy exchange influences the diffusion.

Engdahl and Wahnström[82] investigated the nonequilibrium diffusion of hyperthermal adsorbed oxygen atoms arising on dissociative chemisorption of the O_2 molecule on the Al(111) surface. In view of its complexity, the chemisorption process was not considered. The initial condition chosen was such that the bond in the O_2 molecule had already been ruptured and the atoms had moved apart so much that the interaction had been neglected. The initial energies of the O atoms were chosen to be 3.5 eV, which corresponds to the energy of the chemisorption of O atoms, and 9.5 eV (for comparison). The inserted atom potentials and Tulley's model were employed. In the model, the Langevin equations were used for the atoms of the third layer, while the atoms of the fourth and deeper layers were fixed in the equilibrium positions.

It was shown that the atoms are mainly displaced in the ballistic stage over a period less than 0.5 ns. Further thermalisation requires a longer time (> 5 ns) but takes place without a directional shift. The ballistic shift is 16 Å for an initial energy of 3.5 eV and 52 Å for 9.5 eV. The latter shift (and not the former as one would wish) agrees with measurements by means of scanning tunnel microscopy. The penetration of atoms into the bulk of the support takes place in the first 0.2 ns, whereupon the number of inserted atoms proved to be approximately twice as great as the number observed experimentally. The possible role of nonadiabatic transitions in the diffusion of adsorbed atoms on the surface was not discussed in the above studies.[79–82]

MD studies on surface diffusion have not yet received due recognition. Thus, in a review[83] where the results obtained with the aid of scanning tunnel microscopy for the motion of atoms on different surfaces are analysed, no mention whatever is made of molecular dynamics. It was actually claimed that "surprisingly little is known about the mechanisms of the motion of atoms on the surface". Yet one of the main purposes of MD is in fact the study of such mechanisms of dynamic processes.

5. Interaction of clusters with surfaces

Recently much attention has been devoted to the MD modelling of the processes involving the incidence of atomic and molecular clusters on the surfaces of solids.[84–92] Studies have shown that the cluster–support collisions are not described by simple analytical models, since no account is taken in the latter of the collective effects of interatomic interaction. This is the reason why MD modelling is required.

The scheme used in such modelling does not in essence differ from that described above for the incidence of individual atoms (molecules). On the other hand, the choice of the interparticle interaction potentials depends on the energy of the incoming clusters and the energies of the particles in the final state. The entire range of energies investigated is arbitrarily divided into two regions: high energies (> 1 keV atom^{-1}) and low energies (< 1 keV atom^{-1}).

In the first case, problems such as that of the possible appearance in the collision zone of conditions for an appreciable release of neutrons[84,85] or for the excitation of the internal electron shells of the atoms[86] are investigated. Here the relatively short times after the incidence of the cluster are important, during which the highest concentrations of energy are attained and the result is determined by close pair collisions of the atoms. Comparatively simple pair repulsion potentials are therefore selected.

In the case of low energies of the clusters, the formation and structure (epitaxial, amorphous) of the films arising in the interaction of the clusters with the surface,[87,88] the dependence of the appearance of different structures (films, blobs, craters, insertion zones) on the energy and size of the incident clusters,[89] are investigated as are the angle, size, and velocity distributions of the small clusters dispersed from the surface when ions are incident on it.[90] Here it is necessary to trace the energy relaxation process, sometimes up to the thermal level, so that more realistic and complex, multiparticle interaction potentials are needed.

We shall consider in greater detail the processes of this group in relation to the study of Hsieh et al.[89] The incidence of Cu, Ni, and Al clusters with dimensions ranging from 4 to 92 atoms and energies from 92 to 1000 eV atom^{-1} on the surfaces of the same metals in various combinations was investigated. The inserted atom potentials, modified for short distances in order to take into account correctly the collisions of atoms having high energies, were employed.

Depending on the size and energy of the clusters, the elastic and chemical properties of the materials, and the ratio of the atomic masses of the cluster and the support, significantly different results were observed for the interaction. The cluster consisting of 92 copper atoms, incident on the copper surface at low energies, can form a blob, whereas at high energies it penetrates the support, inducing its marked deformation. If the energy of the cluster exceeds 25 eV atom^{-1}, surface defects arise in the support. A cluster consisting of 92 aluminium atoms hardly deforms a nickel support, spreading on the latter epitaxially despite the 15% discrepancy between the Al and Ni lattice parameters. For an energy of 1 keV atom^{-1}, several Al atoms break away from the cluster and are either deflected into a vacuum or are scattered on the surface. Ni clusters with an energy of 326 eV atom^{-1} are almost fully incorporated in the aluminium support and form local amorphous zones.

Fig. 7 presents a diagram illustrating the mechanisms of the interactions of clusters with a surface,[89] showing what results should be expected depending on the kinetic energy of the incoming cluster and the bond energies for an atom in the cluster and in the support.

It is essential to note that, in the MD modelling of certain cluster processes by using the potential approach, it is also necessary to exercise caution (see Section III). Thus it has been found[90] that numerical data agree qualitatively with experimental data and with data derived by means of the analytical theory of the energy distributions of the atoms and dimers dislodged from the surface of the copper crystal when an argon ion is incident on the latter. On the other hand, in order to achieve a quantitative agreement with the theory, it is necessary to choose a copper sublimation energy which is much smaller than the experimental value. The authors[90] explain this discrepancy by the 'loss' of some of the dislodged low-energy atoms due to the characteristics of the methods used in the MD experiment.

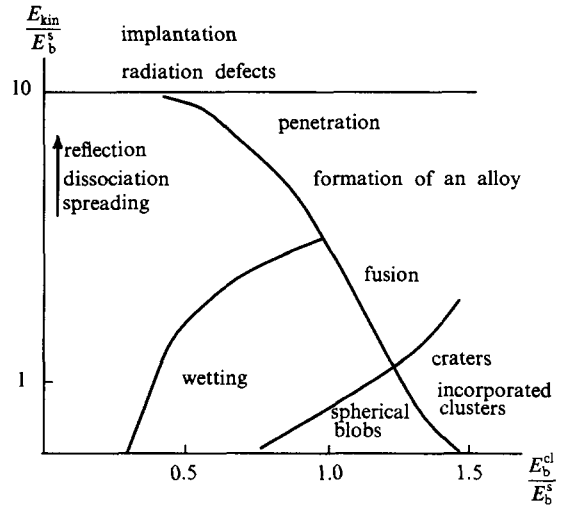

Figure 7. Diagram illustrating the mechanisms of the interaction of clusters with the surface. E_{kin} = kinetic energy of the cluster per atom; E_b^{cl}, E_b^s = the bond energies of the atoms of the cluster and the surface respectively.

However, another interpretation is also possible. If one considers surface + bound atom and surface + free atom states as different electronic states, then the sublimation energy corresponds to the height of the potential barrier between them. As noted in Section III, the interpolated potential surface can model incorrectly the potential barrier between different electronic states. One cannot rule out the possibility that this was in fact the reason for the discrepancy between the qualitative and experimental sublimation energies in the above study.[90]

Insepov et al.[91] investigated the dispersion of the gold surface atoms by argon clusters comprising 87, 141, and 201 atoms. The energy of the cluster was 100 eV atom^{-1}. A method was developed for the removal of the excess pressure arising on impact. The dispersed material of the target consisted of small gold clusters; lateral dispersion was observed.

The limiting case of the spreading of the involatile microblob, present initially on the surface, has been modelled by isothermal MD.[92] Both one-component blobs comprising Lennard-Jones particles and two-component blobs were considered. The second component consisted of a very simple polymer model: a flexible elastic chain consisting of two, four, or eight Lennard-Jones atoms. The total number of atoms in the microblob was $\sim 10^3$. The polymer concentration varied from 0% to 100%. The surface was modelled by a uniform half-space acting on the atoms of the blob via the Mie potential. The initial form of the microblob was specified as a comb periodically extended along its entire length.

The formation of the precursor film was investigated: its width increased initially almost linearly as a function of time and then its growth became diffusional. Its thickness could correspond to the thickness of one or several stepped layers. In the case of polymer solutions, the layers began to mix, which led to their shape approaching hemispherical. The nature of the mixing was investigated for different polymer models and different parameters of the potential. The results agree qualitatively with experimental data.

6. Processes on the surfaces of liquids and polymers

The surface of a liquid differs from that of a solid, apart from lack of order (which incidentally is also characteristic of amorphous solids), also by the fact that it is not as a rule sharp. The density of the surface layer of a liquid gradually decreases from the density of the liquid to the density of the saturated vapour over several intermolecular distances in the liquid.

The scattering of Ne atoms on the surface of glycerol has been modelled[93] for collision energies ranging from 25 to 60 kJ mol^{-1}. The glycerol molecule was described by a nine-centre model, which makes it possible to take into account the torsional flexibility. The hydroxyl hydrogen atoms were included explicitly in the model, i.e. the hydrogen bonds appeared directly. The intramolecular potential energy was expressed approximately by the sum of the Coulombic and Lennard-Jones pair interactions and also by torsional terms. The intermolecular interaction was represented by the sum of Coulombic and Lennard-Jones pair-additive terms. The Ne-glycerol interaction involved only the Lennard-Jones interaction. The glycerol surface at $T = 300$ K was modelled by a cubic cell comprising 343 glycerol molecules with two free surfaces along the z axis. A vaporised glycerol molecule was not observed (the melting point is 291 K).

The sticking, reflection and desorption coefficients of the Ne atoms after several collisions were calculated. The energy losses and the energy and angular distributions were found for the reflected Ne atom. The results agree satisfactorily with experimental data. When an attempt was made to describe the results with the aid of a simple binary collisions model, a decrease in the effective mass with increase in the collision energy was observed. This has been explained by the influence of multiple collisions and by vibrations of the liquid. Data on the energy transfer in the liquid were obtained. The collision energy passes to translational and rotational modes and, to a lesser extent, torsional modes. The energy is then rapidly distributed among the neighbouring glycerol molecules.

Ahlström and Berendsen[94] modelled a L-didecanoyllecithin (an example of an amphiphilic molecule) monolayer on the surface of water. The area of the surface was chosen so that 42 lecithin molecules were accommodated on it. The thickness of the layer of water molecules was 4 nm. The water layer was covered by lecithin from below and from above. The density profiles, the surface tension, and the electrostatic surface potential were found. Local penetrations of water molecules into lecithin were observed. The water-lecithin contact surface is very large and disordered. The results proved to be extremely sensitive to the form of the potential energy for lecithin.

Computer modelling of the dynamics of light gases in a 'rigid' dense polymer matrix exhibits apparent discrepancies with experimental data. Modelling shows that light atoms and molecules (H_2, He) easily attain the diffusional regime, whereas the mobility of heavy atoms and molecules proves to be low. The authors[95] conclude that the 'rigid' matrix is an inadequate representation of the dense system comprising polymer molecules. A qualitative agreement with experimental results can be attained by taking into account the influence of the thermal vibrations of the polymer molecules on diffusion.

VI. Chemical reactions in terms of the adiabatic approximation

1. The use of potential surfaces.

Etching. The chemical interaction of fluorine atoms[45] and molecules[96] with a reconstructed Si(100)-(2 × 1) surface has been modelled. The temperature of the surface of the incident atoms was 300 K. Use was made of the SW type interaction potentials (Si-Si, Si-F, F-F), the parameters of which were chosen in order to achieve agreement with independent experimental data. Sticking, the dissociation of molecules on the surface, the formation of various compounds between fluorine and silicon, etc. were investigated. Hypotheses concerning the etching mechanisms were put forward.

It was observed[45] that, when there is less than one monolayer of F atoms on the surface (surface coverage $\theta < 1$), three outcomes of the incidence of a F atom on the Si surface are possible:

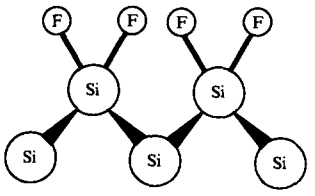
(1) recoil (30%);

(2) chemisorption (the capture of a F atom at the site of rupture of an Si–Si dimer bond or capture by a free bond (60%);

(3) physical sorption (the capture of a F atom by the surface as a whole with retention of the mobility of the F atom along the surface) (10%).

When the coverage of the Si surface by F atoms ranges from $\theta = 1$ to $\theta = 1.25$, the structure of the Si–F surface layer is ordered and stable. There is then no chemisorption, i.e. the physically adsorbed atoms do not penetrate into the bulk of the surface layer and do not form chemical bonds with silicon atoms.

For $\theta > 1.25$, the ordered state of the first adsorbed F layer (illustrated schematically in Fig. 8) becomes unstable. The mutual repulsion of the F atoms distorts the structure. The surplus F atoms can penetrate into the bulk of the surface layer and can break the bonds between the silicon atoms with formation of the complexes SiF, SiF_2, and SiF_3. Subsequently the complex SiF_3 can combine with yet another F atom to form the volatile SiF_4 (etching).



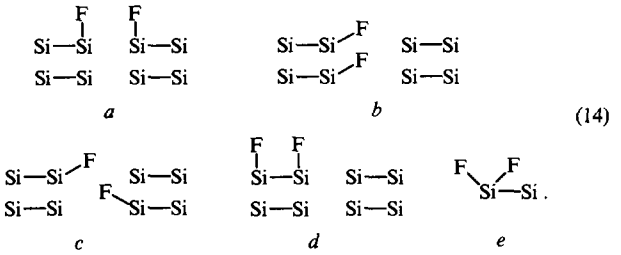


Figure 8. The ordered state of the adsorbed fluorine atoms on silicon.

The overall conclusion of the above study[45] is that, in order to attain the highest rate of etching, the greatest possible disorder of the initial surface is required.

Two main paths in the interaction of an F_2 molecule with the Si surface have been observed[96] — the chemisorption of one of the F atoms and the recoil of the other or, more rarely, the chemisorption of both atoms of the dissociated F_2 molecule. In addition the formation of the Si–F–F complex, where the second F atom is weakly bound to the rest of the complex, has been noted. Rare instances of the reflection of F_2 molecules have also been detected (10^{-3}).

Two chemisorbed F atoms form different combinations of chemical bonds with the Si atoms of the dimers. These bonds can be illustrated schematically as follows:

(14)

Evidently the F atoms can be linked to neighbouring Si atoms belonging to two dimers of different rows (*a*) 'opposite' configuration), two dimers in one row (*b*) 'adjacent' configuration), two dimers in different rows with a displacement by one dimer (*c*) 'diagonal' configuration), one dimer only (*d*) 'the same' configuration). Case (*e*) corresponds to the complex SiF_2.

The numerical probabilities calculated by the MD method can be questioned (see Section III), but the dry etching model agrees qualitatively with experimental data. The study of the role of the removal of heat in the interaction of fluorine molecules with a silicon surface has been initiated.[97]

Surface photochemistry. The dynamics of the surface photochemistry in the system comprising HBr molecules adsorbed on the LiF(001) surface and $\hbar\nu$ quanta has been investigated.[98] The interaction on the surface of the product of the photolysis (H atoms with an energy of 2.6 eV) with H′Br molecules (H and H′ denote simply different hydrogen atoms) has been investigated by the method of classical stochastic Tully trajectories.

$$\mathrm{H'} + \mathrm{HBr} \longrightarrow \begin{cases} \mathrm{H'Br} + \mathrm{H} \\ \mathrm{HH'} + \mathrm{Br} \end{cases} \qquad (15)$$

The interaction energy was specified by the London–Eyring–Polanyi–Sato potential supplemented by the electrostatic and nonelectrostatic potentials of the interaction of the adsorbed atoms with the surface and with one another.

The probabilities of the occurrence of the reactions via paths (15) were investigated, the energy and angular distributions of the H′ atoms were found, and the dependences of these quantities on the surface coverage and temperature were determined. A decrease in temperature increases the probability of the reaction at low coverages and diminishes it at high coverages ($\theta > 0.5$). This effect has been attributed to the formation of a cellular structure of the adsorbent.

Discussion. In the studies considered above and many similar ones, both the results of the dynamic process and the process dynamics itself were investigated. There are no grounds for doubting the reasonableness of this approach to the determination of equilibrium properties — energies, configurations, structures, etc. The process dynamics also has a physical signifiance when one investigates processes occurring on the same potential surface, as specified, for example, in formula (15). As regards processes in which the initial and final stages of the system belong to different electronic states and their wave functions cannot be obtained from one another by any adiabatic alteration of the coordinates of heavy particles, the MMD constitutes for such processes a computational procedure for the determination of the properties of the system in the final equilibrium states. On the other hand, the correspondence of the dynamic process itself to real quantum dynamics requires at least a careful discussion. However, such processes are not even considered in these investigations.

2. Quantum adiabatic calculations

The Car–Parrinello method has been used[100] to investigate the vibrations of hydrogen atoms chemisorbed on the Si(111)–(1 × 1) surface. Fourier analysis of the MD trajectories made it possible to determine the frequencies of the surface phonon mode and to observe an anharmonic relation between the Si–H vibrations and the lower-frequency mode of the surface phonons. The calculated frequencies agree well with the experimental values (except one). The dispersion curves are also close to the experimental ones.

Since the publication of the Car–Parrinello method, investigators made considerable efforts to reduce the expenditure of computer time. One approach involves the improvement of computational schemes (see, for example, Gibson and Carter[101] and Tuckerman and Parrinello[102]). In another approach the number of particles treated quantum-mechanically is reduced and they are surrounded by classical atoms, i.e. a special selection of boundary conditions is made. As an example, we shall discuss a study[103] where the adsorption of the ethyne molecule on the Si(100)–(2 × 1) was modelled.

The basic cell consisted of 360 silicon atoms arranged in ten layers (Fig. 9). The first six layers of atoms moved in accordance with Newton's equations, the seventh, eighth, and ninth layers modelled the removal of heat, and the tenth layer, comprising stationary atoms, bounded the cell from below. Periodic boundary conditions were imposed along the x and y axes. The central group of atoms (quantum cluster), comprising 35 silicon

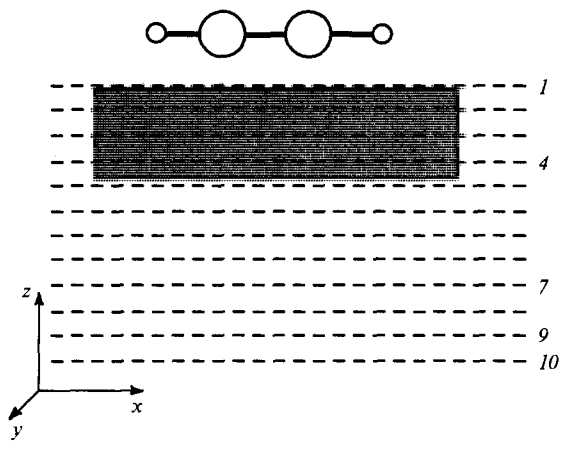

Figure 9. Schematic representation of the basic cell. The quantum cluster is shown shaded: (*1*) – (*10*) numbers of the layers.

atoms in the first four layers (the shaded region in Fig. 9), was examined quantum-mechanically, whilst the remaining atoms interacted with one another in accordance with a potential of the SW type (classical approximation). The problem of the interaction of the "quantum-mechanical" atoms with the "classical" atoms surrounding them was specially solved.

Two configurations of the quantum cluster were considered. The surface layer in a planar projection for the first configuration is illustrated in Fig. 10*a*, while the second layer is show in Fig. 10*b*. The crosses denote the region of incidence and the possible orientations of the C_2H_2 molecule. The first configuration modelled the incidence of C_2H_2 on the dimer or within a row of Si dimers, while the second modelled the incidence between the rows of dimers.

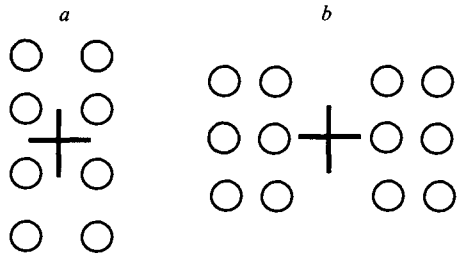

Figure 10. The surface layer of a quantum cluster in plane form. Incidence on a row of dimers (*a*) and between rows (*b*).

The dynamics were considered as follows. With the aid of one of the semiempirical quantum-mechanical methods, the ground electronic state of the system was found: a quantum cluster of Si atoms + C_2H_2 molecule, i.e. a system consisting of 35 Si atoms, two C atoms, and two H atoms. (Additional hydrogen atoms were actually introduced in order to eliminate surface effects — in order to "close" the free valence bonds). The forces found from the quantum-chemical calculations and from the SW potential were then used in Newton's equations, the new positions of all the atoms in the nine layers were found (Fig. 9), and the procedure was repeated. The dynamics of the physical and chemical sorption was investigated in this way, the time characteristics of the interaction were found, and the bond energies and the geometries of the resulting equilibrium configurations were determined.

In the case of a coaxial incidence of the C_2H_2 molecule on the silicon dimer in the geometry presented in Fig. 10*a*, the formation of chemical compounds between C_2H_2 and the silicon surface containing both one σ-type Si – C bond (Fig. 11*a*) and two such

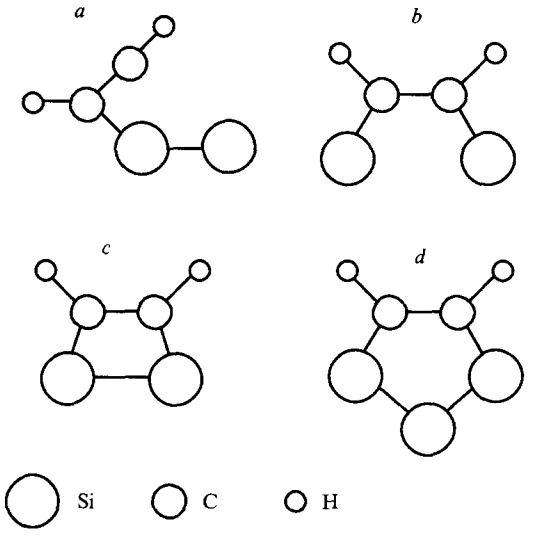

Figure 11. Schemes explaining the formation of chemical compounds between C_2H_2 and the Si surface: (*a*) the formation of one bond with the Si – Si dimer; (*b*) the formation of two bonds with dissociation of the Si – Si bond of the dimer; (*c*) the formation of two bonds without the dissociation of the Si – Si bond of the dimer; (*d*) the formation of a bridged compound.

bonds (Fig. 11*b*) was observed. In the case of the configuration shown in Fig. 11*b*, the Si – Si bond in the dimer was broken. This bond could then be restored without the dissociation of a Si – C bond, but this configuration (Fig. 11*c*) proved to be unstable. After several transitions from the configuration 11*b* to 11*c* and conversely at 100 – 400 fs intervals, the collision configuration 11*b* was established.

The result of the incidence of C_2H_2 depended strongly on the site of incidence. On incidence between neighbouring dimers of the same row, when the axes of the dimer and C_2H_2 are mutually perpendicular (Fig. 10*a*), the bridged configuration 11*d* may be formed. On incidence of C_2H_2 between neighbouring rows of dimers (Fig. 10*b*), bridging configurations were not observed. Only physical sorption was noted and the axis of the C_2H_2 molecule was arranged almost parallel to the surface of silicon. In the case of the migration of C_2H_2 onto the row of dimers, the configurations already considered in Figs. (11*a*) and (11*b*) were formed. The dependence of the outcome of the incidence on the orientation of the molecular axis of C_2H_2 relative to the axes of the dimers was no less marked. For a nonparallel arrangement, the ethyne molecules were reflected.

The criticisms expressed in the previous subsection retain their force in this case too. Indeed, the authors themselves[103] present a plot analogous to that shown in Fig. 1. The physical and chemical sorptions are described by different potential curves (curves *2* and *1*) corresponding to different electronic states. In fact, the calculations[103] are performed for curve *3*, joining both local minima. Thus the dynamics of the transition from physical to chemical sorption within the framework of the above approach[103] is described with the aid of Newton's equations for a single potential surface. However, in actual fact this transition is electronic and should be described by the nonstationary Schrödinger equation. We may note that it is seen from Fig. (11) that a whole series of chemisorption states are possible, i.e. there should be several type *2* curves in Fig. 1 in this case.

However, these questions were not even mentioned in the above study.[103] Thus the time characteristics obtained[103] may not correspond to reality. On the other hand, the equilibrium characteristics of the final state do not give rise to such doubts — the formulation of the problem of their determination is correct and the error may be due only to the approximate nature of the computational procedure or $\Phi(R)$.

VII. Nonadiabatic quantum molecular modelling

Sections II – VI led to a paradoxical conclusion: both the classical and quantum MMD may prove to be inadequate precisely in those applications for which they have been in fact generally speaking designed — for the calculation of the dynamics of the transitions between different states. Such calculations require the solution of the nonstationary Schrödinger equation. The numerical methods for the integration of this equation have been the object of intense investigation (see, for example, Refs 5 and 104 – 110 as well as the references contained therein). By themselves, these methods have no bearing on the MMD, which is based on the calculation of trajectories, although they can be combined with it in order to solve quantum problems, as will be shown below.

Molecular dynamics with electronic transitions. A series of studies associated with Tully's name have been devoted to this question.[5,104–106] We shall explain the idea of the method by means of a schematic example (Fig. 12). Suppose that a particle is reflected during adiabatic motion along trajectory *1*. If the particle causes the excitation of the surface of a solid, it loses part of the energy, a nonadiabatic electronic transition takes place, and the particle trajectory (curves *2*) changes, in particular sticking may occur.

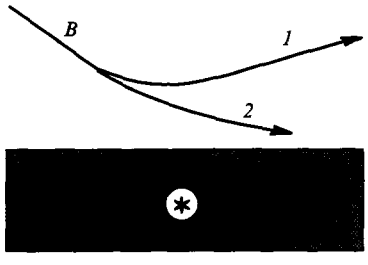

Figure 12. Scheme explaining the splitting of the trajectory in electronic transitions. The star denotes the excitation of the surface.

It is clear from the foregoing that the branching of the trajectories is a distinctive feature of MD with electronic transitions, which has already been discussed in Section III (the potential picture in Fig. 1*b* corresponds to Fig. 12). No jumps in space occur under these conditions, the concept of the trajectory is retained, and the latter remains smooth, but at point *B* the trajectory no longer satisfies Newton's equation. Since the electronic transition has a probability, it is necessary to generate a family of trajectories with the same initial conditions. The frequency of the appearance of points *B* and their spatial distribution are then modelled.

In the general case, the problem involves the nonstationary Schrödinger equation for a quantum particle or a subsystem of particles, the transitions between different adiabatic potential surfaces, and Newton's equations for heavy particles. The Schrödinger equation can be approximately reduced to ordinary differential equations for the expansion coefficients of the wave function in terms of stationary states, the coefficients being time-dependent in the given instances. Newton's equation includes the response of heavy particles to electronic transitions in the quantum subsystem.

In view of the complexity of this problem, solutions have so far been found only for certain special cases. Thus one-dimensional two-level methodological examples have been considered.[5] In other studies,[104,105] a series of results have been obtained for the solvated electron. The study of Webster et al.[106] was devoted to further development of the method and to a methodological two-level example.

In order to illustrate the role of nonadiabatic effects, Dodson[4] carried out the MD modelling of the incidence of silicon atoms onto a silicon support for a single energy (12.5 eV) and two interaction potentials of the incoming atom with the surface atoms: a type SW potential described the adiabatic case and the Ziegler – Biersack – Littmark potential described the case of the complete rupture of Si – Si bonds. The results proved to be very different: thus the depth of penetration of the Si atoms into the surface layer was 2.8 Å in the first case and 10.5 Å in the second.

Tunnelling. It has been noted[5] that this process can be investigated separately from electronic transitions, since the probability of the latter decreases, according to Massey's criterion, with increase in the velocity and is independent of the mass of the particles, whereas the role of tunnelling increases with decrease in velocity and in mass. The object of study was the dissociation of hydrogen molecules on a surface.

The dissociation of H_2 on copper has been considered.[107] In view of inadequate computer capacity, the quantum calculations were restricted to the case of a two-dimensional potential surface. Although the influence of quantum effects on the sticking coefficient was in fact noted, a satisfactory agreement with experiment was attained only on passing to a six-dimensional description of the potential surface within the framework of quasi-classical molecular dynamics.

The grid method was used for the numerical integration of the time dependent Schrödinger equation.[107] In this case, the computation time is proportional to N_g^D, where N_g is the number of points in the grid and D is the dimensionality (the number of degrees of freedom). The nonstationary problem has been solved[108] with the aid of the multiconfiguration Hartree approximation with a natural choice of one-particle states. The computation time proved to be proportional to $N_g^{D/2}$. However, only a two-dimensional model of the dissociation of H_2 on the surface of a generalised transition metal was considered as an example.

An approximate approach, which made it possible to model the dissociation of the hydrogen molecule when it is incident on the Cu(110) surface, has been proposed.[109] The interaction surface of the $H_2 - Cu(110)$ system was six-dimensional. It was found by using the inserted atom method and for H_2 it was brought into correspondence with the LEPS surface. The probability of sticking (α) and the free energy activation barrier (ΔF) were found in terms of the approximation of the quantum theory of the transition state (TTS):

$$\alpha = \exp(-\beta \Delta F) , \tag{16}$$

$$\Delta F = -\int_s f \mathrm{d}s , \tag{17}$$

where s is the trajectory of the hydrogen molecule and f the average force acting on this molecule taking into account the quantum dispersion. The principal TTS approximations are as follows: (1) the inequality $\alpha \ll 1$ must hold for Eqn (17) to be valid; (2) in the phase space of the $H_2 - Cu(110)$ interaction there must be a narrow place which would make it possible to determine clearly the hypersurface separating the region of the initial state (the H_2 molecule) from the region of the reaction product (the H + H atoms); (3) (the main approximation) when the trajectory s of the H_2 molecule intersects the separating hypersurface, determined on the basis of the preceding assumption, the dissociation of H_2 is assumed to have occurred. Thus the integration in Eqn (17) is carried out from the distance where the $H_2 - Cu$ interaction can be neglected up to the intersection by the separating hypersurface.

For the calculation of ΔF by Eqn (17), the following approximate procedure has been proposed.[109] The minimum energy path which smoothly and continuously transfers the system from the initial to the final state is found. This is carried

out by a novel method, developed by Mills and Jonsson,[109] whereby the trajectory s is obtained. Five-dimensional hypersurfaces perpendicular to s are determined in succession along this trajectory. For each surface, the average force f acting on the H_2 molecule located on this hypersurface is found. The calculations are repeated until the hypersurface with $f = 0$ is reached. After this, the integral (17) and then α are found.

All the quantum effects are contained in the force f. In order to determine the latter, the formal treatment involving integrals along the trajectories, already mentioned earlier in connection with molecular modelling, is resorted to.[12,111] The representation of the partition function, proposed by Feynman, in the form of a Wiener integral along the 'trajectories'¶ is employed. Its finite-dimensional approximate representation has the same form as the classical partition function for a cyclic system of linked identical harmonic oscillators with an elastic constant determined by the mass of the particle, temperature, the constant $\hbar$, and the number of subdivisions of the cyclic 'trajectory'.¶ The 'trajectory' characterises the quantum dispersion of the H atom and is specific to each H atom.

Thus, in order to find the quantum dispersion and the average value of f, one may carry out the classical MD modelling of the motion of a cyclic chain of linked oscillators for each atom. The centre of gravity of both chains is then retained by force on the chosen hypersurface. The classical limit of the modelling corresponds to the contraction of the chains into a point on the trajectory s. In addition to hydrogen atoms, such modelling has been carried out for the eight copper atoms closest to the H_2 molecule. The chains consisted of 50 units.

The results of the calculations showed that the quantum effects begin to exert an influence at a temperature below 600 K, where the delocalisation of the hydrogen atoms is manifested, leading to a decrease in the effective activation energy $E_a = \partial(\beta\Delta F)/\partial\beta$ from 0.70 to 0.45 eV. However, the absolute value of $\beta\Delta F$ proved to be somewhat too high. This yielded an unduly low sticking coefficient ($\alpha = 1 \times 10^{-7}$) compared with the measured value ($\alpha = 4 \times 10^{-6}$) at 600 K. The authors[109] attributed the difference to the inaccurate choice of the H_2–Cu model potential surface.

Calculations with frozen vibrational and rotational degrees of freedom showed that the excitation of these degrees of freedom does not play a notable role. The principal quantum effect is delocalisation; the authors[109] attribute the 30% decrease in the energy of activation in the quantum region to tunnelling by the hydrogen atoms.

New numerical approaches to the solution of the nonstationary Schrödinger equation have been considered by Pollard and Friessner.[110]

Trajectory approaches. It is seen from the preceding sections that new molecular modelling methods are continuously being sought for nonstationary quantum problems. Frequently these methods are supplemented by the MMD.

At the same time attempts have been made to devise methods for the numerical solution of the time quantum problem, which are related to the classical MD and are based on the trajectory interpretation of quantum mechanics. The approach, proposed by Podlipchuk[112,113] in studies where a stochastic ordinary differential equation in a complex space was obtained instead of the nonstationary Schrödinger equation for the description of the quantum assembly, is promising. Here it is in fact numerically much simpler to carry out the nonstationary process than to seek stationary states.

A new variant of quantum molecular modelling of time quantum processes, in which the Wigner formulation of quantum mechanics is employed, has been proposed.[114] A combination of the classical MMD and the Monte Carlo method, analogous to the Monte Carlo method developed in statistical dynamics, was used for the solution of the Wigner–Liouville equation.[12] Systematic calculations were performed for the motion of the electron in a one-, two-, and three-dimensional potential well with and without a barrier. The time dependences of the quantum-mechanical average values of the coordinate and momentum, their dispersions, and energy were calculated. Test calculations for a low-energy particle on the bottom of the well yielded results in good agreement with the analytical solution in terms of the harmonic approximation. The rate of tunnelling through the barrier was found by calculating the trace of the operator of the autocorrelation function of the momentum.

VIII. Transition from dynamic to probability modelling

The dynamic methods examined in the previous section proved to be a powerful and flexible instrument for the investigation of a wide variety of elementary processes on the surface. However, a number of difficulties arise in the application of these methods to chemical modification problems. The most evident are the limitations as regards the speed and memory of the computers.

Material limitations of the dynamic methods. The technologically important scales of the surface modification processes are $\tau \sim 1$ μs in time and $l \sim 1-10$ μm in length. Modern computers permit classical MD modelling for times $\tau < 1$ ns and in terms of the length scale $l < 100$ Å. For quantum dynamic modelling, these quantities are even smaller. The limiting possibilities of the existing computers are then employed. Clearly the possibilities of modelling lag by orders of magnitude behind the requirements.

We may note that the current attempts to model, for example, the deposition process employ unrealistically short time intervals between the steps involving the incidence of particles on the surface.[4] On the one hand, this makes the rate of growth of the surface be of the order of magnitude of the speed of sound. On the other hand, the shortening of the time interval between elementary steps distorts the state of the surface which participates in the next elementary step.

Optimists may assume that these are temporary difficulties at the present stage of the development of the computer techniques. Whatever is the truth, there nevertheless are serious limitations which make the task of expanding the scale of the purely dynamic modelling of the chemical modification of surfaces pointless.

Fundamental limitations of the dynamic methods. Chemical reactions with electronic transitions play an important if not the principal role in the chemical modification of the surface. As shown in the previous sections, such processes cannot be modelled with the aid of the classical and adiabatic quantum MD.

Quantum-mechanical approaches based on the solution of the nonstationary Schrödinger equation have been developing for the study of such problems (electronic transitions, tunnelling, etc. — see Sections VI and VII). These methods impose even more severe requirements on the computer resources, particularly in the study of surfaces.† However, this is not the most important factor. The main feature is the appearance of a new qualitative element in such modelling. In the course of the computation, it becomes necessary in fact to make a choice between mutually exclusive possibilities ("splitting" of the trajectory). In the case of a surface, these are, for example, variants of the behaviour of the

¶ The 'trajectory' lies on the five-dimensional surface already discussed above and should not be confused with the trajectory s. For this reason, we place it in quotation marks.

† Apart from the microscopic quantum interactions involving several particles, 'macroscopic' interactions, not localised in space, are significant in this case. The reconstruction of a large section of the surface induced by the incidence and adsorption of a single atom may serve as an example.

particle (adsorbed atom) after its physical adsorption. The adsorbed atom can change its location whilst remaining a physically adsorbed particle, chemical bonds may be formed between the adsorbed atom and the surface atoms, which is accompanied by electronic transitions, and, finally, there is a possibility of quantum diffusion, thermal desorption, etc.

Thus in molecular modelling which uses the nonstationary Schrödinger equation, the extent to which the process is determined is inevitably weakened because at the branching points the choice of the variant is probabilistic in character. This is not associated with the numerical schemes for the solution but is due to the physical significance of the quantum mechanics itself. Indeed, the determination of the state of a quantum system makes it necessary to make a measurement (reduction of the wave packet), i.e. to pass from the probability amplitude (wave function) to the probability density (square of the modulus of the wave function). In a series of measurements, the results will be distributed in accordance with this probability. Such a series of 'measurements' is in fact performed in quantum modelling.

We may note that the classical MMD is also not in fact purely dynamic.[7-9] As a consequence of the instability of the equations of motion for a system of many particles and the errors in the numerical integration, which play the role of perturbations, the MMD trajectory deviates exponentially from the Newtonian trajectory for the same initial conditions, remaining close to the latter only for relatively short times. For long computational times, the MD trajectory moves under these conditions from one set of sections of the Newtonian trajectory to others, which are 'dynamically remote'. These transitions are probabilistic in character because many-particle systems are of the mixing type.

In nature, the phase trajectories of molecular systems, which can be regarded as classical, are also continually perturbed (for example, because any such system is open). For this reason, the motion of such systems is also stochastic in character.[10,11]

It is clear from the foregoing that the need to resort to probability methods in molecular modelling is predetermined by the very physics of the problem. On the other hand, the attempts to remain within the framework of 'pure' dynamics particularly in calculations for large time scales, are not simply unproductive but are in essence pointless.

Probability methods. Since probability modelling is inevitable in the key stages of the solution of the problem, it is useful to exclude altogether from consideration the long sections of the dynamic phase trajectories without an information content. This is possible when the time intervals between successive incidences of the particles on the surface are much longer than the time required for the transition of the system to a new stationary state (the overall time of the chemical reactions, reconstruction, dissipation of excess kinetic energy, etc.). The dynamic methods are retained for the calculation of the probabilities of elementary processes (sticking, chemical reactions, reconstruction shifts, etc.). Knowing the possible states of the system as well as the probabilities of the transitions between them, the kinetic calculations for these transitions can be performed by the Monte Carlo method.

Such an approach makes it possible, in principle, to shorten the computation time by several orders of magnitude, firstly by accelerating the 'selection' of the elementary steps and, secondly, as a result of the fact that the required probabilities should be ideally determined 'once and for all'. However, the multiplicity of the individual surface geometries (steps, groups of adsorbed atoms, vacancies, etc.) is extremely large. It is virtually impossible to guess all the states of the system during its evolution and to calculate beforehand the probabilities of the transitions for these states. It is therefore necessary to have in addition a simple and at the same time an acceptably accurate method for the determination of the electronic structures of the current states of the system and hence the transition probabilities. The method must be applicable in the probability modelling process itself. The principles governing the development of this method on the basis of quantum-chemical ideas are described in the preceding sections.

The loss of information about the dynamics of certain transitions is insignificant for the description of the evolution of the chemical modification of the surface, provided that the rate of modification is determined by the rate of arrival of the reagent on the surface. The knowledge of the times of individual transitions is important in order to be able to discover in which cases this is really so.

Thus it is possible to devise an algorithmic scheme modelling the real shape formation for fairly large crystal specimens. This algorithm must contain the following elements: (1) fragments of the dynamic description; (2) the determination of the stationary states and the probabilities of the transitions between them; (3) the modelling of the probability processes for these transitions (the Monte Carlo method). This modelling procedure constitutes a combination of the MD, quantum-chemical, and Monte Carlo methods.

The dynamic and probability methods were previously compared in attempts to discover which of them is more effective.[4] In fact, they are complementary and their joint employment intensifies the strong aspects and eliminates certain weak aspects of each method.

IX. The simplest probability models. Cellular automata

1. Discrete modelling. Morphology of the surface

The crystal is specified within the framework of the lattice model, a proportion of the crystal lattice sites located on the boundaries of the crystal being assumed vacant. In the simplest models, the crystal lattices are considered in an extremely simplified form (frequently with a smaller dimensionality).

The set of the possible outcomes of the elementary process is determined. The location of the elementary step on the surface is selected at random. The process reaches its conclusion at this point, with the aid of a priori specified probabilities, the crystal is then prepared for the next step, etc. Whatever its form, this procedure is applied in all the simplest models of the chemical modification of the crystal surface considered in this section. Sometimes a model procedure of this type is referred to as cellular (lattice) automata.[115,116]

This aspect may be called morphological because the study of the modification is limited to the 'geometrical' modelling of the morphology and only phenomenological ideas concerning the process on the surface are used. However, the principal concepts and ideas — the language in which one may speak of the form of the surface of the crystal — were formulated in this connection.

Among the studies concerned with this aspect, we may name the simplest models of random deposition.[117-119] The surface is characterised by concepts such as 'coarseness' (roughness, thickness). It has been found that the dispersion of the height of the surface formed (a measure of its roughness) is proportional to the square root of the height of the deposited layer.

The ballistic deposition models,[120-122] describing the appearance of projections, holes, and shadows, may be mentioned as more complex ones. A power dependence of the thickness of the surface not only on the height of the deposited layer but also on the linear dimensions of the support appears. The statistical modelling of various formations with dimensionalities equal to unity or 2 — strings, terraces, etc. — becomes possible.[121-123]

The development of discrete models is virtually completed by the studies described in Refs 124-126 — the transition to the consideration of specific chemical properties begins with the appearance of new information about the surface. The study[127] in which the kinetics of the growth were modelled on the basis of the local properties of the surface being modified is typical. Such properties, in particular the differences between the energies of the surface and bulk-phase atoms, have been calculated[128] in the

form of the stress tensor. Further development should follow the path involving the modelling of chemical bonds.

The simplest models make it possible to represent the way in which the form of the crystal changes and to specify which characteristics describe it sufficiently completely and at the same time are susceptible to investigation. However, the possibilities of such modelling are extremely limited. Firstly, no account is taken of the dependence of the probabilities of the elementary processes at any point on its local environment. Secondly, the set of elementary processes specified a priori does not exhaust the true diversity of the real processes.

2. Continuous modelling

In this approach, the form of the surface is considered as a continuous function $H(r, t)$ of the spatial coordinates and time. The processes involved in the establishment of equilibrium have proved extremely important. There are two limiting cases. In the thermodynamic limit, the surface modification process is infinitely slow so that there is sufficient time for the attainment of thermodynamic equilibrium after each modification step. In this limit, $H(r, t)$ represents either a flat surface or a system of projections and hollows along thermodynamically stable crystallographic faces. The other limit is kinetic. In this case, the modifying particles land so frequently that there is insufficient time for the occurrence of the material transfer processes along the surface between successive collisions.

The real process is always of an intermediate type, i.e. the rate of landing of the modifying particles is finite and the tendency of the form of the surface to attain the thermodynamic equilibrium form is distorted by kinetic processes.

The equation of the surface $H(r, t)$ assumes the following simplest form:

$$\frac{\partial H(r,t)}{\partial t} = \eta(r,t) + \hat{A}\{H(r,t)\}, \tag{18}$$

where $\eta(r, t)$ is a random source describing the variation of the roughness of the surface during the deposition process or during etching as a result of the discreteness of the elementary steps. The operator $\hat{A}$ describes the influence of the smoothing or other shape-forming factors of the type of three-dimensional or surface diffusion. The competition between the processes involving the formation of the locally rough surface and the formation of a gentler relief is the main cause of the diversity of the forms of surfaces.[129-130]

On the most general hypotheses concerning the type of the second term of Eqn (18), one may investigate the degree of roughness of the surface being modified by determining $w_L^2(t) = \overline{(H - \bar{H})^2}$. This quantity exhibits different scaling behaviour depending on the lengths L with respect to which averaging is carried out.[130-132] For small values of L, this quantity is almost independent of time and is determined solely by the value of L, while for large L it ceases to depend on the averaging length and depends solely on the observation time:

$$w_L(t) \sim \begin{cases} L^{\alpha}, & L \ll L_c \\ t^{\beta}, & L \gg L_c \end{cases} \tag{19}$$

The boundary L_c between the regimes depends on time: $L_c \sim t^{\beta/\alpha}$.[130] In the thermodynamic and kinetic limits, the exponent α should become zero (the quantity w_L in the limiting cases should be independent of the averaging length). On attainment of thermodynamic equilibrium, the exponent β should also become zero (the causes giving rise to a time dependence are absent in this case). In the kinetic limit, the function $\bar{H}(t)$ should obey the standard Poisson distribution and hence $\beta = \frac{1}{2}$.

One may expect that, for specific models of the surface modification, the exponent α varies nonmonotonically on transition from the thermodynamic to the kinetic case and reaches a nonnegative maximum at some point. On the other hand, the quantity β apparently varies monotonically — in the kinetic limit the time variation is a maximum, so that the real value of β is in the range $0 < \beta < \frac{1}{2}$.

The constants α and β may be determined for different continuous models with a different specific form of the operator $\hat{A}$. They can be obtained also in computer modelling for different discrete models and in experiments on the deposition and etching of crystal surfaces. The scaling exponents yield information about the extent to which the real modification regimes are close to the thermodynamic or kinetic limit. They make it possible to compare the continuous and discrete models of the modification of the surface and also to discover how well particular models describe the real experiments on deposition and etching.

X. Quantum description of the chemical bond on the surface

Elementary ideas. We may recall the simplest chemical system — two hydrogen-like atoms. In terms of the basis set of atomic wave functions, the diagonal elements of the Hamiltonian coincide with the energies of the electronic states in the individual atoms E_1 and E_2, while the nondiagonal elements represent the amplitude of the probability of the transition of the electron from one atom to another (v). The stationary states of a two-atom system are found to be the bonding and antibonding states with the energies

$$E_{a,b} = \varepsilon \pm (\delta^2 + v^2)^{1/2}, \qquad \varepsilon = \frac{E_1 + E_2}{2}, \qquad \delta = \frac{E_1 - E_2}{2}. \tag{20}$$

For the ground states of identical atoms, $E_1 = E_2$ and $E_{a,b} = \varepsilon \pm v$.

When the chemical interaction of a solid with an atom (molecule) is considered, the state of the atom (molecule) remains as one of the electronic states in Eqn (20), while the set of the electronic states of the solid is chosen as the other. The highest occupied electronic states (the states near the Fermi level) play the main role. Eqn (20) reflects the simplified situation where each chemical reactant has one electronic state ready for coupling. In the general case, there are several (valence) states of this kind and Eqn (20) is accordingly also generalised‡.

The atoms which can modify the surface come into contact only with the surface of the crystal, so that the surface electronic states and not the bulk-phase states should be considered as the electronic states in Eqn (20).

The surface of the crystal is reconstructed, i.e. acquires a lower symmetry compared with the case when the atoms on the surface remain at lattice sites. The spontaneous decrease in the symmetry of the crystal surface is a transition of the Jahn–Teller type, in which the coordinates of the surface atoms and the positions of the surface electronic states change. The energies of the occupied and unoccupied surface states as a rule move apart under these conditions.

Examples involving the consideration of chemical bonds. Tomasek et al.[128] deduced the surface states of adsorbed atoms in a very simple way — from the number of ruptured bonds, i.e. without taking into account reconstruction. They suggest that the differences between the interactions of the surface atoms and the atoms in the bulk phase be described phenomenologically with the aid of the stresses tensor. Chadi[133] surveyed the electronic and atomic structures of semiconductor surfaces with low indices — [100], [111], and [110]. The conclusion that the recon-struction of the covalent surfaces is induced mainly by the tendency towards an increase in the bond orders of the surface atoms agrees well with the possibility of describing the

‡ Henceforth, in referring to Eqn (20) this generalised form will be understood.

differences between the surface and bulk phase with the aid of the stress tensor.[128]

Significantly more detailed methods for the description of chemisorption on semiconductor surfaces have also been adopted.[134,135] The molecular orbital method made it possible to calculate the positions of the oxygen atom on the surface of silicon. A quantitative agreement has been achieved between the calculated and experimental vibration frequencies of the oxygen atoms.[134] Zheng and Cao[135] described three stages in the oxidation of silicon: the chemisorption of oxygen molecules, the dissociation of molecular oxygen, and the diffusion of atomic oxygen from the bridging adsorption layer into the bulk of the crystal with formation of an SiO_2 film. However, progress in the understanding of the process has been achieved at the expense of the loss of flexibility and universality of the description. The three-step representation of the chemical reaction hinders the inclusion of this stage of the computation in the algorithm for the modelling of the chemical modification of the cellular automaton type. Indeed, each of the stages of the process requires the processing of a large amount of information and depends significantly on the composition and state of the vicinity of the section being modified.

The energies of the surface states have been calculated[136] for the reconstructed Si(111)-(2 × 1) surface. The dependences of the energies on the magnitude of the reconstruction shifts were obtained. The study of Yamaduchi and Fujima[137] may serve as an example of the calculation of the surface states localised on a step. Their structure is related to the configuration of the atoms on the edge of the step, which consists of a zig-zag chain of dimers.

This approach proved productive in the study of the interaction of ion beams with the surface of a solid,[139-141] where it was assumed that the structure of the electronic states corresponds to the bulk-phase state. The scattering singularities are manifested in cases where the energies of the electronic states of the incoming ion and the crystal are identical. Electron exchange is of the resonance type. Even if chemical reactions do not occur under these conditions, the scattering singularities constitute high-energy echoes of such reactions.

We may note that the scheme of the bulk-phase electronic states of the crystals employed in the studies of Balidchik and coworkers[139-141] is appropriate only when interactions with high-energy particles (hundreds of eV) are considered. In this case, the interaction energy is so high that the details of the electronic structure of the crystal are unimportant — the position of the Fermi level is the most significant feature. For lower energies, the singularities will arise when the levels of the atomic particle coincide with the unoccupied and occupied surface states closest to the Fermi level. When a sufficiently selective diagnostic procedure is available which permitts the resolution of these singularities, their analysis might prove a promising instrument for the study of the electronic states of a reconstructed surface.

The approach to the description of the chemical properties of solids based on the consideration of surface states, reconstruction, etc. has been used in qualitative studies.[138] Unanimity has been achieved in the understanding of many chemical processes on the surfaces of solids.

The studies under discussion§ have led to progress in the description of individual chemical bonds in the bulk phase and on the surface of a solid, but they cannot serve as a basis for universal modelling. For such modelling, it is necessary to find a standard approach to the calculation of the energies of the surface states and the matrix elements in Eqn (20).[142,143]

XI. The method based on the generalised periodic system of the elements

1. Massive crystals

A method was proposed by Harrison[14] in a general form for definite groups of elements in the Periodic System. For this reason, the method (or more precisely the set of parameters used in it) is referred to as the generalised Periodic System of the elements (GPSE). For elements forming covalent tetrahedral crystals, such parameters are the lattice constant d, the energies ε_s and ε_p of the s and p electrons in the ground configuration of the atom, and the Fermi momentum k_F. The radius r_c of the non-coulombic component of the interaction is also used for the construction of the pseudo-potential describing the interaction of the valence electrons with the core electrons.

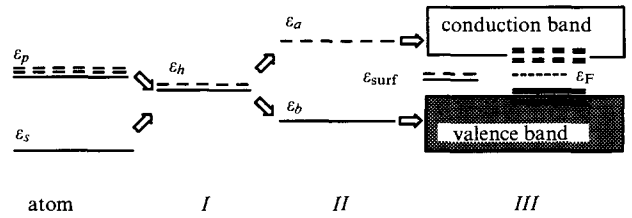

Figure 13. Stages in the construction of the electronic states of a silicon crystal with the aid of the GPSE. Continuous lines — occupied states; dashed lines — unoccupied states. The surface states ε_{surf} are indicated in order to explain Fig. 14.

Fig. 13 explains the essential features of the method. To make the treatment specific, the values of the parameters of the electronic states correspond to silicon. In the first stage, the s and p valence states are hybridised, i.e. a transition to new orthonormalised functions is carried out. They are not eigenfunctions of the Hamiltonian but they do have a symmetry convenient for the description of diamond-like crystals. These states have the same average energy

$$\varepsilon_h = \frac{\varepsilon_s + 3\varepsilon_p}{4}.$$

In the second approximation, account is taken of the overlap of the sp^3-hybridised orbitals in the direction of nearest neighbours only (these are in fact the ones participating in the formation of the chemical bond). The GPSE method involves convenient universal formulae for the overlap integrals. For example, the following expression is used for the overlap integral V_c^h (the energy of the covalent bond involving hybridised orbitals):[14]

$$V_c^h = \frac{-V_{ss\sigma} + 2\sqrt{3}V_{sp\sigma} + 3V_{pp\sigma}}{4},$$

where the subscripts $ij\alpha$ define the atomic (Roman letters) and molecular (Greek letters) quantum numbers. The dependence of the overlap integrals on the distance d is given by the estimate

$$V_{ij\alpha} \approx \eta_{ij\alpha}\frac{\hbar^2}{md^2}, \qquad (21)$$

where m is the mass of the particle. The coefficients $\eta_{ij\alpha}$, where $i, j = s, p, d$ and $\alpha = \sigma, \pi$, have been published.[14] We obtain for the energy of the bonding and antibonding orbitals

$$\varepsilon_{a,b} = \varepsilon^h \pm V_c^h. \qquad (22)$$

For covalent crystals formed by different atoms, for example GaAs or ZnS, a second interatomic matrix element V_i^h (the energy of the ionic bond involving hybridised orbitals) is introduced. It is defined as half the difference between the energies of the hybridised states of different atoms:

$$V_i^h = \frac{\varepsilon_h^A - \varepsilon_h^B}{2}.$$

The energies of the bonding and antibonding states are given by the expression

$$\varepsilon_{a,b} = \frac{\varepsilon_h^A - \varepsilon_h^B}{2} \pm \alpha(d, \varepsilon_s, \varepsilon_p) \ , \qquad (23)$$

where

$$\alpha(d, \varepsilon_s, \varepsilon_p) = [(V_c^h)^2 + (V_i^h)^2]^{1/2}.$$

In the third approximation (Fig. 13), account is taken of the overlap of the orbitals obtained in the direction of the translational vectors.[14] This makes it possible to find the splitting of these levels into valence and conduction bands, to determine the structure of the subbands, and to obtain the dependence of the energies on the quasimomenta k.

The fourth approximation is not fully unambiguous. In the most successful version, the main correction is the matrix element describing the interaction of the valence electrons with the core electrons. For simple metals, such a correction is given by a pseudo-potential, which is regarded as a perturbation. In the case of covalent crystals, the interaction of the valence electrons with the core electrons cannot be regarded as small. Here the wave functions are determined by the maximum Fourier component of such a pseudo-potential with the wave vector along the [111] direction. The additional dependence on k_F and r_c appears only in the fourth approximation.

Somewhat different sets of parameters and other procedures for the construction of the electronic states and for the description of chemical properties have been proposed for other groups of elements — the halogens, simple metals, and metals with an unfilled d or f shell.[14] Thus the GPSE makes it possible to isolate the common features in the description of different groups of substances and to formulate for each of them a procedure analogous to that described above for covalent crystals. Many computational procedures for different groups of elements proved to be similar — LCAO for the construction of valence bands, the approximation of almost free electrons for conduction bands, and the description of the interaction of valence electrons with core electrons with the aid of a pseudo-potential.

2. The surface

a. Surface electronic states

Fig. 14 illustrates the region corresponding to the forbidden band gap *III* in Fig. 13. The surface energy levels are formed in this region. The initial idea concerning the surface state may be the concept of a broken bond arising when some of the atoms are removed from the crystal; the wave functions adopted are those of the sp^3-hybridised state. Neglecting the amplitude of the translational transitions, the energy of such a state may be regarded as identical with ε_h (Fig. 14*a*). Further consideration (allowance for the amplitudes leading to the appearance of bands at the level of the third or fourth approximation) leads to different results depending on the geometry of the interface.

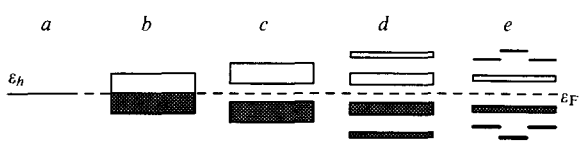

Figure 14. The energy diagrams for surface states: (*a*) crystals with ruptured bonds; (*b*) flat smooth surface; (*c*) reconstructed surface; (*d*) reconstructed surface with regular structures; (*e*) surface with an arbitrary geometry. The occupied bands are shown shaded.

Ideally flat surface. The positions of the atoms in the surface layers coincide with the positions of the crystal lattice sites of the bulk phase crystal and the Miller indices for the surface do not exceed unity. The amplitudes of the transition in the direction of two minimal translational surface vectors can be determined with the aid of the standard GPSE procedure.[14] The solution of the problem of the eigenvalues leads to the appearance of a half-filled band of surface states (14*b*). The energy of these states $\mathscr{E}_0(\mathscr{K})$ depends on the two-dimensional quasi-momentum $\mathscr{K}$, which ranges over the values in the Brillouin surface band determined by the symmetry of the interface.

Reconstruction. Linear structures. The set of reconstruction and relaxation shifts is described by the vector $\vec{\Delta}$. In the simplest case, where the reconstructed surface has two-dimensional translational symmetry, the dimensionality of $\vec{\Delta}$ is $3 \times m$, where n is the number of atoms in the surface unit cell for the nonreconstructed surface and m is the number of nonreconstructed cells in the reconstructed surface (we restrict the treatment to the approximation where the displacement of surface atoms may be regarded as sufficient for the description of the reconstruction). For example, for the 2×1 reconstruction the number of cells $m = 2$, whilst for the 2×4 reconstruction the corresponding number is $m = 8$.

As a result of the reconstruction, the bands of surface states are changed. As a rule, an unoccupied band tends to be 'repelled' from an occupied one (Fig. 14*c*) and their positions on the energy scale are altered (sometimes they move outside the limits of the forbidden band gap). Even greater changes are observed as a function of the energy of the quasi-momentum $\mathscr{E}_{\Delta,i}(\mathscr{K})$ in different bands (the subscript i indicates that the surface states belong to a particular band). As a rule, the region where this function is defined diminishes on reconstruction (for example, the Brillouin surface band decreases by a factor of 2 for the 2×1 reconstruction); there is a corresponding increase in the number of bands of surface states (Fig. 14*d*).

Under certain conditions, structures possessing only linear translational symmetry arise on the interface. the simplest examples may be the bands of the reconstruction dimers, the symmetry of which is disturbed in the direction perpendicular to the band or the polyatomic steps arising on the interface when the latter is a plane perpendicular to one of the crystallographic axes and is inclined at a low angle relative to the integral crystallographic plane. In this case, additional bands of surface states arise, for which the range of values of the quasi-momentum degenerates to a one-dimensional segment.

For the construction of a system of linear equations defining the energies of the surface states, the overlap integrals, found with the aid of the GPSE, are sufficient.

A surface with a complex shape. When partial symmetry is retained (reconstruction with a large cell, repeating corners, steps, etc.), the number of components of the vector $\vec{\Delta}$ and the range of values of i increase. The nature of the band structure remains the same as in Fig. 14*d* and the only difference is that new bands of surface states arise and hence the region where the functions $\mathscr{E}_{\Delta,i}(\mathscr{K})$ are defined becomes depleted (for certain values of i, the range of values of $\mathscr{K}$ may degenerate to a segment).

Further specification of the shape of the surface in an individual form leads to loss of symmetry. Together with bands of surface states, individual states appear (Fig. 14*e*), in which the range of values of $\mathscr{K}$ is zero-dimensional. These surface states are

localised in one or several cells; they are formed as a rule on individual (nonrepeating) pits, irregular hillocks, or even atoms. The decrease in symmetry is accompanied by an increase in the dimensionality of the vector $\vec{\Delta}$. When the surface has fully lost the two-dimensional translational symmetry, the dimensionality of $\vec{\Delta}$ is equal to three times the number of surface atoms.

In order to determine the electronic spectrum and the electronic surface states, it is necessary to solve a system comprising a larger number of equations than in solid state problems having three- or two-dimensional translational symmetry. The lack of symmetry in a surface with an individual shape makes it necessary to calculate a set of different overlap integrals and to solve systems of equations of an enormous dimensionality—this is in fact the main difficulty. In reality, only the GPSE in the form of Eqn (21) permits numerous valid solutions of this problem for a wide variety of configurations.[142,143] In addition, it is necessary to investigate the dependence of the reconstruction shifts on the nature of the assumptions made.

b. The model of the chemical modification of the surface

Fig. 15 illustrates schematically a block-diagram for the modelling of the chemical modification of the surface.[97,143]

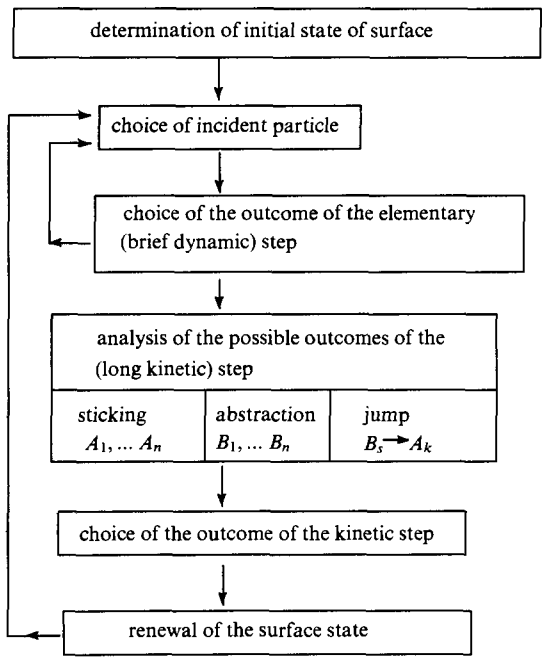

Figure 15. Block diagram of the modelling algorithm.

1. Initial state of the surface. The geometry of the near-surface atoms is specified by a three-dimensional Boolean matrix. Each lattice site is characterised by the numerals 1 or 0 depending on whether the site is occupied by an atom or not. The reconstruction and relaxation shifts of the atoms (the vector $\vec{\Delta}$) are calculated or those known beforehand are employed. The atoms are assumed to be stationary and their positions are averaged with respect to thermal motion. The spectrum and wave functions of the electronic surface states are calculated.

2. The choice of the incident particle. The number of the projection of the unit cell entered by the particle is selected. If the stream of particles has a nonuniform composition, then the kind of incident particle is selected.

3. The outcome of the elementary dynamic step. With the aid of the probabilities of elementary processes selected beforehand and averaged in one way or another, the specific outcome of a dynamic event is determined: sticking, dissociative sticking, etc. In the case of reflection the calculation has to be restarted again from block 2.

4. Analysis of the possible outcomes of the kinetic process. The sticking particle does not immediately occupy a stationary state. This process is fairly prolonged and its result (at least at nonzero temperatures) may not be unambiguous. The particle passes from one metastable state to another (if the activation energy is comparable to the temperature) in the search for the most stable state. We shall regard this process as kinetic and shall describe it statistically.

In the case of the deposition of particles, for example those of silicon, on the surface of a silicon crystal, all the vacancies A_i which the given adsorbed atom can fill are considered. The bond energy is calculated for each of them. This is done with the aid of the standard expression (20) for the surface + adsorbed atom system, the spectrum and wave functions of the surface states determined in the first stage of the algorithm being used for the surface, while the nondiagonal elements are adopted in the form of overlap integrals, which are estimated in accordance with the general GPSE rules.

In the vicinity of the incidence of the modifying particle, the possibility of the extraction of each surface atom B_i is considered in succession. The energies of such extraction are calculated (the procedure is in a certain sense the opposite of that mentioned above for the calculation of the bond energy). A procedure is specified for the removal from the surface of clusters of definite composition (for example, SiF_2 in the etching of silicon by fluorine-containing substances)

Furthermore, the possibility of the extraction of any of the surface atoms at the point B_s with its subsequent deposition at the point A_k, which describes surface diffusion, is considered. With the aid of the combination of the procedures classified previously, the activation energies for each of the possibilities and the extent to which they are energetically favourable are determined.

5. Selection of the outcome of the kinetic step. The result of the kinetic step arises statistically depending on the temperature of the surface and the energy changes in each of the alternative transitions.

6. The renewal of the state of the surface. In conformity with the results obtained in block 5, the Boolean matrix of the state is corrected, the construction shifts $\vec{\Delta}$ are redetermined, and the spectrum of the electronic surface states is found. The computation returns to block 2, after which a new particle is incident on the surface.

Measured quantities. Despite its apparent self-evident nature, the determination of the local surface level is not entirely unambiguous. Its position has been determined[97,143] on the basis of the condition that the number of atoms above the surface level is equal to the number of vacancies under it in the same column of atoms (a column of the Boolean matrix).

The average characteristics, the simplest of which is the average surface level and the rate of its change v, as well as the fractal dimensionality of the surface d and the dynamics of its change $d(t)$, are of principal interest. The quantities v, d, and $d(t)$ are found to depend only slightly on the method used to find the local surface level, which indicates that their determination is correct.

Furthermore, it is possible to determine the statistical properties of the surface—the scaling exponents α and β. A necessary condition for this is the possibility of modelling sections of the surface, the linear dimensions of which exceed L_c significantly.

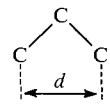
The geometrical properties of the surface were considered above. Together with these, it is possible to determine the parameters characterising the chemical properties of the individual surface obtained in the computation. The algorithm makes it possible to calculate the energies of the unoccupied and occupied electronic surface states relative to the Fermi level and to model the possible overlap integrals of these states with the wave functions of the additional adsorbed atoms.

3. The surfaces of polymers

The differences between the structures and the electronic states of polyethylene molecules on the surface and in the bulk phase are not quite so great as, say, in silicon. In the modelling of the chemical modification of the surface by reactive incident particles, this makes it possible to disregard the surface state of the polymer and to employ the states of the molecules. Thus we do not differentiate between the modification of the units on the surface and the units in the succeeding layers to which the reactive particle can permeate by diffusion.

Extremely sophisticated computational methods have been developed in the theory of polymers. The GPSE method cannot compete with them as regards the accuracy of the determination of the structure and properties of specific molecules. However, this method permits estimates in fairly complex cases, in particular for large organic molecules, which can be regarded as a set of fragments the centres of which are tetravalent carbon atoms. In the consideration of covalent bonds between the atoms of Group IV elements, the simplicity and universality of the GPSE method have been manifested particularly clearly. We shall demonstrate this approach to the qualitative description of the chemical modification of polymers[142] in relation to polyethylene as an example.

a. The molecule



Polyethylene consists of macromolecules the structural unit of which is the $-CH_2-$ fragment. Since the pitch of the helix is significantly greater than the distance between these fragments, we shall consider it as a chain based on a zig-zag arrangement of carbon atoms. By virtue of the similarity of the energy of the *s* state of hydrogen and the average energy of the sp^3-hybridised state of carbon, a tetrahedral symmetry of the chemical bond is obtained for each carbon atom. In this approximation, the angles between the bonds in the $-CH_2-$ fragment of the polyethylene molecule are the same as in the CH_4 molecules or in the diamond crystal.

In considering the C–C bond (Fig. 16a), we can employ the same procedure as in the consideration of the chemical bonds in crystallised silicon (Fig. 13). The overlap integral between the orbitals of the nearest carbon atoms, calculated with the aid of the GPSE procedure, determine the bonding and antibonding states of the C–C bond [Eqn (22)], while the overlap integrals between the bonding and antibonding states of neighbouring units determine the width of the one-dimensional quasi-band.

The C–H bond can be considered similarly (Fig. 16*b*), but in this case the bonding and antibonding states in Eqn (23) are made up of the *s* orbital of hydrogen and the sp^3-orbital of carbon (approximation *IIa*). The smallness of the overlap integral between the two bonding (as well as antibonding) states adjoining a single carbon atom gives rise to some scatter of the latter as a function of the type of symmetry in relation to the transposition of the hydrogen atoms (approximation *IIb*). The width of the one-dimensional quasi-bands may be neglected for C–H bonds.

The complete scheme of the electronic states is presented in Fig. 16*c*.

For a rough test of our model, one can compare the form of the zig-zag with the real, experimental shape of the polyethylene molecule. The angle between two C–C bonds is tetrahedral and the length of the C–C bond obtained by the GPSE procedure is 1.54 Å; accordingly, the linear period of the molecule *d* is found to be 2.50 Å. The measured bond angle in the polyethylene molecule is 112° and the measured period is 2.55 Å, which are close to the calculated values (109° and 2.50 Å). This shows that the model which we have proposed describes the real molecule quite well.

b. Modification of the surface

In order that the metal atoms (M) should be able to modify polyethylene, it is necessary that the energies of the vacant states of the metal should be significantly higher than the energy of the antibonding orbital of the C–H bond. In this case, the valence electrons of the metal pass to the antibonding C–H orbitals (Fig. 16*c*). The presence of an electron in this orbital weakens the C–H bond, the hydrogen atom is split off, and the electron given up by the metal occupies an even more favourable position at the bonding level of the C–M bond formed.

The appearance of the metal on the surface of polyethylene decreases its permeability to gases. Firstly, the metal atoms are positively charged owing to the displacement of electrons towards carbon, which leads to their interaction with the induced dipole moments of the molecules of the permeating gases. Secondly, the residual partially unpaired valence electrons of the metal lead in some cases (for example on permeation of oxygen) to the formation of oxides which decrease the unoccupied gaps between the molecules. Thirdly, the metal atoms may cross-link the neighbouring polyethylene molecules.

We may note that the deposition of the metal on polyethylene presents certain difficulties. This problem has been studied experimentally, for example for magnesium.[144] It was noted that sticking becomes possible if polyethylene is first treated with a plasma or by ion bombardment. Novak et al.[144] did not explain this effect. The application of the GPSE method makes it possible to understand that in this type of treatment an electron is transferred from the bonding C–H state to the antibonding state and the mechanism under discussion ceases to operate immediately from the second stage, which does not require any additional assistance.

Thus, by virtue of its relative simplicity, the GPSE method makes it possible to model fairly complex processes which have not been investigated by other methods. We emphasise that the GPSE method can be applied in two stages of the investigation. With its aid, one models, firstly, the interaction of the incident particle with the surface and, secondly, the surface itself.

XII. Results of the modelling of the modification of the surface

1. Continuous models

Apart from the competition between random deposition or etching (increase in the roughness of the surface) and diffusion (smoothing), which are common to the majority of such models, Karkar et al.[145] took into account also the competition within the $\hat{A}\{H(r,t)\}$ term between processes with different spatial locations.[129]

$$\frac{\partial H(r,t)}{\partial t} = \gamma\nabla^2 H(r,t) + \frac{\lambda}{2}[\nabla H(r,t)]^2 + \eta(r,t) \ .$$

The first term takes into account the revaporisation-condensation of the substance and hence the decrease in the surface area owing to the decrease in the height of hills and the filling of valleys. The second describes the growth of the surface in the direction of the local normal (which happens in the isotropic deposition of the modifying particles, i.e. at high pressures). The scaling exponents α and β proved to be independent of the numerical values of γ and λ: $\alpha = 0.38$ and $\beta = 0.24$.

Another smoothing mechanism—diffusion along the surface—has been considered by Wolf and Villain.[146] This process is characterised by a smaller scale than that considered by Kardar et al.[145] The equation for $H(r,t)$ was proposed in the following form:

$$\frac{\partial H(r,t)}{\partial t} = -\nu\nabla^4 H(r,t) + \eta(r,t) \ .$$

The values $\alpha = 1$ and $\beta = 1/4$ were found. A deficiency of the proposed operator $\hat{A}$ in this form is the failure to retain the surface diffusion flux. A nonlinear term was introduced to retain this flux.[147,148] In this case

$$\frac{\partial H(r,t)}{\partial t} = -\nu\nabla^4 H(r,t) + \lambda\nabla^2[\nabla H(r,t)]^2 + \eta(r,t) \ .$$

It has been shown[147] that for short times the first term predominates and the scaling exponents are close to those obtained by Wolf and Villain.[146] In the course of time, the second term becomes dominant and the scaling exponents approach $\alpha = 2/3$ and $\beta = 1/5$. It has been shown that allowance for nonlinearity in any form should decrease the scaling exponents.

Experimental values of the scaling exponents. A study has been made[149] of the deposition of copper chloride on the (111) surface of calcium fluoride by the method of molecular-beam epitaxy. The measured local static roughness index α proved to be 0.84 ± 0.05, which permitted the conclusion that the smoothing processes which accompanied the nonuniform deposition are much closer to surface diffusion[146] than to revaporisation.[145] The value of α found is somewhat lower than that determined by Kardar et al.,[145] which is evidence in support of the view that nonlinearity in the equation for $H(r,t)$ exerts an influence, but α is greater than in studies[147,148] involving a specific form of the nonlinear term ensuring the retention of the surface diffusion flux.

Iwamoto et al.[150] investigated the kinetics of the surface roughness in the electrodeposition of copper. The local roughness index, measured over small sections, proved to be identical, within the limits of the accuracy of measurement, with the index found by Tong et al.:[149] $\alpha = 0.87 \pm 0.05$. This confirms the conclusion[149] that surface diffusion predominates over revaporisation.

The results of averaging over large distances proved to be more unexpected. The measured dynamic exponent β proved to be 0.45 ± 0.05, which does not fit the concept that nonlinear terms exert an influence.[149] This has been attributed[150] to the effect of the electric field, which increases the vertical component of the growth of the surface, suppressing the lateral component.

2. Corrosion

A method has been proposed[151] for modelling corrosion within the framework of a two-dimensional cell model, only two parameters being employed: the passivation rate constant k_p and the depassivation rate constant k_d. The initial state is a two-dimensional rectangular grid (periodic boundary conditions are imposed along one of the coordinates) divided in such a way that the metal atoms are located at the nodes of one half-plane (capable of corroding) while particles inducing corrosion are at the nodes of the other half-plane. The interface is represented by passivating particles (oxide molecules adsorbed on the metal). Particles of a fourth kind can arise during corrosion: an inactive particle (a nonadsorbed molecule of the corrosion product, a neutral molecule, or an unoccupied node).

The process begins with spontaneous breakdown of the integrity of the interface. After a certain time δt, the probabilities of passivation (P_p) and depassivation (P_d) are established.

$$P_p = \delta t\, N_s k_p, \qquad P_d = \delta t\, N_p k_d \, .$$

In these expressions, N_s and N_p are the number of unprotected metal atoms (capable of coming into contact with the corroding particles) and the number of protected metal atoms (on which oxides are adsorbed) respectively. During corrosion, each lattice site can be occupied by a particle of one of the four kinds indicated above.

The cases of small scales and times (specimen length equivalent to 128 particles) and large scales and times (specimen length equivalent to 8192 particles) were considered. The first case (to some extent arbitrary owing to its two-dimensionality) corresponds to the condition $L_c \ll L$, whilst the second corresponds to $L_c \gg L$ in Eqn (19). The methods used to represent the results are also different.

In the first case, virtually nothing happens for large values of k_p—the cavity formed passivates itself. For low values of both k_p and k_d, the cavities grow in a stable manner and have an approximately hemispherical shape and relatively smooth edges. For large values of k_d, the structure of the interface becomes increasingly irregular. The fractal dimensionality of the interface increases with increase in the ratio k_d/k_p.

In the second case, the time variations of the corrosion current yields more information. Such variations have as a rule a typical pulsed form with a characteristic sharp initial rise corresponding to the onset of the formation of the cavity. The rises on the curve indicate the onset of the formation of new corrosion centres in the cavity. It has been noted that minor corrosion current pulses and shorter intervals between the pulses correspond to large values of k_p and k_d respectively. A universal empirical time dependence of the average corrosion current has been proposed:

$$I(t) \sim \frac{f(t/t^*)}{\ln t} \ ,$$

where the function $f(x)$ is constant for small values of x, decreasing rapidly for high values of x. The parameter t^* is related to the passivation rate constant by the expression

$$k_p^2 t^* \ln t^* \sim \text{const.}$$

Despite its approximate nature, this model describes correctly many aspects of the phenomenon and the principal process. Agreement has been found with the results of the continuous modelling of the morphology of the surface. The parameters k_d and k_p apparently characterise the universal corrosion mechanisms for different solid and liquid metals under the influence of various corrosion factors. Depending on their magnitude, the model describes both stable and unstable growth of the corrosion cavities.

3. Deposition and etching

The modelling of the chemical modification of the surface carried out [97, 143] with the aid of the algorithm described in Section X may be regarded as a demonstration. Many processes determined by surface states have not so far been modelled. At the same time modelling even at this level makes it possible to describe the selective filling of vacancies with the largest number of possible bonds (or the elimination of the least bound atoms) and to discover the characteristic features of the crystal lattice shape formation. It permits the description of different modification regimes: deposition, polishing, and etching, and permits a comparison of the qualitative aspects of the morphology with certain models by using literature data.

The chemical modification of the crystal surface of silicon with the base perpendicular to the [001] direction has been modelled. The initial surface (Fig. 17) was specified in a form such that the evolution of both smooth and sharp changes in relief could be observed. Streams of particles characterised by a conventional chemical energy E were considered for the modelling of the possible regime. Numerical experiments with various values of this quantity revealed three characteristic regimes: the changes in the form of the surface in all these regimes after the deposition of 20 000, 80 000, and 200 000 particles on the support are illustrated in Figs. 18*a*, 18*b*, and 18*c*.

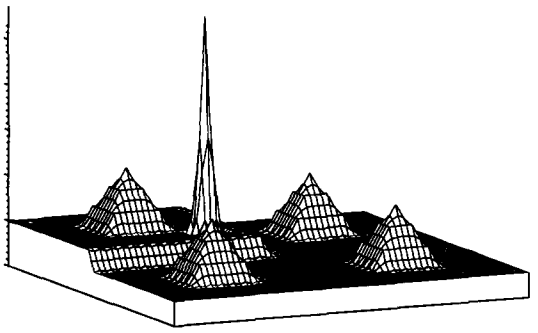

Figure 17. Initial relief of the modelled surface. The size of the section is 123 × 123 Å.

Deposition. In the first regime, particles with a low value of E fall on the support. There is then a certain number of particles capable of rupturing one and two bonds and very few particles capable of rupturing three bonds; there are virtually no particles which can rupture four bonds. If surface atoms with free bonds fall within the range of the influence of the valence electrons of the incident particles, new bonds may be formed. The effect of particles with such energy leads to a gradual growth of the crystalline layer, whereupon the form of the surface is approximately retained, being distorted mainly as a result of nonuniform sticking. Particles are eliminated rarely, such elimination being most notably manifested in the smoothing of sharp variations of the relief, in which the particles have the smallest number of bonds.

In the initial stage, the modification of the surface is close to that described by the simplest random deposition model.[117] It may be assumed that in the given instance the quantity L_c is fairly small and the roughness of the film is approximately proportional to the square root of the change in the height of the support. In the course of time (with increase in the number of incident particles), features characteristic of the ballistic deposition model appear [120–122] and projections and holes arise. The quantity $L_c \sim t^{\beta/\alpha}$ also increases and exceeds the size of the modelled crystal specimen. The dependence of the thickness of the film not only on the height of the support but also on its linear dimensions also begins to correspond to a power function. The fractal dimensionality of the surface formed increases. It may be expected that it tends to a definite limit with increase in the number of deposited particles.

Polishing. When particles with higher values of E are deposited, the situation changes radically. In this regime, almost all the deposited particles are capable of breaking one bond, quite a few particles are capable of breaking two and three bonds, and there are also particles able to break four bonds. The quantity E is

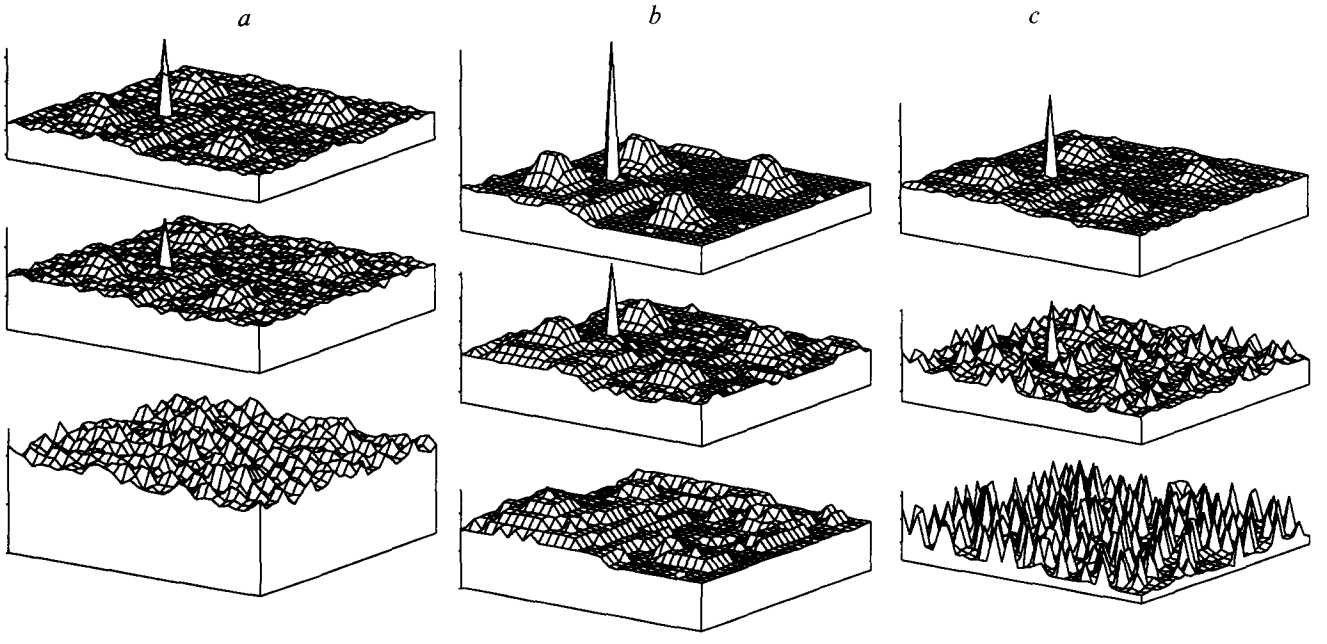

Figure 18. Modification of the surface in different regimes: (*a*) deposition; (*b*) polishing; (*c*) etching. The successive diagrams (from top to bottom) correspond to the deposition of 20 000, 80 000, and 200 000 particles.

selected so that the probability of rupture of the existing bonds corresponds to the probability of the formation of new ones. In the course of time, the surface relief becomes increasingly even. Projections are disrupted (the disruption of sharp ones is particularly rapid), but the average height of the support does not increase. The description of the surface modification processes under the influence of particles with such energy no longer corresponds to the models.[117,120] These processes are closer to those which may be described in terms of the statistical terraces model[121,122] and other models[123] describing the dynamics of the variation of formations with dimensionalities 1 or 2.

Etching. The situation again changes for a stream of particles with even higher values of E. In this regime, the majority of the particles have a chemical energy sufficient for the dissociation of three bonds and an appreciable number of particles are capable of rupturing all four bonds. The probability of the sticking of such particles to the surface is low and that of the dislodgment of crystal atoms is high, so that the thickness of the film diminishes. The initial form of the surface is gradually forgotten and is transformed into a very random landscape in the course of time. The fractal dimensionality of the modified surface increases as in the case of particles with low values of E (by analogy with this case, one may expect that the dimensionality tends to a limit with increase in the number of deposited particles). In a certain sense, the random and ballistic etching models, and not deposition models as described in the above investigations,[117,120–122] operate.

Within the framework of the calculations carried out, particles with low values of E play the role of silicon atoms in the absence of oxidising particles, while those with large values of E play the role of atoms (or molecules) of fluorine or other oxidising substances. This analogy, like that with cold or very hot particles, is extremely arbitrary. Effects such as etching after the formation of a monolayer cannot be modelled either.

Thus, within the framework of one model,[97,143] it has been possible to obtain different regimes in the modification of the surface and in the alteration of its morphology (Fig. 19), which had previously been described by means of various approaches.

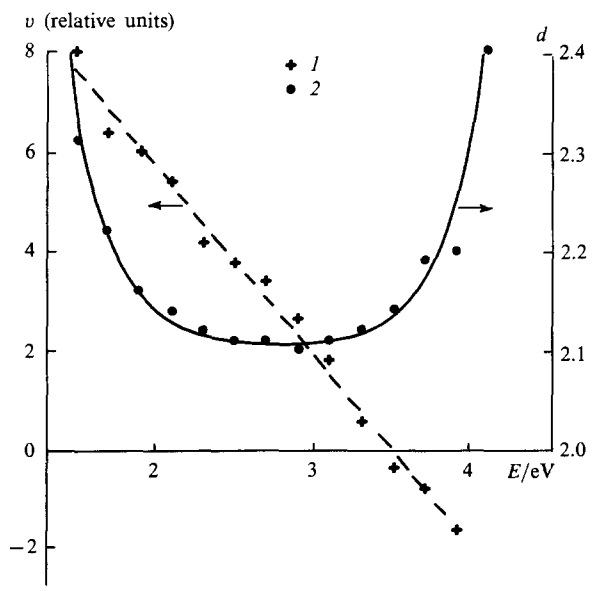

Figure 19. Rate of modification of the surface υ and the fractal dimensionality d as functions of the conventional chemical energy E of the incident atoms. The dashed line was obtained by fitting $\upsilon \sim (3.5 - E)$ and the continuous line was obtained by fitting $-d(E) = 2.1 + 0.1(E - 2.8)^4$.

The rate of change of the average level of the modified surface depends linearly on the quantity E, whereas the fractal dimensionality of the final surface is satisfactorily represented by a fourth degree parabola.

The existence of these relations throws light on the significance of the quantity E, which has hitherto played the role of a model parameter. Its linear relation with the rate of change of the average level of the surface makes it possible to employ E as a unique quantitative parameter (instead of a whole set of concentrations of various particles, their temperatures, etc.) characterising the effectiveness of the chemical action of a gas-plasma stream on the surface.

The minimum in the fractal dimensionality of the final surface is correlated with the passage of the rate of change of the level through zero. We may note that in a real situation the conclusion that the minimum in the fractal dimensionality of the final surface is related to the constancy of the thickness of the support may prove not to be universal. Thus an important factor in the description of surface modification processes may prove to be the presence of several kinds of incident particles with different values of E—some particles may etch the surface, whilst others are deposited. In different situations, the smoothness, the purity of the composition and the rate of change of the thickness of the support may be ensured by different groups of particles.

4. Problems with several time and length scales

As mentioned in Section VIII, the dynamic and probability methods have different applications, which supplement one another. This makes it useful to achieve their joint employment. Both these and other methods have extremely different versions and for this reason the procedures for combining them are also quite diverse.

Thermal desorption. The approaches combining the MMD and the transition state theory (the probability approach) make it possible to investigate rare events. Thus a study has been made[151] of the thermal desorption of a Xe atom from a Pt(111) surface. With the aid of the transition state theory,[152] the process probability being sought is represented by 'equilibrium' and 'dynamic' cofactors. The latter is expressed in terms of the sticking coefficient of the atom incident on the surface and is calculated by the MD method. The equilibrium factor can be determined by various methods, both statistical and dynamic. In both cases the application of special procedures is needed to improve the statistics in the 'bottleneck' within the phase space, the crossing of which by the phase trajectory is unlikely, but this 'bottleneck' determines the thermal desorption section. Several such procedures (stochastic dynamics and the 'boxes' and compensating potential methods) have been described[151] for the dynamic version of the calculation of the equilibrium cofactor.

A similar approach has been used[153] to calculate the rate of evaporation of a 14-atom cluster at low temperatures.

Diffusion of adsorbed atoms. Among the most recent studies, those[154,155] in which the diffusion of adsorbed Si atoms on the Si(100)–(2 × 1) surface and of Ge atoms on the Ge(100)–(2 × 1) surface as well as the dynamics of the adsorbed Si atom and the mechanism of the epitaxial growth of the Si(100)–(2 × 1) surface with a terrace are the most characteristic.

Such processes are characterised by two time scales: for short times, the atom captured by the surface seeks a stable adsorption site, while for long times the atom diffuses by jumps from one adsorption site to another and the scale is determined by the residence time of the atom at the sites. The calculation is therefore carried out in two stages, in each of which different methods are applied.

In the first stage, the adsorption energy profile was determined by the MD method along the surface modelled by several layers of mobile particles. The Tersoff potential was used.[23] The Si

atom was projected onto the Si surface and was allowed to select a sticking point (long arrest at a particular site). The surface was then gradually brought to zero temperature and its energy was calculated. The energy difference between the equilibrium surface and the surface with an adsorbed atom at the given point was assumed to be the adsorption energy. Such depositions were repeated many times at different points on the surface, which made it possible to construct a detailed adsorption energy profile.

The activation energies for the jump to a neighbouring adsorption site and the vibration frequencies of the adsorbed atoms at different sites were determined from the calculated profile and were subsequently used in the second stage of the calculation, where a probability method was employed. The Si atom was placed at random at a certain point on the calculated surface $E_a(x, y)$, where E_a is the adsorption energy and x and y are the coordinates along the surface. The probability P_{ij} of a jump from the adsorption site i to a nieghbouring site j was then selected stochastically. According to the transition state theory, $P_{ij} = \upsilon_{ij} \exp(E_{ij}/kT)$, where υ_{ij} is the vibration frequency of the adsorbed atom at i in the direction of the transition to j and E_{ij} is the activation energy for the transition.

The results[154] showed that the adsorbed atoms diffuse predominantly in the direction along rows of dimers, which has in fact been observed experimentally.

In epitaxy on a stepped surface,[155] the procedure is similar. The diffusion of the given adsorbed atom is terminated artificially at the instant when the next adsorbed atom appears on the surface (in accordance with the rate of deposition).

Condensation of supersaturated vapour. A model of the initial stage in the formation of clusters in supersaturated vapour has been considered.[156,157] The problem involves processes differing in both time and length scales: elementary steps involving sticking and evaporation and the kinetics of the growth of the size and number of drop nuclei. Processes of the first type are dynamic, while those of the second are statistical. The system of kinetic equations for the variation of the concentrations of the atoms in the clusters in a rarefied gas is used as the initial system. These equations include the rate of formation of dimers, the rate of sticking of atoms to the clusters and of the clusters to one another, and the rate of evaporation of atoms from the clusters and of the break up of the clusters. The problem is divided into two stages. In the first stage, the rates of elementary processes are calculated by the MD method, whilst in the second the kinetic equations are integrated numerically. This approach has been used in a calculation for the condensation of metals behind the shock wave front propagated in an inert gas in the presence of different amounts of an added volatile compound of the metal[156] and for the condensation of argon in a hypersonic stream.[157]

Deposition. As an example of the possible application of the ideas outlined in Section XI, we shall consider the deposition of gold on a silver support at room temperature. This problem has been modelled[158] by the MD method. Two assumptions were made. Firstly, the rate of deposition (one gold atom during a period $\lesssim 1$ ns on an area comprising 6×8 silver atoms) was assumed to be greater by many orders of magnitude than in the real deposition. Secondly, in order to compensate for such a high rate, an annealing procedure was introduced: each Au atom fell on a surface heated to 810 K, which was cooled after relaxation. This simulated the conditions where after each elementary step the surface returned to the equilibrium state. In particular, the gold atoms diffused into the first and second layers of silver atoms and the silver atoms were displaced to the state of adsorbed atoms.

In a real process, there are two markedly different time scales. With the aid of the above procedures, the authors[158] shortened the deposition time to values close to the time of an elementary step. The problem can be solved also by a different procedure after dividing it into two stages. In the first stage, the elementary steps modelled by the MD method are differentiated: the incidence of a gold atom on a clean silver surface and on sections of the silver surface with one, two, three, and more gold atoms in characteristic positions. Together with sticking processes, the subsequent diffusion is modelled and the energies of the potential barriers and the temperature variations of the pre-exponential factors are determined and extrapolated to low temperatures.

In the second stage, the deposition process at the required temperature is modelled with the aid of probability approaches using the information already obtained about the elementary steps. This approach would make it possible to expand significantly the temporal and spatial framework of the problem compared with those considered in the study of Haftel et al.[158] and also to turn attention to cases where there is insufficient time for the attainment of equilibrium between successive incidences of the atoms. In order to determine the extent to which the state of equilibrium is attained in the given processes, it is necessary to include in the consideration surface phonons and other types of surface excitation arising during the incidence of the particles.

5. Certain future tasks

Without claiming to quote a complete list, we shall present certain examples from the physics and chemistry of surfaces which may become the field of the active application of molecular modelling methods.

Elementary chemical processes. Scanning tunnel microscopy and certain other methods have made it possible to proceed to the study of the structure of the surface and the processes occurring on it at the level of individual molecules or atoms, for example the dynamics of the dissociative chemisorption of $Cl_2/Si(111)-(2 \times 1)$,[159] the dynamics of the deposition of an individual atom (iridium) on the iridium surface (steps and clusters),[160] the diffusion of $Si(001)-(2 \times 1)$ vacancies,[161] etc. Such studies naturally stimulate the development of molecular modelling methods.

Heterogeneous catalysis. The phenomena in heterogeneous catalysis are based on the change of the chemical properties of the atoms and molecules which have formed chemical bonds with the surface. For example,[143] data on the decrease in the dissociation energy of the O_2^- molecular ion on the surfaces of transition metals by an order of magnitude (under certain conditions by two orders of magnitude)[162] and on the increase in the interatomic distance[163] have been quoted to illustrate the enhancement of the oxidative properties of an adsorbed oxygen molecule. Quali-tatively, this phenomenon can be understood within the framework of the idea concerning the chemical properties of a surface described in Section X. This refers also to the results of a study[164] where an increase in the Fermi level as a result of the additional filling of the surface states by the valence electrons of the adsorbed sodium atoms and its decrease as a result of the reverse process in the adsorption of sulfur atoms were described. For a quantitative description and development of methods for controlling catalytic properties, molecular modelling is required.

Reconstruction dynamics. The calculation of the surface reconstruction time is an interesting and hitherto unsolved problem. Here there are no differentiated atoms and it is not always evident how many atoms should be considered in the modelling of a nonstationary quantum process. There remain many problems even for the stationary case of a thoroughly investigated surface such as $Si(001)-(2 \times 1)$.[165]

Nonequilibrium materials. The study of the structure of a surface with different ratios for the rate of reconstruction and the rate of deposition may lead to the explanation of the difference between the lattice constants of the ultradisperse powders obtained by the plasmochemical method[166] and its value for a massive specimen.

Multilevel molecular modelling makes it possible to understand the properties of nonequilibrium crystals and facilitates the search for ways of synthesising them.

Modification of the surface. The structure of the surface and the dynamics of its variation have become the object of experimental studies at the molecular level, in particular by means of tunnel microscopes.[167–169] The effect involving the appearance of instability in the form of the surface in molecular-beam epitaxy as a function of changes in the deposition regime has been observed.[167,168] Modelling demonstrated its usefulness even in the simplest geometric version.

Multilevel modelling. The problem is formulated so that: all the levels into which the problem is divided (elementary steps, collective processes, macroscopic description, etc.) are discovered; descriptive procedures for each level are selected; the channels for the transmission of information between the levels (initial data, parameters, initial and boundary conditions etc.) are established; the required level of accuracy of the final result is specified in the scheme, establishing thereby the required accuracy at each level or, conversely, the attainable accuracy of the final result is determined on the basis of the worst current accuracy for one of the levels.

In Dodson's review,[4] it is concluded that, because of the abundance of unelucidated questions, the molecular modelling methods still remain the objects of study and not a means of carrying out studies. The authors of the present review attempted to show how, by combining the dynamic and probability modelling procedures, it is possible to convert them into a means whereby research can be carried out. The choice of modelling problems is determined by physical effects, applied purposes, and the possibility of comparison with experiment.

This review has been written with the financial support of the Russian Fundamental Research Fund (Project 94-03-08069).

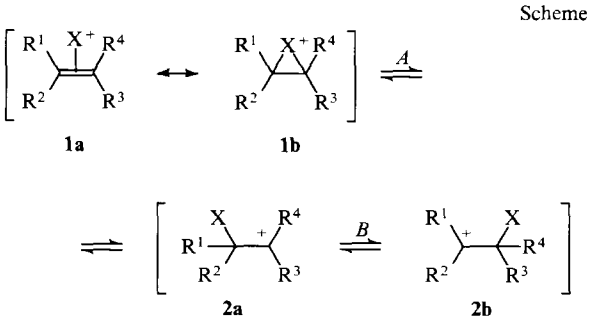
VI.	On the possibility of 2-σ,π-rearrangements	652

Abstract. The structure-kinetic and stereochemical aspects of rearrangements of cationic σ- and π-complexes of unsaturated organic compounds with electrophilic reagents containing no metal atoms and the effects of the medium and phase state on these rearrangements are considered. The bibliography includes 299 references.

I. Introduction

In recent decades the structures and reactivities of cationic organic σ- and π-complexes† generated under 'long lifetime' conditions have been intensively studied.[1–33] 'Long-lived' σ- and π-complexes attract the steady attention of researchers, because they are close structural analogues of the intermediates of some organic reactions of great theoretical and practical importance. These reactions include electrophilic aromatic substitution,[20,36–38] acid-catalysed transformations of organic compounds,[39–41] electrophilic addition,[42] and solvolysis with anchimeric assistance.[43]



The wide use of modern physical methods has produced extensive information on the structures and reactivities of cationic σ-complexes.[1–33] However, studies of the structures and reactivities of cationic π-complexes are few, and their results are often ambiguous (see, for example, Refs 2, 23, 25, 29). Experimental data on the interconversion of cationic σ- and π-complexes (Scheme 1, path *A*) are even more scarce, despite the fact that in many cases this interconversion is the key step and determines the composition of the reaction products.[20,42,43]

† We use the term 'σ-complex' in its traditional sense [20] to denote a species that is formed by one-centred σ-bonding of an electrophilic agent to an unsaturated system via two electrons of the π-system. The term π-complex corresponds to an adduct formed by *n*-centred bonding ($n > 1$) of an electrophilic agent to the π-system of an unsaturated compound.[34,35]

Scheme 1

In principle, data on the energy of interconversion of cationic and anionic σ- and π-complexes can be obtained from quantum-chemical calculations (see Refs 44–47). However, this approach has essential limitations caused, in particular, by the unreliability of the calculation techniques.[46,48] This is clearly demonstrated by the results of quantum-chemical calculations on the simplest σ- and π-complexes, the ethyl cation and its π-analogue, for which the of relative energy varied over very wide limits (from 23.5 to −33.2 kcal mol^{-1}), depending on the chosen method of calculation.

The purpose of the present review is to consider the state of investigations, first of all, of the experimental ones, on rearrangements of cationic σ- and π-complexes. This is necessary for the development of approaches to the control of numerous organic reactions involving these complexes as intermediates. We shall confine the discussion to complexes formed by compounds and electrophilic reagents containing no metal ions. Considerable attention is paid to degenerate rearrangements of σ- and π-complexes in which the initial and the final species have identical energies. In conformity with the Marcus concept [49,50] and other similar approaches,[51] the kinetic characteristics of the degenerate processes are fundamental in the structural kinetic theory.

II. Types of rearrangements of σ- and π-complexes

Three main types of rearrangements of σ- and π-complexes can be distinguished, namely, σ,σ-, σ,π-, and π,π-rearrangements (see Fig. 1). One-step rearrangements of σ-complexes (*a*) as well as two-step rearrangements involving the formation of π-complexes as unstable intermediates (*b*) belong to the first type. The rearrangements characterised by similar stabilities of σ and π-complexes may be assigned to the σ,π-type (*c*). Finally, one-step

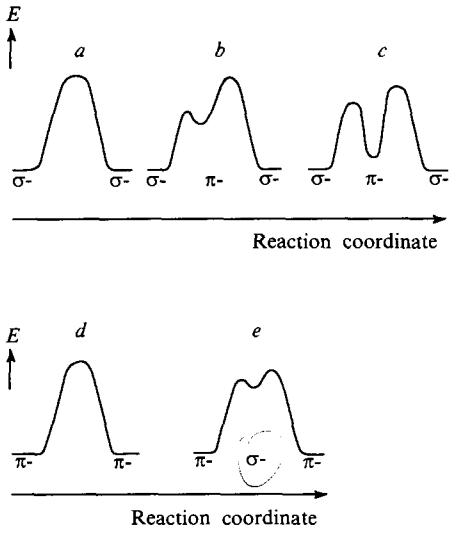

Figure 1. Dependence of the energy on the reaction coordinate for some types of rearrangements of σ- and π-complexes.

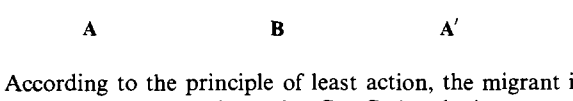


rearrangements of π-complexes (*d*) or two-step rearrangements involving the formation of unstable σ-complexes (*e*) may be referred to as π,π-rearrangements.

A more detailed classification of σ,σ-rearrangements includes allowance for the number of cleaved (*n*) and of formed (*m*) σ-bonds (an *n*σ,*m*σ-rearrangement). If one takes into account the possibility of coordination of the apical group (migrant) with different numbers of atoms of the complex core, then interconversions of π-complexes may be defined as π(*n*η),π(*m*η)-rearrangements. In conformity with this the interconversion of σ- and π-complexes may be referred to as a *n*σ,π(*m*η)-rearrangement.

III. σ,σ-Rearrangements

The most significant and extensively studied of σ,σ-rearrangements of cationic σ-complexes are those occurring through the 1,2-shift of a migrant (R_m) to the electron-deficient carbon atom, viz. the carbocationic centre (C_t) (Scheme 2).

Scheme 2

According to the principle of least action, the migrant in a 1,2-shift should move along the C_0-C_t bond via a state of π-bonding (an intermediate or transition state **B**),[20,22] and, with certain assumptions, the kinetic parameters of these rearrangements can characterise the relative stabilities of σ- and π-complexes. The main tool for the investigation of these rearrangements which occur at high rates is dynamic NMR,[15,16,20,21,52] while slow transformations are mostly studied by the radioactive tracer method.[15-17,20,53] Degenerate rearrangements of 'long-lived' cationic σ-complexes with a variety of migrants of σ-, π-, or *n*-type have been studied. The kinetic characteristics of the 1,2-shifts of these migrants are presented in Tables 1-4.

An important point is that the published data[15,17,20,21] indicate that the nature of the counter-ion or the solvent does not significantly affect the rates of intramolecular rearrangements of 'long-lived' cationic σ-complexes. Therefore, we shall consider initially the structure-kinetic regularities of these rearrangements. An approach consisting in separating a σ-complex into two structural fragments, the migrant (R_m) and the core (the rest of the ion), and in establishing the relationships between the structures of these fragments and the rate of the rearrangement was successful in identifying these regularities.[3,15,20,21]

1. The structural effects of the core

It is apparent that, in the absence of complicating factors, the rate of rearrangement for a given migrant should increase with the electrophilicity of the carbocationic centre C_t (see Ref. 76). In fact, for 1,2-shifts of migrants of σ-(H,Me), π-(Ph), and *n*-(Cl) types in arenonium ions (see Tables 1-4), the following linear correlations have been identified:

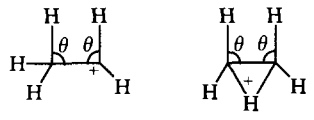
$$y = a_i + b_i\zeta\,, \qquad (1)$$

where y is $\lg k$ (k is the rate constant), free energy of activation ($\Delta G^{\neq}$), or activation energy (E_a); ζ, the chemical shift of the C_t atom (δC_t^+), reflecting the degree of electron deficiency,[138] or q_i^+ the total or π-charge.[78-81,97,102,111,125,129,134]

Borodkin et al.[102] reported a simplified interpretation of dependences of this sort in terms of the method of vacant molecular orbitals.[139] A more rigorous quantum-chemical analysis of the variation of the coefficients a_i and b_i with variation of the migrants R_m was later carried out.[140-143] The a_i and b_i coefficients in the relationship (1) behave so that the relative abilities of R_m of different types (H, Me, Ph, Cl, NO_2) to migrate do not form a universal sequence.[21,78,129]

It is noteworthy that $\Delta G^{\neq} = 0$ for the extrapolation curves is achieved at various values of δC_t^+. This apparently indicates the possibility of inversion of the relative arrangement of energy levels of the σ-complexes (**A**, **A'**) and the π-complex (**B**) (or the corresponding transition state **B**) (see Scheme 2) with increase in the charge on the carbonium centre; the tendency of the migrants R_m to form π-complexes increases in the sequence $H < Me < Ph < NO_2 < Cl$.[78,129]

The degree of electron deficiency on the C_t atom in a series of related σ-complexes can be characterised, as well as by δC^+ and q_i^+, by the σ^+-constants of the substituents[78,102,125] or by the ν(CO) stretching frequencies of the ketones resulting from the replacement of the C_t^+-Me fragment in the σ-complex by a C = O fragment.[78,125,144] The validity of linear correlation dependences of this type has been confirmed using the 1,2-shifts of hydrogen atoms,[78] Me[144] and Ph[125] groups in arenium ions as examples.



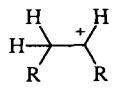
The relationships of type (1) ($\zeta = \delta C_t^+$ or q_π^+) do not hold for rearrangements of 1-R_m-1,2-dimethyl-3,4,5,6-tetrafluorobenzenium ions (R_m = H, Cl)[80,135] or 1-R_m-1,2,3,4-tetramethylbiphenylenium ions (R_m = H, Me).[82,98] In the former case the quality of the correlation can be substantially improved by using the difference between the chemical shifts of the C_t atom of the arenium ion and its precursor, the corresponding arene, instead of δC_t^+ (see Ref. 135). Morozov et al.[145] have shown that by taking into account the logarithms of the basicity constants of arenes ($\lg K$), obtained by the imaginary abstraction of the migrant R_m^+ from the cation, as well as the q_π^+ parameter, one can quantitatively describe rearrangements of arenium ions of both the benzoid and nonbenzoid types in the framework of the two-parameter correlation

$$\Delta G^{\neq} = a + bq_i + c\lg K\,. \qquad (2)$$

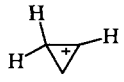
This approach was later extended to the rearrangements of aliphatic carbocations.[146]

More serious limitations arise when one attempts to use type (1) relationships for quantitative descriptions of the rearrangements of σ-complexes with different types of cores. For example, in the case of 1-R_m-1,2-dimethylacenaphthylenium ions (R_m = H, Me,[85] Cl[134]), the differences between experimentally determined $\Delta G^{\neq}$ values and those calculated from type (1) relationships can reach 5-7 kcal mol^{-1}. An increase in the

activation barrier with decrease in the size of the ring against which the migration occurs has also been found for the isomeric σ-complexes **24a** and **25** (see Table 1). A similar increase in ΔG is observed on going from the 2-butyl cation ($\Delta G^{\neq}_{-140\,°C} < 1.9$ kcal mol^{-1})‡ (see Refs 15, 54) to the cyclobutyl ion (**5a**) (see Table 1).[57] Using MINDO/3 and ab initio calculations, Chandrasekhar and Schleyer[149] have determined the dependence of the difference between the energies of the σ-complex (**C**) and the π-complex (**D**) on the magnitude of the angle θ and have shown that the activation barrier to the 1,2-shift of a hydrogen atom increases as this angle decreases.



C **D**



c **d**

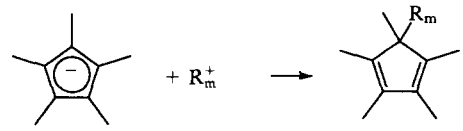
One of the reasons for the increase in the activation barrier to the 1,2-shift is the increase in the antibonding interaction between the atomic orbitals in the occupied MO (**c** and **d**) corresponding to structures **C** and **D**, which is due to the shortening of the C_0-C_t bond (1.49 and 1.40 Å, respectively). MINDO/3 and ab initio calculations of the barriers to the 1,2-shifts of hydrogen in acyclic and in cyclic σ-complexes **5a**, **6a**, **9a**, **77 – 79** confirm the conclusions suggested by the above-mentioned model.

R = H (**77**), Me (**78**)

79

Apart from the 'ring effect' against whose background the migration occurs, the influence of other factors (in particular, orbital orientation) also can lead to deviations from type (1) dependences.[17, 21, 22, 103, 150 – 153] An unfavourable mutual orientation of the C_0-R_m bond and the vacant atomic *p*-orbital makes the transition state more strained[153] (see Ref. 71) and the rate of the rearrangement decreases. The allowance for the aromatic or antiaromatic character of the transition state can be important[21] (see Ref. 71). The latter is probably responsible to a substantial degree for the increase in the activation barriers to the 1,2-shifts of hydrogen and methyl groups in the ions **24a, b** and **37** compared with those expected from calculations using dependences of type (1).[82, 83, 98] This retarding factor is even more pronounced in the case of 1-R_m-1,2,3,4-tetramethylcyclobutenyl cations for which no rearrangements occurring via 1,2-shifts of migrants (R_m = H, Me, Ph) can be detected even under quite rigorous conditions (see Tables 1 – 3), although other rearrangements associated with the reconstruction of the system of bonds in these ions occur quite readily.[15, 88, 89] (see Ref. 71).

The aggregate of the charge factor and other factors can be taken into account (at least, for identical migrants) by choosing a 'chemical' parameter, the free energy of activation (or lg *k*, E_a) of the 1,2-shift of the standard migrant as a generalised parameter.§ The legitimacy of using this approach to the quantitative description of rearrangements of different cationic σ-complexes has been shown for the first time for the 1,2-shifts of hydrogen atom and methyl group chosen as the standard group.[155] It turned out that for a wide range of rearranging ions, 1-R_m-1,2,3,4,5,6 hexamethylbenzenium, 2,7- and 3,6-substituted 9-R_m-9,10-dimethylphenanthrenium, 1-R_m-1,2-dimethyl-acenaphthylenium, and 1,4-di-X-2-R_m-2,3-dimethylnorbornyl ions the following correlation relationships hold:[78]



$$\Delta G^{\neq}(R_m) = a_1 + b_1 \Delta G^{\neq}(Me), \quad (3)$$

$$\lg k(R_m) = a_2 + b_2 \lg k(Me), \quad (4)$$

$$E_a(R_m) = a_3 + b_3 E_a(Me). \quad (5)$$

Later the range of rearranging σ-complexes covered by analogous dependences has been extended by including the data for rearrangements of 2-R_m-2,3-dimethylbutyl, 2-R_m-1,2,3,4-tetramethylnaphthalenium, and 2-R_m-1,2,3,4-tetramethylbiphenylenium ions and neutral structures, i.e. 5-R_m-1,2,3,4,5-pentamethyl-1,3-cyclopentadienes (**80**),[156] which can be regarded as neutral σ-complexes formed by linking a 1,2,3,4,5-pentamethylcyclopentadienyl anion to an R_m^+ cation (Scheme 3).[98]

Scheme 3

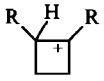
80a – d

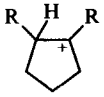
R_m = H (**a**),[156, 157] Me (**b**),[158] Ph (**c**),[159] NO_2 (**d**).[160]

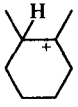
It should be noted that when the whole set of data is processed, the above-presented correlation relationships can describe a very wide range of rearrangement rates $\Delta\Delta G^{\neq}(Me) \approx 40$ kcal mol^{-1} including structures with formal charges between 0 and 1.

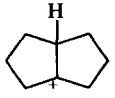
Analogous dependences have also been found for other migrants (Ph[159] and NO_2[160]) using the methyl group as the standard migrant. The fact that dependences of types (3) – (5) are valid for both cationic and uncharged σ-complexes indicates a fundamental inherent alliance between rearrangements of carbocations and those of neutral compounds. An analysis of the behaviour of type (3) dependences for the H, Me, Ph, and NO_2 migrants has shown[159] that as the activity grows [the $\Delta G^{\neq}(Me)$ value decreases], the selectivity [$\Delta G^{\neq}(R_m^1) - \Delta G^{\neq}(R_m^2)$] diminishes until the isoselectivity points located in the region of low $\Delta G^{\neq}(Me)$ values are reached, which is in conformity with the 'activity – selectivity'¶ principle (see Refs 161 – 164).

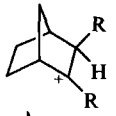
2. Influence of the nature of the migrant

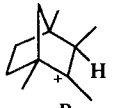


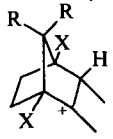












Predicting the rates of rearrangements of carbocations that occur via 1,2-shifts of various atoms or groups is one of the fundamental problems in the theory of molecular rearrangements,[15, 20, 21, 166, 167] and, it is also one of the most complex problems, since both the structure of the core of the carbocation (electrophilic agent) and the nature of the migrant atom subjected to the attack vary over wide limits. As was noted above, quantum-chemical calculations do not allow the rates of carbocation rearrangements to be predicted reliably enough (see Refs 168 – 180). We believe that the approach based on the use of correlation relationships and experimentally determined parameters characterising the nature of the migrant is a more promising approach to the quantitative description of the rearrangements of cationic σ-complexes. In this connection, illustrative data have been obtained for the 1,2-shifts of isosteric migrants, *meta*- and *para*-substituted phenyl groups. The rearrangements of 9-(X-phenyl)-9,10-dimethylphenanthrenium

‡ The value of $\Delta G^{\neq}$ probably refers to the interconversion of the 2-butyl cation and the corresponding π-complex of type **B** (see Scheme 2 and Refs 25, 147, 148).

§ The fruitfulness of using 'chemical' parameters in organic chemistry is well known. Typical examples are Hammet and Brønsted equations, etc.[154]

¶ Note that the behaviour of the migrants C_6F_5S or C_6F_5Se in similar rearrangements does not obey the 'activity-selectivity' principle.[165]

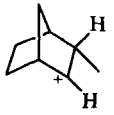
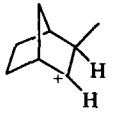
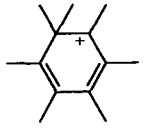
Note. From this point on, free valence lines in structural formulae denote methyl groups. For the sake of simplicity, π-,σ-delocalisation is not shown in the structural formulae.

[a] The values of $\Delta G^{\neq}$ have been calculated from the equation: $\Delta G^{\neq} = 2.3RT[\lg(kT/h) - \lg k_{1,2}]$ (the corresponding temperatures are given in parentheses), $\lg A_{1,2} = \lg A - \lg f$, where f is the statistical factor taken as $f=4$ for the ion **16a**, $f=2$ for the cations **16b,c**, **17**, **18**, **20**, **21**.







[b] The acid is not specified, it is probably SbF_5.

[c] Based on the data, it was assumed that $k < 10\,s^{-1}$.

[d] The temperature is not given.

[e] According to the published data,[61,63] the values of the kinetic parameters given in the Table refer to the 1,2-shift of the *exo*-H atom; the value of $\Delta G^{\neq}$ for the 1,2-shift of the *endo*-H atom exceeds 20 kcal mol^{-1}.

Table 2. Kinetic characteristics of the 1,2-shifts of alkyl groups in degenerate rearrangements of σ-complexes.

[a] See footnote 'a' to Table 1; the values were taken as $f = 4$ for ion **35**, $f = 3$ for ion **29**, $f = 2$ for cations **36–40**, **41c**.
[b] The acid is not given, it is probably SbF_5.
[c] The value has been evaluated (the temperature was not given). [d] For the shift of the *exo*-methyl group; for the shift of the *endo*-methyl group, $\Delta G^{\neq}_{-64\,°C} > 10.7$ kcal mol^{-1} (see Refs 4, 87).
[e] For the shift of the *exo*-methyl group; for the shift of the *endo*-methyl group, $\Delta G^{\neq}_{-64\,°C} = 19.5$ kcal mol^{-1} (see Ref 63).
[f] Apparently, for the shift of the *exo*-methyl group.
[g] Based on the published data, it was assumed that $k < 10\,s^{-1}$.
[h] The values were calculated by Koptyug and Shubin[15] based on the kinetic data reported in the literature.[91]

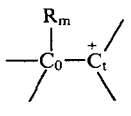
[a] See footnote 'a' to Table 1; f = 2 for the ions **62**, **64a**, **70**, **71a**, **75a**.
[b] Calculated by Koptyug and Shubin[15] based on the kinetic data reported in the literature[127], see Ref 106.
[c] In these experiments, $0 < n < 1$, the value of n increases from bottom to top. The acid : diluent ratio is 1 : 2.
[d] Based on the published data,[133] it was assumed that $k < 10$ s^{-1}.

(**58a–g**),[124] 1-(X-phenyl)-1,2,3,4,5,6-hexamethylbenzenium (**56a–d**),[120,121] and 1-(X-phenyl)-1,2-dimethylacenaphthylenium (**57a–f**)[122,123] ions have been used to demonstrate the validity of the relationships $\lg(k_X/k_H) = \rho\sigma_X^+$. Judging by the absolute values of $\rho^+_{-50\,°C}$ (−4.5, −4.47, and −6.64, respectively), the series of the relative migration ability are not universal even in the case of structurally similar migrants, i.e. substituted phenyl groups. Analogous dependences hold for the nondegenerate rearrangements of 1-(X-phenyl)-2-hydroxy-1,3,4,5,6-pentamethylbenzenium ions (**81a–f**) ($\rho^+_{-50\,°C} = -3.37$)[181] and also for the 1,2-shifts of $XC_6H_4CH_2$ groups in 1-(X-benzyl)-1,2,3,4,5,6-hexamethylbenzenium cations ($\rho^+_{-50\,°C} = -4.42$)[113] and 9-(X-benzyl)-9,10-dimethylphenanthrenium cations ($\rho^+_{-50\,°C} = -1.08$).[115] Borodkin et al.[115,120] have analysed the behaviour of the sensitivity constants ρ^+ for the 1,2-shifts of XC_6H_4 and $XC_6H_4CH_2$ groups as a function of the structure of the core in terms of the O'Ferrall–Jencks model.



81a–f

X = H (**a**), *p*-Me (**b**), *p*-MeO (**c**), *p*-CF_3 (**d**), *m*-CF_3 (**e**), *p*-Cl (**f**).

A comparison of the selectivity (ρ^+) and activity [$\lg k$(Ph)] parameters for the rearrangements of ions **56a–d**, **57a–f**, **58a–g**, and **81a–f** shows that the 'activity-selectivity' principle (cf Refs 161–164) is not obeyed even for the isosteric XC_6H_4 migrants.[113] One may expect an antiparallel relationship between the activity and the selectivity when only one of the factors influencing the reaction rate is varied (for example, the inductive or the resonance effect)[22] (cf Ref 164). Comparing the activation free energies of the 1,2-shifts of the CH_2R groups (R = H, Me, Cl) in arenium ions with the chemical shifts of the carbocationic centre indicates that the 'activity-selectivity' principle is obeyed in the case of σ-migrants whose migration ability for ions with a fixed core is mainly determined by the inductive effect of the substituent R.[111] The $XC_6H_4CH_2$ groups behave anomalously in the series of migrants of the CH_2R type. This is shown by the intersection of the lines corresponding to the *p*-$ClC_6H_4CH_2$, $C_6H_5CH_2$, and CH_3CH_2 groups which intersect in the region of experimentally accessible values of δC^+ and $\Delta G^{\neq}$ (see Ref. 115). The violation of the 'activity-selectivity' principle in this case, as also for XC_6H_4 groups, may be associated with the simultaneous influence of the inductive and resonance effects of the substituents R (or X), the ratio between whose contributions probably varies with the activity parameter.[113,115]

A substantially more complicated problem arises in developing approaches to the quantitative description of the migration ability of different types of migrant (see Refs 140–143). Borodkin et al.[182] took the first step in this direction. They assumed that the activation free energy of the 1,2-shifts of different migrants in the cationic σ-complexes can be expressed as the sum of two constituents one of which (E_1) reflects the consumption of energy for elongation of the C_0-R_m bond and for deformation of the $C_t-C_0-R_m$ bond angle when the transition state is achieved, and the other (E_2) is the gain in energy resulting from the interaction of the migrant with the carbocationic centre.

$$\Delta G^{\neq} = a + b_1E_1 + c_1E_2. \quad (6)$$

The energy required to cleave the $C-R_m$ bond in the compounds CH_3R_m [$E_b(CH_3R_m)$] [or the force constant of the deformation vibration of the $C_t-C_0-R_m$ fragment (K_{def})] and the proton affinity of compounds CH_3R_m (PA) have been suggested as characteristic parameters of the E_1 and E_2 energies. It would be more reasonable to use the affinity of CH_3R_m to the CH_3^+ cation, but these data are quite limited. In terms of this simplified model, allowing for the limited relationship of the charge on the carbocationic centre (q^+) to the value of chemical shift of the C_t atom,[138] we obtain:

$$\Delta G^{\neq}(R_m) = a + bD + cq_t^+[d + e(PA)(CH_3R_m)], \quad (7)$$

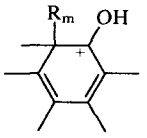
where $D = E_b(CH_3R_m)$ or K_{def}; $q_t^+ = f + g\delta C^+$.

A comparison of the free energies of activation of the 1,2-shifts of the migrants in 1-R_m-1,2,3,4,5,6-hexamethylbenzenium, 9-R_m-9,10-dimethylphenanthrenium, 9-R_m-9,10-dimethylpyrenium, and 2-R_m-1,2,3,4-tetramethylnaphthalenium ions (R_m = Me, Et, XC_6H_4, Cl, Br) (see Tables 2–4) with the corresponding values of $E_b(CH_3R_m)$, $(PA)(CH_3R_m)$, and $\delta C^+(CH_3)$ produces the following correlation:†

$$\Delta G^{\neq}_{25\,°C} = 0.9 + 0.329E_b - 0.00129(PA)(\delta C^+ - 130), \quad (8)$$

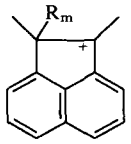
$$r = 0.987,\ s = 0.7,\ n = 29.$$

The activation free energies of the 1,2-shifts of hydrogen atoms do not obey the correlation (8). This may be due to the fact that the deformation of the C_t-C_0-H fragment occurs more easily than that of other fragments, which results in an increase in the migration ability of hydrogen and probably reflects the well known tendency of hydrogen to form bridged structures (see Refs 183–187). However, when the parameter E_1 is characterised by the force constant of the deformation vibration of the $C_t-C_0-R_m$ fragment, the correlation is more general:



$$\Delta G^{\neq}_{25°C} = 17.1 + 14.5K_{def} - 0.00127(PA)(\delta C^+ - 130), \quad (9)$$

$$r = 0.963,\ s = 0.7,\ n = 33.$$



For a series of cationic σ-complexes with a fixed core ($q_t^+ \approx$ const, $\delta C^+ \approx$ const), the relationships (8) and (9) are transformed into simpler dependences:

$$\Delta G^{\neq} = a + bD + d(PA). \quad (10)$$

This makes it possible to verify the applicability of these dependences to the quantitative description of nondegenerate rearrangements of arenonium ions and of rearrangements of carbocations that differ from arenium ions in the type of core. A comparison of the activation free energies of the 1,2-shifts of migrants in 1-R_m-2-hydroxy-1,3,4,5,6-pentamethylbenzenium ions (**81, 82**)[181,188,189] and 1-R_m-1,2-dimethylacenaphthylenium ions (**83**) with the corresponding $E(CH_3R_m)$, K_{def}, and (PA) parameters produces correlation relationships whose characteristics are presented in Table 5.[100,190] The values of the free energies of activation of degenerate and nondegenerate 1,2-shifts of the migrants R_m in arenium ions and in 1-R_m-1,2-dimethylacenaphthylenium cations calculated from type (7) and (10) relationships are in good agreement with experimental data: the discrepancy between $\Delta G^{\neq}$ values normally does not exceed 1 kcal mol^{-1}, the range of their variation being ~ 20 kcal mol^{-1}.[100]

82a–c

83a–c

† The chemical shifts of the corresponding ions with the standard migrant, the Me group, were taken as the values of δC^+.

Table 5. The parameters of correlations of type (10) for 1,2-shifts of the R_m migrants in 1-R_m-2-hydroxy-1,3,4,5,6-pentamethylbenzenium and 1-R_m-1,2-dimethylacenaphthylenium ions at 25 °C.

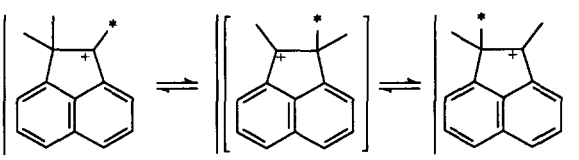
3. Influence of the medium on the rates of degenerate σ,σ-rearrangements

When the data on the rearrangements of cationic σ-complexes are compared in terms of structure-kinetics relationships the question of how the medium influences the rate of an 1,2-shift is of importance. The influence of the liquid medium (solvent and counter-ion) has been most extensively studied for the 1,2-shift of a methyl group in the heptamethylbenzenium ion (**35**). The rate constants of the rearrangement of this ion turned out to be virtually identical in the following media: HSO_3F,[191] HSO_3Cl,[90,191] H_2SO_4,[91,191,192] CF_3COOH,[92] HCOOH,[191] HSO_3F-SbF_5 (9:1),[191] a 20% solution of SO_3 in HSO_3F,[192] CH_2Cl_2 (with $AlCl_4^-$ as the anion),[93,191] $HC(SO_2F)_3$,[193] $SOCl_2$ (with $SbCl_6^-$ as the anion),[94,95] $PhNO_2$ (with the $AlCl_4^-$ anion),[191] C_6F_6 (with the $Al_2Cl_7^-$ anion),[21] $PhNO_2$ (with the Ph_4B^- anion).[21] The same conclusion applies to the rearrangements of 9,9,10-trimethylphenanthrenium (**39a**),[101,102,104,194,195] 3,6,9,9,10-pentamethylphenanthrenium (**39c**),[102,193] and 1,1,2-trimethylacenaphthylenium (**38**)[85] ions. No appreciable influence of the medium on the rates of 1,2-shifts of hydrogen has been detected for 1-*H*-1,2,3,4,5,6-hexamethylbenzenium (**21**),[21,76,78] 9*H*-3,6,9,10-tetramethylphenanthrenium (**27c**),[78] 2-*H*-1,2,3,4-tetramethylbiphenylenium (**24a**),[82] 1-*H*-1,2-dimethylacenaphthylenium (**26b**),[84,85] 2,3-dimethyl-2-norbornyl (**11a**),[65] 1-*H*-1,2-dimethyl-3,4,5,6-tetra-X-benzenium (X=Cl, F (**22b**),[80] 1,2,3,4-tetramethylnaphthalenium (**23**),[81] 2-methyl-2-butyl,[21,152,196–198] or 4-R-1,2,3,4,5-pentamethylcyclopentenyl (R = H, Me)[21,199] ions. Likewise, very low sensitivities of the rearrangement rates to variation of the medium have been found for the 1,2-shifts of XC_6H_4 groups in 1-phenyl-1,2,3,4,5,6-hexamethylbenzenium (**56a**),[118] 9-phenyl-9,10-dimethylphenanthrenium (**58a**),[124,125] and 9,9,10-tri-(*p*-X-phenyl)phenanthrenium[200] ions as well as for the 1,2-shifts of halogen atoms in 1-chloro-1,2,3,4,5,6-hexamethylbenzenium (**71a**)[134] and 1-bromo-1,2-dimethylacenaphthylenium (**76**)[137] cations (see Table 4). The rate of the 1,2-shift of the $AlCl_3^-$ group in the ion **62** is also virtually unchanged on going from CH_2Cl_2 to $CHCl_2CHCl_2$.[126]

The lack of influence of the medium on the rates of the 1,2-shifts in the π-delocalised carbocations considered above is probably due to the fact that the location of the 'centre of gravity' of the positive charge on the cation varies only slightly on going from the ground state to the transition state.[21]



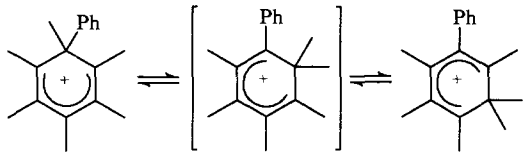
As would be expected, in the case of migrants susceptible to specific solvation the influence of the medium on the rates of rearrangements becomes dominant. For example, the rate of the degenerate rearrangement of the 1-nitro-1,2,3,4,5,6-hexamethylbenzenium ion (**64a**) in the $HSO_3F-SbF_5-SO_2ClF$ system, which occurs via the 1,2-shift of the nitro group, decreases as the concentration of SbF_5 increases.[129] Similar effects have been observed for OH,[130] OMe,[132] and Alk–OCO [201] groups (see Ref. 202). It is likely that in these cases, owing to specific solvation of the migrant by the medium, the magnitude of the positive charge on the migrant increases and this leads to a diminution of the rate of rearrangement.

In view of the data considered above, the problem of controlling the rates of 1,2-shifts of migrants by using ordered media is of great interest. The first attempts along these lines were undertaken by Borodkin et al.,[203] who studied the rearrangement of the 1,1-dimethyl-2-ethyl-acenaphthylenium ion to the 1-ethyl-1,2-dimethylacenaphthylenium cation (**43**). However, it was found that the rate of this rearrangement virtually does not change on going from liquid to frozen CF_3SO_3H as the solvent. Later it was shown[204] by CPMAS ^{13}C NMR that the rates of hydride shifts in norbornyl and 2-butyl cations are also almost insensitive to the change in the phase state of solutions in SbF_5 (see Ref. 205).

Data on the strong influence of an ordered medium on the rates of 1,2-shifts in cationic σ-complexes were obtained for the first time for the crystalline tetrachloroaluminate of the hexamethylbenzenium ion.[93] The values of the kinetic parameters (E_a, lg*A*) of the 1,2-shift of the methyl group in this cation in the crystalline state were found to be appreciably lower than those in solution (see Table 2). At −77 °C an isokinetic point was observed and at higher temperatures the rate constants of the rearrangement were larger in the case of the liquid phase. Variation of the counter-ions in crystalline heptamethylbenzenium salts ($AlCl_4^-$, BF_4^-, BPh_4^-, $SbCl_6^-$) results in strong changes in both the kinetic parameters (see Table 2) and the rate of the 1,2-shift of the methyl group.[95] Unexpectedly, the intramolecular rearrangement of the $SbCl_6^-$ salt of this ion accelerates on going from solution to the crystalline state (see Table 2).[94,95] This fact and also the decrease in the activation energy found in some other cases are probably due to the Coulomb interaction of the neighbouring counter-ions with the rearranging ion, in particular, the stabilising interaction of the neighbouring anion with the methyl group which carries a partial positive charge in the transition state.[93,95] This is confirmed by the existence of linear correlations of the logarithms of the ratios between the rate constants of the 1,2-shifts of Me and Ph migrants in the ions **35** and **56a** in the crystalline phase and in solution with the values of the difference between the energies of Coulomb interaction of the rearranging ion with their environment in the ground and the transition states.[95] Considerable retardation of the carbocation rearrangements on going from solution to the crystalline state has been found for the tetrachloroaluminate of 1-phenyl-1,2,3,4,5,6-hexamethylbenzenium ion[119] (**56a**, see Table 2).

In the crystalline state the rearrangements of 1-R_m-1,2,3,4,5,6-hexamethylbenzenium ions (R_m = Me, Ph) are degenerate rearrangements as regards both the structure of the ion and the environment, i.e. the rearranging ion preserves its topochemical properties after each act of migration of the R_m group.[206] These rearrangements may be referred to as 'topodegenerate'. Another type of solid-state carbocationic rearrangement, which is degenerate as regards the structure of the ion but nondegenerate as regards the environment ('topo-nondegenerate' rearrangement), has been found in a study of the crystalline tetrachloroaluminate of the 1,1,2-trimethylacenaphthylenium ion (**38**)[99] by the radioactive tracer method. The 1,2-shift of methyl in this ion leads to a structure that is formally identical to the original one (Scheme 4),‡ but has a distorted unit cell. The rate of the rearrangement of ion **38** in the crystalline state is appreciably lower than in solution (see Table 2), which is obviously due to the fact that the structure of ion **38′** does not correspond to the unit cell.

Scheme 4



38 **38′**

‡ The vertical line in Scheme 4 conventionally denotes the dissimilar environments of ions **38** and **38′** in the crystal.

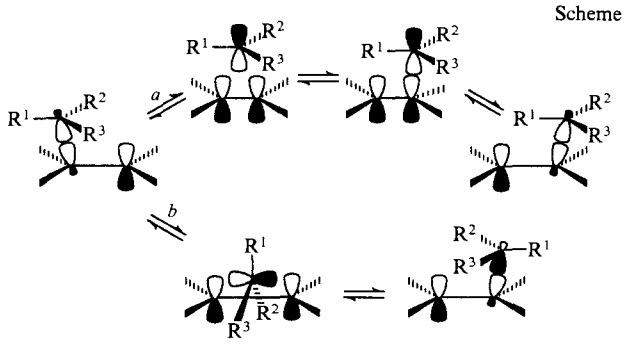
One might expect that similar retardation effects would be seen in the case of carbocationic rearrangements that are non-degenerate with respect to both the ion structure and the environment. In fact, the nondegenerate rearrangement of ion **56a** occurring in solution via a 1,2-shift of the methyl group (Scheme 5),[118] does not proceed in the crystalline state to any noticeable degree even under very rigorous conditions (70 °C, 2 h).[119]

Scheme 5

56a

Thus, the selectivity of the process (the k^{Ph}/k^{Me} ratio) increases on passing from solution to the crystalline state.

Surprisingly, the Arrhenius parameters of the rearrangement of heptamethylbenzenium tetrachloroaluminate deposited on Al_2O_3 are intermediate between those found for the reactions in solution and in the crystalline phase (see Table 2).[96] The fact that lg$A$ is larger than in the crystalline state may indicate that this cation possesses a relatively high mobility on the Al_2O_3 surface. By analogy with the crystal-degenerate rearrangement of this ion, the decrease in the activation energy compared with the E_a value for the solution may be caused by the electrostatic interaction of the partial positive charge of the migrant with the nucleophilic centres of alumina and $AlCl_4^-$.



These results show that the transition to ordered or 'partially ordered' media is an effective means of controlling rearrangements in cationic σ-complexes.

4. Stereochemical aspects of cationic σ,σ-rearrangements

The stereochemistry of a migrant is one of the most important aspects of the theory of sigmatropic rearrangements occurring via 1,2-shifts of alkyl or other similar groups. For suprafacial 1,2-shifts of $CR^1R^2R^3$ groups,§ (see Refs 207, 208) the configuration of the C atom bound to R^1, R^2, and R^3 groups can be either retained (Scheme 6, path *a*) or inverted (path *b*).

The stereochemistry of tetragonal migrants involved in 1,2-shifts in 'long-lived' carbocations has been studied for the first time for 1-CH_2R-1,2-dimethylacenaphthylenium ions (R = Me, *p*-ClC_6H_4)[107,114] by an approach based on the fact that the methylene protons are diastereotopic and by using dynamic NMR.[52] A comparison of the rate constants of the rearrangement determined from the variation of the forms of signals of the CH_3 and CH_2R groups showed that they are almost identical. This implies that the 1,2-shifts of C_2H_5 and *p*-$ClC_6H_4CH_2$ groups in ions **43** and **52** occur with retention of the configuration of the methylene C atom, which is consistent with the theory of pericyclic reactions.[207,208]

Scheme 6

§ Antarafacial 1,2-shifts seem to be very unlikely, especially in cyclic systems.[153,207] In a study of degenerate rearrangement of 4,5,9,9,10-pentamethylphenanthrenium ion, it has been found that the 1,2-shift of methyl occurs as a suprafacial process.[103]

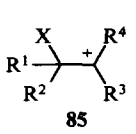
Later similar results were obtained for an ion of a different structural type, i.e. the 9-(3′,5′-dichlorobenzyl)-3,6,9,10-tetramethylphenanthrenium cation (**53e**).[116] Assuming that 1,2-shifts in these ions are one-step processes, one can treat these results as experimental evidence for the Miller[209] postulate concerning the stereospecificity of the elementary step of a chemical reaction.[107]

As in the data obtained for 'long-lived' cations, retention of the configuration at the migrating centre has also been observed in the pinacol–pinacolone[210] and other cationoid rearrangements[211–213] whose key step is the 1,2-shift of a migrant to a carbonium centre.

It is noteworthy that the 1,2-shift of the methyl group in the 1,1,2,3,4-pentamethylcyclobutenyl cation (**34a**) does not occur even under very rigorous conditions ($\Delta G^{\neq} > 27.5$ kcal mol^{-1}),[88,89] though according to the theory of pericyclic reactions, this shift is allowed as a suprafacial process with inversion of the configuration of the migrant.

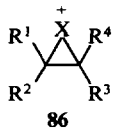
IV. σ,π-Rearrangements

The tendency of cationic σ-complexes to rearrange caused by their 'inherent instability' is closely related to their tendency to form in some cases multicentre migrant—core bonds. Owing to the large deviations of the bond angles from their normal values, the resulting π-complexes are rather strained systems, and the peculiarities of their electronic structures are not adequately characterised by the classical views of the nature of the chemical bond[214] (cf Ref. 35).



84a **84b**

These structures were described for the first time by Dewar[34] in the framework of the method of molecular orbitals. Dewar et al.[35,139] considered the evolution of concepts in the field of the theory of π-complexes. According to the modern views, strong and weak π-complexes are distinguished depending on the ratio between the forward ($\pi-p$) and back (π^*-p) donation.[35] In the case of strong π-complexes (**84a**), the contribution of the forward donation predominates, whereas for weak π-complexes (**84b**), these contributions are comparable.[35] As the electronegativity of the X fragment increases, the role of back donation should diminish.[35,214] The foregoing should be taken into account while considering the relative stabilities of σ- and π-complexes.



According to Dewar and Dougherty,[139] the change in energy on going from a σ- to a π-complex is determined by the following relationship:

$$\Delta E = (E_{C-X} - E_{\pi}) + (E_{C-C} - E_{C=C}),$$

where E_{C-X}, E_{C-C}, and $E_{C=C}$ are the energies of the corresponding bonds and E_{π} is the energy of the bond between the apical group and the core in the π-complex. Despite the fact that the strengths of the C–X bonds in σ- and π-complexes should vary in parallel, the C–X bond in a σ-complex is the stronger and the variation of the E_{C-X} value should be greater than that of E_{π}. Therefore, the stronger the C–X bond, the more stable is the σ-complex. In addition, one might expect that the transition from a σ-complex to a π-complex would lead to an increase in the positive charge on the X fragment.[139] Therefore this transition should be hampered for electronegative groups or atoms X (see Ref. 35). Finally, when X has unshared *p* or *d* electrons, back coordination is possible in the π-complex. The interaction between the occupied AO of the X fragment and the antibonding π-MO will be more effective, the closer their energies. Most of these views are qualitatively confirmed by calculated and experimental data on the relative stabilities of σ- and π-complexes and **85** and **86** (Table 6).

85

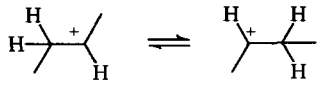
86

As shown in Table 6, those X groups whose central atoms are elements of the third or higher periods and have lower electronegativities and relatively less strong C–X bonds tend to stabilise a π-complex.[215] Depending on the chosen quantum-chemical approximation, the ΔE values are in some cases substantially different. The order of relative stabilities of σ- and π-complexes is indicated somewhat better.

It should be emphasised that experimental data on the relative stabilities of the cationic σ- and π-complexes are scarce and mostly refer to the gaseous phase. The construction of a 'chemical scale' of relative stabilities of σ- and π-complexes based on the data on rearrangements of long-lived carbocations occurring via 1,2-shifts is of great interest. During a 1,2-shift the migrant passes through a π-bonded state, and if the distinctions between the transition state and the π-complex are small (see Refs 44, 218), the $\Delta G^{\neq}_{1,2}$ values should reflect the relative stabilities of σ- and π-complexes. To construct this 'chemical scale', which is essentially a kinetic scale, relationship (8) (obtained for degenerate rearrangements of arenium ions by extrapolating the δC^+ values to the region of carbocations of the aliphatic series) has been used. The $\Delta E_{\sigma,\pi}$ values thus found are in agreement with the experimental and quantum-chemical data on the relative stabilities of σ- and π-complexes (see Table 6). The negative values of $\Delta E_{\sigma,\pi}$ indicate that, for aliphatic systems, π-complexes are more stable than σ-complexes. In fact, stable cyclic cations **86** ($R^1 = R^2 = R^3 = R^4 = H$) with $X^+ = RS^+$,[222] RO^+,[223] Ph^+,[224] I^+, Br^+, Cl^{+2} have been detected experimentally.

Borodkin et al.[225] suggested a similar scale based on 1-R-1,2-dimethylacenaphthylenium ions as model systems and a relationship of type (10).

The relative stabilities of the σ- and π-complexes **85** and **86** are substantially affected by the substituents $R^1 - R^4$ at basal C(1), C(2) atoms. As can be seen from the data of Table 6, the relative stabilities of σ-complexes **85** increase as the number of methyl groups at these atoms increases. Previously it has been noted that the 2,3-dimethyl-2-butyl cation **3a** is an open ion that undergoes a very rapid degenerate rearrangement (see Table 1). As estimates for the gaseous phase have shown, in the of case the ethyl cation the equilibrium *A* (see Scheme 1) is shifted toward the π-complex ($\Delta G^\circ = 0.8 \pm 0.1$ kcal mol^{-1}).[226] This is consistent with the results of high-level ab initio calculations.[170] A similar situation might also be expected for 2-butyl cation (**87**). In fact, the ^{13}C NMR spectrum of ion **87** shows a signal at δ 173.4 ppm (see Ref. 25) corresponding to the C(2) and C(3) atoms; no exchange broadening of this signal has been detected up to −140°C.[54] This gives the upper limit of 2.4 kcal mol^{-1} for the free energy of activation of a hypothetical rearrangement occurring via the 1,2-hydride shift (see Ref. 54).



The application of the CPMAS ^{13}C NMR method yielded the spectrum of the 2-butyl cation in the solid state; no static structure was detected down to −190 °C.[227] Since the rates of intramolecular sigmatropic processes in carbocations normally diminish on going from the liquid to the solid state (cf Ref. 205), the $\Delta G^{\neq}$ value of this rearrangement in solution should apparently be lower than 2.4 kcal mol^{-1}. The chemical shift due to equilibrium **87** ⇄ **87′** averaged, and Et evaluated using the data for 2-propyl- and 2-methyl-2-butyl cations is equal to (320 + 57.5)/2 = 189 ppm, which differs from the observed value (173.4 ppm).[25] This may be accounted for by assuming that bridged structures **88a,b** are involved in the equilibrium, apart from σ-complexes **87**, **87′** (a σ,π-rearrangement). The relatively small value of the isotopic perturbation on replacement of one hydrogen atom in the methyl group by deuterium ($\delta_{-111\,°C}$ = 11 ppm) compared with the corresponding value (22.5 ppm) for the equilibrium of 2,3-dimethyl-2-butyl cations[228] is consistent with this assumption. Nevertheless,

Table 6. Relative energies of isomeric σ- and π-complexes **85**, **86**.

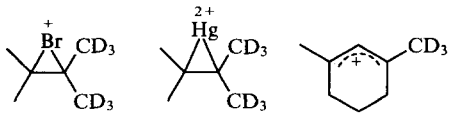
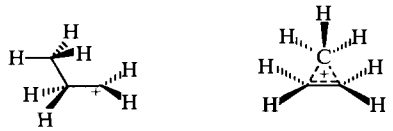
[e] Calculated from Eqn (8) with the value δC^+ = 309.2, obtained from the data for Pr^{i+} cation with allowance for the increment that reflects the replacement of the methyl group by the hydrogen atom.[138] The value for X = H is not presented, since in this case Eqn (8) does not hold. The E_b and (*PA*) values were taken from the literature.[182, 215, 216]



87 87'

88a 88b



the observed δ value for 2-butyl cations is appreciably greater than those detected in the case of the 'isotopic perturbation of resonance' [17,147,229] in structures **89**, **90**,[230] and **91**[185] (1.81, 3.08, and 0.3 ppm, respectively), which contain more 'perturbing' deuterium atoms. According to the evaluation made by Edward,[148] based on the data on isotopic perturbation, the energy of the π-complex **88** is lower by 0.29 – 0.77 kcal mol^{-1} than that of the σ-complex **87**.

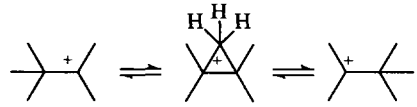
89 90 91

The introduction of more effective electron-donating groups in the core of type **85** carbocations favours an increase in the stability of σ-complexes compared with π-complexes **86**. This is illustrated by the data in Tables 1 and 2.

In conformity with the kinetic scale of relative stabilities of σ- and π-complexes, the methyl group shows a moderate tendency to form bridged structures (see Table 6), therefore one might expect that systems with poor delocalisation of the positive charge in the core would contain appreciable quantities of π-complexes in equilibrium with σ-complexes. Cations of the general formula $C_3H_7^+$ are one of these systems. According to detailed ab initio calculations in the STO-3G basis set with refinements in the STO-4-31G basis set, the difference between the energy of the 1-propyl cation (**92**) and that of the corresponding bridged structure **93** is small (<1 kcal mol^{-1}) and the open structure has a distorted geometry with an unusual C – C – C angle (83.4°). This geometry is favourable to the transition to the bridged ion[231] (see Ref. 232).

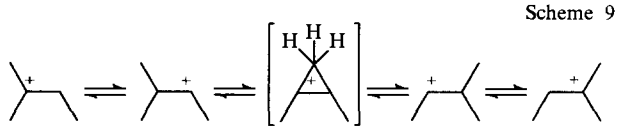
92 93

More recent and rigorous ab initio calculations with allowance for electron correlation (the CTHF method) as well as experimental data for the gaseous phase indicate that the π-complex **93** is more stable than the σ-complex **92** (see Table 6). Experimental data on the relative stability of the σ- and π-complexes under consideration are lacking. However, the results of a study of the isotope distribution of the label in (1,1,1-D_3), (2-D), and (2-^{13}C) enriched isopropyl cations [233,234] suggest easy interconversion of these complexes in accordance with Scheme 7.



Scheme 7

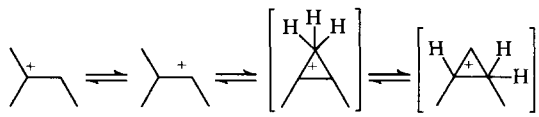
As has been noted above, the 2,3,3-trimethyl-2-butyl cation undergoes a very rapid degenerate rearrangement ($\Delta G^{\neq}_{-136\,°C}$ = 3.8 kcal mol^{-1}),[54] and, according to the data on isotopic perturbation, the proportion of the π-complex existing in equilibrium with it (Scheme 8) is small.[24]



In the case of the 2-methyl-2-butyl cation (**94**), one might expect a situation intermediate between those considered above

Scheme 8

for the 1-propyl and 2,3,3-trimethyl-2-butyl cations. In fact, the ion **94** undergoes degenerate rearrangement via 1,2-H and 1,2-methyl shifts, as shown in Scheme 9, and the activation energy of the rearrangement is 15.3 ± 0.2 kcal mol^{-1}.[196]



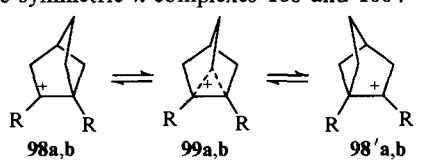
Scheme 9

94 95 96

Taking into account the difference in energy between the tertiary (**94**) and secondary (**95**) ions (10 – 11 kcal mol^{-1}),[27,235] one can infer that the 1,2-shift of the methyl group should occur with an activation energy of less than 5 kcal mol^{-1}, which may be regarded as the upper limit of the relative stability of the σ- and π-complexes **95** and **96**. The assumption that the π-complex **96** is an intermediate rather than a transition state is supported by the following data. At temperatures of >100 °C, 'confusion' of the protons of the CH_3 and CH_2 groups occurs in ion **94**, apart from the above-mentioned rearrangement (E_a = 18.8 ± 1 kcal mol^{-1}).[236] Since the mechanism involving the formation of primary ions is characterised by a higher energy barrier (~ 30 kcal mol^{-1}, see Ref. 24), this rearrangement involves the intermediates **96** and **97**: (Scheme 10).[236]

Scheme 10

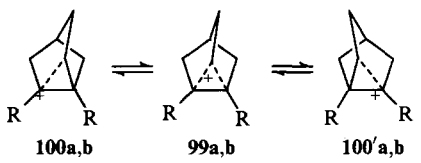
94 95 96 97



In the case of polycyclic carbocations the specific spatial arrangement of their fragments may result in an increase in the stabilities of π-complexes with respect to σ-complexes even in the presence of apical groups with a low tendency to form multi-centre electron-deficient bonds. Systems of the norbornane series, in particular, 2-norbornyl cation, which has been the object of investigation in the series of nonclassical cations for more than 30 years, can serve as examples.[1,7,23,27] As investigations have shown, the 2-norbornyl cation is thermodynamically more stable in the gaseous phase than the secondary aliphatic ions[237] (see Refs 238, 239). Although the numerous quantum-chemical calculations produce contradictory results for this cation (see citations in Ref 240), the most rigorous of these (ab initio 4-21P* with allowance for electron correlation)[240] support the π-complex. The assemblage of data on the ^{1}H and ^{13}C NMR spectra, heats of formation, and effects of the increase in the electron demand and isotopic perturbation obtained for this ion generated in condensed media under 'long lifetime' conditions show its π-complex (nonclassical) nature.[23]

This point of view has been confirmed by the CPMAS ^{13}C NMR data obtained for a frozen solution of 2-norbornyl cation at 5 K.[241] An attempt to interpret these data by invoking the concept of double-well potential and heavy atom tunneling[242] (see Ref. 243) was unsuccessful,[244] since the ^{13}C NMR spectrum of the norbornyl ion did not show the expected splitting of the corresponding signals even at 5 K, and on raising the temperature no broadening of the signals was observed.¶

¶ Recently Kramer and Scouten criticised the concept of a 2-norbornyl cation as a nonclassical ion.[28]

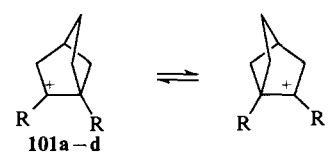


The introduction to the C(1) and C(2) atoms of methyl groups should apparently lead to an increase in the proportion of the σ-complex in equilibrium with the π-complex. The data on the isotopic perturbation for ions **98b** and **99b** ($R = CD_3$) are consistent with this assumption.[147] Taking into account the data from ^1H and ^{13}C NMR spectroscopy (see Ref. 245), one may infer that interconversion of the ions **98**, **98′** proceeds according to either Scheme 11 or Scheme 12 involving interconversions of the symmetric π-complexes **100** and **100′**.

Scheme 11

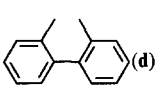
98a,b **99a,b** **98′a,b**

Scheme 12



100a,b **99a,b** **100′a,b**

R = Me (**a**), CD_3 (**b**).

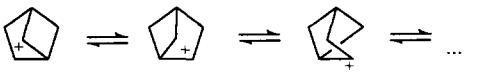


The latter scheme is supported by the results of an X-ray structural study[246] in which the 1,2,4,7-tetramethyl-2-norbornyl cation was shown to be an asymmetric bridged ion with C(1)–C(6) and C(2)–C(6) bond lengths of 1.74 Å and 2.09 Å, respectively. In view of the fact that the mechanisms under consideration differ from one another only in some details of the structures of the interconverting initial cations **98** and **100**, it is difficult at present to choose between these mechanisms.

The addition to the C(1), C(2) atoms of groups more electron-donating than methyl increases the stability of σ-complexes compared with π-complexes. For example, Nickon and Lin[247] have found that the 1,2-dimethoxy-2-norbonyl cation **101a** is classical and undergoes a rapid degenerate rearrangement, in conformity with Scheme 13.

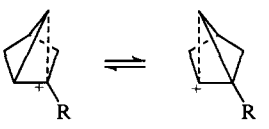
Scheme 13

101a–d



R = MeO (**a**), Ph (**b**), *p*-$MeOC_6H_4$ (**c**), R + R =  (**d**)

A similar situation has been observed for the ions **101b–d** with π-electron delocalisation in the core.[248–251]



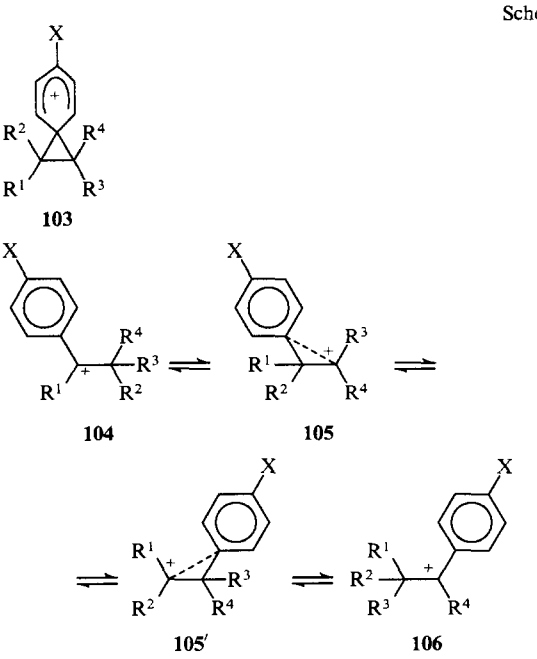
It is of interest to compare the properties of 1,2-R-2-norbornyl ions with those of their closest lower homologues, i.e. 1,2-R-2-bicyclo[2.1.1]hexyl cations. The shortening of the apical group by one unit may lead to a change in the relative proportions of σ- and π-complexes in the equilibrium mixture. The views on the structure of the parent ion of this series, the 2-bicyclo[2.1.1]hexyl cation, have varied and have not yet settled. For example, Seybold et al.[252] who studied the structure of this ion under 'long lifetime' conditions by ^1H NMR, rationalised the results obtained by assuming 'extra fast' equilibrium of nonclassical ions (π-complexes).

MINDO/3 calculations confirmed the bridged structure of the ion.[253] At the same time, analysis of the ^{13}C NMR spectra of 2-bicyclo[2.1.1]hexyl cations[254] and of 2-aryl-2-bicyclo-[2.1.1]hexyl ions[255] (the method of increase in the electron demand) suggested the presence of an equilibrium in which interconverting σ-complexes make the greatest contribution to the averaging of the corresponding NMR signals.

Sorensen and Schmitz[256] attempted to clarify the situation by solving the structure of the 2-bicyclo[2.1.1]hexyl ion. In their opinion, this ion exhibits properties intermediate between those of classical (σ-complexes) and nonclassical (π-complexes) ions, i.e. it is an asymmetric nonclassical ion (asymmetric π-complex) that undergoes degenerate rearrangement:

102a,b **102′a,b**

R = H (**a**), D (**b**).



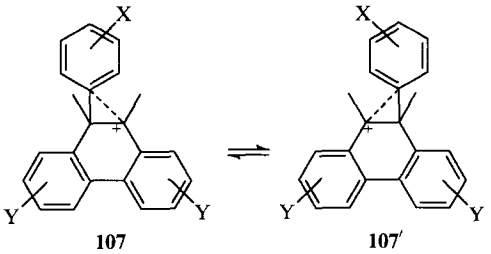
The small magnitude of the isotopic perturbation in the D-analogue of the **102b** ion ($\delta_{-115\,^\circ C}$ = 1.18 ppm)[147] is consistent with this inference.

The introduction of methyl groups in positions 1 and 2 dramatically lowers the π-complex character of the ion, which is shown by the large isotopic perturbation δ on replacing one of these groups by a CD_3 group ($\delta_{-100\,^\circ C}$ = 36.5 ppm).[256] This value is intermediate between those observed for 1,2-dimethyl-2-norbornyl[257] and 1,2-dimethylcyclopentyl cations.[25,257] Thus, the 1,2-dimethyl-2-bicyclo-[2.1.1]hexyl cation is a σ-complex that undergoes very rapid degenerate rearrangement ($\Delta G^{\neq} < 2.8$ kcal mol^{-1}), the relative proportion of the isomeric π-complex in the equilibrium being probably small.

In conformity with the kinetic scale of the relative stabilities of σ- and π-complexes (see Table 6), the phenyl group exhibits a greater tendency to form bridged structures than alkyl groups. The experimental data obtained so far are not inconsistent with this inference. In fact, the ionisation of 2-chloroethylbenzene in superacids affords a π-complex (**103**, X = R^1 = R^2 = R^3 = R^4 = H).[224,258] Ab initio calculations (STO-3G) confirm the greater stability of this complex compared with the β-phenylethyl cation[172] (see Refs 259, 260).

The evaluation of the relative proportions of σ- and π-complexes for the model structures **103** and **104** (Scheme 14) is complicated by the presence of isomeric ions of the benzyl type (**106**). In fact, the ionisation of 2-chloro-3-

Scheme 14



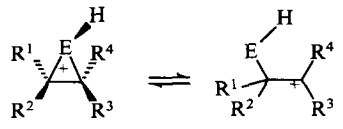
103 **104** **105** **105′** **106**

(*p*-methoxyphenyl)butane in the $HF-SbF_5-SO_2FCl$ system at −78°C affords exclusively 2-(*p*-methoxyphenyl)-2-butyl cations.[261] A similar picture has been observed for 2-chloro-3-phenylbutane.[261] According to the interpretation of Olah et al.,[261] during ionisation of 2-chloro-3-phenyl-2,3-dimethylbutane under these conditions, an equilibrium mixture is formed consisting of an ion of the benzyl type (**104**) and asymmetric π-bridged cations **105** and **105′** that undergo very rapid degenerate rearrangement (see Scheme 14) ($\Delta G^{\neq} < 5$ kcal mol^{-1}). Similarly, ions with substituents X = CF_3, Me, ($R^1 = R^2 = R^3 = R^4$ = Me) are considered to be asymmetric π-bridged structures (**105** and **105′**) existing in a rapid equilibrium with the isomers **104**,[261] (see Ref. 262). The presence of more effective electron-donating substituents X in the phenyl ring (X = MeO) produces the ion **104** of the benzyl type in the SbF_5-SO_2ClF acid system (X = MeO, $R^1 = R^2 = R^3 = R^4$ = Me).[261]

Among the transformations of ions of type **103–106** considered above, the 'extra fast' interconversion of ions **105** ⇄ **105′** is of special interest. The possibility of interaction of the aromatic ring with a carbocationic centre has been shown in a study of the donor-acceptor interaction in 9-(*p*-X-phenyl)-9,10-dimethylphenanthrenium ions (**58**)[263] as well as in 2,7- and 3,6-substituted 9-phenyl-9,10-dimethylphenanthrenium[264] ions. However, the energy of this interaction in the ground state is small, as shown by the low sensitivity of the chemical shift of the C atom carbocationic centre to the effects of substituents X in the XC_6H_4 group[265] and also by the fact that the activation free energies of the rotation barriers of XC_6H_4 groups for substituents with different types of electronic affect (X = Me, Cl, CF_3; $\Delta G^{\neq}_{-100\,°C} = 8.5 \pm 0.1$ kcal mol^{-1}) coincide.[263] The facts that the chemical shifts of the C atoms — carbocationic centres — in 2,7- and 3,6-di-Y-9-R-9,10-dimethylphenanthrenium ions (R = Ph, Me) are close to each other and the difference between them is approximately constant (3–4 ppm) are in agreement with this assumption[102,264] (see Ref. 266).

Although the donor-acceptor interaction in the ground state is weak, the degenerate rearrangements of type **107** ions mentioned above (Scheme 15) can also be considered to be interconversions of asymmetric π-complexes.

Scheme 15



107 **107′**

It is reasonable to assume that owing to the increase in the positive charge on the carbocationic centre on going from ions **107** of the phenanthrene series to cations **105** of the β-arylethyl type, the extent of the donor-acceptor interaction in the ground state increases. This has been confirmed by ab initio calculations, according to which the 3-phenyl-2,3-dimethyl-2-butyl cation has a very distorted geometric structure with an unusually small C(2)–C_{ipso} distance (1.925 Å).[178]

In conformity with the kinetic scale of the relative stabilities of σ- and π-complexes (see Table 6), the migrants EH incorporating Group VI elements E (Scheme 16) show a pronounced tendency to form bridged structures. In the gaseous phase, π-complexes **108a,b** are more stable than isomeric σ-complexes **109a,b**, which is consistent with the data of quantum-chemical calculations (see Table 6).

A number of π-complexes (**108b–e**) have been generated in superacid systems at low temperatures. The oxygen-containing complexes **108c,e** were shown to be converted into the corresponding protonated aldehydes on raising the temperature, apparently via the isomeric σ-complexes **109c,e**.[267] The

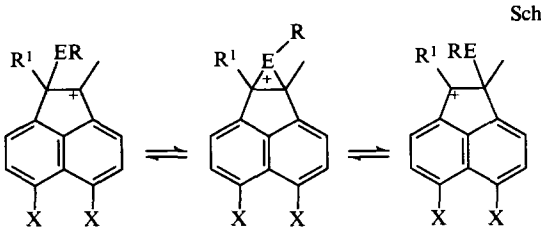
authors cited were not able to isolate the π-complexes **108f,g** with a symmetrical arrangement of R^1-R^4 substituents in the individual state under the conditions studied, since these complexes were rapidly converted into the corresponding protonated ketones.[267] This indirectly indicates that the interconversion of σ- and π-complexes **108f,g** ⇄ **109f,g** occurs readily. The analogous sulfur-centred π-complexes **108** are probably more stable than the corresponding isomeric σ-complexes (see Refs 267, 268). This is shown, in particular, by the fact that the ^1H NMR spectra of solutions of salts of π-complexes **108h,j,k** and **108i** are invariably in the temperature ranges from −50 to −80 °C and from 20 to −110 °C, respectively.[268]

There is little information concerning the interconversion of episulfonium ions and of the σ-complexes isomeric to them (see Refs 269, 270). For example, Vorob'eva et al.[271] discovered interconversion of π-complexes **110a** or **112a** kept in CH_2Cl_2 solutions at ambient temperature for ~1 h, which obviously proceeds via opening of the bridge and formation of the σ-complex **111a** as an intermediate (π,σ-rearrangement) (Scheme 17).

Scheme 17

110a,b **111a,b** **112a,b**



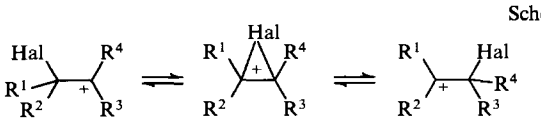
Ar = 2,4-$(O_2N)_2C_6H_3$ (**a**), 4-ClC_6H_4 (**b**).

The cleavage of the episulfonium ring is more difficult for ArS groups containing less electronegative substituents in the aromatic ring. For example, in the case where Ar is *p*-ClC_6H_4, more prolonged storage at ambient temperature (up to 24 h) is required to detect the interconversion shown in Scheme 17. This is probably caused by the fact that the stability of the π-complex relative to that of the σ-complex increases with decrease in the electron-withdrawing ability of the Ar groups.

Borodkin et al.[272] discovered a unique example of interconversion of the episulfonium ion **113f** and of the σ-complexes **114f** and **115f** isomeric to it (Scheme 18, see over).

The extremely high rate of the **113f** ⇄ **115f** interconversion even at −120 °C ($k_{114f \to 113f} \geq 10^8$ s^{-1})[273] implies easy cleavage of the episulfonium rings in the corresponding π-complexes. A similar σ,π-rearrangement has been found for selenium-centred ions at −80 °C: **113n** ⇄ **115n** ($k \geq 10^7$ s^{-1}).[274] The equilibrium between the σ- and π-complexes, **113** ⇄ **115**, is appreciably influenced by the nature of the substituents R, R^1, and X and the element E.[273–275] Analysis of these data resorting to those reported for 1-OR-1,2-dimethylacenaphthylenium ions[130] allowed Borodkin et al.[273–275] to draw the following conclusions:

Scheme 18



114a–s **113a–s** **115a–s**

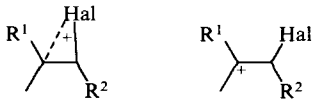
s	Se	C_6F_5	CH_2D	Me

the proportion of the cationic π-complexes **113** in the equilibrium (see Scheme 18) increases with increase in the electron-donating properties of substituents R and R^1, with increase in the atomic number of the central element, and with diminution of the electron-donating properties of the substituents X. Using the **113f** ⇄ **115f** interconversion of the ions as an example, the authors cited showed that equilibria between cationic σ- and π-complexes with π-electron delocalisation in the ion core are not very sensitive to the effects of the medium.[275,276]

According to the kinetic scale of relative stabilities of σ- and π-complexes (see Table 6), the tendency to form bridged ions in the case of the halogen-centred complexes **116–118** (Scheme 19) should increase in the following sequence: F < Cl < Br < I.



Scheme 19

116a–m **117a–m** **118a–m**

	Hal	R^1	R^2	R^3	R^4
a	Cl	H	H	H	H

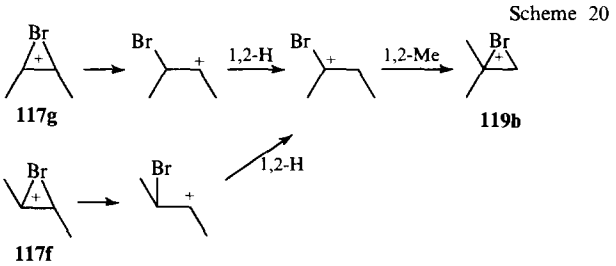
l	I	H	Me	Me	H
m	I	Me	Me	Me	Me

This is supported by the results of quantum-chemical calculations (see Table 6) and also by the ^1H and ^{13}C NMR spectroscopy data for the ions **116–118**.[2] The influence of substituents has been considered in a general form.[2] The vast majority of the spectral data can be accounted for by assuming the existence of static σ- and π-complexes, however some cases do not fit this concept. Indeed, it is difficult to explain large differences between the chemical shifts of C(1) and C(2) atoms for 1-methyl- and 1,1-dimethylethylenebromonium ions by the presence of symmetrical π-complexes of type **117**. As suggested,[2] this indicates either the formation of asymmetric π-complexes **119a,b** or rapid interconversion of these π-complexes and the corresponding σ-complexes **120a,b**.



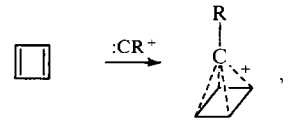
119a–d **120a–d**

	Hal	R^1	R^2
a	Br	H	H
b	Br	Me	H
c	Br	Me	Me
d	Cl	Me	H

This suggestion is supported by the substantial temperature dependence of the chemical shifts of the C(1), C(2) atoms in 1,1-dimethylethylenebromonium ion.[2] A similar interconversion of an asymmetric π-complex and a σ-complex has been suggested in the case of Hal = Br, R^1 = R^2 = Me (**119c** ⇄ **120c**). It is noteworthy that at Hal = Cl, R^1 = Me, R^2 = H, the σ-complex **120d** is more stable than the isomeric π-complex.[2]

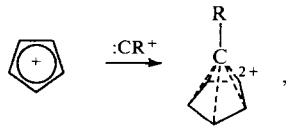
The most probable structures for symmetrically substituted halogenonium ions must be either static symmetrical π-complexes of type **117** or σ-complexes **116**, **118** existing in a dynamic equilibrium with one another. Judging by the ^1H and ^{13}C NMR spectra, *cis*- and *trans*-2,3-dimethylethylenebromonium ions resulting from the action of SbF_5 on *meso*- or *d,l*-dibromobutanes in SO_2 do not undergo rapid interconversion on the NMR time scale. This allowed Olah et al.[2] to assign these structures to π-complexes. A similar situation occurs in the case of 1,2-dimethylethyleneiodonium ion in which the *cis* : *trans* ratio depends on the precursor used to generate the geometric isomers of the ion in a superacid medium.[2] Nevertheless, the π-complexes **117g** and **117f** are slowly converted at −40 °C into the complex **119b**, apparently, according to Scheme 20:[2]

Scheme 20



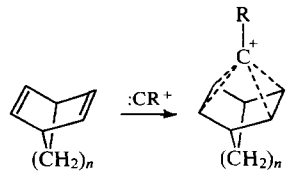
This confirms to the easy cleavage of the bromonium ring in these complexes.

An analysis of the ^{13}C NMR spectra of the tetramethylethylenebromonium ion led Olah et al.[2] to the conclusion that these spectra are inconsistent with a π-complex like **117** or the rapid **116** ⇄ **118** interconversion of σ-complexes. The interconversion of both forms of complexes according to Scheme 19[2,277] is the most likely. However, judging by the small value of isotopic perturbation, (δ = 1.81 ppm),[230] the proportion of σ-complexes **116** and **118** equilibrium with the π-complex **117** is very low.



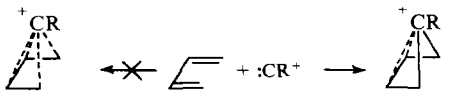
V. π,π-Rearrangements

Carbocations are frequently regarded as a connecting link between organic and organometallic chemistry.[45,278,279] Typical objects for investigation in the latter are π-complexes with multicentre metal-ligand bonds. These bonds are also found in carbocations. 'Long-lived' pyramidal carbocations (π-complexes) in which the coordination number of the carbon atoms can be 5 or more can serve as an example. These π-complexes may be formally regarded as resulting from the interaction of a $:CR^+$ fragment with antiaromatic or other four-electron systems (Scheme 21):[279]

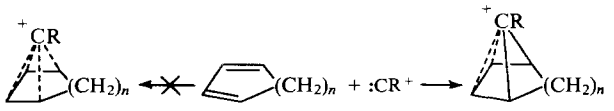


Scheme 21

121

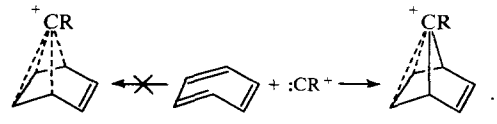


122



123

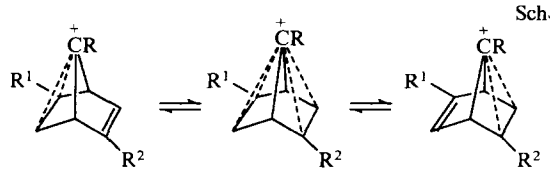
The main feature required for the formal construction of these systems from fragments is the similarity of the MO of these fragments as regards their symmetry.[45] If the four-electron component of the diene is not symmetrical, nonclassical ions of type **124a–c**, rather than pyramidal ions, are more stable (Scheme 22):[278,279]



Scheme 22

124a

124b



124c

Among the latter set of π-complexes, systems of type **124c** are the most interesting, since in these complexes there is a possibility that bonding of the CR^+ fragment 'switches' from one double bond to the other (π,π-rearrangement of the 'flipping' type[23,280]), in accordance to Scheme 23.

The apical atom in structures **126** has 10 electrons, two of which are located in an antibonding MO, which results in destabilisation of this structure.[45] According to MINDO/2 calculations,[281] the symmetrical structure **126a** corresponds to the transition state rather than to an intermediate state, the energy barrier to the π,π-rearrangement **125a** ⇄ **125'a** being rather high (26 kcal mol^{-1}). The theoretical data have been confirmed experimentally[280,282] (see Ref. 283).

Scheme 23

125a–h **126a–h** **125'a–h**

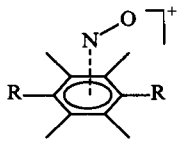
	R	R^1	R^2
a	H	H	H
b	Me	H	H
c	Ph	H	H
d	$HC=CH_2$	H	H
e	OH	H	H
f	OMe	H	H
g	H	Me	H
h	H	H	Me

A kinetic study of the rearrangement of the π-complex **125a** (see Scheme 23) by the radioactive tracer method made it possible to determine the lower limit of the free energy of activation ($\geq$19.6 kcal mol^{-1}).[280] High barriers to π,π-rearrangements are also characteristic of π-complexes **125g** and **125h** (>22.1 kcal mol^{-1} and > 16.6 kcal mol^{-1}, respectively).[280] The introduction in position 7 of a methyl group (π-complex **125b**) leads to a decrease in the activation free energy ($\Delta G^{\neq}_{-14\,°C}$ = 12.4 kcal mol^{-1}),[280] which is obviously due to the larger stabilising effect of this group in the transition state of type **126** compared with that in the ground state. This distinction is probably caused by the greater fraction of the positive charge on the C(7) atom in the symmetrical structure **126**, since, as was mentioned above, the simultaneous interaction of the two double bonds with this atom is unfavourable.

In the case where $R^1 = R^2 = H$ and R = Ph or $CH=CH_2$ rapid interconversion of π-complexes **125** ⇄ **125'** ($\Delta G^{\neq} < 5.2$ and < 8.2 kcal mol^{-1}, respectively) is more likely, whereas the presence in position 7 of a methoxy group having more pronounced electron-donating properties probably results in the formation of the symmetrical π-complex **126f**.[280,284] The latter is consistent with the results of a study of the basicities of 7-substituted norbornene derivatives, where it was shown that the introduction of an OH group in position seven of the 7-norborn-2-enyl cation removes the non-vertical interaction of the carbocationic centre with the double bond.[285]

To draw a parallel between the properties of carbocations and those of organometallic compounds, let us turn our attention to the rearrangements consisting in the migration of a π-bound fragment over a cyclic or open conjugated system. These rearrangements are rather typical of organometallic compounds (see, for example, Ref. 286), however, there is little information on these rearrangements in π-complexes derived from normal (not metal-centred) electrophilic reagents and unsaturated compounds.

Minkin et al.[287] have reported the results of MINDO/3 calculations of the structures of complexes derived from one of the classical electrophilic reagents, i.e. the nitrosonium cation, and benzene, indicating that minima on the potential energy surface correspond to π-complexes **127** and **128**, whereas the top of the hill corresponds to the centrally symmetrical π-complex **129** (see, however, Ref. 288).



127 **128** **129**

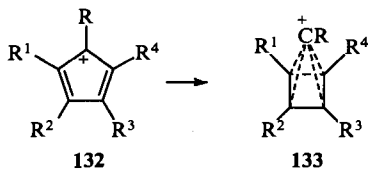
The symmetry of π-complexes **127** and **128** was found to be substantially lower than could have been expected for the gaseous

phase and the solution.[289,290] In the latter case, in view of the isochronism of the protons of the aromatic ring in the ^{1}H NMR spectrum, the centrally symmetrical π-complex structure **129** was attributed to the complex. Although the π-complexes **127** and **128** possess much lower symmetries than the C_{6v} symmetry detected by NMR, this contradiction was eliminated by quantum-chemical calculations which showed that the complexes **127** and **128** can undergo a rapid degenerate rearrangement (with a barrier of < 3 kcal mol^{-1}) through 'sliding' of the NO group over the aromatic ring plane with 'switching' of the C–N bonds.[287]

Recent X-ray structural studies of π-complexes formed from durene[291] or hexamethylbenzene[291] (see Ref. 292) with the nitrosonium cation (with the $AlCl_4^-$ anion) have shown that the traditional view (see Refs 289, 290) that π-complexes of aromatic compounds with electrophilic reagents are highly symmetrical systems should be reconsidered.[47] It was found that the NO group in these complexes is displaced from the centre of the aromatic ring [towards two (2η) or three (3η) carbon atoms] and is arranged at an angle of ~50° with respect to the plane of the ring.

R = H (**130**), Me (**131**)

According to CNDO/2 calculations carried out using the real geometry of the complex **131**, the values of the positive charge on the basal C atoms of the aromatic ring (and on the methyl groups) are appreciably different.[291] Nevertheless, the ^{13}C NMR spectra recorded both for the liquid (HSO_3F–SO_2ClF, −130 °C)[293] and for the solid state (CPMAS spectra)[291] exhibit only two rather narrow singlets. This may be explained by the degenerate π,π-rearrangement of the complex occurring rapidly on the NMR time scale as 'sliding' of the NO group over the plane of the ring or as the rotation of this ring, about a normal to it, involving 'switching' of the C_{arom}–N bonds, and in the crystalline state the latter mechanism is the more likely.

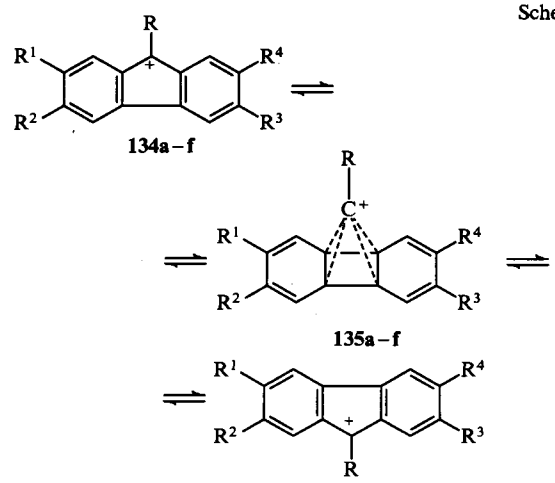


Mefed et al.[293] have studied a polycrystalline specimen of tetrachloroaluminate of complex **131** by relaxation NMR spectroscopy and determined the kinetic parameters of this rearrangement ($E_a = 10.2 \pm 0.6$ kcal mol^{-1}, $\lg A = 13.9 \pm 0.1$ kcal mol^{-1}). As shown by calculations of atomic interactions, the rotation of the hexamethylbenzene ring in the crystalline state should occur more easily ($E_a < 1$ kcal mol^{-1}) than that of the NO group, the latter being tightly clamped by the environment (20 or 150 kcal mol^{-1} depending on the direction of the rotation).

Judging by the NMR spectra, analogous rearrangements via 'sliding' of the NO^+ group over the aromatic ring are also realised in the case of complexes formed from nitrosonium cation and other alkyl-substituted benzene derivatives[292, 294] (see Ref. 295), fluorene,[296] and methyl-substituted naphthalenes.[297,298]

VI. On the possibility of 2-σ,π-rearrangements

The pyramidal cations like **133** can formally result from the rearrangement of cations **132** (Scheme 24) that consists in the cleavage of two σ-bonds to yield a conjugated cyclic π-system reacting with the apical :CR$^+$ fragment (2-σ,π-rearrangement (see Ref. 26).

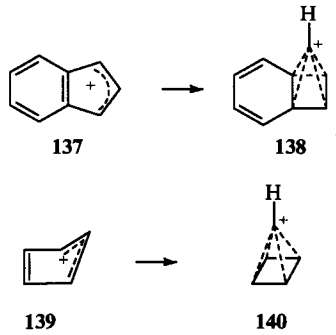


Scheme 24

132 **133**

The possibility of these rearrangements has been verified[299] experimentally for substituted fluorenyl cations **134** (Scheme 25).

Scheme 25



134a–f **135a–f** **136a–f**

	R	R^1	R^2	R^3	R^4
a	Me	D	H	H	H
b	Me	H	D	H	H
c	Me	H	Me	H	H
d	Me	Me	H	H	Me
e	Me	H	Me	Me	H
f	Me	Me	H	Me	H

It was found that the ion **134a** generated in the HSO_3F–SO_2ClF system is not converted into the cation **136b** at −78 °C. Similarly, no 2-σ,π-rearrangement shown in Scheme 25 proceeds in the case of the methyl-substituted fluorenyl ions **134c–f** up to 25°C.

Previously it had been shown that the 9-methyl- and 9-ethylfluorenyl cations are static on the ^{1}H NMR time scale up to −10°C.[194]

The possibility of the degenerate rearrangement of the fluorenyl cation in conformity with Scheme 25 has been studied by MINDO/3.[299] The energy of the pyramidal structure of type **135** was found to be 73.0 kcal mol^{-1} greater than that of the fluorenyl ion. However, the removal of benzoannelation leads to a decrease in the barrier.

137 **138**

139 **140**

Cation	**137**	**138**	**139**	**140**
ΔH_f/kcal mol^{-1}	247.8	296.9	255.3	269.7
	$\Delta\Delta H_f$ = 49.1		$\Delta\Delta H_f$ = 14.4	

The electronic structure of the fluorenyl ions **134** does not correspond to the ion **139**, but is more in agreement with the structure **141**.[299]

141 **140** **139**

We should note that the thermal rearrangement **139** → **140** is symmetry allowed, whereas the transformation **141** → **140** is a disallowed process.[299]

* * *

Thus, the cationic σ,σ-rearrangements have been most extensively studied to date. The σ,π- and π,π-rearrangements still remain poorly investigated. This reflects the fact that in general the chemistry of 'long-lived' π-complexes derived from ordinary electrophilic reagents and unsaturated systems lags behind the chemistry of σ-complexes. However, the number of studies of the structures and dynamics of π-complexes is rapidly increasing. This is because of the need to extend and deepen our theoretical views of the processes involving cationic π-complexes as well as to use the knowledge of their properties for developing methods of controlling organic reactions.

The review has been written with the financial support of the Russian Fundamental Research Fund (Grant No. 93-03-47159) and the International Scientific Fund (Grant No. NQO 000).

Abstract. Data on nontraditional complex formation reactions in iron(II, III), cobalt(II), cobalt(III), nickel(II), and copper(II) hexacyanoferrate(II) gelatin-immobilised matrices with fixation of the immobilised substances by intermolecular forces are surveyed and described systematically. Such reactions proceed when the matrices come into contact with aqueous solutions of nitrogen-, oxygen-, and sulfur-containing polydentate ligands. The practical possibilities for complex formation reactions in metal hexacyanoferrate(II) gelatin-immobilised matrices are demonstrated. The bibliography includes 147 references.

I. Introduction

Investigators in the field of coordination chemistry have shown in recent years an increased interest in metal–ion ligand systems in which the initial complex formation conditions differ significantly from those in solutions and in the solid phase. One of the most promising aspects is the study of complex formation in the so called metal-containing immobilised matrix systems where the initial chemical compounds and the products formed in the process are more or less rigidly fixed in the bulk of a polymer. Theoretically it is possible to represent two types of immobilisation of the substance: via the functional groups of the polymer or as a result of the operation of intermolecular forces.

In the former case, the corresponding polymers must contain structural fragments capable of binding the metal ions chemically to the polymer; the type of the metal–polymer bonds formed under these conditions (ionic, covalent, etc. bonds) is determined exclusively by the nature of the reactants.[1]

The second version presupposes a kind of 'fixation' of the immobilised substance as a result of dispersion, orientation, inductive, and other similar types of interaction. The 'fixation' requires only the presence of a large surface of the polymer. This type of immobilisation can be achieved via operations such as dispersion, adsorption, or precipitation of the substance in the polymer layer, sputtering, impregnation etc.[1]

Uspekhi Khimii **64** (7) 704–720 (1995); translated by A K Grzybowski

Naturally, there is also the possibility of an intermediate version where the 'fixation' as a result of the above types of interaction is accompanied also by the formation of fairly strong chemical bonds between the metal ions and the polymer molecules. The preparation of immobilised matrix systems of the first of the above types has promoted progress primarily in the field of metal complex catalysis; two parallel scientific fields began to develop simultaneously in this direction — immobilisation of coordination compounds on inorganic and organic bulk phase polymers.[1–5] Metal complex catalysis and organic synthetic reactions on polymer supports closely related to it[6–9] remain the main 'users' of the immobilised metal-containing matrix systems,[3] although to be fair one has to note that the range of their applications and their potential possibilities are much greater.[10–19] The extensive use of such systems has stimulated a series of specialised conferences during the last decade on problems of the synthesis and application of immobilised matrix systems.[20–23] The proceedings of these scientific forums constitute the contents of special issues of journals such as the *Journal of Molecular Catalysis* [**11**, 1, 2 (1981)] and the *British Polymer Journal* [**16**, 4 (1984)].

Analysis of the literature data makes it possible to claim that on the whole the immobilised matrix systems of the first type and the complex formation processes in them have by now been already fairly well investigated; at any rate, a whole series of monographs and review articles have been devoted to them and a list of these may be found, in particular, in Pomogailo's book.[1] On the other hand, complex formation in metal-containing immobilised matrices with fixation of the substance by intermolecular forces as well as the matrix systems themselves have not so far attracted any serious attention by investigators. The aim of the present review is to fill the existing gap to some extent.

II. Metal hexacyanoferrate(II) gelatin-immobilised matrices

The nature of both the polymer binder (which may influence significantly the selectivity of the complex formation reaction and the morphology of the reaction products) and of the immobilised chemical compound itself is of fundamental importance for the achievement and subsequent investigation of complex formation under the specific conditions created when chemical reactions take place in immobilised metal-containing matrices, where the substance is attached via intermolecular forces. The screening

which we carried out of natural and synthetic polymers in the immobilised substances showed that a low-molecular-mass polypeptide, namely gelatin, which is distinguished by the isotropic nature of its physicomechanical characteristics, transparency, hydrophilicity, and plasticity, is most suitable for the solution of the above problem. Among immobilised substances, preference should be given to 3*d* metal hexacyanoferrates(II) (MHCF), which successfully combine rigidity of attachment to the polymer, optimum kinetic lability, stability, and extremely low solubility in water.[24] Typical examples of such matrix systems are hexacyanoferrate(II) gelatin-immobilised matrices (MHCF-GIM), where iron(III), cobalt(II, III), nickel(II), and copper(II) hexacyanoferrates(II) are most often employed. In such matrices, the complex formation reactions take place as a result of the contact between the matrices and aqueous solutions of chelating ligands.[25]

1. Synthesis and structure

Despite its apparent simplicity, the synthesis of the MHCF-GIM is a specific and fairly laborious process.[24] Silver halide gelatin-immobilised matrices (AgHal-GIM), which are none other than the photosensitive emulsions in modern photographic materials, serve as a convenient starting material. Such matrices can be transformed fairly readily into silver-containing GIM, since the size of the silver particles is comparable to that of large clusters. For this purpose, one can employ the development and subsequent fixation processes well known in chemical photographic science and practice.[26-28] In its turn, it is possible to obtain from the silver-containing GIM, by means of specific chemical reactions, immobilised matrix systems with a very wide assortment of metal-containing compounds, retaining at the same time the quasi-molecular dispersity level of their particles which has been achieved for silver-containing GIM. The synthesis of the MHCF-GIM with iron(III), nickel(III), and copper(II) metal ions from the initial silver-containing GIM is carried out in two stages.[25,29-31]

In the first stage, the matrix is treated with a solution containing potassium hexacyanoferrate(III) and the oxalate, citrate, or tartrate complex of the corresponding 3*d* metal ion, as well as an agent for the establishment of the optimum pH in the precipitation of the target metal hexacyanoferrate(II). As a result, MHCF containing the given ion and silver(I) hexacyanoferrate(II) or other silver(I) compounds still less soluble in water, in particular AgCl or AgBr, are precipitated in the gelatin layer of the photographic material.

In the second stage, the GIM obtained are treated with an aqueous solution of sodium thiosulfate, as a result of which $Ag_4[Fe(CN)_6]$ or AgHal is transformed into the readily water-soluble compound $Na_3[Ag(S_2O_3)_2]$, which is removed from the bulk of the polymer to the solution. On decomposition of the polymeric binder in the resulting metal-containing GIM by protolytic enzymes, the complexes $KFe[Fe(CN)_6]$, $Ni_2[Fe(CN)_6]$, and $Cu_2[Fe(CN)_6]$ can be isolated from these matrices.[24] Bearing in mind the factors noted above as well as data on the compositions of the oxalate, citrate, and tartrate complexes of the corresponding 3*d* elements,[32-34] the transformation of the silver-containing GIM into the target iron(III), nickel(II), and copper(II) hexacyanoferrate(II)-GIM can be described with the aid of the following reactions[35]

$$\{2\,AgHal\} + HO\text{-}C_6H_4\text{-}OH + 2\,OH^- \longrightarrow \{2\,Ag\} + HO\text{-}C_6H_4\text{=O} + 2\,Hal^- + H_2O, \quad (1)$$

$$\{Ag + AgHal\} + 2S_2SO_3^{2-} \longrightarrow \{Ag\} + Ag(S_2O_3)_2]^{3-} + Hal^-, \quad (2)$$

$$2Fe_2(HCt)(HTr) + 4\{Ag\} + 4[Fe(CN)_6]^{3-} + 3K^+ \longrightarrow \{3KFe[Fe(CN)_6] + Ag_4[Fe(CN)_6]\} + 2HCt^{3-} + [Fe(HTr)_2]^{3-}, \quad (3)$$

$$\{3KFe[Fe(CN)_6] + Ag_4[Fe(CN)_6]\} + 8S_2O_3^{2-} \longrightarrow \{3KFe[Fe(CN)_6]\} + 4[Ag(S_2O_3)_2]^{3-} + [Fe(CN)_6]^{4-}, \quad (4)$$

$$6[Ni(HCt)_3]^{7-} + \{Ag\} + 4[Fe(CN)_6]^{3-} + 4Cl^- \longrightarrow \{3Ni_2[Fe(CN)_6] + 4AgCl\} + [Fe(CN)_6]^{4-} + 18HCt^{3-}, \quad (5)$$

$$\{3Ni_2[Fe(CN)_6] + 4AgCl\} + 8S_2O_3^{3-} \longrightarrow \{3Ni_2[Fe(CN)_6]\} + 4Ag(S_2O_3)_2]^{3-} + 4Cl^-, \quad (6)$$

$$6[Cu(Ox)_2]^{2-} + 4\{Ag\} + 4[Fe(CN)_6]^{2-} \longrightarrow \{3Cu_2[Fe(CN)_6] + Ag_4[Fe(CN)_6]\} + 12Ox^{2-}, \quad (7)$$

$$\{3Cu_2[Fe(CN)_6] + Ag_4[Fe(CN)_6]\} + 8S_2O_3^{2-} \longrightarrow \{3Cu_2[Fe(CN)_6]\} + 4[Ag(S_2O_3)_2]^{3-} + [Fe(CN)_6]^{4-}, \quad (8)$$

where H_2Ox, H_4Ct, and H_4Tr are oxalic, citric, and tartaric acids respectively, the immobilised chemical compounds being indicated in braces.

The synthesis of the cobalt(II) hexacyanoferrate(II)-GIM is more complex and includes three stages:[35-37]

$$4\{Ag\} + 4[Fe(CN)_6]^{3-} \longrightarrow \{Ag_4[Fe(CN)_6]\} + 3[Fe(CN)_6]^{4-}, \quad (9)$$

$$\{Ag_4[Fe(CN)_6]\} + 2CoCl_2 \longrightarrow \{Co_2[Fe(CN)_6] + 4AgCl\}, \quad (10)$$

$$\{Co_2[Fe(CN)_6] + 4AgCl\} + 8S_2O_3^{2-} \longrightarrow \{Co_2[Fe(CN)_6]\} + 4[Ag(S_2O_3)_2]^{3-} + 4Cl^-. \quad (11)$$

As regards cobalt(III) hexacyanoferrate(II) matrices, the nature of the immobilised substance contained in them still cannot be regarded as finally established. It has been suggested that the compound present in the GIM is the simple cobalt(III) hexacyanoferrate(II) $Co_4[Fe(CN)_6]_3$,[24,35,38] but the latest data indicate that $KCo[Fe(CN)_6]$ should be regarded as a more probable compound. This compound is diamagnetic,[24] which indicates the presence in the latter of Fe(II) and Co(III) ions in an octahedral environment of CN-ligands with O_h symmetry. This complex should be considered as a kind of intermediate between $KCo^{III}[Fe^{II}(CN)_6]$ and $KFe^{II}[Co^{III}(CN)_6]$. Like the $KFe[Fe(CN)_6]$, $Ni_2[Fe(CN)_6]$ or $Cu_2[Fe(CN)_6]$-GIM, the KCo.[Fe(CN)$_6$]-containing GIM may be synthesised from silver-containing gelatin-immobilised matrices in a two-stage treatment in accordance with the equations

$$3[Co(HCt)_2]^{3-} + 4\{Ag\} + 4[Fe(CN)_6]^{3-} + 4Cl^- + 3K^+ \longrightarrow \{3KCo[Fe(CN)_6] + 4AgCl\} + 6HCt^{3-} + [Fe(CN)_6]^{4-}, \quad (12)$$

$$\{3KCo[Fe(CN)_6] + 4AgCl\} + 8S_2O_3^{2-} \longrightarrow \{3KCo[Fe(CN)_6]\} + 4[Ag(S_2O_3)_2]^{3-} + 4Cl^-. \quad (13)$$

The technological processes involving the preparation of the target MHCF-GIM and the compositions of the solutions with which the system was treated in each of the stages have been described in detail.[39-84]

It is known that, in terms of its chemical nature, gelatin is a polydisperse mixture of low-molecular-mass polypeptides ($M = 50\,000 - 70\,000$) and their aggregates ($M = 200\,000 - 300\,000$).[27,28,85,86] According to the literature,[87,88] gelatin molecules consist of three α-type polypeptide chains with almost identical molecular masses, two α-chains being usually almost identical as regards the set and sequence of the aminoacids (α1-chains), while the third (the α2-chain) differs in this respect from the other two. A structure has been proposed for such molecules,[89,90] in which a left-handed helical structure of the α-type was attributed to each polypeptide chain. Within the framework of such a structure, all three helices are 'plaited' with one another to form a single 'right-handed' helix, hydrogen bonds playing a significant role in the stabilisation, as was to be expected.[87] The α2-chains are characterised overall by the same set of polypeptide fragments as the α1-chains, but their aminoacid sequence contains fewer aminoacids such as proline, hydroxyproline, and lysine, the predominating aminoacids being tyrosine, valine, leucine, isoleucine, histidine, and hydroxylysine.[28]

The sequence of the peptide fragments in the α1-chains with more than 700 aminoacid residues has now been fully elucidated.[27,28] It is of interest that, in contrast to other proteins, where no common features in the alternation of the aminoacids in the peptide fragments have been found, in gelatin, starting with the 17th residue, glycine invariably occupies each third position, so that the overall formula of the polypeptide units in the α1-chain can be written in the form Gly–X–Y, where Gly = glycine, while X and Y are other aminoacid residues. The glycine–proline–hydroxyproline combination is most frequently encountered.[27] The sequence of the aminoacid residues in the α2-chain has still not been accurately established.[28]

Like other proteins, gelatin is an ampholyte because it includes 'free' acid and basic groups (i.e. groups which can be titrated in aqueous solution) such as the β-carboxy-group of aspartic acid, the β-carboxy-group of glutamic acid, the β-imidazolyl group of histidine, the ε-amino-group of lysine, the δ-guanidino-group of arginine, and the phenolic hydroxy-group of tyrosine.[27,28] Their nitrogen and oxygen atoms can play the role of donor centres in relation to various *d* element ions, but, overall, gelatin is a fairly weak complex-forming agent.[27,28]

The present author's electron microscope studies of the MHCF-GIM classified above have shown that all these matrices are transparent to the electron flux and hence the particles of the immobilised MHCF attain a quasi-molecular level of dispersity. They can therefore be regarded as coordination polymers with a relatively low molecular mass and a fairly regular structure, being located in the cavities between the polypeptide units of the gelatin molecules.[35] Such polymers have a face-centred lattice with the *Fm*3 or the *Fm*3*m* symmetry space group and unit cell dimensions of 9.93 Å (Co), 10.18 Å (Ni), and 10.03 Å (Cu).[91] The coordination number (C. N.) of Fe(II) is 6 and an octahedral envirnonment comprising the CN-groups is characteristic of this ion. The ions of the other 3*d* element in the MHCF have coordination numbers of 4 and 6 (tetrahedral and octahedral environments).

Quantum-chemical calculations for the CN^- ions have shown that the electron density on the carbon atom is almost three times greater than on the nitrogen atom,[92] so that the carbon atom is a harder donor centre than nitrogen. Since Fe(II) is a harder Pearson acid than Co(II), Ni(II), and Cu(II) (their orbital electronegativities in solution are +0.69, +0.52, +0.29, and −0.55 eV respectively)[93] and exhibit a lower affinity for nitrogen, the Fe–CN–M (M = Co, Ni, Cu) structural fragments are formed. Similar group of atoms arise also in the complex $KCo[Fe(CN)]$ or $Co_4[Fe(CN)]_3$ because the affinity of Co(III) for nitrogen is much higher than that of Fe(II), while the affinity of Fe(II) for carbon greatly exceeds the affinity of Co(III) for this element. Some of the iron atoms in $KFe[Fe(CN)]$ are coordinated via the carbon atom, whilst others are coordinated via the nitrogen atom, so that the Fe–CN–Fe groups are produced.[91] Thus, in all the MHCF coordination polymers considered here, iron is coordinated to the cyano-group via the carbon atom, whilst all other *d* elements are coordinated via the nitrogen atom.[92]

The elastic properties of bulk-phase gelatin resemble those of rubber; this is quite natural for infinite chains formed by long chains of molecules connected by a limited number of cross links.[94] This structure is potentially suitable for the formation of polymer-immobilised matrices because it does not permit the formation of any kind of rigid crystalline blocks and furthermore contains a fairly large number of cells for the reception and subsequent fixation of the molecules of the immobilised substance. When filled with the molecules of the corresponding chemical compund, these cells retain a certain freedom of migration in space. With a polymer of such a structure it is possible, in principle, to obtain immobilised matrices characterised by a fairly uniform distribution of the metal-containing substance in some part of the bulk-phase polymer. Furthermore, such matrices are sterically accessible for the occurrence of diverse chemical processes, in particular complex formation. Gelatin has an extremely high surface area and an extensive system of micropores, so that when it comes into contact with any kind of aqueous solution the permeation of both the solvent molecules and of the solute into the bulk-phase polymer is as a rule ensured comparatively readily.[27,28]

2. Specific features of the complex formation reactions

Taking into account the entire set of data concerning gelatin as a polymeric material and also the topography of the immobilised matrix system obtained on its basis, one can discern the following features of complex formation reactions occurring in these systems:[24,35] hindered contacts between the reactants; the presence of a charge on the polymer molecules in contact with the ligand solution because gelatin is an ampholyte; an extremely small reaction volume in which the complex formation process takes place; limited mobility of the complex-forming agent [i.e. of the immobilised metal hexacyanoferrate(II)]; a low rate of 'supply' of the ligand to the bulk-phase polymer; the nonequilibrium nature of the complex formation process.

The above factors make it possible to predict the preferential formation and accumulation in the GIM of the following coordination compounds which are not characteristic of complex formation in solution and in the solid phase:[24,35] intermediate complex forms, ligand-deficient complexes, coordination dimers and polymers, and chelates with a pronounced deficiency of protons. Complex formation in MHCF-GIM systems should therefore be regarded as a completely specific phenomenon in coordination chemistry, requiring for its description a model different from that of complex formation in solution and in the solid phase.

The methodological foundations of such a model have been considered.[95] Although all the MHCF-GIM–aqueous chelating ligand solution systems are typically heterogeneous, complex formation reactions in them can be regarded, to a satisfactory approximation, as quasi-homogeneous because they take place not at the solid–liquid (matrix–ligand solution) interface but in the bulk phase of the polymer.

The point is that, according to electron microscope data, the hexacyanoferrate(II) in the MHCF-GIM is present in the massive gelatin in the form of a layer 10–20 μm thick, above which there is a layer of gelatin with a thickness ranging from 2 to 15 μm.[35] On this basis, the MHCF-GIM can be regarded as the reaction microvolume present in the solid phase and in contact with the aqueous ligand solution, on the one hand, and as a kind of intermediate state between the solution and the solid phase, on the other. When this matrix comes into contact with an aqueous ligand solution capable of forming with the ion of the metal M

thermodynamically more stable coordination compounds of the hexacyanoferrate complex, the ligand, diffusing in the massive polymer, reacts with M and binds it in the corresponding chelate complex. On the other hand, the iron(II) in the metal hexacyanoferrate(II) coordination polymer is transformed into the kinetically extremely inert and thermodynamically stable anion $[Fe(CN)]^{4-}$, which passes from the MHCF-GIM to the solution in contact with it.

When Fe–CN–M (M = Fe, Co, Ni, Cu) groups are attacked by an alkaline solution of the ligand, their fate is determined by the ratio of the M–N and M–O bond energies. One may predict that, for $E_{M-N} > E_{M-O}$, the metal hexacyanoferrate(II) will prove resistant to the action of the OH^- ions present in the alkaline solutions of the ligands and will enter into a direct interaction with the corresponding ligand. For $E_{M-N} < E_{M-O}$, the M–N bonds will initially dissociate and will be replaced by the M–O bonds, so that the metal ion–ligand interaction in the MHCF-GIM will be preceded by the decomposition of the hexacyanoferrate(II) by the OH^- ions, which will be accompanied by the formation of coordination polymers of the corresponding oxides, oxide hydroxides, and hydroxides with O or OH bridging groups.[24] The version with $E_{M-N} > E_{M-O}$ occurs in the case of the $Ni_2[Fe(CN)]$ and KCo[Fe(CN)] matrices, while that with $E_{M-N} < E_{M-O}$ occurs in the case of KFe[Fe(CN)], $Co_2[Fe(CN)]$, and $Cu_2[Fe(CN)]$ matrices.

It may be expected that, in the first two matrices, interaction between the hexacyanoferrates(II) of the 3*d* elements and moderately soft and soft Pearson bases (the nitrogen-, nitrogen- and oxygen-, and nitrogen-containing ligands considered below are in fact of this kind) is accompanied by the dissociation of the M–NC bonds and the formation of stronger bonds between the metal and the donor centres of the ligand, the Fe–CN bonds being retained under these conditions. When the coordination number of Fe(II) in the structures of the hexacyanoferrates(II) of 3*d* elements is 6, there is no steric hindrance to the formation of the very stable inert anion $[Fe(CN)]^{4-}$ of configuration $t_{2g}(\pi^2_{d_{xy}}\pi^2_{d_{xz}}\pi^2_{d_{yz}})$ and ligand field stabilisation energy (LFSE) equal to $+24D_q$.[91,96] However, in the case of matrix systems with KFe[Fe(CN)], $Co_2[Fe(CN)]$, and $Cu_2[Fe(CN)]$, the hexacyanoferrates(II) interact with the OH^- ion, the process being accompanied by dissociation of M–NC bonds and formation of M–O bonds with retention of the Fe–CN bonds and hence the formation of the anion $[Fe(CN)]^{4-}$.[24,91]

Special studies by the present author showed that gelatin does not interact with any of the (N, O)-, (N, S)-, (O, S)-, and (S, S)-ligands or with any of the hexacyanoferrates(II) of 3*d* elements.[24,35,95,97,98] Furthermore, the complex formation products diffusing from the matrix to the solution also do not interact with any of these ligands or with gelatin. One can therefore claim that the solid–solution interface should not influence complex formation processes occurring in the GIM.[95] Previously it was mentioned that the substance contained in the MHCF-GIM is not located on the surface of the matrix and is not dispersed uniformly throughout the massive polymer, but is, as it were, 'imbedded' at a certain depth. This factor and also the inertness of gelatin to the ligands suggests that the ligand diffusion process is not accompanied by a chemical reaction over the entire path traversed and that the MHCF–ligand interaction occurs only after the ligand 'diffusion path' has been traversed. It has therefore been suggested that complex formation in the MHCF–GIM systems be described in terms of the mathematical procedures of the so called external problem of diffusion kinetics.[24,95,99]

3. Kinetic aspects of the complex formation

The complex formation process in the MHCF–GIM systems can occur theoretically either via an associative mechanism (S_N2) or via a pseudo-dissociative mechanism (S_N1).[24,25,35,95] In the former case, the MHCF is stable towards OH^- ions and the ligand molecules therefore gradually enter the inner sphere of the MHCF coordination polymer and $[Fe(CN)]^{4-}$ is then eliminated; this version occurs on complex formation in the KCo[Fe(CN)]–GIM [25,38] and $Ni_2[Fe(CN)]$–GIM [25,30,96,97] systems. The rate of complex formation is governed by a bimolecular reaction. In the second case, the MHCF present in the matrix undergoes alkaline degradation by the OH^- ions to the corresponding oxide or oxide hydroxide, which are involved in the subsequent reaction between the metal ion and the ligand.

On the one hand, the rate of formation of the oxide or hydroxide depends on the MHCF concentration in the matrix but is independent of the ligand concentration in solution and this reflects the clear analogy with typical dissociative processes. On the other hand, the rate of complex formation proper is in this case also limited by a bimolecular reaction. The mechanism of this version of complex formation in the MHCF–GIM has in fact been referred to as of the 'pseudo-S_N1' type;[25,31] it operates in complex formation reactions in the KFe[Fe(CN)]–GIM [25,29,70] and $Cu_2[Fe(CN)]$–GIM [25,32,76] systems and partly in the $Co_2[Fe(CN)]$–GIM.[37]

The model of complex formation in the MHCF–GIM which combines the mathematical procedures of the external diffusion kinetic problem with the kinetic equations within the framework of the Guldberg–Waage law has been used to analyse the experimental relations

$$D' = f(c_F,\ c_L^0,\ t),$$

where D' is the optical density of the metal chelate GIM, c_F the molar concentration of the MHCF in the matrix, c_L^0 the molar concentration of the ligand in solution, and t the duration of the complex formation reaction.

In the case of an associative mechanism, the set of proposed computational equations is

$$\lg\left(c_F\frac{d\alpha}{dt}\right) = \lg k_1 + m\lg c_F(1-\alpha) + l\lg c_L^0 + l\lg\left[1-\exp\left(-\frac{\Delta t}{Mh^2}\right)\right], \quad (14)$$

$$\lg\left(c_F\frac{d\beta}{dt}\right) = \lg k_2 + p\lg c_F(\alpha-\beta) + q\lg c_L^0 + q\lg\left[1-\exp\left(-\frac{\Delta t}{Mh^2}\right)\right], \quad (15)$$

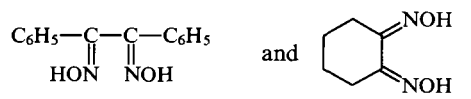
$$\lg\left(c_F\frac{d\omega}{dt}\right) = \lg k_i + y\lg c_F(\psi-\omega) + z\lg c_L^0 + z\lg\left[1-\exp\left(-\frac{\Delta t}{Mh^2}\right)\right]. \quad (1)$$

The following set of equations correspond to a dissociative mechanism:

$$\lg\left(c_F\frac{d\alpha'}{dt}\right) = \lg k_{OH} + m'\lg c_F(1-\alpha') + l'\lg c_L^0 + l'\lg\left[1-\exp\left(-\frac{\delta t}{Mh^2}\right)\right], \quad (17)$$

$$\lg\left(c_F\frac{d\beta'}{dt}\right) = \lg k_1 + p'\lg c_F(\alpha'-\beta') + q'\lg c_L^0 + q'\lg\left[1-\exp\left(-\frac{\Delta t}{Mh^2}\right)\right], \quad (18)$$

$$\lg\left(c_F\frac{d\omega'}{dt}\right) = \lg k_j + y'\lg c_F(\psi'-\omega') + z'\lg c_L^0 + z'\lg\left[1-\exp\left(-\frac{\Delta t}{Mh^2}\right)\right]. \quad (19)$$



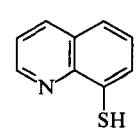
In these equations, k_1, k_2, k_i, and k_j are the rate constants for the consecutive complex formation stages, k_{OH} is the rate constant for the alkaline degradation of the MHCF, *m*, *l*, *p*, *q*, *y*, *z*, *m'*, *l'*, *p'*, *q'*, *y'*, and *z'* are the stoichiometric coefficients in the equations for the complex formation reactions, α' is the degree of accumulation of the hydroxide (or oxide hydroxide) of the corresponding metal ion in the GIM, α, β, ψ, ω, β', ψ', and ω' are the degrees of accumulation of various complexes in the matrix, Δ and δ are the diffusion coefficients of the ligand molecules and OH^- ions for diffusion from the solution to the bulk-phase polymer respectively, *M* is the molecular mass of the ligand, and *h* is the length of the 'diffusion path' traversed by the ligand from the surface of the matrix to the surface of the layer of the MHCF present in it.[35] A program for the computer-mathematical treatment of the experimental relations $D' = f(c_F, c_L^0, t)$ has been compiled with the aid of these equations. It made it possible to calculate the stoichiometric coefficients in the equations for the elementary steps and the overall complex formation processes for a whole series of MHCF-(N), (O), (S), (P)-ligand systems. The theoretical aspects of the kinetics of the complex formation reactions in the MHCF-GIM have been studied in detail.[24,95]

III. Complex formation in the nickel(II) hexacyanoferrate matrix

1. Complex formation in the Ni(II)-(N, O)-ligand systems

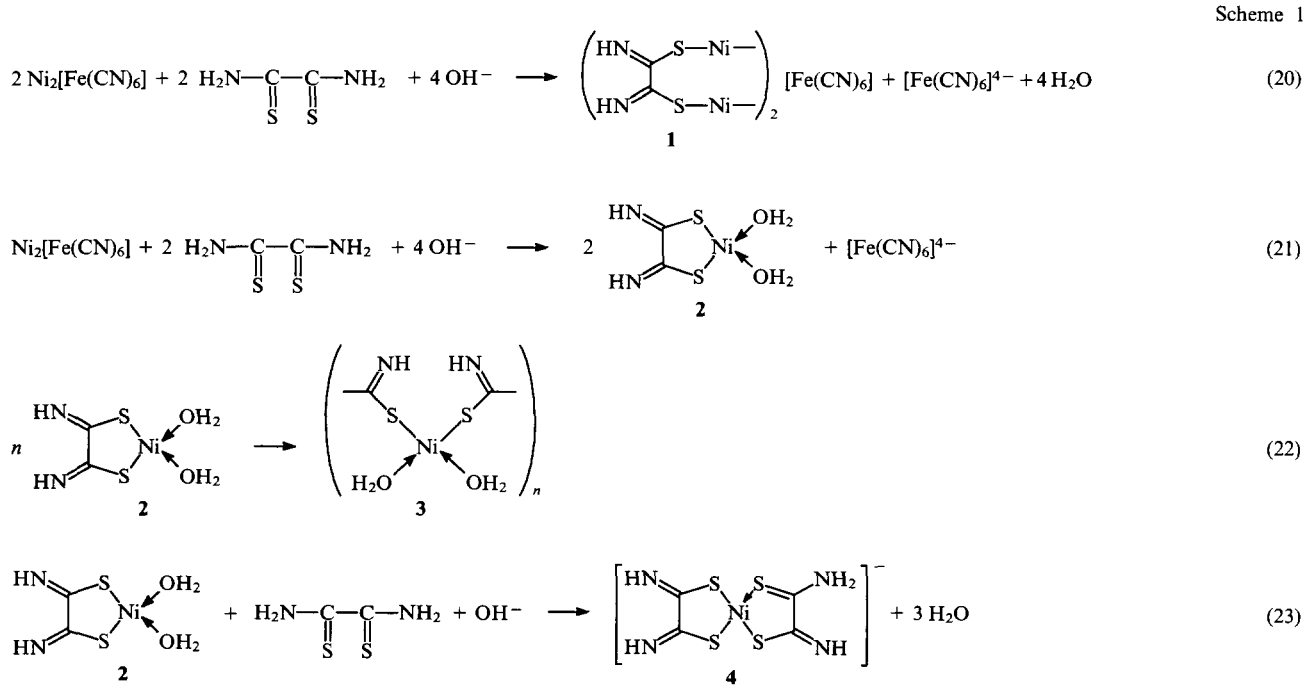
According to the available data,[100-105] nickel(II) forms a fairly large number of sparingly soluble chelate complexes with various (N, O)-ligands. Despite this, there are only isolated instances of their employment for complex formation in the $Ni_2[Fe(CN)_6]$-GIM. The Ni(II)-dimethylglyoxime system has been indisputably characterised in greatest detail among the systems considered.

The study of complex formation in a MHCF-GIM system was first reported by Mikhailov and Polovnyak.[40] The results of their study as well as those of later and detailed investigations[24,35,77] indicate the formation in this system of four different dimethylglyoximate complexes, namely $Ni(HL)_2$ (purple), $NiL(H_2O)_2$ (carmine red), $[Ni(H_2L)]Cl_2$ (yellow-green), and $[Ni(H_2L)_2]Cl_2$ (blue) (H_2L = dimethylglyoxime). In two other systems, containing ligands related to dimethylglyoxime, namely benzil glyoxime [diphenylglyoxime] and nioxime [1,2-cyclohexanedione dioxime]



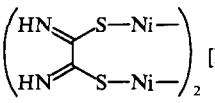
the complex formation processes proceed in approximately the same way as in the Ni(II)-dimethylglyoxime system, as was to be expected. However, the number of coordination compounds formed in this process {$Ni(HL)_2$ and $[Ni(H_2L)_2]Cl_2$} is smaller than in the Ni(II)-dimethylglyoxime system.[24]

The formation of only one complex NiL_2 (L^- = deprotonated form of the ligand) has been detected in the Ni(II)-1-nitroso-2-naphthol, Ni(II)-2-nitroso-1-naphthol, Ni(II)-8-hydroxyquinoline, and Ni(II)-8-hydroxy-5-methylquinoline systems.[24] It is remarkable that the nature of the complex formation in all the systems enumerated remains virtually the same both in aqueous solutions and in the solid phase; the number and compositions of the complex species formed in both cases are the same.[35]



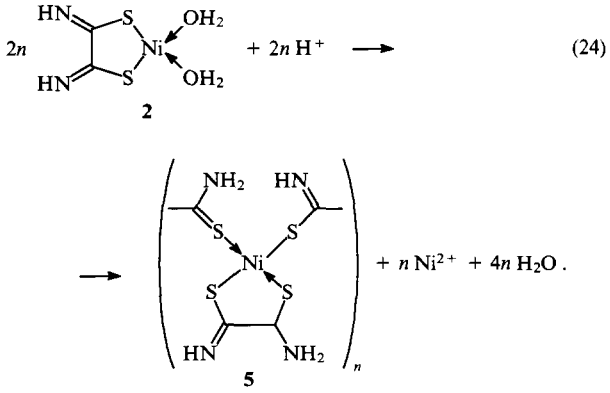
2. Complex formation in the Ni(II)-(N, S)-, (O, S)-, (S, S)-ligand systems

The rule governing the formation of the Ni(II)-ligand complexes in the $Ni_2[Fe(CN)_6]$-GIM system noted above holds also when any kind of (N, S)-, (O, S)-, or (S, S)-ligand capable of giving rise to only one deprotonated species in aqueous solution participates in this process.[24,35] As an example, one may quote 8-mercaptoquinoline



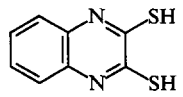
and its alkyl, aryl, and halo-derivatives. A number of studies have been devoted to the formation of complexes in the $Ni_2[Fe(CN)_6]$-GIM with participation of such ligands.[25,30,60,68,74,81] Only coordination compounds having the composition NiL_2, where L^- = singly deprotonated ligands, are formed in the Ni(II)-8-mercaptoquinoline system, exactly as in the systems Ni(II)-alkyl, aryl, and halo-derivatives of 8-mercaptoquinoline (in particular 2-methyl, 5-methyl, 2,7-dimethyl-, 2,4,6-trimethyl-, 5-phenyl-, 6-phenyl-, 5-bromo-, and 5-methylthio-8-mercaptoquinoline) at pH > 9.

Scheme 1



The conclusion reached in the studies quoted above concerning the number and composition of the complex species formed agrees completely with data for complex formation with the 8-mercaptoquinolines listed above in solution and in the solid phase. These are presented in a monograph[106] and in later communications, in particular in Refs 107–109. However, the situation changes significantly when the (N, S)-ligand is capable of forming several species with different degrees of deprotonation, for example HL^- and L^{2-}.[35] In conformity with the prediction made above, in this case ligand- and proton-deficient metal chelates do indeed arise on complex formation in the $Ni_2[Fe(CN)_6]$ matrix. Incidentally many of them have still not been detected in the corresponding Ni(II)–(N, S)-, (O, S)-, (S, S)-donor atom ligand systems in solution and in the solid phase.

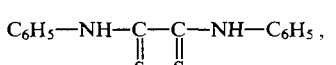
The formation of the complex



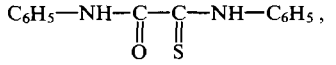
in the $Ni_2[Fe(CN)_6]$–GIM system, considered in detail in a number of investigations,[25,30,40,58,66,69,71,97] constitutes the most striking example. Analysis of relations of the type $D' = f(c_F, c_L^0, t)$ in various coordination regimes in the Ni(II)–dithiooxamide system[25,30,97] shows that the anions $[Fe(CN)_6]^{4-}$ are gradually eliminated from the inner sphere of the $Ni_2[Fe(CN)_6]$-coordinated polymers during complex formation, the process being accompanied by an increase in c_L^0 in accordance with the S_N2 mechanism. The ligand-deficient complex $(Ni_2L)_2[Fe(CN)_6]$ (grey-blue) **1**, the monomeric (complex **2**), the polymeric (complex **3**) proton-deficient complexes $NiL(H_2O)_2$ **2** (pink-violet) and $[NiL(H_2O)_2]_n$ **3** (violet), and a soluble complex having the probable composition $[Ni(L)HL]^-$ **4** with the ratio Ni(II) ion : ligand = 1 : 2, where H_2L = dithiooxamide, are formed in succession under these conditions. According to literature data,[30,97,110] their formation in the GIM can be represented with the aid of Scheme 1 (see previous page).

It is striking that the monomeric chelate is rapidly and irreversibly transformed at pH<5 into the coordination polymer $[Ni(HL)_2]_n$ (dark blue)[30,97,110] in accordance with the scheme

(24)



Thus, in the formation of the Ni(II)–dithiooxamide complexes in the $Ni_2[Fe(CN)_6]$–GIM system, at least five different coordination compounds arise, whereas in solution only one complex, namely $[Ni(HL)_2]_n$, is produced.[111–119] The diversity of coordination compounds arising during complex formation in the Ni(II)–quinoxaline-2,3-dithiol system is somewhat smaller.



Quinoxaline-2,3-dithiol can be regarded as a rigidly structured analogue of dithiooxamide, which is invariably coordinated to Ni(II) via two sulfur atoms.

According to the results of the mathematical analysis of the $D' = f(c_F, c_L^0, t)$ curves and the chemical analysis of the compounds isolated from the corresponding metal chelate GIM, the complexes $(Ni_2L)_2[Fe(CN)_6]$ (orange), $NiL(H_2O)_2$ (pink), and the soluble complex $[NiLHL]^-$ are formed in succession with increase in c_L^0 in the Ni(II)–quinoxaline-2,3-dithiol system, as in the Ni(II)–dithiooxamide system.[30,69,120,121] Like the monomeric chelate $NiL(H_2O)_2$ with dithiooxamide, the chelate $NiL(H_2O)_2$ with quinoxaline-2,3-dithiol is readily transformed at pH < 5 into a 1 : 2 chelate with a singly deprotonated ligand. However, in contrast to the Ni(II)–dithiooxamide system, in this case the conversion of complex **2** into complex **5** is reversible and at pH > 9 the chelate **5** is converted reversibly into $NiL(H_2O)_2$. According to the literature data,[25,30,120] this difference is associated with the fact that the 1 : 2 complex with the HL^- form of quinoxaline-2,3-dithiol is a monomer whereas the chelate, having a similar composition, with the HL^- form of dithiooxamide is a coordination polymer. The formation of the polymeric chelate $[Ni(HL)_2]_n$ with quinoxaline-2,3-dithiol is sterically hindered because the ligand is cumbersome; for the same reason, quinoxaline-2,3-dithiol does not form with Ni(II) the coordination polymer $[NiL(H_2O)_2]_n$ either.[25,35] On the other hand, data[122,127] concerning complex formation in the Ni(II)–quinoxaline-2,3-dithiol system in solution indicate unambiguously the formation of only one coordination compound, namely $Ni(HL)_2$.

All that has been said about the Ni(II)–dithiooxamide and Ni(II)–quinoxaline-2,3-dithiol systems permits the conclusion that, with the aid of complex formation processes in the $Ni_2[Fe(CN)_6]$–GIM systems, it is indeed possible to synthesise many more coordination compounds than in solution or in the solid phase. On the other hand, the complex formation process in the system containing Ni(II) and another cumbersome structural analogue of dithiooxamide, namely *N*,*N*′-diphenyldithiooxamide

results in the formation of only one coordination compound — $Ni(HL)_2$, as in complex formation in solutions.[69,71,98,128] However, when another ligand, namely *N*,*N*′-diphenylthiooxamide

which differs from the preceding one only by the fact that one of its sulfur atoms has been replaced by an oxygen atom, is used in the complex formation process in the nickel(II) hexacyanoferrate(II)–GIM, a much greater number of coordination compounds (namely four) can again be obtained than on complex formation in solution or in the solid phase (one complex).[78,98]

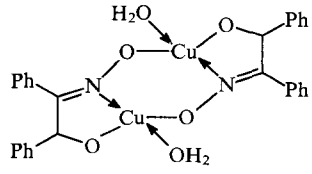
The causes of such a sharp difference in the nature of complex formation in the Ni(II)–(N, O)-ligand and the Ni(II)–(N, S)-, (O, S)-, or (S, S)-ligand systems in the $Ni_2[Fe(CN)_6]$–GIM have been considered.[24,98] The small tendency of the Ni(II) chelates with the HL^- forms of the (N, S)-, (O, S)-, and (S, S)-ligands to split off protons even at high

pH (13 and above) and the fact that (N, S)-, (O, S)-, and (S, S)-ligands of the type H_2L, the proton-donating capacity of which is usually much smaller compared with their (N, O)-analogues even in a highly alkaline medium, generate insufficient amounts of the L^{2-} forms of the ligands for the formation of complexes with Ni(II) were specified as the most important causes. The deficiency of the L^{2-} form prevents the formation of the Ni(II) chelates with this species on complex formation in solution.

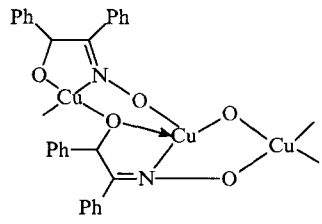
However, the migration of some of the protons from the inner coordination sphere of the Ni(II) chelates with the HL^- forms of the (N, S)-, (O, S)-, and (S, S)-ligands and their binding by the negatively charged gelatin molecules become possible on complex formation in the $Ni_2[Fe(CN)_6]$-GIM system where the molecules of the massive polymers have a negative charge (see Section II, 2).

By virtue of this factor, the possibility of the formation of metal chelates with a pronounced deficiency of protons, which is ruled out in solution and in the solid phase, appears on complex formation in the $Ni_2[Fe(CN)_6]$-GIM system. On the other hand, in the case of the (N, O)-donor atom ligands of the type H_2L, the ligands themselves are capable of generating sufficient amounts of the L^{2-} species for the formation of Ni(II) complexes in a highly alkaline solution. This ensures the possibility of formation in solution of chelates both with the HL^- and L^{2-} species. Therefore in the case of the (N, O)-ligands the formation of any new complex species, which would not be detected on complex formation in the Ni(II)-(N, O)-donor atom ligand systems in solution, is not observed in the $Ni_2[Fe(CN)_6]$-GIM system.[24,77] Thus the study of the complex formation processes in the $Ni_2[Fe(CN)_6]$-GIM has fully confirmed the prediction that ligand-deficient complexes, coordination polymers, and chelates with a pronounced proton deficiency may be formed under these specific conditions.[25,30,97,98,111]

IV. Complex formation in the copper(II) hexacyanoferrate matrix



1. Complex formation in the Cu(II)-(N, O)-ligand systems

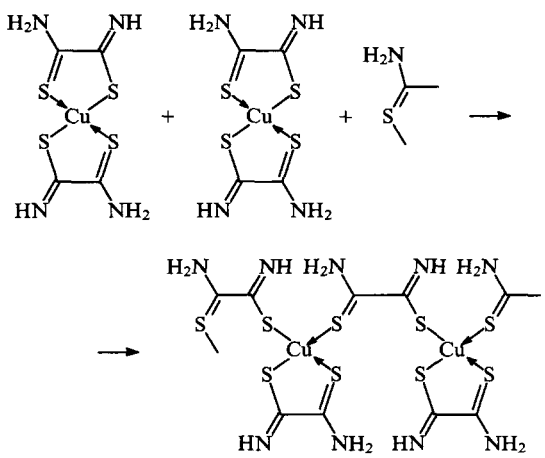


Like Ni(II), Cu(II) belongs to the class of fairly soft Pearson acids.[129] Nevertheless Cu(II) forms an extremely large number of chelate complexes with organic ligands, the donor centres of which are the 'hard' nitrogen and oxygen atoms, in particular with complexones,[96,100,130-132] oximes,[104] 8-hydroxyquinoline, nitrosonaphthols and their substituted derivatives,[105] and Schiff bases.[96,100] Therefore comparison of the possibilities for the formation of Ni(II) and Cu(II) complexes with (N,O)-ligands in the corresponding MHCF-GIM systems is particularly interesting because in the case of the $Ni_2[Fe(CN)_6]$-GIM system the process proceeds via an associative S_N2 mechanism,[25,30] while in the case of the $Cu_2[Fe(CN)_6]$-GIM system it proceeds via a pseudo-dissociative S_N1 mechanism.[25,31] The available literature data on this subject, in particular data concerning the formation of complexes in the Cu(II)-8-hydroxyquinoline, Cu(II)-8-hydroxy-2-methylquinoline, Cu(II)-8-hydroxy-2-methylquinoline,[24,35] and Cu(II)-α-benzoin oxime[24,35,80] systems in the $Cu_2[Fe(CN)_6]$-GIM show that the alkaline degradation of copper(II) hexacyanoferrate(II) take place initially in all cases with its transformation in the first stage into polymeric copper(II) hydroxo-complexes and ultimately into the polymeric hydroxide $[Cu(OH)_2]_n$.

$$\{Cu_2[Fe(CN)_6]\}_n + 2m\,OH^- \longrightarrow \longrightarrow 2[Cu_n(OH)_m]^{(2n+m)+} + n[Fe(CN)_6]^{4-}, \quad (25)$$

$$[Cu_n(OH)_m]^{(2n+m)+} + (2m-n)\,OH^- \longrightarrow [Cu(OH)_2]_n \quad (2)$$

The polymeric copper hydroxide formed as a result of these processes becomes a kind of 'starting area' for the subsequent interaction of copper(II) with the (N, O)-ligands indicated above, which causes the latter to enter the coordination sphere of Cu(II). The validity of processes (25) and (26) is indicated by the results of the mathematical analysis of the corresponding $D' = f(c_F, c_L^0, t)$ kinetic curves in the Cu(II)-(N,O)-ligand systems indicated, according to which for $t < 1$ min the chemical process proceeds without the attachment of ligand molecules to copper(II) ions over the entire range of c_F and c_L^0 investigated. Furthermore, the results of chemical analysis indicate unambiguously that, for $c_L^0 < 10^{-5}$ M and $t < 10$ min, only the polymeric hydroxo-complex $[Cu(OH)_2]_n$ is formed in all these systems in the GIM.[24,35] The clear predominance of the process involving the formation of copper(II) complexes with the ligands compared with the alkaline degradation of the $Cu_2[Fe(CN)_6]$-GIM has been noted only for $c_F < 1.0$ M, $c_L^0 > 1.0 \times 10^{-2}$ M, and $t >$ min.[24,35] In all the Cu(II) systems considered with 8-hydroxyquinoline and its derivatives, it has been possible to establish reliably the existence of only one complex species—CuL_2 (L^- is the deprotonated form of the ligand). In the Cu(II)-α-benzoin oxime system, only one coordination compound is also formed in the $Cu_2[Fe(CN)_6]$-GIM. Judging from the results of elemental analysis, the compound has an empirical formula close to CuL, where L^{2-} is the doubly deprotonated form of the ligand. Either a dimeric structure with two five-membered and one six-membered metallocycles and two coordinated water molecules[80] or a polymeric structure with a three-dimensional macrostructure, incorporating five-membered rings without coordinated water molecules,[24] may be attributed to the compound.



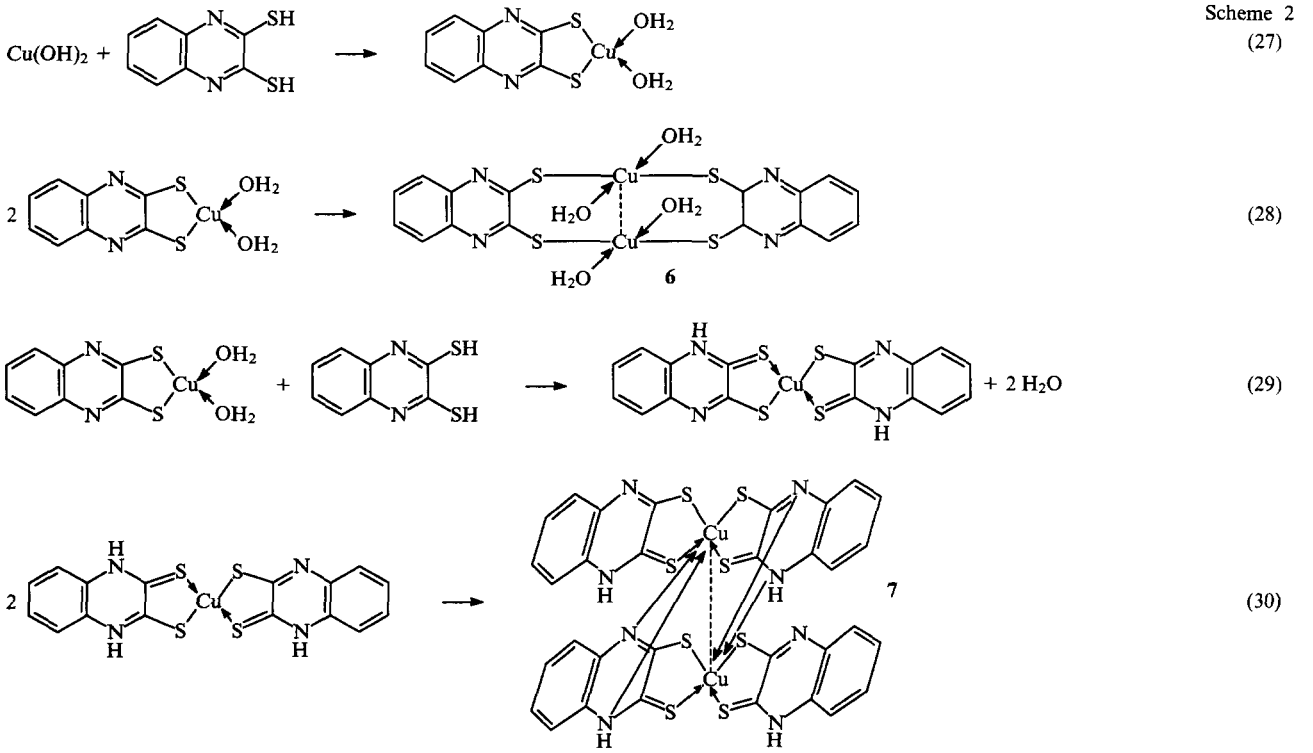
An unambiguous choice between them on the basis of the results of physical research methods is so far impossible. It is remarkable that the ligand in the system inhibits fairly appreciably the alkaline degradation of copper(II) hexacyanoferrate(II).[24,80] If (N, O)-ligands participate in the complex formation process in the $Cu_2[Fe(CN)_6]$-GIM, as in the $Ni_2[Fe(CN)_6]$-GIM, no new coordination compounds unknown for the corresponding Cu(II)-ligand systems in solution or in the solid phase are detected. The possible causes of this phenomenon have been discussed.[24] They resemble the causes discussed for the Ni(II)-(N, O)-donor atom ligand system (see Section III, 2).

2. Complex formation in the Cu(II)-(N, S)-, (O, S)-, (S, S)-ligand systems

The Cu(II)-dithiooxamide system is the most interesting and most thoroughly investigated.[25,31,58,67,72,79,133]

Analysis of the $D' = f(c_F, c_L^0, t)$ kinetic curves in terms of various coordinates[25,31] as well as the results of physicochemical studies of the substances isolated from the corresponding metal chelates matrices[79,133] permitted the conclusion that three coordination compounds are formed in the $Cu_2[Fe(CN)_6]$-GIM system, namely $[CuL(H_2O)_2]_n$,

$[Cu(HL)_2]_n$, and $[Cu(HL)_2(HL)]^-$ (H_2L^- = dithiooxamide), the first two of which are insoluble whilst the third is soluble in water. It is striking that, as for the Cu(II) – (N, O)-ligand systems, in this case complex formation in the $Cu_2[Fe(CN)_6]$ – GIM system involves the initial alkaline degradation of the MHCF in accordance with reactions (25) and (26) and only then does the incorporation of the singly deprotonated form of the ligand (HL^-) in the inner sphere of the copper(II) hydroxide coordination polymer begin.[25,31,79,133] The fact that compounds analogous to $[CuL(H_2O)]_n$ and $[Cu(HL)_2]_n$ are formed also in the complex formation reactions in the Ni(II) – dithiooxamide system is striking (see Section III, 2). According to the literature,[31,133] the monomers $CuL(H_2O)_2$ and $Cu(HL)_2$ arise initially in the Cu(II) – dithiooxamide system and then polymerise as a result of the 'cross-linking' of their molecules. In particular, for $[Cu(HL)_2]_n$ the process takes place in the following way:

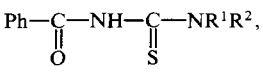


The monomeric intermediates $CuL(H_2O)_2$ and $Cu(HL)_2$ are also formed in the Cu(II) – quinoxaline-2,3-dithiol system, but ultimately the products formed in the matrix are not coordination polymers, as in the Cu(II) – dithiooxamide system, but the dimers $Cu_2L_2(H_2O)_4$ **6** and $Cu_2(HL)_4$ **7**. The diamagnetism of these compounds indicates the presence of a Cu – Cu bond in them.[31] In the case of the $Cu_2L_2(H_2O)_4$ chelate, the appearance of this bond is accompanied by the formation of two additional six-membered chelate rings ensuring a lower ground state energy than in the initial $CuL(H_2O)_2$ monomers. The formation of the dimer $Cu_2(HL)_4$ is promoted by the donor – acceptor interaction of Cu(II) with the nitrogen atoms of the quinoxaline ring, as a result of which the mutual approach of the copper chelate rings (and hence of the copper atoms), accompanied by the $\delta(3d_{xy} - 3d_{xy})$ overlap of the atomic orbitals of the Cu(II) atoms, enables the formation of the metal – metal bond.[24] The formation of the coordination compounds indicated above, based on the present author's data,[24,31] is illustrated in Scheme 2.

We may note that the ν(N – H) band in the IR spectrum of $Cu_2(HL)_4$ occurs at 3380 cm^{-1}, this frequency being characteristic of the N – H groups coordinated around the metal ion.[134] This serves as yet another piece of evidence in support of the dimeric structure of the copper(II) chelate with singly deprotonated quinoxaline-2,3-dithiol and of the presence in the latter of additional weak copper – 'quinoxaline' nitrogen coordinate bonds. It is striking that, for $c_L^0 > 10^{-1}$ M, a third ligand molecule becomes attached to the 1:2 chelates both in the Cu(II) – quinoxaline-2,3-dithiol system and in the Cu(II) – dithiooxamide system considered previously, this being accompanied by the formation of soluble compounds of the type $[Cu(HL)_2(HL)]^-$.[24,31,133] A tetragonal-pyramidal structure, in which two molecules of the ligand are bidentate, their donor atoms being located in the base of the pyramid, whilst the third molecule is monodentate and the sulfur atom coordinated to the metal ion is at the apex of the pyramid, has been postulated for these complexes.[24,133] However, neither chelate accumulates in any appreciable amounts either in the metal chelate GIM or in the solutions of the corresponding ligands in contact with them, so that the mechanism of their formation has still not been investigated in detail.

As can be seen from the foregoing, exactly as in the Cu(II) – dithiooxamide system, complex formation in the $Cu_2[Fe(CN)_6]$ – GIM in the Cu(II) – quinoxaline-2,3-dithiol system results in the formation of three coordination compounds, whereas complex formation reactions in solution or in the solid phase give rise only to chelates with the ratio H : L = 1 : 2.[98,100,102,135,136] However, in the case of the

Scheme 2

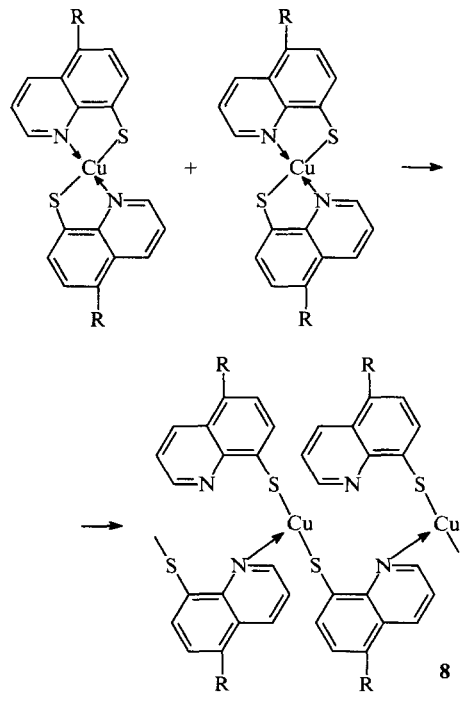


Cu(II)–*N*,*N*′-diphenylthiooxamide and Cu(II)–*N*,*N*′-diphenyldithiooxamide systems, complex formation in the Cu_2.[$Fe(CN)_6$]–GIM leads to the formation of only the paramagnetic monomeric compounds $Cu(HL)_2$, as happens also under the traditional conditions.[31,79] The formation of polymeric complexes of these systems is subject to steric hindrance, as for the analogous system containing Ni(II).[31,79]

The causes of the formation in the Cu(II)–*N*,*N*′-diphenylthiooxamide and Cu(II)–*N*,*N*′-diphenyldithiooxamide systems of the monomers $Cu(HL)_2$ rather than the dimers $Cu_2(HL)_4$ [although both these ligands have, like quinoxaline-2,3-dithiol, electron-donating nitrogen atoms capable of being coordinated to Cu(II) in the complex formation reaction] are not entirely understood. It is most likely that in the monomers $Cu(HL)_2$ free rotation of the phenyl groups about the C–N bonds is possible, which hinders the mutual approach of the planar fragments of these monomeric molecules (particularly when the phenyl groups have rotated by an angle of 90° relative to the plane of the chelate ring). A similar situation arises also in the copper(II) chelate complex of dithiooxamide.[24,133] On the other hand, in the case of the monomeric $Cu(HL)_2$ complex of quinoxaline-2,3-dithiol, the phenylene groups are in the same plane as the metal chelate rings, so that steric hindrance to the mutual approach of the $Cu(HL)_2$ fragments is absent.

The formation of Cu(II) complexes with 1,2-dithiocarbamoylhydrazine and 1-carbamoyl-2-thiocarbamoylhydrazine may serve as yet another piece of evidence for the greater synthetic possibilities of complex formation in MHCF–GIM systems.[31,82] Two Cu(II) complexes have been detected in these systems—an insoluble dimeric complex and a soluble monomeric complex; on the other hand, in solution and in the solid phase only one coordination compound is produced.[100,137] These systems are of interest because with their aid it is possible to obtain nonsilver photographic images, the colour and optical-sensitometric characteristics of which are very close to the corresponding characteristics of the initial black and white silver images on silver halide light-sensitive materials.[82]

A series of new coordination compounds, previously undetected on complex formation under traditional conditions, have been discovered in the complex formation reactions of 3-benzoylthiourea derivatives having the general formula [75,76]



R^1, R^2 = aryl or arylalkyl.

In this connection, it is remarkable that, when the Cu_2[$Fe(CN)_6$]–GIM system is brought into contact with alkaline solutions of 1-naphthyl- and 1-(3,5-di-*tert*-butyl-4-hydroxy)phenetyl-3-benzoylthiourea, neither the formation of Cu(II) complexes with the above organic compounds nor even the alkaline degradation of copper(II) hexacyanoferrate(II) were detected in the systems.[75,76] Clearly the cumbersome nature of these ligands strongly hinders their diffusion into the polymer layer of the matrix and they therefore accumulate at the matrix–solution interface, where they create a kind of 'protecting shell', which in fact prevents the permeation of the OH^- ions into the bulk of the polymer. This phenomenon evidently requires further studies.

Under traditional conditions, the nature of complex formation in the Cu(II)–8-mercaptoquinoline and Ni(II)–8-mercaptoquinoline systems is known to be similar and only one chelate ML_2 (M = Ni, Cu; L^- = deprotonated form of 8-mercaptoquinoline) is formed in both cases.[107] A similar picture is observed also in the complex formation reaction between Ni(II) and 8-mercaptoquinoline in the corresponding metal hexacyanoferrate gelatin-immobilised matrices.[25,31] In the majority of the Cu(II)–alkyl, aryl-, or halo-8-mercaptoquinoline systems, the chelates CuL_2 are also the only products of the complex formation reaction in the MHCF–GIM.[31,35] The few exceptions include the Cu(II)–2-methyl-8-mercaptoquinoline, Cu(II)–2,7-dimethyl-8-mercaptoquinoline, and Cu(II)–2,4,6-trimethyl-8-mercaptoquinoline systems, in which the Cu(II) → Cu(I) redox process occurs, as in complex formation in solution, and hence complexes of the type CuL are formed.

In the Cu(II)–5-bromo-8-mercaptoquinoline and Cu(II)–5-methylthio-8-mercaptoquinoline systems, the formation of the monomeric chelates CuL_2 in the complex formation reaction in MHCF–GIM is accompanied by the formation at fairly high concentrations c_F and c_L^0 (>1.5 M and $>1.5 \times 10^{-2}$ M respectively) of coordination polymers having the same stoichiometric composition, which arise, according to the present author's data,[24] as a result of the 'cross-linking' of the CuL_2 monomers in accordance with the scheme

(31)

R = Br, SMe.

Such a polymer is stable only so long as it is in the reaction space of a matrix having a small volume. On the other hand, when attempts are made to isolate it from the GIM, it instantly depolymerises. However, in a gelatin-immobilised matrix at high concentrations c_F and c_L^0, the association of the CuL_2 monomers in accordance with Scheme (31) is energetically more favourable than the dissociation of the polymer formed in this way into the initial CuL_2 fragments. In contrast to the CuL_2 monomer, the coordination polymer synthesised is not a chelate and its absorption in the visible part of the spectrum is much weaker than that of the monomer. As a result of this, the $D' = f(c_F, c_L^0, t)$ (c_L^0 = const.) relations for the two systems Cu(II)–5-bromo-8-mercaptoquinoline and Cu(II)–5-methylthio-8-mercaptoquinoline systems are much more complex and have distinct maxima.[24]

It is easy to note that steric hindrance to the formation of type **8** polymeric complexes of Cu(II) with various substituted 8-mercaptoquinolines is smallest precisely when the substituent is in the 5-position, so that the formation of these polymers specifically when 5-bromo-8-mercaptoquinoline and 5-methylthio-8-mercaptoquinoline are used in the complex formation

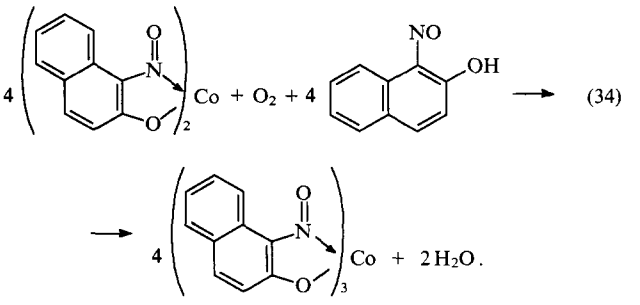
reaction in the $Cu_2[Fe(CN)_6]$–GIM can be fully accounted for. However, the formation of such polymers in the $Cu_2[Fe(CN)_6]$–GIM has not been detected in the Cu(II)–5-chloro-8-mercaptoquinoline and Cu(II)–5,8-dimercaptoquinoline systems, as in the Cu(II)–8-mercaptoquinoline system.[24]

Presumably the absence of the polymers $(CuL_2)_n$ from the first of the above systems is associated with the lower donor capacity of the nitrogen atom in the 5-chloro-8-mercaptoquinoline molecule compared with that of 5-bromo-8-mercaptoquinoline because the chlorine atom is more electronegative and hence has a greater capacity for electron density withdrawal from the nitrogen atom. On the other hand, in 5,8-dimercaptoquinoline the sulfur atom in the 5-thiol group is a more effective electron pair donor than the sulfur atom in the methylthio-group. Because of this, at high concentrations c_F and c_L^0 in the Cu(II)–5,8-dimercaptoquinoline system, the formation of the polymer $[Cu_2L_2(H_2O)_{2n}]$, where L^{2-} is a doubly deprotonated ligand, rather than the $(CuL_2)_n$ coordination polymer indicated by Scheme (31), is more likely.[138]

It follows from the foregoing that, in complex formation reactions in the $Cu_2[Fe(CN)_6]$–GIM systems containing Cu(II) and (N, S)-, (O, S)-, and (N, S)-ligands capable of giving rise to two species differing in the degree of deprotonation, the same tendency towards the formation of coordination compounds with L^{2-} in the inner sphere is observed as in the formation of complexes in the $Ni_2[Fe(CN)_6]^-$–GIM. However, one may note at least two differences. Firstly, the complex formation reaction in the $Cu_2[Fe(CN)_6]$–GIM system proceeds in accordance with a pseudo-S_N1 mechanism and is preceded by the alkaline degradation of copper(II) hexacyanoferrate(II) in accordance with Eqns (25) and (26). For this reason, even before the start of the interaction of Cu(II) with the corresponding (N, O)- or (N, S)-ligand, the $[Fe(CN)_6]^{4-}$ anion is removed from the reaction sphere and does not enter the inner coordination sphere of the Cu(II) complexes formed. A direct consequence of this is the absence from all the Cu(II)–(N, O)-, (N, S)-, (O, S)-, or (S, S)-ligand systems investigated hitherto of 'mixed' complexes of the type $(M_2L)_2[Fe(CN)_6]$, observed in a series of Ni(II)–(N, S)-ligand systems (see Section III, 2). Secondly, the more marked tendency towards the formation of dimeric and polymeric complex species by Cu(II) compared with Ni(II) [92,96,139] is still more pronounced in the complex formation reaction in the MHCF–GIM than in solution or in the solid phase. On the other hand, overall, the data for complex formation in the $Cu_2[Fe(CN)_6]$–GIM confirm primarily the prediction that coordination dimers and polymers may be formed under these specific conditions.[35]

V. Complex formation in cobalt(II) and cobalt(III) hexacyanoferrate matrices

In contrast to nickel and copper, which form stable hexacyanoferrate(II) and stable chelate complexes with specific (N, O)-, (N, S)-, (O, S)-, or (S, S)-donor atom ligands in only one oxidation state (namely the +2 state), cobalt is capable of forming two fairly stable hexacyanoferrate complexes, $Co_2[Fe(CN)_6]$ and $KCo[Fe(CN)_6]$, and fairly stable complexes with the above ligands in which it is present in the +2 and +3 oxidation states. It is therefore useful to examine complex formation reactions in the $Co_2[Fe(CN)_6]$–GIM and $KCo[Fe(CN)_6]$–GIM systems.



1. Complex formation in the Co(II)/Co(III)–(N, O)-ligand systems

Judging from its orbital electronegativity in aqueous solutions (+0.52 eV),[92] Co(II) is a somewhat harder Pearson acid than Ni(II) and Cu(III). Cobalt(II) belongs to the class of hard Pearson acids.[129] Both these ions have a fairly high affinity for nitrogen. They therefore form extremely readily coordination compounds with a fairly large series of (N, O)-donor atom ligands.[96,139] So far, however, more or less detailed data on complex formation in the MHCF–GIM are available only for the Co(II)–1-nitroso-2-naphthol[24,37] and Co(II)–2-nitroso-1-naphthol[24,36,37] systems. When the $Co_2[Fe(CN)_6]$–GIM comes into contact with alkaline solutions of these ligands (pH ≃ 12), the alkaline degradation of cobalt(II) hexacyanoferrate(II) takes place initially in accordance with the equations

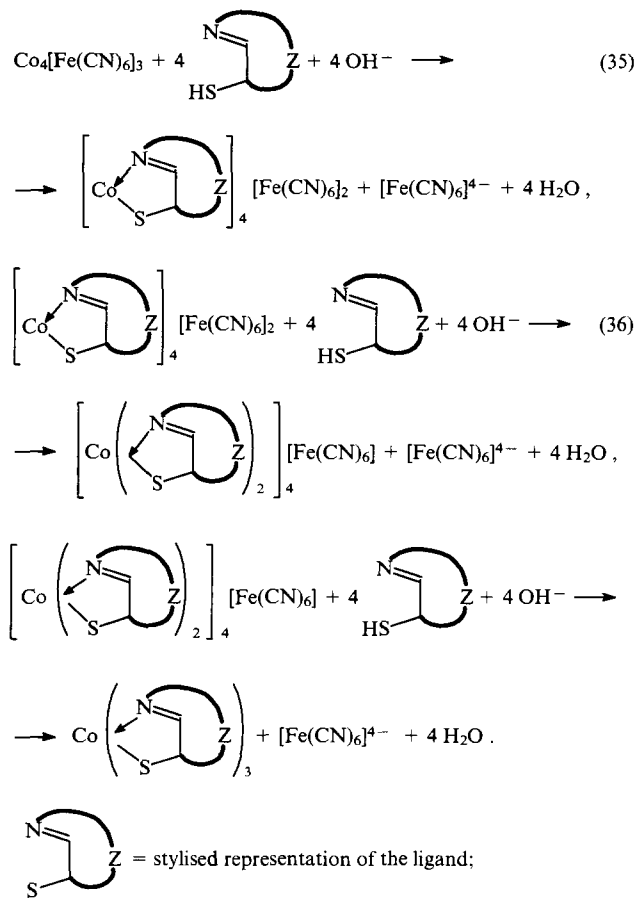
$$\{Co_2[Fe(CN)\ ]\}_n + 2m\,OH^- \longrightarrow \longrightarrow 2[Co_n(OH)_m]^{(2n-m)+} + n[Fe(CN)\ ]^{4-}, \quad (32)$$

$$[Co_n(OH)_m]^{(2n-m)+} + (2m-n)OH^- \longrightarrow [Co(OH)_2]_n. \quad (33)$$

It is easy to see that Eqns (32) and (33) are analogous to Eqns (25) and (26) describing the degradation of $Cu_2[Fe(CN)_6]$ by OH^- ions. Subsequently, the polymeric cobalt(II) hydroxide interacts both with 1-nitroso-2-naphthol and with its isomer 2-nitroso-1-naphthol; the only product is then CoL_2.[24,36,37] It was shown in the studies quoted above that, for $c_F < 0.15$ M, $c_L^0 > 1.0 \times 10^{-2}$ M, and $t \geqslant 10$ min, CoL_2 is partially oxidised by atmospheric oxygen to the corresponding cobalt(III) chelate. In particular, in the case of 1-nitroso-2-naphthol this process proceeds in accordance with the equation[24]

In terms of the nature of the $D' = f(c_F, c_L^0, t)$ relations, the Co(II)–8-hydroxyquinoline and Co(II)–α-benzoin oxime systems are close to the Co(II)–1-nitroso-2-naphthol and 2-nitroso-1-naphthol systems. Similar complex formation reactions probably take place in them.[37] When the $Co_2[Fe(CN)_6]$–GIM system comes into contact with an alkaline solution of dimethylglyoxime, the gelatin layer initially acquires a violet colour, which vanishes after 20 s. According to Mikhailov and Polovnyak,[37] this unusual phenomenon is associated with the oxidation of the dimethylglyoxime chelate $Co(HL)_2$ (violet in colour) formed initially to the corresponding colourless and water-soluble chelate $Co(HL)_3$, which is removed from the matrix when the latter comes into contact with the ligand solution.

In contrast to the Co(II)–(N, O)-ligand systems already considered, complex formation in the $Co_2[Fe(CN)_6]$–GIM has not been detected in any of the Co(III)–(N, O)-ligand systems [where the (N, O)-ligands were 1-nitroso-2-naphthol, 2-nitroso-1-naphthol, 8-hydroxyquinoline, and α-benzoin oxime]. It has been suggested that the reason for this phenomenon arises from the extremely high thermodynamic stability of cobalt(III) hexacyanoferrate(II) and the fact that ligand exchange between the inner sphere of the cobalt(III) hexacyanoferrate(II) coordination polymer and the (N, O)-ligands is difficult.



2. Complex formation in the Co(II)/Co(III)–(N, S)-, (O, S)-, (S, S)-ligand systems

According to the present author's data,[24] the nature of the $D' = f(c_F, c_L^0, t)$ relations in the Co(II)–dithiooxamide, Co(II)–*N,N'*-diphenyldithiooxamide, Co(II)–*N,N'*-diphenyldithiooxamide, Co(II)-quinoxaline-2,3-dithiol, and Co(II)-8-mercaptoquinoline systems for complex formation in the $Co_2[Fe(CN)_6]$–GIM is the same as that discussed above in the Co(II)–(N, O)-donor atom ligand systems. Accordingly, the

alkaline degradation of $Co_2[Fe(CN)_6]$ in accordance with Schemes (32) and (33), the formation of the chelates $Co(HL)_2$ (HL^- is the singly deprotonated ligand), and their subsequent oxidation by atmospheric oxygen to the corresponding chelates $Co(HL)_3$ are observed in all these systems when the $Co_2[Fe(CN)_6]$-matrix comes into contact with solutions of the (N, S)-ligands listed above. However, in contrast to complex formation in the MHCF–GIM in the Co(II)–(N, O)-ligand systems, in the case of the (N, S)-ligands the cobalt(II) complexes are in fact intermediates and do not accumulate in any appreciable amounts in the matrices whatever the values of c_F, c_L^0, and t.[24,35] In this connection, one should note that, according to the results of a whole series of investigations,[116,118,119,127,140,141] the complex formation reactions between cobalt(II) and dithiooxamide, its *N*,*N*′-substituted derivatives, and quinoxaline-2,3-dithiol in solution result in the formation of the chelates $Co(HL)_2$ or CoL_2, which are fairly resistant to oxidation. The fact that the chelates CoL_2 formed in the $Co_2[Fe(CN)_6]$–GIM are detected only as intermediates has been attributed[24] to the high dispersity of cobalt(II) hexacyanoferrate(II) in the matrix and the high concentration of OH^- ions in the system, which increases the probability of the oxidation of Co(II) to Co(III) in the MHCF–GIM compared with solution. As in the $Cu_2[Fe(CN)_6]$–GIM, the complex formation reaction in the $Co_2[Fe(CN_6]$–GIM takes place in accordance with a pseudo-S_N1 mechanisms.[25,35] For the same reasons as in the case of the $Cu_2[Fe(CN)_6]$–GIM, no sphere complexes of any kind with OH^- or $[Fe(CN)_6]^{4-}$ anions arise in the $Co_2[Fe(CN)_6]^-$–GIM on complex formation in the Co(II)–(N, S)-, (O, S)-, and (S, S)-ligand systems.[24,25,35]

As regards complex formation in the Co(III)–(N, S)-, (O, S)-, and (S, S)-ligand systems in the cobalt(III) hexacyanoferrate(II)–GIM, the situation is on the whole much more complex.[25,35] The clearer evidence for this is provided by the complex formation reaction in the Co(III)–dithiooxamide system, which has been investigated in detail.[25,38,65] It was noted that the complex formation in this system proceeds in accordance with an S_N2 mechanism and is accompanied by multistage elimination of the $[Fe(CN)_6]^{4-}$ anion from the inner sphere of the cobalt(III) hexacyanoferrate(II) coordination polymer. This results in gradual complex formation, giving rise to the sparingly soluble chelates $[Co(HL)]_4[Fe(CN)_6]_2$, $[Co(HL)_2]_4[Fe(CN)_6]$, and $Co(HL)_3$ (HL^- is the singly deprotonated ligand). The ratios of these complexes in the matrix depend both on the values of c_F, c_L^0, and t and on the degree of dispersity of elemental silver in the silver-containing matrices from which the cobalt(II) hexacyanoferrate(II) matrices have been obtained.[25,38,65] It is therefore extremely difficult to predict the final result of the complex formation reaction for a particular set of parameters c_F, c_L^0, and t.

The situation is complicated further also by the fact that, at fairly high ligand concentrations in solution and for prolonged contact between the matrix and the solution in the Co(III)–dithiooxamide system, the soluble complex $[Co(HL)_2(HL)_2]^-$ also appears. An octahedral structure of this compound with two monodentate and two bidentate ligand molecules has been postulated.[38] The bidentate molecules are coordinated to Co(III) via the nitrogen and sulfur atoms, while the monodentate ligands are coordinated via the sulfur atoms. Similar sparingly soluble chelates with the metal : ligand = 1 : 1, 1 : 2, and 1 : 3 ratios have been detected also in the Co(III)–*N*,*N*′-diphenylthiooxamide, Co(III)–*N*,*N*′-diphenyldithiooxamide,[25,38] and Co(III)-8-mercaptoquinoline[24,25] systems. According to data of Mikhailov and Budnikov,[25] their formation reactions can be described by the following general equations:

Z = open chain or cyclic group of atoms.

It is noteworthy that that 1 : 1 and 1 : 2 chelates have not been detected in the complex formation reactions in solution and in the solid phase.[106,140] Apart from these types of complexes, the formation of the complex $(Co_2L)_2[Fe(CN)_6]$ in the Co(III)–*N*,*N*′-diphenylthiooxamide system has also been postulated.[38] The following remarkable factor is striking in this connection. As already stated above, Ni(II) and Cu(II) form fairly stable coordination chelate compounds with the L^{2-} forms of dithiooxamide and *N*,*N*′-diphenylthiooxamide. However, Co(III) has a higher charge and a smaller radius than Ni(II) and Cu(II), so that the Co(III) chelates formed with the HL^- forms of both these ligands should be more effective proton donors, like the chelates with the corresponding form of *N*,*N*′-diphenyldithiooxamide, than the analogous Ni(II) and Cu(II) chelates. It can therefore be expected that the probability of the formation of the Co(III) chelates with the L^{2-} forms of all the above three ligands is much greater than the probability of the formation of the corresponding Ni(II) and Cu(II) chelates.

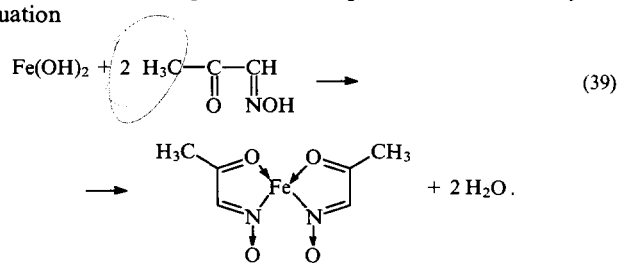
However, the HL^- forms and not the L^{2-} forms of the above ligands are in fact present in the inner spheres of virtually all the Co(III) compounds with dithiooxamide *N*,*N*′-diphenylthiooxamide, and *N*,*N*′-diphenyldithiooxamide synthesised by the complex formation reactions in the cobalt(II) hexacyanoferrate(II)–GIM. This paradox may be accounted for by the fact that theoretically the *trans*-HL^- or *trans*-L^{2-} forms of the above ligands with nitrogen and sulfur donor atoms should participate in the formation of the complexes of Co(III), since the latter is a harder Pearson acid than Ni(II) and Cu(II), and not the *cis*-HL^- or *cis*-L^{2-} forms (with two donor sulfur atoms), as happens in the case of Ni(II) and Cu(II).[24] On the other hand, the participation of the *trans*-L^{2-} forms in the complex formation reaction automatically presupposes that any of the above ligands is tetradentate and hence this should lead theoretically to the formation of polymeric chelates. However, the formation of

polymeric structures by Co(III), involved exclusively in octahedral coordination, with the tetradentate *trans*-L^{2-} forms of such ligands is sterically hindered, whereas the formation of chelates with the bidentate *trans*-HL^- forms does not encounter such hindrance. In all the Co(III) chelate complexes with dithiooxamide, *N*,*N'*-diphenylthiooxamide, and *N*,*N'*-diphenyldithiooxamide formed by complex formation reactions in the cobalt(III) hexacyanoferrate(II) matrix, the ligands are coordinated to the metal ion via the nitrogen and sulfur atoms.[24,35] One can therefore expect that complex formation in the MHCF–GIM should not occur in the Co(II)-quinoxaline-2,3-dithiol system, where the ligand is a structurally rigid analogue of dithiooxamide and contains only sulfur atoms as the donor centres.[24,35,38]

In conclusion one should note that the nature of complex formation in the cobalt(III) hexacyanoferrate(II)–GIM in all the Co(III)–(N, S)-ligand systems investigated is independent of the number of species with different degrees of deprotonation formed by the ligand.[24,25,35,38] This constitutes a sharp difference between complex formation reactions in the cobalt(III) hexacyanoferrate(II)–GIM, on the one hand, and in the nickel(II) and copper(II) hexacyanoferrate(II) matrices, on the other, where such a dependence can be seen (see Sections III, 2 and IV, 2) to be quite distinct. One can also conclude that, overall, the characteristic features of complex formation in the cobalt(III) hexacyanoferrate(II)–GIM clearly confirm the validity of the prediction that intermediate coordination compounds, which are not detected under the 'traditional' conditions (see Section II, 2), can be formed under the specific conditions of the MHCF–GIM.

VI. Complex formation in the iron(III) hexacyanoferrate(II) matrix

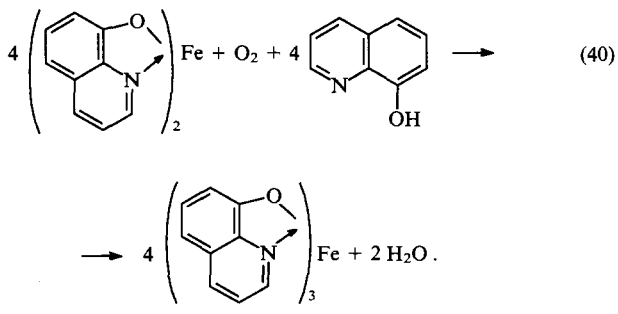
The uniqueness of the situation consists in the fact that the metal-containing components of this MHCF–GIM contain ions of the same 3*d* element in different oxidation states [Fe(II) and Fe(III)]. Each of them is potentially capable of forming complexes mainly with 'hard' donor centres.



1. Complex formation in Fe(II, III)–(N, O)-ligand systems

The Fe(II) and Fe(III) atoms present in $KFe[Fe(CN)_6]$ belong to the category of moderately hard and hard Pearson acids respectively[129] (their orbital electronegativities in aqueous solution are +0.69 and +2.22 eV respectively).[92] Their extremely stable complexes with (N, O)-ligands such as 8-hydroxyquinoline, nitrosonaphthols and their derivatives,[105] oximes,[104] and complexones,[100,101] are known. However, only two of these — 8-hydroxyquinoline[70,72] and isonitrosoacetone $H_3CC(O)CH{=}NOH$ — have so far been used in complex formation reactions in the $KFe[Fe(CN)_6]$–GIM. The study of complex formation in the $KFe[Fe(CN)_6]$–GIM system is extremely seriously restricted by the fact that the Fe(II) and Fe(III) complexes formed with ligands containing both nitrogen and oxygen usually absorb extremely weakly in the visible part of the spectrum, have relatively low stability constants, and dissolve appreciably in water.[29,72] It has been shown in the studies quoted that, when the $KFe[Fe(CN)_6]$–GIM comes into contact with alkaline solutions of the above ligands ($pH \geqslant 12$), the alkaline degradation of the metal-containing component of the MHCF–GIM takes place initially in accordance with the equations

$$KFe[Fe(CN)]+3OH^- \longrightarrow \longrightarrow FeO(OH)+[Fe(CN)]^{4-}+K^++H_2O\ , \quad (37)$$

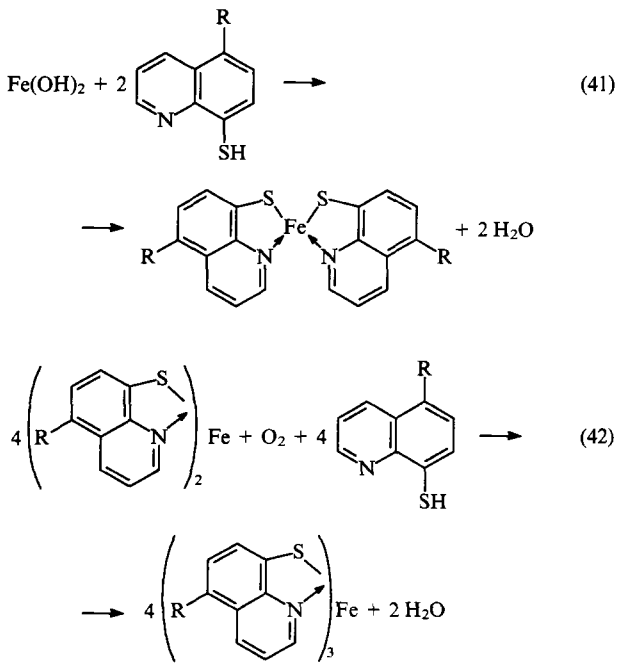


$$KFe[Fe(CN)]+2OH^- \longrightarrow \longrightarrow Fe(OH)_2+[Fe(CN)]^{3-}+K^+\ . \quad (38)$$

This results in the formation of a mixture of Fe(II) and Fe(III) oxide hydroxides in the GIM, the ratio of which probably depends very significantly both on the experimental conditions and on the degree of dispersity of iron(III) hexacyanoferrate(II) in the immobilised matrix.[24] However, only the Fe(II) hydroxo-complexes interact with each of the ligands indicated above.[29,70] The $D'=f(c_F, c_L^0, t)$ curves for the Fe(II)–isonitrosoacetone system are extremely simple: with increase in $c_F t$ and c_L^0 (at a fixed concentration c_F), the optical densities of the polymer layer of the matrix increase monotonically, tending to certain limiting values which depend on c_F.[70] According to Mikhailov and Polovnyak,[70] the complex formation process is described by the equation

(39)

The chelate FeL_2 is virtually the only complex formation product also in the Fe(II)–8-hydroxyquinoline system.[70] However, in this case the $D'=f(c_F, c_L^0, t)$ relations are somewhat more complex than in the Fe(II)–isonitrosoacetone system: in particular, for $c_F < 0.3$ M and $c_L^0 > 1.0 \times 10^{-2}$ M, with increase in t the quantities D' begin to decrease after attaining a certain maximum value.[70,72] This finding has been attributed[29,70,98,142] to the occurrence in the system under consideration of the Fe(II) → Fe(III) redox process in accordance with the overall scheme



(40)

It has been stated that the natures of the $D'=f(c_F, c_L^0, t)$ curves for the Fe(II)–1-nitroso-2-naphthol and Fe(II)–2-nitroso-1-naphthol systems are similar to those for the Fe(II)–isonitrosoacetone system, but these systems have not been characterised in greater detail.[24,70]

2. Complex formation in the Fe(II), (III)–(S, S)-, (N, S)-, and (O, S)-ligand systems

There are also hitherto extremely few examples of complex formation in the Fe(II)–(N, S)-ligand systems under the specific conditions which obtain in the $KFe[Fe(CN)_6]$-GIM. There are data on complex formation in the iron(III) hexacyanoferrate(II) matrix when the latter comes into contact with aqueous alkaline solutions of 8-mercaptoquinoline and its 5-bromo- and 5-methylthio-derivatives.[24] In all three cases, three ligand molecules become attached in succession to one $Fe(OH)_2$ fragment during the complex formation process, the third molecule being attached much more slowly than the first two. It has been suggested that initially Fe(II) complexes with the corresponding ligands arise in all the iron(II)–ligand systems indicated, but the complexes are instantaneously oxidised by atmospheric oxygen to the corresponding Fe(III) coordination compounds.

(41)

(42)

It is striking that the chelates FeL_3 are formed in all these cases actually from $Fe(OH)_2$ and not from FeOOH or some other iron(III) oxide hydroxide.[24] On the other hand, one should note that, when the $KFe[Fe(CN)_6]$-GIM comes into contact with alkaline solutions of ligands such as dithiooxamide, *N*,*N*′-diphenylthiooxamide or *N*,*N*′-diphenyldithiooxamide, quinoxaline-2,3-dithiol, 1,2-dithiocarbamoylhydrazine, and 1-carboxyl-2-thiocarbamoylhydrazine, only the alkaline degradation of iron(III) and potassium hexacyanoferrates(II) is detected and no Fe(II) and Fe(III) coordination compounds with the ligands indicated are produced.[25,29] In contrast to complex formation in the $M_2[Fe(CN)_6]$-GIM [M = Ni(II), Cu(II), Co(II)] and the $KCo[Fe(CN)_6]$-GIM, in the complex formation reaction in the $KFe[Fe(CN)_6]$ matrices it was not possible to detect in any of the systems considered any kind of new coordination compounds which had not been detected previously in the interaction of Fe(II) with the corresponding ligands in solutions or in the solid phase.[35,70,98] The high lability of the high-spin Fe(II) and Fe(III) chelates and also the low probability of the formation of dimeric and polymeric species with the ligands considered by both iron(II) and iron(III) have been specified as the probable causes of this phenomenon.[24,29]

To a first approximation, all the 3*d* element-chelating (N,O)-, (N,S)-, (O,S)-, and (S,S)-ligand systems described in the literature can be quite definitely assigned to one of two types of complex formation: in the first of these, the process proceeds by a formal S_N2 mechanism [systems in which the metal-containing components are nickel(II) and cobalt(III) hexacyanoferrates(II)], while in the second it proceeds via a formal pseudo-S_N1 mechanism [systems in which the metal-containing components are copper(II), iron(III), and cobalt(II) hexacyanoferrates(II)]. Both homoligand and heteroligand {i.e. containing ligand molecules deprotonated to a particular extent and the $[Fe(CN)_6]^{4-}$ anion} chelate complexes may be formed in systems of the first type. Only homoligand coordination compounds are formed in systems of the second type and, despite the fact that theoretically there is a possibility in this instance of the existence of complexes containing in the inner coordination sphere any of the forms of the ligands indicated above as well as the OH^- group, their appearance has not been detected in the complex formation reaction in the MHCF-GIM in any of the systems examined in the literature.

Only one variant of complex formation is as a rule characteristic of each of the metal hexacyanoferrate(II)-GIM considered. Depending on the nature of the ion of the 3*d* element (but regardless of the nature of the ligand), the formation of the above heteroligand complexes in such a variant either always occurs [in the complex formation reaction occurring in the cobalt(III) hexacyanoferrate(II)-GIM] or, on the contrary, it never occurs [in the complex formation reaction in the cobalt(II) hexacyanoferrate(II)-GIM]. Only the $Ni_2[Fe(CN)_6]$-GIM is an exception, where complex formation can take place in accordance with one or another variant depending on the nature of the ligand. The first variant occurs for ligands containing nitrogen, which are capable of generating under the complex formation conditions at least two species with different degrees of deprotonation, while the second occurs in the case of ligands containing both nitrogen and sulfur, which give rise to only one deprotonated species, and also in the case of ligands containing both nitrogen and oxygen. One can therefore conclude that the nature of the differences between the complex formation reactions in solutions and in the metal hexacyanoferrate(II) gelatin-immobilised matrix systems is fully consistent with the predictions which can be made on the basis of the considerations described in Section II, 2.

VII. Practical possibilities for complex formation reactions in metal hexacyanoferrate(II) matrices

1. The production of nonsilver photographic images on silver halide photosensitive materials

The process involving the formation of nonsilver photographic images consists of three stages: (1) bleaching of the silver image obtained on the photographic material by means of its standard treatment[26-28] in a solution containing potassium hexacyanoferrate(III), the soluble salt of a 3*d* element ion (as a rule the chloride or sulfate), and any organic hydroxyacid (citric, oxalic [sic], or tartaric); (2) fixation of the bleached image by treating the photographic emulsion with an aqueous solution of sodium thiosulfate; (3) toning of the image by treating the photographic emulsion with an alkaline solution of the corresponding chelating organic compound. In terms of the composition of the solutions used to treat the photographic materials and the chemistry of the processes occurring, the first two stages correspond to the synthesis of the MHCF-GIM and the third to the complex formation reaction in such GIM.[35] It is noteworthy that in a number of instances the nonsilver photographic image obtained from the metal chelates can be produced also by a shorter procedure: the exposed silver halide photographic material is initially developed and then subjected to treatment involving the successive operations 1-3. It is then possible to shorten the time required to obtain the nonsilver metal chelate image and also to improve the efficiency and accelerate the oxidation of the elemental silver to the corresponding silver(I) compounds [the hexacyanoferrate(II) or the chloride).[143] Several tens of technological processes of this type have already been described in the literature. The main bulk of the publications have been devoted to the synthesis of nonsilver images from nickel(II) chelates;[40,41,43,49,53,57,58,60,66,68,69,71,72,74,77,78,81] and a somewhat smaller number have been devoted to the synthesis of images from copper(II) chelates;[36,39,42,46,50,51,54,55,58,62,67,72,75,76,79,80] on the other hand, instances of the employment of the chelates of other 3*d* elements are the carriers of nonsilver images are encountered much more rarely.[36-38,44,47,48,56,63,65,72] In particular, technologies for the production of nonsilver images by means of carriers such as the nickel(II) chelate complexes of dimethylglyoxime,[40,77] dithiooxamide and its *N*,*N*′-diphenyl derivatives,[41,57,58,64,66,69,71] and *N*,*N*′-diphenylthiooxamide,[53,78] the copper(II) chelate complexes of α-benzoin oxime,[46,60] 8-hydroxyquinoline,[50] and dithiooxamide,[39,64,72,79] the cobalt(II) chelate complexes of nitrosonaphthols,[36,37,44] the cobalt(III) chelate complex of dithiooxamide,[38,45,65] and the iron(II) complex of 8-hydroxyquinoline.[45,70]

The formation of nonsilver images from nickel(II) chelate complexes of dithiooxamide is the most interesting process.[40,58,64,66,69,71,72] It has been used, in particular, for the preparation of 'blue slides'.[58] This procedure for the preparation of 'blue slides' is less laborious and, what is most important, is less demanding as regards external conditions compared with the familiar traditional processes based on organic dyes.[143] The dark blue or blue images obtained from the $[Ni(HL)_2]_n$ chelate complexes of dithiooxamide are distinguished by a greater purity of the light lines, greater contrast, and greater photostability. Yet another important quality of this procedure is that, in contrast to all the other processes for the intensification of photographic images known hitherto,[26] in many cases it does not increase but actually diminishes the degree of fogging compared with the initial silver image.[40,58,64] The cause of this phenomenon is closely associated with the occurrence of process (23).

The above phenomenon is fairly typical for technologies for the synthesis of nonsilver images from the chelates of 3*d* elements. It is observed, in particular, also in the formation of images from the copper(II) chelate complex of dithiooxamide (dark-green),[39,64,79] the copper(II) chelate complex of 1,2-dithiocarbamoylhydrazine (black),[50,82] the copper(II) chelate complex of 1-carbamoyl-2-thiocarbamoylhydrazine (black-brown),[51,82] and the cobalt(III) chelate complex of dithiooxamide (amber-yellow).[38,48,65] It is striking that the images generated by the copper(II) chelate complex of 1,2-dithiocarbamoylhydrazine[50,82] and the iron(III) complex of 8-hydroxyquinoline[45,70] are very close to the initial neutral grey silver images. This is particularly effective in those cases where after intensification it is desirable to retain the black or grey-black colour of the image.

One should note especially that the employment of all these technologies makes it possible to vary widely the photographic characteristics of the treated materials. In particular, by altering the concentrations and the duration of the toning stage, it is possible to both decrease and increase the photographic sensitivity achieved in the formation of the initial silver image.[72] Review articles have been published on the problem under consideration.[72,143]

2. Synthesis of test objects for the measurement of optical absorption spectra

A fundamentally new variant of the preparation of test objects has been developed with the aid of complex formation in the MHCF–GIM systems. Its significant features reduce to the fact that the substance analysed is synthesised in a gelatin layer as a result of a series of specific chemical reactions.[144–146] In particular, test objects comprising nickel(II)–dimethylglyoxime, copper(II)–dithiooxamide, cobalt(II)-2-nitroso-2-naphthol, and iron(II)–8-hydroxyquinoline coordination compounds have been prepared in this way. In principle, the ideas underlying this method can be used to prepare also test objects comprising a series of other inorganic compounds, in particular oxides and sulfides.[144] This method is probably fairly promising also for the preparation of test objects comprising certain organic compounds which absorb intensely in the visible part of the spectrum.[145]

3. Modelling of complex formation in bulk-phase polymers

There are indications in the literature that complex formation in a MHCF–GIM system may serve as a useful model for the interpretation of the stabilising effect of certain antioxidants for polymeric materials, in particular derivatives of 3-benzoylthiourea. Such a stabilising effect reduces to the 'complexing' of the microimpurities comprising the ions of the 3*d* elements, for example copper(II), present in bulk-phase polymers.[138,147] However, the study of this problem is in the initial stage.

VIII. Conclusion

It follows from the foregoing that complex formation in the metal hexacyanoferrate(II) gelatin-immobilised matrix systems is a specific phenomenon in chemical science in general and in coordination chemistry in particular. A new field of science has arisen — involving the study of the reactivities of polymer-immobilised coordination compounds with fixation of the substance by means of intermolecular forces and the study of the characteristics of complex formation involving such compounds. In essence, only the first steps have been taken on these lines, but it is already evident that complex formation under the nontraditional conditions described can lead to the formation of coordination compounds the existence of which investigators have sometimes not even suspected. There is no doubt that, as the range of the metal–ligand systems employed within the framework of the 'classical' complex formation expands, the very considerable potential synthetic possibilities of complex formation in metal hexacyanoferrate(II)-GIM as well as its possible practical applications will be manifested to a much greater extent.

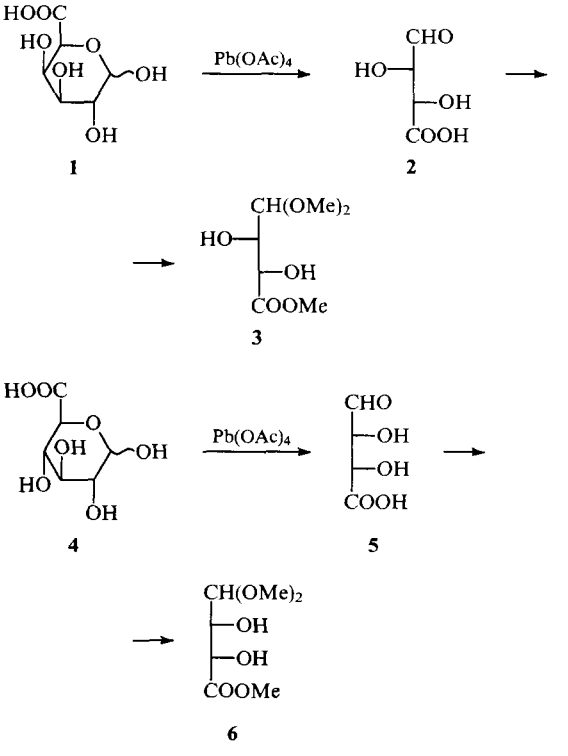
VIII.	Conclusion	701

Abstract. The review describes the methods of synthesis of uronic acids involving both the catalytic oxidation of sugars and their oxidation by nonspecific oxidants. The principal paths in the transformations of uronic acids and their derivatives, characteristic of compounds of this class, which make it possible to synthesise new compounds that are otherwise difficult to obtain are considered. The bibliography includes 217 references.

I. Introduction

By definition, the term uronic acid is applied to monosaccharides in which the primary hydroxy-group has been transformed as a result of oxidation into a carboxy group. Uronic acids are usually understood only as alduronic acids, which are derivatives of aldoses, while the preferred name for keturonic acids is ketoaldonic acids. However, in the present review the term 'uronic acids' is used in a wide sense for all polyhydroxy-compounds containing carbonyl and carboxy-groups simultaneously. The presence of the carboxy-group in the structure of uronic acids is reflected in the relative reactivities of the hydroxy-groups, in the resistance to hydrolysis of the *O*- and *N*-glycosidic bonds, and also in their tendency to undergo β-elimination, leading to the formation of unsaturated sugars, which frequently serve as valuable intermediates in the synthesis of compounds which are difficult to obtain. The chemistry of uronic acids abounds with examples of the successful employment of the carboxy-group in monosaccharides in the construction of molecules having a specified structure.

The aim of the present review is to give a systematic account and to survey the extensive and interesting data on the synthesis and reactions of uronic acids. The review summarises data on the methods of synthesis of uronic acids with different carbon chain lengths, attention being concentrated on the oxidation reactions of monosaccharide derivatives. The methods of synthesis of diverse derivatives of uronic acids, which may be of interest in experimental studies and which may serve as synthons in the synthesis of optically active noncarbon compounds, are also examined.



The last section of the review is devoted to numerous chemical reactions of uronic acids, which illustrate the extensive synthetic possibilities of compounds of this class.

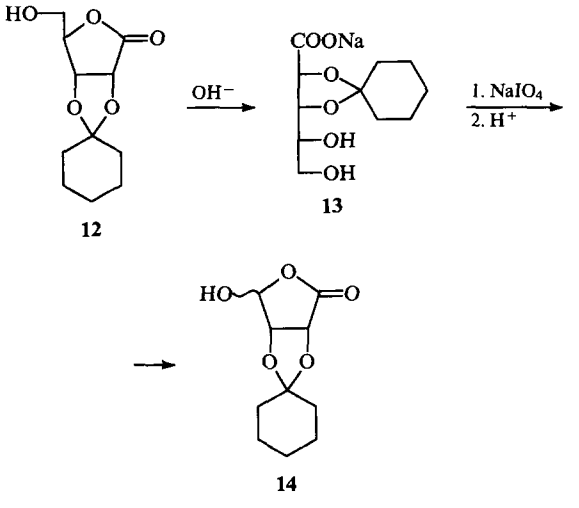
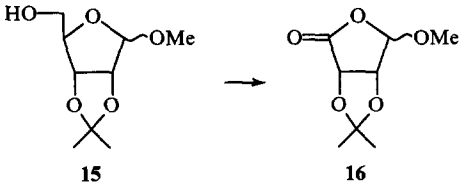
II. Tetruronic acids

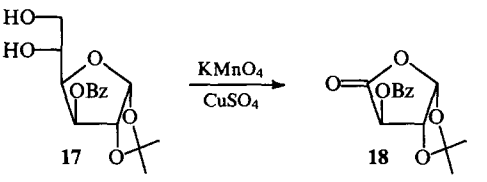
D-*threo*-Tetruronic acids **2** and D-*erythro*-tetruronic acids **5** are readily formed when D-galacturonic acid **1** and D-glucuronic acid **4** are treated with two equivalents of $Pb(OAc)_4$. Tetruronic acids have been isolated and characterised as the dimethyl acetals of their methyl esters **3** and **6**.[1]



1 **2** **3** **4** **5** **6**

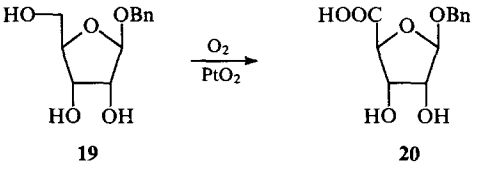


The source of L-*threo*-tetruronic acid is L-tartaric acid **7**, which is converted, as a result of treatment with acetic anhydride, into the anhydride **8**, affording the monomethyl ester **9** in methanol. The Rosenmund reduction of the acid chloride **10** leads to the methyl ester of 2,3-di-*O*-acetyl-L-*threo*-tetruronic acid **11**.[2]

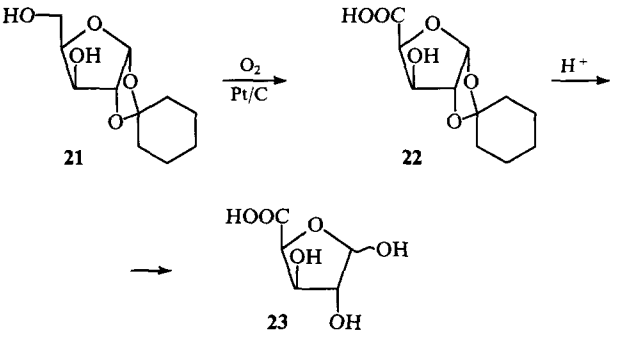


The cyclohexylidene derivative of the lactone of L-*erythro*-tetruronic acid **14** has been obtained in 93% yield by the periodate oxidation of the salt **13** formed from D-ribonolactone **12**.[3]

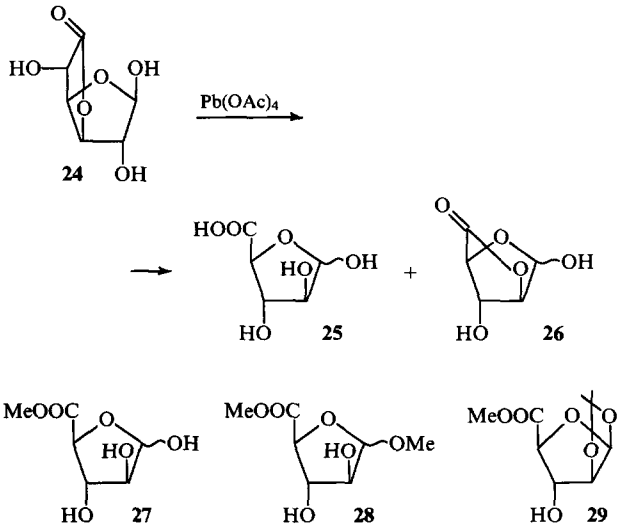
An unexpected result has been obtained in the oxidation of the methyl riboside **15**. Refluxing it with pyridinium chlorochromate in benzene, using a Dean–Stark procedure, leads to D-erythruronolactone **16**.[4]



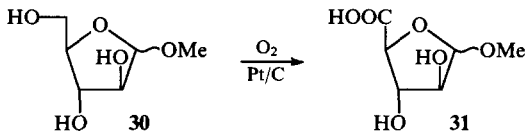
The lactone of L-*threo*-tetruronic acid **18** is formed smoothly on oxidation of 3-*O*-benzoyl-1,2-*O*-isopropylidene-α-D-glucofuranose **17** by $KMnO_4$ in the presence of $CuSO_4$.[5]



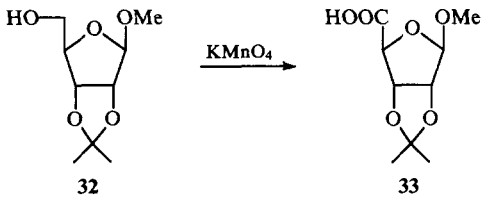
III. Penturonic acids



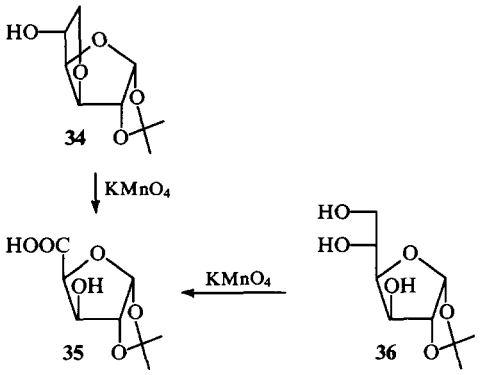
A convenient, albeit expensive and not always satisfactorily reproducible, method of synthesis of penturonic acids is the oxidation of pentofuranosides by oxygen over platinum or platinum black. The catalytic oxidation of benzyl β-D-ribofuranoside **19** over platinum black leads to the corresponding riburonide **20** in 48% yield. Oxidation by oxygen in the presence of platinum on charcoal affords a less satisfactory result (yield 13%).[6]



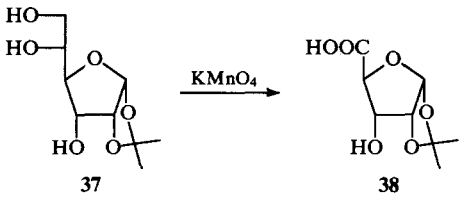
The acid **22**, the acid hydrolysis of which gives rise to D-xyluronic acid **23**, has been synthesised by the catalytic oxidation of 1,2-*O*-cyclohexylidene-α-D-xylofuranose **21**.[7]



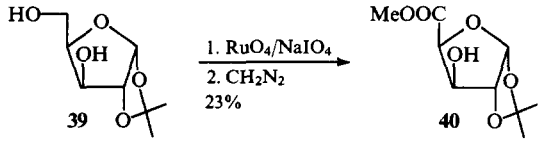
Treatment of the glucurone **24** with one equivalent of $Pb(OAc)_4$ leads to the formation of D-arabinuronic acid **25** and its lactone **26**, which has been identified as the methyl ester **27**, its glycoside **28**, and its acetal **29**.[1]



The catalytic oxidation of the arabinoside **30** to the arabinuronide **31** has been described.[8]

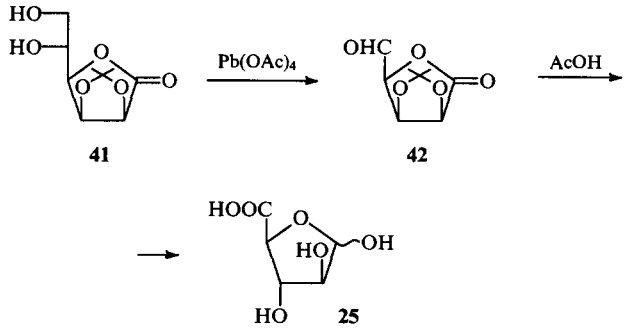


$KMnO_4$ has been used successfully for the oxidation of appropriately protected pentoses. The acetal of the methyl riboside **32** is oxidised to the acid **33** in 31% yield in an aqueous alkaline solution.[9] Acidification of the reaction mixture and rapid removal of the acid **33** formed by extraction with ether makes it possible to increase its yield to 65%.[10] Oxidation in a mixture of acetone and acetic acid leads to the formation of the acid **33** in 54% yield.[11]

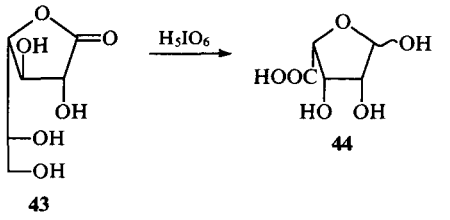


Anhydroglucofuranose **34** is oxidised by $KMnO_4$ to xyluronic acid **35**.[12]

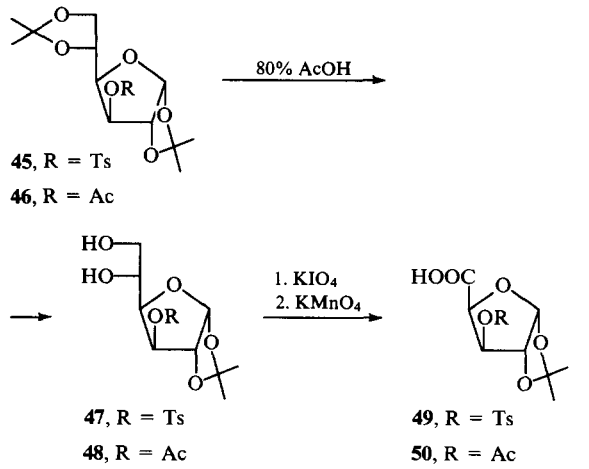
The acid **35** is formed readily when the acetal of glucofuranose **36** is treated with $KMnO_4$. Riburonic acid **38** has been obtained from the acetal of allofuranose **37** under similar conditions.[13]



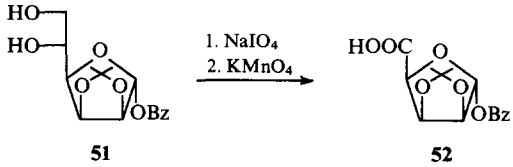
Ruthenium tetroxide in the presence of sodium metaperiodate can be used as the oxidant in the synthesis of penturonic acids. The acid **33** has been synthesised from compound **15** by this method.[14] The xyluronic acid ester **40** has been obtained by the oxidation of [the acetal of] xylofuranose **39** with subsequent esterification.[15]



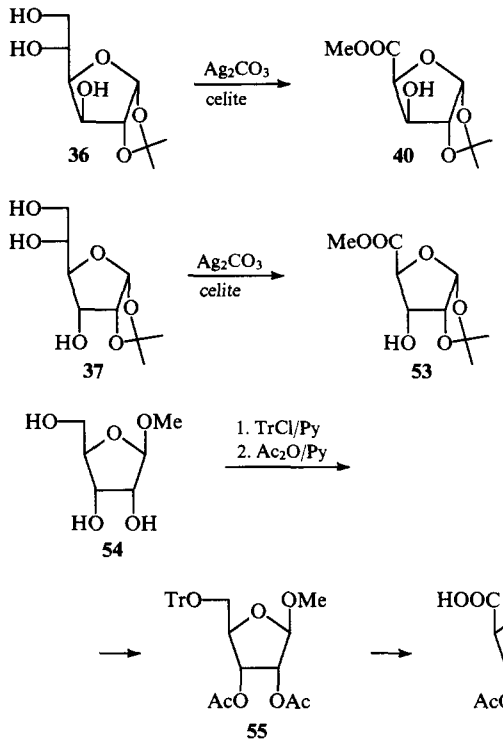
The preparation of the acid **35** by the successive oxidation of the glucofuranose acetal **36** by $Pb(OAc)_4$ and bromine in the presence of $BaCO_3$ has been described.[16]



One of the sources for the synthesis of penturonic acids is glyconic acid γ-lactones. An example of such synthesis has been demonstrated by Mashida.[16] The aldehyde **42** has been obtained by oxidising the mannonolactone **41** by $Pb(OAc)_4$ and was then transformed in 10% acetic acid into arabinuronic acid **25**.

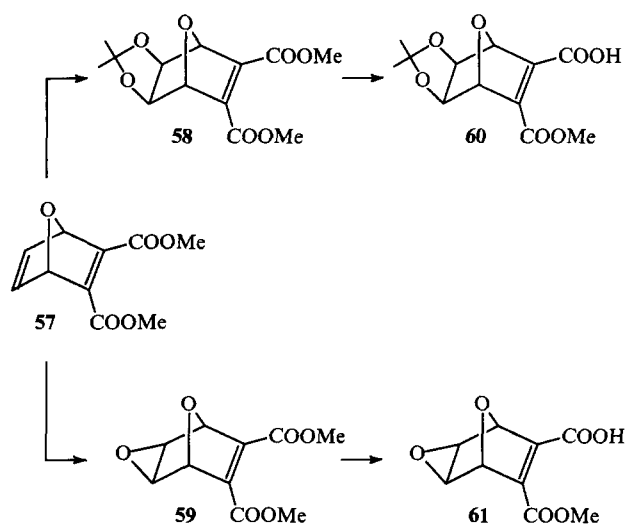


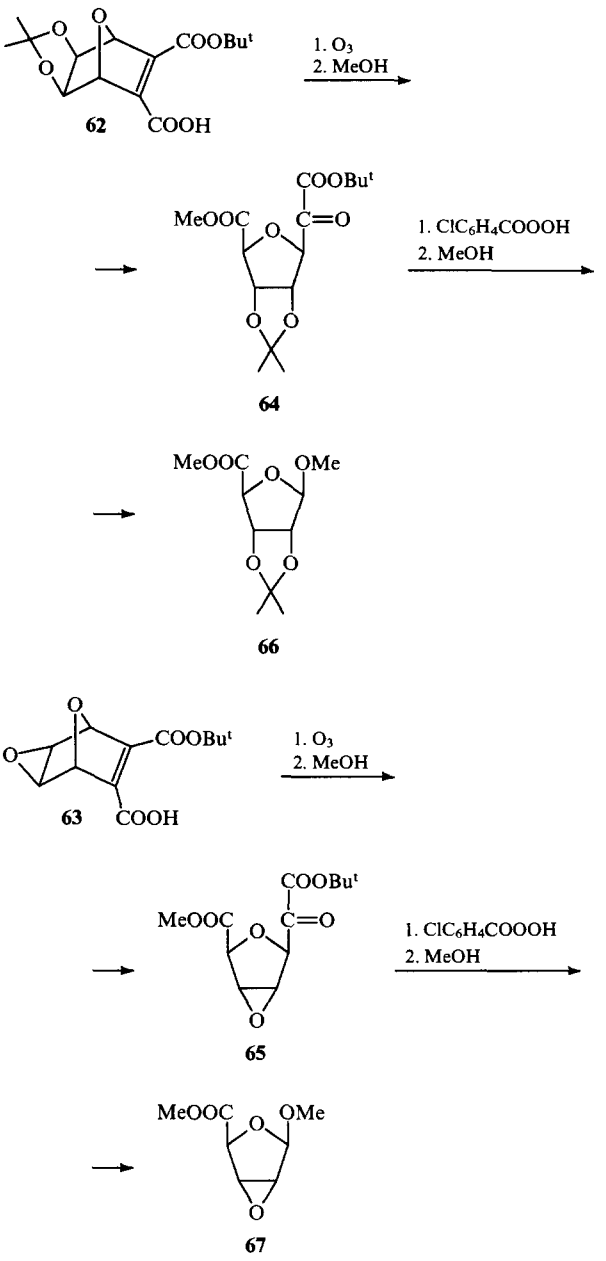
This approach has been used successfully in the synthesis of L-lyxuronic acid **44** from D-gulonolactone **43**.[17]



The derivatives of glucofuranose diacetals **45** and **46** are readily available starting compounds for the synthesis of penturonic acids with various substituents at C(3). The diols **47** and **48** obtained from them by mild acid hydrolysis are oxidised in succession by potassium metaperiodate and permanganate. The yield of the acids **49** and **50** is 50%.[18]

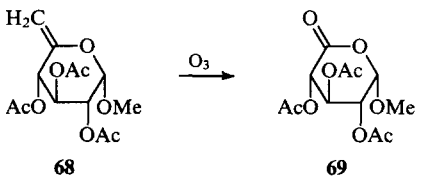
The successive oxidation of 1-*O*-benzoyl-2,3-*O*-isopropylidene-α-D-mannofuranose **51** initially with $NaIO_4$ and then $KMnO_4$ leads to the formation of the D-lyxuronic acid derivative **52**.[19]





Silver carbonate on celite has been used as the oxidant for the synthesis of penturonic acids. Methyl D-xyluronate **40** and methyl D-riburonate **53** have been obtained by oxidising the hexofuranose acetals **36** and **37** in methanol.[20]

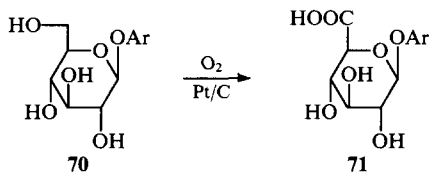
A procedure has been developed for the transformation of *O*-glycosides into *O*-glycuronides.[21] The successive tritylation and acetylation of the methyl riboside **54** afforded a fully protected derivative **55**, the oxidation of which with CrO_3 in acetone in the presence of sulfuric acid (the Jones reagent) gives rise to the D-riburonide acetate **56** in 67% yield.



A chemical-enzymic strategy has been used in the total enantioselective synthesis of riburonides.[22] The Diels–Alder adduct **57** (the result of the condensation of furan with dimethyl ethynedicarboxylate) was transformed into the unsaturated esters **58** and **59**. Their asymmetric hydrolysis by pig liver esterase gave the half-esters **60** and **61** in fairly high optical yields. The *tert*-butyl esters **62** and **63** obtained from them were converted by ozonisation in methanol into the ketoacids **64** and **65**, the Baeyer–Villiger oxidation of which followed by methanolysis, afforded derivatives of D-riburonic acid — the acetal **66** and the epoxide **67**.

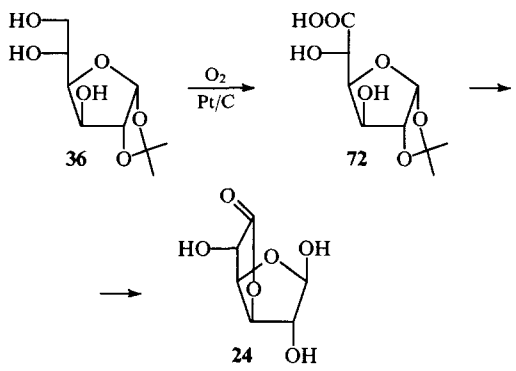
The L-enantiomer of the riburonide **66** has been obtained by the ozonolysis of the half-ester **60** and oxidation with *m*-chloroperbenzoic acid.

The conversion of the glucosene **68** into the 1,5-lactone of D-xyluronic acid **69** may serve as an example of a nontrivial and fairly general method of synthesis of penturonic acids.[23]



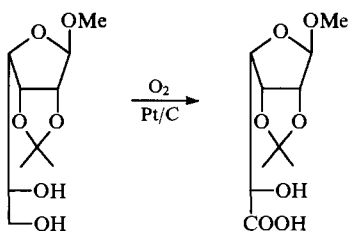
IV. Hexuronic acids

Like penturonic acids, hexuronic acids are obtained either by the catalytic oxidation of *O*-glycosides or by treating appropriately protected sugars with nonselective oxidants.



The conditions for the catalytic oxidation and the methods for the isolation and identification of alkyl *O*-glucuronides,

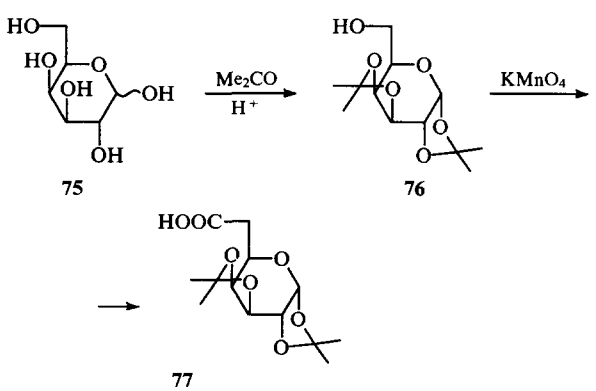
O-galacturonides, and *O*-mannuronides have been described.[24-26] Methyl α- and β-2-deoxyglucuronides and galacturonides have been synthesised by catalytic oxidation.[27] The methods of synthesis of phenyl and naphthyl β-D-glucuronides **71** from the corresponding aryl glycosides **70** have been described.[28,29]



70 **71**

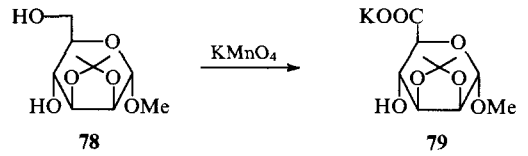
Derivatives of hexofuranoses can also be used for the preparation of uronic acids. Thus the oxidation of the glucofuranose acetal **36** with oxygen over platinum leads to the acid **72**, which is converted by lactone-formation into the glucurone **24** on heating in water.[30]

36 **72** **24**



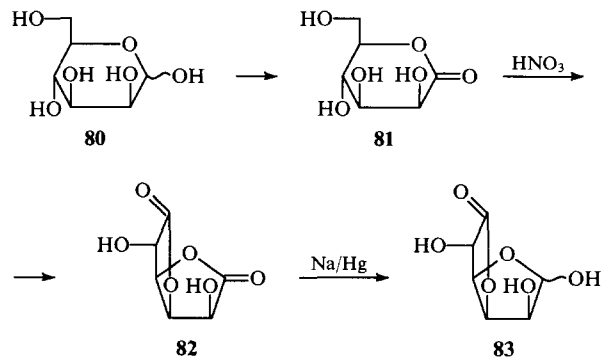
The catalytic oxidation of the D-gulofuranoside acetal **73** has been used in the synthesis of the D-guluronide **74**.[31]

73 **74**



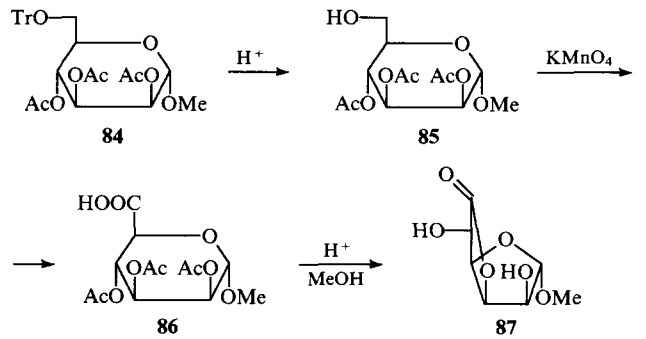
A review presenting more detailed data has been devoted to the catalytic oxidation of sugars.[32]

Appropriately protected sugars with a free primary hydroxy-group are smoothly oxidised to uronic acids by nonselective oxidants. The oxidation of the diacetal **76** obtained from D-galactose by $KMnO_4$ affords the galacturonic acid derivative **77**.[33]



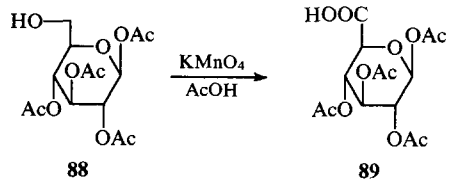
75 **76** **77**

The D-mannopyranoside acetal **78** can be oxidised by $KMnO_4$ to the acid **79** in an acceptable yield even in the presence of a free secondary hydroxy-group.[34]



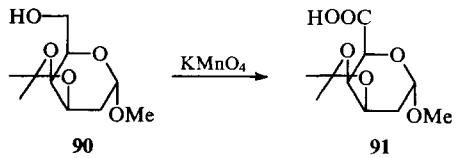
78 **79**

The electrolytic oxidation of D-mannose **80** leads to the formation of δ-mannonolactone **81**, the treatment of which with nitric acid gives rise to the dilactone of D-mannosaccharic acid **82**, while the reduction of the latter with sodium amalgam results in the formation of the 6,3-lactone of D-mannuronic acid **83**.[35]



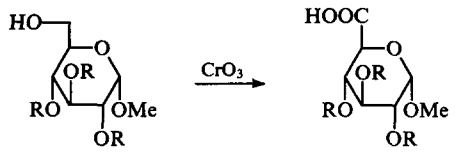
80 **81** **82** **83**

The oxidation with potassium permanganate in an acetone–acetic acid mixture of the sugar **85**, obtained from its 6-*O*-trityl precursor **84**, is yet another example of the synthesis of derivatives of D-mannuronide **86** and its lactone **87**.[36]



84 **85** **86** **87**

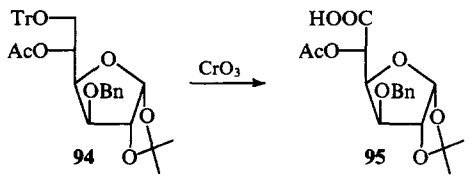
A similar synthetic scheme has been used in the oxidation of β-D-glucopyranose tetraacetate **88** to the full acetate of D-glucopyranuronic acid **89**.[37]



88 **89**

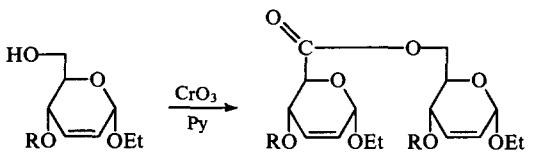
$KMnO_4$ has been used to oxidise the acetal of methyl 2-deoxy-α-D-galactopyranoside **90** to the acid **91**.[38]

90 **91**



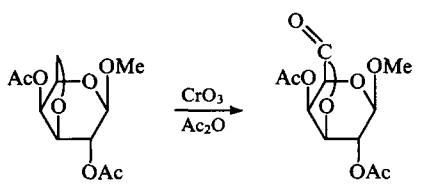
92 93

R = Me, Bn.



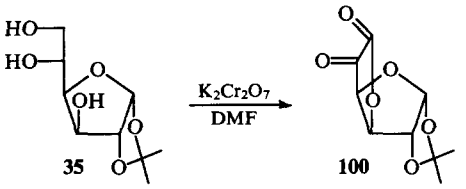
CrO_3 may be used as the oxidant in the synthesis of glucuronic acid derivatives **93** from the partly protected glucopyranosides **92**.[39,40]

A convenient method of synthesis of the D-glucofuranuronic acid derivative **95** involves the oxidation of the fully protected glucofuranose **94** by CrO_3 in acetone in the presence of sulfuric acid.[41]



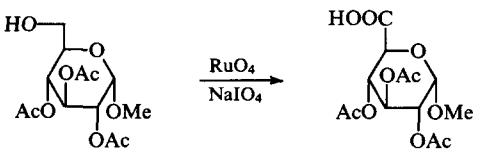
94 95

The formation of the ester **97** has been observed in the oxidation of the unsaturated sugar **96** with CrO_3 in pyridine.[42]



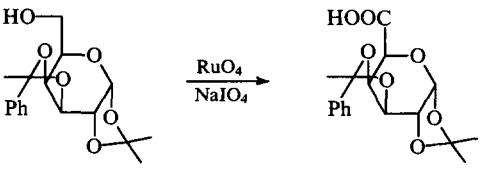
96 97

The oxidation of 3,6-anhydrogalactopyranoside **98** with CrO_3 in acetic anhydride leads to the 6,3-lactone **99**.[43]

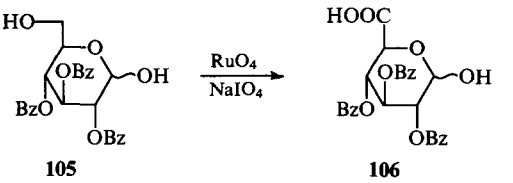


98 99

The sugar **35** can be oxidised by potassium dichromate in dimethylformamide (DMF) to the ketolactone **100**.[44]

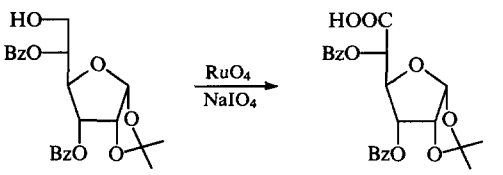


35 100

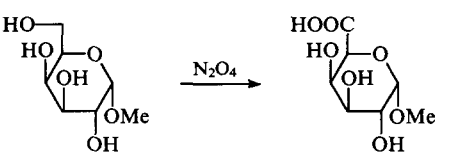


Ruthenium tetroxide together with sodium metaperiodate has found an application as the oxidant in the synthesis of hexuronic acids. The acids **103** and **104** have been obtained by this method from the sugars **101** and **102**. It has been shown for sugar **105**, with free primary and hemiacetal hydroxy-groups, that the oxidation does not involve the anomeric centre and leads to the acid **106**.[15]

101 103

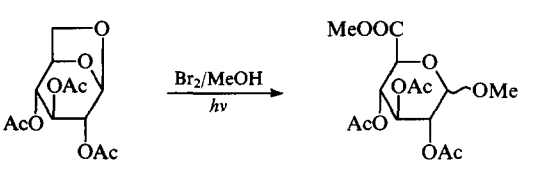


102 104



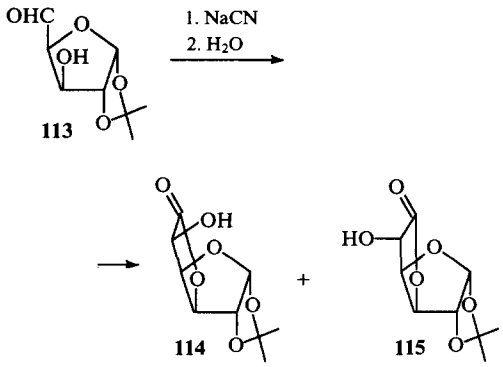
105 106

D-Allofuranose **107** is transformed into D-allofuranuronic acid **108** on oxidation with RuO_4.[45]



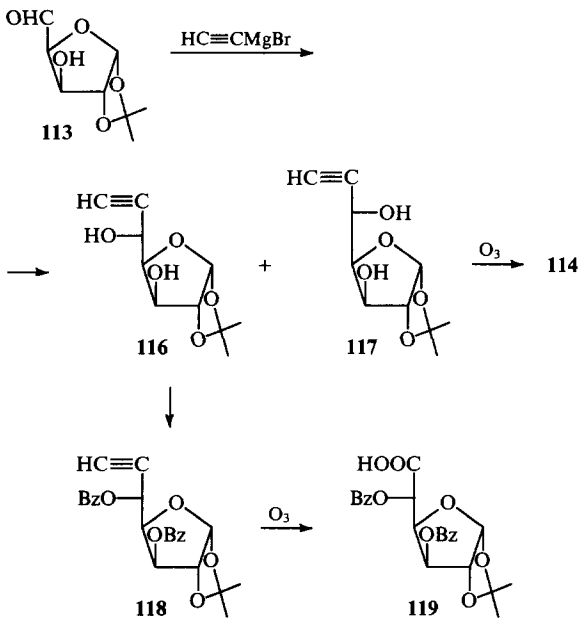
107 108

When the D-galactopyranoside **109** is treated with nitrogen(IV) oxide, the latter exhibits an oxidative selectivity, affording the D-galacturonide **110**.[46]



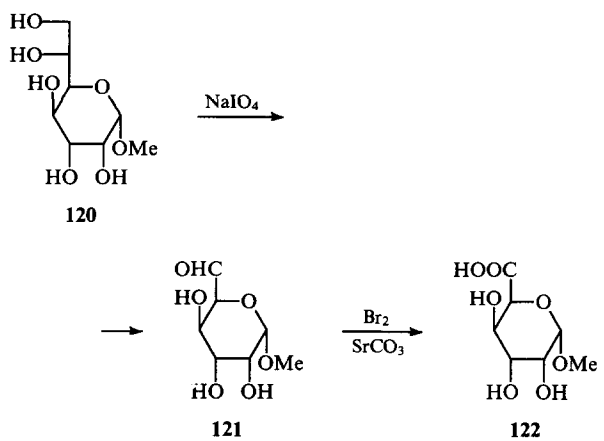
109 110

Despite the low yield, the oxidation of the levoglucosan acetate **111** with bromine on irradiation with UV light to give the ester **112** is nevertheless of interest.[47]

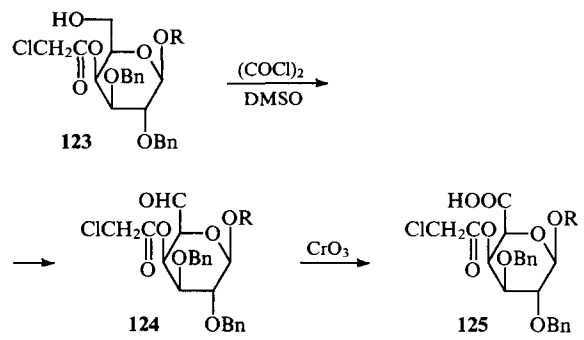


111 112

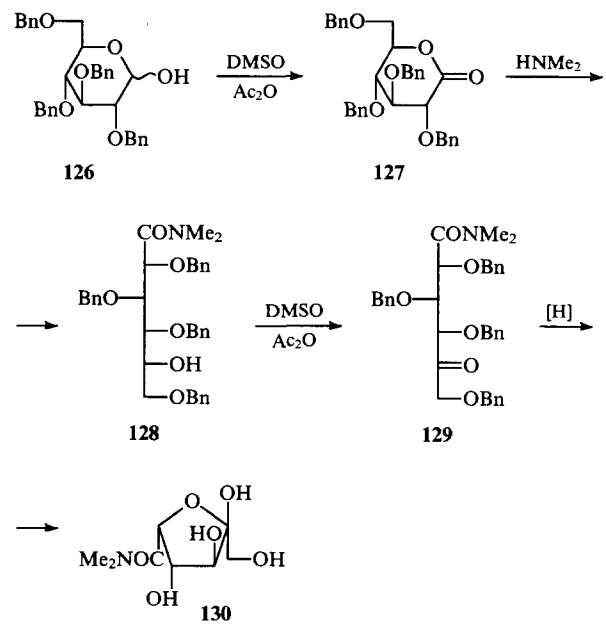
The introduction of a carboxy-group is achieved in a number of instances by the addition of nucleophiles to the aldehyde group. Two lactones — L-iduronolactone **114** and D-glucuronolactone **115** — have been obtained from 1,4-pento-dialdoxylofuranose **113** by the cyanohydrin synthesis.[48]



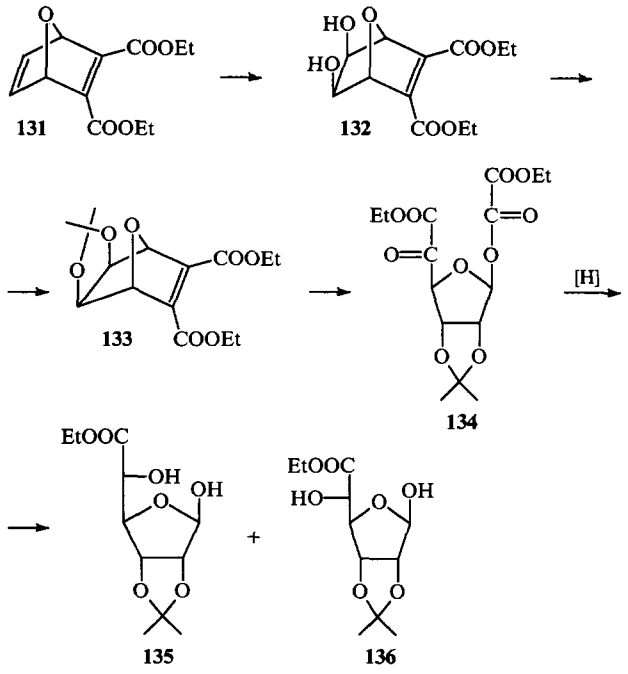
The addition of ethynylmagnesium bromide to the aldehyde **113** affords ethynyl sugars with D-gluco- and L-ido-configurations (compounds **116** and **117** respectively). The lactone **115** and the acid **119** have been obtained by the ozonolysis of compound **116** and the dibenzoate **118**.[49]



1,4-Pentodialdoribofuranose has also been used for reactions of a similar type.[50]

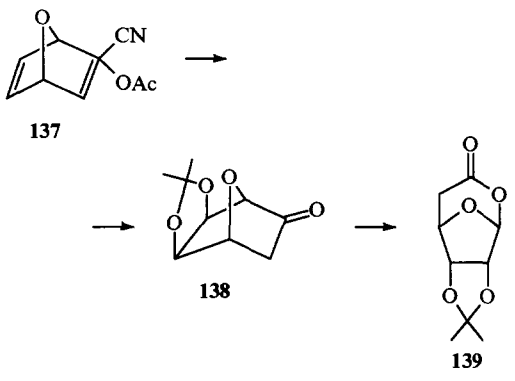


Heptopyranosides can also serve as a source of hexuronic acids. Thus oxidation of the sugar **120** (the product of the cyanohydrin synthesis from D-glucose) with sodium metaperiodate results in the formation of the aldehyde **121**, the treatment of which with bromine in the presence of strontium carbonate gives the D-guluronide **122**.[51]

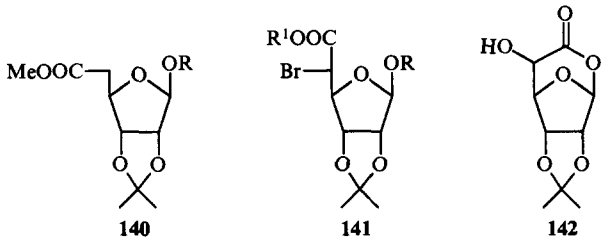


The Swern oxidation of the primary hydroxy-group in sugars to the aldehyde group followed by the conversion of the latter in one way or another into a carboxy-group constitutes yet another procedure for the preparation of uronic acids. Treatment of the galactopyranoside **123** with the dichloride of oxalic acid in dimethyl sulfoxide (DMSO) at −78 °C leads to the aldehyde **124**, the oxidation of which by the Jones reagent affords the acid **125**.[52]

A rare example of the synthesis of uronic acids in a series of ketoses has been demonstrated by Kuzuhara and Fletcher.[53] The glucopyranose **126** with the free hemiacetal hydroxy-group was oxidised by Pfitzner–Moffatt method to the D-gluconolactone **127**. The gluconamide **128** obtained from it was oxidised by the same method to the ketone **129**. The removal of the protecting benzyl groups from the latter leads to the amide of L-sorburonic acid **130**.

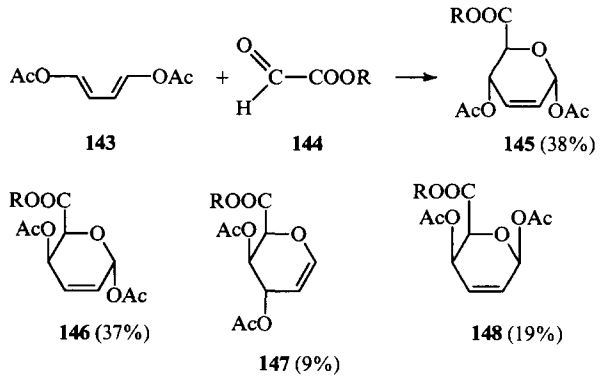


Fairly effective methods have been developed for the preparation of hexuronic acids by the diene synthesis. The total synthesis of uronic acids with the D,L-talo- and allo-configurations has been described.[54] The adduct **131**, obtained as a result of the condensation of furan with methyl ethynedicarboxylate, is oxidised by OsO_4 to the diol **132**. The ozonolysis of its acetal **133** followed by a thermal rearrangement leads to the ester of the ketoacid **134**, the hydrogenation of which over platinum affords the D,L-taluronate **135** and the D,L-alluronate **136**.



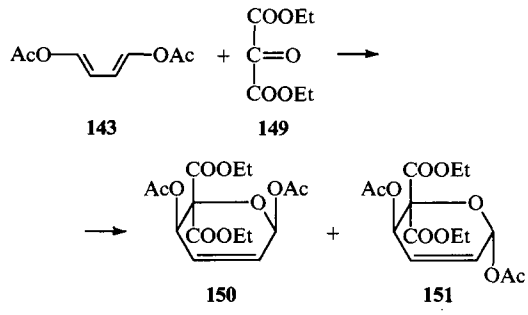
131 132 133 134 135 136

The condensation of furan with α-acetoxyacrylonitrile leads to the formation of the adduct **137**, which is transformed into the ketone **138** by successively: oxidation with OsO_4, acetal formation, and treatment with MeONa. Its oxidation with *m*-chloroperbenzoic acid leads to the acetal of 5-deoxy-D,L-ribo-hexofuranurono-6,1-lactone **139**.[55]



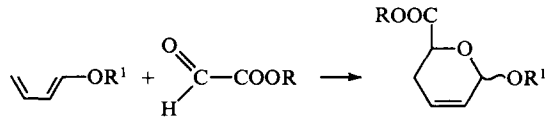
137 138 139

The use of cyanovinylcamphanate for the condensation makes it possible to obtain, as a result of total asymmetric synthesis, the optically active uronic acid derivatives **140**–**142**.[56–60]



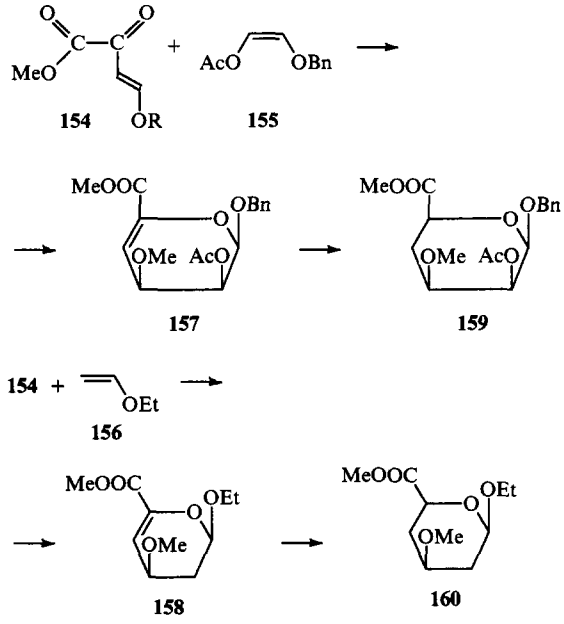
140 141 142

The Diels–Alder reaction between 1,4-diacetoxybuta-1,3-diene **143** and the alkyl glyoxylate **144** leads to a way of synthesising racemic unsaturated hexopyranuronic acids **145**–**147**.[61] When the reaction is carried out under mild conditions, the isomer **148** with an admixture of compound **145** (13%) is formed.



143 144 145 (38%) 146 (37%) 147 (9%) 148 (19%)

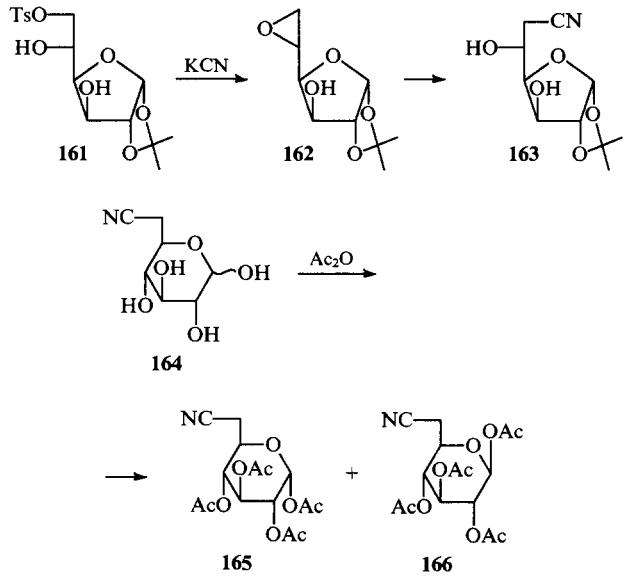
The condensation of the substituted butadiene **143** with diethyl mesoxalate **149** leads to the formation of the isomeric compounds **150** and **151**,[61] which are related to uronic acids.



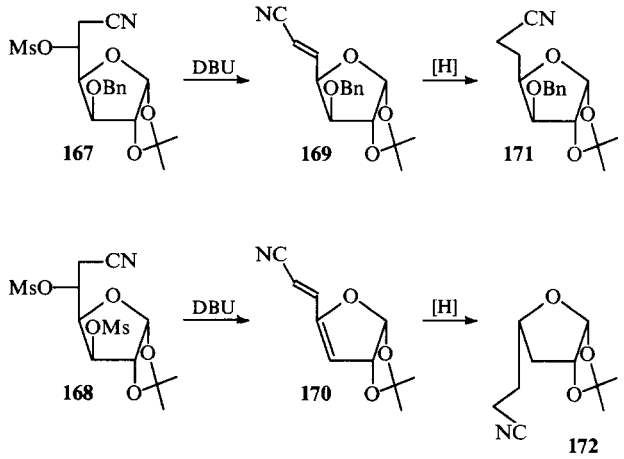
143 149 150 151

The unsaturated 2,3,4-trideoxyuronides **153** are formed on condensation of the glyoxylates **144** with 1-alkoxybuta-1,3-dienes **152**.[62–64]

152 144 153



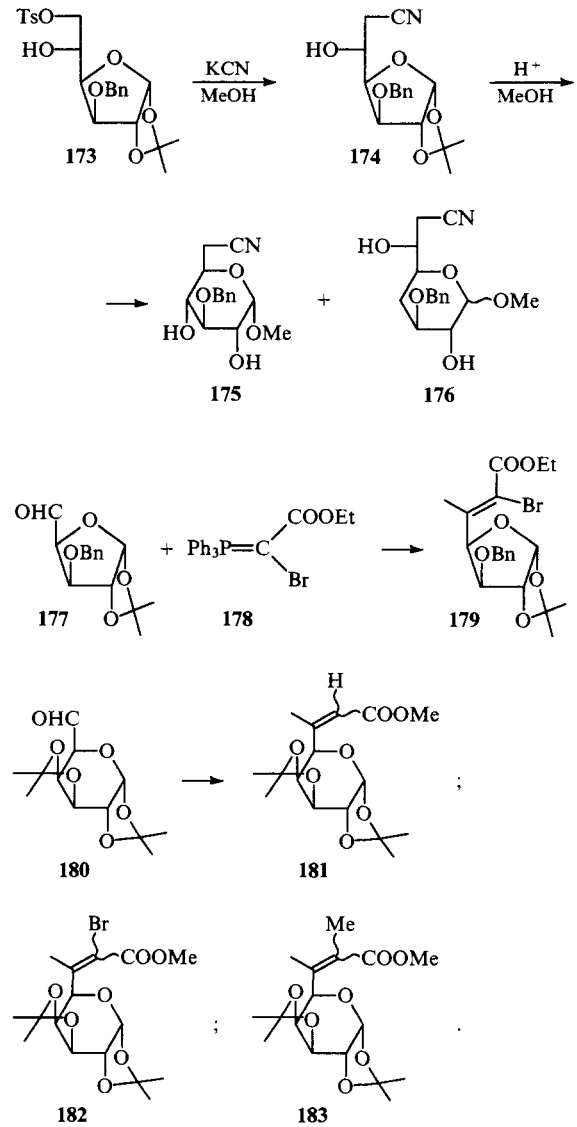
The 4-deoxy- and 2,4-dideoxy-D,L-mannopyranuronides **159** and **160** have been obtained by the hydrogenation of the Diels–Alder adducts **157** and **158** formed as a result of the condensation of compound **154** with the dienophiles **155** and **156**.[65]



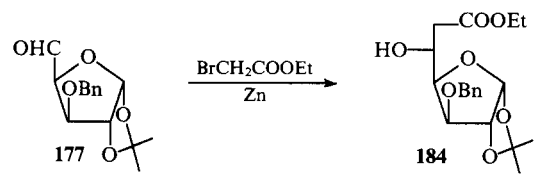
154 155 157 159 156 158 160

V. Higher and branched uronic acids

The substitution of primary tosyloxy-groups in sugars by potassium cyanide is used to obtain uronic acids with a lengthened carbon chain. It has been shown[66] that the interaction of D-glucofuranose tosylate **161** with potassium cyanide in acetone leads to the formation of the α-epoxide **162**, while the reaction in ethanol affords the nitrile **163**. The acetates of the α- and β-anomers of 6-deoxyhepturonitrile **165** and **166** have been obtained by the acid hydrolysis of the nitrile **163** and the acetylation of the D-pyranuronitrile **164** formed.



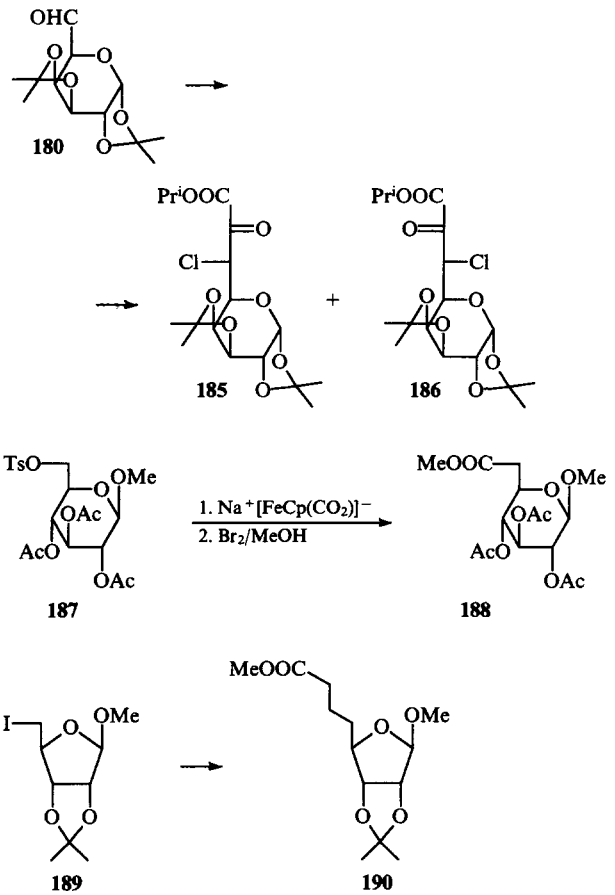
The monomethanesulfonyl derivative **167** and the di(methanesulfonyl) derivative **168** of the nitrile **163** are readily transformed on treatment with 1,5-diazabicyclo[5.4.0]undec-5-ene (DBU) into the unsaturated nitriles **169** and **170**, the reduction of which gives rise to D-dideoxyheptofuranurono-nitrile **171** and L-trideoxyheptofuranurononitrile **172**.



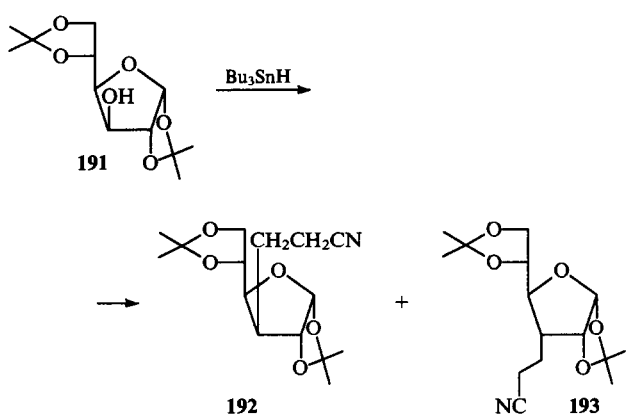
The interaction of the tosylate **173** with potassium cyanide in methanol leads to the 6-deoxyurononitrile **174**, the methanolysis of which results in the formation of the nitriles of the hexopyranuronide **175** and the hexofuranuronide **176**.[67]

The carbon chain of sugars can be built up by several units at once with the aid of the Wittig reaction. Treatment of the aldehyde **177** with bromoethoxycarbonylmethylenetriphenylphosphorane **178** affords a satisfactory yield of the unsaturated uronic acid ester **179**.[68]

This approach has been used to obtain the analogues of lincomycin **181**–**183** from the aldehyde **180**.[69]

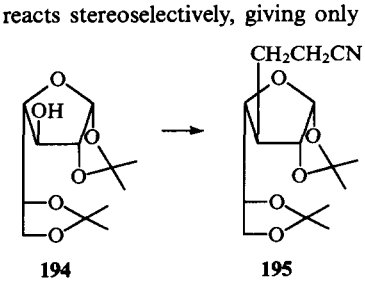


The Reformatskii reaction has been used to synthesise higher uronic acids. The condensation of the aldehyde **177** with ethyl bromoacetate and zinc gives rise to the ethyl 6-deoxyheptofuranuronate derivative **184**.[70]

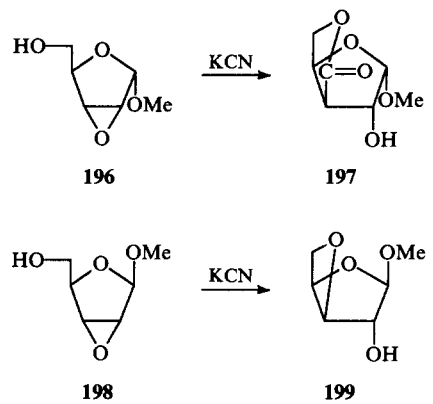


Under the conditions of the Darzens condensation, the aldehyde **180** condenses with dichloroacetic acid ester to form a diastereoisomeric mixture of glycidic esters, which are converted by treatment with $MgCl_2$ into the chlorodeoxyketouronic acid esters **185** and **186**.[71]

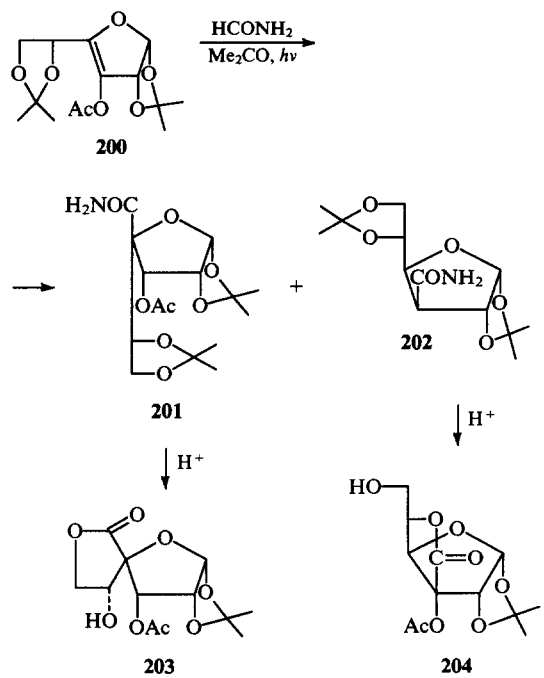
A method for lengthening the carbon chain of sugars with formation of uronic acids has been demonstrated.[72] It was shown that the interaction of the tosylate **187** with sodium dicarbonylcyclopentadienylferrate and then with bromine in methanol leads to the hepturonic acid ester **188**.



The free radical species generated from the iododeoxysugar **189** in the Zn–$FeCl_3$–NaI–Py system adds to methyl acrylate, affording the trideoxyoctofuranuronic acid ester **190**.[73]

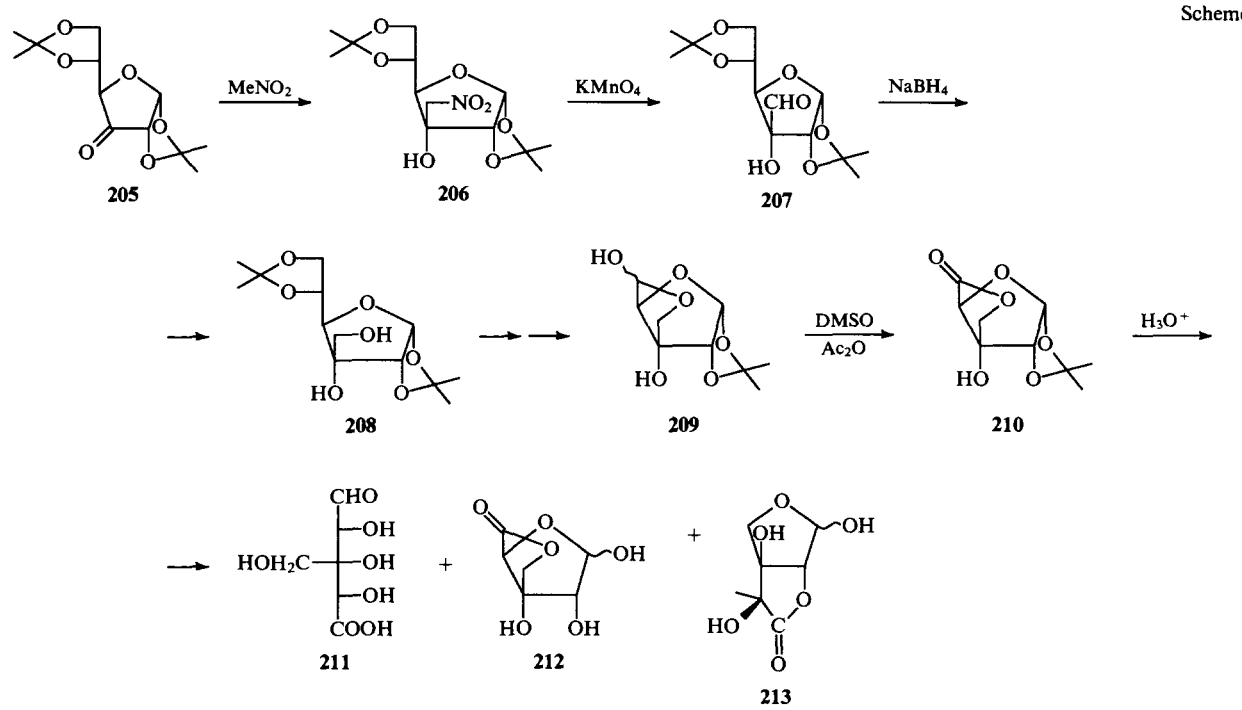


Alkyl halides form a C–C bond with electron-deficient alkenes in the presence of tributyltin hydride. It has been shown[74] that this reaction can be extended also to alcohols. The interaction of glucose diacetal **191** with acrylonitrile and tributyltin hydride results in the formation of a mixture of the isomeric uronic acid nitriles **192** and **193** branched at the C(3) carbon atom.

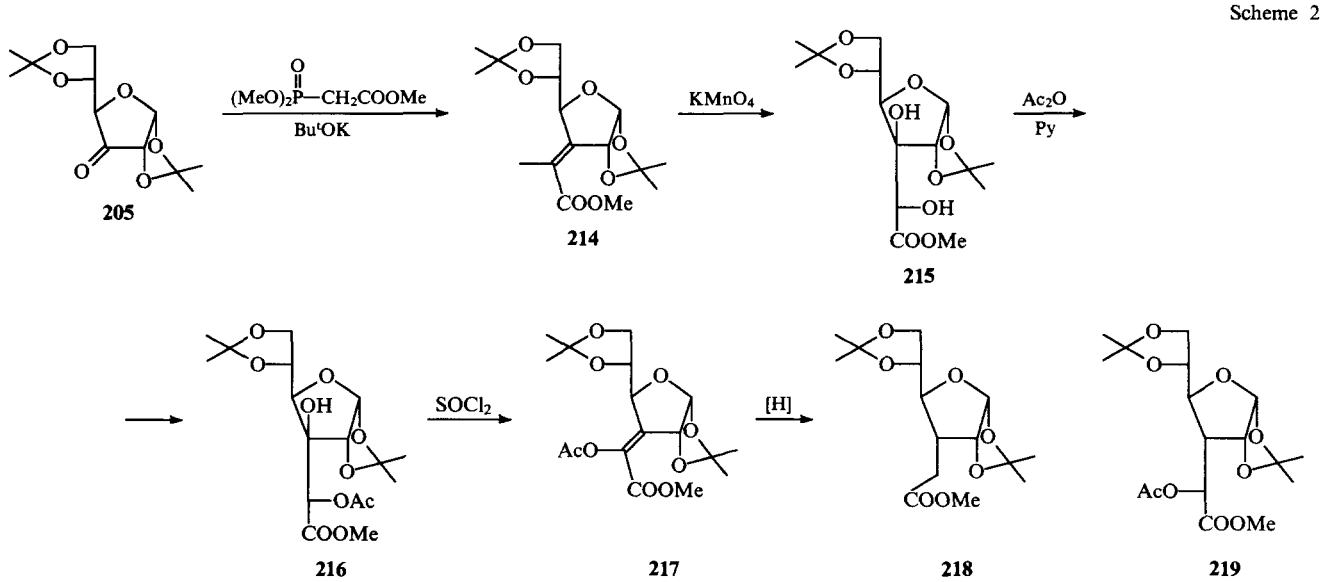


In contrast to the sugar **191**, the galactofuranose diacetal **194** reacts stereoselectively, giving only the nitrile **195**.

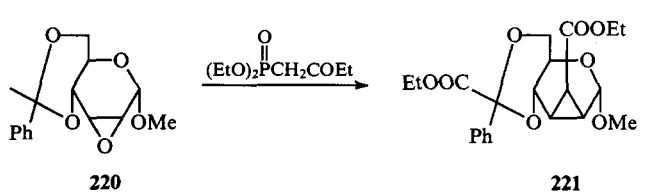
The opening of the oxirane ring on treatment with potassium cyanide can be used to obtain branched uronic acids.[75] Thus heating of 2,3-anhydro-α-D-riboside **196** in an aqueous solution of KCN gives rise to the lactone **197**. The β-D-riboside **198** is converted under these conditions into the 3,5-anhydro-β-D-riboside **199**.



The photoamidation of the unsaturated sugar **200** leads to the formation of the two isomeric carbamoylation products **201** and **202**.[76] Mild acid hydrolysis results in the formation of the spirolactone **203** from the amide **201** and of the lactone **204** from the isomer **202**.

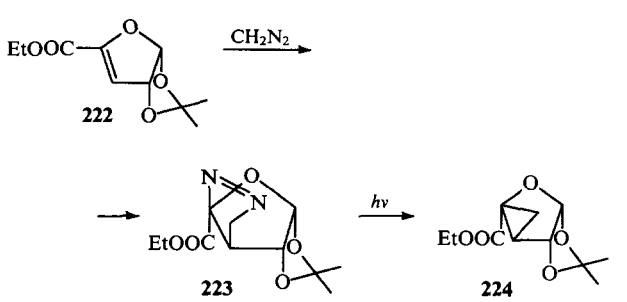


3-*C*-Hydroxymethyl-D-riburonic acid **211** has been detected in human bile as a complex of bilirubin glycosides. It was synthesised by treating the keto-derivative **205** with nitromethane and Bu^{t}OK. The Nef oxidation of the resulting nitroalcohol **206** with $KMnO_4$ led to the formation of the aldehydoalcohol **207**, which was smoothly reduced with $NaBH_4$ to the alcohol **208**. Successive acylation of the primary hydroxy-group in compound **208**, the removal of the isopropylidene protecting group, and the metaperiodate oxidation of the 5,6-diol group, and deacetylation led to the synthesis of the hemiacetal **209**. Its Pfitzner–Moffatt oxidation leads to the lactone **210**, the mild acid hydrolysis of which affords the acid **211** together with two of its isomeric lactones—**212** and **213** (Scheme 1).[77]

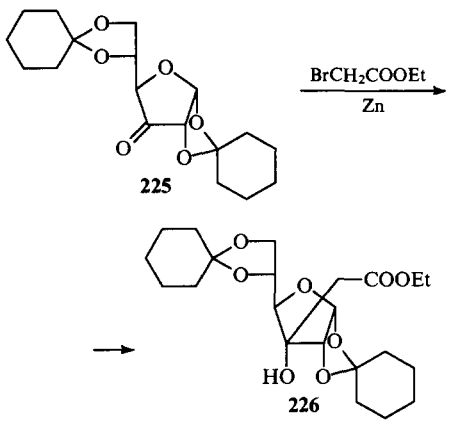


Scheme 1

Scheme 2

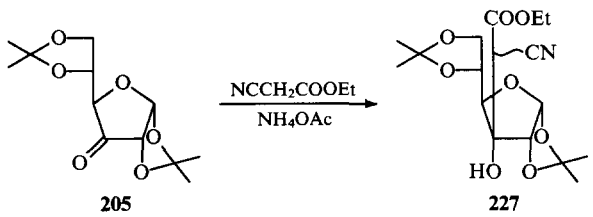


The condensation of the hexulose **205** with trimethyl phosphonoacetate in the presence of Bu^{t}OK leads to the unsaturated ester **214**, the hydroxylation of which with $KMnO_4$ in pyridine leads stereospecifically to the diol **215**. Its monoacetate **216** is transformed on treatment with thionyl chloride in pyridine into the enol acetate **217**, the reduction of which with hydrogen over platinum in methanol affords the deoxyacid ester **218**. The hydrogenation of the enol acetate **217** over palladium in ethyl acetate produces the acetate of the ester **219** (Scheme 2).[78]

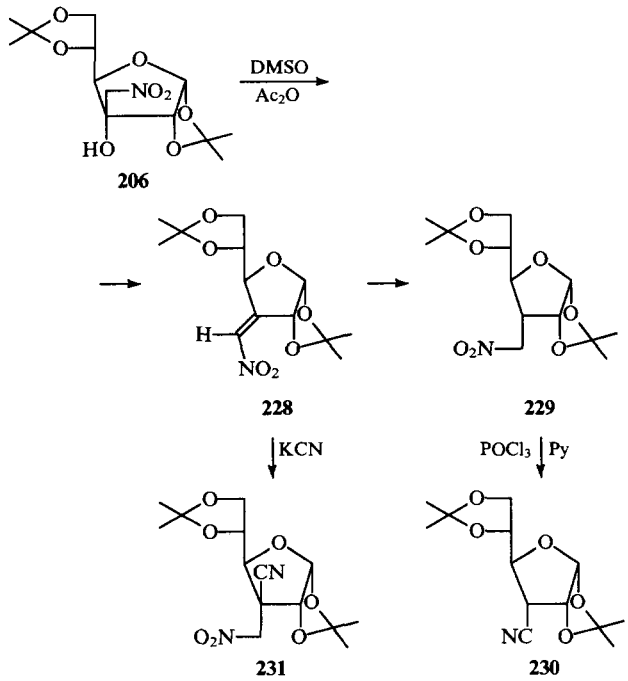


The ethyl ester of the branched uronic acid **221** has been obtained by treating the oxirane **220** with triethyl phosphonoacetate.[79]

The interaction of the eneuronate **222** with diazomethane and subsequent photolysis of the pyrazoline **223** formed give rise to the uronic acid ester **224** with a cyclopropane ring.[80]



The applicability of the Reformatskii reaction in the synthesis of branched deoxyuronic acid esters has been demonstrated.[81] The condensation of the ketone **225** with ethyl bromoacetate and zinc affords the deoxyacid ester **226**.

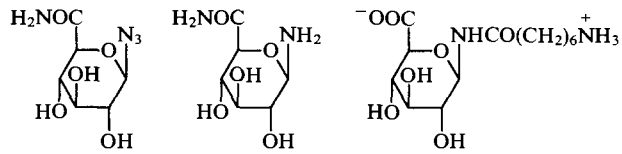


225 **226**

The Knoevenagel reaction between the carbonyl compound **205**, cyanoacetic ester, and ammonium acetate leads to the ester nitrile **227**, which gives rise to the possibility of synthesising branched uronic acids with an additional carboxy-group.[82]

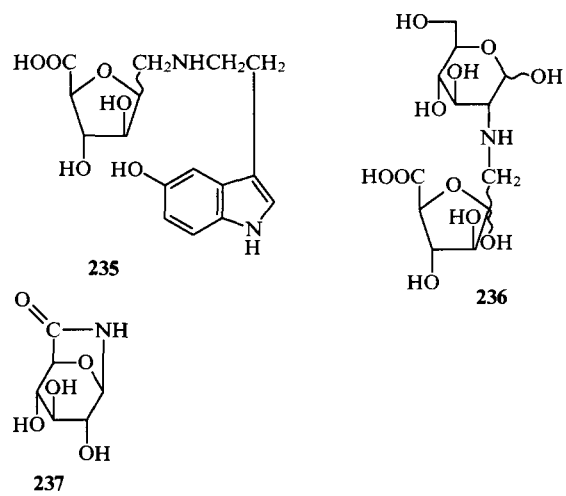
205 **227**

The nitroalcohol **206**, formed as a result of the condensation of compound **205** with nitromethane, leads to extensive possibilities for the synthesis of a whole series of derivatives of branched uronic acids.[83] The dehydration of the nitroalcohol by acetic anhydride in DMSO affords the 3-*C*-methylene derivative **228**. The product of its reduction **229** is converted into the nitrile **230** on treatment with phosphoryl chloride in pyridine. The alkene **228** readily combines with potassium cyanide, giving the nitrile **231**.



206 **228** **229** **231** **230**

VI. Aminodeoxyuronic acids

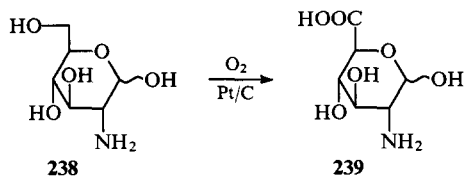


Aminodeoxyuronic acids are fairly common in nature. They have been detected in many bacterial polysaccharides and in nucleoside antibiotics.

The glycosylamines derived from uronic acids, which on the grounds of formal considerations can be considered in this section, are obtained by reducing the corresponding glycosyl azides; the latter are formed in their turn from acetylated halogenoses and sodium azide. The azide **232** and the amine **233** synthesised in this way exhibit antitumour activity.[84]

232 **233** **234**

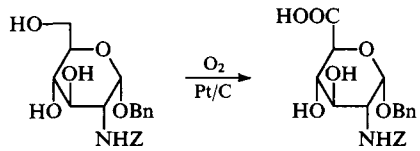
The ω-aminoheptanoyl derivative of β-D-glucuronopyranosylamine **234** is an effective inhibitor of β-D-glucuronidase.[85] Direct treatment of uronic acids with amines is accompanied by the Amadori rearrangement. Thus the condensation of glucuronic acid with serotonin and glucosamine afforded the derivatives **235** and **236** of 1-amino-1-deoxy-D-fructuronic acid,[86,87] although the lactam **237** could be isolated on treatment with ammonia.[88]



235 **236**

237

The synthesis and reactions of uronic acid nucleosides (*N*-uronides) have been considered in a review.[89]

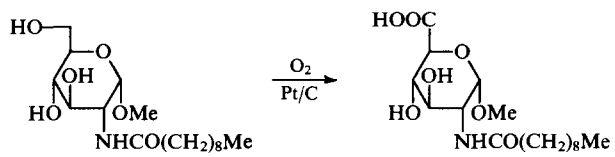


The methods of synthesis of the aminodeoxyuronic acid forming part of the composition of nucleoside antibiotics have been partly described in Suhadolnik's book.[90]

Mild oxidation by oxygen over platinum at pH 7 makes it possible to obtain 2-amino-2-deoxy-D-glucuronic acid **239** from glucosamine **238**.[91]

238 **239**

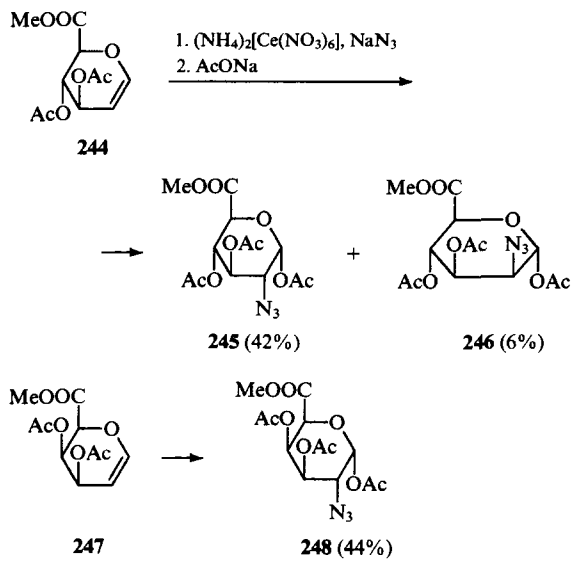
Since the free amino-group lowers the activity of the platinum catalyst, sugars with protected amino-group and hemiacetal hydroxyl are usually employed for the oxidation. The oxidation of the sugar **240** yields the acid **241**, the hydrolysis of which leads to the aminoacid **239**.[92]



240 241

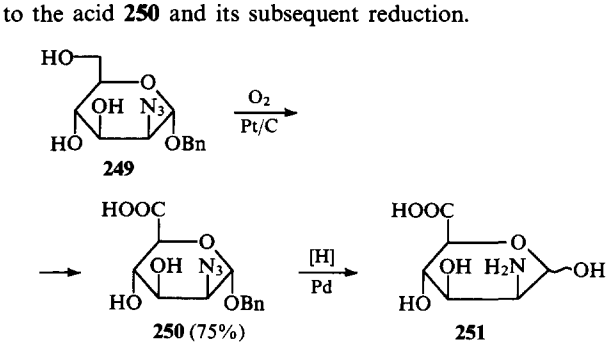
Z = $C_6H_5CH_2COO$.

It has been shown[93-95] that an increase in the rate of stirring of the solution leads to an appreciable improvement of the yield of the acid synthesised from the sugar **240** and its β-anomer.



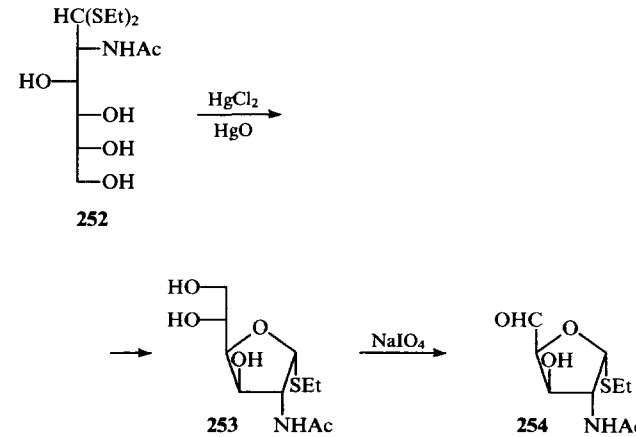
The corresponding aminouronic acids have been obtained similarly from D-galactosamine and D-mannosamine.[96-98]

Oxidation by oxygen over platinum has been used to obtain from the methyl glycoside derived from *N*-decanoyl-D-glucosamine **242** the aminodeoxyuronic acid derivative **243**, which forms part of the composition of the antibiotic aridicin.[99]



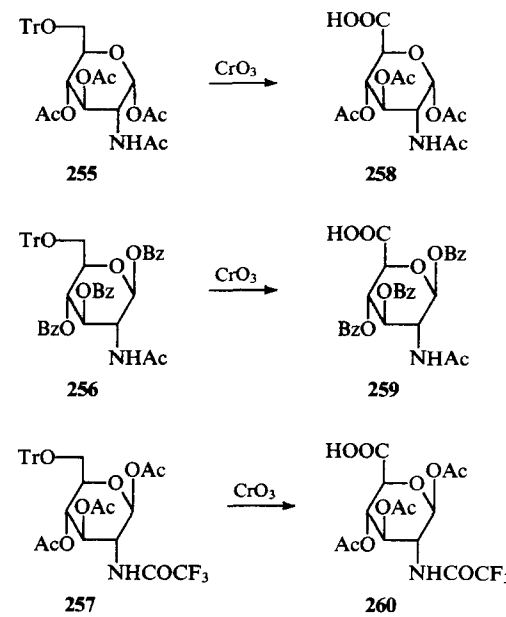
242 243

Another approach to the synthesis of 2-amino-2-deoxyuronic acid has been proposed.[100] It consists in the successive treatment of the glycal **244** with cerium ammonium nitrate and sodium azide and acetate, which results in the formation of the azides **245** and **246**. The azide **248** was obtained from the glycal **247**. The hydrogenolysis of the azides affords high yields of the corresponding amines.



244 245 (42%) 246 (6%) 247 248 (44%)

An alternative scheme for the synthesis has been developed by Paulsen et al.[98] who employed catalytic oxidation of the azide **249** to the acid **250** and its subsequent reduction.

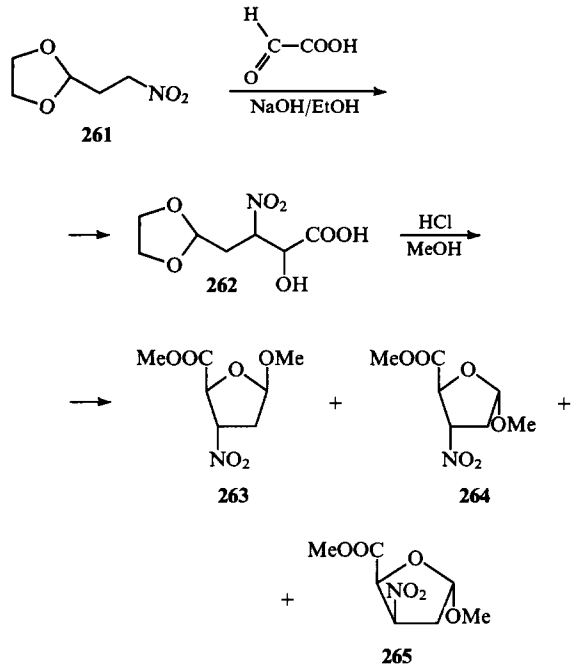


249 250 (75%) 251

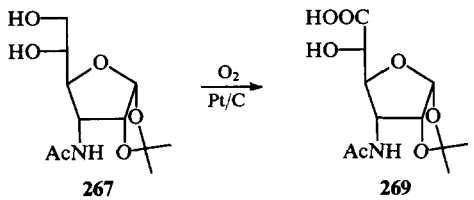
The diethyl dithioacetal of 2-acetamido-2-deoxy-D-glucose **252** is a potential source for the synthesis of aminodeoxyuronic acids. The aldehyde **254**, obtained from the furanose **253** by periodate oxidation, may be readily converted into the corresponding acid.[101]

252 253 254

It has been shown[102] that the trityl derivatives **255**, **256**, and **257** of the acylated glucosamine are readily oxidised by the Jones reagent to the corresponding aminodeoxyglucuronic acids **258**–**260**.

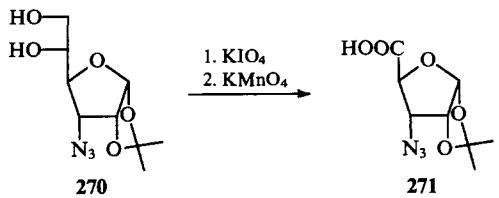


255 258 256 259 257 260

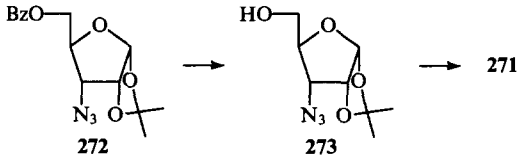


Since the nitro-group in sugars can be readily reduced, nitrodeoxyuronic acids are of definite interest. The synthesis of compounds of this type has been described. The nitroacid **262**, formed from the ethylene acetal of 3-nitropropanal **261** and glyoxylic acid, affords a mixture of the isomeric 2,3-dideoxynitro-D,L-furanuronates **263**, **264**, and **265** in HCl solution in methanol.[103]

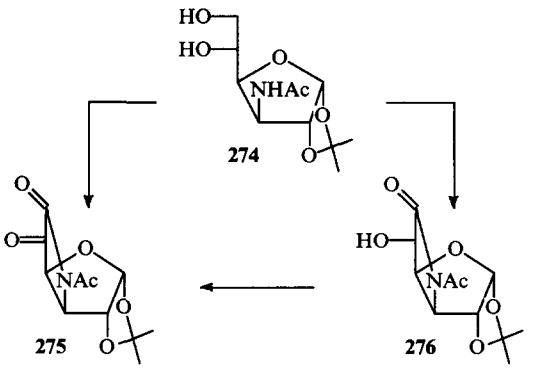
The same authors proposed 2,3-*O*-isopropylidene-D-glyceraldehyde as the initial compound for the synthesis of 3-nitrouronic acids of this type.[104]



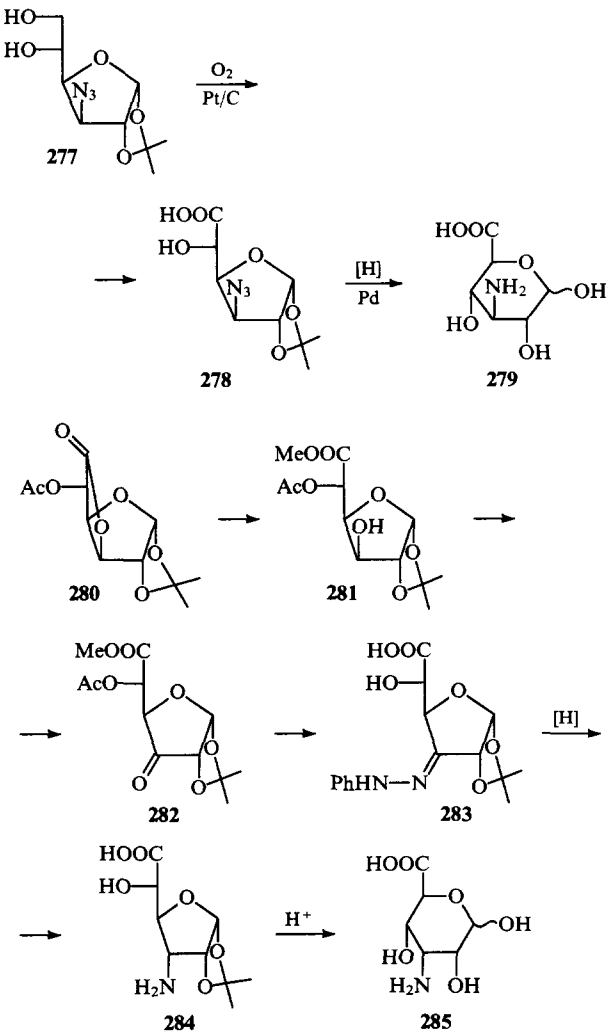
3-Acetamido-3-deoxy-α-D-ribofuranuronic acid **268** has been obtained by oxidising the pentofuranose **266** with $KMnO_4$ and by the successive treatment of the hexofuranose **267** with $NaIO_4$ and Br_2.[105]



Catalytic oxidation of 3-acetamidoallofuranose **267** leads to the 3-amino-3-deoxy-D-allofuranuronic acid derivative **269**.[106,107]

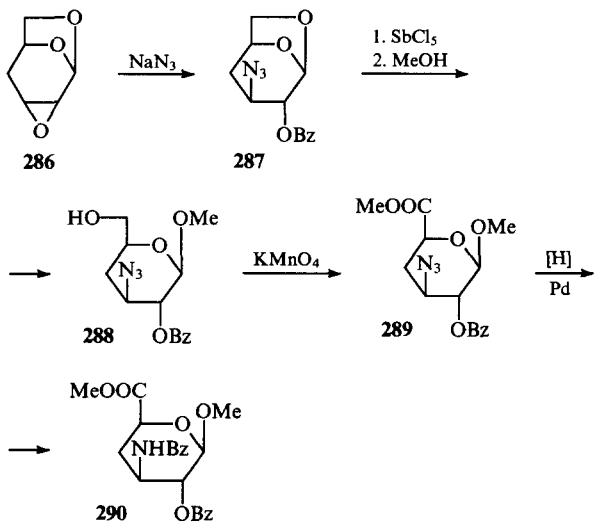


The successive oxidation of the azide **270** with KIO_4 and $KMnO_4$ leads to a satisfactory result in the synthesis of 3-azido-3-deoxyriburonic acid **271**.[108]

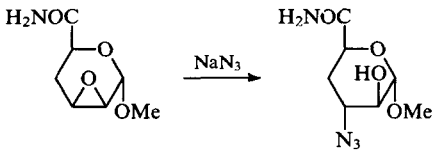


The acid **271** has been obtained by the debenzoylation of the azide **272** and the oxidation of the resulting alcohol **273** with $KMnO_4$.[109]

The oxidation of 3-acetamido-3-deoxyglucofuranose **274** with pyridinium dichromate in DMF leads to the ketolactone **275**, while oxidation with the Jones reagent affords the lactam **276**.[44]

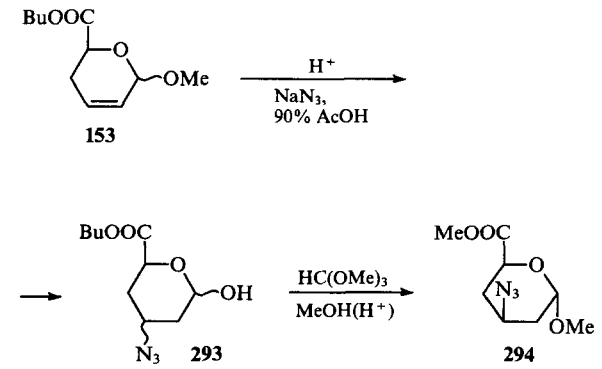


3-Amido-3-deoxyglucuronic acid **279** has been obtained from the azide **277**, which was oxidised by oxygen over platinum to the acid **278** and the product of its spontaneous hydrolysis was reduced over palladium, which led to the isolation of the required aminoacid **279**.[110]



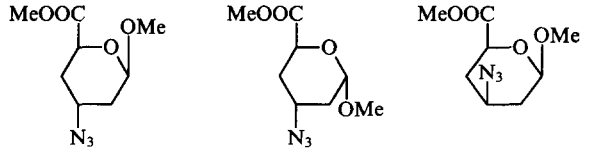
The transesterification of the lactone **280** in methanol, catalysed by an anion-exchange resin, and the oxidation of the resulting alcohol **281** with chromium trioxide in ethyl acetate lead to the ketone **282**. Its phenylhydrazone **283** is reduced by hydrogen over platinum to the aminoacid **284**, the acid hydrolysis of which affords 3-amino-3-deoxy-D-alluronic acid **285**.[111]

The ezoaminuronic acid derivative **290**, which forms part of the composition of the antibiotic ezomycin, has been obtained from the oxirane **286**, which is converted into the azide **287** on heating with sodium azide and acylation. The alcohol **288**, formed as a result of the opening of the 1,6-anhydro-ring by antimony pentachloride, is oxidised with $KMnO_4$, the acid is esterified, the ester **289** is reduced, the amino-group is benzoylated, and 3-benzamido-3,4-dideoxy-D-glucopyranuronide **290** is obtained.[112]



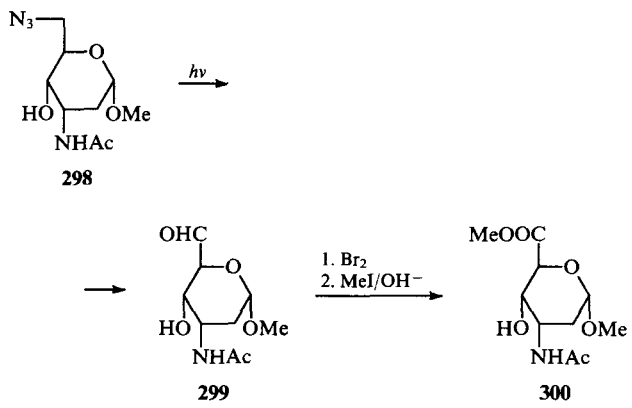
286 287 288 289 290

The 3-azido-3,4-dideoxyuronamide **292** is formed as a result of the interaction of the oxirane **291** with sodium azide.[113]

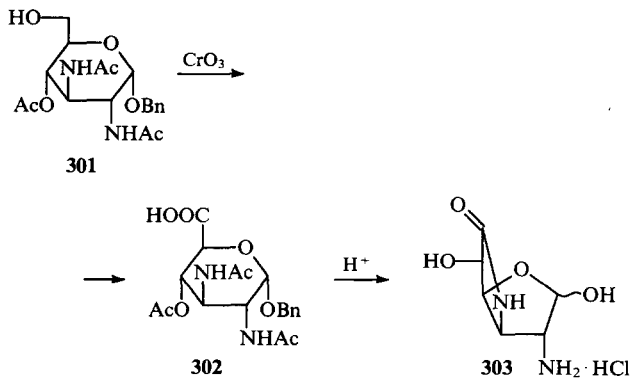


291 292

The unsaturated 4-deoxyuronides **153** interact with sodium azide in 90% acetic acid to form a mixture of the isomeric azides **293**, the treatment of which with orthoformic ester in methanol leads to the isomeric 3-azido-3-deoxypyranuronides **294**–**297**.[114]

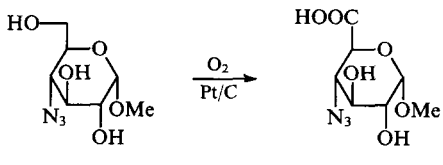


153 293 294



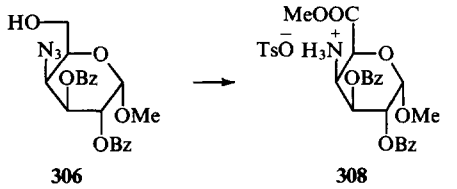
295 296 297

The primary azido-group in sugars is capable of being transformed into an aldehyde as a result of photocleavage. The aldehyde **299**, obtained on UV irradiation of the azide **298**, is oxidised with bromine, esterified, and the ester of the methyl glycoside derived from 3-acetamido-2,3-dideoxy-D-allopyranuronic acid **300** is isolated.[115]



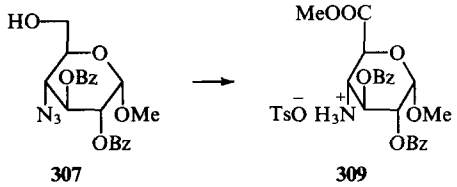
298 299 300

Diaminouronic acids have been detected in certain polysaccharides. The 2,3-diacetoamidouronic acid **302** has been obtained when the α-benzyl glycoside derived from 2,3-diacetamidoglucopyranose **301** was oxidised with the Jones reagent. Hydrolysis of the acid **302** leads to the 2-amino-6,3-lactam **303**.[116]



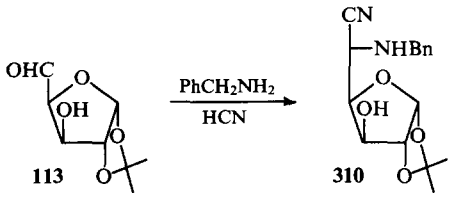
301 302 303

Apart from the methods of synthesis of 4-amino-4-deoxyuronic acids (forming part of the composition of the nucleoside antibiotics gougerotin and blasticidin S) considered in Suhadolnik's review,[90] there are at least two further examples of their synthesis in the literature. It has been shown[108] that the 4-azido-4-deoxy-D-glucopyranoside **304** is smoothly oxidised by oxygen over platinum to the azidoacid **305**.

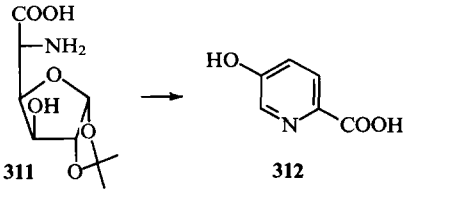


304 305

The oxidation of the 4-azidosugars **306** and **307** with the D-galacto- and D-gluco-configurations by $KMnO_4$ in acetone and acetic acid afforded the corresponding acids, the esterification and hydrogenolysis of which give rise to the aminodeoxyuronic acid esters **308** and **309**.[117]

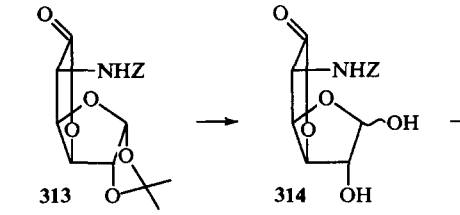


306 **308**

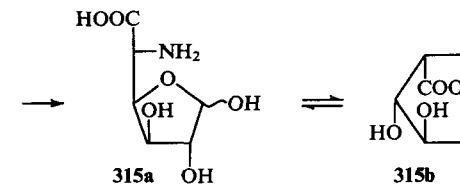


307 **309**

5-Aminodeoxyuronic acids have been detected in polyoxine antibiotics.[90] One of the first syntheses of compounds of this group described involves the addition of benzylamine and hydrocyanic acid to the aldehyde **113** with formation of 5-benzylamino-L-iduruononitrile **310**.[118]

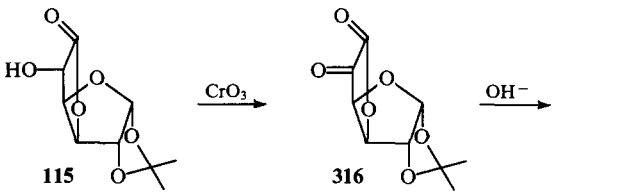


113 **310**

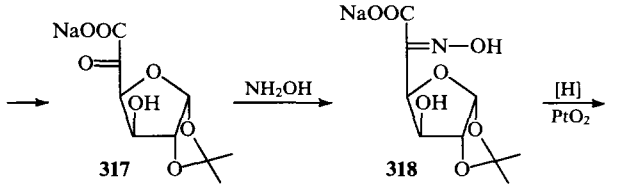


The hydrolysis of the nitrile **310** and the reductive elimination of the *N*-benzyl group over Raney nickel lead to the aminoacid **311**, the acid hydrolysis of which results in the formation of the pyridinecarboxylic acid **312**. 5-Amino-5-deoxy-L-iduronic acid has been obtained as an equilibrium mixture of the isomers **315a** and **315b** after the hydrolysis of the *N*-benzyloxycarbonyl derivative **313** and the removal of the *N*-protecting group from compound **314**.[119]

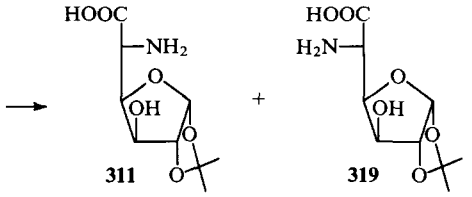
311 **312**



313 **314**

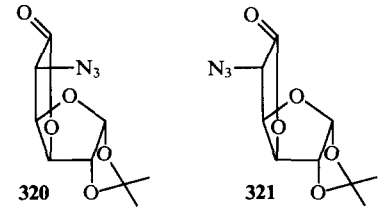


315a **315b**

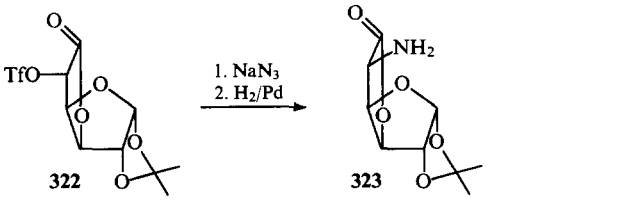


L- and D-5-amino-5-deoxyidoglucofuranuronic acids (compounds **311** and **319**) have been obtained from the glucurone acetal **115** as a result of its oxidation to the ketolactone **316**, the conversion of the salt **317** into an oxime, and the reduction of the oxime **318** by hydrogen over platinum black under pressure.[120]

115 **316**

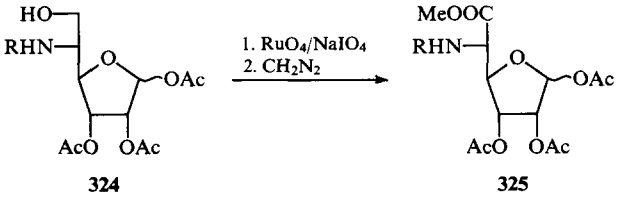


317 **318**



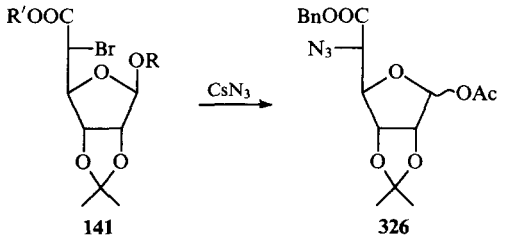
311 **319**

5-Azido-5-deoxyhexofuranuronolactones have found an application in the synthesis of 5-aminodeoxyuronic acids. The interaction of the lactone **115** with hydrazoic acid in the presence of triphenylphosphine and azodicarboxylic acid ester leads to the formation of 5-azidolactones with the L-ido- and D-idogluco-configurations (compounds **320** and **321**) in 45% and 20% yields respectively.[121]



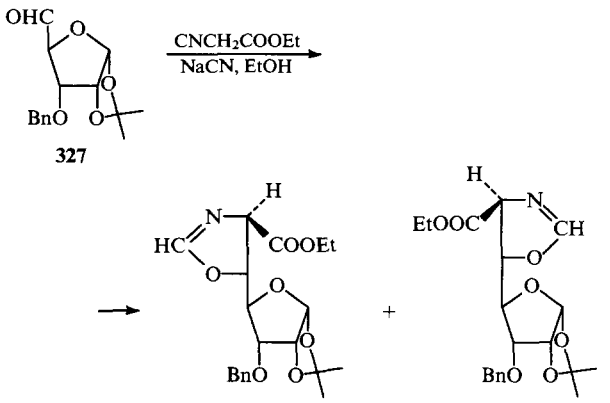
320 **321**

Treatment of the glucurone triflate **322** with sodium azide at −20 °C affords a satisfactory yield of the azide **320**, the reduction of which leads to the aminolactone **323**.[122]



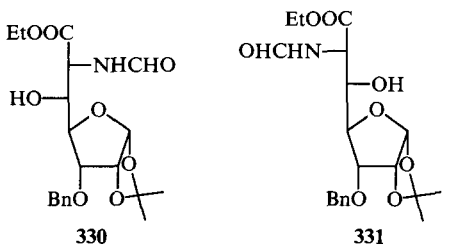
322 **323**

324 **325**

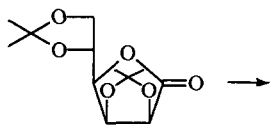


The oxidation of a derivative of the amine **324**, obtained as a result of asymmetric synthesis from the *N*-BOC-*N*,*O*-isopropylidene derivative of D-serinal and the ester of lithioethynecarboxylic acid (BOC = *tert*-butoxycarbonyl), to the aminodeoxyuronate **325** has been described.[123]

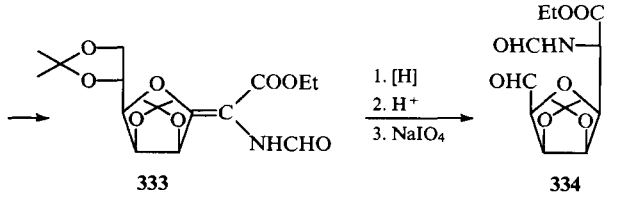
5-Azido-5-deoxy-D-allofuranuronate **326** has been obtained by the nucleophilic substitution reaction between the bromoderivative **141** and caesium azide.[58]



141 **326**

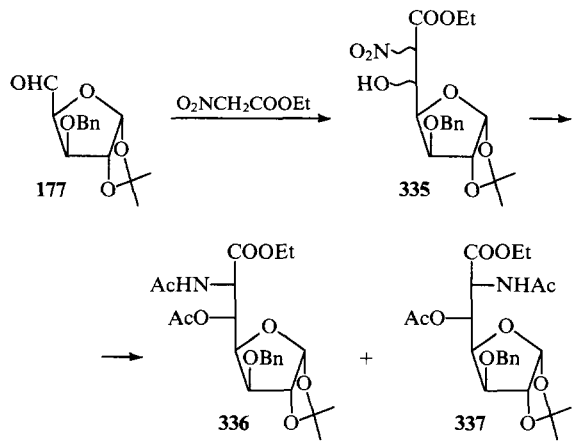


In connection with the problem of the synthesis of the structural fragments of certain antibiotics, methods have been developed for the synthesis of higher and branched aminodeoxyuronic acids. Thus treatment of the aldehyde **327** with ethyl isocyanoacetate and sodium cyanide in ethanol results in the formation of a diastereoisomeric mixture of the oxazolines **328** and **329**, the hydrolysis of which leads to the formation of isomeric 6-formamido-6-deoxyhepturonates **330** and **331**.[124]



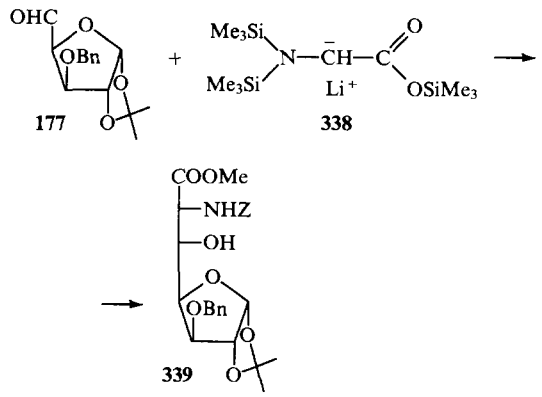
327 **328** **329**

330 **331**



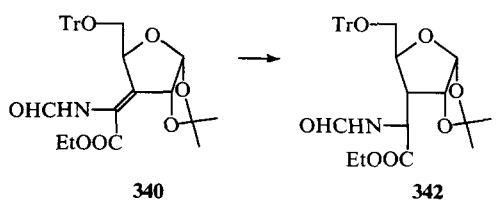
332

333 **334**



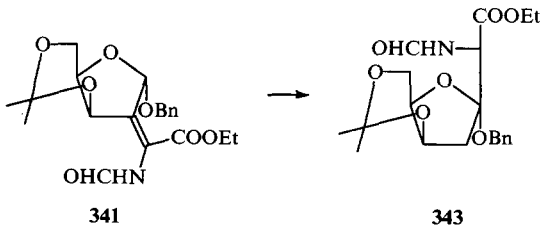
The unsaturated adduct **333**, formed from the lactone **332** and ethyl isocyanoacetate, is transformed into 6-formamido-6-deoxy-L-hepturonate **334** as a result of hydrogenation, the selective removal of one isopropylidene group, and oxidation with sodium metaperiodate.[125]

The nucleophilic addition of ethyl nitroacetate to the aldehyde **177**, the hydrogenation of the nitroester **335**, and subsequent acetylation also lead to the formation of 6-amino-6-deoxyhepturonate derivatives (compounds **336** and **337**).[126]



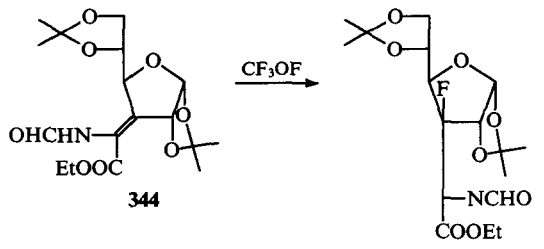
177 **335** **336** **337**

The 6-amino-6-deoxy-L-hepturonate derivative **339** was obtained in the same laboratory by adding the lithium salt of silylated glycine **338** to the aldehyde **177**.[127]

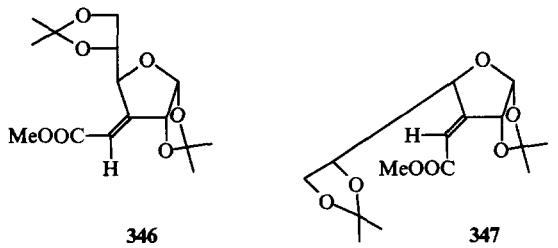


177 **338** **339**

The unsaturated esters **340** and **341**, obtained from the corresponding ketones and ethyl isocyanoacetate, are used for the synthesis of branched aminodeoxyuronic acids. The hydrogenation of compounds **340** and **341** leads to the aminoacid derivatives **342** and **343**.[128,129]

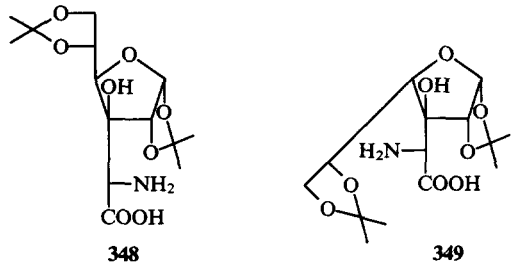


340 **342**



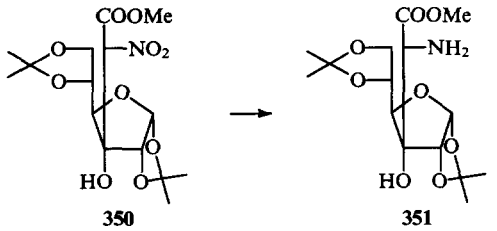
341 **343**

The fluorine-containing aminouronic acid derivative **345** is formed when the adduct **344** interacts with trifluoro-(fluorooxy)methane.[130]

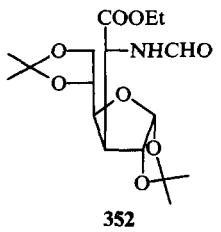


344 **345**

The unsaturated esters **346** amd **347** are converted by hydroxylation with the aid of $KMnO_4$ into branched uronic acids, which are transformed into the aminodeoxyuronic acids **348** and **349** as a result of the substitution of a hydroxyl by an amino-group.[131,132]

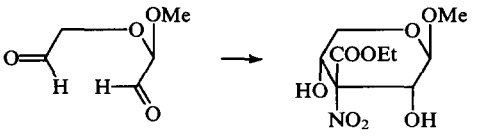


346 **347**



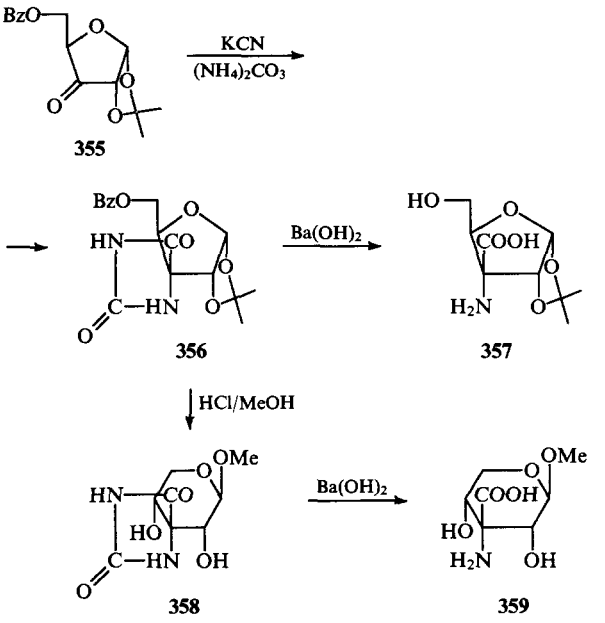
348 **349**

The addition of methyl nitroacetate to the aldehyde **205** with formation of the nitroester **350** is one of the ways of obtaining the branched aminouronate **351**.[133]



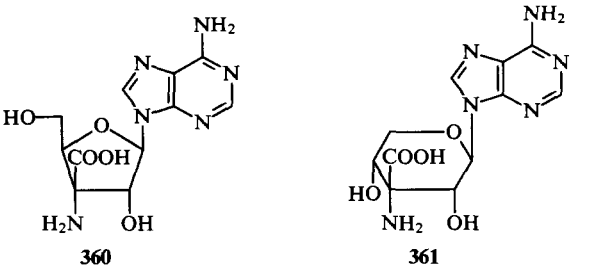
350 **351**

The aminouronate **352**, having a similar structure, has been synthesised by adding ethyl isocyanoacetate to the aldehyde **205**.[134]



352

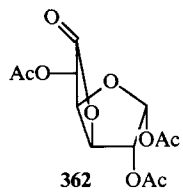
The ability of type **353** dialdehydes, synthesised from pyranosides, to interact with ethyl nitroacetate, forming, for example, the nitroester **354**, may serve as yet another way of synthesising branched aminouronic acids.[135]



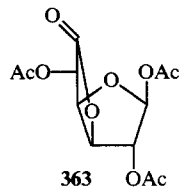
353 **354**

Another scheme for the synthesis of branched aminouronic acids involves the Bucherer conversion of the ketone **355** into the hydantoin **356**, the hydrolysis of which with $Ba(OH)_2$ leads to the aminoacid **357**, while methanolysis affords the hydantoin **358**, which is easily hydrolysed by $Ba(OH)_2$ to the aminoacid **359** with a pyranose ring.[136]

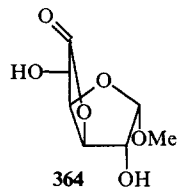
355 **356** **357** **358** **359**



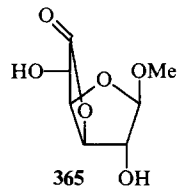
The sugars **358** and **359** obtained have been used to synthesise analogues **360** and **361** of the nucleoside antibiotic puromycin.



360 **361**

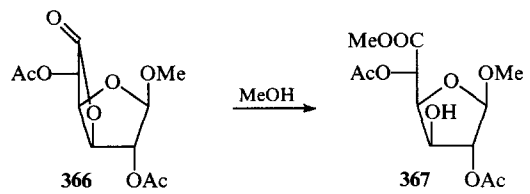


VII. Reactions of uronic acids



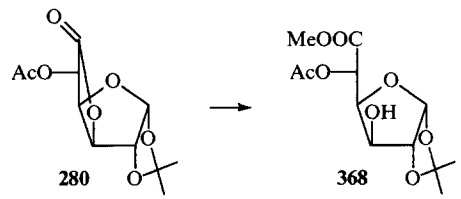
One of the most typical reactions of uronic acids is the formation of lactones. Lactones with different positions and sizes of the lactone rings are in their turn widely used for the synthesis of sugars with the necessary set of protecting groups. D-Gluco-furanurono-6,3-lactone (glucurone) **24** is formed when an aqueous solution of D-glucuronic acid is evaporated. The acetates **362** and **363** with the α- and β-anomeric configurations are synthesised by acetylating glucurone with acetic anhydride in the presence of pyridine or $ZnCl_2$.[137] Brief treatment of glucurone with boron trifluoride etherate in acetic anhydride gives the acetate **363** in 90% yield.[28]

362



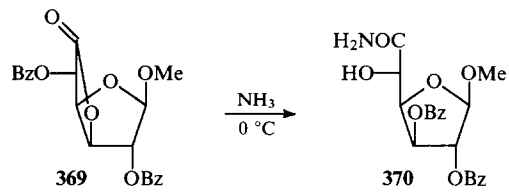
363

A convenient method of synthesis of 1,2-*O*-isopropylidene-glucurone **115** involves the refluxing of glucurone in acetone over a cation-exchange resin.[138] Treatment of glucurone with methanol and the cation-exchange resin leads to a mixture of the α- and β-D-glucofuranuronides **364** and **365**.[139]



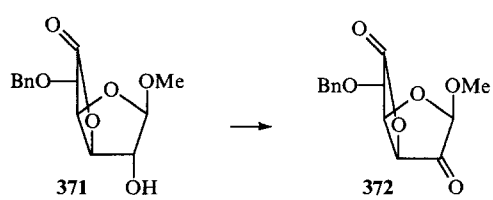
364

365



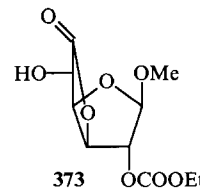
It has been shown that under controlled conditions the lactone **366** is deacetylated (with retention of the lactone ring) by ammonia to the lactone **365**, while refluxing in methanol converted it into the methyl ester **367**.[140]

366 → 367

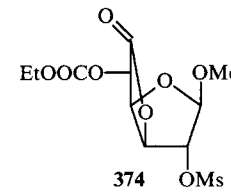


The opening of the lactone rings in the lactone **280** with formation of the ester **368** is readily achieved with the aid of triethylamine or an anion-exchange resin.[141,142]

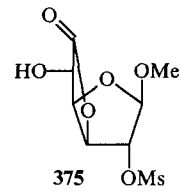
280 → 368



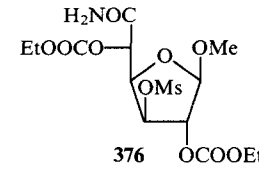
On treatment of the lactone **369** with ammonia in chloroform, the benzoyl group is found to migrate from the 5-position to the 3-position with formation of the amide **370**.[143]



369 → 370



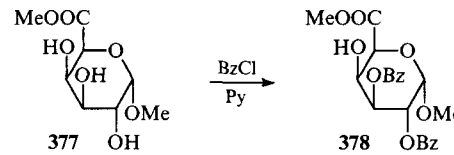
The ketolactones **100** and **372** have been obtained from the lactones **115** and **371** by treatment with DMSO and acetic anhydride as well as RuO_4.[144,145]



371 → 372

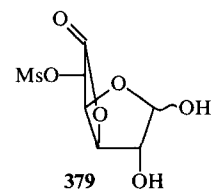
A difference between the reactivities of glucurone and its derivatives has been demonstrated.[146] Conditions were selected under which it is possible to obtain the sugars **373**–**376** protected in different ways.[146]

373

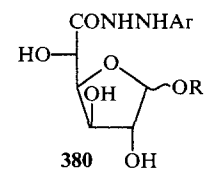


374

375

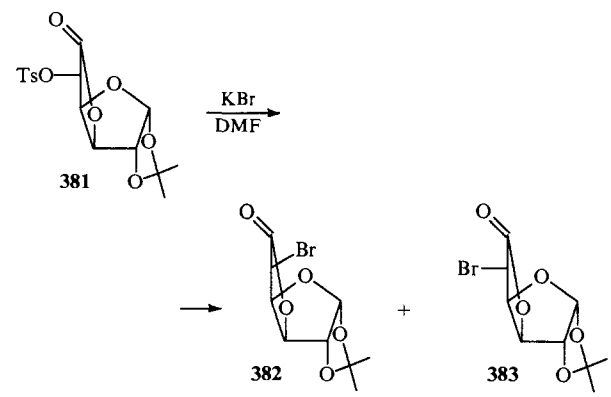


376



Selective acylation of glucurone and its derivatives by pivaloyl chloride in pyridine affords reaction products with different numbers of pivaloyl groups. The relative reactivities of the hydroxy-groups [OH(5) > OH(2) > OH(1)] depend to a large extent on the reaction conditions.[147]

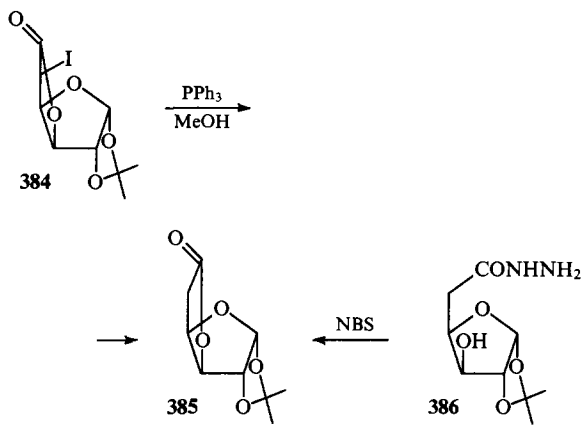
The dibenzoate **378** can be obtained by the selective benzoylation of the galacturonide **377**.[148]



377 → 378

The methods of synthesis of various amides and *N*-aryl-glucuronides from D-glucurone, ammonia, and aromatic amines have been described.[149] The methanesulfonate **379** was found to possess an antitumour activity,[150] while the hydrazides having the general formula **380** were found to offer protection against hepatitis.[151]

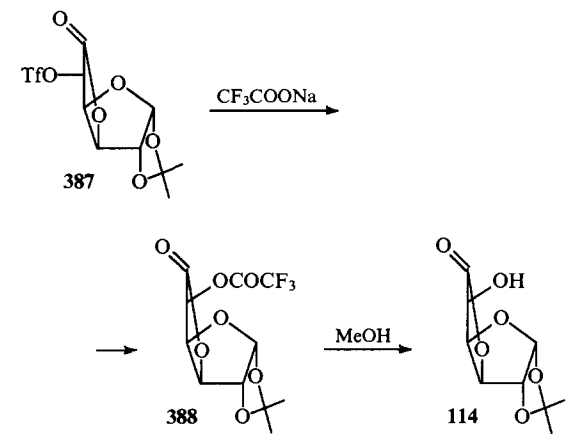
379



380

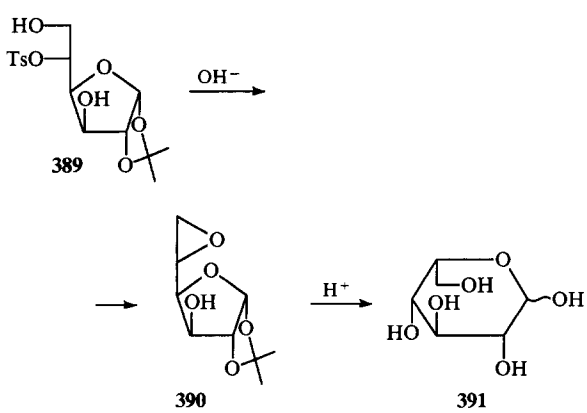
A characteristic property of glucurone derivatives is their extensive decomposition with formation of conjugated polyenes as a result of β-elimination, which competes with nucleophilic substitution at the C(5) carbon atom. Examples of reactions of this kind have been reviewed.[152]

381 → 382 + 383

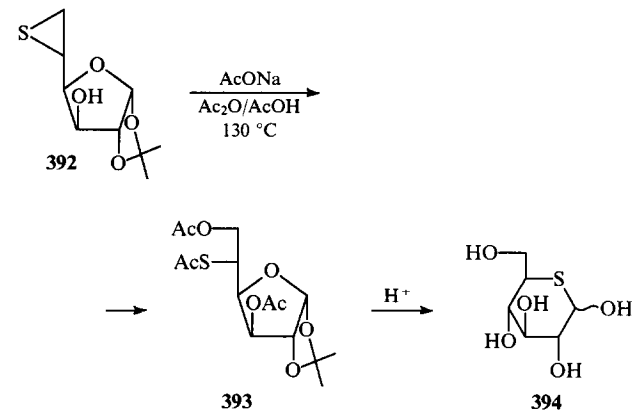


Nucleophilic substitution of the tosyl group can be achieved only with the aid of nucleophiles having a low basicity. Thus a mixture of the isomeric bromo-derivatives **382** and **383** is obtained when the tosylate **381** is heated with KBr in DMF.[153]

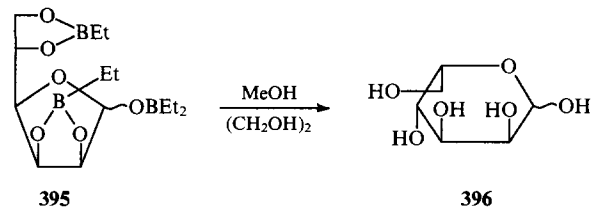
The interaction of the lactone **115** with triphenylphosphine iodide leads to the iodo-derivative **384** (with inversion of configuration), which is converted into 5-deoxylactone **385** on treatment with triphenylphosphine in methanol.[154]



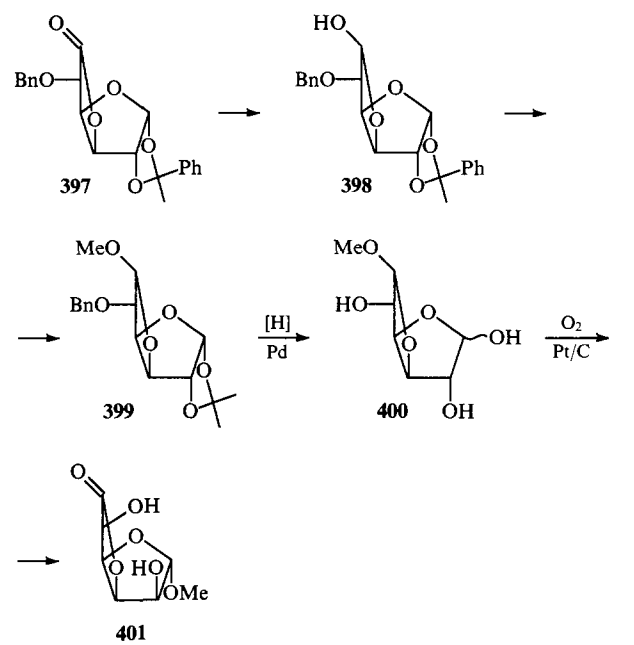
It has been observed that the tosylate **381** is readily converted into the 5-deoxysugar **386** as a result of its reaction with hydrazine.[105] Treatment of the hydrazide **386** with *N*-bromosuccinimide (NBS) leads to the 5-deoxylactone **385**.[154]



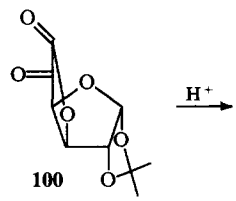
The triflate **387** is transformed under very mild conditions into the trifluoroacetate **388**, the methanolysis of which results in transition to the L-iduronolactone **114**.[155]



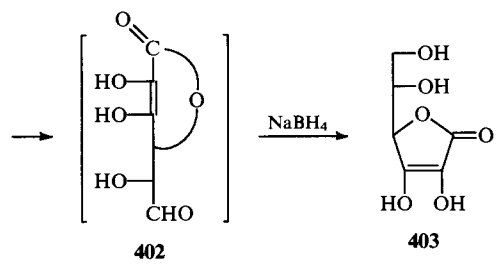
The lactone **381** is smoothly reduced by $NaBH_4$ to the alcohol **389**, from which the oxirane **390**, transformed further to L-idose **391**, is obtained on treatment with a base.[156]



The oxirane **390** interacts with thiourea to form the thiirane **392**. Its treatment with sodium acetate in an acetate anhydride–acetic acid mixture leads to the triacetate **393** and to 5-thio-D-glucose **394** after the removal of the protecting groups.[157]

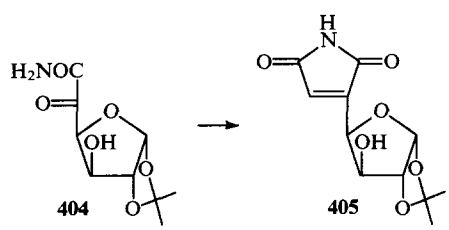


The reduction of glucurone by diethylborane takes place with formation of the borate **395**, which is readily hydrolysed to L-gulose **396**.[158]

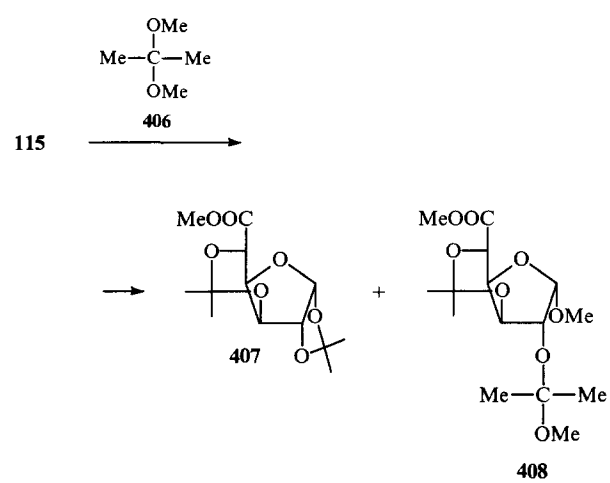


Yet another example of the transformation of the lactones into sugars which are otherwise difficult to obtain is the reduction of the D-glucuronolactone derivative **397** to the hexodialdofuranose **398**, the formation of the methyl glycoside **399**, its hydrogenolysis to the sugar **400**, and the catalytic oxidation of the latter to L-gulofuranourono-6,3-lactone **401**.[159]

Hydrolysis of the ketolactone **100** gives the aldehyde **402**, the reduction of which with $NaBH_4$ leads to L-ascorbic acid **403**.[160,161]

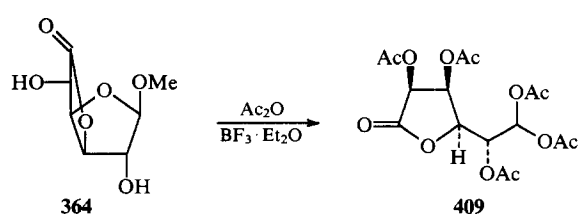


100



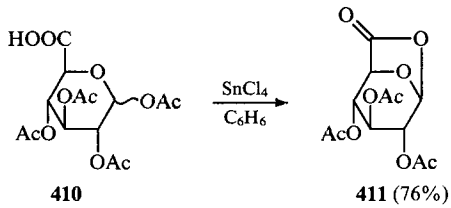
402 403

The ketoamide **404**, obtained from the lactone **100**, reacts with ethoxycarbonylmethylenetriphenylphosphorane to form the analogue of the antibiotic showdomycin **405**.[162]



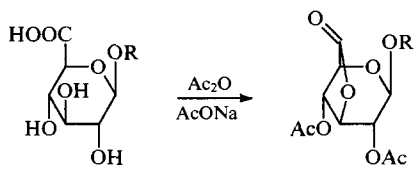
404 405

Prolonged refluxing of the lactone **115** with dimethoxypropane **406** and *p*-toluenesulfonic acid in acetone results in the formation of the diacetal **407** and the uronide **408**.[163]



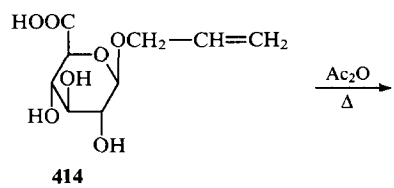
115 406 407 408

Acetolysis of the lactone **364** gives rise to the acylal **409**.[164]

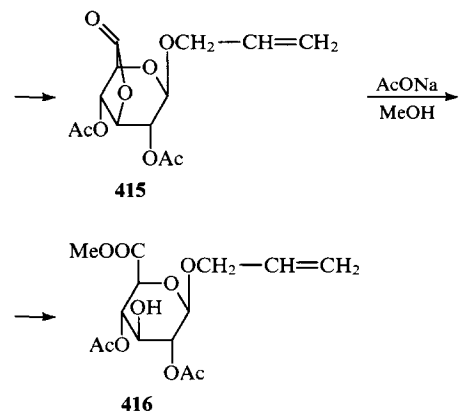


364 409

Acetylation of the sodium salt of D-glucuronic acid by acetic anhydride and *p*-toluenesulfonic acid makes it possible to obtain an anomeric mixture of the tetraacetates **410**. Its refluxing with $SnCl_4$ in benzene leads to the 6,1-lactone **411**.[165]

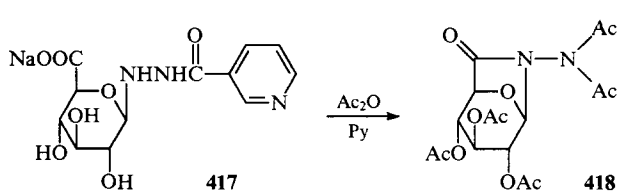


410 411 (76%)

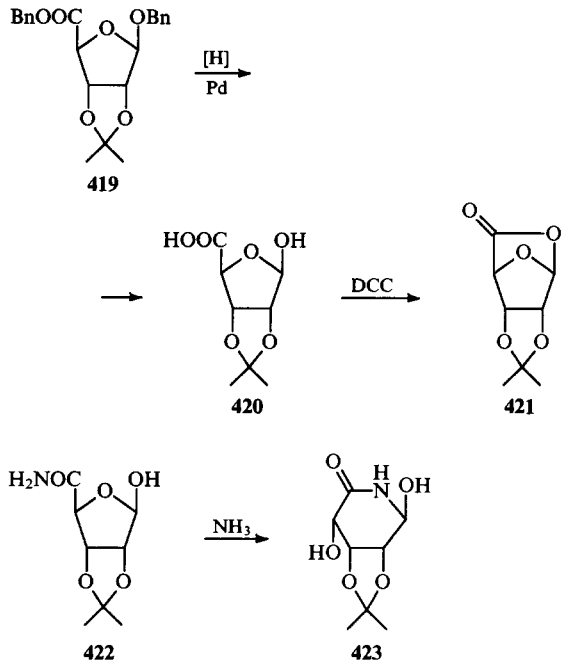


D-Glucopyranurono-6,3-lactone **413** has been obtained by treating the glucuronide **412** with sodium acetate in acetic anhydride at room temperature.[166] Brief heating of the glucuronide **414** in acetic anhydride with subsequent addition of pyridine also makes it possible to obtain the 6,3-lactone **415**, which is converted on treatment with sodium acetate in methanol into the uronate **416** with a free hydroxy-group.[167]

412 413

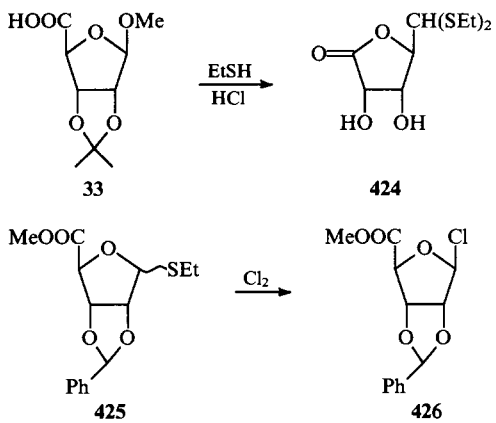


414

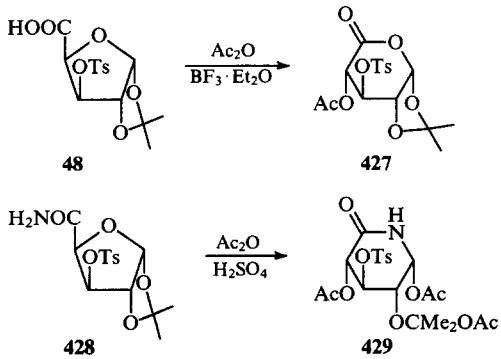


415 416

The formation of the lactam **418** has been detected after prolonged treatment of the hydrazide **417** with acetic anhydride and pyridine.[168]

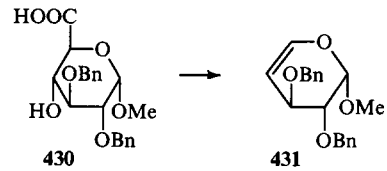


417 418

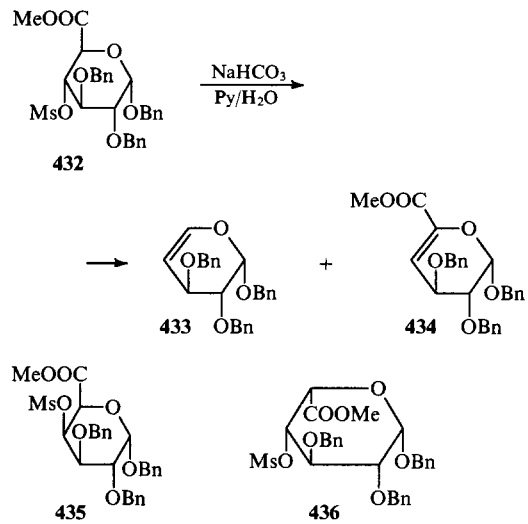


The formation of the lactones and lactams having different structures is characteristic also of penturonic acids. Thus the acid **420**, formed as a result of the hydrogenolysis of the D-riburonate **419**, can be cyclised to the 5,1-lactone **421** with the aid of dicyclohexylcarbodiimide (DCC) in ether. On treatment with ammonia, the amide **422** is converted into the lactam **423**.[169]

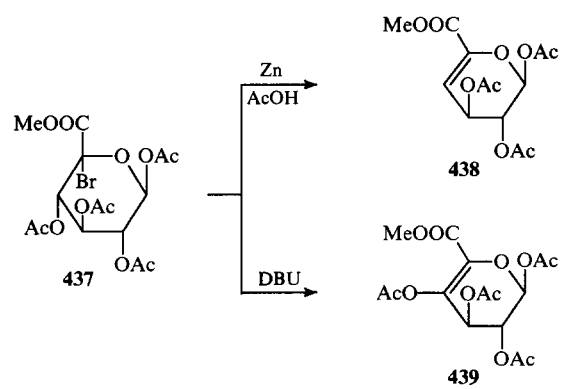
The acid **33** reacts with ethanethiol and concentrated HCl to form the lactone **424**. Chlorination of the ribouronate **425** obtained from compound **424** led to the synthesis of the glycosyl chloride **426** and some of its analogues.[170]



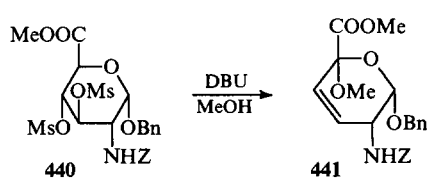
On treatment with acetic anhydride and boron trifluoride etherate, the acid **49** rearranges to the lactone **427**. Under acetolysis conditions, the amide **428** is transformed into the lactam **429**.[171,172]



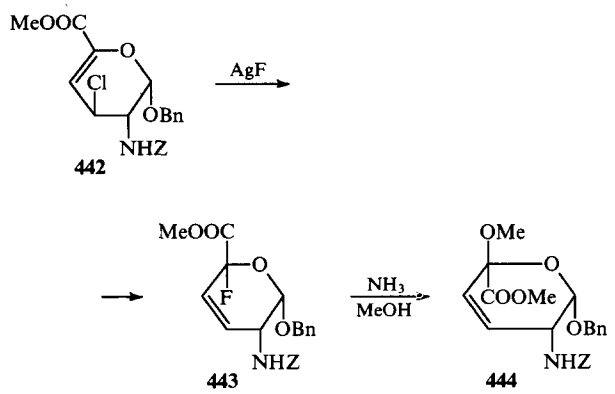
A characteristic feature of uronic acids is their ability to be converted by bases, as a result of β-elimination reactions, into unsaturated compounds, which are used in their turn in the synthesis of diverse derivatives of uronic acids. The principal characteristics and a large number of examples of β-elimination reactions have been described in a review.[173]



The β-elimination reaction coupled with decarboxylation merits special attention. Thus heating of the glucuronide **430** with the dineopentyl acetal of dimethylformamide leads to the formation of the unsaturated sugar **431**.[174]

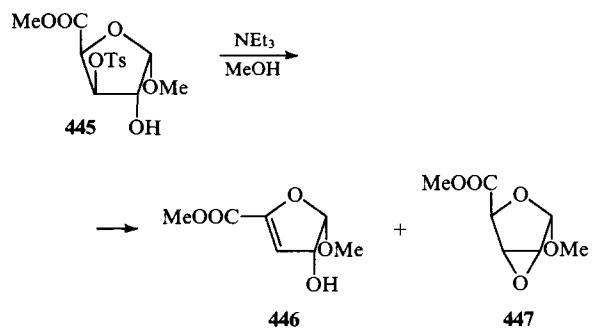


Treatment of the glucuronate **432** with sodium bicarbonate in aqueous pyridine leads to the formation of the decarboxylated sugar **433** and the eneuronate **434**. The galacturonate **435** is not decarboxylated under these conditions, giving rise only to the uronate **434**. The L-iduronate **436** is converted into the uronate **434** and a small amount of the sugar **433**.[175]

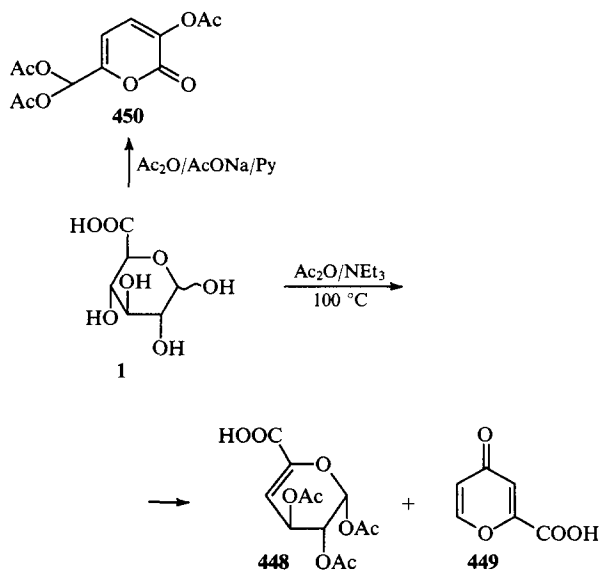


The 5-bromouronate **437** interacts with zinc in acetic acid to form the 4,5-unsaturated uronate **438**, whilst its reaction with DBU leads to its 4-acetoxy-analogue **439**.[176]

Treatment of the di(methanesulfonate) **440** with DBU in methanol led to the formation of the 3,4-unsaturated 4-methoxyuronate **441**.[177]



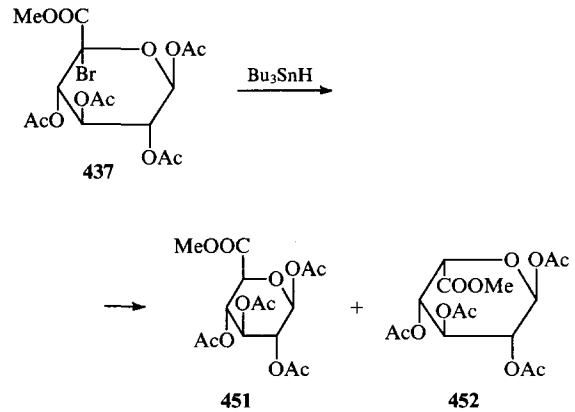
The unsaturated 3-chlorouronate **442** interacts with AgF, affording the 5-fluorouronate **443**, which is converted on treatment with ammonia in methanol into the uronate **441** and its isomer **444**.[178]



442 **443** **444**

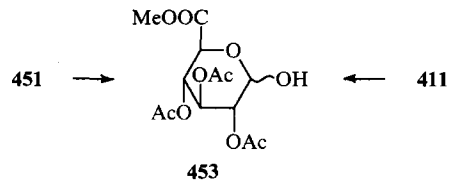
The xyluronate **445** exhibits a dual reactivity.[179,180] Its refluxing with triethylamine in methanol gives rise to the 3,4-unsaturated uronate **446** and the oxirane **447**.[21]

445 **446** **447**



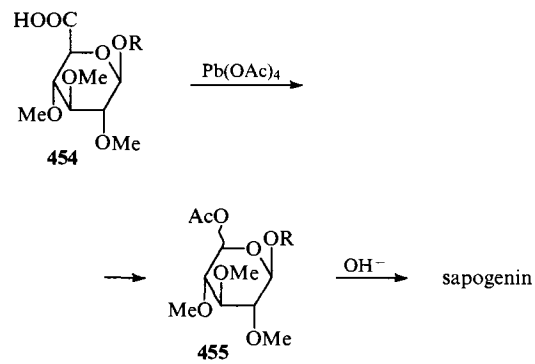
The formation of β-elimination products is observed in the interaction of free uronic acids with weak bases in acetic anhydride. When D-glucuronic acid **1** is heated with triethylamine in acetic anhydride, the 4,5-unsaturated acid **448** and coumanic acid **449** are formed. Heating of the acid **1** with pyridine in a mixture of acetic acid and its anhydride leads to the acylal of the unsaturated lactone **450**.[181]

450 **1** **448** **449**



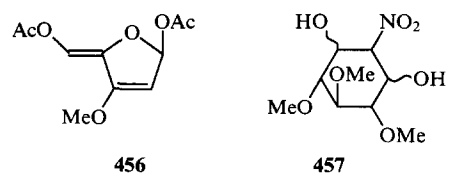
Coumanic acid **449** is formed in a satisfactory yield on heating the peracetate of D-glucuronic acid **410** with pyridine in acetic anhydride.[182]

On interaction with tributyltin hydride, the 5-bromouronate **437** already mentioned is converted into a mixture of the D-glucuronate **451** and the L-iduronate **452**.[183,184]



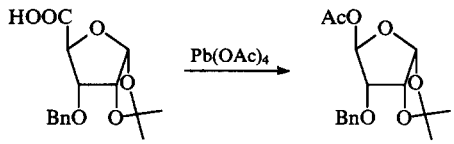
437 **451** **452**

The acetate of D-glucuronic acid **453** with a hemiacetal hydroxy-group, which is of definite interest, may be obtained in two ways: by heating the peracetate **451** with Bu_3SnOMe in toluene and by treating the lactone **411** with methanol in the presence of pyridine.[165]

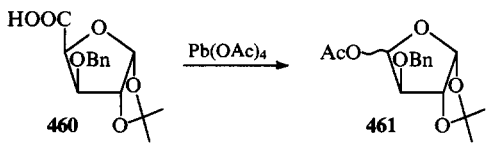


453

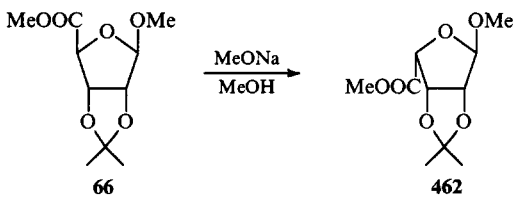
The methylated glycosides of uronic acids are decarboxylated by refluxing them with lead tetraacetate in benzene. The acetate **455** formed from the acid **454** as a result of the decarboxylation decomposes on treatment with alkali, liberating the aglycone and a product the acylation of which leads to the diene **456**.[185,186]



454 **455**

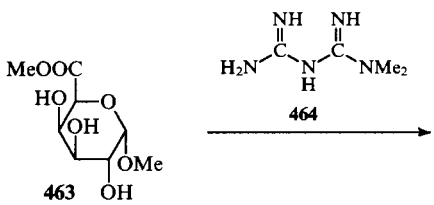


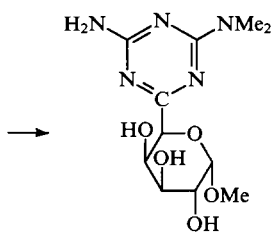
The condensation of the acetate **455** with nitromethane has found an application in the synthesis of the nitrocyclitols **457**.[187]



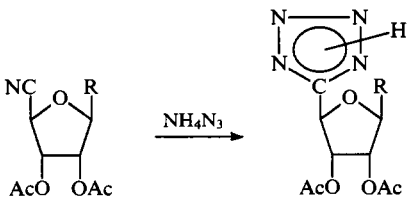
456 **457**

The interaction of protected riburonic and xyluronic acids (compounds **458** and **460**) with $Pb(OAc)_4$ results in the formation of the corresponding acetates **459** and **461**.[188]

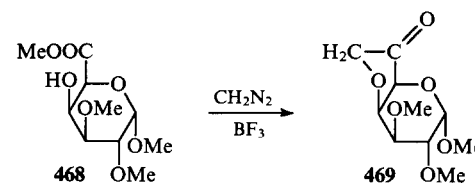




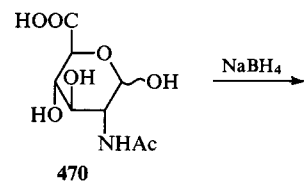
The D-riburonic acid ester **66** can be converted into the L-lyxuronic acid ester **462** by simple treatment with sodium methoxide in methanol.[11,189]

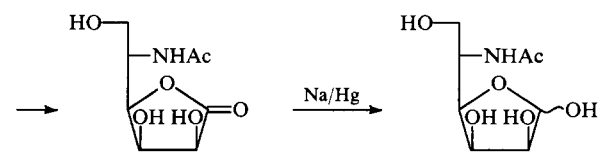


Reactions characteristic of the carboxy-group and its derivatives constitute yet another means for the modification of uronic acids. On treatment with dimethylbiguanidine **464**, the galacturonate **463** is transformed into the 5-triazine derivative of the β-L-arabinopyranoside **465**.[190]

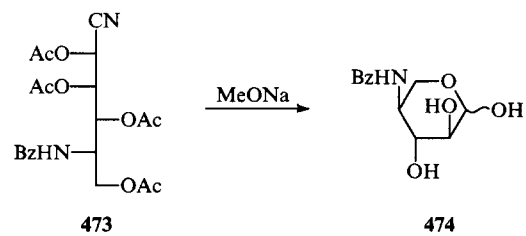


On treatment with ammonium azide, the nitrile **466** is converted into the tetrazole derivative **467**.[191]

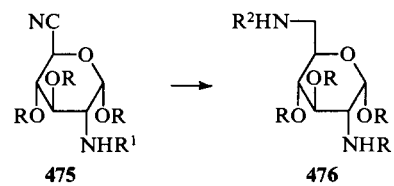




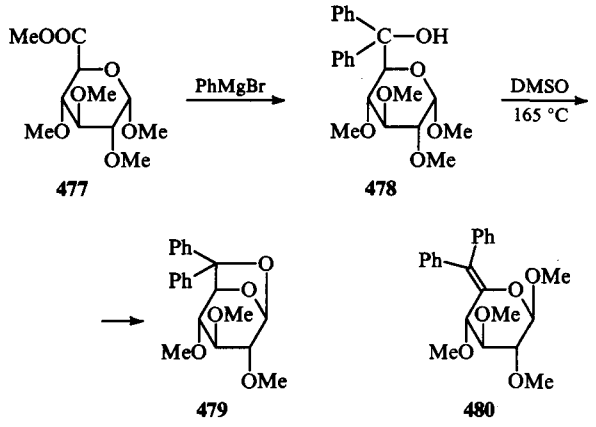
An unusual result has been obtained on treating the galacturonate **468** with diazomethane in the presence of BF_3. Together with the expected methylation product, the formation of the ketone **469** was observed.[192]



Uronic acids serve as a source of glyconolactones. L-Gulono- and L-galactono-lactones are obtained by reducing D-glucuronic and D-galacturonic acids with $NaBH_4$.[193]



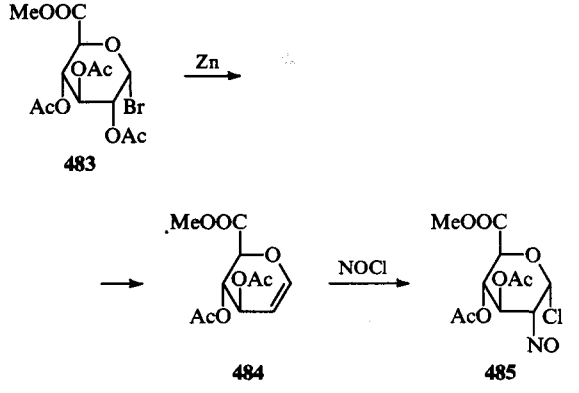
The possibility of using aminodeoxyuronic acids for the synthesis of aminosugars which are difficult to obtain has been demonstrated.[194] The lactone **471** has been obtained by reducing 2-acetamidoglucuronic acid **470**. Its reduction with sodium amalgam affords 5-acetamido-L-gulofuranose **472**. The nitrile **473**, obtained from the *N*-benzoylated lactone, is converted into 4-benzamido-L-xylopyranose **474** on treatment with sodium methoxide.



The reduction of the nitrile **475** makes it possible to synthesise the diaminosugar **476**.[195]

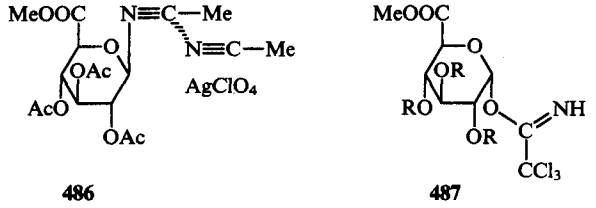
Treatment of the permethylated methyl α-D-glucuronide **477** with phenylmagnesium bromide gives the tertiary alcohol **478**, which is converted into the anhydrosugar **479** on heating in DMSO, whereas the corresponding β-glycoside preferentially forms the 5-enylpyranoside **480** under the same conditions.[196]

Numerous examples of the synthesis of glycuronides have been described systematically in a review.[197]

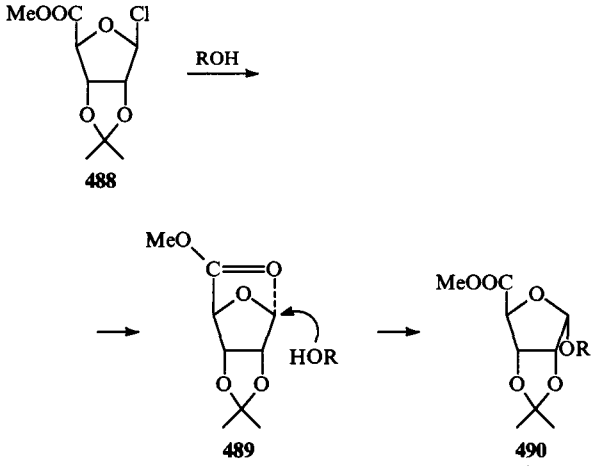


The presence of an alkoxycarbonyl group in the molecule exerts a significant influence on the stereochemical result of the reactions involving glycosylation by uronic acids, which depends in many respects on the selected reaction conditions (solvent, condensing agent, temperature). Halogenoses

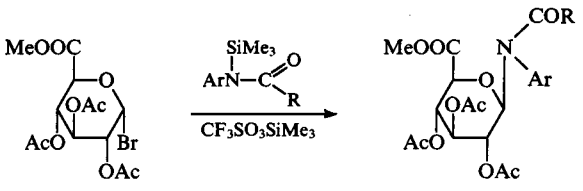
[haloakylhalides? Ed.] are the most active glycosylating agents. The formation of the halo-derivatives of uronic acids is achieved with the aid of dihalomethyl methyl ether together with the employment of the traditional method. The $ZnCl_2$-catalysed reaction of the galacturonide **481** with dichloromethyl methyl ether affords the chlorosugar **482** in a satisfactory yield.[198]



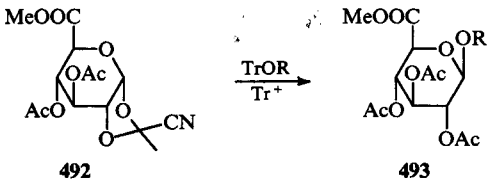
The addition of nitrosyl chloride to the glycal **484**, synthesised from the bromo-derivative **483**, leads to the chlorosugar **485** containing a nitroso-group, which is capable of being transformed further into an aminosugar.[199]



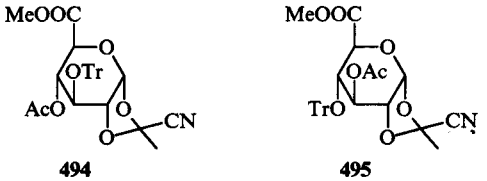
Alcohols are glycosylated by the peracetate **451** in the presence of $SnCl_4$ in dichloroethane in satisfactory yields, both α- and β-anomers being formed under these conditions.[200]



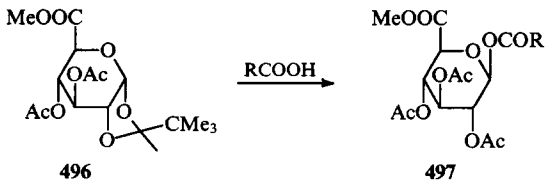
It has been shown[201] that the stereochemical specificity of the glycosylation of alcohols by the bromo-derivative **483** in acetonitrile in the presence of $AgClO_4$ is controlled by the presence in solution of type **486** conjugated compounds, which results in the preferential formation of the α-anomers. It has been suggested that trichloroacetimidates, for example compound **487**, be employed as active glycosylating agents.[202,203]



The synthesis of mainly the α-riburonide **490** from the chlorosugar **488** has been explained by the formation of the intermediate **489**, which can undergo nucleophilic attack only in the α-region.[204]

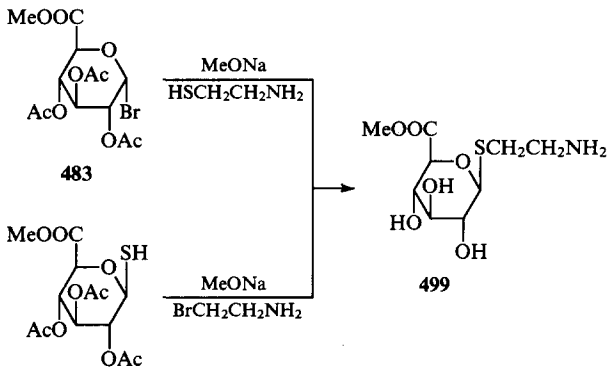


Trimethylsilyl triflate is a very effective condensing agent for the synthesis of uronides. The condensation of the bromo-derivative **483** with alcohols in its presence makes it possible to obtain glucuronides in satisfactory yields.[205] The condensation of the bromo-derivatives **483** with secondary arylamides to the *N*-glycuronides **491** has been carried out with its aid.[206]

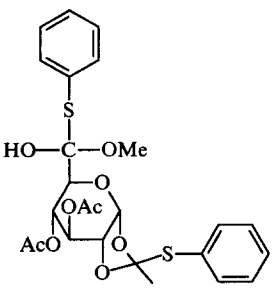


An effective method has been developed for the synthesis of the β-D-glycuronides **493**, which consists in the condensation of the cyanoethylidene derivative **492** with tritylated alcohol in the presence of a triphenylmethylium salt.[207]

In order to obtain disaccharides by this method, the cyanoethylidene derivatives of glucuronic acids **494** and **495** with the trityl group in different positions were synthesised.[208]

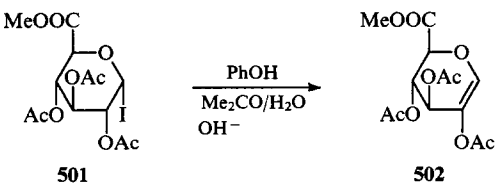


The *tert*-butoxyethylidene D-glucuronate derivative **496** is converted into the 1-*O*-acylates **497** on treatment with carboxylic acids.[209]



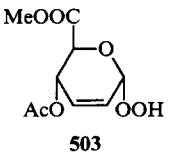
496 497

The β-*S*-alkylglucuronide **499** has been obtained by condensing the bromo-derivatives **483** with cystamine or the mercaptan **498** with 2-bromoethylamine.[210]



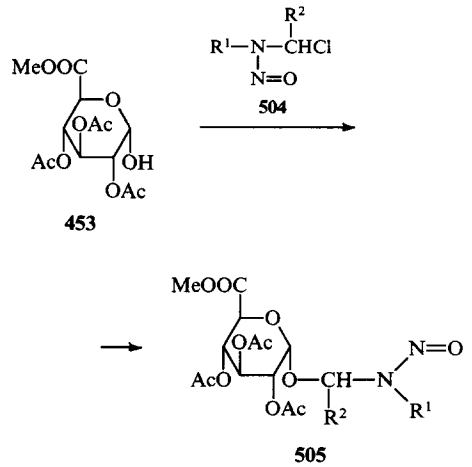
483 498 499

The glycosylation of thiophenol by D-glucopyranose pentaacetate in dichloroethane in the presence of $SnCl_4$ affords the tetraacetate of phenylthio-β-D-glucopyranoside. The 1-[2-phenylthio]orthoacetate of 3,4-di-*O*-acetyl-6-methoxy-6-phenylthio-α-D-glucopyranose **500** is formed from the acetate **451** under the same conditions.[211]



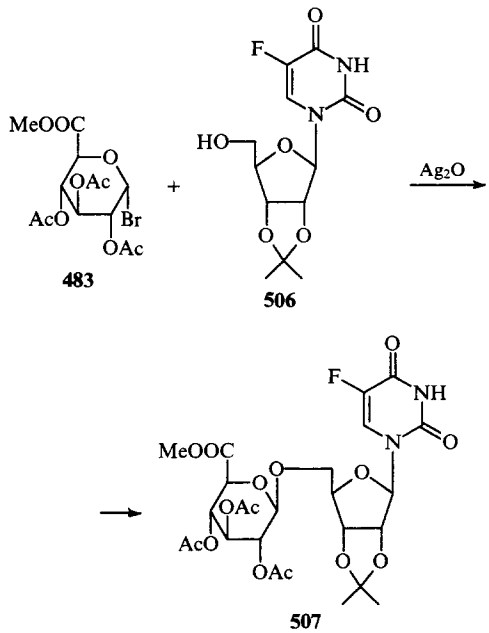
500

Instead of the expected *O*-phenylglucuronide, the glycosylation of phenol by the iodo-derivative **501** in aqueous acetone in the presence of base led to the isolation of the 2-acetoxyglycal **502** as the main reaction product.[212]



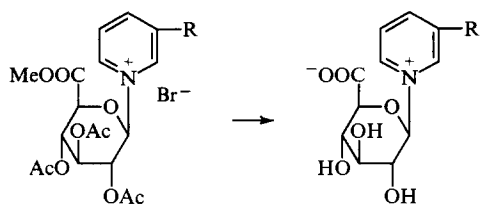
501 502

On treatment with 85% H_2O_2, the glycal **484** is converted into the hydroperoxide **503**.[213]



503

The glucuronate **453** condenses in pyridine with the chloroderivative of the *N*-nitrosodialkylamine **504** to the glucuronide **505**, which models the conjugates of D-glucuronic acid with nitrosoaminoalcohols formed in the organism.[214]



453 505

In order to synthesise the conjugate of D-glucuronic acid with 5-fluorouridine (a cytostatic agent), the bromo-derivative **483** was condensed with the 5-fluorouridine acetal **506** in the presence of Ag_2O, which led to the formation of the glucuronide **507**.[215]

483 506 507

The bromo-derivative **483** interacts with pyridines, affording the *N*-glycuronides **508**, which hydrolyse to analogues of nicotinamidoriboside **509** on treatment with bases.[216,217]

508 509

R = H, Me, $CONH_2$.

VIII. Conclusion

The data presented in the review make it possible to establish a general idea about the possibilities in the synthesis of uronic acids with a specified structure, in particular the methods for the oxidation or the conditions governing the transformation of monosaccharide derivatives.

The unique combination of functional groups in uronic acids and especially aminodeoxyuronic acids is the reason for the diversity of their chemical properties. The numerous examples of the nontrivial reactions of uronic acids described in this review should be borne in mind in planning new synthetic approaches to the preparation of chiral natural products which are difficult to obtain on a preparative scale. The broad spectrum nucleoside antibiotics, the composition of which incorporates uronic and aminodeoxyuronic acids, may serve as an example of a class of such substances which are important from the practical standpoint.[89] The syntheses of the natural representatives of this class and their structural analogues, based on the chemical reactions of uronic acids, are very important for the development of ideas concerning the biological role of uronic acid residues in the molecules of these compounds.

Abstract. Data concerning the chemical processes occurring under light irradiation of complexes of aromatic amines with polyhalomethanes are critically reviewed. It is shown that electron transfer from an amine to a halomethane is the main photochemical reaction of the complexes. The properties and reactions of primary radical-ion species and secondary inter-mediates formed are discussed. The mechanisms of photo-induced formation of triphenylmethane dyes and acridine derivatives are considered in detail. The bibliography includes 234 references.

I. Introduction

Charge transfer complexes (CTC) are rather labile self-organising systems consisting of at least two components, an electron donor and an electron acceptor. The formation of a CTC manifests itself most clearly in the appearance of a new absorption band, the charge transfer (CT) band, in the electronic spectra of the mixtures of components. Electron transfer (ET) is the most typical reaction of such complexes. Depending on the properties of the donor and acceptor and on the external conditions, ET can occur either thermally or under light irradiation. Therefore, CTC provide a convenient model for studying the ET process.[1–6] In recent years, the attention of investigators has been attracted to molecular-bonded donor-acceptor systems.[7–13]
