Abstract. Data concerning the *O*- and *C*-acylation of carbonyl compounds under acid catalytic conditions are surveyed. The properties of little-studied products of these reactions, i.e., acylals, α -haloalkyl acylates, and enol acylates are described. The acyloxycarbenium ions formed by the acylation of aldehydes and ketones are characterised. The recently discovered new reactions of carbonyl compounds that lead to various heterocyclic and polyfunctional compounds are discussed. The bibliography includes 275 references.

I. Introduction

The acylation of carbonyl compounds is traditionally considered as a means of lengthening a carbon chain together with the introduction of the carbonyl function. Such reactions include ester condensation and related reactions (i.e., Claisen, Dieckmann, Darzens reactions, etc.).^{1–6} These processes are catalysed by bases, while *O*-acylation which sometimes occurs is usually regarded as an undesirable side reaction. The preparative application of these methods was so successful and fruitful that the analogous acid-catalysed conversions were considered only as theoretically, rather than practically, interesting reactions. Only in some cases, when acid and base catalysis results in different products (e.g., acylation of asymmetric ketones), have syntheses been developed.^{1,2} Perhaps only acylation of ketones by anhydrides in the presence of boron trifluoride is an exception.^{5,6}

The technique of base-catalysed acylation of carbonyl compounds has been improved and modified (e.g., in Taylor–McKillop and Passerini reactions,^{7,8} phase-transfer catalysis,⁹ and the application of acyl anions¹⁰), whereas acid-catalysed reactions have remained much less investigated until now. This is explained by difficulties in the effective stabilisation of cationoid intermediates, as cationoid chemistry has been less well studied than carbanion chemistry.¹¹

Although the importance of the reaction between carbonyl compounds and aprotic acids was noted thirty years ago,¹² few publications concerning this problem are available. On the other hand, two reactions of aldehydes with anhydrides and acid halides in the presence of Lewis acids have been known since the beginning of this century. These reactions lead to the acylals **1** and the α -haloalkyl acylates **2**, respectively.

LA — Lewis acid; X = Cl, Br.

The attitude of synthetic chemists towards acid-catalysed carbonyl reactions can be illustrated by the history of compounds **1** and **2**: the properties of the acylals **1** have been very little investigated until now. The α -haloesters **2** were recalled in the sixties only as subjects of a series of studies under the common title 'A forgotten carbonyl reaction' (see Section IV).

II. Acylals

The esters formed from geminal diols (i.e., acylals, also called aldehyde diacylates) have been known for more than 120 years. Chloral diacetate was described as one of the first acylals.¹³ The synthesis based on the acid-catalysed *O*-acylation of aliphatic and aromatic aldehydes by acetic anhydride in the presence of various catalysts was elaborated later.^{14,15} Scant information about acylals can be found in some monographs.^{5,16–18} For a long time, acylals were regarded only as convenient intermediates for the preparation of aldehydes and ketones from methylarenes **3** by oxidation with a $\text{CrO}_3\text{—Ac}_2\text{O}$ mixture^{5,18,19} as well as by oxidative decarboxylation of malonic acid derivatives **4**.⁵

Received 24 April 1995

Uspekhi Khimii 65(1) 3–28 (1996); translated by S S Veselyi

Only recently have acylals attracted special attention as compounds having independent synthetic value. Acylals can serve as convenient precursors of not only aldehydes but also of enol acylates, e.g., in the conversion of crotonaldehyde into 1-acetoxybutadiene **6**²⁰ and other synthetically difficult compounds.^{21,22}

The *gem*-diacetate moiety turned out to be quite stable toward dilute acids, but it is easily removable in weakly alkaline solutions.²¹ This group can therefore serve as a suitable complement of the well-known acetal protection for aldehydes.²³ Examples of acylal protection have been mentioned in the literature, but this topic is outside the scope of the present review, which is devoted to the activation rather than the passivation of the carbonyl function.

In the early eighties, several authors reported the preparation of acylals by the acid-catalysed acylation of aldehydes with acetic anhydride. Diacetates of aliphatic and aromatic aldehydes can be obtained in high yields in the presence of PCl_3 (Ref. 24 and the references cited therein). The use of FeCl_3 instead of PCl_3 allows one to extend the aldehyde series and to reduce the duration of the acylal synthesis; detailed spectroscopic data (IR, ^1H NMR and ^{13}C NMR) and mass spectra for the acylals were also obtained.²¹ The undesirable treatment of reaction mixtures with water can be excluded using the solid superacid 'Nafion-H', which also allows one to simplify the isolation of the acylation products.²⁵ The preparation of acylals in the presence of protic acids (e.g., sulfuric, perchloric, methanesulfonic acids) was reported in several studies.²⁶⁻²⁹ A series of acylals **8** have been obtained by the acyloxylation of cyclohexane-1,3-diones **7** with diacyl peroxides.³⁰

$\text{R}_2^1 = \text{Me}_2, -(\text{CH}_2)_5-$; $\text{R}^2 = \text{Ar}, \text{PhCH}_2\text{O}$.

Compounds **8** are ketone acylals. It has been mentioned in earlier publications that ketones do not yield *gem*-diacetates.¹⁴ Subsequently, it was shown that cyclohexanone and its 4-alkyl derivatives react with an $\text{Ac}_2\text{O}-\text{H}_2\text{SO}_4$ mixture to form the corresponding enol acetates, but hitherto unknown 1,1-diacetates were also isolated in low yields from these reaction mixtures.³¹ However, cyclopentanone affords only an acylal under the same conditions.³² Mazur and coworkers^{33,34} have described the preparation of ketone acylals by the action of trichloroacetic anhydride without a catalyst. However, the reactions of ketones (mainly cyclic ones) with Ac_2O require the presence of an acid.³⁴ It is remarkable that cyclobutanone reacts with Ac_2O and HClO_4 to yield only the 1,1-diacetate.³⁴ Obviously, the strain in small rings prevents the transformation of acylals into enol acylates.

The mechanism of the formation of acylals derived from both aldehydes and ketones was studied using mixed anhydrides²¹ as well as initial ketones labelled with the ^{18}O isotope.^{33,34} It has been shown that acylation, which is a reversible reaction, occurs with the participation of two anhydride molecules. Conditions for the conversion of acylals into carbonyl compounds by hydrolysis³⁵⁻³⁷ and for the transformation of diacylates into enol acylates were also described.^{31,33,38}

Acylals undergo many reactions typical of aldehydes, such as condensations with CH -acids³⁹ and with alkenes according to the Prins reaction scheme [Eqns (1) and (2)].⁴⁰⁻⁴²

On the other hand, syntheses based on acylals were described in which the aldehydes themselves proved to be ineffective. Thus, in the reaction of benzylidene diacetate **9** with styrene, it is possible to avoid the telomerisation usually occurring in reactions between aldehydes and carboxylic acids (Scheme 1).⁴³ Acid-catalysed reactions of aldehydes with salicylic acid involve the alkylation of the aromatic ring, whereas the use of acylals yielded a series of 2-substituted 4-oxo-1,3-benzodioxanes **10**.⁴⁴ Acylals react with methyl ketones in the presence of triphenylmethyl perchlorate to form the pyrylium salts **11** and the 2-benzopyrylium salts **12**.²⁹

Methylene diacetate **13** undergoes self-condensation in the presence of SnCl_4 to give the ester and ether derivatives **14-16**.⁴⁵ It was found recently^{46,47} that aliphatic and aromatic aldehyde diacetates **17** react with CHCl_3 under phase-transfer catalytic conditions. These reactions proceed with substitution of an acetoxy group by a CCl_3 group with lengthening of the carbon chain by one atom to yield acetates of α -trichloromethyl carbinols **18** (Scheme 2). Apparently, this reaction is general and can also be expanded for other carbanion precursors. For example, analogous conversions were carried out with phenylmethylacetonitrile **19** and phenylacetonitrile **21** (Scheme 2).⁴⁸

Scheme 1

Scheme 2

The substitution products obtained (18, 20, and 22) are valuable intermediates for subsequent transformations.

At present, isopropylidene malonate, Meldrum's acid 23, is the best known acylal (see the relevant reviews^{49–51}). This acid, which is an important precursor of many synthons and carbon suboxide and is a valuable starting material for the preparation of aliphatic-aromatic ketones and synthetically difficult 1,3,5-tricarbonyl compounds,^{52,53} has recently attracted keen attention. Meldrum's acid can be prepared by the acid-catalysed acetylation of acetone with acetic anhydride and malonic acid [Eqn (3)]⁵⁴ as well as by the acidolysis of isopropenyl acetate 24.⁵⁵

Mixed geminal α -acyloxyalkyl ethers 26 and 27, that can be obtained in reactions of carboxylic acids with vinyl ethers^{56–59} or aryl chloromethyl ethers,⁶⁰ are also called acylals in the chemical literature.

Compounds 26, 27, and 28 are noteworthy because their conversions always proceed with substitution of the acyloxy- rather than alkoxy-group, i.e. the more stable alkoxy-carbocations 29 arise (see Section V). Kinetic investigations confirmed this observation.⁶¹ Some examples of such reactions are shown in Scheme 3.^{62–65}

Scheme 3

It is appropriate to mention in this Section the unusual sulfur-containing hetero-analogues of acylals 33, which are products of the Pummerer reaction.^{7,66} This reaction is, in essence, acylation of the sulfoxides 31, which are sulfur analogues of ketones.

Acylals formed by ketones and an inorganic acid, the geminal diperchlorates $\text{R}^1\text{R}^2\text{C(OCIO}_3)_2$, have also been described.⁶⁷

III. Enol acylates

Compared with acylals, vinyl esters, i.e. enol acylates, particularly vinyl acetate, are better known because they are widely used. Syntheses based on enol acylates are of great importance, particularly in steroid chemistry. The extensive literature concerning enol acylates has been surveyed in several reviews.⁶⁸⁻⁷¹ A series of papers have been devoted to modifications of well-known preparative methods, for example, the acetoxymercuration of alkynes,^{72,73} as well as to the formation of enol acylates under unusual conditions (thermal opening of cyclobutene derivatives,⁷⁴ electrochemical acylation of indenones⁷⁵) and the syntheses of unusual enol acylates (benzenesulfonates,⁷⁶ triflates⁷⁷⁻⁷⁹). The syntheses of enol acylates from α -halogenated aldehydes and ketones by the action of acid halides in the presence of zinc are of interest.^{80,81}

As to syntheses of enol acylates by the acid-catalysed acylation of carbonyl compounds, new variants of this approach were also reported side by side with new examples of traditional procedures (e.g. treatment of ketones with Ac_2O in the presence of perchloric⁸² or sulfuric acid⁸³). For example, deoxybenzoins **34** react with carboxylic acids or their anhydrides in polyphosphoric ester (PPE) to give the *O*-acylation products **35**.⁸⁴ It was found that the arylacetic acids **36** can undergo fourfold self-acylation to form the α -acyloxy- γ -pyrones **37** under these conditions.⁸⁵

Ar = Ph, 4- $\text{NO}_2\text{C}_6\text{H}_4$.

The use of an $\text{Ac}_2\text{O} + \text{Me}_3\text{SiCl}$ mixture represents a new method for the preparation of enol acylates from ketosteroids.⁸⁶ This mixture acts as an acylating reagent because trimethylsilyl chloride cleaves Ac_2O to give trimethylsilyl acetate and acetyl chloride.⁸⁶ *N*-Acylpyridinium salts **38**⁸⁷ and acyloxyacylphosphonium salts **39**⁸⁸ have also been used as acylating agents (Scheme 4).

$\text{R}^1 = \text{Pr}^i, \text{Ph}, \text{Ar}; \text{R}^2 = \text{Me}, \text{Ph}$.

Scheme 4

Investigations of the behaviour of labelled (^{18}O) ketones confirmed that acylals are intermediates in the formation of enol acylates by the acid-catalysed acylation of ketones with acetic anhydride.³⁴ A correlation between the rate of this reaction and the nucleophilicity of the anion of the protic acid was demonstrated. Thus, in the acylation of cyclohexanone by Ac_2O the degree of conversion of the ketone into the corresponding enol acetate reaches 80% after 20 min in the presence of HClO_4 , in contrast to only 10% after 10 h in the presence of H_2SO_4 .³⁴ The reactions of cyclic ketones with isopropenyl acetate **24** in the presence of both perchloric and sulfuric acids were described in the same paper.³⁴ According to ^1H NMR data, these reactions occur considerably faster in the presence of HClO_4 than with H_2SO_4 , because in the former case the intermediates **40** and **42** have a cationoid structure, in contrast to the predominantly covalent nature of the intermediates **41** and **43** in the latter case (Scheme 5).

Scheme 5

X = ClO_4 , SO_4H .

Among enol acylate reactions, the interaction of the latter with cationoid electrophiles (E) is of particular interest. It is generally known that vinyl ethers **44** always combine with an electrophile at the double bond carbon atom most remote from the oxygen atom and are then converted into carbonyl compounds [see Kulish et al.,⁸⁹ Shostakovskii,⁹⁰ and also Barton and Ollis⁷⁰ (p. 351)]. This is due to the formation of the alkoxy-carbenium ions **46**, which are much more stable than the alternative carbocation **45** (even tertiary ones).^{91,93}

This difference in the stability of cations **45** and **46** explains the pinacol rearrangement with group migration from the carbon atom linked to the ether oxygen atom^{94,95} (see Ref. 1, p. 461). It should be noted that the concept of carbocation resonance stabilisation by heteroatoms at the carbenium centre is so common now that any carboxonium ions are regarded as *a priori* stable. If this were really so, there would be no need to continue this review.

Scheme 6

Many of the reactions involving electrophilic addition to vinyl esters reported in the literature are fully consistent with the above ideas. Thus, both the enol acetate of propanal **47** and ethyl propenyl ether **48** react with mercuric acetate to form α -acetoxymercuriopropenal **49** (Scheme 6).^{96,97} Acylation of vinyl acetates **50** leads to the β -ketoaldehyde acylals **52** via the acyloxycarbenium ions **51**.^{98,99} Nitration of 1-acetoxycyclohexenes **53** gives the nitroketones **54**,¹⁰⁰ while its acylation affords the 1,3-diketones **55**.¹⁰¹ The diethoxycarbenium **56** formed from ethyl orthoformate also attacks the enol acetate of 3-oxobutanal **57** at the position as the C=C double bond most distant from the ether oxygen atom.¹⁰²

The addition of phenols **59** to the C(α) atom bearing an acetoxy-group in vinyl acetate **58** occurs due to protonation of the latter at the methylene group.¹⁰³ All of the enol acylates used in the above reactions contained a primary or secondary carbon atom at the position in the double bond most distant from the oxygen atom (which will be, for convenience, henceforth called the β -carbon atom).

However, it was found recently that enol acylates containing a tertiary β -carbon atom react with electrophiles in a fundamentally different way. Thus, the enol acetate of isobutyraldehyde **60** gives under acyloxymercuration conditions⁹⁶ a 1,2-diol derivative **61** rather than an aldehyde.¹⁰⁴ Dissolution of the enol acetate **60** in 98% sulfuric acid yields a 1,3-dioxolanylium salt **62**, the ¹H NMR spectrum of which is fully identical to that of the product of protonation of methylallyl acetate **63**.¹⁰⁵ Benzoylation and alkylation of the enol benzoate **64** in weakly nucleophilic media yield 4-benzoyl-**65** and 4-*tert*-butyl-1,3-dioxolanylium salts **66**, respectively.¹⁰⁴ It should be emphasised that the above 1,3-dioxolanylium salts **62**, **65**, and **66** are derivatives of 1,2-glycols, into which they can be readily converted by hydrolysis¹⁰⁶ (Scheme 7).

Thus, if an enol acylate is branched at the position in the C=C double bond most distant from the oxygen atom, the addition of an electrophilic species occurs at the α -carbon atom linked to the oxygen atom. Hence, the energies of the alternative cations, i.e. the acyloxycarbenium cations **67** and the tertiary carbenium cation **68**, are almost the same (see Section VI) (Scheme 8).

Scheme 7

a: $\text{PhCO}^+\text{SbCl}_6^-$, -10°C , CH_3NO_2 ;

b: $\text{Me}_3\text{C}^+\text{SbCl}_6^-$, -60°C , CH_2Cl_2 .

R = Me, Ph.

This conclusion is in good agreement with the results of the alkylation of the enol acetate **47** under the same conditions leading to 1,3-dioxanylium hexachloroantimonate **73**.¹⁰⁴ The reaction mechanism presupposes the formation of the acyloxy-carbenium ion **70**, which is more stable than the secondary carbocation **69**, and two consecutive migrations of a hydrogen atom and the methyl group (Scheme 9).

It should be noted in conclusion that the acid-catalysed acylation of aldehydes and ketones leads to enol acylates, provided that the reaction mixtures contain bases capable of eliminating a proton from the product of the *O*-acylation of the carbonyl compound. This function can be performed by isopropenyl acetate,³⁴ pyridine,⁸⁷ or the acetate anion at elevated temperatures. In the cold, nucleophilic addition of acylate anions takes place and is accompanied by the formation of acylals. If other acylating reagents are used, such as acyl halides, then the halogen atom should play the role of the nucleophile.

IV. α -Haloalkyl acylates

The acid-catalysed acylation of aldehydes by acid chlorides was discovered in 1901.^{107,108} The α -chloroalkyl carboxylates **2** were obtained from formaldehyde and acetaldehyde in the presence of anhydrous zinc chloride. Later several studies were published in which this reaction was extended to higher aldehydes and acrolein.^{109–112}

The α -haloalkyl acylates **2** have aroused interest only since the middle of this century. This was connected with the possible use of these compounds for the preparation of vinyl monomers,¹¹³ but primarily for application in studies of the nucleophilic substitution mechanism. In the sixties and seventies, Euranto and coworkers published the results of very detailed investigations of the noncatalytic hydrolysis of various α -haloesters under a wide range of conditions (see the relevant communications^{114–120} and the references therein). The methods for the preparation of α -haloalkyl acylates reported up to that time were surveyed in a separate article,¹²¹ in which the merits and drawbacks of ten different approaches were listed. Preference was given to methods involving the chlorination of alkyl carboxylates as well as the halogenation and hydrohalogenation of enol acylates. Five of these procedures, including the acylation of aldehydes, were used for the preparation of samples employed in kinetic investigations.¹²¹ Brief historical surveys concerning the topic discussed were also given in Refs 109 and 113.

However, a preparative application of the reaction of carbonyl compounds with acyl halides was not found until the late sixties, when Neuenschwander and coworkers^{122,123} developed a new method to prepare fulvenes. It was found that only α -chloroalkyl acetates are capable of reacting effectively with cyclopentadiene to form differently substituted fulvenes in up to 70% yields.^{122–125} Neither their precursors, i.e. carbonyl compounds, nor the related simple α -chloroesters react in this way. A detailed investigation of the mechanism of the formation of the key starting materials, i.e. α -haloalkyl acylates (acyloxy-chloromethanes), became the subject of a series of papers. Two papers^{126,127} reported the applicability of the haloacylation of carbonyl compounds to the synthesis of α -haloalkyl acylates.

The equilibrium of the reaction between the aliphatic aldehydes **74** and the acetyl halides **75** is so shifted towards the products **76** that the equilibrium constant cannot be determined by ¹H NMR spectroscopy. The authors believe that the reaction considered was rarely used for preparative purposes because of the poor yields of the target products **76** resulting from imperfect techniques for the isolation of the latter. This problem can be solved by using low temperatures (from -10 to 0°C) and by removing the catalyst (ZnCl_2) before the fractional distillation of the reaction mixtures.

R = H, Me, Et, Pr, Prⁱ, Bu, Buⁱ, Bu^t, CH=CH₂, CH=CHOAc,

CH=CHCl, C \equiv CH, Ph, Ar, , X = Cl, Br.

The haloacylation of α,β -unsaturated aldehydes occurs readily (68%–94% yields).¹²⁷ In contrast to the situation with aliphatic aldehydes, the equilibrium position of the reaction involving aromatic aldehydes is measurable; substituents having +*M* and +*I* effects shift this equilibrium to the left. Therefore, excess acetyl chloride should be used in reactions involving starting aldehydes such as 4-methoxy- and 4-dimethoxy-amino-benzaldehydes. Other aromatic aldehydes afford the products **76** in 96%–99% yields.

The haloacylation of ketones **77** gives the products **78** in 76%–93% yields, which were observed to depend on the ring size of the alicyclic ketones. In the case of cyclobutanone and cyclohexanone, the equilibrium position is shifted towards the product **78**, whereas for cyclopentanone and cycloheptanone it is nearer to the starting reactants. Aromatic ketones such as acetophenone practically do not form α -haloalkyl esters. Tropone **79**, which gives the acylation product **80** with an ionic structure, occupies a particular position.¹²⁷

$\text{R}^1, \text{R}^2 = \text{Me}, -(\text{CH}_2)_n-, n = 3, 5; \text{X} = \text{Cl}, \text{Br}$

An analysis of the side products formed by the haloacetylation of aldehydes has been carried out¹²⁸ in order to optimise the synthesis conditions. The structure of the aliphatic aldehydes, the reaction time, the concentrations of the catalysts and starting reactants, as well as the polarity of the solvent were varied during this investigation. It was concluded that (a) dilute solutions, (b) nonpolar solvents, (c) higher concentrations of acetyl halides, achieved by the dropwise addition of the aldehyde to the reaction mixture, (d) low temperatures, and (e) higher concentrations of the catalyst dissolved in the acyl halide should be used for the successful suppression of side reactions mentioned above.

The dependence of the equilibrium position on the reaction conditions in the above processes [Eqns (8) and (9)] was considered in detail in Ref. 129. The equilibrium constants were measured as a function of the structure of the carbonyl component, the composition of the acyl halide, solvent polarity, and temperature. The results of exact measurements¹²⁹ fully agree with the practical recommendations specified above.¹²⁸

Finally, the possible mechanisms of the haloacylation of carbonyl compounds, namely, the two 'polar mechanisms' (a, b), the synchronous mechanism (c), and the ketene mechanism (d) have been thoroughly discussed¹³⁰ (Scheme 10). It was shown by ¹H NMR kinetic measurements that aliphatic acyl halides react according to the 'polar mechanism' b via the intermediates **84** and **85**, i.e. without ionisation, while aromatic acyl chlorides follow the mechanism a with the participation of the acyloxycarbocations **82**.¹³⁰ This can be attributed to the lower energy (i.e. higher stability) of the benzoyl cations **81** ($\text{R}^1 = \text{Ar}$) in comparison with that of aliphatic acyl cations.

In relation to the facts considered above, we should also mention the long known intramolecular interaction between the functional groups in the chlorides of γ - and δ -keto- and aldehydo-carboxylic and *o*-acylbenzoic acids **87**.

The majority of such compounds are stable only as cyclic α -chloroalkyl acylates **88**, and only a few examples are known where steric hindrance prevents cyclisation.^{131–134} More than a hundred of such structures, both aliphatic and aromatic, were considered in a review¹³⁵ containing an extensive bibliography. The existence of tautomeric equilibrium between the open form **87** and the cyclic form **88** is completely rejected in Refs 133–135.

As mentioned above, until now there has been little information about the synthetic application of α -haloalkyl acylates. These compounds can be used as alkylating reagents in reactions with 2-(trimethylsilyloxy)furan,²² pyridine,¹¹³ secondary amines,¹³⁶ silver salts of *N*-nitrosohydroxylamines,¹³⁷ and phenols,¹³⁸ as well as for forming carbon–manganese bonds.¹³⁹ However, the same α -haloesters behave as acylating agents under other conditions.^{136, 138, 140} The chlorine atom in α -chloroalkyl acetates, similarly to that in acylals (see Section II), can be substituted by the trichloromethyl group under phase-transfer catalytic conditions.¹⁴¹ However, the most interesting properties of α -chloroesters were found when the latter were used for the synthesis of oxygen-containing heterocyclic compounds (see Section V).

V. Acyloxycarbenium ions

It was shown by kinetic studies of the hydrolysis of the α -haloesters **83** and **89** that the majority of the latter react according to a *S_N1* mechanism^{114–120} via the acyloxycarbenium ions **82** and **90** as intermediates.

Scheme 10

It was established¹¹⁵ that α -chloroethyl benzoate **89** ($\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{H}$, $\text{R}^3 = \text{Ph}$) hydrolyses via a unimolecular $\text{S}_{\text{N}}1$ mechanism almost 100 times more quickly than chloromethyl benzoate **89** ($\text{R}^1 = \text{R}^2 = \text{H}$, $\text{R}^3 = \text{Ph}$), the solvolysis of which occurs by an $\text{S}_{\text{N}}2$ mechanism. Secondary α -haloalkyl acylates **89** ($\text{R}^1, \text{R}^2 = \text{Alk}$, $\text{R}^3 = \text{Me, Et, CCl}_3$) are hydrolysed a thousand times more quickly than the corresponding primary esters **89** ($\text{R}^1 = \text{Alk}$, $\text{R}^2 = \text{H}$, $\text{R}^3 = \text{Ph}$).¹¹⁶ α -Chlorobenzyl esters **89** ($\text{R}^1 = \text{Ar}$, $\text{R}^2 = \text{H}$, $\text{R}^3 = \text{Ph}$) also undergo substitution of the chlorine atom by a unimolecular mechanism.^{118, 119}

The formation of cyclic acyloxycarbocations **91** is suggested by kinetic data for the hydrolysis of the cyclic α -chloroalkyl acylates **88** mentioned above.^{133, 134, 142}

The hydrolysis of the acylals **1** can also occur by different pathways. Ethylidene diacetate $\text{MeCH}(\text{OAc})_2$ reacts by an $\text{A}_{\text{AC}}2$ mechanism,³⁶ like *p*-nitrobenzylidene diacetate, $4\text{-O}_2\text{NC}_6\text{H}_4\text{-CH}(\text{OAc})_2$.³⁷ However, *p*-methoxybenzylidene diacetate, $4\text{-MeOC}_6\text{H}_4\text{CH}(\text{OAc})_2$, undergoes unimolecular hydrolysis via acyloxycarbocation ions.³⁷ It was shown that primary α -chloroalkyl esters react with oxygen- and nitrogen-containing nucleophiles by a bimolecular mechanism,^{136, 138} whereas the analogous α -chloroalkyl ethers react by an $\text{S}_{\text{N}}1$ mechanism.⁹⁴ It is known that vinyl ethers hydrolyse via the same mechanism 10⁴ times more quickly than vinyl acetate, which was supposed to form a π -complex with the proton.⁸⁹ However, the next homologue, isopropenyl acetate **24**, can be readily transformed into the acyloxycarbocation **40**,^{143, 144} which was detected by ¹H NMR spectroscopy.¹⁴⁵ It was assumed that both the acetolysis of

α -acetoxystyrene, $\text{PhC}(\text{OAc})=\text{CH}_2$,¹⁴⁶ and the formation of phthalides from *o*-aroylbenzoic acids¹⁴⁷ proceed with formation of acyloxycarbocation ions.

These results allow us to conclude that the generation of the acyloxycarbocations **90** requires a considerably higher energy than the formation of the related alkoxy carbocations **46** and depends very strongly on both the precursor structure (acylal, enol acylate, or α -haloalkyl acylate) and on reaction conditions. The high energy of the acyloxycarbocations follows from the unusual mode of electrophilic addition to β -branched enol acylates (see Section III) and from some indirect evidence, such as the possibility of an equilibrium between the acyloxycarbocation ion **92** (in this case, considerably stabilised) and the acylium ion **93** (Scheme 11).¹⁴⁸

Thus, an acyloxy group linked to a carbocation centre stabilises the latter, but to a much lower extent than a hydroxy- or alkoxy-group. Apparently, the relatively high stability of acylals in weakly acid media²¹ (see Section II) can be explained by difficulties in their ionisation (in comparison with acetals).

Perhaps the fact that acyloxycarbocation ions have never been mentioned in any of the reviews dealing with carboxonium ions⁹¹⁻⁹³ can be explained only by their unpredictable formation conditions and behaviour. At the same time, the information presented above suggests that these species cannot be regarded as just one example of the ion series $\text{R}^1\text{R}^2\text{C}^+-\text{OR}^3$. In addition to the high energy of acyloxycarbocations, their tendency to decompose into a carbonyl compound and a quite stable acylium cation should be taken into account as their characteristic feature.^{129, 149, 150} However, since acyloxycarbocation ions are intermediates not only in the acid-catalysed acylation of carbonyl compounds but also in the reactions of its products, it is quite appropriate to make a compilation of the scattered data on these species.

In addition to the instances presented above [reactions (3)-(6), (10)-(13); Schemes 9 and 10], the acyloxycarbocations **95**, **98**, **100**, and **101** were assumed as intermediates in a number of reactions of carbonyl compounds with acylating agents: the reaction of succinic anhydride with 2-acetoxybut-2-ene **94** for the preparation of the key intermediate **96** in steroid syntheses;¹⁵¹ the conversion of 2,6-diphenyl-4-pyrone **97** into cyanine dyes;¹⁵² the reaction of 3,5-di-*tert*-butyl-1,2-benzoquinone **99** with acetic anhydride (Scheme 12).^{153, 154}

The acyloxycarbocation ions **103**, **104**, and **106** are formed by the acylation of the α, β -unsaturated carbonyl compounds **102** and **105**.^{155, 156}

Scheme 11

(13)

Scheme 12

Scheme 12 illustrates the synthesis of 1,2-dimethylcyclopentanone and 1,2,4,6-tetra-*tert*-butyl-3,5-diacetoxycyclohexa-2,5-diene.

Top Reaction: Succinic anhydride reacts with 4-methyl-3-penten-2-one (**94**) in the presence of AlCl_3 and PhNO_2 to form 1,2-dimethylcyclopentanone (**96**). The mechanism involves the formation of a complex intermediate (**95**), which is a 1,2-dimethyl-3-(2-oxocyclopentyl)propan-1-one derivative, followed by rearrangement and elimination to yield **96**.

Bottom Reaction: 1,4-dimethyl-2,5-cyclohexadien-1-one (**97**) reacts with Ac_2O to form a resonance-stabilized cationic intermediate (**98**), which is a 1,4-dimethyl-2,5-cyclohexadien-1-yl cation with an OCOMe group and an AcO^- counterion. This intermediate then reacts with AcO^- to form a 1,4-dimethyl-2,5-cyclohexadien-1-yl cation with an OAc group and a ClO_4^- counterion. This cationic intermediate reacts with Ac_2O and HClO_4 to form a 1,4-dimethyl-2,5-cyclohexadien-1-yl cation with two OAc groups and a ClO_4^- counterion (**101**). Finally, **101** reacts with Me_3C^+ and ClO_4^- to yield 1,2,4,6-tetra-*tert*-butyl-3,5-diacetoxycyclohexa-2,5-diene.

Both the nitration of cyclohexanone enol acetates **53**¹⁰⁰ and the formylation of formylacetone mono-enol acetate **57**¹⁰² considered above (see Section III) also proceed via acyloxy-carbenium ions as intermediates. It was assumed that the latter (compounds **122**–**124**) can serve as intermediates in acid-catalyzed transformations of sulfur-containing compounds (Scheme 14).^{164–166}

Scheme 13

Tf = SO₂CF₃.

Scheme 14

R¹ = Me, Ph; R² = Me, Ar.R¹ = H, Me.

The unusual cationoid species **125** and **126** are formed by the *O*-acylation of amides.^{167, 168}

The carbocations **128**, **130**, and **132** are intermediates in reactions of trifluoromethanesulfonic anhydride with the butyrones **127**¹⁶⁹ and the terpene ketones **129** and **131**.^{170, 171}

The reaction of 1-adamantyl triflate **133** with carbon monoxide and adamantane (AdH) in the presence of trifluoromethanesulfonic acid (TfOH) gives the products **137**, **139**, and **140**, the formation of which was explained by the participation of acyloxycarbenium intermediates **136**, **136a**, and **138**.¹⁷² Although one of them (**136**) was represented as a covalent structure,¹⁷² its ability to be a hydride acceptor and to undergo a rearrangement suggests that it is readily transformed into the cation **136a** (the low nucleophilicity of the triflate anion is well known¹⁷³).

Finally, stable acyloxycarbenium salts have been described: acyloxypyrylium (**141**, **142**, and **143**),^{174–176} 4-oxo-1,3-dioxolan-2-ylum (**144**), and 4-oxo-1,3-dioxolan-2-ylum (**145**),¹⁷⁷ as well as 4-oxo-1,3-dioxolan-2-ylum (**146**)¹⁷⁸ salts. Papers dealing with the synthesis of the carbocyclic and heterocyclic systems **147** and **148** containing an acetoxy group as a substituent have been published.^{179, 180}

To sum up the above information, five general methods for the generation of the acyloxycarbeniums **149** can be distinguished: (a) ionisation of the α -chloroalkyl acylates **150**,¹¹⁹

(b) ionisation of the acylals **151**;³⁷ (c) addition of cationoid electrophiles to the enol acylates **152**;¹⁴⁵ (d) oxidative dehydrogenation of the esters **153**;^{149, 157} and (e) direct *O*-acylation of the carbonyl compounds **154**;¹⁵⁶ (Scheme 15).

Scheme 15

It is known that the stability of highly reactive species such as carbocations can be characterised by the conditions of their existence as salts. Many hydroxy- and alkoxy-carbenium ions are so stable that they can readily be detected in solution by ¹H NMR spectroscopy or even isolated as salts with nonnucleophilic anions.^{91, 92} The conversion of the diacetates of benzaldehyde and its substituted derivatives **155** into arylacyloxycarbenium perchlorates **156**, characterised by ¹H NMR spectra of the acylals **155** in solutions in concentrated H₂SO₄, have been reported.¹⁸¹ The chemical shifts presented¹⁸¹ agree well with those for methoxycarbenium ions formed from dimethyl acetals of the same aldehydes.⁹² However, the author's statement¹⁸¹ concerning the isolation of solid acyloxycarbenium salts is doubtful. As shown in another study,¹⁸² treatment with SbCl₅ of the α-chloroalkyl acetates **157** derived from aliphatic aldehydes leads only to complexes of the latter with SbCl₅ (**158**). Mixing the α-chlorobenzyl acylates **159** with SbCl₅ at temperatures higher than -60 °C also gives the colourless complexes **161**.¹⁸³ Only at -95 °C were bright yellow precipitates of the salts **160** obtained and could be characterised by IR spectra. Heating their suspensions in CH₂Cl₂ to -60 °C results in their decomposition. The product **163** of the reaction between α-chloro-*o*-nitrobenzyl acetate **162** and SbCl₅ turned out to be somewhat more stable.¹⁸³ Its stability (10 to 15 min at 20 °C) can be explained by the participation of the *ortho*-nitro group in cyclisation¹⁸⁴ (Scheme 16).

Scheme 16

Scheme 16 continued

As in *Ad_E* reactions of enol acylates (see Section III), the situation changes sharply when the α-chloroalkyl acylates **165**, obtained from the α-branched aldehydes **164**, are treated with SbCl₅. Colourless stable salts were isolated in quantitative yields; according to ¹H NMR and IR spectroscopic data, these turned out to be 1,3-dioxolanylium hexachloroantimonates **168**.^{182, 185, 186}

R¹ = Me, Ph;

R² = Me, Et, Ph; R¹ + R² = -(CH₂)₄-, -(CH₂)₅-;

R³ = H, Ph, PhCH₂; R⁴ = Me, Et, Ph.

Thus, the same 1,3-dioxolanylium salts as those derived from branched enol acylates **60** and **64** are formed from the α-chloroesters **165**. However, isomerisation of the acyloxycarbenium ions **166** to the tertiary carbenium ions **167**, already shown above (see Scheme 9), occurs in this reaction. It must be emphasised that rearrangements with 1,2-migration to a carbon atom linked to an oxygen atom (see Section VI) are not typical of carboxonium ions and thus differentiate sharply the acyloxy-carbenium ions **171** from the well-known hydroxy-(**169**) and alkoxy-carbenium (**170**) ions.

Moreover, an important feature of the cations **171** is the combination of electrophilic (the carbenium atom) and nucleophilic (the carbonyl oxygen atom) centres within the same species. This makes them suitable for interaction with unsaturated compounds in polar 1,4-cycloaddition reactions.¹⁸⁷ Thus, benzyloxyphenylcarbenium hexachloroantimonate **173**, obtained beforehand from α-chlorobenzyl benzoate **172**, reacts with the

alkanes **174** to give the 1,3-dioxanylium salts **175**.¹⁸³ The 5-acyloxy-1,3-dioxanylium salts **177** can be derived from the enol acylates **60** and **64** as unsaturated components.¹⁸³

Hydrolysis of 1,3-dioxanylium salts **175** readily yields 1,3-diols with a branched skeleton.¹⁸⁸ Correspondingly, the salts **177** can be precursors of 1,2,3-triol derivatives.

The interaction of the carboxonium salt **173** with 2-butene **179** leads to a separable mixture of the isomers **182** and **183** in a 6:1 molar ratio. It is obvious that cyclisation of the secondary cationoid intermediate **180** is accompanied by partial isomerisation of the latter to the more stable tertiary cation **181**.¹⁸³ However, cyclohexene reacts with the salt **173** to give only the 1,3-dioxolanylium derivative **185**. Apparently, immediate cyclisation in the less flexible structure **184** is difficult (Scheme 17).¹⁸³

A contradiction is evident in the above cycloaddition processes. On the one hand, no five-membered heterocycles **178** arise in the reaction of the enol acylates **60** and **64** with the salt **173** by the pathway described in Section III. Cyclisation through one of the two acyloxy groups in the intermediate **176** results only in the 1,3-dioxanylium salts **177**, which supports the concerted 1,4-addition of the cation **173** to the C=C double bond. On the other hand, the addition to cyclohexene has an obviously stepwise mechanism.

As shown by ¹H NMR spectroscopy,^{188, 189} the concerted and stepwise cycloaddition mechanisms can operate simultaneously, and the structure of the end-products is determined by the configuration of at least two transition states arising from the differing chirality of α-chlorobenzyl benzoate **172**.¹⁸⁸

Scheme 17

VI. Direct O-acylation of aldehydes and ketones

The use of acylals, enol acylates, and α-haloalkyl acylates for preparative syntheses of acyloxycarbocations suffers from several drawbacks. On the one hand, these approaches are in essence 'two steps forward and one step back' because carbonyl compounds acylated under acid catalytic conditions are common starting materials in all these reactions. On the other hand, only aldehydes can be employed successfully, since ketones usually do not form stable acylals and α-haloesters.

Therefore, attempts were made to perform the above syntheses by obtaining the required acyloxycarbocations directly from aldehydes and ketones by path *e* (see Scheme 15). To solve this problem, some requirements had to be fulfilled. First, it was necessary to exclude from the reaction mixtures both any 'external' nucleophiles, such as halide, acylate, and hydroxide anions to avoid the formation of the adducts **1** or **2**, and any bases to prevent the deprotonation of the acyloxycarbocations to give enol acylates or the fragmentation of the former with loss of an acyl cation. Obviously, the presence of protons as competing electrophiles is also undesirable.

All of these requirements can be satisfied by employing cationoid complexes, namely, acylium salts that have recently found extensive use for the controlled and directed functionalisation of unsaturated compounds under *Ad_E* reaction conditions.^{190–192} The benzoyl and *tert*-butyl hexachloroantimonates (see Schemes 7 and 9) can be used as such cationoid complexes.

The interaction of a series of aldehydes and ketones **186** with benzoyl hexachloroantimonate **187** gave the 1,3-dioxolanylium salts **188** in 32%–86% yields.^{193–195} It was found that nitromethane is the optimum solvent for these processes as it can

Scheme 18

$$R^1, R^2 = \text{Me, Ph, PhCH}_2; \quad R^3 = \text{H, Me, Ph, PhCH}_2; \quad R^4 = \text{H, Me, Et, Pr}^i, \text{Ph.}$$

R = Me, Ph.

effectively stabilise the cationoid intermediates.¹⁹⁴ The acylation of the ketoaldehydes **189** under the same conditions gave the hitherto unknown 4-acyl-1,3-dioxolanylium salts **190**. Hydrolysis of the salt **190a** yielded the polyfunctional compounds **191** and **192**.¹⁹⁶ 1,3-Diketone **193** behaves similarly (Scheme 18).¹⁹⁶

Studies of the structures of the products of these reactions, **190** and **194**, and compositions of the reaction mixtures [Eqns (16) and (18)] showed that these processes involve 1,2-acyl migrations.¹⁹⁶ It should be noted that 1,2-shifts of acyl groups between carbon atoms in cations are very rare and have been studied only in the ketoxirane series.^{197–200} However, the isomerisation of the acyloxycarbobocations already mentioned in Sections V and VI [Eqns (14)–(16) and (18); Scheme 9] is worthy of particular consideration.

Sextet rearrangements so typical of carbenium ions^{94, 201} are not in any way characteristic of the carboxonium cations **169** and **170**, which arise in acid-catalysed reactions of carbonyl compounds. The Danilov aldehyde-ketone isomerisation,²⁰² the acyloin rearrangement,⁹⁴ as well as the dienone-phenol rearrangement¹² are perhaps the only ones known. Therefore, the isomerisation discovered in reactions involving acyloxycarocations at once attracted attention. The isomerisation is, in essence, the transformation of carbonyl compounds into 1,2-diols, i.e. the reverse of the pinacol (diol-ketone) rearrangement; hence it was described as a retopinacol rearrangement. This term is about 90 years old and is most frequently used for the conversion of pinacol into tetramethylethene. However, this conversion is in fact not a retro-reaction relative to the pinacol rearrangement. This fact has been repeatedly noted, and it was even proposed to exclude altogether this inappropriate term.²⁰³

The discovery of a reaction actually corresponding to this concept required reasoned criteria to determine the place of the process among other rearrangements. Structural, functional, and redox features were proposed for this purpose, according to

which this conversion of carbonyl compounds is fully the reverse of the pinacol rearrangement.^{194, 195, 204–206}

A few further examples of the retropinacol rearrangement, also proceeding upon acylation of carbonyl compounds, have been described in the literature. The action of trichloroacetic anhydride on camphor **195**³³ and of trifluoromethanesulfonic anhydride on 1-methylnorborn-5-en-2-one **197**¹⁷⁰ leads to the allyl alcohol derivatives **196** and **198**. These reactions are the reverse of the second variant of the pinacol rearrangement, viz. the L'vov-Sheshukov reaction (conversion of allyl alcohols into aldehydes²⁰²). The acylation of the aldehydes **199** by the acyl triflates **200** also occurs through the retropinacol rearrangement to give the 1,2-diols **201**.²⁰⁷ An analogous transformation of the aldehyde **199a** by treatment with benzoyl chloride in the presence of AlCl₃ was recently described.²⁰⁸ Pinacolone **202** undergoes a rearrangement on treatment with SO₃ (Scheme 19).²⁰⁹

All these reactions are possible owing to the high energy of the acyloxycarbenium intermediates. According to quantum chemical calculations, the energy of the latter is almost equal to that of tertiary carbenium ions [ΔH_f (**166**) = 94.8 kcal mol⁻¹; ΔH_f (**167**) = 97.2 kcal mol⁻¹].²¹⁰

Such a low stability of the acyloxycarbenium ions **171** relative to the carboxonium ions **169** and **170** permits other conversions that are also unusual for carbonyl compounds. Fragmentation of the cationoid intermediate with cleavage of the C–C bond can occur under conditions complicating the rearrangement. Thus, not migration but loss of the benzoyl group in the intermediate **204** takes place upon the benzylation of 1,1-dibenzoylcyclopentane **203**.¹⁹⁶ Under the same conditions, the β -branched ketone **206** gives the acyloxycarbocation **207**, which is incapable of rearrangement (which would result in a less stable secondary carbocation) and therefore undergoes fragmentation. C-Acylation of its products **208–210** gives the pyrylium salt **211**¹⁹⁶ (Scheme 20).

Scheme 19

R = H, Ph, 1-adamantyl.

Scheme 20

Information from this series of investigations revealed the following series based on the thermodynamic stability of cations.¹⁰⁴

VII. Acid-catalysed C-acylation of carbonyl compounds

The aforementioned (see Section I) method of synthesis of 1,3-diketones by the acylation of ketones in the presence of boron trifluoride⁶ has never been widely used. This was prevented by various side reactions (acylation of diketones, see Section VI) as well as the successful development of alternative approaches using fixed enolic derivatives of ketones, particularly silyl enol ethers (see, for example, Tirpak and Rathke²¹⁹ and a review²²⁰). On the other hand, these side reactions were the basis of many one-pot syntheses of oxygen-containing heterocyclic compounds. These syntheses involve the repeated acylation of the starting carbonyl compounds and intermediates, and are in essence chains of consecutive conversions of cationoid (or similar) structures, terminated by cyclisations to highly stable heterocyclic cations.

Syntheses of the 4-pyrones **227** by the acylation of acetone and its symmetrical homologues **226** have been reported. In these processes, carboxylic acids or their anhydrides in the presence of polyphosphoric acid²²¹ or acetyl chloride with AlCl_3 ²²² were used as acylating agents. Repeated acylation of phenylethanol **228** gives the unsymmetrical 4-pyrones **233**.²²³ This reaction involves successive lengthening of the carbon chain via the intermediates **230** and **231**, which are represented as uncharged species but can hardly remain uncharged under these reaction conditions.

However, pyrylium salts (e.g. **225** and **232**) occupy a dominant position among the heterocyclic compounds discussed. Practically all the information concerning these compounds is concentrated in two comprehensive reviews^{224, 225} and in several papers.^{91, 174, 226} Therefore, the methods of synthesis of pyrylium salts by the acylation of carbonyl compounds will be outlined only briefly in the present review.

It turned out that the mixture of acetic anhydride with 70% perchloric acid was the most suitable acylating agent for the synthesis of pyrylium salts.²²⁶ This mixture converts acetone into 2,4,6-trimethylpyrylium perchlorate **234**;²²⁷ unsymmetrical 6-alkyl-2,4-diarylpyrylium salts **236** were obtained from the aryl methyl ketones **235** under the same conditions.¹⁷⁴

Noteworthy modifications of the latter process are acylation of aromatic compounds **237** having electron-donating substituents and protonation of the aryl methyl ketones **235** with strong inorganic acids.²²⁴ In the former case, the initial Friedel-Crafts ring C-acylation to the ketone **235** is followed by its reaction according to Eqn (21). In the latter case, the interaction involves self-condensation of the ketone **235** to the dypnone **238**, which is partially deacylated by the acid [Eqn (22)].^{224, 228} It should be mentioned that this reaction [Eqn (22)] is of a rather theoretical interest because abundant charring takes place, whereas the yields of the salts **240** do not exceed 12%–15%.

Until recently, there were no commonly accepted opinions concerning the pathway of the methyl ketone acylation [Eqns (20) and (21)]. Arguments have been put forward in the literature both in favour of the initial C-acylation of the starting ketones **241** to give the 1,3-diketones **242**, which subsequently react with a second molecule of the ketone **241** (pathway *a*), and in favour of the preliminary crotonic condensation of the ketones **241** to give the α,β -unsaturated ketones **244**, which then undergo C-acylation (pathway *b*).²²⁴ Recently, investigations showed that condensations of the unsymmetrical 1,3-diketones **242** ($\text{R}^1 \neq \text{R}^2$) with methyl ketones **241** always lead to mixtures of isomeric pyrylium salts **243** and **245**, while acylation of the ketones **241** gives only the asymmetric isomers **236** and **245**.²²⁹ Hence, it was concluded that the latter reaction occurs by pathway *b* (Scheme 22).

Scheme 22

The acylation of the α, β -unsaturated ketones **244** represented by Scheme 22 is one more widely used method for synthesising pyrylium salts,²²⁴ particularly when salts **245** containing definite substituents at positions 2 and 4 are required. The use of dypnone [1,3-diphenyl-2-buten-1-one (Ed.)] and mesityl oxide has been reported most frequently.²²⁴ Evidently, the process occurs by Eqn (19) including isomerisation to a β, γ -unsaturated ketone (or the corresponding enol acylate **244**).²¹⁸

Finally, one more reaction, very important in pyrylium chemistry, cannot be disregarded, namely, the acylation of the benzyl ketones **246** to give the 2-benzopyrylium salts **12** and **247**.²³⁰ These salts can be readily transformed into isoquinolines, including natural alkaloids which are difficult to obtain. The key step of this process is acylation of the aromatic ring which must contain electron-donating substituents (this is possibly the only preparative restriction of this method). In the absence of such substituents, competitive *O*-acylation prevails, which prevents the formation of the target products **247**.

The benzyl ketones **246** can be regarded as fixed β, γ -unsaturated ketones undergoing *C*-acylation at the γ -position.^{231, 232} The reaction considered was discovered in 1966²³³ and was later extended to various heterocyclic ketones (**248**, **250**, **252**, **254**, and **256**). As a result, fused polyheterocyclic derivatives such as the thienopyrylium salts **249**,²³⁴ **251**,²³⁵ **253**, and **255**,²³⁶ as well as the indolopyrylium salts **257**²³⁷ were obtained. These salts can be converted into the corresponding pyridine derivatives, particularly, β -carbolines.²³⁷ The novel indolo-1,4-oxazinium salts **259** were prepared by the acylation of 1-phenacyl-3-methylindole **258**.²³⁸

The products **259** are interesting as precursors of indolopyrazines used as psychotropic preparations and antibiotics.²³⁸

VIII. Electrophilic catalysis by acyl cations

While investigating the acid-catalysed reactions of carbonyl compounds, it was observed long ago that the addition of acetic anhydride to an acidic reaction medium can change the direction of such processes. Thus, isomerisation of dienone **260** occurs by the usual mechanism involving the dienone-phenol rearrangement with migration of the methyl group to form the phenol **261**, but the anomalous product **262** was obtained in the presence of Ac_2O .^{239, 240} Protonation of the α, β -unsaturated ketone **263** gives the dihydrofurylium salt **264**,²⁴¹ while the addition of acetic anhydride leads to the pyrylium salt **265**.²⁴²

One of the three-component syntheses of pyrylium salts presented above [see Eqns (20) and (21) and Scheme 22, pathway *b*] involves the interaction of the methyl ketone **241** (the C_2 -component) with the precursor of the acyl cation (the C_1 -component). According to the formation pattern of the five-carbon chain of the ring, this synthetic method can be represented as $C_2C_2C_1$.^{224,225} Other precursors of carboxonium ions can be also employed as C_2 -components: aromatic aldehydes **266** ($X = H, Y + Z = O$, hydroxycarbocations), acetals **266** ($X = H, Y = Z = OAlk$, alkoxy carbocations), orthoesters **266** ($X = Y = Z = OAlk$, dialkoxy carbocations).^{224,225} However, these processes give symmetrical pyrylium salts **243** via the $C_2C_1C_2$ pathway.

It was found that the reactions of the methyl ketones **241** with analogues of the above C_1 -components, e.g. α -chloroalkyl acylates **266** ($X = H, Y = Cl, Z = OAc$), chloromethyl methyl ether **266** ($R^2 = X = H, Y = Cl, Z = OMe$), as well as alkyl α, α -dichloromethyl ethers **266** ($R^2 = H, X = Y = Cl, Z = OAlk$), preferentially follow the $C_2C_2C_1$ path.^{224,225,243} This fact evidently implies initial fast self-condensation of the methyl ketone **241** to the α, β -unsaturated ketone **244** (Scheme 22). It should be noted that reactions using these α -chloroethers and α -chloroesters were carried out in AcOH. It was found that the formation of unsymmetrical pyrylium salts **245** predominates when acylium ions are present in the reaction mixture or conditions for the generation of these ions in situ are created.²⁴³

Hence acyl cations are the factor that promotes the rapid self-condensation of the methyl ketones **241** in accordance with the assumed scheme.²⁴³

If the *O*-acylation of the keto-component **241** is suppressed, the reaction follows the $C_2C_1C_2$ path. Thus, the addition of ethyl orthoformate (which irreversibly binds the acyl cations to form the corresponding ester and to liberate diethoxycarbenium ions) to the same mixture, 'acetophenone + acetic anhydride + perchloric acid', leads to 2,6-diphenylpyrylium perchlorate (**268**) in high yield.²⁴⁴

As shown recently, the 1,5-dicarbonyl compounds **269** react with azomethines in AcOH to give the dihydroisoquinolines **270**; this reaction does not occur either in acetonitrile or in *N,N*-dimethylformamide.²⁴⁵

Although acyl cations do in fact participate in the conversions of carbonyl compounds considered, they are included among the end-products only provided that the process involves *C*-acylation. In other words, here we deal with electrophilic catalysis by acylium ions in reactions of carbonyl compounds with weak nucleophiles; such catalysis involves the conversion of an aldehyde or ketone into the highly reactive acyloxycarbenium ions **267** (see Section V).

The most typical example of the application of catalysis by acyl cations is the interaction between carbonyl compounds and nitriles. The syntheses of 1,3-oxazine derivatives **272** from aldehydes, nitriles and alkenes are usually carried out with a mixture of sulfuric and acetic acids, although the role of the latter in the reaction has not been clarified.²⁴⁶⁻²⁴⁸

271

272

273

In the absence of an alkane component, the *N*-acyliminium intermediates **271** combine with another nitrile molecule to give the geminal bis-amides **273**.²⁴⁹

These reactions are well-known in the aldehyde series; however, attempts to extend them to ketones have failed until recently.^{249, 250} This problem was solved using $HClO_4 + Ac_2O$ as the acylating mixture. The 1,3-diketones **274** readily react with benzonitrile in the presence of this mixture to yield the little-known 3-azapyrylium salts **275**, the hydrolysis of which gives the β -acylamino vinyl ketones **276**.²⁵¹

R = Me, Ph.

Under the same conditions, the alkyl aryl ketones **277** give the 3-azapyrylium salts **278**, which are structurally isomeric with compounds **275**.²⁵² These reactions do not occur in the absence of acetic anhydride (when the nitrile is absent, the reaction follows Schemes 21 and 22).

The large series of 3-azapyrylium salts **280** were obtained by treating mixtures of benzonitrile and the ketones **277** with the acylium salts **279**.²⁵³

R¹ = H, Me; R² = Ph, 4-MeC₆H₄.

R¹ = Me, Et, Bu^t, Ph; R² = H, Me; R¹ + R² = -(CH₂)₄-;
R³ = Me, Et.

The transformations of a series of aliphatic ketones under the conditions of electrophilic catalysis by acyl cations were described in Ref. 254. Pinacolone **281** (R = Me) combines with benzonitrile in the presence of the $HClO_4 + Ac_2O$ mixture to furnish 1,3,5-oxadiazinium perchlorate **284**, which is decomposed on heating to form the *N*-acyliminium intermediate **283**. The latter, which is a heteroanalogue of **282**, can isomerise to the tertiary carbocation **285**. This process is another variant of the retropinacol rearrangement (see Section VI), which is the reverse of the Tiffeneau and MacKenzie reactions²⁵⁴ (it should be noted that the 2-oxazolines **286** are direct derivatives of 1,2-aminoalcohols). Pivalophenone **281** (R = Ph) behaves similarly. Its transformations also occur in the presence of Ac_2O , but the acyl fragment is not included in the product structure (Scheme 23).

Scheme 23

R = Me, Ph.

Scheme 24

The structure of the products obtained from diisopropyl ketone **287** and cyclohexanone **290** under the same conditions suggest that the *N*-acyliminium ions **288** and **291** are formed as intermediates.²⁵⁴ The hypothesis that the aldol condensation of the ketone may initially occur has been disproved, for example, by obtaining different products (**294** and **295**) from acetone and diacetone alcohol²⁵⁴ (Scheme 24).

As shown by experiment and quantum-chemical calculations, the interaction of carbonyl compounds with nitriles occurs by different pathways depending on whether the process is catalysed by protic acids or acylium ions.^{255–258} In the former case, the nitrile component undergoes electrophilic activation (protonation, pathway *a*, E = H). The nitrilium cation **296** formed attacks a molecule of the carbonyl compound. On the other hand, in the presence of acylium ions, the carbonyl component undergoes electrophilic activation (pathway *b*, E = Ac). Both pathways lead to the *N*-acyliminium ions **298** via the intermediates **297** and **299**.

While pathway *b* is analogous to the Ritter reaction (but fundamentally differs from it in a number of features^{255, 257}), the interaction following pathway *a* was unknown until recently. Only recently has it been found that the nitrilium salts **296** (E = Alk) prepared beforehand (they are, incidentally, heteroanalogues of acylium ions) readily react with carbonyl compounds to give the *N*-acyliminium ions **298** (E = Alk).^{259–261} Some aspects of the interaction of aldehydes and ketones with nitriles were thoroughly discussed in a recent review.²⁶²

Remarkable processes take place in the acylation of compounds containing both a keto-group and a nitrile moiety (e.g. compound **300**).^{263–266}

R = Me, Et.

Acylation of propiophenone or butyrophenone with propionic anhydride in benzonitrile leads to the 6-acylmethyl-3-azapyrylium salts **301**, which can be converted into derivatives of the 1,3,5-triketones **302**, which are difficult to synthesise, and into the pyridones **303**.²⁶⁷

Electrophilic catalysis by acylium ions was found to be the most effective means for the transformation of the benzyl ketone **246** into a natural alkaloid of the isoquinoline series **304**,²⁶⁸ as well as for the cyclisation of the polysubstituted 1,5-diketones **305** to the pyrans **306**.²⁶⁹ These reactions did not occur in the presence of other acid catalysts.

$$R^1, R^2 = \text{Ar, cyclo-Alk};$$
$$R^3 = H, Alk, Ar; \quad R^4 = H, R^5 = Ph.$$

* * *

The examples presented above illustrate the wide scope of the synthetic application of acyl cations as catalysts in condensations and cyclisations of carbonyl substrates. Moreover, going beyond the limits of this review, it should be mentioned that the applicability of the above reactions can be considerably extended using derivatives of carbonyl compounds. Some of them, such as acylals, α -haloalkyl acylates, enol acylates and acetals, have been described in this review. Vinyl halides and ethynes also belong to this series. For example, the reactions of acylium salts with *tert*-butylethyne and the chloroalkenes $R^1-CH=C(Cl)R^2$ present one more example of the retropinacol rearrangement.^{270, 271} The same rearrangement, i.e. conversion of ketones into vicinal chloroamides, occurs via highly reactive chlorocarbenium ions in the interaction of geminal dichlorohydrocarbons with nitriles.²⁷² β,γ -Unsaturated chloroketones, allenic 1,5-diketones, and 4-chloropyrylium salts can be obtained by the acylation of vinyl chlorides.^{271, 273} Vinyl chlorides react with nitriles to give pyrimidines in the presence of trifluoromethanesulfonic acid²⁷⁴ or 3-azapyrylium hexachloroantimonates in the presence of acylium salts.²⁵³ Finally, pyrimidines and 3-azapyrylium salts

can be prepared by the interaction of vinyl chlorides with nitrilium salts.²⁷⁵

Thus, the acid-catalysed acylation of carbonyl compounds is not only an alternative to traditional methods using base catalysis but is also a new approach to the activation of aldehydes and ketones in reactions with various carbo- and hetero-nucleophiles. Previously unknown reactions of carbonyl compounds, rearrangements, and fundamentally new methods of synthesis of valuable oxygen- and nitrogen-containing heterocyclic and polyfunctional compounds have already been found in this promising synthetic field.

Dibenzo-*p*-dioxins.

Methods of synthesis, chemical properties, and hazard assessment

A D Kunzevich, V F Golovkov, V R Rembovskii

Contents

I. Introduction	27
II. Nomenclature and structure	27
III. Methods for the formation of the tricyclic system of dibenzo- <i>p</i> -dioxin	28
IV. Reactions of dibenzo- <i>p</i> -dioxins	31
V. Toxic properties of compounds of the dibenzo- <i>p</i> -dioxin class	35
VI. Formation and occurrence in nature	36
VII. Conclusion	36

Abstract. The review surveys and gives a systematic account of the data on the methods of synthesis and chemistry of dibenzo-*p*-dioxins including their halogenated derivatives. The hazard of these compounds to mammals is discussed. The bibliography includes 219 references.

I. Introduction

Never before has the world community been so concerned about the hazard caused by any class of chemicals as in the case of dibenzo-*p*-dioxins. Year after year scientists from all over the world have met at conferences in an attempt to assess the hazard due to these substances generated during the industrialisation of human society.

The first representatives of dibenzo-*p*-dioxins were synthesised late in the 19th century. However, over a long period they remained known only to a narrow circle of researchers, until the terrible consequences of the chemical warfare in Vietnam (1961–1971) and an accident in Seveso (Italy, 1976) demonstrated to the whole world the potential danger inherent in these compounds.

The above and some other events associated with the discharge of halodibenzo-*p*-dioxins into the atmosphere have stimulated research dealing with their properties. The development of national ecological programmes in which dibenzo-*p*-dioxins occupy an important place has begun in many countries.

A large number of papers including reviews have been devoted to dibenzo-*p*-dioxins. This comes as no surprise in view of the hazard associated with some representatives of these compounds. The surprising thing is that no surveys of the chemistry of dibenzo-*p*-dioxins have yet been published. The published papers^{1–5} do not provide exhaustive information. We have, therefore, ventured to fill this gap to some extent.

Since the danger coming from dibenzo-*p*-dioxins is attributed to their halogenated derivatives, these compounds receive

particular attention in the literature. While preparing the present review we also used our practical experience in working with these substances.

The first mentions of dibenzo-*p*-dioxins date back to 1872, when Merz and Weith⁶ obtained octachlorodibenzo-*p*-dioxin while heating potassium perchlorophenoxide at a high temperature and described its properties. In 1894, Zinke⁷ found that octachlorodibenzo-*p*-dioxin is produced on heating many other chlorinated compounds. The same was observed by Biltz⁸ in 1904 and again by Zinke⁹ in 1908.

The parent compound of this class, dibenzo-*p*-dioxin, was synthesised by Ullman and Stein¹⁰ in 1906. Later, various derivatives of dibenzo-*p*-dioxin were prepared by several workers^{11–19} and up to the 1970s many of them were regarded as promising compounds for practical purposes. Attempts have been made to develop dyes^{20–23} and medicinal preparations^{24–28} based on these compounds. It has been suggested that some halogenated dibenzo-*p*-dioxins be used as fireproofing agents.^{26,29,30} The possibility of developing promising polymeric materials based on some dibenzo-*p*-dioxin derivatives has been studied.^{31,32}

In view of the events mentioned above, since the middle 1970s the primary emphasis has shifted to the investigation of polyhalogenated dibenzo-*p*-dioxins (PHDD) as potential ecotoxins. In 1972–1976, the main approaches to synthesis of these compounds were developed. At present, all the possible polychlorinated dibenzo-*p*-dioxins (PCDD) have been prepared in a pure state; bromine-, fluorine-, and iodine-containing dibenzo-*p*-dioxins as well as compounds incorporating functional groups (NO₂, CN, CH₃, CF₃, etc) have been synthesised.

II. Nomenclature and structure

The molecule of dibenzo-*p*-dioxin **1** is a fused heterocyclic system formed by two benzene rings and an inner six-membered heterocycle incorporating two oxygen atoms. In conformity with the IUPAC rules,³³ the name of dibenzo-*p*-dioxin is based on fusing 1,4-dioxin **2** with two benzene rings. {The names dibenzo-1,4-dioxin and dibenzo[*b,e*]dioxin for **1** and *para*-dioxin for **2** can also be found in the literature}.

The molecule of dibenzo-*p*-dioxin is planar. The crystal and molecular structures of compound **1** and some of its derivatives have been discussed in a number of papers.^{34–41} The dipole moment of compound **1** is zero or close to zero, and the dipole moments of some alkyl- and halo-substituted dibenzo-*p*-dioxins have been reported.^{42,43} The IR spectra of dibenzo-*p*-dioxins exhibit characteristic absorption bands in the region of 1330–1280 cm⁻¹,^{1,44,45} which are due to antisymmetric vibrations of the C–O–C group. An exception is provided by octahalo-derivatives, whose absorption in this region is weak.⁴⁵ The ¹H NMR spectrum of dibenzo-*p*-dioxin is an AA'BB' system centred at 6.89 ppm.⁴⁶ The ¹H NMR spectra of almost all the halogenated dibenzo-*p*-dioxins have also been obtained.^{46–53} In concentrated sulfuric acid in the presence of an oxidising agent, dibenzo-*p*-dioxins produce a characteristic green-blue colour (dioxin test), which is attributed to the formation of radical-cations.^{54,55} The EPR spectra and the properties of these radical-cations have been discussed in a number of papers.^{56–60}

III. Methods for the formation of the tricyclic system of dibenzo-*p*-dioxin

1. Self-condensation of diphenyl ethers

Among diphenyl ethers, *o*-phenoxyphenols, the so-called pre-dioxins, are of practical interest for the preparative synthesis of dibenzo-*p*-dioxins. Various dibenzo-*p*-dioxins can be prepared from these compounds, their yields being frequently quantitative.⁶¹

3–10

Z = Y = OH (**3**), OMe (**4**), NH₂ (**5**);

Z = OH, Y = H (**6**), NH₂ (**7**), Br (**8**), Cl (**9**);

Z = OMe, Y = Cl (**10**).

The condensation is often carried out by heating the corresponding ether (**3** and **4**) in hydrobromic acid in the presence of phosphorus.¹⁰ Two functional groups in the ortho-positions are not required for cyclisation to take place. For example, compound **1** can be formed on treatment of 2-hydroxyphenyl phenyl ether **6** with nitrobenzene or selenium.⁶² The diphenyl ethers **8–10** containing a hydroxy- (or methoxy-) group and a halogen atom in the ortho-positions undergo condensation in the presence of hydrogen chloride acceptors. The best results have been achieved by using K₂CO₃ in an appropriate solvent.^{50,61,63} Electron-donating groups facilitate condensation,⁶⁴ as is the case with *tert*-butyl in compound **11**.

11

The tricyclic dibenzo-*p*-dioxin system has also been obtained by the diazotisation of the corresponding amines.^{62,65} For example, compound **1** can be obtained from 2-aminophenyl 2-hydroxy-phenyl ether **7** or di(2,2'-aminophenyl) ether **5**.

The closure of the ring in *o*-phenoxyphenols can also occur under the action of UV irradiation in the presence of sensitizers.^{66,67} In this case, 3,4,5,6-tetrachloro-2-(pentachlorophenoxy)phenol **12** is converted into octachlorodibenzo-*p*-dioxin **14** (OCDD, **14**). Cyclisation is supposed to occur via the biradical-cation **13**.

Fairly pure specimens, suitable as reference materials, can be obtained from diphenyl ethers. However, this method has not found wide application owing to the low availability of the starting compounds.

2. Condensation of halogenated phenols and other hydroxy-compounds

Generally, condensation of halogenated phenols occurs according to Scheme 1.

Scheme 1

R¹, R² = Hal, CN, NO₂, Alk;

Y = Hal, NO₂; n = 1–4.

The first representative of halogenated dibenzo-*p*-dioxins, octachlorodibenzo-*p*-dioxin **14**, was synthesised in this way by heating potassium perchlorophenoxide to a high temperature.⁶ Octafluorodibenzo-*p*-dioxin⁶⁸ and some other PCDD have been obtained in a similar way.⁶⁹ Potassium salts are most frequently used for the condensation of halogenated phenols. They are prepared by the following general method. The corresponding phenol is added to a methanol solution of potassium methoxide or potassium hydroxide or to a methanol suspension of potassium carbonate, and the solvent is evaporated. However, potassium phenoxides are normally not isolated in a pure state. Instead, a mixture of phenol and a 5–10-fold excess of the alkaline reagent are refluxed in an appropriate solvent. The use of a calcium salt has also been reported; compound **14** was obtained in 28% yield by heating perchlorophenol in the presence of marble.⁷⁰

Copper and its salts are used as condensation catalysts.^{6,45,68–70,71–73} An example of using a palladium-copper catalyst has been reported.⁷⁴ However, pure copper is preferred. For example, by heating *o*-bromophenol in the presence of the Cu + Cu(OAc)₂ system, compound **1** was obtained in 40% yield.⁷¹ When pure copper was used, the yield increased to 65%.⁷¹ The replacement of *o*-bromophenol by *o*-chloro- or *o*-iodophenol does not result in an increase in the yield. In the latter case, it amounted to 8%.⁷¹ Under similar conditions, *o*-chlorophenol affords compound **1** in 25% yield. When polyhalogenated dibenzo-*p*-dioxins are synthesised using copper without a solvent, the yields usually do not exceed 20%.^{45,70,72,73} The main side reaction that decreases the yields of dibenzo-*p*-dioxins is polyoligomerisation.^{63,72}

Pyrolytic condensation of potassium chlorophenoxides has been used to prepare 22 isomers of tetrachlorodibenzo-*p*-dioxins.⁷⁵ However, purification of the products obtained by this method requires the combination of liquid and gas chromatography, which seriously restricts the applicability of the method.

The condensation of phenols containing functional groups is frequently accompanied by partial elimination of these groups,^{76,77} and therefore this method is not used for preparing functionally substituted dibenzo-*p*-dioxins. In some cases, the abstraction of halogen atoms has also been observed.^{45,78,79} In fact, whereas the condensation of potassium 2,6-dibromophenoxide in methanol yields 1,6-dibromodibenzo-*p*-dioxin^{45,78} **15**, the condensation of the same salt in pyridine⁷⁸ gives a mixture of compounds **1** and **15**.

It is not strictly necessary to use salts of phenols. Some workers^{1,6-8,45,70,80,81} have shown that pyrolysis of perhalogenated phenols and a number of oxo-compounds gives the corresponding octahalodibenzo-*p*-dioxins. However, it should be noted that this reaction occurs via a different mechanism.

Among other hydroxy-compounds, naphthols^{76,82} and hydroxyquinolines⁸³⁻⁸⁵ can be involved in the condensation. The properties of the resulting naphthalene and other analogues

of dibenzo-*p*-dioxins have scarcely been studied. At the same time, these compounds may be formed as minor products in the production of dyes. For example, it has been found⁸⁶ that in the presence of tetranitromethane in an alkaline medium, aminonaphthalenesulfonic acids are converted into the corresponding salts of sulfodinaphtho[5,6-*b,e*]-1,4-dioxin **16**. This reaction was assumed to proceed via the oxidation of the CH and NH₂ groups in the 1- and 2-positions to COH and NHOH (NO) groups followed by the condensation of two molecules.

3. Condensation of catechols with halobenzenes

The method of condensation of catechols with halobenzenes⁴⁶ suggested in 1972 is, perhaps, the most convenient way of preparing various dibenzo-*p*-dioxins including those incorporating functional groups^{47,87-91} (see Scheme 1, pathway *b*). This method is preferred when a high-purity compound is needed. The analytical standards for 22 tetrachlorodibenzo-*p*-dioxins,^{92,93} some pentachloro- and heptachlorodibenzo-*p*-dioxins,^{49,94} and some other compounds,^{79,95-97} including mixed bromine- and chlorine-containing dibenzo-*p*-dioxins,⁹⁶ have been prepared by

Scheme 2

this procedure. Fluorine-containing dibenzo-*p*-dioxins have also been synthesised and suggested as internal standards for gas-chromatographic and mass-spectrometric analyses of PCDD.⁹⁸⁻¹⁰⁰

The condensation of catechols is carried out under mild conditions by refluxing a mixture of reactants in a solvent. DMSO, DMF, acetone, or, more rarely, alcohols are used as solvents in this reaction. The yield of reaction products is fairly high and obviously does not depend substantially on the nature of the halogen in the halogenated benzene. In fact, the replacement of dichlorobenzene by dibromobenzene in the condensation with catechol^{65,101} does not result in a substantial increase in the yield of compound 1. Good results have been obtained by Kunzevich et al.,¹⁰² who carried out the condensation of the disodium salt of catechol with various chlorine-containing benzenes in hexamethylphosphoramide. The yields of dibenzo-*p*-dioxins varied from 40% to 66% depending on the chlorine-containing reagent used.

Better results are achieved when the catechol or benzene molecule contains a strong electron-withdrawing group (or several groups). This group generally acts as the leaving group, other functional groups remaining unaffected.⁹¹ For example, the condensation of catechol with picryl chloride (see Scheme 2)¹¹ affords 1,3-dinitrodibenzo-*p*-dioxin (20a, 20b, X = H) in 85% yield.¹¹ Catechol reacts with 2,4-dinitrochlorobenzene¹⁰³ just as easily. It has been found that a nitro group in the lateral position is replaced by a halogen. Therefore, the condensation of 4,5-dichlorocatechol with 2,5-dichloro-1,4-dinitrobenzene gives 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD, 21) in 90% yield.¹⁰⁴

Halogenated *o*-quinones also undergo condensation. For example, in a study of the properties of tetrabromo(or chloro)-*o*-quinones, it has been found¹⁰⁵⁻¹⁰⁷ that these compounds can condense to give halogenated dibenzo-*p*-dioxin-2,3-quinones 22a. Reduction of the latter gives the corresponding hydroxy-compounds 23.

In the presence of strong dehydrating reagents, for example, P₂O₅, the condensation of catechol to compound 1 has been observed,⁶⁵ while in the presence of oxygen or sodium nitrite, dibenzo-*p*-dioxin-2,3-quinone 22b is produced.^{105,108,109} The reaction occurs via a radical mechanism involving the oxidation of the dimer 24, formed from the radical in the first stage of the process, to the quinone 25, which then undergoes rapid heterolytic ring closure to give compounds 22b (Scheme 3).

X = Cl, Br (a), H (b).

o-,*p*-Quinones^{105-107,110} and cyclic triketones¹¹¹ also undergo cyclisation.

4. The mechanism of the formation of the tricyclic dibenzo-*p*-dioxin system

The condensation of halophenols and catechols (or their salts) with halobenzenes is based on aromatic nucleophilic substitution. This substitution must occur by an S_N2Ar mechanism¹¹² (in other sources,¹¹³ this mechanism has also been called S_NAr). We can follow this mechanism in relation to the condensation of catechol with 2,4,5-trinitrochlorobenzene¹⁰³ (see Scheme 2).

The first stage of this process gives *o*-diphenoxyphenol (predioxin, 17), whose subsequent cyclisation is intramolecular and yields the Meisenheimer spiro-complex 18. The latter complex is formed as an intermediate in the Smiles rearrangement,¹¹⁴ and in the example under consideration¹⁰³ it was isolated in a pure state (X = H) as the sodium salt. The spiro-complex is then converted to complex 19a,b, from which the dioxin ring is formed (compounds 20a and 20b) after the abstraction of the NO₂ group. The presence of two isomers in the reaction mixture has been accounted for^{63,73,115} by the Smiles rearrangement. The fact that some predioxins^{61,63} yield mixtures of isomers of dibenzo-*p*-dioxins is also evidence in support of the rearrangement.^{61,63}

The pyrolysis of phenols and other hydroxy-compounds proceeds unlike the reactions of the salts, via a radical mechanism (Scheme 4). In particular, some researchers^{1,7,8,18,80} have studied the formation of octachloro- and octabromodibenzo-*p*-dioxins in the pyrolysis of perhalophenols or a number of oxo-compounds, for example, octachlorocyclohexenone 26 and found that these reactions involve the formation of the pentachlorophenoxy radical 27.

In all probability, the condensation of other phenols occurs by the same mechanism. Octabromo- and 1,2,4,6,7,9-hexabromo-3,8-dichlorodibenzo-*p*-dioxins have been obtained in this way, and it was suggested that the method may find wide application.¹⁸

Scheme 3

with this system occurs via a transition state with a fairly low activation energy. In the case of compound **28**, the stable σ -complex **29** is formed, whose existence is in all probability caused by the presence of the CF_3 group, which has a strong inductive effect. Hydroxylation is the rate-determining step of this process. The radical substitution of chlorine (or CF_3) by the OH group proceeds more slowly than the nucleophilic substitution by a factor of approximately 3.

IV. Reactions of dibenzo-*p*-dioxins

The molecular structure of dibenzo-*p*-dioxin allows one to treat it as a cyclic aromatic diether. Accordingly, dibenzo-*p*-dioxins enter into all the reactions characteristic of aromatic compounds, namely, electrophilic and nucleophilic substitution in the benzene rings, radical reactions, as well as reactions of functional groups. Among the reactions typical of the heterocyclic nucleus, one should note the relatively easy formation of the radical-cation and reactions peculiar to it, and also reactions involving the cleavage of the C–O–C linkage.

There are almost no papers devoted to the general reactivity of dibenzo-*p*-dioxins, including their halo-derivatives. A comparative analysis of the nucleophilic and radical substitution of the functional groups in the aromatic systems of dibenzo-*p*-dioxins by the hydroxy-group has been carried out.¹¹⁶ In relation to 2-trifluoromethyl-3,7,8-trichlorodibenzo-*p*-dioxin **28** and model compounds (4,5-dichlorocatechol and 5-chloro-4-trifluoromethylcatechol), it has been shown that the reaction of the OH^- anion

1. Electrophilic substitution reactions

a. Halogenation of dibenzo-*p*-dioxins

Direct halogenation of dibenzo-*p*-dioxin occurs according to the rules common to aromatic compounds. This process may be used for preparing PCDD.

The presence of the heterocycle influences the order in which the hydrogen atoms in the dibenzo-*p*-dioxin molecule are replaced. This is determined by the overall mesomeric and inductive effects of the oxygen atom on the benzene ring.^{112, 117}

The mesomeric effect is illustrated by the resonance structures **30** and **31**, which determine the occurrence of ortho- or para-substitution with respect to the oxygen atoms in the dioxin ring.

Scheme 5

However, the ortho-position is deactivated by the inductive effect of oxygen to a larger extent than the para-position. Therefore, the first stage of the halogenation of dibenzo-*p*-dioxin **1** yields the isomer **32** (Scheme 5). The order in which subsequent substitution occurs is an interesting theoretical problem. Due to the deactivating influence of the first halogen atom, the second substitution should occur in ring *B*. The most theoretically probable substitution positions are 7 and 8 (compounds **33** and **34**). When further halogenation is carried out, the hydrogen atoms in the 3- and 7-(or 8)-positions, which are equivalent in terms of the substitution order, are successively replaced by the halogen. As a result, the highly toxic 2,3,7,8-tetrahalodibenzo-*p*-dioxin **21** is formed. Further substitution involves the 1-position (compound **36**) and then the 6- or 9-position (compounds **37** and **38**). The remaining free positions are equivalent in terms of the substitution order, and exhaustive halogenation yields the weakly toxic octahalodibenzo-*p*-dioxin **14**. According to published data, the toxicities of the remaining halogenated dibenzo-*p*-dioxins are intermediate between those of 2,3,7,8-tetra- and octahalo-substituted compounds.^{2,118}

The chlorination of dibenzo-*p*-dioxin **1** proceeds to a greater extent than the bromination. It has been shown^{46,119} that chlorination yields a mixture of products with various degrees of substitution that are difficult to separate. Therefore, this method was⁴⁶ considered to be unsuitable for the synthesis of individual chlorinated dibenzo-*p*-dioxins. Bromination of dibenzo-*p*-dioxin **1** normally comes to a halt at the stage where 2,3,7,8-tetrabromodibenzo-*p*-dioxin is formed.^{102,120} Under certain conditions, this compound can be obtained in a quantitative yield.¹⁰²

It has been reported that chlorination in the second stage gives mostly the 2,7-isomer, while in the case of bromination, the 2,8-isomer predominates;^{19,102} however, this conclusion is questionable. In fact, the yield of the 2,7-dichloro-isomer obtained by the chlorination of dibenzo-*p*-dioxin **1** was only 3%. This fact made it possible to suggest⁴⁶ that the 2,8-dichloro-isomer is more soluble and this is why it had not been isolated by the authors of the previous paper.¹⁹ In any case, there are no serious reasons for believing that chlorination in this stage differs from bromination.

The foregoing considerations are also valid for the halogenation of dibenzo-*p*-dioxins in which the hydrogen atoms of one ring have been completely replaced by chlorine:⁴⁶ substitution occurs in the 7- and 8-positions of the free ring. The presence of other halogens in the molecule also does not change the order in which substitution occurs. In the chlorination of 2,3-dibromo-**(39)** and 2,3-difluoro-**(40)** derivatives, 2,3-dibromo-7,8-dichloro-**(42)** and 2,3-difluoro-7,8-dichlorodibenzo-*p*-dioxins **(43)** have been isolated.¹¹⁹ The nitro-group deactivates ring *A* to such an extent that 2-nitrodibenzo-*p*-dioxin **(41)** is halogenated in the unsubstituted ring *B*,^{121,122} yielding 7,8-dichloro-2-nitrodibenzo-*p*-dioxin **44**.

X = Y = Br (**39**, **42**), F (**40**, **43**); X = H, Y = NO₂ (**41**, **44**).

Conversely, the amino group activates dibenzo-*p*-dioxin. For example, bromination of amino- or acetamido-derivatives **45-48** occurs fairly readily^{121,123} and substitution involves the ring containing the amino-group (Scheme 6, compounds **50-55**). Unlike bromination, the chlorination of the amino-derivatives **45** and **47** is accompanied by the resinification of the reaction mixture.¹²¹ The corresponding acetyl-derivatives **46** and **48** are susceptible to resinification to a lesser degree. For example, the chlorination of 2-acetamido-7,8-dichlorodibenzo-*p*-dioxin **46** gave 2-acetamido-3,7,8-trichlorodibenzo-*p*-dioxin **49** in good yield.^{121,123}

X = Cl, R = H (**45**), Ac (**46**, **49**, **50**, **53**);

X = Br, R = H (**47**, **51**, **55**), Ac (**48**, **52**, **54**).

The influence of various catalysts on the process of chlorination of dibenzo-*p*-dioxins has been described.¹²² The authors found that among the catalysts studied, namely I₂, FeCl₃ + I₂ and 18-crown-6, the last named is the most active. The chlorination pattern in all these cases is the same. In particular, irrespective of the nature of the catalyst, the chlorination of dibenzo-*p*-dioxin **1** affords a mixture of products in which, in addition to TCDD **21**, 2,3,7-trichloro-**(35)** and 1,2,3,7,8-pentachlorodibenzo-*p*-dioxins **(36)**, have been detected.

It is likely that the presence of catalysts can result in more extensive bromination. For example, the bromination of dibenzo-*p*-dioxin in the presence of FeCl₃ gave¹¹⁹ a mixture of compounds containing, in addition to 2,3,7,8-tetrabromodioxin, the products of its further bromination. Therefore, while brominating compound **1** by bromine in the presence of a catalyst, one should take into account the possibility of the formation of polybrominated compounds.

b. Nitration of dibenzo-*p*-dioxin and its derivatives

Dibenzo-*p*-dioxin **1** can be nitrated by conventional nitration reagents such as nitric acid or nitric acid in concentrated sulfuric acid.^{16,124-130} Depending on the reaction conditions, a series of successive substitution products are formed, and the order in which substitution occurs follows the rules which govern halogenation. Owing to the strong deactivating effect of nitro-groups, nitration proceeds only until 2,3,7,8-tetranitrodibenzo-*p*-dioxin is formed.¹³⁰

The influence of various substituents and various nitrating agents on the nitration process has been studied.^{124,125,128,131,132} For example, depending on the reaction conditions, the first substitution in the nitration of 1-acetyldibenzo-*p*-dioxins **(56 and 57)** may involve either the ring containing the functional group or the unsubstituted ring as well, as shown in Scheme 7. The ratio between the isomers obtained and their quantity depends on the nature of the substituent and the nitrating agent. When an excess of the latter is used, 2-, 7-, or 8-nitro-derivatives (compounds **58-63**) are formed. However, in some cases, this order of nitration may be violated. For example, when compound **57** is nitrated by the NH₄NO₃ - (CF₃CO)₂O - THF mixture, substitution involves only the ring containing the functional group and mostly the 4-position of this ring (compound **64**).¹²⁹ Some instances where the acetyl group is replaced by the nitro-group during nitration have also been reported.¹²⁵ Dibenzo-*p*-dioxins incorporating methyl or methoxy groups are readily nitrated by nitric acid in either sulfuric or acetic acid.^{124,131,132}

Scheme 7

R = Me (56, 58, 60, 62), CF₃ (57, 59, 61, 63, 64).

The nitration of halogen-containing dibenzo-*p*-dioxins presents certain difficulties associated with the deactivating effect of the halogens. For example, it has been noted that 1,6-dibromodibenzo-*p*-dioxin **15** does not undergo nitration with nitric acid in concentrated sulfuric acid.¹²⁴ This task can be accomplished by using fuming nitric acid in acetic acid at $T = 70^\circ\text{C}$;¹³¹ this nitrating agent can also be used successfully in other cases, for example, to nitrate mono- and dihalo-substituted dibenzo-*p*-dioxins.^{121, 123, 130, 133} Good results have also been obtained in the nitration by this mixture of polyhalogenated dibenzo-*p*-dioxins containing halogens in one ring, in particular, of 1,2,3,4-tetrachlorodibenzo-*p*-dioxin.^{121, 123, 133} The nitro group goes to the unsubstituted ring. 2,3,7-Trihalo-substituted derivatives are also nitrated under these conditions to give the mono-substitution product.¹³³

Tetrahalo-derivatives are more stable. The most stable are isomers with a lateral arrangement of the halogens. In particular, TCDD **21** does not react with a mixture of nitric and acetic acids¹²⁸ and is destroyed on treatment with fuming nitric acid in sulfuric acid.⁹⁵ This behaviour can be explained, on the one hand, by the low stability of the σ -complex **65** arising in the course of the reaction (which is due to the fact that the positive charge in this complex cannot be delocalised owing to the electron pairs of the oxygen atoms) and, on the other hand, by the decomposition of the σ -complex **65** via pathway *a* to the radical-cation **66** and the NO₂[•] radical.¹³⁴ Under these conditions, oxidation processes leading to the destruction of the dioxin nucleus prevail. In the case where complex **65** decomposes via pathway *b*, nitration affording compound **67** takes place.¹³³

In the nitration of 2,3,7,8-tetrachloro-derivative **21**, satisfactory results have been obtained¹³⁵ by using nitronium tetrafluoroborate in sulfolane at $T = 125^\circ\text{C}$. This reaction yields a

disubstitution product. Compound **21** can also be nitrated by an NH₄NO₃–(CF₃CO)₂O–MeNO₂ mixture. In this case, substitution involves the 1-position and gives compound **67** (yield 1%–2%).¹³⁷ The tetrahalo-derivatives in which the arrangement of halogen atoms is other than lateral form the more stable σ -complexes **68**. Therefore, 1,3,6,8-tetrachloro- and 1,3,7,8-tetrachloro-dibenzo-*p*-dioxins are readily nitrated by the NH₄NO₃–(CF₃CO)₂O–MeNO₂ mixture.^{87, 136}

c. Acylation and alkylation of dibenzo-*p*-dioxin and its derivatives

Dibenzo-*p*-dioxins are fairly smoothly acylated by acyl chlorides in the presence of aluminium chloride (or bromide).^{15, 22, 27, 125, 129, 137–145} The reaction is most frequently carried out in carbon disulfide. The hydrogen atoms in the 2- and 7-positions are substituted preferentially. If these positions are occupied, substitution involves the 3-position. For example, acylation of 2,7-dihalodibenzo-*p*-dioxins by acetyl chloride gives the corresponding 2-acetyl-3,8-dihalodibenzo-*p*-dioxins.¹⁴⁵ If the 1-position is occupied by a substituent, the reaction may involve the 4- and 9-positions.¹⁴²

The third halogen atom deactivates the nucleus to such an extent that, for example, 2,3,7-trichlorodibenzo-*p*-dioxin **35** cannot be acylated by acetyl chloride even in the presence of aluminium chloride.¹³³ Compound **21** also does not undergo acylation. In the case where the halogen atoms are located in one ring, the unsubstituted ring is acylated. For example, by acylating 2,3-dichlorodibenzo-*p*-dioxin **69** by acetyl chloride, one can obtain 2-acetyl-7,8-dichlorodibenzo-*p*-dioxin **70**.¹³³

The alkylation of dibenzo-*p*-dioxin **1** has been studied in detail¹⁹ and has some peculiarities. In particular, it was found that in the alkylation of compound **1** by isopropyl chloride, the second substitution in the resulting 2-isopropyl-dibenzo-*p*-dioxin involves the 3-position, in contrast to halogenation, nitration, or acylation. After that, the 7-position is substituted. Exhaustive alkylation is not observed even when an excess of isopropyl chloride is employed. Under these conditions, the authors cited isolated

one of the possible hexaisopropyl derivatives. If there is steric hindrance, for example if the alkylation is carried out with *tert*-butyl chloride, only a disubstitution product is formed, the second substitution involving the 7- or 8-position.

No examples of the alkylation of halogenated dibenzo-*p*-dioxins have been reported. However, from general considerations, it may be suggested that this process would be substantially hampered owing to the deactivating effect of the halogens.

d. Sulfonation (sulfochlorination) of dibenzo-*p*-dioxin and its derivatives

Sulfonation of dibenzo-*p*-dioxin **1** by sulfuric acid or oleum gives the 2,7-disulfonic acid.¹⁴⁶ When chlorosulfonic acid is used, the 2-chlorosulfonyl chloride is formed.³² Halodibenzo-*p*-dioxins are sulfonated under similar conditions.¹³³ For example, when the sulfonation of 2,3,7-trichlorodibenzo-*p*-dioxin **35** is carried out with oleum at room temperature, the hydrogen atom in a lateral position is replaced by the sulfo group and the reaction yields the sulfonic acid **71** (Scheme 8). Sulfochlorination of dioxin **35** gives¹³³ 2-chlorosulfonyl-3,7,8-trichlorodibenzo-*p*-dioxin **72**; the sulfone **73** is formed as a side product.

and hydrogen peroxide¹⁴⁸ have been suggested for the practical removal of PCDD from the gas phase. It is believed that, among all the chemical methods recommended for the detoxification of PCDD-containing waste, the alkaline dehydrochlorination technology, applicable to both liquid and solid waste, is the most promising.¹⁴⁹ In addition, nucleophilic species are known to participate directly or indirectly in many processes involving PCDD and occurring in the environment and in the organs of mammals.^{4,150} For example, it has been found that ring hydroxylation is the dominant route in the metabolism of chlorinated dibenzo-*p*-dioxins.^{151,152} It was found that the metabolism of dioxin **21** involves hydroxylation in lateral positions with migration of chlorine to the 1-position and gives 2-hydroxy-1,3,7,8-tetrachlorodibenzo-*p*-dioxin¹⁵¹ **74**. 1-Hydroxy-2,3,7,8-tetrachlorodibenzo-*p*-dioxin **75** and 2-hydroxy-3,7,8-trichlorodibenzo-*p*-dioxin **76** are also metabolites of TCDD. Dibenzo-*p*-dioxins chlorinated to lesser degrees are converted into 2- and 3-hydroxy-derivatives.¹⁵³ The metabolism in dogs and rats may involve the cleavage of the dioxin nucleus to give bis(dichlorohydroxyphenyl) ether¹⁵¹ and 4,5-dichlorocatechol.¹⁵⁴

Dibenzo-*p*-dioxins are capable of forming radical cations when treated with strong oxidising agents in combination with photoirradiation.^{155,156} The radical-cations of functionally substituted dibenzo-*p*-dioxins are generated, for example, on treatment with concentrated sulfuric acid in the presence of potassium nitrate,⁵⁶ nitric acid, potassium perchlorate, manganese dioxide, hydrogen peroxide,⁵⁸ or antimony pentachloride¹⁵⁷ and also during electrochemical oxidation.^{54,158–160} The chemical and physical properties and the EPR spectra of the radical-cation derived from compound **1** and a large number of its substituted derivatives have been studied.^{57,58,157,161–166} It was shown that the dibenzo-*p*-dioxin radical-cation **77** (Scheme 9), stabilised by an anion, possesses a certain stability. For example, stable acetonitrile solutions of the tetrafluoroborate of the radical-cation **77** have been obtained by treating compound **1** with NO^+BF_4^- .¹⁶⁷

2. Reactions involving nucleophiles

Despite the fact that nucleophilic substitution plays a significant role in the chemistry of dibenzo-*p*-dioxins, this problem has not been adequately addressed in the literature. Methods based on the nucleophilic substitution of hydroxy groups for chlorine atoms on treatment with potassium hydroxide^{2,147} or potassium carbonate

In another study,¹⁵⁸ the perchlorate of the radical-cation **77** was isolated and its reactivity was studied. The radical-cation **77** was found to react with pyridine giving *N*-(2-dibenzo-*p*-dioxinyl)pyridinium perchlorate **78**. The nitrite anion reacts with the radical-cation as a nucleophilic agent to form 2-nitro-dibenzo-*p*-dioxin **41**. The nitro compound **41** was also obtained when the radical-cation **77** was treated with nitrate anions or with tetranitromethane. In addition to the perchlorate of the radical-cation **77** the dimer of dibenzo-*p*-dioxin **79** was isolated,¹⁵⁸ however, its structure was not discussed. Taking into account the melting point of the compound obtained, one may suggest that it is 2,2'-bis(dibenzo-*p*-dioxin), which was described previously.¹²⁷ It has also been found^{54,159} that the perchlorate of the radical-cation **77** in solution reacts with water to give dibenzo-*p*-dioxin-2,3-quinone **22b**.

Apart from the reaction products, the initial dibenzo-*p*-dioxin **1** has been recovered in all cases. Reactions with other nitrogen-containing nucleophiles (CH₃, NH₃, RNH₂) led only to the recovery of compound **1**. It is believed¹⁵⁸ that, for nucleophilic substitution to occur, a stronger nucleophile is required.

3. Reactions of functional groups

Among the functionally substituted dibenzo-*p*-dioxins, the nitro- and amino-derivatives are of prime interest and have been the most thoroughly studied.^{47,128,136,168–170} These compounds are more frequently encountered than is believed.¹⁶⁸ They present a severe hazard to mammals and are environmental pollutants.¹²³ Aminodibenzo-*p*-dioxins have found application in the development of a radio-immune method for the assay of PCDD.^{171,172}

No data have been published that would make it possible to speak of any influence of the dioxin nucleus on the reactivity of nitro- and amino-derivatives. In some studies, the Sandmeyer reaction has been used to prepare halogenated dibenzo-*p*-dioxins from the corresponding amino-derivatives.^{95,104,136,173} It was noted that in some cases the reaction is complicated by a rearrangement and consequently may give unexpected products, for example, compound **80**.¹⁰⁴

Nitro-derivatives can be reduced, and this reaction is the main method of synthesis of amino-containing dibenzo-*p*-dioxins. Various reducing reagents have been used,^{121,130,136,173–175} however, the highest yield was achieved in the case of tin dichloride.¹²¹ Aminodibenzo-*p*-dioxins are readily acylated,¹²³ enter into the Skraup reaction to form the corresponding quinoline derivatives,^{176,177} and condense with quinones¹⁷⁸ to give phenazines. Hydroxy-derivatives are acylated in a similar way.¹⁷⁹

Halogen-containing dibenzo-*p*-dioxins can condense,^{102,127} affording products with enlarged structures.

V. Toxic properties of compounds of the dibenzo-*p*-dioxin class

1. Toxic properties

It is believed, with good reason, that PCDD are products of human technological activity.^{4,180} The pathways to the formation

of PCDD are known and have been fairly extensively studied, but the formation of functionally substituted dibenzo-*p*-dioxins still remains unexplored. There are data showing that halogenated nitro-derivatives of dibenzo-*p*-dioxins are formed on the fly ash from incinerators via the nitration of the corresponding dibenzo-*p*-dioxins by the nitrogen dioxide present in the exhaust gases.¹⁶⁸ Although the potential hazard of functionally substituted dibenzo-*p*-dioxins is quite considerable,^{87,123} they have scarcely been studied.

The urgent need to study dibenzo-*p*-dioxin class compounds arises primarily from the results of toxicological studies. A large number of publications, including several detailed reviews, have been devoted to this problem.^{2,181–183} Analysis of these and other data makes it possible to make some generalisations concerning the toxicology of compounds of this class.

Among dibenzo-*p*-dioxins and compounds with similar structures—polychlorinated dibenzofurans, biphenyls, and naphthalenes—those substances in whose molecules all the lateral positions are occupied by halogen atoms are the most toxic. It has been found that TCDD **21** exhibits the highest toxicity toward the most sensitive species (guinea pigs), while 2,3,7,8-tetrachloronaphthalene has the lowest toxicity. When the number of halogen atoms in the ring decreases or increases, the toxicity diminishes sharply.^{2,183} Completely halogenated compounds exhibit virtually no toxicity, at least, under the conditions of an acute experiment.

The positions of the halogen atoms in the ring are significant for biological activity. For example, symmetrical derivatives are as a rule more toxic than their nonsymmetrical analogues.

TCDD possesses the highest biological activity among all the classes of compounds under consideration. It comes as no surprise that most of the published data are devoted to the toxicology of this compound.

The high toxicity of TCDD for warm blooded animals is combined with pronounced interspecific differences in sensitivity to it.¹⁸⁴ The coefficient of interspecific differences is as high as four orders of magnitude.^{150,183–186} Another important feature of the biological action of TCDD is the presence of clear-cut individual intraspecific distinctions, which is indicated by the fact that the slopes of 'dose-effect' plots are small, compared with those for other xenobiotics.¹⁸⁷ Interstrain differences in the sensitivity to TCDD are fairly clear-cut (~250 for rats and ~20 for mice).¹⁸³ The presence of paradoxical behaviour in the 'dose-effect' relations should be regarded as significant evidence in support of intraspecific polymorphism in the sensitivity to TCDD and its analogues.¹⁸⁸

Studies of the chronic action of small TCDD doses have demonstrated the presence of pronounced supercumulative effects,^{184,189–191} which is significant for the regulation of the maximum permissible concentrations of this compound in the environment.

The most general symptoms of the TCDD poisoning of various types of warm blooded animals are liver enlargement, thymus atrophy, progressive weight loss, and a clear-cut latent period of up to 10–15 days after contact with the poison. Other clinical manifestations are fairly polymorphic. In fact, in mice, rats, and rabbits, apart from hepatomegaly, pronounced centrolobular necrosis of liver tissue, in some cases turning into hepatargia, has been observed.^{183,189,192} The edematous syndrome, accompanied by intense secretion of transudate in pericardial, pleural, and abdominal cavities, is typical for chickens. In the case of guinea pigs and monkeys (rhesus, macaque), the prevailing symptoms are those indicating deep suppression of the immune system. The data concerning symptoms of the effects of TCDD on humans are less definite, because they have been obtained in relation to accidental contacts with the xenobiotic or by examining the personnel engaged in the production of 2,4,5-trichlorophenol containing TCDD as an impurity.

Nevertheless, it has been reported^{192,193} that the TCDD intoxication in humans is manifested as skin changes (chloracne), weight loss, high susceptibility to fatigue, muscle

asthenia, insomnia, high irritability, decrease in libido, reduction of sensory functions, tendency to hepatomegaly, decrease in the concentration of serum lipids, increase in the prothrombin time, and porphyria. In addition, there are data on more severe pathologies: the people under examination suffered more frequently from soft tissue sarcoma.¹⁹¹ This last fact is the reason why studies dealing with remote consequences of the action of TCDD, and, in particular, with mutagenic, carcinogenic, teratogenic, and embryotoxic effects, are urgently required.

In 1972, a mutagenic effect of solutions of TCDD was observed in bacterial test systems, and a mechanism of this phenomenon, involving the intercalation of TCDD with the DNA helix, was suggested.¹⁹³ Somewhat earlier, Courtney and Moore,¹⁹⁴ who carried out experiments with various strains of mice and rats, discovered embryotoxic and teratogenic effects of TCDD: the cleaving of the hard palate and defects in kidney embryogenesis. Discussions concerning the character of the carcinogenic effect of TCDD still continue.¹⁹⁵ The authors of another study¹⁹⁶ are apt to regard TCDD as a pronounced promoter of carcinogenesis, at least in rodents. In conformity with their data, the tumour-stimulating effect of PCDD is comparable with that of aflatoxin B₁. According to other data,¹⁹⁷ at concentrations that can occur in an organism, TCDD is neither a classical carcinogen nor a mutagen. One may speak only of its promoting effect with respect to some carcinogens, such as nitrosamines.

2. The mechanism of action

To explain the mechanism of the toxic action of TCDD, several hypotheses have been put forward.

1. The toxic effect of TCDD arises through bonding to the highly specific cytosol Ah-receptor. The complex is then translocated to the nucleus and expresses the DNA sections, responsible for the synthesis of pools and the RNA initiating the synthesis of cytochrome P-450 (or 448)-dependent monooxygenases.^{183, 198} This hypothesis adequately explains the extraordinarily high degrees of induction of microsomal monooxygenases.

2. TCDD exhibits a thyroxine-like action, which is indicated by a number of hyperthyroid symptoms, enhancement of the catabolism of lipids and biopolymers, weight loss, additivity of the toxic effects of TCDD and thyroid hormones.^{183, 199}

3. The toxic action of TCDD is due to the relative deficiency of carotinoids.^{183, 200} This hypothesis was based on the sharp decrease in the concentration of carotinoids, in particular vitamin A, in the liver of rats exposed to TCDD. This approach is supported by the syndrome (skin changes, hyperkeratosis, lesion of the sclera and the cornea, etc.) in laboratory animals poisoned by TCDD.

Among other attempts to explain the mechanism of the toxic action of TCDD, the assumption that disturbance of the flavin metabolism, in particular the metabolism of riboflavin, whose structure is similar to that of TCDD, plays the key role in the pathogenesis of TCDD intoxication deserves attention.²⁰¹ The above structural similarity accounts for the fairly successful use of riboflavin preparations in the experimental therapy of TCDD poisoning. It should be noted that none of these hypotheses concerning the pathogenesis of TCDD toxification can explain fully by itself the whole diversity of the clinical pattern of the poisoning and especially the very pronounced inter- and intra-specific differences in the sensitivity to this xenobiotic.

At the same time, there is the noteworthy possibility that all the above approaches can be interpreted in terms of the disturbance of the equilibrium between the pro- and antioxidant systems in an organism. In fact, the hypothesis of the leading role of the Ah-locus accounts for the activation of prooxidant processes. Thyroid hormones also exert an indirect prooxidant effect. Carotinoids as well as tocopherols are obligatory constituents of the antioxidant protection of an organism.

We believe that all the above hypotheses could be accommodated within the framework of a unified theory of the pathogenesis of the intoxication by polychlorinated polyaromatic hydrocarbons, which would be based on the assessment of the

degree of prooxidant action and on the determination of the actual balance between the pro- and antioxidant systems, especially since the intensification of the peroxide oxidation of lipids and the enhancement of the generation of active oxygen forms in an organism under the influence of TCDD (i.e. the existence of prooxidant action) are established facts.²⁰² Such activity is manifested by the characteristic features of the functioning of pro- and antioxidant systems in various species.

VI. Formation and occurrence in nature

The causes of the formation of technogenic PHDD and the pathways by which they arrive in the environment have been studied quite extensively.^{4, 180, 181, 185} However, dibenzo-*p*-dioxins of natural origin have scarcely been studied. At the same time, the presence of a large number of hydroxy-derivatives of benzene in plants makes it possible to infer that the compounds under consideration are not rarities.²⁰³ The oxidation of hydroxy-compounds is most probably the main pathway to the formation of the tricyclic dibenzo-*p*-dioxin system in plants. For example, dibenzo-*p*-dioxin is known to be formed on oxidation of *p*-benzoquinone,¹¹⁰ catechol,^{106, 108} and certain pyrogallol derivatives.^{109, 204} It has been established^{205–208} that such oxidation can occur in plants through the action of certain enzymes. In fact, an enzyme that oxidises catechol to dibenzo-*p*-dioxin-2,3-quinone²⁰⁸ with a high specificity has been isolated from an extract of *Tecoma stans* leaves. In another study,²⁰⁷ this quinone was isolated in a pure state after the oxidation of catechol by polyphenol oxidase, and its structure was confirmed by an alternative synthesis.

In a study of keto-derivatives of inositol,¹¹¹ it was found that the acetylation of these compounds in the presence of an acid catalyst yields completely hydroxylated dibenzo-*p*-dioxin. It was suggested that dibenzo-*p*-dioxin derivatives may be synthesised via this route in nature.

The discovery of the alkaloid trilobine and the determination of its structure served as direct confirmation of the formation of dibenzo-*p*-dioxin in nature. In 1924, Kondo and Nakasato studied an extract from the roots of cocculus (*Cocculus trilobus* DC) and isolated an alkaloid which was called trilobine.²⁰⁹ Eight years later, Kondo and Tomita found that the trilobine structure is based on the heterocyclic system of dibenzo-*p*-dioxin.²¹⁰ In 1942, Tomita and Tani^{211, 212} published the full formula of trilobine **82**.

The alkaloid micranthine, isolated from the plant *Daphnandra micrantha*,²¹³ as well as the alkaloids tiliacresine, tiliacorine, and tiliacoronine, obtained from the plant *Tiliacora racemosa*,^{214–216} have structures similar to that of trilobine.

VII. Conclusion

The data presented in this review indicate that studies devoted to dibenzo-*p*-dioxins are progressing vigorously. The methods of synthesis of compounds of this class are being improved, and insight is being gained into processes occurring in nature and in the organs of animals involving halo-derivatives of dibenzo-*p*-dioxins. However, the knowledge accumulated does not yet make it possible to speak of an ultimate solution of the problem of dioxin-like xenobiotics. Although the latter have mostly been created by human activity, one should keep in mind that the

dibenzo-*p*-dioxin structure has been invented by nature. From this viewpoint, this class of compounds remains poorly investigated. For this reason, humankind has probably been deprived of many useful things, ranging from medicines to various materials. However, in recent years some studies dealing with this problem have been published. These were mostly attempts to develop new medicines.²¹⁷

Comprehensive investigation of halogenated dibenzo-*p*-dioxins has been the dominant factor in the development of the chemistry of dibenzo-*p*-dioxins. One significant property of these compounds that has not yet received the due attention of scientists is noteworthy, namely that, in some cases, it is expedient to treat dibenzo-*p*-dioxin (and its halo-derivatives) as a crown ether (dibenzo-6-crown-2). Some of the properties of PCDD, including their toxic properties may be associated with the ionophoric and complex-forming capacities of these compounds. In any case, the toxicity of octabromodibenzo-18-crown-6 is comparable with that of 2,3,7,8-tetrabromodibenzo-*p*-dioxin.¹⁰² In addition, TCDD exhibits a growth-stimulating activity with respect to herbaceous plants, typical of crown ethers.²¹⁸

The complex-forming capacity of dibenzo-*p*-dioxins forms the basis of a photometric determination of PCDD.²¹⁹

Thus, the data considered in the present review indicate that careful study of the properties of dibenzo-*p*-dioxins may lead to new possibilities in the investigation of the physiological activity of compounds of this sort.

VII. Biological activities and applications of heterylferrocenes	76

Abstract. Data on the synthesis of ferrocene derivatives containing heterocyclic substituents linked directly to the ferrocene system or separated from it by a chain of carbon atoms are described systematically and surveyed. Data on the biological activities and applications of these compounds are presented. The bibliography includes 229 references.

I. Introduction

In 1951, Kealy and Pauson¹ reported for the first time the synthesis of ferrocene and in the same year the first organic compound containing the ferrocenyl and heterocyclic groups was obtained.² Such compounds immediately attracted the attention of many investigators and in subsequent years ferrocene derivatives were synthesised in which there are various heterocyclic substituents both linked directly to the ferrocene system and separated from it by a chain of carbon atoms. The considerable interest in heterylferrocene was aroused not only by the unusual chemical behaviour of the ferrocene system, which enters into electrophilic and radical substitution reactions, but also by the unusual properties of the heterocyclic residue due to the presence of the ferrocene fragment. In addition, diverse biological activities of these compounds were observed. It is also significant that heterylferrocenes have found extensive practical applications as medicinal preparations, as components of nonsilver photosensitive compositions and materials, as dyes, and also as additives improving the most important characteristics of rocket fuels and explosives.

The first review devoted to the synthesis of ferrocene derivatives with heterocyclic groups appeared in 1971.³ It presented an analysis of studies published up to the middle of 1971. The literature data on the synthesis of compounds containing heterocyclic nuclei condensed with the ferrocene system were surveyed in a later communication.⁴ The present

author's previous review⁵ was fully devoted to the chemistry of heterylferrocenes, but it dealt mainly with studies which had been published up to 1972.

The present review gives a systematic account and surveys data published after 1971. Earlier studies containing interesting and important results which were not reflected in subsequent publications are considered as an exception. The review includes data on the synthesis of compounds containing the ferrocenyl group linked directly to an atom of the heterocycle as well as compounds in which the ferrocenyl and heterocyclic groups are separated by a chain of carbon atoms. Compounds in which the ferrocenyl system is condensed with the heterocyclic nucleus, ferrocenophanes, as well as compounds containing the ferrocenyl and heterocyclic groups separated by heterocycles or chains incorporating heteroatoms are not considered. The review presents data on the biological activities and applications of heterylferrocenes.

Sections II–VI present information about the synthesis of compounds containing heterocyclic nuclei with three, four, five, six, and more atoms. In each of these sections, the derivatives of ferrocene containing nitrogen, oxygen, and sulfur atoms in the heterocyclic nuclei are considered in succession. Next compounds with heterocycles containing simultaneously nitrogen and oxygen, nitrogen and sulfur, or oxygen and sulfur atoms are described. At the end of each section, data are presented on other heterocyclic systems. Each section deals at the beginning with compounds in which the ferrocenyl group is linked directly to an atom of the heterocycle and then with compounds containing the ferrocenyl and heterocyclic groups separated by a chain of carbon atoms. If the compound contains two or more heterocyclic nuclei (condensed or noncondensed), then its location in a particular section is determined by the heterocyclic system closest to the ferrocenyl nucleus.

II. Compounds containing three-membered heterocycles

When ferrocenyl azide is irradiated with UV light in cyclohexene, the aziridine derivative **1** is formed in a low yield.⁶ The reaction evidently proceeds via the intermediate generation of the nitrene **2**, which adds to the double bond of cyclohexene. It has been noted that the aziridine **1** is formed both under nitrogen and under oxygen atmospheres. Consequently the nitrene **2** exists in the singlet state.⁶

Received 13 June 1995

Uspekhi Khimii 65 (1) 43–83 (1996); translated by A K Grzybowski

Here and henceforth Fc = ferrocenyl ($\eta^5\text{-C}_5\text{H}_4\text{Fe}(\eta^5\text{-C}_5\text{H}_5)$).

When the aziridine derivatives **4** interact with the chloride of ferrocenecarboxylic acid in the presence of triethylamine, *N*-ferrocenoylaziridines **3** are obtained.⁷

R, R¹ = H, Me.

On *N*-acylation of the monosubstituted aziridine derivatives **5** by the chlorides of ferrocenyl-substituted monocarboxylic and dicarboxylic acids **6** in the presence of potassium carbonate at 10–30 °C, compounds **7** are produced in 40%–90% yields.^{8,9}

$n = 0-3$; R¹ = H, COCl; R² = H, Me, Et;

R³ = H, $\text{—C(=O)—N} \begin{array}{c} \diagup \text{R}^2 \diagdown \end{array}$.

The tetrafluoroborates of the α -ferrocenylcarbonium ions **8** and trimethylferrocenylmethylammonium iodide have been used recently for the *N*-alkylation of aziridine derivatives.¹⁰

R = H, Me, Ph, Fc; R¹ = H, Me, Et.

Compound **9**, containing two epoxy-groups, has been synthesised in 44% yield by the reaction of 1,1'-dilithioferrocene with epichlorohydrin at –40 °C.¹¹

A novel method of synthesis of the epoxy-compounds **10** has been described.¹² The authors believe that, in the reactions of the carbonyl derivatives of ferrocene with dimethyloxosulfonium methylide, the epoxides **11** are formed in the first stage and are converted into the aldehydes **12** under the reaction conditions. The latter react with a further molecule of the methylide and are converted into compound **10**.

R = H, Me.

A mechanism involving the lithiation of the methyl group attached to the sulfur atom, the interaction of the aldehyde **14** with the lithio-derivative **15**, the conversion of the reaction product into the spiro-compound **16**, and the rearrangement of the latter to a new oxazoline derivative **17** and its cleavage to the thiirane **13** has been put forward for the synthesis of ferrocenylthiirane **13** from formylferrocene **14** and 2-methylthio-4,4-dimethyloxazoline.^{13,14}

German investigators¹⁵ synthesised unusual heterocyclic compounds containing ferrocenyl groups. Thus the reaction of FcPCL_2 , FcPH_2 , and $(\text{Ph}_3\text{P})_2\text{Pt}(\text{C}_2\text{H}_4)$ in the presence of diazabicycloundecene (DBU) resulted in the formation of (diferrocenyldiphosphene)bis(triphenylphosphine)platinum(0) **18** in a quantitative yield.

Triferrocenyltriarsirane (**19**) has been synthesised in 66% yield by the reduction of FcAsCl_2 with lithium tetrahydroaluminate in boiling ether.¹⁵

The latter was made to react with $(\text{Ph}_3\text{P})_2\text{Pt}(\text{C}_2\text{H}_4)$ at room temperature, which led to compound **20** in 68% yield.

III. Compounds containing four-membered heterocycles

Numerous derivatives of 4-ferrocenylazetidin-2-ones **21** have been synthesised by the addition of chloroketene (synthesised from chloroacetyl chloride) to ferrocenylmethylideneimines **22**.^{16–20} The reactions were carried out in dioxane at 20–25 °C, the reaction time (ranging from several hours to several days) depending on the structure of the initial imine **22**. The reaction products and their yields are listed in Table 1.

There are no literature data on the derivatives of ferrocene containing four-membered heterocyclic rings with oxygen atoms in the ring.

A series of 3-ferrocenylthiete derivatives have been synthesised from acetylferrocene **23**.²¹ Thus its treatment with dimethylamine in the presence of TiCl_4 leads to α -dimethylaminovinylferrocene **24** (yield 89%), which affords the sulfone **25** (yield 46%) on treatment with methanesulfonyl chloride in the presence of triethylamine. The sulfone may be reduced to the thietane **26** (yield 78%) and also deaminated by treatment with H_2O_2 in an acid medium to 3-ferrocenyl-2*H*-thiete dioxide **27** (yield 34%). Compound **26** was converted in two stages into 3-ferrocenylthiete **28** (yield 36%).²¹

On heating ferrocenyldichlorophosphine with lithium tetrahydroaluminate in ether, tetraferrocenyltetraphosphetane **29** is formed in 11% yield.¹⁵

IV. Compounds containing five-membered heterocycles

3-Ferrocenylpyrrole is formed in 21% yield on reduction of the dinitrile of 2-ferrocenylsuccinic acid **30** with diisobutylaluminium hydride (DIBALH) and subsequent hydrolysis.²²

In the presence of sodium hydride, methyl 3-ferrocenylacrylate reacts with the isonitrile **31**, affording 3-ferrocenyl-4-methoxycarbonylpyrrole.²³

The cyclocondensation of the oximes of the acylferrocenes **32** with ethyne on treatment with alkali leads to the pyrrole derivatives **33**.²⁴ It has been noted that, when the reaction is carried out in a microwave oven, the yield of the reaction products increases appreciably.

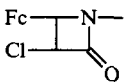

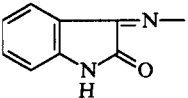

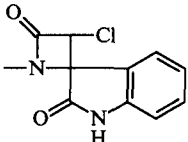

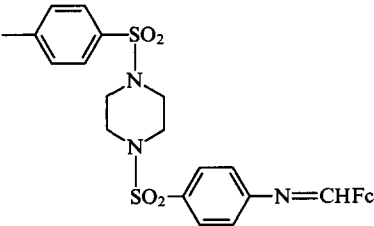

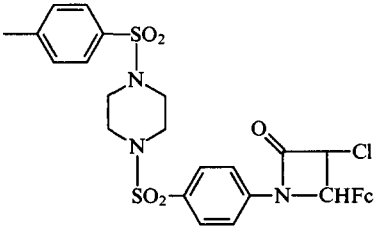

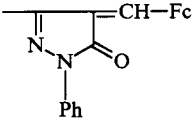

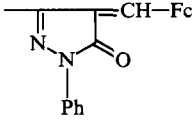

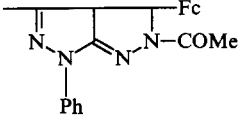

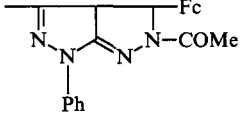

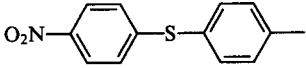

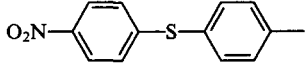

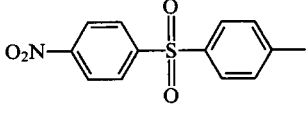

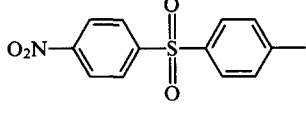

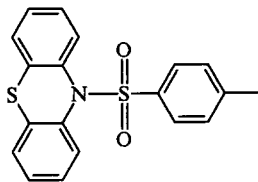

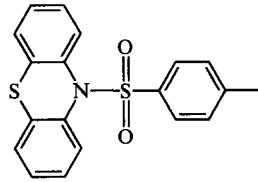

Ferrocene derivatives containing a phthalimide residue have been synthesised by heating the halo-derivatives **34** with copper phthalimide.^{25–27}

(R ² = H, Cl)	(R ² = H, Cl)		

In the presence of an alcoholic solution of NaOH, the aldehyde **14** condenses with 2-acetyl-1-methylpyrrole, while the ketone **23** condenses with 2-formyl-1-methylpyrrole to form the corresponding chalcones **35** and **36**.²⁸

The alcohol **37** has been synthesised from the bromo-derivative **38** and FcCHO **14**.²⁹

The synthesis of *N*-(2-ferrocenylethyl)pyrrole from 2-hydroxyethylferrocenyl toluene-*p*-sulfonate and potassium pyrrolide has been described.³⁰

Two procedures have been proposed for the synthesis of *N*-ferrocenylmethylpyrrolidine: the interaction of ferrocenylmethyl(trimethyl)ammonium iodide with pyrrolidine in the presence of aqueous sodium hydroxide^{31,32} and condensation of ferrocene with formaldehyde and pyrrolidine (yield 50%).³³

Unusual compounds have been obtained by the reactions of complex **39** with unsaturated compounds.³⁴ The interaction with fumaric acid ester affords the tetraester **40** (solvent – pyridine, refluxing for 2.5 h, yield 44%), while the reaction with 1,1-diphenylethene gives rise to the derivative **41** (inert atmosphere, in the dark, heating up to 136 °C for 3.5 h, yield 7%).

The group Y in compound **42** is substituted on treatment with pyrrolidine or its derivatives (refluxing in methanol for 5–8 h or maintenance in acetonitrile at 20 °C for 12 h); the yields of the products **43** are 55%–88%.^{35,36}

The reaction of 3,4-dimethylpyrrolone-2-one with FcCHO results in the formation of the product **44** of the kinetically controlled addition almost exclusively in the form of the (*Z*)-isomer.³⁷

R = H, Me.

If 3-methylpyrrolin-2-one is made to react with the aldehyde **14**, then the product **44** (R=H) is formed as a 1 : 1 mixture of the (*Z*)- and (*E*)-isomers.³⁸

In the synthesis of the amide **45**, the reaction of FcCHO with the arsonium salt **46** was carried out in the presence of potassium carbonate in aqueous tetrahydrofuran (THF).³⁹

In the presence of ZnCl₂, the aldehyde **14** reacts with two molecules of indole, producing the ferrocene derivative **47**.⁴⁰

When the ferrocenyl carbinols **48** are treated with strong acids, highly reactive α -carbonium ions are formed. However, when strong acids are employed, the reaction is complicated by oxidation-reduction processes due to the presence of the ferrocene fragment in the substrate. In order to suppress these processes, the reaction is carried out in the CH_2Cl_2 - H_2O two-phase system and the KU-2 cation-exchange resin is employed instead of strong acids.⁴¹⁻⁴⁵ The $[\text{Fc}-\text{CHR}]^+$ cations readily react with nitrogen heterocycles, affording the ferrocene derivatives **49** in 60%–80% yields.

Refluxing of an alcoholic solution of FcCOMe **23** and isatin **50** in the presence of diethylamine for 1 h and subsequent standing at room temperature for several days led to the synthesis of compound **51** in 93% yield.⁴⁶

The naphthopyrrole derivatives **52** have been obtained in 80%–85% yields by heating the dibromo-derivative **53** with 2-aminonaphthalene.⁴⁷

The dyes **54** and **55**, containing the ferrocenyl group, are formed as a result of the condensation of the perchlorate **56** with the immonium salts **57** and **58**.⁴⁸

The ferrocenium cation, arising on interaction of ferrocene with concentrated sulfuric acid, reacts with diazotised 5-amino-2,3,3-trimethylindolenine, which results in the formation of 5-ferrocenyl-2,3,3-trimethylindolenine in 23% yield.⁴⁹

The 1,3-dienes **59**, containing a ferrocenyl substituent, are capable of undergoing the diene synthesis reaction with *N*-substituted maleic acid imides **60**.^{50,51} A mixture of the *endo*- and *exo*-isomers is formed as a rule and the *endo*-isomer has been obtained exclusively only in the case of the diene **59** ($\text{R} = \text{Me, R}^1 = \text{H}$).

H	Me	Ph

Schmidt et al.⁵² synthesised *meso*-tetrakis(4-ferrocenylphenyl)porphyrin by condensing 4-ferrocenylbenzaldehyde with pyrrole.

The direct conversion of ferrocene into a heteryl derivative has been achieved by treating ferrocenium hexafluorophosphate with the sodium derivatives of pyrazole or 3,5-dimethylpyrazole.⁵³ 1-Ferrocenylpyrazole and 1-ferrocenyl-3,5-dimethylpyrazole were synthesised. The following process mechanism has been put forward:

3-Chloro-3-ferrocenylacrylic aldehyde **61** and 3-chloro-3-ferrocenylacrylonitrile **62** are convenient starting compounds for the synthesis of ferrocenylpyrazoles. Thus the condensation of the aldehyde **61** with hydrazine hydrate or phenylhydrazine hydrochloride leads to the formation of 5-ferrocenylpyrazole and 5-ferrocenyl-1-phenylpyrazole respectively.⁵⁴

R	HX	Yield (%)
H	H ₂ O	18
Ph	HCl	41

If the nitrile **62** is introduced into the reaction with hydrazine hydrate, then the product is 3-amino-5-ferrocenylpyrazole (yield 68%).

The reactions of acetoacetylferrocene **63** with hydrazine and its derivatives may lead to the formation of the two isomeric pyrazoles **64** and **65**. However, only the isomers **64** have been isolated from the reaction mixture.⁵⁵ The author explained this by the smaller steric hindrance in the cyclisation stage.

R	H	Me	Ph	2,4-(O ₂ N) ₂ C ₆ H ₃	CONH ₂
Yield (%)	81	30	70	21	90

A similar situation is observed in the condensation of the tetraketone **66** with hydrazine and its derivatives. Out of the three possible regioisomers, only the isomer **67** is formed. Together with steric factors, the stability of the corresponding intermediate hydrazones apparently plays a no less important role.⁵⁵

Compound	R	Yield (%)
a	H	60
b	CONH ₂	80

1-Benzoyl-1'-(5-trifluoromethylpyrazol-3-yl)ferrocene has been synthesised by condensing 1-benzoyl-1'-(4,4,4-trifluoro-3-oxobutanoyl)ferrocene with hydrazine.⁵⁶

An unusual method of synthesis of 3-ferrocenylpyrazol has been described.⁵⁷ Acetylferrocene **23** was treated with ethyl formate in the presence of sodium ethoxide in toluene, after which the reaction mixture was treated initially with hydrazine hydrochloride in water and then with hydrazine hydrate in methanol. The yield of 3-ferrocenylpyrazole reached 61%.

α,γ -Diketoacids of the ferrocene series and their esters have been used successfully as the starting compounds in the synthesis of ferrocenylpyrazoles. Thus condensation of the diester **68** with hydrazine (in the presence of acetic acid) or with phenylhydrazine afforded the corresponding pyrazole-containing diesters **69** (the yields of compound **69a** and **69b** were 56% and 52% respectively).⁵⁸ It was shown in the same study that the dihydrazide **71** is formed in 76.5% yield after brief refluxing of the dicarboxylic acid **70** with an excess of hydrazine.

$R = H$ (a), Ph (b)

Depending on the reaction conditions, either 3-ethoxycarbonyl-5-ferrocenylpyrazole **73** or the hydrazide of 5-ferrocenylpyrazole-3-carboxylic acid **74** may be obtained from the ethyl esters of α -hydroxy- or α -amino- β -ferrocenoylacrylic acids **72** and hydrazine.⁵⁹

$R = NH_2, OH, NHMe, NHEt, NHPr^i, NHPh, NHC_6H_4Cl-m, NHC_6H_4OMe-o$.

It is of interest that the reaction of β -ferrocenoyl- α -hydroxyacrylic acid with semicarbazide in the presence of sodium acetate and sodium bicarbonate afforded 5-ferrocenylpyrazole-3-carboxylic acid.⁵⁹ Consequently semicarbazide serves as a source of hydrazine under these conditions.

Derivatives of ferrocenylpyrazolones **75** are formed when the esters of the ketoacids **76** interact with hydrazine or phenylhydrazine in the presence of acetic acid.⁶⁰

$R, R^1 = H, Me; R^2 = H, Ph$.

The most general method of synthesis of ferrocenylpyrazolines involves the reaction of the vinyl ketones $FcCR=CR^1-COR^2$ or $FcCO-CH=CHR$ with hydrazine or its derivatives. As a rule, ferrocenylpyrazolines with a hydrogen atom at the N(1) atom are unstable and are therefore converted into the *N*-acetyl derivatives. For example, when the pyrazoline derivatives **77**, obtained from the vinyl ketones **78** and hydrazine, were treated with acetic anhydride, the *N*-acetyl derivatives **79** were isolated in 72%–75% yields.⁶¹

$R, R^1 = H, Me$.

The reactions of the vinylketones **80** with hydrazine and its derivatives have been investigated in a series of studies;^{62–67} the pyrazoline derivatives **81** (Scheme 1) were obtained in 60%–95% yields. When the reaction was carried out in the presence of acetic acid, the reaction products were the *N*-acetyl derivatives. For $R^1 = Ph$, the reaction was carried out in the presence of piperidine.

The pyrazoline derivatives **82** with a different disposition of the substituents have been synthesised by the cyclocondensation of the vinyl ketones **83** with hydrazine and its derivatives;^{47,62,64,65} the yields were 60%–95% (Scheme 2).

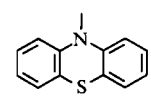

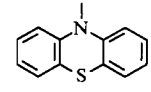

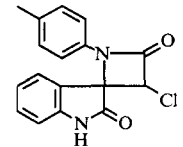

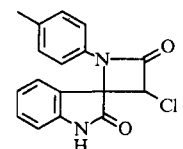

The behaviour of polyene ketones in their reactions with hydrazine and its derivatives has been studied in fair detail. The ketones **84**, containing two or three conjugated double bonds, react regioselectively with phenylhydrazine in the presence of piperidine, affording the pyrazoline derivatives **85** in 86%–91% yields.⁶⁸

$n = 2, 3$.

The addition of RNHNH₂ (R = H, Ph) to the divinyl ketone derivative **86** leads to a mixture of the isomeric pyrazolines **87** and **88**.⁶⁸ The regioselectivity of the reaction in favour of the formation of compound **88** has been noted and has been explained by the greater electron-donating capacity of the ferrocenyl substituent compared with the phenyl substituent.

R = H, Ph

In the case of the ketone **89**, the addition of hydrazine takes place regioselectively,⁶⁸ whereupon the pyrazoline **90** is formed. Apart from the electronic factors quoted above, the proximity of the carbonyl group and the Fc fragment apparently plays a role.

The ferrocenylmethylidene-substituted cyclic ketones **91** are converted into the bicyclic compounds **92** on condensation with hydrazine or its derivatives.

R = H, 2,4-(O₂N)₂C₆H₃; n = 1, 2.

The ferrocene derivatives **93** with two condensed pyrazoline rings have been synthesised by the reaction of the ferrocenylmethylidenepyrazolones **94** with hydrazine or phenylhydrazine (in the presence of piperidine) in alcohol (10 h) or dioxane (3 h), the product yield amounting to 50%–70%.^{17, 69}

A series of pyrazoline derivatives **95** have been synthesised by the cycloaddition of the vinyl ketones **96** to diazomethane.⁶³

R = H, Cl, Br, Me, Et, OMe, Ph.

Two methods of synthesis of pyrazolone derivatives containing the ferrocenyl group in the side chain have been described: by the condensation of formylferrocene **14** with 3-methyl-1-phenylpyrazol-5-one or by the addition of the latter to the double bond of the vinyl ketones **97**.⁶⁹

R = 4-MeC₆H₄, 4-ClC₆H₄, 4-BrC₆H₄, 4-MeOC₆H₄, 4-PhC₆H₄.

When the aldehyde **14** is heated with the salt **98** in alcohol in the presence of piperidine, the monomethinecyanine **99** is formed in 50% yield.⁷⁰

The cyanine dyes **100** have been synthesised by condensing the pyrazolone derivatives **94** with 1-ethyl-2-methylquinolinium iodide **101** in the presence of piperidine.^{17, 69}

R = Me, R¹ = Ph, 2,4-(O₂N)₂C₆H₃; R = FcCH=N–, R¹ = Ph.

An analogue of the salt **100** (R = Me, R¹ = Ph), with a pyridine instead of a quinoline ring, has been obtained by the same procedure.⁶⁹

Compounds **100** are also formed as a result of the condensation of the salts **102** with FcCHO.⁶⁹

R = Me; R¹ = Ph, 2,4-(O₂N)₂C₆H₃.

The ferrocenylmethyl group can also be introduced into the purine nucleus in two ways: as a result of the alkylation of 6-X-purines (X = NH₂, Cl) by ferrocenylmethyl-(trimethyl)ammonium iodide or aminomethylferrocene.⁷¹

R	R ¹	R ²	Conditions	Yield (%)
NH ₂	N ⁺ Me ₃ I ⁻	NH ₂	H ₂ O, refluxing, 6 h	47

N-Ferrocenylimidazole has been synthesised by treating the sodio-derivative of the imidazole with ferrocenium hexafluorophosphate.⁵³

2-Ferrocenylimidazole and its derivatives **103** are formed in 15%–50% yields as a result of the condensation of FcCHO **14** with the α -hydroxycarbonyl compounds **104** and ammonia in the presence of copper acetate.⁷²

R = H: R¹ = H, Me, Ph;

R = Me: R¹ = Me, Ph;

R = R¹ = Ph; R + R¹ = -(CH₂)₄-.

The salt **105**, which is obtained from imidazole and benzenesulfonylbenzimidoyl chloride **106**, is converted into 1,3-bis(benzenesulfonylbenzimidoyl)-2-ferrocenylimidazoline **107** on heating with ferrocene in benzene.⁷³

The selectivity of the reaction of FcCHO with the hydroxylamine derivatives **108**–**110** is influenced by the nature of the substituent at the keto-group.⁷⁴ 2-ferrocenyl-1-hydroxy-4,5,5-trimethylimidazoline is formed from the methyl ketone **108** (the reaction was carried out at 0 °C for 0.5 h with subsequent maintenance at 20 °C for 0.5 h; the yield was 30%); the *N*-oxides **111** and **112** were obtained from the phenyl ketone **109** and the oxime **110** (in 25% and 60% yields respectively). It has been suggested that compound **111** is formed as a result of the rapid oxidation in solution of the intermediate hydroxyimidazoline.⁷⁴

The salt **114** was used as the starting material for the synthesis of 2-ferrocenyl-1,3-dihydroxy-4,4,5,5-tetramethylimidazoline **113**.⁷⁵

5-Ferrocenylhydantoin has been obtained in 85% yield from the cyanohydrin **115** and ammonium carbonate in aqueous alcohol (the reaction was carried out at 50 °C for 2 h with subsequent maintenance at 20 °C for two days).⁷⁶

German investigators⁷² synthesised a series of derivatives of 2-ferrocenylbenzimidazole **116** (in 70%–90% yield) by condensing FcCHO **14** with substituted 1,2-diaminobenzenes in the presence of copper acetate.

R = H, 4-Me, 5-Me, 5,6-Me₂, 4-Cl, 5-Cl, 5-Br, 4-NO₂,

5-NO₂, 5-CN, 5-OMe, 5-NH₂, 4,5-(-CH=CH-CH=CH-).

The benzimidazole derivatives **117**, containing the ferrocenyl group linked directly to the heterocycle or separated from it by a chain of 1–5 carbon atoms, are formed in 45%–98% yields on heating ferrocenyl-substituted carboxylic acids **118** with substituted 1,2-diaminobenzenes under an argon atmosphere in the presence of hydrochloric and boric acids.⁷²

R = H ($n = 1-5$), 4-Me ($n = 0, 1$), 5-Me ($n = 1$), 5,6-Me₂ ($n = 1$), 4-Cl ($n = 1$), 5-Cl ($n = 1$), 5-OMe ($n = 1$), 4,5-(-CH=CH-CH=CH-) ($n = 1$).

Their analogues **117**, methylated at the N(1) atom, have been obtained under similar conditions from the acids **118** ($n = 0, 1$) and 1-amino-2-methylaminobenzene, while the *N*-phenylated

analogue **117** has been obtained from the acid **118** ($n = 1$) and 1-amino-2-phenylaminobenzene.⁷² The yields of compounds **117** were 54%–81%.

When benzimidazoles are treated with ferrocenylmethyl-(trimethyl)ammonium iodide, the N(1) atom is ferrocenylmethylated.^{77, 78}

R = H: R¹ = H, Me, Ph;
R = 5-NO₂: R¹ = H, Me.

The FcCH₂ substituent can also be introduced at the nitrogen atoms of the benzimidazole derivatives **119** by the reaction with hydroxymethylferrocene in the presence of tetrafluoroboric acid. Depending on the ratios FcCH₂OH:119:HBF₄, one or both nitrogen atoms of the heterocycle are alkylated. The mono-alkylated products **120** (R² = H) are obtained for the ratios 1:1:2, while the dialkylated products **120** (R² = FcCH₂) are formed for the ratios 2:1:2.⁷⁸

R	R ¹	R ²	Yield (%)

6-NO ₂	Me	FcCH ₂	62

Ferrocene-containing imidazolines and benzimidazoles are formed in high yields (80%–93%) on condensation of the iminoester hydrochlorides **121** with ethylenediamine or 1,2-diaminobenzene.^{79, 80}

$n = 0, 1$.

The configuration of the ethene fragment in the product is the same as in the initial iminoester **121** ($n = 1$).^{81, 82}

The reaction of ethylenediamine with the hydrochloride of the iminoester of 3-ferrocenyl-3-hydroxypropionic acid results in the formation of 1-ferrocenyl-2-(2-imidazolyl)ethene **122** in the form of a mixture of the *cis*- and *trans*-isomers.⁸²

The condensation of the aldehyde **14** with 2-methylimidazoline constitutes a stereoselective method of synthesis of the *trans*-isomer of the imidazoline **122**.^{82–84}

Conditions	Yield of 122 (%)
RONa, ROH (R = Me, Et)	54
KU-2, PhH	32

2-(2-Benzimidazolyl)-1-ferrocenylethene has been obtained similarly from 2-methylbenzimidazole.^{83, 84}

2-Mercaptobenzimidazole reacts in the thiono-form with two molecules of ferrocenyl vinyl ketone in the presence of potassium fluoride, affording the adduct **123** in 94% yield.⁸⁵

In the reaction of 3-acetyl-2-thiohydantoin with FcCHO on aluminium oxide, deacetylation takes place together with ferrocenylmethylation; the reaction product is compound **124** (yield 75%).⁸⁶

The synthesis of 2-ferrocenyl-5-mercapto-4-phenyl-1,2,4-triazoline by the condensation of phenyl isothiocyanate with the hydrazide of ferrocenecarboxylic acid has been described.⁸⁷

In the presence of acetic acid, the ferrocenylcarbinols **125** react regiospecifically with 5-nitro- and 3,5-dinitro-1,2,4-triazoles, forming the products of alkylation at the N(1) atom.⁸⁸ The ferrocene derivatives **126** with heteryl-containing substituents in both rings can be obtained under these conditions.

R	R ¹	R ²	R ³	Yield (%)

The reaction of the sodio-derivative of benzotriazole with the salts **129**, formed from the ferrocenylcarbinols **125** and HBF₄, leads to *N*-substituted benzotriazoles **130** in 54%–96% yields.⁴³ According to the authors, the reaction proceeds via a stage involving the one-electron oxidation of the benzotriazole anion.

R	H	Me	Ph	FcCH=CH	Fc	
Reaction time/h	0.25	1.25	1.75	20	0.5	0.5

The alkylation of the substituted benzotriazoles **131** by treatment with the ferrocenylcarbinols **125** in 48% aqueous HBF₄ in the course of 3–5 min leads to the salts **132** in 92%–96% yields.⁹¹

R = H, Me; R¹ = H, CH₂OH; R² = H, Me, Br, NO₂;

The alkylation of tetrazole and its derivatives **133** by various cationoid ferrocene-containing reagents has been investigated.^{88,92} The reagents employed were the alcohols **125** of the ferrocene series, which readily generate α -ferrocenyl-carbonium ions in an acid medium, as well as α -haloalkyl-ferrocenes **127**. In these reactions, electrophilic functional groups were present in only one as well as in both rings of the ferrocene system.

127 (R = H)

127 (R = CH₂Cl)

Treatment of tetrazole (or 5-R¹-tetrazole) **133** or of its sodio-derivative by the above reagent gave the products of alkylation at the N(1) atom (compound **134**) or the N(2) atom of the tetrazole ring (compound **135**).

It has been observed that tetrazole and its alkyl derivatives (R¹ = H, Alk) are alkylated nonselectively, which results in the formation of a mixture of regioisomers (compounds **134**, **135**, and **136–138**). The introduction of electron-accepting or aromatic substituents (R¹ = Ar, NO₂) into the tetrazole ring promotes substitution at the N(2) atom. In the case of 5-nitrotetrazole, only the N(2)-alkylated derivatives are obtained (compounds **135** and **137**).

138

The influence of the acidity of the medium on the selectivity of the alkylation of tetrazole by the alcohols **125** has been investigated.⁹³ It was found that alkylation at the N(1) atom predominates in an acid medium.

The ferrocenylfuran derivative **139** has been obtained in 45% yield by heating a mixture of diphenylethyne with pentacarbonyl[ferrocenyl(methoxy)carbene]chromium(0) **140** in dibutyl ether.⁹⁴

139

A mixture of the two dihydrofuran derivatives **141** and **142** is formed as a result of the reaction of vinylferrocene with tris(3-iodopentane-2,4-dionato)cobalt **143** in the presence of palladium acetate and triphenylphosphine.⁹⁵

141

142

2-Ferrocenyltetrahydrofuran and its derivatives **144** have been synthesised in 90%–95% yields by the dehydrocyclisation of the corresponding 1,4-diols **145** on treatment with sulfuric acid or on heating in vacuo.^{96,97}

R	R ¹	R ²

The unsaturated alcohols **146** or the 1,4-diol monoethers **147** are converted into the tetrahydrofuran derivatives **148** by the reaction with trifluoroacetic acid and subsequent treatment with an aqueous solution of sodium carbonate. According to the authors,⁹⁸ the reaction proceeds via a stage involving the formation of the carbonium ions **149**. The yields of compounds **148a, b** were 84% and 88% respectively.

R = H (a), Me (b)

148a,b

Japanese investigators have described a new method of synthesis of 2,5-diferrocenyltetrahydrofuran derivatives **150**.^{99,100} They treated the alcohols **151** or the alkenes **152** with oxygen in hexane in the presence of silica gel or acid aluminium oxide.

The authors believe that the reaction proceeds via the intermediate formation of a peroxide as a result of the oxidative dimerisation of the initial compounds.

When 1,6-dioxaspiro[4.4]nonane **153** is activated by Lewis acids (AlCl_3 , BF_3), it is capable of alkylating ferrocene with the opening of one of the rings of the spiro-system.^{101,102} After treatment with water, 2-ferrocenyl-2-(3-hydroxypropyl)tetrahydrofuran **154** is formed in 55%–89% yield.

Ferrocene adds to the dihydrofuranone derivative **155** under similar conditions.¹⁰³

2-Ferrocenylfuran-5-carboxylic acid has been synthesised by the cyclocondensation of 3-chloro-3-ferrocenylacrolein **61** with glycolic acid. It was noted that, when the reaction is carried out in a microwave oven, the yield of the cyclocondensation product increases appreciably.²⁴

The interaction of the diketone **156** with benzoquinone in the presence of $\text{Et}_2\text{O} \cdot \text{BF}_3$ results in the formation of the benzofuran derivative **157** in 30% yield.¹⁰⁴

The alcohols obtained from 3-ferrocenylpropionic acid or its methyl ester cyclise to the tetrahydrofuranone derivative **158** on treatment with MeMgI or NaBH_4 in situ.^{98,105}

The acylation of ferrocene by the chloride of 5-(2-furoyl)-valeric acid in the presence of aluminium chloride is accompanied by the intramolecular crotonic condensation; the final reaction product is 2-ferrocenyl-1-(2-furoyl)cyclopentene **159**.¹⁰⁶

R = H, Me.

Australian investigators¹⁰⁷ described a novel method of synthesis of 3-ferrocenylmethyl-2,3-dihydrobenzofuran by the cyclocondensation of ferrocene with the diazonium cation **160**.

The naphthofuran derivatives **162** have been synthesised in 70%–78% yields by heating a mixture of β -naphthol and the dibromo-derivatives **161** above the melting point.⁴⁷

R = Ph, 4- ClC_6H_4 , 3- $\text{O}_2\text{NC}_6\text{H}_4$, 4- $\text{O}_2\text{NC}_6\text{H}_4$.

The reaction of ferrocene with the lactones **163** in the presence of aluminium chloride¹⁰³ leads to compounds **164–166** with five-membered rings, which are formed as a result of the carbonium ion rearrangement **167** → **168**.

The synthesis of the ferrocenyl-substituted succinic anhydrides **170** from the corresponding acids **169** on treatment with Ac_2O or $(\text{CF}_3\text{CO})_2\text{O}$ has been described.^{108–110}

R	R ¹	Yield (%)	Ref.

	Fc(Me)C=	100	108
	Fc(Ph)C=	90	108
	FcHC=	53	110

The Horner–Emmons interaction of FcCHO **14** with the phosphonates **171** leads to the unsaturated lactones **172**.¹¹¹

R = H, Me.

The ferrocene-containing chalcones **173** and **174** have been obtained^{112,113} by condensing compound **14** with 2-acetylfuran (on treatment with aqueous alkali at 20 °C for 24 h or on treatment with piperidine in methanol) and also by condensing 1,1'-diacetylferrocene with furfural.

On treatment with the glycols **175** in the presence of toluene-*p*-sulfonic acid, the aldehyde **14** and acetylferrocene **23** afford the corresponding dioxolanes **176** (yield 68%–77%).^{114,115}

R	R ¹	R ²	Ref.
Me	H	H	114
H	Me	H	115
H	Me	Me	115

It has been established by ¹H NMR spectroscopy¹¹⁵ that the reaction with aldehyde **14** proceeds stereoselectively: for R¹ = Me and R² = H, a 6:5 mixture of (*Z*)- and (*E*)-isomers is formed; the *dl*- and (*E*)-isomers are formed in proportions of 6:1 from the symmetrical diol, where R¹ = R² = Me.

The introduction of the dioxolane fragment into the ferrocene system is also possible on treatment with epichlorohydrin in the presence of tin(IV) chloride.^{114,116} The maximum yields of the products **177** have been obtained for the ratio ferrocene derivative: epichlorohydrin = (1:2)–(1:4).

A method of synthesis of 1,1'-bis(2-thienyl)ferrocene, involving the reaction of 1,1'-dibromoferrocene with an excess of (2-thienyl)magnesium iodide has been patented.¹¹⁷

The cyclocondensation of 3-chloro-3-ferrocenylacrolein **61** with thioglycolic acid in the presence of triethylamine [60–80 °C, dimethylformamide (DMF)]^{24,118} leads not only to the expected 2-ferrocenylthiophene-5-carboxylic acid (yield 12%) but also to its decarboxylation product — 2-ferrocenylthiophene (yield 20%).

The condensation of ethyl thioglycolate proceeds without complications¹¹⁸ and the corresponding thiophene derivative **178** (X = OEt) has been isolated in 63% yield. The amide **178** (X = NHPh) has been obtained in 36% yield from the anilide of thioglycolic acid.

X = OEt, NHPh.

The same communication reports the synthesis of the amino-derivatives **179** (X = OEt, yield 49%; X = NHPh, yield 65%) when the 3-chloro-3-ferrocenylacrylonitrile **62** is condensed with thioglycolic acid derivatives.

X = OEt, NHPh.

In a basic medium, the diene derivative **180** undergo transcondensation with ethyl thioglycolate. This leads to the product **181**, unstable under the reaction conditions, which cyclises to the thiophene derivative **178** (X = OEt).¹¹⁹

When ferrocene is acylated by the chlorides of thiophene-3-carboxylic acids, the ketones **182** are formed in low yields (14%–20%).¹²⁰

R = 2-COOMe, 4-COOMe.

The acylation of ferrocene by the acid chlorides **183** and **184**, containing a sulfolane or sulfolene fragment, is also ineffective for preparative purposes (the product yields are 14%–20%).¹²¹

When the acylferrocenes **185** are acylated by the chloride of thiophene-2-carboxylic acid **186**, the attack by the electrophile is directed to the unsubstituted cyclopentadienyl fragment.¹²²

R = Me (80%), Et (83%), Ph (81%), PhCH₂ (85%).

When 1-acetyl-1'-ethylferrocene is used as the substrate, substitution takes place in the ring with the alkyl substituent (the yield of the acylation product is 16%).¹²²

The acylation of ferrocene by the chloride **187** under the conditions of the Friedel-Crafts reaction is accompanied by cyclisation with formation of the ketone **188**.¹⁰⁶

The 1,3-dithiolanes **189** have been synthesised in 51%–81% yields by the thioketalisation of the acylferrocenes **185** on treatment with the 1,2-dithiols **190** in the presence of acid catalysts.¹¹⁵

R = H, Me, Ph.

More severe conditions are required for the synthesis of the bistioketals **191** from 1,1'-diacylferrocenes **192**, the product yields being 29%–31%.

R = Me, Ph.

The vinylferrocene derivative **193** has been synthesised by the Wittig reaction from the aldehyde **194** and ferrocenylmethyl-(triphenyl)phosphonium iodide in 58% yield.¹²³

Compounds **195** have been obtained from 1,1'-diacetylferrocene and the reagents **196** by the Horner-Emmons method in 60%–70% yields.¹²³

R = H, Me.

On heating the unsaturated ketones **197** with hydroxylamine in the presence of alkali, the adduct was unexpectedly readily aromatised, the isoxazoles **198** being obtained instead of the isoxazolines.¹²⁴

R = Fc; R¹ = Fc, Ph, , R = *p*-FC₆H₄, R¹ = Fc.

5-Ferrocenylisoxazole has been synthesised in 25% yield by heating the aldehyde **61** with the hydrochloride of hydroxylamine in methanol. On treatment with hydroxylamine in the presence of sodium ethoxide, the nitrile **62** affords a 56% yield of 3-amino-5-ferrocenylisoxazole.⁵⁴

The ethyl ester of 5-ferrocenylisoxazole-3-carboxylic acid is formed in 61%–86% yield in the reaction of 3-ferrocenylacrylic acid derivatives **199** with hydroxylamine hydrochloride.⁵⁹

R = NH₂, R¹ = OEt; R = OH, R¹ = OH.

The ferrocene derivatives **201**, containing isoxazole fragments in one or both cyclopentadienyl rings, have been obtained in 47%–81% yield by the cyclocondensation of the diketone-derivatives **200** on refluxing with HONH₂·HCl in alcohol.^{55,58} For R¹ = Me in the initial diketone-derivative **200**, the reaction is carried out in the presence of pyridine.

R ¹	R ²	R ³

3-(10-Phenothiazinyl)-5-ferrocenylisoxazoline has been synthesised in 40% yield by refluxing a mixture of 10-(3-ferrocenyl-1-oxoprop-2-en-1-yl)phenothiazine with hydroxylamine in ethanol for 6 h.⁶⁶

The 1,3-dipolar addition of the *N*-oxides of carboxylic acid nitriles to unsaturated ferrocene derivatives is a convenient method of synthesis of 5-ferrocenylisoxazole and 5-ferrocenylisoxazoline derivatives. Ferrocenylethyne, vinylferrocene, and ferrocenyl vinyl ketone have been used as the dipolarophiles. Their cycloaddition to the *N*-oxides of aliphatic and aromatic acid nitriles led to the series of derivatives **202**–**204**.¹²⁵

R = Me, Et, COMe, COOEt, Ph, 3-O₂NC₆H₄, 4-O₂NC₆H₄.

R = Me, Et, COMe, COOEt, Ph, 3-O₂NC₆H₄, 4-O₂NC₆H₄.

Compound **205** with two condensed heterocyclic rings is formed in 60% yield as a result of the interaction of the pyrazolone derivative **94** (R = Me, R¹ = Ph) with urea in boiling acetic acid.⁶⁹ The following reaction mechanism has been proposed:

Treatment of 1-ferrocenylaziridines **3** with sulfuric acid in the dark leads to the expansion of the ring and the formation of the oxazoline derivatives **208** (yields 24%–58%).⁷

R = R¹ = H (a); R = H, R¹ = Me (b); R = R¹ = Me (c).

A further two methods of synthesis of the oxazolines **208** have been patented: by the reaction of FeCN with 1-aminopropan-2-ol (compound **208b** is obtained) or by the reaction of FeCOCl with 2,2-dimethylaziridine (compound **208c** is obtained).¹²⁶

A method has been proposed recently for the synthesis of 4-substituted 2-ferrocenyloxazolines from cyanoferrocene and the aminoalcohols **209** in the presence of zinc chloride (yields 15%–38%).¹²⁷ Best results are achieved when the β -hydroxyamides **210** are cyclised on treatment with triphenylphosphine (yield 77%–92%).¹²⁸

R = Me, Prⁱ, Buⁱ, Bu^t, Ph, PhCH₂.

$$R = H, Pr^i.$$

Cyclocondensation of the hydrochloride of the methyl iminoester of ferrocenecarboxylic acid with *o*-aminophenol in boiling methanol leads to 2-ferrocenylbenzoxazole in 84% yield.⁷⁹ The latter has also been obtained in 70% yield by irradiating the imine **211** with light of 348 nm wavelength in boiling toluene for 10 s.¹²⁹ The unstable 2-ferrocenylbenzoxazoline, which is rapidly oxidised, is formed as an intermediate.

An alternative route to 2-ferrocenylbenzoxazole involves the treatment of the imine **211** with lead tetraacetate in glacial acetic acid.¹²⁹

The lithium derivative, formed on deprotonation of 2,4,5-trimethyloxazole by treatment with lithium diisopropylamide (LDA), reacts with FcCHO **14**, affording (after hydrolytic treatment) the alcohol **212** (yield 57%).¹³⁰

The *N*-oxides of the carboxylic acid nitriles **213**, generated by the dehydration of the primary nitro-compounds **214** by phenyl isocyanate in the presence of triethylamine, were made to undergo the 1,3-dipolar cycloaddition to phenylethyne or alkenes.^{131, 132} This resulted in the synthesis of 3-ferrocenylmethyl-5-phenylisoxazole **215** or of the isoxazoline derivatives **216**.

Interaction of the hydrochlorides of the iminoesters **120** with *o*-aminophenol results in the formation of the benzoxazole derivatives **217** in 84%–100% yields.^{82,133}

$$n = 0, 1.$$

It has been found that the cyclocondensation does not affect the configuration of the double bond.⁸¹ The individual *cis*- and *trans*-iminoesters **120** ($n = 1$) afforded the corresponding diastereoisomers **217** in 90%–93% yields.

Compound **217** ($n = 1$) has been synthesised by condensing the aldehyde **14** with 2-methylbenzoxazole in the presence of bases (MeONa, NaNH₂).^{83, 84, 133} If the substrate is 2,3-dimethylbenzoxazolium iodide, the condensation product is the corresponding salt of the *N*-methyl derivative **217**.

A condensation of the same type has been used to synthesise the more complex ferrocene-containing benzoxazoles **218** and **219** (yields 75%–80%).⁸⁴

$$R = \text{SO}_3\text{H}, \text{CN}$$

Ferrocene-containing cyanines having the general formula $\text{FcCH}=\text{CHR}$ have been synthesised from the aldehyde **14** and the methiodides of 2-methylbenzoxazole and its derivatives.⁸⁴ The compounds with

have been described.

The condensation of the salt **220** with hydroxylamine results in the formation of 1-acetyl-1'-(1,2,5-oxadiazol-4-yl)ferrocene in 73% yield.¹³⁴

Refluxing of the diacetate of 1-ferrocenyl-2-methylglyoxime **221** in aqueous alkali leads to 5-ferrocenyl-4-methyl-1,2,5-oxadiazole.¹³⁵ On the other hand, when there is a hydrogen atom attached to the carbonyl carbon atom in the glyoxime derivative, the 1,2,4-oxadiazole derivative **222** is formed under the same conditions.

The *N*-oxides of the nitriles **223**, generated from primary nitro-compounds on treatment with phenyl isocyanate in the presence of triethylamine, dimerise in the absence of dipolarophiles and are converted into the furoxanes **224**.^{131, 132}

The 1,2,4-oxadiazole derivatives **225** have been obtained¹³⁶ by the reaction of ferrocenylmethyl(trimethyl)ammonium iodide with sodium nitrite in acetonitrile or propionitrile.

Apparently the *N*-oxide of the nitrile $\text{FcC}\equiv\text{N} \rightarrow \text{O}$ is formed as an intermediate, undergoing subsequently the 1,3-dipolar cycloaddition reaction with the nitrile group.

The phosphonic acid derivatives **226**, containing the 1,3,4-oxadiazole ring, react under very mild conditions with the aldehyde **14** to form compounds **227**.¹³⁷

5-Ferrocenylisothiazole has been synthesised from the aldehyde **61** on treatment with ammonium thiocyanate (refluxing in acetone for 20 min; yield 42%).⁵⁴

The cyclocondensation of the imines **229** with thioglycolic acid is frequently used to synthesise 2-ferrocenylthiazolin-4-one **228**.^{16, 18-20}

2-Phenylthiazolidine-4-carboxylic acid **239** is alkylated at the N atom of the heterocycle on treatment with ferrocenylmethyl perchlorate or tetrafluoroborate **129**, which are generated from ferrocenylmethanol under phase-transfer conditions.^{41,44}

The condensation of the aldehyde **14** with rhodanine yields 5-ferrocenylmethylidene-4-oxo-2-thionothiazolidine.¹⁴²

$$\text{Fc}-\overset{\text{R}}{\underset{|}{\text{CH}}}-\text{OH} + \text{benzothiazole} \xrightarrow[20^\circ\text{C, 4 h}]{\text{KU-2, CH}_2\text{Cl}_2} \text{benzothiazole-2-yl}-\overset{\text{R}}{\underset{|}{\text{CH}}}-\text{Fc}$$

240

When the α -carbonium ion salts **129** were allowed to react with the 2-methylbenzothiazole derivatives **241**, the nitrogen atom of the heterocycles was alkylated and the corresponding salts **242** were formed in 77%–100% yields.^{143, 144}

The methyl group at the C(2) atom of the heterocycle in 3-ferrocenylmethyl-2-methylbenzothiazolium tetrafluoroborate **242** (R = R¹ = H, X = BF₄) contains mobile hydrogen atoms and is able to condense with 5-acetylphenylaminomethylene-3-ethylrhodanine **243** to form dimethinemerocyanine **244** (yield 39%).⁴²

The carbocyanine **246** has been obtained in 64% yield by treating 3-ethyl-2-(2-methylthiovinyl)benzothiazolium methanesulfate **245** with the reagent **242** ($R = R^1 = H$, $X = BF_4$).⁴²

Compounds **248** have been synthesised (yields 7%–9%) by the reaction of the ferrocenium cation, formed when ferrocene is treated with concentrated sulfuric acid, and 5- and 6-diazo-2-methylbenzothiazolium chloride **247**.⁴⁹

It has been shown^{83,84} that in the presence of bases 2-methylbenzothiazole condenses with $FcCHO$ **14** to form 2-(2-ferrocenylvinyl)benzothiazole.

Solvent	Reaction time/h	Yield (%)	Ref.

EtOH, Py	0.5	97	83, 84

2,3-Dimethylbenzothiazolium iodide, in which the mobility of the H atoms of the methyl group at the C(2) atom is greater, reacts more readily with $FcCHO$ ⁸³ and 2-(2-ferrocenylvinyl)-3-methylbenzothiazolium iodide is formed in a virtually quantitative yield in the presence of piperidine.

Ferrocenyl vinyl ketone is a Michael acceptor in relation to 2-mercaptobenzothiazole.⁸⁵ When the radiation is carried out on aluminium oxide, a 96% yield of the adduct **249** is attained.

The acylferrocenes **185** react with 2-mercaptoethanol **250** to form the 1,3-oxathiolane derivatives **251**. It has been established¹¹⁵ that, depending on the nature of R, various catalysts are required for the successful synthesis.

On treatment with ferrocenyllithium, the chlorine atom in compound **252** is substituted by the ferrocenyl group, whereupon 1-ferrocenyl-2,5-dimethyl-1,2,5-diazaphospholane **253** is formed.¹⁴⁵

Compound **254** has been obtained in 49% yield as a result of the reaction of dichloro(ferrocenyl)arsine **255** with sulfur in the presence of 2,4,6-tris(*tert*-butyl)phenylphosphine and diazabicycloundecene.¹⁵

V. Compounds containing six-membered heterocycles

Condensation of the aldehyde **61** with the β -dicarbonyl compound **256** in the presence of ammonium acetate leads to the 3-acyl-6-ferrocenylpyridine derivatives **257**.¹⁴⁶ The same result has been achieved by treating the pyrilium salts **258** with ammonium acetate.¹⁴⁷

4-Ferrocenyl-2,6-dimethylpyridine is formed in 63% yield on treatment of 4-ferrocenyl-2,6-dimethylpyrylium perchlorate with aqueous ammonia.¹⁴⁸ A similar transformation of 6-ferrocenyl-2,4-diphenylpyrylium perchlorate into 6-ferrocenyl-2,4-diphenylpyridine requires more severe conditions: refluxing with an alcoholic solution of ammonia for 10 min (yield 45%–51%)¹⁴⁹ or heating with an alcoholic solution of ammonia in a sealed tube at 100 °C for 7 h (yield 27%).¹⁵⁰

When the salt **259** was heated with ammonium acetate in aqueous acetic acid, 2-ferrocenylpyridine **260** was obtained in 57% yield.¹⁵¹

3,5-Dicyano-4-ferrocenyl-2,6-dimethyl-1,4-dihydropyridine, formed as a result of the condensation of FcCHO with diacetonitrile (refluxing for 1 h in acetic acid under a nitrogen atmosphere), is converted into 3,5-dicyano-4-ferrocenyl-2,6-dimethylpyridine on oxidation with chloranil.¹⁵²

The accelerating effect of ultrasound on chemical reactions has been demonstrated by Japanese investigators.¹⁵³ They showed that the sonolysis of unsaturated ferrocenyl-substituted ketones **261** in acetonitrile at 35 °C for 2 h leads to the pyridine derivatives **262** in 60%–85% yields. The authors¹⁵³ believe that diacetonitrile, generated from acetonitrile under the reaction conditions, participates in the formation of the pyridines.

In the presence of bases, the unsaturated ketones **261** react with 3-aminocrotonitrile. If the reaction is carried out in 2-ethoxyethanol,¹⁵⁴ then the products are the substituted pyridines **263**.

When the condensation is carried out in butanol with subsequent heating of the reaction products with water, substituted nicotinamides are obtained.¹⁵⁴

The condensation of the aldehyde **14** with ethyl 3-amino-crotonate in the presence of ammonium carbonate leads to the 1,4-dihydropyridine derivative **264**, which is oxidised by sulfur and is converted into 3,5-bis(ethoxycarbonyl)-4-ferrocenyl-2,6-dimethylpyridine **265**.¹⁵⁵

In the diphosphine **266**, one of the PPh_2 groups is substituted by the 2,2'-bipyridyl group on treatment with the lithium derivative formed from 2,2'-bipyridyl and phenyllithium.¹⁵⁶

A series of quinoline and naphthyridine derivatives **268**, containing the ferrocenyl group, have been synthesised by the Friedlaender reaction from acylferrocenes **185** and the aminoaldehydes **269**.¹⁵⁷

Compounds **270** are obtained under similar conditions from the 1,1'-diacylferrocenes **192** and 2 mol of the aminoaldehydes **269**.

Et	Me	COMe	24

Benzenesulfonylbenzimidoyl chloride **106** adds to quinoline or isoquinoline with formation of the salts **271** or **272**, which alkylate ferrocene (refluxing in benzene for 2.5 h), affording compounds **273** or **274** in 42% or 51% yields respectively.⁷³

The aldehyde **61** reacts with two molecules of 3-hydroxy- or 3-methoxyaniline with formation of the salts **275**, the subsequent treatment of which with aqueous ammonia leads to cyclisation to the quinoline derivatives **276** and **277**.¹⁴⁶ ¹H NMR data revealed the regioselectivity of the cyclisation in favour of compound **277**. In the case of unsubstituted aniline, the reaction stops at the stage involving the formation of the salt **275** (R = H).

On treatment with boron trifluoride etherate, the amide **278** gives rise to the chelate **279**, which cyclises on heating with orthophosphoric acid and is converted into 4-ferrocenyl-7,8-dimethyl-2-quinolone.¹⁵⁸

R = OH (15%), OMe (44%).

In the presence of alkali, the aldehyde **14** condenses with the hydrochloride of quinuclidin-3-one, which affords 2-ferrocenyl-methylidenequinuclidin-3-one **280**.¹⁵⁹

Methods for the synthesis of a series of ferrocene-containing derivatives of bipyridyl (compounds **281**) and terpyridyl (compounds **282** and **283**) have been developed based on the carbonyl derivatives of ferrocene.¹⁶⁰⁻¹⁶²

The method of synthesis of 2-ferrocenyl-4-methyl-5,6-benzoquinoline **284**, proposed in a patent,¹⁶³ involves the condensation of 4-ferrocenylbut-3-en-1-ol with β -naphthylamine in the presence of aluminium chloride.

Two other methods of synthesis of compound **284** are based on the acid-catalysed condensation of carbonyl compounds with β -naphthylamine or *N*-ferrocenylmethylidene- β -naphthylamine.¹⁶⁴

Compound **285**, in which condensed pyridine and cyclohexadienyl rings alternate, has been synthesised in 26% yield by treating with ammonium acetate the product **286** formed when the aldehyde **14** reacts with the enamine **287**.¹⁶⁵

Compound **288**, containing two ferrocenyl groups and five pyridine rings, has been obtained by a two-stage synthesis from the aldehyde **14** and 2,6-diacetylpyridine.¹⁶⁶

The pyridopyrazole derivative **290** is formed in 70% yield on refluxing the chalcone **289** with 3-amino-1-phenylpyrazol-5-one in ethanol.¹⁶⁷

A single example of the synthesis of 1-ferrocenylpiperidine by the reaction of chloroferrocene with piperidine in the presence of butyllithium has been described.¹⁶⁸

Bis(ferrocenylcarbothionyl) sulfide thioacylates piperidine, affording *N*-(ferrocenylcarbothionyl)piperidine **291**.¹⁶⁹

The mono- and di-lithio-derivatives of 4,4'-dimethyl-2,2'-bipyridyl, generated by treatment with LDA, add to the carbonyl group of compound **14**, which leads to the alcohol **292a** or the diol **292b**.¹⁷⁰

292a: $n = 1$, $R = \text{Me}$ (77%);

292b: $n = 2$, $R = \text{CH}_2\text{CH}(\text{OH})\text{Fc}$ (55%).

Bis(triphenylphosphine)palladium dichloride catalyses the nucleophilic substitution of the halogen atoms in 2,6-dibromopyridine on treatment with ferrocenylethyne in the presence of bases and copper(I) salts.¹⁷¹ After reaction for 1.5 h, the mono-substitution product **293a** is formed in 78% yield. When the reaction is carried out over a period of 24 h, the disubstitution product **293b** is formed in 90.4% yield.

$R = \text{Br}$ (**a**), $\text{C}\equiv\text{C}-\text{Fc}$ (**b**).

It was shown in the same investigation that both bromine atoms in 3,3'-dibromo-2,2'-bipyridyl are substituted by the FcC≡C group [the yield of 3,3'-bis(2-ferrocenylethynyl)-2,2'-bipyridyl was 89% after 48 h].

The condensation of the aldehyde **14** with 2-methylpyridine on treatment with sodium in liquid ammonia leads to the alcohol **294** in 57% yield.⁸³ It may be dehydrated to 2-(2-ferrocenylvinyl)pyridine **295** by treatment with tin(II) chloride.

When an excess of sodium amide⁸³ or sodium alkoxide in pyridine⁸⁴ is used, the alkene **295** is formed in 51% yield. 2-(2-Ferrocenylvinyl)quinoline has been obtained similarly (yield 94%).

The amide **297** has been synthesised by converting the aldehyde **14** into an alkene by treatment with the arsonium salt **296** in the presence of potassium carbonate in THF containing traces of water.³⁹

The alkylation of the lithio-derivative of 4,4'-dimethyl-2,2'-bipyridyl with 3-bromopropylferrocene affords compound **298**.¹⁷²

N-(4-Ferrocenylphenyl)-2,4,6-trimethylpyridinium perchlorate **299** has been obtained in 65% yield as a result of the substitution of the oxygen atom in the heterocyclic nucleus of 2,4,6-trimethylpyrylium perchlorate on treatment with *p*-ferrocenylaniline.¹⁵⁵

The 1,4-dihydropyridine derivative **300** is formed on cyclocondensation of the imines **301** with acetoacetic ester.¹⁵⁵

1,1'-Bis(hydroxymethyl)ferrocene is able to alkylate pyridine at the nitrogen atom on activation with toluene-*p*-sulfonyl chloride or thionyl chloride.¹⁷³ The mixed salt **302** (X = OTs) and a dichloro-derivative are formed in the first and second cases respectively.

A = 4-MeC₆H₄SO₂Cl, X = OSO₂C₆H₄Me-4;
A = SOCl₂, X = Cl.

The synthesis of compounds with fragments of viologens (*N,N'*-dialkyl-4,4'-bipyridyls) linked covalently to photosensitive groups constitutes a complex task. The study¹⁷⁴ in which a method was described for the preparation of the viologen-metalloenes (ferrocenyl-containing viologens) **303** and **304**, capable of displacing hydrogen from water in the presence of catalysts, is therefore of significant interest.

Boev and coworkers^{42,45,143,144} investigated the reactions of hydroxymethylferrocene and 1-ferrocenylethanol with six-membered nitrogen heterocycles in the presence of HBF₄ or HClO₄.

It was found that the reaction proceeds via a stage involving the formation of the salts **129**, which attack the heterocyclic nucleophiles. This is confirmed by the finding that salts of the heterocycles with HX obtained beforehand do not react under the conditions investigated with the alcohols FcCH(R)OH .¹⁴⁴

R = H, Me; X = BF_4 , ClO_4 ;

Piperidine is alkylated similarly by hydroxymethylferrocene in the presence of an acid.¹⁷⁵

The amins formed from the aldehydes **305** and piperidine undergo transcondensation with acetone cyanohydrin, affording the aminonitriles **306**.¹⁷⁶

When the aldehyde **14** or the ketone **23** interacts with phosphorous acid esters and piperidine, the α -aminophosphonates **307** are formed.¹⁷⁷ Of the two possible mechanisms (*A* and *B*, Scheme 3), the first is preferable since it has been shown¹⁷⁷ that piperidine does not displace phosphorous acid esters from specially prepared α -ferrocenyl- α -hydroxyalkylphosphonates (150–160 °C, 10–12 h).

In the presence of trichloroacetic acid, electrophilic substitution in the ferrocene nucleus by treatment with

trimethylacetaldehyde and subsequent protonation and dehydration lead to the salt **308**, which is converted into *N*-(1-ferrocenyl-2,2-dimethylpropyl)piperidine **309** in 68% yield on treatment with piperidine.¹⁷⁸

The alkylation of piperidine by α -carbonium ion intermediates (generated from the sulfides **310** on treatment with mercury salts), leading to the amines **311**, takes place similarly.¹⁷⁹

R = H (30%), Me (90%).

On refluxing in methanol, piperidine substitutes the acetoxy-group in compound **42**.³⁵

Another method for the introduction of the piperidiny group into ferrocene derivatives involves the Michael addition of piperidine to the pyrazolones **94**, which leads to compound **313**.⁶⁹

R = Ph, 2,4-(O₂N)₂C₆H₃.

A mixture of the two isomeric tetrahydroisoquinolinone derivatives **314** and **315** has been obtained (in 10% and 81% yields respectively) by refluxing the imine **316** and compound **317** in benzene for 82 h.¹⁸⁰

Indian investigators^{167, 181} made a detailed study of the reaction of 1-ferrocenyl-2-(*p*-methoxyphenyl)ethene with primary heterocyclic amines and guanidine. The structures of the products and the yields of compounds **318**–**322** are presented in Table 2.

The derivatives of dihydropyrimidine-2-thione **323**–**326** have been synthesised by condensing α,β -unsaturated cyclic ferrocene-containing ketones with thiourea in the presence of alkali in ethanol.¹⁸²

323a: R = R¹ = H (95%);
323b: R = H, R¹ = OMe (95%);
323c: R = OMe, R¹ = H (90%).
324, n = 1 (95%), 2 (75%).

Table 2. The reactions of 1-ferrocenyl-2-(*p*-methoxyphenyl)ethene with nitrogen-containing heterocyclic compounds and guanidine.

		56	181
		75	167

Note. The reactions were carried out in boiling ethanol for 18–24 h. The group R in the reaction product is 4-MeOC₆H₄.

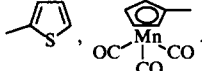

A series of similar compounds (compounds **327**) have been synthesised from the ketones **328** and thiourea with irradiation by ultrasound (US).¹⁸³

R = Fc: R¹ = Ph, 4-MeC₆H₄, 4-MeOC₆H₄, 4-ClC₆H₄,
 3,4-(OCH₂O)C₆H₃;
 R = 4-MeOC₆H₄, R¹ = Fc.

A wider range of the ketones **328** were later involved in this reaction^{184,185} and conditions were found under which the products **327** are obtained in yields from 70% to 95%. Here

$R = \text{Fc}$, $R^1 = 4\text{-Me}_2\text{NC}_6\text{H}_4$;

$R^1 = \text{Fc}$, $R = \text{Ph}$, $4\text{-FC}_6\text{H}_4$, $4\text{-IC}_6\text{H}_4$, 

The synthesis of 5-ferrocenylmethylidenearbituric acid (yield 94%) by condensing barbituric acid with the aldehyde **14** has been patented.¹⁸⁶

The coupling of ferrocenylethyne with 5-chloromercurio-derivatives of uracil, cytosine, and adenine, as well as the corresponding nucleosides, which leads to compounds having the general formula $\text{FcC}\equiv\text{C}-\text{R}$, where R is a group derived from a heterocyclic base or a nucleoside, has been described.¹⁸⁷

The adenosine derivative **329** has been obtained in 19% yield as a result of the condensation of the aldehyde **14** with compound **330** and subsequent aromatisation under the influence of palladium.^{188,189}

a: NaOH, MeOH, 20 °C, 3 days; b: Pd/C, EtOH, H₂O, 80 °C.

The dihydropyrimidine-2-thione derivatives **331** are formed in 58%–79% yield on interaction of the ketone **332** with thiourea or phenylthiourea.⁶²

$R = \text{H}$, Ph .

High-molecular-mass compounds containing quinoxaline nuclei have been obtained by the polycondensation of 1,2,4,5-tetraaminobenzene or 3,4,3',4'-tetraaminobiphenyl with 1,1'-bis-(glyoxalyl)ferrocene.

The chloride of ferrocenecarboxylic acid acylates piperazine or 1-(2-aminoethyl)piperazine (at 25 °C for 24 h) with formation of 1,4-bis(ferrocenoyl)piperazine or 1-(2-ferrocenoylaminoethyl)-4-ferrocenoylpiperazine.¹⁹⁰

Ferrocene derivatives containing piperazine fragments have been synthesised by the nucleophilic substitution of the $\text{N}^+\text{Me}_3\text{I}^-$ or OAc groups in compound **42** on treatment with N-methylpiperazine.^{35,36}

R	R ¹	X	Ref.
P(O)Ph ₂	H	$\text{N}^+\text{Me}_3\text{I}^-$	35
PPh ₂	PPh ₂	OAc	35, 36

1,3,5-Tris(ferrocenylmethyl)hexahydro-1,3,5-triazine **333** has been obtained in 85% yield by the cyclocondensation of aminomethylferrocene with paraformaldehyde.¹⁹¹

Two methods of synthesis of ferrocenylpyrylium salts have been patented.¹⁴⁸ 2,6-Diferrocenylpyrylium perchlorate **334** has been synthesised by the reaction of the aldehyde **14** with orthoformic ester in the presence of perchloric acid.

4-Ferrocenyl-2,6-dimethylpyrylium perchlorate has been synthesised by another method—treatment of the lithio-derivative **335**, obtained from 2,6-dimethyl-4-pyrone and ferrocenyllithium, with perchloric acid.

The thermal decarboxylation of the acid salt **337** in boiling acetic acid in the presence of ferrocene leads to the formation of the ferrocenylpyrylium salt **338** (yield 47%).¹⁵⁰ The authors postulate a mechanism involving the insertion of a carbene intermediate in the $\text{Fc}-\text{H}$ bond.

The salt **338** has also been obtained as a result of the interaction of acetylferrocene with the chalcone $\text{PhCH}=\text{CH}-\text{COPh}$ in the presence of perchloric acid.¹⁵⁰

The interaction of the aldehyde **61** with the β -dicarbonyl compounds **339** on treatment with acetic anhydride in acetic acid can lead to various intermediates, which should be converted into the pyrylium salts **340** or **341** on treatment with perchloric acid (Scheme 4). It was found that treatment of the primary reaction product with ammonium acetate affords 3-acyl-6-ferrocenylpyrylium derivatives, which may be formed only from the salts **341**, demonstrating that the reaction proceeds via route *B*.¹⁴⁷

R	R ¹	Yield (%)

4-(2-Ferrocenylvinyl)-2,6-diphenylpyrylium **342** has been synthesised by three procedures:¹⁴⁹ by the reaction of the salt **343** with ferrocene (yield 55%), by the condensation of 4-methyl-2,6-diphenylpyrylium perchlorate with the aldehyde **14** (yield 88%), or by the condensation with ferrocene and orthoformic acid ester (yield 46%).

4-(2-Ferrocenylvinyl)-2,6-dimethylpyrylium perchlorate has been obtained by the last method from 2,4,6-trimethylpyrylium perchlorate (in 52% yield).¹⁴⁹

The 4-ferrocenylpyrylium salts **344** are formed in 81%–82% yields on refluxing the corresponding 2,6-diphenylpyrylium salts with ferrocene in acetic anhydride.¹⁴⁹

The methyl group in 2-methyl-4,6-diphenylpyrylium tetrafluoroborate exhibits an enhanced reactivity and condenses with the aldehyde **14** to form the derivative **345**.¹⁹²

In the presence of piperidine, the aldehyde **14** reacts with 3-acetyl-4-hydroxy-6-methyl-2-pyrone, affording the vinyl ketone **346**.¹⁹³

3-Aryl-5-ferrocenyl-5-oxovaleric acids **347** are dehydrated by trifluoroacetic anhydride and are converted into the dihydropyrone derivatives **348** in 92%–98% yields.¹⁹⁴

R = Ph, 4-MeOC₆H₄, 4-O₂NC₆H₄.

The cyclodehydration of 1-ferrocenylpentane-1,5-diol results in the formation of 2-ferrocenyltetrahydropyran.⁹⁶

The dehydration of the glutaric acid derivatives **349** by treatment with trifluoroacetic anhydride in CH₂Cl₂¹⁰⁹ or dichloroethane¹⁹⁵ with formation of the derivative **350** has been described.

R	R ¹	Yield (%)	Ref.
FcCH ₂	H	70	109
FcCH=		98	196

The ketoacid **351**, obtained as a result of the acylation of ferrocene with homophthalic anhydride, is converted into 3-ferrocenylisocoumarin on refluxing with a solution of HCl in ethanol.¹⁹⁶

The substitution of a hydrogen atom in compounds **352** by the ferrocenylmethyl group has been achieved by treatment with dialkylaminomethylferrocene derivatives in the presence of acetic anhydride.¹⁹⁷

R = Me (70%), Et (66%), Ph (92%); R¹ = Me, Et.

The tricyclic compound **353**, containing a 1,4-dioxane fragment, has been synthesised by heating 3,4,5,6-tetrachloro-*o*-benzoquinone with 3-ferrocenylthiethene.¹⁹⁸

The condensation of the ketone **23** with 6-formyl-1,4-benzodioxane leads to compound **354** in 54% yield.¹¹²

The acid-catalysed transesterification¹⁹⁹ of the acetal **355** leads to the 1,3-dioxane derivative **356**.

Thioacetylferrocene plays the role of the dienophile in relation to cyclopentadiene.²⁰⁰ The adduct **357** is obtained even at room temperature in the form of a mixture of the *endo*- and *exo*-isomers.

The reaction involving the conversion of the aldehyde **14** into an alkene by the ylide **358** afforded 2-ferrocenylmethylidene-1,3-dithiane **359** in 63% yield.²⁰¹

The preparation and certain properties of the isomeric *cis*- and *trans*-1,3,5-trithiacyclohexanes **360**, containing ferrocenyl substituents, have been described.²⁰²

The ratio of the *cis*- and *trans*-isomers depends on the medium in which the reaction is carried out. The ratio is 5:1 in EtOH-HCl and 1:4 in concentrated HCl. When the reaction is carried out in concentrated HCl in the presence of Na₂S₂O₃·5H₂O, mainly the *cis*-trithiane (yield 35%) and traces of the *trans*-isomer are formed.²⁰²

The synthesis of 2-ferrocenyl-1,3,5-trithiane **361** from the aldehyde **14** and bis(mercaptomethyl) sulfide **362** has been reported recently.²⁰³

The *N*-acylation of morpholine by the chloride of ferrocene-1,1'-dicarboxylic acid affords the dimorpholide **363** (yield 83%).²⁰⁴

The quaternary ammonium salt **42** alkylates morpholine, whereupon the N⁺Me₃I⁻ group is substituted by the heterocyclic group. The product **364** is formed in 92% yield.³⁵

Electrophilic substitution in the ferrocene nucleus on treatment with the aldehydes **365** under superacid conditions leads to the salts **129** (formed as a result of the acid-catalysed dehydration of the intermediate carbinols), which are converted on treatment with morpholine into α-morpholino-derivatives of ferrocene **366**, with yields of 49% to 59%.¹⁷⁸

The aldehydes **305** react with acetone cyanohydrin and morpholine, which affords the aminonitriles **367** (yields 93%–96%).¹⁷⁶

Compounds **368** have been synthesised by condensing carbonyl compounds of the ferrocene series with morpholine and phosphorous or phosphorothious acid esters.^{177, 205}

R	R ¹	X	Yield (%)	Ref.
H	Et	S	60	205
H	Me	O	55	177
H	Et	O	81	177

The addition of morpholine to the enones **94** leads to the pyrazolone derivatives **369** in 47%–57% yields.⁶⁹

Ar = Ph, 2,4-(O₂N)₂C₆H₃.

The chloride of ferrocene-1,1'-dicarboxylic acid acylates thiomorpholine with formation of the product **370** (yield 85%).²⁰⁴

In the presence of alcoholic alkali, 10-acetylphenothiazine **371** condenses with the aldehyde **14**; the reaction product is the unsaturated amide **372**.⁶⁶

2-Ferrocenyl-1,3-dithia-5-oxacyclohexane **373** has been synthesised from FcCHO and di(mercapto)ether **374**.²⁰³

On treatment with ferrocenyllithium, 2,4,6-triphenylphosphinine **375** gives rise to the anion **376**, which, on treatment with water, is converted into 1-ferrocenyl-2,4,6-triphenyl-1,2-dihydrophosphinine **377**. As a result of oxidative alkoxylation, the latter affords 1-ferrocenyl-1-methoxy-2,4,6-triphenylphosphinine **378**.²⁰⁶

The interaction of the phosphorine **375** with 1,1'-dilithioferrocene takes place similarly.²⁰⁶ The diphosphorylated ferrocene **379** is converted on treatment with water into the dihydrophosphinine **380**, which is converted into compound **381** after treatment with mercury acetate in ethanol.

The transmetalation of 1,1,4,4-tetramethyl-1,4-distannacyclohexa-2,5-diene **382** on treatment with dibromo(ferrocenyl)borane leads to 1,4-diferrocenyl-1,4-diboracyclohexa-2,5-diene **383**.²⁰⁷

One²⁰⁸ or two²⁰⁹ fluorine atoms in 2,2,4,4,6,6-hexafluorocyclotriphosphazene **384** can be substituted by ferrocenyl groups on treatment with ferrocenyllithium.

Apart from the monosubstitution product **386** (yield 31%), compound **387** was obtained (yield 20%) in the reaction of ferrocenyllithium with 2,2,4,4,6,6-hexachlorocyclotriphosphazene **385**. Compound **387** is evidently formed as a result of the interaction of the product **386** with the initial cyclophosphazene **385**.²⁰⁹

The interaction of the hexachloro-derivative **385** with 1,1'-dilithioferrocene proceeds in a more complex manner: the reaction products **388** and **389** contain a heterocyclic substituent only in one of the ferrocene rings.²⁰⁹

Two methods of synthesis of 2,2,6,6-tetrachloro-4-ferrocenyl-4-methylcyclotriphosphazene **390** were described in the same investigation: by treatment with iodomethane of the product of the reaction of FcLi with the hexachloro-derivative **385** or by the reaction of 4-bromo-2,2,6,6-tetrachloro-4-methylcyclotriphosphazene **391** with FcLi .

Interesting and unusual heterocyclic compounds—pyrazaboles **392**—have been synthesised by the reaction of 3-ferrocenylpyrazole with trimethylamine–borane or trimethylamine–diethylborane in boiling toluene.⁵⁷

R	Reaction time/h	Yield (%)

Et	8	35

The interaction of diferrocenyldithiatetraazadiarsocine **393** with norbornadienenchromium tetracarbonyl **394a** or norbornadienemolybdenum tetracarbonyl **394b** results in the formation of the complex tetracarbonyl(diferrocenyldithiatetraazadiarsocine)-chromium(0) **395a** and the corresponding molybdenum(0) complex **395b**.¹⁵

VI. Compounds containing heterocycles with more than six atoms

The synthesis of dihydro-1,2-diazepine derivatives **396a, b** from the diketone **397** on treatment with hydrazine or phenylhydrazine has been described.¹⁸¹

The 1,3-dihydrobenzo-1,4-diazepin-2-one derivatives **398** have been synthesised in two stages: by treating the ketoamides **399** with liquid ammonia and the subsequent cyclisation of the aminoketones **400** formed.²¹⁰

R = H, I.

The Wittig insertion of the ferrocenylvinyl fragment into the crown-ether derivatives **401** has been achieved²¹¹ by treatment with the ylide **402** under an inert atmosphere in the absence of light.

The crown-ethers **404**, containing a ferrocenyl substituent, have been synthesised (yields 25%–30%) by coupling the ferrocenium cation with the diazonium salts **403**.²¹²

The ferrocene derivatives **406**, containing two crown-ether fragments in the molecule, are formed in 80%–85% yields as a result of the acylation of the aza-crown-ethers **405** by the dichloride of ferrocene-1,1'-dicarboxylic acid in the presence of triethylamine.²¹³

Three ferrocenyl groups have been introduced into the triaza-crown-ether **407** by treatment with the ferrocenecarboxylic acid chloride in the presence of triethylamine and 4-dimethylaminopyridine (DMAP) (the yield of the product **408** was 85%).²¹⁴

The aza-crown-ethers **407** and **409** are smoothly alkylated by ferrocenylmethyl(trimethyl)ammonium iodide, affording the corresponding ferrocenylmethyl-substituted macrocycles.²¹⁴

The ferrocenyl-substituted crown-ethers **411**, containing oxygen and sulfur atoms in the ring, have been obtained from the aldehyde **14** by its conversion into an acetal with the aid of the bismercapto-derivatives **410** in the presence of Lewis acids.^{203, 215, 216}

The reaction of 2,2,4,4,6,6,8,8-octafluorocyclotetraphosphazene **412a** with ferrocenyllithium results in the formation of the products of the substitution of one or two fluorine atoms by the Fc groups (Scheme 5).^{208, 209}

Treatment of a mixture of hexachlorocyclotriphosphazene **385** and octachlorocyclotetraphosphazene **412b** with ferrocenyllithium leads to the formation of compounds **413**, containing cyclotriphosphazene and cyclotetraphosphazene fragments in the molecule.²¹⁷

Scheme 5

R = H, Cl.

Diferrocenyldithiatetraazadiarsocine **414** has been synthesised in 73% yield from dichloro(ferrocenyl)arsine and compound **415**.¹⁵

415

VII. Biological activities and applications of heterylferrocenes

It has been found that many heterylferrocenes exhibit a biological activity. Thus ferrocenyl-containing derivatives of 6-aminopenicillanic or 7-aminocephalosporanic acids have been recommended as effective antibiotics and inhibitors of β -lactamase.^{218, 219} The tetrafluoroborates and perchlorates of benzothiazolium derivatives inhibits the growth of staphylococci and streptococci as well as the yeast fungi of the genus *Candida*.¹⁴³ Derivatives of ferrocene-containing fragments of the diethyl esters of phosphonic and phosphonotheic acids and morpholine¹⁷⁷ or 1,3,4-triazole²⁰⁵ as well as thiophene and 1,3-thiazolidin-2-one rings¹³⁹ in the molecule exhibit an antimicrobial activity against both Gram-positive and Gram-negative microorganisms.

3-Ferrocenyl-1-(2-furyl)cyclopent-1-ene has been patented as an agent counteracting the anaemia induced by iron deficiency in

the organism.¹⁰⁶ The product of the condensation of 2,4,6-trichloro-1,3,5-triazine with the disodium salt of ferrocene-1,1',-dicarboxylic acid is active against a series of bacteria.²²⁰

The nonsilver photosensitive compositions and materials frequently include charge-transfer complexes (CTC). It has been stated that CTC based on the copolymer of vinylferrocene with *N*-vinylcarbazole and 2,4,7-trinitrofluorenone²²¹ as well as the copolymer based on 4-cyano(or phenyl)-3-ferrocenylisoxazolines and CBr₄ have been synthesised.^{131, 222} The products of the condensation of FcCHO with benzothiazole derivatives or with 1,3-diazolidine-2,4-dione have been recommended as components of nonsilver photosensitive compositions.¹⁹² Compounds containing the FcCH=CH groups and 1,3,4-oxadiazole rings may be used as electrophotographic materials.¹³⁷ Derivatives of 2,3-bis(2-ferrocenylvinyl)quinoxaline are electrophotographic semiconductors and are used in compositions for the preparation of effective and long-lived printing plates, which make it possible to obtain many thousands of impressions.²²³

2-Ferrocenyl-1,4-dimethyl-5,6-benzoquinolinium iodide is a dye for polyamide and polyester fibres.¹⁶⁴ Derivatives of ferrocene-containing quinoline and pyrazoline rings have been recommended as cyanine dye-sensitisers.^{17, 69, 70} Ferrocenyl-containing cyanine dyes with an indole ring fragment in the molecule have been described.⁴⁸

Heterylferrocenes are used as modifying agents which improve the operational characteristics of rocket fuels and explosive compositions. *N*-Ferrocenylmethylpyrrolidine has been used as an additive improving the ballistic and mechanical characteristics of rocket fuels.^{31, 32} 1,4-Bis(*N*-ferrocenyl)piperazine and analogous compounds,¹⁹⁰ 2-ferrocenyltetrahydrofuran,²²⁴ and 2-ferrocenyl-1-isopropenylcarborane²²⁵ may be used to regulate the rate of combustion of rocket fuels based on NH₄ClO₄. 2-Ferrocenyl-2-(hydroxypropyl)tetrahydrofuran has been proposed as a catalyst for the combustion of rocket fuel.¹⁰² 2-Ferrocenyltetrahydrofuran increases the rate of combustion of rocket fuel and its efficiency.²²⁶ 5-Ferrocenylmethylenebarbituric acid is a catalyst of the combustion of explosive compositions based on nitramines.¹⁸⁶

Crown-ethers containing a ferrocenyl group are interesting as regards practical use.^{212, 213, 216}

The polymers obtained by condensing furfural with ferrocene in the presence of AlCl₃ have been proposed as thermostable and radiation-resistant coatings, adhesives, and insulators.²²⁸ 6-(2-Ferrocenylvinyl)-2,4-diphenylpyrylium tetrafluoroborate has been patented as a dye-hardening agent for gelatin in photographic compositions.¹⁹² The polymer formed on heating ferrocenyldihydrobenzofuranone in the presence of ZnCl₂ or AlCl₃ exhibits an effective thermal stability and may be used in many fields: as a coating, as an adhesive, as an insulator, as an ion-exchange resin, as a combustion catalyst, as films resistant to irradiation, and as an inhibitor of the ageing of silicone rubbers and other elastomers.²²⁸

Isoxazoline derivatives containing ferrocenylalkyl groups in the 3-position exhibit pesticidal, herbicidal, acaricidal, and fungicidal activities and are plant growth regulators.¹³¹ It has been reported²²⁹ that the 4,5-diphenyloxazole derivative containing the NHN=CHFc group in the 2-position may be used to combat plant viruses.

V. Conclusion	91

Abstract. The results of studies on various properties of polyacetylene by the high-resolution EPR method in the 2 mm wavelength range are surveyed and treated systematically. The structures and dynamic properties of the paramagnetic centres as well as the mechanism of charge transfer in the neutral polyacetylene are discussed. The bibliography includes 76 references.

I. Introduction

During recent years, polyacetylene (PA) has attracted considerable attention by investigators because of the uniqueness of its electrodynamic properties, which may prove promising in molecular electronics. Thus when donor or acceptor dopants are introduced, its d.c. conductivity changes by 10–14 orders of magnitude and reaches $\sigma_{dc} \approx 10^5\text{--}10^7 \text{ S m}^{-1}$.^{1–3} PA is the simplest conducting polymer in a large class of organic conducting compounds (polyphenylene, polypyrrole, polythiophene, polyaniline, etc.) with similar magnetic and electrodynamic properties; this led to the most vigorous study of these properties in relation to this particular compound.

The *cis*- and *trans*-conformations of PA are distinguished, the latter being thermodynamically more stable.^{2,3} The morphology of this polymer depends on the method of synthesis, the structure of the initial monomer, and also on the nature and amount of the dopant introduced. The polymer chains of PA are arranged parallel to one another, forming a fibril several tens of nanometres in diameter and several hundreds of nanometres long. The longitudinal axes of the fibrils are usually randomly oriented in space, but they can be partly or fully oriented during synthesis or by stretching the resulting polymer. The polymer chains in such fibrils are close-packed. The PA crystal lattice has the following parameters: $a = 0.761 \text{ nm}$, $b = 0.439 \text{ nm}$, and $c = 0.447 \text{ nm}$ (*cis*-PA) and $a = 0.424 \text{ nm}$, $b = 0.732 \text{ nm}$, and $c = 0.246 \text{ nm}$ (*trans*-PA).^{4,5}

In each monomer unit of PA, three out of four valence electrons are in the hybridised sp^2 orbitals: two electrons

participate in the formation of two σ -bonds responsible for the formation of the quasi-one-dimensional (1D) lattice, while the third is involved in the formation of a bond with a hydrogen atom. The last valence electron is in the $2p_z$ orbital oriented at right angles to the plane in which the remaining three electrons are located. Thus the σ -bonds form a low-lying completely filled valence band, while the π -bonds of the monomer units form a partly filled conduction band. If the lengths of all the C–C bonds were equal, then undoped *trans*-PA could be regarded as a 1D-metal with a half-filled conduction band. In reality, the system represents a set of monomeric CH groups linked by alternating double and longer single bonds, which execute longitudinal vibrations. Such a system is unstable (Peierls instability) and the alternation in it takes place almost without energy expenditure. Calculation has shown⁶ that the degeneracy of the system leads to the generation on the *trans*-PA chains (with an energy expenditure of 0.42 eV) of nonlinear topological excitations — solitons — with a spin $s = \frac{1}{2}$, an effective number of C–C bonds $N \approx 15$, an effective mass m_s^* equal to six times the free electron masses m_e , and a high 1D-mobility. The energy level of the solitons is located at the centre of the energy gap of the polymer. This phenomenon determines to a large extent the fundamental properties of *trans*-PA, including the relatively large width of the energy gap, which is $\sim 1.4 \text{ eV}$. Some experiments (see, for example, Refs 7–9) yield the effective number of C–C bonds $N \approx 50$ and $m_s^* = (0.15 - 0.40)m_e$.

The spin–charge conversion is characteristic of a single soliton in *trans*-PA: the neutral soliton corresponds to a radical with a spin $s = \frac{1}{2}$, whereas a negatively or positively charged soliton lacks spin and becomes diamagnetic. Therefore, in n-type doping, the energy level of the soliton becomes fully occupied, whilst in p-type doping it becomes entirely unoccupied. For a low level of doping, only some of the neutral solitons become charged. With increase in the level of doping, all the solitons become diamagnetic and their individual energy levels merge into the soliton band located in the middle of the energy gap of the polymer. The formation of the soliton band leads to charge transfer by the spin-free carriers after the semiconductor–metal transition. This conduction mechanism, which includes the motion of charged solitons in an occupied or unoccupied band, differs significantly from the charge transfer process in classical semiconductors.

In PA, there is the possibility of the occurrence of various charge transfer processes, which may be arranged in the following sequence in order of their decreasing probability: 1D-conduction along polymer chains; charge transfer in hops between polymer chains; tunnelling of the charge between highly conducting

domains of fibrils separated by regions with a lower conductivity; or fluctuation-induced tunnelling of the charge between fibrils.

It is entirely evident that the contribution of each of these processes depends on the properties of the initial polymer and may change during its doping.

Conjugated polymers are characterised by the presence of a π -electron system and a partly filled band structure, which determines important electronic properties of these systems. In contrast to the classical semiconductors, apart from the activated electron transport,¹⁰ in PA there is also the possibility of phonon-assisted charge tunnelling between the energy levels of solitons¹¹ and of variable range hopping conductivity (VRH)¹² characterised by different frequency and temperature dependences $\sigma(\nu_e, T)$. Such diversity of electron transport is associated with the generation of nonlinear soliton-type excitations and may be associated directly with the evolution of both the crystalline and the electronic structures of the system.

Several theoretical approaches have been put forward for the description of the mobility of the soliton in *trans*-PA. They were developed in terms of the concept of the Brownian 1D-diffusion of solitons interacting with the lattice phonons¹³ and of the scattering of solitons by optical and acoustic phonons in *trans*-PA.¹⁴ One of them predicts a quadratic dependence of the frequency of the 1D-diffusion $\nu_{1D} = D_{1D}c_{||}^{-2}$ (D_{1D} is the 1D-diffusion coefficient and $c_{||}$ is the length of the soliton jump along the polymer chain) on temperature. In the second case, the dependences have the form $\nu_{1D}(T) \sim T^{-1/2}$ and $\nu_{1D}(T) \sim T^{1/2}$ for the optical and acoustic phonons respectively. Calculations showed¹⁵ that the frequency of the 1D-diffusion of the soliton should not exceed the limiting value $\nu_{1D}^F = 3.8 \times 10^{15}$ Hz near the Fermi level.

Many fundamental properties of PA and other conjugated polymers are determined by the existence in them of the localised paramagnetic centres (PC) and/or such centres delocalised along the polymer chains, so that the majority of the investigations of these compounds have been carried out by the EPR method.^{16,17} We shall consider certain possibilities for the study of PA by this method.

At relatively low measuring frequencies ($\nu_e \leq 10$ GHz), PA gives rise, like the classical π electron systems, to a single symmetrical EPR line with $g = 2.002634 \pm 0.000015 \approx g_e$.¹⁸ The g -factor deviates from g_e mainly owing to some contribution by the orbital angular momentum of the unpaired electron to its overall magnetic moment. The EPR line consists of a superposition of individual weakly resolved lines corresponding to the hyperfine interaction of the spin with the carbon nuclei on which the soliton is localised.

According to the model proposed by Su et al.,⁶ the defect-free undoped *cis*-PA contains no paramagnetic centres and should therefore be diamagnetic. In reality, *cis*-PA contains 5%–10% of short segments of *trans*-PA, mainly at the ends of the chains^{3,16} where the trapping of solitons is most likely.¹⁹ Such an isomer therefore gives rise to a relatively weak broad EPR line, in which the distance between the peaks is $\Delta B_{pp} = 0.6$ –1.0 mT ($g = 2.002634$) and the hyperfine interaction tensor constants are $A_{xx} = -1.16$ mT, $A_{yy} = -3.46$ mT, and $A_{zz} = -2.32$ mT²⁰ (the x , y , and z axes are directed along the crystallographic a , c , and b axes respectively). On thermal *cis*–*trans* isomerisation, the concentration of paramagnetic centres increases from $N \sim 10^{18}$ spins g^{-1} (this is equivalent to one spin per $\sim 44\,000$ CH groups) in *cis*-PA to $N \sim 10^{19}$ spins g^{-1} (or one spin per 3000–7000 CH groups) in *trans*-PA.²¹ This is accompanied by a sharp narrowing of the line of 0.03–0.50 mT.^{16,22} The latter quantity depends on the average length of the *trans*-sections and represents a linear function of the concentration of the sp^3 -defects.²³ A dependence of the type $\Delta B_{pp} \sim Z^{2.3}$ has been obtained for PA doped with metal ions having an atomic number Z .²⁴ The line width of *trans*-PA partially ordered by stretching proved sensitive to the direction of stretching c of the specimen in a magnetic field with a strength

B_0 .^{23,25–28} Thus, in the case of the parallel direction of the external magnetic field strength vector relative to the c axis, the line width is 0.48 mT, whilst in the case of the perpendicular direction it is 0.33 mT.²³

The EPR spectrum of *trans*-PA may be represented by a superposition of the contributions of the trapped and highly mobile solitons with concentrations n_1 and n_2 respectively, the ratio of which varies with temperature, and also of the contributions due to other fixed centres, the appearance of which is associated with the presence of traces of catalyst and/or oxygen molecules. In n - and p -doping, the concentration of paramagnetic centres in *trans*-PA changes monotonically for a virtually constant g -factor,^{16,17} which indicates the retention of the nature of the paramagnetic centres responsible for the EPR signal.

Numerous studies on the paramagnetic susceptibility χ of neutral PA have shown¹⁷ that both its conformers exhibit Curie paramagnetism ($\chi \sim T^{-1}$) at $T \leq 300$ K, whereas, according to the data of Tomkiewicz et al.,²⁹ the magnetic susceptibility of *cis*-PA does not obey the Curie law in the temperature range 4–300 K. The reasons for this discrepancy are so far obscure.

High-frequency magnetic field modulation as well as electron spin-echo have been used to investigate the interaction of the unpaired electron with other electrons or with the *trans*-PA lattice. Since a neutral soliton has an electron spin interacting with the spins of the hydrogen nuclei, its dynamics may be investigated by complementary NMR and EPR methods.

The quasi-one-dimensional mobility of the soliton has been investigated by NMR within the framework of the Brownian 1D-diffusion of the soliton.^{30,31} The dependence of the nuclear spin–lattice relaxation time τ_1 on the precession frequency of the nuclear spin $\tau_1 \sim \nu_p^{1/2}$, obtained for undoped and doped *trans*-PA specimens, corresponded to the characteristic spectrum of the spin 1D-diffusion. The frequency of the 1D-diffusion of the soliton in undoped *trans*-PA proved to be 6×10^{14} Hz (at room temperature) and showed a quadratic temperature dependence. Estimates showed³⁰ that the rate of diffusion may increase by more than three orders of magnitude following the introduction of various dopants into the polymer.

However, it must be emphasised that the motion of the soliton influences only indirectly the nuclear spin relaxation time. Since the interaction of the diffusing proton with a fixed electron spin is also characterised by the frequency dependence $\tau_1 \sim \nu_p^{1/2}$,³² this can lead to an incorrect interpretation of the results obtained by NMR spectroscopy. Thus, on the basis of the kinetics of the decay of the ^{13}C NMR signal, it has been concluded³³ that there are no mobile unpaired electrons at all in *trans*-PA. However, according to Ziliox et al.,³⁴ this conclusion may be valid only for the specific specimens investigated by Masin et al.³³

The EPR spectroscopic method is a priori more effective in the study of the dynamics of the soliton in *trans*-PA, since the electronic relaxation times are unambiguously related to the diffusion of the soliton.

The spin dynamics in *trans*-PA has been investigated with the aid of low-frequency steady-state EPR^{26–28,35,36} and the spin-echo method.^{37–39} The relations $\tau_{1,2} \sim \nu_e^{1/2}$ and $\nu_{1D}(T) \sim T^2$ (τ_1 and τ_2 are the spin–lattice and spin–spin relaxation times) were obtained by the first method in the frequency range $\nu_e = 5$ –450 MHz. They indicate the 1D-diffusional spin motion in *trans*-PA with $\nu_{1D} \geq 10^{13}$ Hz and the anisotropy $\nu_{1D}/\nu_{3D} = 10^6$ – 10^7 (at room temperature). A similar frequency dependence of the rate of diffusion has been observed also at higher recording frequencies $\nu_e = 9$ –14 GHz.^{38,40} However, the spin diffusion frequency determined by the spin-echo method is $\nu_{1D} \leq 10^{11}$ Hz (at room temperature) and exhibits a more complex temperature dependence.³⁷

Thus the data obtained by different methods and by different investigators concerning the dynamics of solitons in *trans*-PA are extremely contradictory and do not always find an unambiguous interpretation. EPR spectroscopy is the most promising method

for the investigation of the composition and dynamics of the paramagnetic centres. However, it suffers from considerable limitations owing to the low spectral resolution and the high spin-spin exchange at $\nu_e \leq 40$ GHz. This prevents the separate recording in *trans*-PA of localised and mobile π -radicals with similar magnetic parameters.²²

It had been shown earlier in relation to certain organic radicals^{41,42} that in the 2 mm wavelength range there is a significant increase in the accuracy and the information content of the EPR method in the study of the structure and molecular dynamics of radicals with $g \approx g_e$ in model systems and biological polymers. The high resolving power of the method, attained in this frequency range, converts the g -factor of organic free radicals into an important information parameter. This makes it possible to discover the anisotropic character of the slow molecular motions, to extend the range of the measured correlation times for the rotation of the radical, and also to identify the structure of the radical and of its microenvironment.

The high spectral resolution of the EPR method in the 2 mm range yields important information about the spin and molecular dynamics in organic conducting compounds.⁴³ The present review is devoted to the consideration of the experimental data obtained in the study of the structure and electrodynamic properties of PA by two-millimetre EPR spectroscopy. The theoretical foundations of the method have been described in fair detail in a number of monographs† and will not therefore be considered here.

II. Magnetic parameters of the charge carriers in *trans*-polyacetylene

For a more correct determination of the magnetic resonance parameters of the paramagnetic centres in PA, various films of *cis*- and *trans*-PA were investigated over a wide EPR frequency range.⁴⁴

In the 3 cm EPR range ($\nu_e = 9.8$ GHz), the *cis*- and *trans*-PA specimens are characterised by a single symmetrical line with $g = 2.0026$ and the width between the peaks $\Delta B_{pp} = 0.67$ mT (*cis*-PA) and 0.22 mT (*trans*-PA) (Fig. 1). The latter quantity exceeds the minimum width of the *trans*-PA spectral line,¹⁶ and is apparently associated with the presence in the specimen of oxygen molecules or shorter π -conjugated chains, but is within the limits of the variation of the ΔB_{pp} obtained for different *trans*-PA specimens.²² This line is broadened by 0.05–0.17 mT at 77 K, probably as a consequence of the decrease in the frequency of the librations of the polymer chains and is additionally broadened by 0.1 mT when the polymer comes into contact with atmospheric oxygen, apparently owing to the strengthening of the trapping of the mobile solitons in *trans*-PA.⁴⁵

An increase in the recording frequency to 37.5 GHz results in a slight increase in the width of the lines in the PA spectrum (Table 1) with retention of the symmetry.

In the 3 mm EPR range, the line width of the *cis*-PA spectrum increases to 0.84 mT. This is accompanied by an additional broadening of the high-field spectral peak owing to the manifestation of the anisotropy of the g -factor. *trans*-PA is characterised by a line with $g = 2.00270$, $\Delta B_{pp} = 0.37$ mT, and the asymmetry factor $A:B = 1.1$ (the ratio of the amplitudes of the high-field and low-field spectral peaks).

Figure 1. EPR spectra of *cis*-(I) and *trans*-polyacetylene (II) recorded in the 3 cm (a), 2 mm (b), and 0.6 mm (c) ranges at room temperature under an inert atmosphere. The positions of the components of the g -tensor of the localised solitons (g_{\parallel} and g_{\perp}) and the g_s -factor of the delocalised solitons are indicated.

Table 1. The line widths (in mT) and the distances between the spin packets (in Hz) for the paramagnetic centres in neutral polyacetylene at different recording frequencies at 300 K.

ν_e /GHz	ΔB_{pp}			$\Delta\omega_{ij} \times 10^8$		
	I	II	III	I	II	III
9.8	0.70	0.25	0.06 ^a	1.7	1.0	0.8 ^a
37.5	0.75	0.30	0.11 ^a	1.8	1.2	1.3 ^a
94.3	0.85	0.45	0.18	1.9	1.4	1.7
139	0.95	0.61	0.30	2.3	2.2	2.2
250	1.82	1.60	0.50	2.8	2.8	2.9
349	2.42	2.52	0.62	3.2	3.5	3.2
428	2.53	1.91	0.81	3.3	3.1	3.7

Remarks. I—solitons localised in *cis*-PA; II—solitons localised in *trans*-PA; III—solitons delocalised in *trans*-PA.

^a Values obtained by extrapolation.

In the 2 mm range for the recording of the EPR spectrum, there is a further increase in ΔB_{pp} to 1.1 mT (in *cis*-PA) and 0.5 mT (in *trans*-PA) accompanied by a more marked manifestation of the anisotropy of the g -factor in *cis*-PA and a greater asymmetry of the spectral line ($A:B = 1.3$) in *trans*-PA (Fig. 1).

In order to elucidate the possible dependence of the PA spectral line width on the orientation of the magnetic field, a study has been made⁴⁶ of partly oriented *cis*- and *trans*-PA specimens. The investigation showed that the line width in the spectrum of the initial *cis*-PA specimen increases after slight stretching of the film from 1.23 to 1.45 mT ($T = 300$ K).

† J D Memory *Quantum Theory of Magnetic Resonance Parameters* (McGraw-Hill, New York, 1968)

B Ranby, J F Rabek *EPR Spectroscopy in Polymer Research* (Springer, Berlin, 1977)

C P Slichter *Principles of Magnetic Resonance* 2nd Ed. (Springer, Berlin, 1978)

Theoretical Foundations of Electron Spin Resonance Ed. J E Harriman (Academic Press, New York, 1978)

The magnetic parameters of the partly oriented *cis*-PA did not change significantly on varying the angle between the directions of stretching and the external magnetic field, whereas the line width in *trans*-PA changed nonmonotonically from 0.60 to 0.68 mT at room temperature.

With increase in the recording frequency, a further broadening and a further increase in the asymmetry of the EPR spectral lines of both conformers were observed (Fig. 1). Analysis carried out by the method described by Lebedev and Muromtsev⁴⁷ showed that the spectrum of *cis*-PA, presented in Fig. 1, may be assigned to paramagnetic centres with the g -tensor components $g_{\parallel} = 2.00283(5)$ and $g_{\perp} = 2.00236(5)$ (g_{\parallel} and g_{\perp} correspond to the parallel and perpendicular directions of the external magnetic field relative to the crystallographic c axis of the polymer chain). The values of the g -tensor quoted exceed somewhat the values of g_{\parallel} and g_{\perp} determined experimentally⁴⁸ but are close to $g_{\parallel} = 2.0034$ and $g_{\perp} = 2.0028$ calculated in the same study for localised paramagnetic centres. The quantity g_{\parallel} differs from g_e by $\Delta g = 5 \times 10^{-4}$. This deviation corresponds to the excitation of the electron from the bonding σ_{C-C} orbital to the antibonding π^* orbital with $\Delta E_{\sigma\pi^*} = 2\lambda_c \Delta g^{-1} = 14.4$ eV (here $\lambda_c = 3.6$ meV is the constant for the spin-orbital interaction of the unpaired electron with the nucleus of the carbon atom), which is close to the corresponding value calculated for the C-C bond in π -conjugated systems.⁴⁹ Other electronic transitions with a greater ΔE_{ij} do not contribute significantly to Δg . Thus the line form in the *cis*-PA spectrum as well as the agreement between the experimental and theoretical values of $\Delta E_{\sigma\pi^*}$ indicate the existence of localised paramagnetic centres in this isomer.

The transformation of the line shape on *cis-trans* isomerisation of PA evidently indicates the appearance in the PA of mobile paramagnetic centres with $g_s = 2.00268$ (Fig. 1) during the occurrence of this process. The similarity of the isotropic g -factor of the localised paramagnetic centres [$\langle g \rangle = \frac{1}{3}(g_{\perp} + 2g_{\parallel}) = 2.00267$] and the g -factor of the delocalised paramagnetic centres indicates the virtually complete averaging of the components of the g -tensor of the mobile paramagnetic centres owing to their 1D-diffusion at a minimal rate.⁵⁰

$$\nu_{1D}^0 \geq \frac{1}{h} (g_{\parallel} - g_{\perp}) \mu_B B_0 \quad (1)$$

Computer simulation⁴⁴ confirmed this hypothesis. A similar averaging of the components of the anisotropic g -factor was recorded by ourselves also on 'unfreezing' the 1D-diffusion of polarons in other organic conducting polymers.⁴³ Thus two types of paramagnetic centres exist in undoped *trans*-PA, namely the neutral soliton trapped at the ends and/or on short segments of the π -conjugated chain¹⁹ and the soliton moving along the polymer chain with a frequency $\nu_{1D}^0 > 2 \times 10^8$ Hz. The value of ν_{1D}^0 obtained is significantly less than the lower limit of the rate of diffusion of solitons previously predicted.³⁰ The concentrations of the corresponding paramagnetic centres are $n_1 = 1.1 \times 10^{-3}$ and $n_2 = 6 \times 10^{-5}$ spins per carbon atom. It is necessary to note that the latter quantity is almost two orders of magnitude smaller than the value predicted previously.^{18,51}

Analysis of the form of the spectra of *cis*- and *trans*-PA specimens by the method of Tikhomirova and by Voevodskii⁵² showed that, for $\nu_e \geq 140$ GHz, the distribution of the individual spin packets in their low-field sections is described by Lorentzian (at the centre) and Gaussian (on the wings) functions. On the other hand, the high-field parts of the spectra are characterised by a Lorentzian distribution of the spin packets. This made it possible to calculate the frequencies of the spin-spin exchange ν_{ex} between the localised paramagnetic centres in *cis*- and *trans*-PA, which are 3×10^7 and 1.2×10^8 Hz respectively. These quantities are consistent with $\nu_{ex} \geq 10^7$ Hz obtained for *trans*-PA.²² Thus, at a recording frequency $\nu_e \geq 16$ GHz, the distance between the spin packets $\Delta\omega_{ij}$ exceeds ν_{ex} , so that the spin packets may be regarded as virtually noninteracting and the

width of the lines of the localised paramagnetic centres is described by the equation⁵³

$$\Delta B_{PP} = \Delta B_{PP}^0 + \frac{\Delta\omega_{ij}^2}{8\nu_{ex}}, \quad (2)$$

where ΔB_{PP}^0 is the line width in the absence of interaction between the paramagnetic centres. Assuming that the relaxation time τ_2^{mob} of the delocalised paramagnetic centres is 1.8×10^{-7} s for *trans*-PA at room temperature⁵⁴ and taking into account the strong interaction between solitons with different mobilities, it is possible to calculate the line width in the spectrum of the mobile soliton ΔB_{PP} , which proved to be 32 μ T. This quantity agrees well with the line width in the spectrum of the mobile soliton (12–38 μ T) predicted by Holczer et al.²²

The values of $\Delta\omega_{ij}$ calculated for the paramagnetic centres in *cis*- and *trans*-PA by Eqn (2) are presented in Table 1. The table shows that the isomerisation of PA is accompanied by a decrease in $\Delta\omega_{ij}$ for the paramagnetic centres in both conformers. Taking into account the increase in ν_{ex} indicated above, one may conclude that the change of precisely these quantities is the cause of the sharp narrowing of the EPR spectra (for $\nu_e \leq 10^{10}$ Hz) during the *cis-trans* isomerisation of PA. This conflicts with the view current up to the present time that the line narrowing indicated above is possible only by virtue of the 'unfreezing' of the 1D-diffusion of most of the solitons in *trans*-PA.^{13,16,30}

The dependences of the broadening of the lines of the localised and mobile paramagnetic centres on the measuring frequency are illustrated in Fig. 2. The latter shows that the line width in the spectrum of the paramagnetic centres localised in both conformers varies almost quadratically with ν_e , in conformity with Eqn (2), which constitutes additional evidence for the weak interaction of the spin packets in PA. On the other hand, the line width in the spectrum of the delocalised paramagnetic centres increases in accordance with the law $\Delta B_{PP}^{\text{mob}} \sim \nu_e^{3/2}$, which is a consequence of the stronger spin-phonon interaction in *trans*-PA owing to the 1D-motion of the solitons.

Figure 2. Logarithmic dependences of the broadening ($\delta\Delta B_{PP}$) of the EPR lines of the paramagnetic centres localised in *trans*-polyacetylene (line 1) and *cis*-polyacetylene (line 2) (relative to the quantity ΔB_{PP}^0 measured at 9.8 GHz), as well as the paramagnetic centres delocalised in *trans*-polyacetylene (line 3) (relative to the quantity ΔB_{PP}^0 measured at 94.3 GHz) on the recording frequency at room temperature.

It is seen from the analysis of Table 1 that, at least for $\nu_e \leq 140$ GHz, the following familiar relation holds:⁵⁵

$$(\Delta B_{PP}^{\text{mob}})^3 = \frac{\gamma_e (\Delta B_{\perp}^{\text{loc}})^4}{\nu_{1D}'} \quad (3)$$

where γ_e is the gyromagnetic ratio for the electron. This follows from the theory of random motion and characterises the line narrowing in the EPR spectrum of a semiconductor when spin 1D-diffusion arises in the latter with an effective rate $\nu'_{1D} \approx 2 \times 10^{11}$ Hz.⁵⁶ We may note that another relation is valid for spin 3D-motion:

$$\Delta B_{pp}^{\text{mob}} = \frac{\gamma_e (\Delta B_{\perp}^{\text{loc}})^2}{\nu'_{1D}}.$$

This constitutes additional evidence for the 1D-diffusion of solitons in *trans*-PA. For $\nu_e > 140$ GHz, Eqn (3) does not hold, apparently owing to the similarity of the quantities ν_e and ν'_{1D} .

Fig. 3a presents the temperature dependences of the reduced concentrations of the paramagnetic centres (N) of certain *cis*-PA specimens, which can be fitted by the following function:

$$N(T) = A \exp\left(-\frac{E_a}{kT}\right) + BT^{-n} \quad (1 \leq n \leq 2), \quad (4)$$

where A and B are constants and E_a is the activation energy. The first term of Eqn (4) is determined by the librations of the polymer chains, the activation energies of which for different specimens are 0.035–0.055 eV. A similar manifestation of the electron–phonon interaction (mainly in the form of fluctuations of the electronic polarisation energy of the order of several millielectron volts) has been observed in organic crystalline semiconductors.⁵⁷ As can be seen from the figure, the activated ordering of the magnetic moments of the spins makes the main contribution to the paramagnetic susceptibility only at high temperatures. In the range of temperatures below a critical temperature $T_c \approx 150$ K, this process competes with others, in particular with the process described by the Curie equation ($n = 1$). The contributions of the processes involving the orientation of the magnetic moments of the unpaired electrons are different for different *cis*-PA specimens.

The concentration of the paramagnetic centres in the *trans*-PA specimens is also characterised by an anomalous temperature dependence (Fig. 3b). As in the case of *cis*-PA, the main contribution to the paramagnetic susceptibility of *trans*-PA in the high-temperature region comes from the first term of Eqn (4). The increased value of E_a ($E_a = 0.06 - 0.19$ eV) may be explained by the increase in the rigidity of the polymer chains and in their packing density on *cis*–*trans* isomerisation. This is apparently

also the cause of the shift of the critical temperature into the region $T_c \approx 250$ K.

In contrast to *cis*-PA, *trans*-PA is characterised by a steeper initial section of the $N(T)$ curve at $T < T_c$. [The quantity n in Eqn (4) varies from 1 to 4 for the *trans*-PA specimens obtained] and reaches a plateau at $T \leq 140$ K. The latter fact is analogous to the manifestation of the so called magnetic saturation. However, for the given temperature range, magnetic saturation may occur when the condition $g\mu_B SB_0 > kT$ is fulfilled, i.e. for $B_0 > 100$ T, which greatly exceeds the magnetic field strength $B_0 \leq 5$ T used in our experiments. Most probably, this effect may be induced by the significant increase in the concentration of neutral solitons with an amplitude A and hence by the shortening of the inter-radical distance R and the intensification of the interaction between these charge carriers with the probability $W_R \sim A \exp(-2AR)$.⁵⁸ Furthermore, the ‘unfreezing’ of the 1D-diffusion of a proportion of solitons at a rate ν_{1D} leads to an additional increase in the probability of the intersoliton interaction $W_{ss} \sim \nu_{1D} \sim \nu_{1D}^0 T^{-2}$ (see below). As a consequence of the overlap of the wave functions of the unpaired electrons of neighbouring solitons, their discrete levels, located in the energy gap, are broadened and transformed into a soliton band of finite width. As in the case of *cis*-PA, the constants A , B , and n are determined by the different properties of the *trans*-isomer.

The study of *trans*-PA specimens lightly doped with iodine vapour has shown⁵⁴ that the form of the spectra and the ratio of the concentrations of the mobile and localised paramagnetic centres do not vary. This finding agrees with the earlier hypothesis⁴⁵ of the existence in *trans*-PA of both mobile solitons and solitons trapped in short conjugated sections of the chain. Although the paramagnetic centres indicated do in fact have different mobilities, in the course of the doping process they acquire a charge with equal probabilities and become diamagnetic.

The magnetic properties of PA thus depend significantly both on the conformation of the polymer chains and on the concentration and mobility of the neutral solitons. In the *cis*–*trans* isomerisation of the initial PA specimen, the concentration of the trapped solitons increases appreciably and mobile charge carriers appear. The ‘unfreezing’ of the mobility of a small proportion of the solitons does in fact increase the conductivity of the film by several orders of magnitude. The transition to high fields for the recording of the EPR spectra increases significantly the resolution of the method and diminishes the probability of the

Figure 3. Temperature dependences of the concentrations of the paramagnetic centres in specimens 2 (1), 4 (2), 6 (3), and 5 (4) (Table 2) of (a) *cis*- and (b) *trans*-polyacetylenes relative to values measured at room temperature.

interaction between paramagnetic centres having different mobilities, which makes it possible to analyse more correctly and accurately the magnetic properties of the localised and delocalised solitons in PA.

III. Passage effects and the electronic relaxation of the charge carriers in polyacetylene

With increase of the amplitude of the magnetic component of the UHF field B_1 , dome-shaped components with a Gaussian distribution of the spin packets were recorded in the 2 mm EPR spectra of *cis*- and *trans*-PA (Fig. 4).^{54,59} The intensity and form of these components depend on the amplitude B_m and the frequency ω_m of the HF modulation, the quantity B_1 , and the relaxation times of the paramagnetic centres. The appearance of these signals is associated with the manifestation of the effects of the rapid adiabatic passage of a nonuniformly ordered line.⁶⁰ Such passage effects had not been recorded previously in the study of PA in the frequency range $\nu_e \leq 37$ GHz.¹⁶ The following explanation of this finding can be put forward. The form of an individual spin packet in PA is determined by a set of time characteristics: τ_1 , τ_2 , $(\gamma_e \Delta B_{PP})^{-1}$, ω_m^{-1} , $(\gamma_e B_m)^{-1}$, $(\gamma_e B_1)^{-1}$, and $B_1(dB_0/dt)^{-1}$.

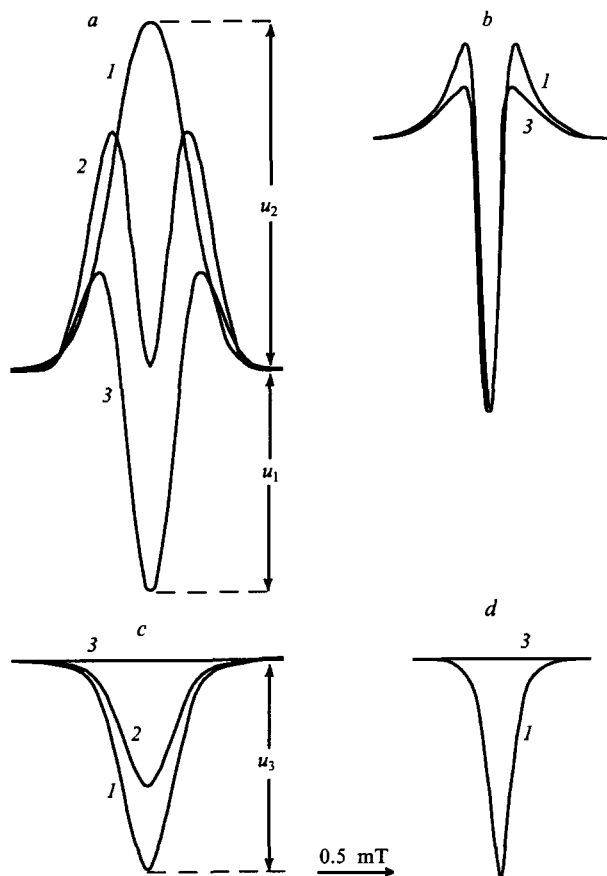

Figure 4. In-phase (a, b) and quadrature (c, d) components of the first derivatives of the dispersion signals of specimens of *cis*-(a, c) and *trans*-PA (b, d) recorded in the two-millimetre EPR range for different values of B_1 (mT): (1) 0.2; (2) 0.2–20; (3) 20.

On transition to high magnetic fields, the probability of the cross-relaxation of the paramagnetic centres with $s = \frac{1}{2}$ and $g \approx 2$, localised at a distance $r_{1,2}$, diminishes in accordance with the law⁶¹

$$W_{cr} \sim r_{1,2}^{-3} \exp(-0.25 B_0^2 r_{1,2}^6 \mu_B^{-2}),$$

as a consequence of which the interaction between the spin packets diminishes and they may be saturated under the usual experimental conditions. When the conditions for the saturation of the signal [$s = \gamma_e B_1(\tau_1 \tau_2)^{1/2} \geq 1$] and for the adiabatic nature of the passage of its envelope ($\gamma_e \omega_m B_m \ll \gamma_e^2 B_1^2$) are fulfilled and also when the signal passage time exceeds the effective relaxation time $\tau = (\tau_1 \tau_2)^{1/2}$, i.e. $B_1(dB_0/dt)^{-1} \gg \tau$, there is insufficient time for the relaxation processes to influence significantly the nature of the motion of the magnetisation vector M of the paramagnetic centres during the period of its precession around the direction B_m . The repeated passage through resonance leads to the establishment of a stationary trajectory of the vector M and to the appearance of three components (u_1, u_2, u_3) of the dispersion signal U with the shape function $g(\nu_e)$.⁶²

$$U = u_1 g'(\nu_e) \sin(\omega_m t) + u_2 g(\nu_e) \sin(\omega_m t - \pi) + u_3 g(\nu_e) \sin(\omega_m t \pm \pi/2), \quad (5)$$

along the z , $-z$, and $-x$ axes respectively. These components can be recorded separately with the appropriate tuning of the phase detector of the instrument. The contribution of each component u_i depends on the ratio of τ to the rate of passage through resonance $B_1(dB_0/dt)^{-1}$. Evidently $u_2 = u_3 = 0$ when $s \ll 1$. In this case, the classical u_1 dispersion signal is recorded. When the inequality $B_1(dB_0/dt)^{-1} \geq \tau$ holds, the vector M has sufficient time to relax to the equilibrium state during each modulation period and the U dispersion signal is determined mainly by the components $u_1 g'(\omega_e)$ and $u_3 g(\omega_e)$ with the intensities at the centre of the spectrum (for $\nu = \nu_e$)

$$u_1 = M_0 \pi \gamma_e^2 B_1 B_m \quad \text{and} \quad u_3 = \frac{1}{2} M_0 \pi \gamma_e^2 B_1 B_m \tau_1 \tau_2.$$

At a low rate of relaxation, the spin 'sees' only an average applied field and the signal is described by the integral terms of Eqn (5) with the central intensities

$$u_2 = \frac{1}{2} M_0 \pi \gamma_e^2 B_1 B_m \tau_2 \quad \text{and} \quad u_3 = M_0 \pi \gamma_e^2 B_1 B_m \tau_2 (4\omega_m \tau_1)^{-1}.$$

The case $\omega_m \tau_1 > 1$ occurs for *cis*-PA, so that the dispersion signal is determined mainly by the last two terms of Eqn (5). Calculations have shown^{54,59} that in this case the relaxation times may be calculated from the ratio of the central amplitudes of these components by means of the following formulae:

$$\tau_1 = \frac{3\omega_m(1+6\Omega)}{\gamma_e^2 B_{10}^2 \Omega(1+\Omega)}, \quad (6a)$$

$$\tau_2 = \frac{\Omega}{\omega_m}, \quad (6b)$$

where $\Omega = u_3 u_2^{-1}$, and B_{10} is the value of the component B_1 for which the condition $u_1 = -u_2$ holds.

In the EPR spectra of *trans*-PA, the passage effects are manifested to a much lesser extent (Fig. 4). The condition $\omega_m \tau_1 < 1$ holds for this substance, so that the relaxation times can be calculated by the formulae^{54,59}

$$\tau_1 = \frac{\pi u_3}{2\omega_m u_1}, \quad (7a)$$

$$\tau_2 = \frac{\pi u_3}{2\omega_m(u_1 + 11u_2)}. \quad (7b)$$

The temperature dependences of the quantities τ_1 and τ_2 , determined from the 2 mm EPR spectra of the specimens of *cis*- and *trans*-PA of different thickness and obtained under different conditions of synthesis, are presented in Table 2 in the functional form $\tau_{1,2} = AT^a$. Fig. 5 presents the functions $\tau_1(T)$ and $\tau_2(T)$ for

Table 2. Temperature dependences of the relaxation times [$\tau_{1,2} = AT^\alpha(s)$] for different *cis*- and *trans*-polyacetylene specimens.

Remarks. The measurements were performed

^a in the presence of atmospheric oxygen,

^b after storage for 6 months under an inert atmosphere,

^c after doping with iodine vapour up to $\sigma_{dc} \approx 10 \text{ S m}^{-1}$,

^d after annealing under an inert atmosphere. Specimens 1–8 investigated were obtained under different conditions and had different thicknesses.

Figure 5. Temperature dependences of the spin–lattice (τ_1) (lines 1 and 3) and spin–spin (τ_2) (lines 2 and 4) relaxation times of *cis*–(lines 1 and 2) and *trans*–polyacetylenes (lines 3 and 4).

the *cis*- and *trans*-isomers of PA (No. 4 in Table 2). It is seen from the data presented that the spin–lattice relaxation times of the paramagnetic centres in both isomers diminish monotonically with increase in temperature, whereas the spin–spin relaxation times exhibit different temperature dependences in the case of *cis*- and *trans*-PA.

It is necessary to note that the PA relaxation times are effective relaxation times of the localised and mobile paramagnetic centres. Therefore, under the conditions where the dipole–dipole interactions of the paramagnetic centres in PA predominate, one can write

$$\left(\frac{1}{\tau_{1,2}}\right)_{cis} \approx \left(\frac{1}{\tau_{1,2}}\right)_{loc}, \quad (8a)$$

$$\left(\frac{n}{\tau_{1,2}}\right)_{trans} \approx \left(\frac{n_1}{\tau_{1,2}}\right)_{loc} + \left(\frac{n_2}{\tau_{1,2}}\right)_{mob}, \quad (8b)$$

where $n = n_1 + n_2$. This makes it possible to determine separately the relaxation times of paramagnetic centres with different mobilities in *trans*-PA, using the experimental quantities τ_1 , τ_2 , n , and n_1/n_2 .

If the spin–lattice relaxation time is formulated as $\tau_1 = An^{-\alpha}v_e^\beta T^{-\gamma}$ (A is a constant), then α varies from 0.7 to 1.0 in the temperature range from 330 to 90 K, β is 3 for *cis*-PA and -0.5 for *trans*-PA, and γ varies from 1.4 to 3.5 for *cis*-PA and from 1.0 to 2.6 for *trans*-PA depending on the thickness of the specimen (Table 2). This shows that mainly Raman two-phonon relaxation processes occur in *cis*-PA,⁶¹ whereas more complex spin–lattice interactions take place in *trans*-PA. The latter factor may be accounted for by the fact that a joint Raman spin–lattice 1D- and 3D-interaction of the immobilised spins with an overall probability⁶³

$$W_R \sim k_1 n_1 v_e^{-1} T^2 + k_2 n_1 v_e^{-1} T,$$

(k_1 and k_2 are constants) and diffusional modulation of the spin–lattice interaction by the 1D-motion of some of the neutral solitons with a probability $W_D \sim v_e^{1/2}$ take place in *trans*-PA.⁶⁴

Table 3 presents the temperature dependences of the relaxation times of *cis*- and *trans*-PA specimens (No. 8, Table 2) partly oriented by stretching. The data presented demonstrate convincingly that the relaxation times $\tau_1(T)$ and $\tau_2(T)$ of the oriented *cis*-PA vary only slightly with the angle ψ between the direction of the external magnetic field and the direction of stretching of the specimen, whereas for the oriented *trans*-PA film the relaxation times are functions of the angle ψ as a result of the 1D-diffusion of a paramagnetic centre of finite extent within the film.

It is essential to note that the relaxation times are important parameters of PA, characterising its structural and conducting properties. Thus it has been shown⁶⁵ that an increase in molecular mass diminishes the electronic spin–lattice relaxation time of the paramagnetic centres in PA. This parameter should therefore be sensitive to the degradation of the polymer. Indeed, the storage of the initial *cis*-PA specimen for six months under an inert atmosphere leads to a significant increase in τ_1 owing to its partial degradation (Fig. 6).^{54,59}

A similar change in τ_1 is observed on irradiation of this specimen with a beam of fast electrons at a dose of 1 MGy.

Table 3. Temperature dependences of the relaxation times [$\tau_{1,2} = AT^2(s)$] of specimens 8 (Table 2) of *cis*- and *trans*-PA, partly oriented by stretching, as a function of the direction of stretching in the external magnetic field.

Figure 6. Dependence of the spin-lattice relaxation time τ_1 ($T = 120$ K) for the initial *cis*-PA specimen (specimen 3 in Table 2, curve 1) and after its storage under an inert atmosphere for 6 months (line 2) and 12 months (line 3) as a function of the dose of irradiation by a beam of fast electrons.

However, on irradiation of the specimen with an electron beam at a dose of 0.50–0.75 MGy, the time τ_1 remains virtually constant during the above period of storage (Fig. 6). After more prolonged storage of the initial specimen and the specimen irradiated with a dose of 1 MGy, τ_1 diminishes somewhat, which may be attributed to some increase in the length of the chains and to the *cis*–*trans* isomerisation of PA. This phenomenon demonstrates the possibility of the effective stabilisation and even an improvement of the electrodynamic characteristics of *cis*-PA when the latter is irradiated with the optimum dose.

The increase in the concentration of paramagnetic centres on *cis*–*trans* isomerisation of PA accelerates the spin-lattice relaxation. Since in massive PA films with a low-density of the polymer chains such isomerisation proceeds most readily, longer *trans*-sections with an increased rigidity are formed in them, and is accompanied by an increase in the activation energy for the libration of the chains (E_a). The latter quantity may be determined by analysing the temperature dependence of the width of the spectral line of a trapped soliton.⁵⁴ Since the unpaired electron, delocalised within the limits of a neutral mobile soliton, has a finite density $\rho(n)$ on N hydrogen nuclei, there is a possibility of their hyperfine interaction. In this case the effective width of the delocalisation of the unpaired electron $N = \rho(n)^{-1}$ in *trans*-PA can be found from the equation for the Gaussian component of the line width⁶⁶ $\Delta B_{pp}^G \approx N^{1/2} \rho(n)$ subject to the condition $\sum \rho(n) = 1$.

Figure 7 presents the $\tau_1 - N - E_a$ correlations for *trans*-PA specimens of different thicknesses. It is seen from the figure that, as the specimen becomes more massive, a tendency is observed towards the acceleration of the spin-lattice relaxation processes and towards an increase in the activation energy for the libration of the polymer chains. This constitutes additional evidence for the increase in rigidity, packing density, and length of the *trans* chains with increase in the thickness of the *trans*-PA specimen.

Figure 7. Dependence of the spin-lattice relaxation time τ_1 ($T = 80$ K) and the activation energy for the librations of the chains E_a on the effective spin delocalisation length N in *trans*-PA specimens with different thicknesses (μm): (1) 90; (2) 110; (3) 350; (4) 180.

The correlations presented are useful for the standardisation of *trans*-PA films.

It is essential to note that a light doping of *trans*-PA with iodine vapour (up to $\sigma_{dc} \approx 10 \text{ S m}^{-1}$) leads to a fourfold decrease in the overall spin concentration and to a decrease in τ_2 approximately by an order of magnitude (Table 2). Some change in τ_1 occurs on diffusion of atmospheric oxygen into the *trans*-PA matrix. Taking into account the concentration dependence of this quantity, one may conclude that the introduction of I_2 and O_2 molecules reduces the packing density of the PA chains and increases the number of traps for mobile solitons.

IV. Dynamics of the soliton and the mechanism of charge transfer in *trans*-polyacetylene

The diffusion of the soliton along the polymer chain is characterised by the translational propagator of motion $P_{tr}(r, r_0, \tau)$. If in the initial instant the j th particle is located at a point r_0 relative to the i th particle, then the propagator defines the probability that at the instant $t = \tau$ the i th particle is located in the region $r + dr$ relative to the new position of the j th particle.

For the Brownian model of diffusional motion, the propagator $P_{tr}(r, r_0, \tau)$ constitutes the solution of the familiar equation

$$\frac{\partial P_{tr}(r, r_0, t)}{\partial t} = D_{tr} \Delta P(r, r_0, t), \quad (9)$$

subject to the initial condition $P_{tr}(r, r_0, t) = \delta(r - r_0)$, where $D_{tr} = [D_i]$, $D_i = v_i c_i$ is the diffusion coefficient, v_i is the rate of diffusion, c_i is a constant introduced owing to the discrete nature of the system, and i is a unit vector of the molecular coordinate system. In an explicit form, the above propagator for a 1D-system is given by the following relation:⁶⁷

$$P(r, r_0, \tau)_{1D} = (4\pi v_{\parallel} \tau)^{-1/2} \exp\left[-\frac{(r-r_0)^2}{4v_{\parallel}^2 \tau}\right] \exp(-v_{\perp} \tau), \quad (10)$$

where v_{\parallel} and v_{\perp} are the rates of spin diffusion along the polymer chain and between the chains respectively.

The diffusing soliton induces a local magnetic field $B_{loc}(t)$ at the sites of other electron or nuclear spins, thereby influencing the electronic relaxation times of neighbouring spins. The following general expression may be written for the relaxation time:

$$\tau_{1,2} = f[J(\omega)],$$

where $J(\omega)$ is a function of the spectral density given by

$$J(\omega) = \int_{-\infty}^{+\infty} G(\tau) \exp(-i\omega\tau) d\tau. \quad (11)$$

The autocorrelation function of the oscillating local field $B_{loc}(t)$ for a discrete system is

$$G(\tau) = c_i \sum \sum A(r, t) P(r, r_0, \tau) F(r_0) F^*(r) dr_0 dr, \quad (12)$$

where c_i is the lattice constant for the discrete system, $A(r, t)$ the probability of finding the spin at a distance r at time t , equal to the spin concentration per monomer unit n , and $F(r)$ is the probability of finding two spins at a distance r at time t .

For frequencies $\omega \ll v_{\parallel} c_i^2 (r-r_0)^{-2}$, the spectral density function can assume the following form:

$$J(\omega) = n J_{1D}(\omega) \sum \sum F(r_0) F^*(r) f_{1D}(|r-r_0|), \quad (13)$$

where $n = n_1 + \sqrt{2}n_2$ is the probability of finding the spin in the initial instant in the position r_1 , $J_{1D}(\omega) = (2\pi v_{\parallel} v_e)^{-1/2}$ for $v_{\perp} \ll v_e \ll v_{\parallel}$, and $J_{1D}(\omega) = (2\pi v_{\parallel} v_{\perp})^{-1/2}$ for $v_{\perp} \gg v_e$. The expression under the summation sign[†] can be written in the form

$$F(r_0) F^*(r) f_{1D}(|r-r_0|) = \frac{(3 \cos^2 \vartheta - 1)^2}{r_1^3 r_2^3},$$

where ϑ is the angle between the vectors r_1 and r_2 .

Since PA is characterised mainly by an anisotropic dipolar (and to a lesser extent by an isotropic scalar) hyperfine interaction of the electron (S) and nuclear (I) spins, in the case of the dipolar interaction between equivalent spins ($S=I$), the equations for the rates of electronic relaxation in a polycrystalline specimen can be written in the form⁶⁷

$$\tau_1^{-1} = \langle \Delta\omega^2 \rangle [J(\omega_e) + 4J(2\omega_e)], \quad (14a)$$

$$\tau_2^{-1} = \frac{1}{2} \langle \Delta\omega^2 \rangle [3J(0) + 5J(\omega_e) + 2J(2\omega_e)], \quad (14b)$$

where

$$\langle \Delta\omega^2 \rangle = \frac{1}{5} \left(\frac{\mu_0}{4\pi} \right)^2 \gamma_e^4 \hbar^2 S(S+1) n \sum \sum$$

(here ω_e is the frequency of the precession of the electron spin and m_0 is the magnetic permeability in *vacuo*).

The anisotropic hyperfine interaction accelerates the electronic relaxation by the amounts

$$\begin{aligned} \tau_1^{-1} = & \frac{1}{15} a^2 I(I+1) n \sum \sum [J(\omega_e - \omega_1) + 3J(\omega_e) \\ & + 6J(\omega_e + \omega_1)] + \frac{1}{15} a^2 S(S+1) n \sum \sum [-J(\omega_e - \omega_1) \\ & + 6J(\omega_e + \omega_1)] \frac{\langle I_z \rangle - I_0}{\langle S_z \rangle - S_0}, \end{aligned} \quad (15a)$$

[†] Henceforth double summation will be designated for simplicity by $\sum \sum$.

$$\begin{aligned} \tau_2^{-1} = & \frac{1}{30} a^2 I(I+1) n \sum \sum [4J(0) + J(\omega_e - \omega_1) \\ & + 3J(\omega_e) + 6J(\omega_1) + 6J(\omega_e + \omega_1)], \end{aligned} \quad (15b)$$

(ω_1 is the frequency of the precession of the nuclear spin and $a = \mu_0 \gamma_e \gamma_I \hbar / 8\pi$ is the hyperfine interaction constant), whereas the isotropic interactions of the electron and nuclear spins make an additional contribution to the rate of electronic relaxation:

$$\tau_1^{-1} = \frac{1}{3} n_p a^2 I(I+1) J(\omega_e - \omega_1) \left[1 - \frac{S(S+1)(\langle I_z \rangle - I_0)}{I(I+1)(\langle S_z \rangle - S_0)} \right] \quad (16a)$$

$$\tau_2^{-1} = \frac{1}{6} n_p a^2 I(I+1) [J(0) + J(\omega_e - \omega_1)]. \quad (16b)$$

By setting the expression under the summation sum in Eqn (14) equal to $2 \times 10^{58} \text{ m}^{-6}$ and that in Eqn (15) to $2.8 \times 10^{59} \text{ m}^{-6}$ and also assuming that $(\langle I_z \rangle - I_0)(\langle S_z \rangle - S_0)^{-1} = 0.078$,³⁵ one can formulate simpler expressions for the rate of relaxation of *trans*-PA with randomly oriented polymer chains:⁵⁶

$$\tau_1^{-1} = 1.3 \times 10^{16} (v_e v'_{1D})^{-1/2} (2.7 \times 10^4 n + 1), \quad (17a)$$

$$\begin{aligned} \tau_2^{-1} = & 6.3 \times 10^{15} v_{1D}^{-1/2} [(7.6 \times 10^9 n + 3.4 \times 10^5) v_{3D}^{-1/2} \\ & + (4.3 \times 10^4 n + 1) v_e^{-1/2}]. \end{aligned} \quad (17b)$$

In the case of the predominantly dipole-dipole interaction of the paramagnetic centres, the equations for the rates of relaxation of the partly oriented *trans*-PA with a degree of orientation of the polymer chains A consist of two components:

$$\begin{aligned} \tau_1^{-1} = & A \langle \Delta\omega^2 \rangle [J(\omega_e) P_1 + 4J(2\omega_e) P_2] \\ & + (1-A) \langle \Delta\omega^2 \rangle [J(\omega_e) P'_1 + 4J(2\omega_e) P'_2], \end{aligned} \quad (18a)$$

$$\begin{aligned} \tau_2^{-1} = & \frac{A}{2} \langle \Delta\omega^2 \rangle [3J(0) P_0 + 5J(\omega_e) P_1 + 2J(2\omega_e) P_2] \\ & + \frac{(1-A)}{2} \langle \Delta\omega^2 \rangle [3J(0) P'_0 \\ & + 5J(\omega_e) P'_1 + 2J(2\omega_e) P'_2], \end{aligned} \quad (18b)$$

where the constants P_i and P'_i correspond to the oriented and randomly disposed polymer chains respectively.

If we put $P_0 = 4.3 \times 10^{58} \sin^4 \psi$, $P_1 = 4.8 \times 10^{57} (1 - \cos^4 \psi)$, $P_2 = 4.8 \times 10^{57} (1 + 6 \cos^2 \psi + \cos^4 \psi)$, $P'_0 = 1.6 \times 10^{58}$, $P'_1 = 2.7 \times 10^{57}$, and $P'_2 = 1.1 \times 10^{58} \text{ m}^{-6}$,²⁷ Eqns (18) can be written in a simpler form:

$$\begin{aligned} \tau_1^{-1} = & 5.0 \times 10^{19} n (v_e v'_{1D})^{-1/2} \\ & \times [6.8 - A(1.1 - 14.0 \cos^2 \psi + \cos^4 \psi)], \end{aligned} \quad (19a)$$

$$\begin{aligned} \tau_2^{-1} = & 2.8 \times 10^{20} n v_{1D}^{-1/2} \{ (1-A + A \sin \psi) v_{3D}^{-1/2} \\ & + [2.1 + A(1.1 + 1.3 \cos^2 \psi - 2.9 \cos^4 \psi)] v_e^{-1/2} \}. \end{aligned} \quad (19b)$$

Figure 8 presents the temperature variations of the rates of diffusion v_{1D} and v_{3D} calculated for the initial *trans*-PA specimen ($A=0$) (specimen 8 in Table 2) and for the same specimen with polymer chains partly oriented by stretching ($A=0.07$).

When the unpaired electron is delocalised over 15 carbon nuclei, the rate of 1D-diffusion of the soliton in the initial *trans*-PA specimen is $v_{1D} = 0.25 v'_{1D} N^2 \leq 5.6 \times 10^{11} \text{ Hz}$ at room temperature. The latter quantity is approximately two orders of magnitude smaller than that obtained earlier by magnetic resonance methods.^{22,35} Furthermore, the relation $v'_{1D}(T) \sim T^{-2}$ does not agree with the existing theoretical ideas.^{13,14} The anisotropy of the spin dynamics depends only slightly on

Figure 8. Logarithmic temperature dependences of the quantities v_{1D} (a) and v_{3D} (b) for a neutral soliton in the initial (line 1) and partly oriented ($A = 0.07$) *trans*-PA with the crystallographic c axes oriented at the angles

$\psi = 90^\circ$ (line 2), 60° (line 3), 30° (line 4), and 0° (line 5) relative to the external magnetic field. The temperature dependence of the quantity σ_{ac} , calculated by Eqn (20b) for $\nu_e = 1.4 \times 10^{11}$ Hz, is shown by a dashed line.

temperature and amounts to $v_{1D} v_{3D}^{-1} \geq 30$ in this specimen and to $10 - 10^4$ in other *trans*-PA specimens,⁵⁶ which is significantly less than the values obtained previously.^{22,35}

If the rates of spin diffusion are expressed in the form $v_{1D} = AT^{-\alpha}$ and $v_{3D} = BT^{-\beta}$, then the increase in the anisotropy of the spin diffusion by three orders of magnitude in different specimens is accompanied by the simultaneous increase in the quantities α (from 2 to 5) and β (from 0.4 to 7) at room temperature. When *trans*-PA is doped, it becomes disordered and the Coulombic and confinential trapping of the charge carriers increase.¹⁹ However, if these factors are neglected and it is supposed that all the mobile carriers with the mobility μ participate in the charge transfer process, then the conductivity of *trans*-PA, calculated from the equation $\sigma = Ne\mu = Ne^2 v_{1D} c_{\parallel}^{-1} T^{-1}$ (e is the electronic charge), does not exceed $0.02\ S\ m^{-1}$ at room temperature, which is several orders of magnitude less than the value usually attainable for heavily doped *trans*-PA.¹⁻³ Furthermore, even light doping leads to a significant alteration of the frequencies of spin diffusion in *trans*-PA (Fig. 9). Hence it follows that, in order to attain a high conductivity of the polymer, the condition of the multiple charge transfer by each soliton within a limited section of the polymer chain must be fulfilled.

The dynamic properties of solitons can be described more correctly within the framework of the formal treatment involving the isoenergetic intersoliton charge transfer proposed by Kivelson.¹¹ The essential feature of the method consists of the phonon-assisted interchain tunnelling of the charge between the energy levels of the solitons, based on the Coulombic interaction

Figure 9. Temperature dependences of the ratios of the quantities v_{1D} (line 1) and v_{3D} (line 2) for a neutral soliton in the initial *trans*-PA to the corresponding values for a soliton in *trans*-PA doped with iodine up to $\sigma_{ac} \approx 10\ S\ m^{-1}$.

of the solitons having a charge q_1 with ions having the opposite charge q_2 present in the undoped and lightly doped *trans*-PA. The excess charge $\Delta q = q_1 - q_2$ may undergo a phonon-assisted transfer, with a finite probability, to a neutral soliton moving along a neighbouring polymer chain. If at the instant of such transfer the neutral soliton is also located close to a charged ion, the energy of the charge carrier before and after charge transfer remains unaltered. In this case, the conductivity of the polymer (the d.c. conductivity σ_{dc} and the a.c. conductivity σ_{ac}) is determined by the probability that the neutral soliton is located near an ion and also by the probability of finding its initial and final energies within the limits of kT .¹¹

$$\sigma_{dc} = k_1 e^2 \frac{\gamma(T) \xi n_n n_{ch}}{k T N R_0^2 (n_n + n_{ch})^2} \exp\left(-\frac{2k_2 R_0}{\xi}\right) = \sigma_0 T^n, \quad (20a)$$

$$\sigma_{ac} = \frac{e^2 n_i^2 n_0 (1 - n_0) \xi_{\parallel}^3 \xi_{\perp}^2 \nu_e}{384 k T} \left[\ln \frac{4\pi \nu_e L_c}{n_0 (1 - n_0) \gamma(T)} \right]^4$$

$$= \frac{\sigma_0 \nu_e}{T} \left[\ln \frac{k_3 \nu_e}{T^{n+1}} \right]^4. \quad (20b)$$

Here $\gamma(T)$ is the hopping frequency of the charge carriers, k_1 , k_2 , and k_3 are constants ($k_1 = 0.45$, $k_2 = 1.39$), $\xi = (\xi_{\parallel} \xi_{\perp}^2)^{1/3}$, ξ_{\parallel} and ξ_{\perp} are the average parallel and perpendicular lengths of the soliton respectively, n_n and n_{ch} are the numbers of neutral and charged solitons per monomer unit, n_0 is the relative content of the charged solitons, $R_0 = (\frac{2}{3} \pi n_i)^{-1/3}$ is the average distance between inhomogeneities with a concentration n_i , and L_c is the degree of polymerisation or the number of monomer units in the polymer chain. A weak bond between the charge carriers and the polymer lattice is characteristic of the case under consideration, which results in the occurrence of hopping charge transfer between relatively remote states of the soliton. The temperature dependences presented above were obtained experimentally in a study of lightly doped *trans*-PA^{10,69} and other conducting polymers.^{70,71} Fig. 8 presents the temperature dependence of σ_{ac} calculated by Eqn (20b) with $\nu_e = 1.4 \times 10^{11}$ Hz, $n = 8.0$, $k_3 = 2.9 \times 10^{23}\ sK^9$, and $\sigma_0 = 9.3 \times 10^{-15}\ S\ s\ K\ m^{-1}$ ($\xi_{\parallel} = 1.0$, $\xi_{\perp} = 0.25$ nm, $n_i = 1.3 \times 10^{25}\ m^{-3}$, and $L_c = 2000$)^{10,11,72,73} for the initial *trans*-PA specimen. As can be seen from the figure, the $v_{1D}(T)$ and $\sigma_{ac}(T)$ relations are quite satisfactorily correlated. Adopting $\sigma_{dc} \sim 10^{-3}\ S\ m^{-1}$ (see, for example, Epstein¹⁰) and $\sigma_{ac} \sim 3\ S\ m^{-1}$ at $T = 300\ K$ (Fig. 8), we obtain $\sigma_{dc}/\sigma_{ac} \approx 3 \times 10^3$, which agrees well with the value calculated¹⁰ within the framework of Kivelson's theory¹¹

$$\frac{\sigma_{ac}(\nu_e \rightarrow \infty)}{\sigma_{ac}(\nu_e \rightarrow 0)} \approx 10^4.$$

This confirms the applicability of the approach used to the interpretation of the transport properties of the soliton in *trans*-PA.

In the initial *trans*-PA specimen, the crystallographic *c* axes of the polymer chains are randomly oriented in space. It follows from Fig. 8 that, under the conditions of the orientational ordering of some of the polymer chains, the rates of the spin 1D- and 3D-diffusion are sensitive to the rotation of the specimen by an angle ψ in the external magnetic field, apparently owing to the finite length of the quasi-particles. The function $v'_{1D}(\psi)$, i.e.

$$\langle v'_{1D}(\psi) \rangle = v_{1D}^{\parallel}(\psi) \sin^2 \psi + v_{1D}^{\perp}(\psi) \cos^2 \psi, \quad (21)$$

where $v_{1D}^{\parallel}(\psi)$ and $v_{1D}^{\perp}(\psi)$ are extrema in the function $v'_{1D}(\psi)$, is in the antiphase relative to $v'_{3D}(\psi)$. We may note that the effective spin diffusion can be described with the aid of a similar relation also in other low-dimensional systems.^{74,75} Thus the inequality $v_{1D}^{\parallel}(\psi) \ll v_{1D}^{\perp}(\psi)$ is evidence for the delocalisation of the unpaired electron along the *c* axis within the limits of the soliton. Bearing in mind the fact that the soliton hops are limited by the interchain lattice constant and that the square of the length of the average diffusional hop along the *c* axis is $0.25(N^2 c^2)$, the width of the soliton N can be calculated with the aid of the following simple equation:⁴⁶

$$N^2 = \frac{4v_{1D}^{\perp}(\psi)}{v_{1D}^{\parallel}(\psi)}. \quad (22)$$

Figure 10 presents the temperature dependence of the width of the soliton calculated by Eqn (22) using the quantities v_{1D}^{\parallel} and v_{1D}^{\perp} , found graphically with the aid of Fig. 8. The value $N = 14.8$ found for room temperature agrees well with the theoretical⁶ and the earlier experimental⁴⁵ values of N . Extrapolation of the $N(T)$ relation to lower temperatures makes it possible to determine the temperature ($T_0 \approx 60$ K) at which the width of the soliton begins to increase. It is important to note that an anomaly in the function $v'_{1D}(T)$ for *trans*-PA,³⁷ accounted for by a change in the mechanism of the electronic relaxation, has been recorded in precisely this temperature range.

Figure 10. Temperature variation of the effective width N of the soliton in *trans*-PA.

Thus the experimental data indicate the 1D-diffusion of solitons into *trans*-PA at a rate appreciably exceeding the minimum rate v_{1D}^0 calculated above by Eqn (1). This conclusion is confirmed also by the averaging of the components of the *g*-tensor of the mobile paramagnetic centres when condition (1) is fulfilled and by the narrowing of the line in the EPR spectrum of *trans*-PA over a wide frequency range in conformity with Eqn (3).

However, the most obvious evidence in support of the 1D-diffusion of the soliton is the sensitivity of the quantities v_{1D} and v_{3D} to the orientation of the polymer in the magnetic field.

The familiar Burgers–Korteweg–de Vries equation, describing the 1D-motion of unified waves in a nonlinear medium, assumes the form⁷⁶

$$\frac{\partial u}{\partial t} + (v_{1D}^0 + \varepsilon u) \frac{\partial u}{\partial x} - \kappa \frac{\partial^2 u}{\partial x^2} + \beta \frac{\partial^3 u}{\partial x^3} = 0, \quad (23)$$

where ε , κ , and β are the parameters of the nonlinearity, dissipation, and ‘reactive’ dispersion of the medium respectively. In a dissipative system with a low nonlinearity ($\beta \approx 0$), there is a possibility of the formation of a mobile front (kink) with the difference $u_2 - u_1$. For such a quasi-particle, the stationary solution of Eqn (23) assumes the following form:

$$u(x, t) = 0.5(u_1 + u_2) - A \tanh\left(\frac{x - v_{1D}t}{2N}\right), \quad (24)$$

where

$$A = \frac{1}{2}(u_2 - u_1), \quad v_{1D} = v_{1D}^0 + \frac{1}{2}\varepsilon(u_1 + u_2), \quad \text{and} \quad N = \frac{\kappa}{2A\varepsilon},$$

are the amplitude, velocity, and width of the kink respectively. If the dissipation of the system is neglected ($\kappa \approx 0$), then other quasi-particles—solitons—are stabilised in the system. For a family of such solitons, Eqn (23) has another integrable solution:

$$u(x, t) = A \operatorname{sech}^2\left(\frac{x - v_{1D}t}{N}\right), \quad (25)$$

where

$$v_{1D} = v_{1D}^0 + \frac{1}{3}A\varepsilon, \quad \text{and} \quad N^2 = \frac{3\beta}{A\varepsilon} = \frac{\beta}{v_{1D} - v_{1D}^0}.$$

It is essential to note that relations similar to Eqns (24) and (25) have been used⁶ to describe nonlinear deformations of the lattice and electronic states of *trans*-PA.

The experimental⁴⁶ functional relations $v_{1D}(T) \sim T^{-n}$ and $N(T) \sim T^{n/2}$ ($n \approx 2$) yield for *trans*-PA a relation of the type $N^2 \sim v_{1D}^{-1}$. This means that the motion of solitons in the given specimen, subject to the condition $v_{1D} \ll v_{1D}^F = 3.8 \times 10^{15}$ Hz, can also be described by Eqn (23), which is universal for nonlinear systems, with the stationary solution (25). Evidently, different specimens of *trans*-PA may be characterised by different sets of the constants ε , κ , and β in Eqn (23), so that the nature of the motion of the quasi-particles in these polymers may differ somewhat from that described above.

V. Conclusion

It was shown above that the mechanism and rate of charge transfer in PA depend on the conformation, packing density, intramolecular dynamics, and lengths of the polymer chains in the undoped sample. In *cis*-PA, the neutral solitons are trapped in short sections of the *trans*-conformer. As a consequence of this, the probability of the intersoliton charge jump is exceptionally low and $\sigma_{dc} \sim 10^{-11}$ S m⁻¹. In the course of the *cis*–*trans* isomerisation, the length of the *trans*-chains increases, which leads to the ‘unfreezing’ of the mobility of some of the solitons. These quasi-particles acquire a charge and transport it along the chain up to the section where its tunnelling transfer to another soliton, moving along a neighbouring polymer chain, is most probable. As a result of this process, characterised by a fairly strong Raman interaction of the electron spins with the lattice phonons, a sharp increase in the electrical conductivity of the undoped PA actually occurs (up to $\sigma_{dc} \sim 10^{-3}$ S m⁻¹). It must be emphasised that the mobile solitons play an indirect role in the charge transfer in PA, so that the electron transport considered

may operate only in undoped and lightly doped *trans*-PA. On doping, the number of mobile and pinned paramagnetic centres diminishes and the dimensionality of the system increases, which alters the mechanism of the charge transfer.

The data obtained demonstrate the evident advantages of the two-millimetre EPR spectroscopy in the study of different *cis*- and *trans*-PA specimens, which make it possible to analyse more fully and correctly the magnetic and relaxation parameters of paramagnetic centres with different mobilities and to obtain information about the detailed characteristics of the molecular and spin dynamics in PA. Evidently this method can be used successfully also in the study of other organic polymeric semiconductors.

Abstract. The results of studies on the nonlinear theory of sorption dynamics and chromatography under conditions of interdependent sorption of the components are surveyed and treated systematically. The principal properties of multicomponent dynamic sorption systems and of the results arising from the nonlinear character of the mass balance equations are analysed in detail. These nonlinear equations describe the propagation and interaction of the multicomponent concentration waves generated in the sorption column during the chromatographic process for a multicomponent mixture of the substances being sorbed. A series of solutions (including those making allowance for dispersion factors in the sorption process), describing the multicomponent concentration waves during their propagation nonlinear multicomponent dynamic sorption systems, are considered. The bibliography includes 224 references.

I. Introduction

Chromatography describes a dynamic process in which at least two phases (one of which is continuous and the other disperse) move relative to one another and mass and/or heat exchange takes place between their interfaces. The general term filtration or percolation processes is frequently applied abroad to such processes.¹ There are phenomenological concepts,¹ potentially common to all filtration processes, which can also be extended to a whole series of other migration phenomena such as sedimentation,² electrophoresis,³ and others.^{1,4–6}

The increased loadings applied to apparatus and columns in connection with the tendency to intensify modern technological processes leads to the need to separate mixtures of substances at high concentrations (including sorption separations).^{7–19} As a result, in the analysis of percolation processes it is necessary to take into account their nonlinearity and nonstationary nature and also the multicomponent nature of the dynamic systems considered.

Even in one-component sorption systems, the effects of nonlinearity play a major role, since they are responsible for the tendency of the concentration wave generated in the column to be stabilised or, conversely, to undergo progressive spreading.²⁰ If the substances sorbed do not interact in the column, the multicomponent system reduces to a one-component system. This special case makes it possible to regard a multicomponent system as a superposition of independent one-component systems. The hypothesis that there is no sorption interaction between the components usually holds in the case of analytical separations at low concentrations and for small loadings applied to the sorbent or in the elution version where the chromatographic peaks move apart rapidly. For preparative separations, where at high concentrations of the molecules the latter compete for a limited number of accessible sorption centres, this hypothesis becomes inapplicable.

When molecules or ions compete for sorption centres, one may speak of the sorption interaction of species in the disperse phase, i.e. of the mutual influence of the components during the sorption process. This effect has been relevantly called the 'interference of species' in the monograph by Helfferich and Klein²¹ (see also Helfferich's review²²). The same term is used in the thermodynamics of irreversible processes²³ to characterise the mutual influence of coexisting processes — the so-called 'cross effects'.²⁴

There exists yet another aspect of the interference of substances — the interference of concentration waves propagating at different wave velocities during their generation, collision, and interaction in the course of the sorption processes.^{21,22}

Received 27 March 1995

Uspekhi Khimii 65 (2) 103–124 (1996); translated by A K Grzybowski

process is completely analogous to the processes considered in fluid mechanics and in gas dynamics.

In the general case, the interference of substances in a dynamic sorption process can arise as a consequence of various types or forms of interaction. Each of the mixture components may affect the equilibrium interphase distribution of other substances (static interference effects) and also the time required for the establishment of equilibrium between the concentrations in the disperse and continuous phases (kinetic interference effects). The molecules of the substances may be transformed to another state as a result of a chemical reaction (for example, on complex formation) and under these conditions both static and kinetic interference effects may arise.^{21, 22}

The static interference effects can be considered on the basis of the ideal equilibrium model of the sorption system. Numerous studies have been considered by the nonlinear theory of isothermal multicomponent sorption dynamics and chromatography involving the application of the ideal model (see, for example, Refs 20–22 and 25–73). In particular, the results of mathematical investigations included the theory of systems of quasi-linear equations in terms of partial derivatives have been used in such studies.^{4, 39, 46, 47, 74–79}

At the present time, the ideal model has been used successfully for a qualitative explanation of a number of characteristics of the behaviour of multicomponent sorption systems and in many cases also for a quantitative prediction of the results. A further increase in the complexity of the behaviour of multicomponent nonlinear sorption systems is associated with the operation of interference effects together with nonideality factors (a finite rate of establishment of an equilibrium interphase distribution of substances, longitudinal dispersion, etc.). The operation of the static interference effects is fundamentally nonlinear and plays the main role in the behaviour of multicomponent concentration waves generated in the column. The additivity of the factors is impossible under these conditions because of the fundamentally nonlinear character of the multicomponent sorption systems.

The equilibrium properties of sorption systems determine the static interference effects and also sequence, types, forms, and propagation velocities of multicomponent concentration waves. The kinetic and dynamic nonideality factors introduce second-order changes under these conditions into the behaviour of concentration waves. The equilibrium properties of sorption systems determine the first statistical moment of the concentration waves, whereas the nonideality factors determine the second and higher statistical moments.²¹

The successful solution of the problem of the interference of substances and concentration waves together with the description of the behaviour of multicomponent sorption systems in terms of the propagating concentration waves became possible after the introduction of the concept of 'coherence'.^{21, 22, 35, 36} This concept was developed by Helfferich^{22, 35, 36, 80, 81} to facilitate the qualitative understanding and quantitative calculations in the theory of multicomponent nonlinear chromatography under arbitrary initial and boundary conditions. This general concept is fundamental and is applicable to a large class of percolation processes of similar nature.

For a compound multicomponent wave in a nonlinear sorption system, the state of coherence means that the concentration waves for each individual component move jointly without 'splitting', and this implies that their velocities are the same at each point. This leads to the problem of the determination of the eigenvalues and eigenvectors in the mass balance equations for the components.^{22, 25–31, 39, 46, 47, 74–79} The problems of the determination of the eigenvalues for the wave velocities in the theory of multicomponent chromatography, in the fluids and gases mechanic and in nonequilibrium thermodynamics are closely related.

The coherence condition determines the response of the multicomponent system to its perturbation and denotes the state to which it tends. A closed system tends in exactly the same way to

attain a state of equilibrium, while an open system with fixed boundaries and constant conditions imposed on them tends to attain a stationary dynamic state.^{22, 81}

Preparative displacement chromatography, which deals with large concentrations and a strong influence of interference, makes it possible to achieve simultaneously enhancement of concentration and purification of substances. In preparative multicomponent sorption and chromatographic separations, the large loadings applied to the columns and the high concentrations of the components to be separated are responsible for the specific features of the multicomponent dynamic sorption process. These specific features are associated with the interference of the species, which is particularly significant for frontal, displacement, elution, and vacancy versions.^{8, 9, 16}

Nonlinear preparative chromatography, which makes it possible to achieve good results in the separation of substances, has undergone a fresh development recently. It has been applied particularly vigorously in biotechnology.^{7, 10–12, 13, 15, 17–19} Despite the relatively high cost of the separation, it is more than worthwhile because the final bioproduct is more expensive.^{10, 11, 13}

The aim of the present review is to present the state of the art in the field of the theory of multicomponent nonlinear sorption dynamics and chromatography and also to consider the fundamental theoretical features of the behaviour of dynamic sorption systems in the separation of interfering species. In studies on such systems, it is possible to distinguish three main aspects: statics, kinetics, and dynamics of sorption.

II. Sorption statics

The statics of sorption processes is the study of the equilibrium relations between the concentrations of substances in the continuous and disperse phases. Under isothermal conditions, the interaction of the mixture of sorbable species in the continuous phase with the disperse phase determines the sorption isotherms of the components. The sorption isotherms of the mixture characterise the fundamental thermodynamic properties of the system and permit the calculation of the concentration distributions on the basis of the solution of the mass-balance equations.

The chromatographic separation is based on the difference between the equilibrium relations for the mixture of sorbable components. The greater this difference the more effective the separation of the components, other conditions being equal. In the competition of different molecules for available free sites in the sorbent, one may refer to the 'interaction' of the substances in the disperse phase or to their interference,^{21, 22} i.e. to the mutual influence of the substances on one another's sorption.

Interference presupposes that the concentration of any component i in the disperse phase (a_i) depends not only on the concentration of this substance in the continuous phase (c_i), as happens in systems without interference, but also on the concentrations (c_j) of all other substances, i.e.

$$a_i = f_i(c_1, \dots, c_m), \quad i, j = 1, 2, \dots, m. \quad (1)$$

Thus the sorption isotherms for the mixture represent the dependences of the concentrations of the substances in the disperse phase on the mixture composition $\{c_1, \dots, c_j, \dots, c_m\}$ at a constant temperature.

The number of multicomponent concentration waves arising in the column is determined by the parameter which is called the variance of the multicomponent sorption system.^{50, 82} The variance (m), the value of which is determined by the Gibbs phase rule,^{83–86} characterises the number of degrees of freedom of the multicomponent system under isothermal conditions, i.e. it characterises the minimum number of concentration variables which determine the composition of the mixture at equilibrium. In order to calculate the concentration distributions in the sorption system with a variance m , it is necessary to specify m isotherms, each isotherm f_i representing a surface in a multidimensional concentration space $\{c_1, \dots, c_j, \dots, c_m\}$.

Using the concentration distribution ratio a_i/c_i , it is easy to determine the sequence of affinities of the substances for the sorbent or, in other words, the 'affinity sequence' of the components: 1, 2, ..., n . The component i has a greater affinity than the component j provided that the inequality $a_i/c_i > a_j/c_j$ holds. Here it is assumed that $i < j$ for the affinity sequence. The separation factor α_{ij} is defined as the ratio

$$\alpha_{ij} = \frac{a_i/c_i}{a_j/c_j}, \quad i, j = 1, \dots, n, \quad (2)$$

where $\alpha_{ii} = 1$, $\alpha_{ij} = 1/\alpha_{ji}$, and $\alpha_{ij}\alpha_{jk} = \alpha_{ik}$.

In the affinity sequence 1, 2, ..., i , ..., j , ..., n , the components are arranged in the order of decreasing affinity.

When the mixture composition is varied, the positions of the components in the affinity sequence may remain unchanged (we have the so-called 'invariant' affinity sequence²¹) or it may vary. The change in the affinity sequence is called 'inversion'^{33, 87} or selectivity reversal.^{52, 88, 89} It is remarkable that in certain cases the components do not change positions in the affinity sequence for a univariant system (when the mixture composition changes in the binary i/j exchange of heterovalent ions), but in multicomponent systems (for example, in the exchange of more than three ions) inversion is possible.^{21, 38}

An even more complex variant of the inversion arises in nonlinear ion-exchange systems, where the equilibria are complicated by the occurrence of chemical reactions, in particular by complex formation. In such cases, inversion is possible even in systems with a variance $m = 1$, i.e. in two-component i/j systems. Combined concentration waves, in which one region of the wave tends to become sharper whilst the other undergoes progressive spreading, may then be generated in the column.

The equivalence (stoichiometry) conditions

$$\sum_i a_i = a_0, \quad \sum_i c_i = c_0$$

or

$$\sum_i Y_i = 1, \quad \sum_i X_i = 1, \quad i = 1, \dots, n, \quad (3)$$

where $Y_i = a_i/a_0$ and $X_i = c_i/c_0$ are dimensionless (normalised) concentrations, are usually valid for ion exchange. When these conditions are taken into account, the variance m of a stoichiometric system in which n ions undergo exchange, is $n - 1$ and the system must be regarded as an m -component system.

The relations

$$\left(\frac{\partial a_i}{\partial c_k}\right)_{c_s} < 0, \quad j \neq k; \quad \left(\frac{\partial a_j}{\partial c_k}\right)_{c_s} > 0, \quad (4)$$

where $s, j, k = 1, \dots, m$, hold for the sorption of competing substances. Thus, as a result of the competition of the components for available sorption sites, an increase in the concentration c_k leads to a decrease in the concentration a_j for all $j \neq k$. The greater the affinity of the k th component for the sorbent, the stronger this effect.

$$\left(\frac{\partial a_j}{\partial c_k}\right)_{c_s} < \left(\frac{\partial a_j}{\partial c_l}\right)_{c_s} < 0, \quad \text{when } \alpha_{kl} < 1 \quad (5)$$

If the sign of the effect is reversed, then the sorption of substances is called synergistic.

$$\left(\frac{\partial a_j}{\partial c_k}\right)_{c_s} > 0, \quad j \neq k \quad (6)$$

An increase in the sorbability of one component (j) with increase in the concentration of another (k) may arise when the molecules

of these substances tend to form complexes or aggregates in the stationary phase.

Having expressed a_j in terms of c_j with the aid of the Law of Mass Action (LMA) [Eqn (2)] and having substituted this value in Eqn (3), we obtain the Langmuir relations for mixture isotherms reflecting the interference of substances in the m -component system:²¹

$$a_i = f_i(c) = \frac{a_0 c_i}{\sum_j \alpha_{ji} c_j}$$

or

$$Y_i = \frac{X_i}{\sum_j \alpha_{ji} X_j}, \quad i, j = 1, \dots, n. \quad (7)$$

The model of an ideal localised monolayer was introduced by Langmuir⁹⁰ for a single component, but the simplicity of the analytical expression (7) for a mixture of substances⁹¹ makes it possible to employ it widely for calculations in the nonlinear theory of multicomponent sorption dynamics and chromatography (see, for example, Refs 92–132).

The Langmuir relations (7) for physical sorption are written in the form

$$a_i = \frac{(a_0/c_0)\alpha_{ik}c_i}{1 + \sum_j b_j c_j}$$

or

$$Y_i = \frac{\alpha_{ik} X_i}{1 + \sum_j (\alpha_{jk} - 1) X_j}, \quad i, j = 1, \dots, m. \quad (8)$$

Langmuir's adsorption theory¹³³ can be extended to the adsorption of gaseous mixtures^{134, 135} if it is supposed that the molecules are adsorbed at specific sites and do not interact with one another. These equations are referred to as the Langmuir equations for the adsorption of a mixture of gases. Similar equations have also been obtained in other studies^{136, 137} employing the Law of Mass Action.

For constant separation factors α_{jk} , the Langmuir relations (8) for an m -component system with nonstoichiometric sorption can be formally reduced to the Langmuir relations for a stoichiometric system with $m + 1$ components. For this purpose, it is necessary to introduce a k th dummy species with a concentration c_k and one must put²¹

$$\Gamma_i = \frac{a_0}{c_0} \alpha_{ik}, \quad V_i \equiv b_i c_i = (\alpha_{ik} - 1) X_i, \quad i = 1, 2, \dots, k-1, \quad (9)$$

$$\Gamma_j = \frac{a_0}{c_0} \alpha_{j+1k}, \quad V_j \equiv b_j c_j = (\alpha_{j+1k} - 1) X_{j+1}, \quad j = k, \dots, m.$$

Thus the stoichiometric system described by Eqns (2) and (3) for the exchange of n equal-valence ions may be reduced to the Langmuir sorption of a mixture of m components (where $m = n - 1$). The Langmuir equilibrium relations for a mixture have been discussed in detail in a monograph.¹³⁸ Various properties of the mixture isotherms, obtained with the aid of derivatives of types (4) and (5), have been described.²⁶ The Langmuir relations (7) or (8) for the mixture isotherms satisfy all the properties described in the above study.²⁶

Several dynamic methods for the construction of isotherms on the basis of column output curves have been developed for one-component sorption systems, among which the elution^{139, 140} and frontal analysis^{141, 142} methods are the most popular. These methods were updated later for the measurement of isotherms

for binary and multicomponent mixtures.^{62, 143-146} However the frontal chromatographic method is fairly laborious, since it requires a large number of measurements, pure substances, and takes a long time. This method has been compared with one based on the nonlinear wave effects involving a transformation of a hodograph and the optimum experimental conditions for the applicability of both methods have been determined.¹⁴⁷

Analytical expressions for mixtures isotherms which could be derived by the methods of statistical physics are lacking. Phenomenological equations for the mixture isotherms, based on the Law of Mass Action, are most widely used.

We shall consider systems in which sorption is stoichiometric [i.e. Eqns (3) hold]. Any composition of a mixture of species can be represented by a point in the 'composition space' $\{c_i\}$ or $\{a_i\}$. This

term is applied²¹ to an m -dimensional (n -dimensional for a stoichiometric system) space, along the axes of which the concentrations of the mixture components X_i or Y_i are plotted, as shown in Fig. 1a for a three-dimensional ($n = 3$) space.

For the normalised concentrations X_i or Y_i , the space of the possible changes in concentrations is a cube for $n = 3$ and a hypercube for $n > 3$, since the inequalities $1 \geq Y_i$ and $X_i \geq 0$ hold. Eqn (3), defining the stoichiometry of the exchange, reduces the dimensionality of the space of the possible changes in concentration to a hyperplane (for $n > 3$) $P_1 \dots P_n$, where, as can be seen from Fig. 1a, at the points P_i the concentration $X_i(P_i) = 1$, while the concentrations of the remaining components are zero. This hyperplane is usually referred to as a 'simplex'.²¹ Figs 1a and 2 present examples of simplexes for a stoichiometric

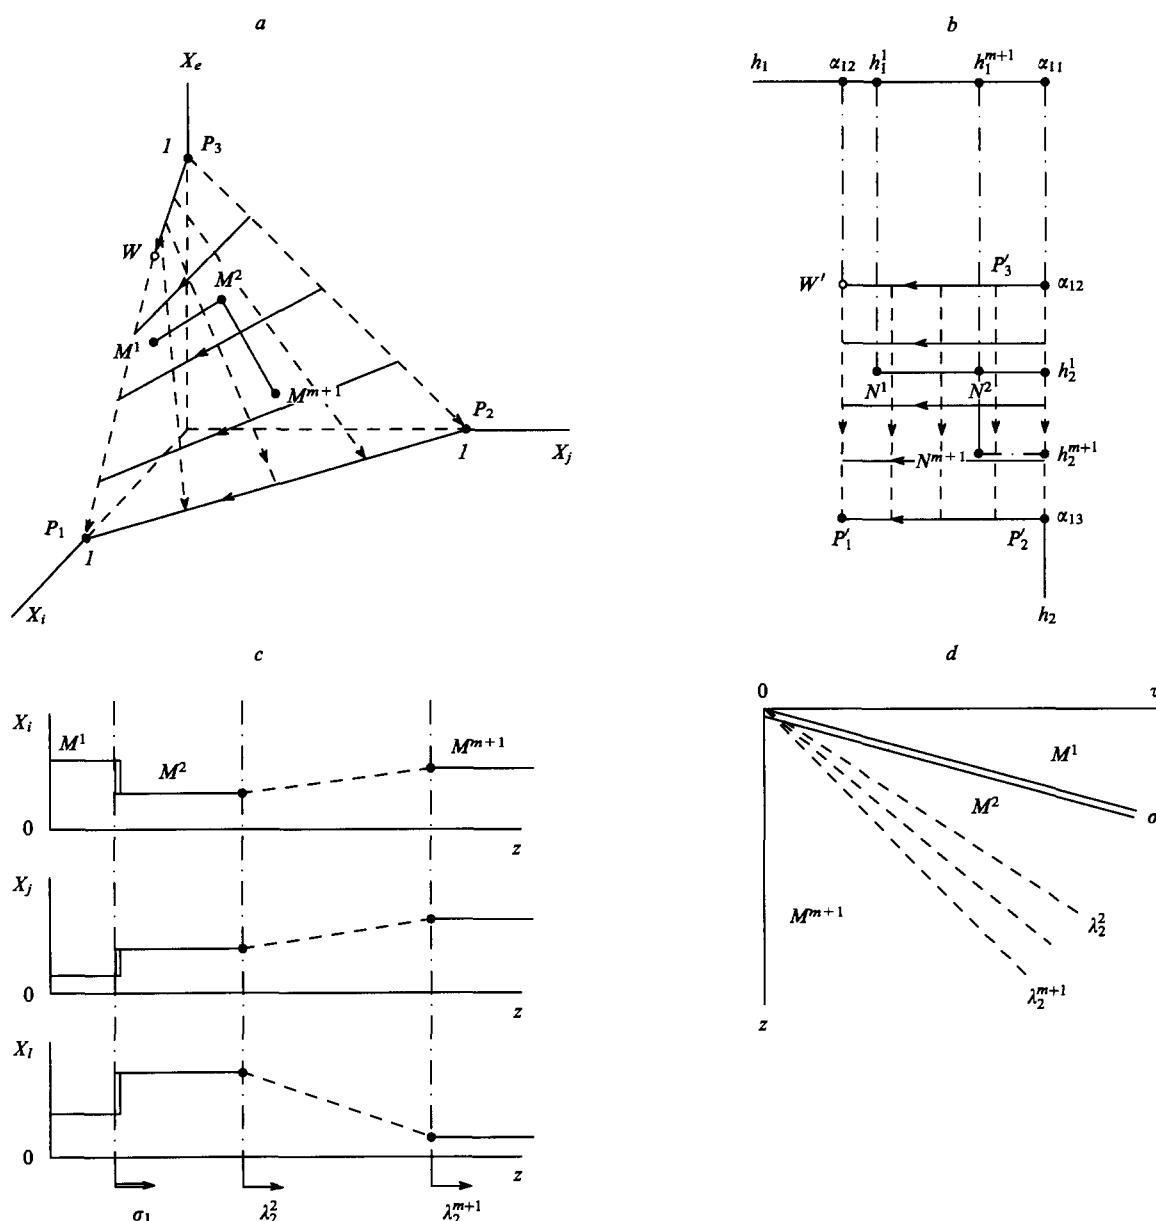

Figure 1. Representations of the characteristics of a three-component stoichiometric system in the composition space and in the physical plane. (a) the simplex $P_1P_2P_3$ for a two-component Langmuir system and the characteristic Γ^k paths corresponding to simple k -waves; (b) the Riemann invariants space $\{h_k\}$ and the h -transformation of the composition space $\{X_i\}$ (a) into the Riemann invariants space $\{h_k\}$ (b). Points M^s represent the concentration plateau in the k -wave; points $N^s\{h_k^s\}$ in the invariants space $\{h_k\}$ correspond to points M^s in the concentration space $\{X_i\}$ in Fig. 1a;

the arrows denote the directions in which the invariants h_k increase along the k -wave; the condition $X_i(P_i) = 1$ holds at points P_i , whilst the condition $h_i = \alpha_{i+1}$ is valid at points P'_i ; (c) the concentration profiles in the shock k -wave M^1M^2 ($k = 1$) and in the spreading k -wave M^2M^{m+1} ($k = 2$) corresponding to the $M^1M^2M^{m+1}$ route in Fig. 1a; σ_1 is the velocity of the first shock wave and $\lambda_2^2, \dots, \lambda_2^{m+1}$ are the velocities of the second spreading wave; (d) is the image on the physical plane (z, τ) of the propagation of the multicomponent concentration k -waves ($k = 1, 2$).

Figure 2. Hodographs for Langmuir two-component sorption systems (8) $\{c_i\}$ and for the equivalent stoichiometric three-component systems (9) $\{X_i\}$. (a) For the competitive sorption of the components ($b_i, b_j > 0$); (b) for the synergistic sorption of the components ($b_i > 0, b_j < 0$). The concentration points A, M, N, etc. correspond to different mixture compositions in the chromatographic process (see text).

Figs 1a and 2 present examples of simplexes for a stoichiometric three-component ($n = 3$) system with a variance of two ($m = 2$). Fig. 2 presents in the same region simplexes for a Langmuir two-component system, which is equivalent [see Eqn (9)] to a stoichiometric three-component system.²¹

The most frequently employed Langmuir multicomponent model lacks thermodynamic rigour, since Eqns (8) expressed in a general form do not satisfy the Gibbs–Duhem relations. Furthermore, the Langmuir model (8) does not yield exact predictions in calculations for elution chromatographic processes involving large loadings^{62, 148} and does not take into account adequately the experimental data for competitive adsorption.^{89, 145, 146} Nevertheless, in many special cases the Langmuir isotherm for a two-component mixture describes experimental data satisfactorily.⁸⁹

Phenomenological bi-Langmuir models for mixture isotherms, represented by the sum of two Langmuir relations, have been proposed:^{121, 149}

$$a_i = \frac{k_{i1}c_i}{1 + \sum_j b_{j1}c_j} + \frac{k_{i2}c_i}{1 + \sum_j b_{j2}c_j}, \quad i, j = 1, 2, \dots, m, \quad (10)$$

where the subscripts $i1$ and $i2$ refer to different adsorption sites¹²¹ or to two different states of the molecules in the sorbent phase (when complex formation takes place in the sorbent phase).¹⁴⁹ Phenomenological equations of the mixture isotherms in the form of the bi-Langmuir relations (10) are frequently used in numerical

calculations of concentration distributions.⁶⁶ It has been shown¹²¹ that type (10) relations describe the sorption isotherms for mixtures of enantiomers, the first term corresponding to selective chiral interactions and the second to nonselective molecular interactions between the enantiomers and the stationary phase.

Generalised phenomenological equations, including Langmuir and Freundlich relations as special cases, have been proposed:^{52, 53}

$$a_i = \frac{k_i c_i^{v_i}}{1 + \sum_j b_j c_j^{v_j}}, \quad i, j = 1, \dots, m. \quad (11)$$

In order to eliminate the thermodynamic inconsistency mentioned above, the Langmuir multicomponent model (8) has been supplemented by the theory of an ideally adsorbed solution proposed by Myers and Prausnitz.¹⁵¹ A thermodynamically consistent model of the competitive adsorption of components has been proposed by LeVan and Vermeulen.¹⁵⁰ The authors introduced into equations (8) of isotherms for two-component systems additional terms taking into account the difference between the column capacities for each component. To a first approximation, subject to the condition that the sorption capacities are the same for both components, the equations which they obtained for the isotherms reduce to the Langmuir equations (8). If the capacities for each component are different, then the LeVan–Vermeulen isotherm¹⁵⁰ can be represented by a rapidly converging series. In practical cases, this series can be restricted to the first two terms

$$a_i = \frac{wb_i c_i}{V} + \left(\frac{a_i}{b_i} - \frac{a_{3-i}}{b_{3-i}} \right) b_1 b_2 c_1 c_2 \ln(V),$$

$$V = 1 + b_1 c_1 + b_2 c_2; \quad w = \frac{a_1 c_1 + a_2 c_2}{V - 1}; \quad i = 1, 2. \quad (12)$$

When two one-component isotherms (for each individual component) are different, then the theory of the ideally adsorbed solution yields a numerical procedure for the determination of the isotherms for the competing components. This approach is based on the normalisation of the spreading pressure.¹⁵¹ It has been shown¹⁵² that the LeVan–Vermeulen model is consistent with the Gibbs adsorption theory. Numerical calculation of two chromatographic peaks with the aid of expansion (12) demonstrates a stronger displacement effect than could be predicted on the basis of the traditional Langmuir adsorption isotherms. For certain experimental systems, the application of isotherms (12) yields a satisfactory approximation.⁸⁹

Analysis of two-component models based on the method of statistical thermodynamics shows that the equations of the isotherms represent the ratio of two polynomials of the same degree.^{153, 154} In the special case of the Langmuir isotherm (8), this is the ratio of first degree polynomials. In another model based on statistical thermodynamics, which yields satisfactory results, the equation of the isotherm has been represented by the ratio of quadratic polynomials of the type.^{148, 153}

$$a_i = \frac{k_i c_i + k_{i(3-i)} c_1 c_2}{1 + b_1 c_1 + b_2 c_2 + b_{i(3-i)} c_1 c_2}, \quad \text{when } i = 1, 2, \quad (13)$$

where $k_{12} = k_{21}$ and the coefficients of this equation are the same as in the equation of a one-component isotherm for an individual i th component. The coefficients k_{ij} and b_{ij} must be determined from experiments on the adsorption of a binary mixture.

Fowler's isotherm

$$\frac{\theta_i}{c_i(1 - \theta_1 - \theta_2)} = b_0 \exp[\chi_i(\theta_1 + \theta_2)], \quad \text{when } i = 1, 2, \quad (14)$$

where θ_i is the ratio of the concentration of the component in the disperse phase to the sorbent capacity and χ_i are numerical coefficients, may be applied to the description of two-component adsorption¹³⁵ taking into account the competitive adsorption of the mixture components. This isotherm is an example of an implicit concentration dependence. The description of the adsorption of a binary mixture with the aid of Eqn (14) requires five parameters: a_{01} , a_{02} , χ_1 , χ_2 , and b_0 .

A binary isotherm model, based on the ion-exchange formalism, has been proposed.¹⁵⁵

Certain models of isotherms for a two-component mixture have been used in the frontal analysis of the output curves for two components^{156–158} for the determination of the constants in the corresponding equations. The simplest model is described by the two-component Langmuir relations (8) (for $i = 1, 2$). In a number of cases, especially when the sorbent capacities are the same for each component, this equation fits satisfactorily the mixture isotherms,¹⁵⁸ but it is more often inconsistent with experimental data.^{146, 157} The binary isotherms have been determined and a comparative study of the four models (presented above) for the description of the sorption of phenylethanols on ODS silica gel has been made with the aid of the two-component frontal analysis of the output curves.¹⁵⁷

We may note that one of the principal problems in the theory of the adsorption of mixtures — the prediction of mixture isotherms based on statistical data obtained for individual isotherms — has still not been solved.

In stoichiometric n -component systems, for which any i/j binary exchange obeys the Law of Mass Action in the form

$$\frac{(Y_i/X_i)^{v_i}}{(Y_j/X_j)^{v_j}} = K_{ij}, \quad \text{when } i, j = 1, \dots, n, \quad (15)$$

(K_{ij} is a concentration constant), the relation between the concentrations Y_i and $\{X_1 \dots X_n\}$ cannot be obtained in an explicit form. The equations of the mixture isotherms can be specified by implicit relations, for example, Eqn (14) or by the combination of Eqns (3) and (15). For systems involving the exchange of heterovalent ions, the quantity $1/v_i$ defines the valence of the i th ion. In nonideal systems obeying the Law of Mass Action, the concentration constants depend on the ratios of the concentrations of the substances undergoing exchange.

The form of the sorption isotherm has a decisive influence on the behaviour of the concentration waves in sorption columns. The criterion of the convexity of the binary i/j exchange isotherm, derived by Samsonov,¹⁵⁹ makes it possible to determine whether a stationary concentration front for the i/j exchange of the components may be established in the column. It is noteworthy that in a binary system, where the equilibrium is described by Eqns (15), the components do not change positions in the affinity sequence [i.e. the f_{ij} binary isotherm is either concave (unfavourable) or convex (favourable)]. In multicomponent systems ($n > 3$) of type (15), there is a possibility of the inversion of the components.^{37, 38}

Inversion takes place also in chromatographic systems with complex formation.^{48, 66, 82} In this case, the selectivity reversal may occur even in a binary system. In other words, the f_{ij} binary isotherm for components i and j can be S -shaped or σ -shaped (with an inflection and an intersection of the diagonal). An inversion of this type influences significantly the form of the chromatograms owing to the appearance of combined concentration waves — partly stationary and partly spreading waves. The occurrence of inversion also influences the form of the chromatographic fronts also in adiabatic sorption columns, where the heat changes may alter the relative affinities of the components for the sorbent. This results in the appearance of combined (stationary-spreading) concentration waves. Their formation may be regarded as the manifestation of 'cross' effects, which are considered in the thermodynamics of nonequilibrium processes.^{23, 24}

III. Theory of nonlinear multicomponent sorption dynamics and chromatography, concentration waves, and velocities

Below we shall speak of the systems investigated as chromatographic systems, emphasising thereby that the behaviour of dynamic systems is considered, although the entire description refers both to multicomponent sorption dynamics and to chromatography.

The nature of the motion, interaction, and spreading of multicomponent concentration waves generated when a mixture of sorbable substances moves through a disperse medium (and hence also the separation of the substances in the mixture) depend on the form of the sorption isotherms for the mixture and on the nonideality factors of the chromatographic process. Such factors include a finite rate of mass exchange between the mixture components in the continuous and disperse phases (kinetic inhibition) and the longitudinal dispersion (usually characterised by the effective dispersion coefficient D_l) of the substances in the continuous phase arising due to various irregularities of the flow in the porous medium of the sorbent (dynamic factor).

In the absence of nonideality factors, when the motion of the mixture of substances is determined solely by the properties of the sorption isotherms for the mixture, the nonlinear theory of sorption dynamics and chromatography is described within the framework of the so-called 'ideal model'.^{1, 20–22, 25–73, 80, 81}

In the general case, the theoretical solution of the problem of the sorption separation of a mixture of interfering substances requires the solution of a system of equations in terms of partial derivatives of concentration functions — a system of nonlinear material balance equations.

Many investigations have been based on a computer-assisted numerical solution of such problems.^{95–103, 106–132, 160–179} An analytical formulation of the mixture isotherms in the form of the Langmuir relations (8) is usually employed in such cases. In these investigations, the numerical simulation of various chromatographic regimes was based on mass balance equations.

Special mention should be made of the theoretical and experimental studies carried out under the overall guidance by Professor Guiochon, which were devoted mainly to the modelling of chromatographic elution regimes for binary mixtures.^{106–122, 156–158, 167–173} In these studies, the numerical calculation was based on the so-called 'semi-ideal model' of sorption dynamics and chromatography in which all the spreading effects are described by a single effective parameter characterising the column (the space integration increment \dagger).^{180, 181}

Theoretical studies based on numerical calculations have shown¹⁰⁶ and experiments have confirmed^{111, 146, 184–187} that two new effects (which do not exist in the linear model of chromatography) arise in nonlinear elution chromatography — displacement and 'tag-along' effects.

Both effects are a consequence of the static effects of the competition between the sorbable molecules of two elutable components for available sorption sites. The displacement effect results in a component with small affinity being 'forced out' ahead, whilst the more effectively sorbed component remains behind. The rear boundary of the first peak on the chromatogram assumes the characteristic L -shape under these conditions.⁶⁰ The second effect is manifested in the form of a plateau of the second component, which arises at the outlet from the column after the completion of the output of the first component (the tag-along effect). It has been shown⁵⁸ that the experimental conditions under which the second effect is significant lead to a decrease in the displacement effect and conversely.⁶⁰ It has been shown on the

[†] Previously a numerical calculation of this type, employing the space integration increment, was described in the Russian literature and was better known under the name 'layer-by-layer calculation'.^{182, 183} This method can be applied only when all the mixture components have the same nonideal parameters.

basis of the ideal model using the Langmuir equation for a two-component mixture¹¹⁵ that the intensities of both effects are determined by the ratios of the loadings factors for each component.‡

In the case of mixtures with large amounts of components having different properties, the numerical calculation is performed by the method of finite differences.^{95–103, 131, 132, 168, 174–179}

Following the ideas of Helfferich and Klein,²¹ we shall consider the propagation of concentration waves and dynamic sorption processes in the sorption column. The velocity of the i th species u_i is the average velocity of the propagation of the molecules of this species in the direction of the flow:

$$u_i = \frac{u_0}{\varepsilon + (1 - \varepsilon)a_i/c_i},$$

or in the dimensionless form

$$U_i = \frac{X_i}{Y_i}. \quad (16)$$

The species velocity u_i is lower than the flow rate u_0 , since the molecules of the i th species, having spent some time in the sorbent, are retarded relative to the flow. As can be seen from Eqn (16), the species velocity is determined solely by the equilibrium properties of the sorption system.

The concentration velocity — the velocity of the k th wave (λ_k) — has a physical significance only in the case where the concentration variables $\{X_i\}$ have a gradient with respect to the column length z (or with respect to the time t when the output curve is considered). Similarly the velocity of the (shock) s th wave σ_s may be determined if the corresponding concentration distributions have a discontinuity which is retained during the propagation along the column. The relations between the concentration velocities λ_k and species velocities are derived from the material balance equations.^{21, 188}

$$\lambda_k = U_k + Y_k \frac{\partial U_k}{\partial Y_k}, \quad k = 1, 2, \dots, m. \quad (17)$$

Eqn (17) represents the formulation of the material balance equations in terms of the velocities. It is completely analogous to the relation known in fluid mechanics.^{4, 189} This expression relates the rate of propagation of a given density to the particle velocity and density. Velocities of the wave (λ_k) and the particle (U_k) have always been distinguished in fluid mechanics and the same difference exists also in the theory of chromatography and sorption dynamics.^{1, 21}

According to Eqns (17), the velocities of the wave and the substances differ both in their significance and in magnitude. Thus the sorbable molecules (or ions) may spread with a velocity U_k greater (or smaller) than the velocity of the wave λ_k moving from the larger to the smaller concentrations or conversely. In conformity with the requirement of continuity of flow, the velocity of the molecules then increases (or diminishes) relative to the velocity in the concentration profile along the wave. This leads to sharpening or spreading effects in the concentration waves, to the instability and abolition of the shock waves (or, conversely to their stabilisation and conservation), and to the accumulation (or depletion) of the species in the region of the concentration plateau.²¹

‡ The loading factor is the ratio of the volume of the injected mixture to the column capacity.^{61, 115}

IV. A model of ideal equilibrium sorption dynamics and chromatography

Within the framework of the ideal model of nonlinear equilibrium sorption dynamics and chromatography (in the absence of kinetic and dynamic effects of nonideality), the principal parameters determining the behaviour of multicomponent concentration waves are the sorption isotherms of the mixture components. Interference of the substances leads to nonlinear effects on the concentration waves. The ideal model has been developed by numerous investigators.^{1, 20–22, 25–73}

The operation of the nonideality factors (kinetic retardation and longitudinal dispersion) leads to the smoothing of the nonlinear effects and to the asymptotic establishment of a stable ('coherent')^{21, 22} state in the system. For example, instead of the shock concentration waves, diffuse stationary waves are formed at the asymptotic stage. However, the nonideality factors cannot alter the fundamentally nonlinear influence of the static effects due to the interference of substances.§

In general mathematical terms, multicomponent nonlinear chromatographic systems are described by a system of nonlinear equations in partial derivatives with respect to functions (concentrations in sorption dynamics and chromatography) which depend on two or more independent variables (time and distance in sorption dynamics and chromatography). The assembly of functions describing the behaviour of the system cannot be obtained by the superposition of the solutions of individual equations in the system for each function separately. Any disturbances in the initial conditions generates a complex response in the system, which is described best on the basis of the theory of propagating multicomponent concentration waves.^{4, 21, 22, 46, 47, 50–73, 80, 81} The term 'wave' is defined for sorption systems as the variation of concentration functions.^{77, 193}

V. Concentration waves in multicomponent chromatographic systems

In terms of the approximation of the ideal equilibrium model, the system of material balance equations for the components being sorbed under isothermal conditions assumes the following form in the case of a stationary disperse phase:^{1, 20–22, 25–74}

$$(1 - \varepsilon) \frac{\partial a_i}{\partial t} + \varepsilon \frac{\partial c_i}{\partial t} + u_0 \frac{\partial c_i}{\partial z} = 0, \quad i = 1, 2, \dots, m. \quad (18)$$

For the adjusted time $\tau = c_0(u_0 t - z)$ and the normalised concentrations $X_i = c_i/c_0$ and $Y_i = a_i/a_0$, these equations are written in the form.^{21, 22}

$$\frac{\partial Y_i}{\partial \tau} + \frac{\partial X_i}{\partial z} = 0. \quad (19)$$

Here ε is the porosity of the bed and u_0 the linear flow rate.

Allowance for the interference of the substances requires the simultaneous solution of Eqns (18) [or (19)], which constitute a system of quasi-linear partial differential equations. The characteristic paths or concentration velocities $\lambda_k = (dz/d\tau)_k$ play a decisive role in the solution of such systems of equations.

§ After the introduction of kinetic equations of specific type or abnormal static relations for multicomponent systems with subsequent solution of characteristic equations, complex values have been obtained^{190–192} for the wave velocities λ_k . This leads to variable-amplitude concentration oscillations within the waves. In practice, however, such theoretical regimes have not been observed hitherto. Furthermore, it has been shown,⁵⁰ on the basis of thermodynamic considerations, that only concentration waves with different wave velocities (the characteristic values of λ_k are real and different) can theoretically be generated in chromatographic systems.

The characteristic equation of system (19), which defines these paths, assumes the form^{21, 74–79}

$$|A - \lambda I| = 0, \quad (20)$$

where $|A|$ is a matrix of the type $|A| = |\partial X_i / \partial Y_j|$ and I is a unit matrix. The characteristic values (or eigenvalues) λ_k ($k = 1, \dots, m$) are solutions of Eqn (20). A multicomponent wave of the k th kind, which will henceforth be designated as the k -wave, corresponds to each eigenvalue of the concentration velocity λ_k . In the general case, the number of characteristic paths (λ_k) is equal to the variance (m) of the chromatographic nonlinear system.

The dynamic behaviour of such nonlinear multicomponent sorption systems is determined by the topology of the characteristic paths in the composition space. These topologies for different nonlinear systems with a variance $m = 2$ are presented as clear examples in Figs 1–4 and will be discussed below.

For multicomponent Langmuir sorption systems (8) [or the equivalent ion exchange system (2), (3)], the characteristic equation corresponding to Eqns (19) has the simple form.^{21, 35, 39}

$$H(h, X) = \sum_i \frac{X_i}{h - \alpha_{1i}} = 0, \quad \text{where } i = 1, \dots, n. \quad (21)$$

The function H describes the transition from the composition space $\{X_i\}$ (Fig. 1a) to the functions space $\{h_i\}$ (Fig. 1b) — the Riemann invariants.²¹ It has been shown²¹ that the reverse transition from the invariants space $\{h_i\}$ to the composition space $\{X_i\}$ or $\{Y_i\}$ is described by the relations

$$X_j = \frac{\prod_i (h_i - \alpha_{1j})}{\prod_i (\alpha_{1i} - \alpha_{1j})},$$

$$Y_j = \frac{\prod_i (1/h_i - 1/\alpha_{1j})}{\prod_i (1/\alpha_{1i} - 1/\alpha_{1j})}, \quad i, j = 1, 2, \dots, n, \quad (22)$$

where the symbol $\prod_i A_i \equiv A_1 A_2 \dots A_n$ denotes the product of all the quantities A_i .

The system of Eqns (18) or (19) is called hyperbolic in a narrow sense — when all the eigenvalues λ_k are real and different:⁴⁷

$$\lambda_1 < \lambda_2 < \dots < \lambda_m. \quad (23)$$

These values define the multicomponent concentration waves propagating different velocities λ_k (Fig. 1c).

Using the principal ideas of thermodynamics and the stability criteria for thermodynamic multicomponent systems, Kvaalen et al.⁵⁰ showed that the roots (eigenvalues) of the characteristic equation (20) are real, positive, and different for physically real sorption systems. The different types of behaviour of multicomponent sorption systems with complex and multiple eigenvalues have been examined theoretically in a number of studies.^{103, 190–192}

The concentration waves formed in a sorption column will be the subject of further exposition and we shall therefore discuss briefly this concept. There is no unique definition of the waves. A wave has been defined in a monograph¹⁹³ as any distinguishable signal propagated from one part of the medium to another at a certain definite velocity. Such a signal may be a perturbation of any kind (for example, a pulse or a step) subject to the condition that the perturbation may be clearly distinguished or its location can be determined at any specified instant. The signal may be distorted or its magnitude may change but it must remain distinguishable. For example, a concentration plateau cannot be a wave. The usual subdivision of waves into two classes — dispersing and hyperbolic waves — is not exhaustive, since there are exceptions which do not correspond to either one of these classes. Mainly hyperbolic concentration waves are formed in the

sorption column. There is a clear definition of hyperbolicity⁴⁷ associated with the difference between the characteristic values λ_k [see Eqn (23)].

One of the most interesting phenomena in nonlinear sorption systems in the absence of nonideality factors is the shock waves, which represent sharp discontinuities (jumps) in concentrations (for example, the $M^1 M^2$ wave in Fig 1a). Shock waves arise in nonlinear systems when waves ‘overlap’^{4, 21, 47, 193} or, in other words, when the characteristics intersect on the physical plane (z, τ). Shock waves may appear and be propagated even when they are not induced by an initial discontinuity. After the appearance of a discontinuity, the shock waves in nonlinear systems are not disrupted on further propagation, except under certain stability conditions.^{21, 39, 74, 78, 79} For essentially nonlinear systems of the hyperbolic type, such conditions have been introduced¹⁹³ and called the entropy conditions. The term ‘Lax’s conditions’ is frequently used in the mathematical literature.⁷⁹ These conditions have a simple physical significance — a shock wave is stable if

(a) the s -wave ‘overlaps’, i.e. the characteristics of the same s th kind intersect on the physical plane (z, t), forming a discontinuity line or a shock line σ (see Fig. 1d) and

(b) the $(s-1)$ -wave cannot catch up with the given s -wave, which in its turn cannot catch up with the next (faster) $(s+1)$ -wave (Figs 1c and 1d).

When applied to sorption dynamics and chromatography, Lax’s conditions are sometimes referred to as ‘convexity conditions’ for the isotherms^{98–103, 163–165} by analogy with a univariant ($m = 1$) system in which a shock sorption boundary of one component arises for a convex $f(c)$ isotherm.²⁰

Chromatographic systems where the equilibrium is described by the Langmuir relations (8) are an example of hyperbolic, truly nonlinear systems. For more complex nonlinear systems, having linearly degenerate regions, the stability conditions are subject to a greater number of limitations.^{78, 79, 98, 99} In these systems, there is a possibility of the appearance of combined concentration waves in which the discontinuity is in contact with a spreading wave of the same family. Contact discontinuities of this type may be formed in chromatographic systems in the presence of regions of selectivity reversals.

On the discontinuity line σ (see Fig. 1d), the material balance differential equations are invalid. They must be replaced by a conservation law expressed in an integral form.^{47, 75, 76, 79} In the integral form, this law does not lose its significance for discontinuous solutions and gives rise to relations between the concentrations on the plateau to the left (X_i^s, Y_i^s) and to the right (X_i^{s+1}, Y_i^{s+1}) of the discontinuity in the shock s -wave (an example of the concentration plateau is presented in Fig. 1c, $M^1 M^2$ wave). These relations are independent of the number (i) of the component, so that for any i and j the following relations are valid:

$$\sigma_s = \frac{\Delta X_i}{\Delta Y_i} = \frac{\Delta X_j}{\Delta Y_j}, \quad (24)$$

$$\Delta X_i = X_i^{s+1} - X_i^s, \quad \Delta Y_i = Y_i^{s+1} - Y_i^s; \quad 1 \leq i, j \leq m,$$

which are called in mathematics the Hugoniot or Rankine–Hugoniot condition,^{4, 47} whilst in the theory of chromatography they are referred to as the compatibility condition^{41, 43} or the integral coherence condition.²¹ These relations form a system of algebraic equations, with the aid of which it is possible to determine the composition $\{X_i^s\}$ on one side of the discontinuity, provided that the velocity of the shock waves σ_s and the composition $\{X_i^{s+1}\}$ on the other side of the discontinuity are known.

For a deeper understanding of the behaviour of concentration waves in multicomponent systems, analysis of the nonideality effects is necessary.

The shock concentration waves are an idealisation. When account is taken of dispersion effects, the shock waves in nonideal models assume the form of a distribution with a finite width.¹⁹⁴ In such models, a stationary regime in the propagation of the wave corresponds to shock waves at the asymptotic stage.^{20, 21, 65, 92–94, 104, 105, 125–128, 195–200}

The special class of solutions, referring to simple waves, is of greatest interest for the solution of the material balance equations (18) or (19) for multicomponent chromatographic systems. Such waves arise in truly nonlinear systems. An example of sorption dynamic systems of this kind is provided by systems with equilibria described by the Langmuir relations (8). The initial and final conditions, corresponding to the frontal-displacement variant of sorption dynamics and chromatography, i.e.

$$X_i(0, z) = X_i^0, 0 \leq z; \quad X_i(t, 0) = X_{i0}H(t), \quad i = 1, 2, \dots, m, \quad (25)$$

[X_i^0 and X_{i0} are constants and $H(t)$ is the Heaviside function] lead to the class of centred simple waves.

The solution of the material balance equations (18) and (19) under these conditions is called the solution of the Riemann problem.^{40, 43, 74, 76, 78, 79} In the Russian literature, this problem is called 'splitting of the initial discontinuity'.⁴⁷

In conformity with the criterion of the stability of shock waves,^{74, 78, 79} the splitting problem has a unique solution in the class of centred spreading and shock waves.^{47, 74, 78} When applied to the theory of sorption dynamics and chromatography, such solutions for different conditions have been considered in a number of studies.^{21, 31–34, 37, 39, 40, 43}

In nonlinear m -component chromatographic systems with an invariant affinity sequence, the initial discontinuity is accompanied by the formation of m concentration waves. This number of waves corresponds to the total number of invariants h which are determined by the characteristic equation (21).

In the m -dimensional composition space $\{X_i\}$, the solution $X_i(h)$ describes the Γ curve with the characteristic parameter h , which varies along this curve. The Γ curve is the geometrical image of the solution (see Figs 1a and 2–4). Sometimes the composition space is referred to as the hodograph space,^{4, 40, 43, 158} although this term is used more frequently in mathematics for the special case with $m = 2$ (Courant and Freidrichs⁴) when the composition space is a plane.

The Γ^k curves have been called the composition paths²¹ and the corresponding concentration waves the coherent^{21, 22} or simple^{46, 47, 77} waves. The term 'coherence' has been defined^{21, 22} as the mutual consistency of the concentrations of the components in the concentration k -wave propagating along the sorption column.

Any changes in the compositions along the composition path grid Γ^k are coherent and all other changes are incoherent. It is important to note that the path grid is determined by the type of the material balance equations and the system parameters — the separation factors in adsorption and ion exchange processes and the relative permeabilities in a multiphase flow in porous media. The topology of the composition path grid is independent of the compositions in the influent and initial flows. Therefore, for given components, the grid of Γ^k paths may be determined and then used to predict the response of the system under arbitrary initial and boundary conditions. The combination of the time–distance diagram with the $M^1M^2M^{m+1}$ route, which corresponds to the composition waves in the composition space, yields a full and compact quantitative description of the behaviour of the system in time and in space. An example of such description is presented in Fig. 1: the $M^1M^2M^{m+1}$ route in Fig. 1a and the corresponding $M^1M^2M^{m+1}$ chromatogram in Fig. 1c as well as the physical plane distance–time (z, τ) with the M^1M^2 shock and the M^2M^{m+1} spreading wave in Fig. 1d. In the presence of the path grid in the composition space, it is easy to predict (at least qualitatively) the response of the multicomponent system to any perturbation.

Any pair of constant compositions in the composition space, the images of which lie on a same Γ^k path, are connected by a simple wave and the solution is given by the one-parameter family $\{X_i(h)\}$. The images of the initial and boundary conditions are presented by two different points M^1 and M^{m+1} respectively. The image of the solution of the Riemann problem [Eqns (19) and (25)] in the composition space represents the $M^1M^2 \dots M^{m+1}$ route consisting of sections of the Γ^k paths; each corresponds to the k th wave M^kM^{k+1} of a different ($k = 1, \dots, m$) kind. The route contains the highest values of m for the different sections, which are disposed consecutively from Γ^1 to Γ^m . Each break point M^k on the route (see Figs 1a and 1c) corresponds to a constant state $\{X_i^k\}$. Thus, together with the terminal points M^1 and M^{m+1} , there are $m+1$ concentration plateaux on a multicomponent chromatogram (see Figs 1a, 1c, and 1d).

The solution represented in the physical plane (z, τ) yields the inverse image of this route (Fig. 1d). The physical significance of the picture considered is that the initial discontinuity in the concentrations [Eqn (25)] splits into m concentration waves. The slowest wave corresponds to the characteristic value λ_1 and the fastest to λ_m value. Any of the waves may be of the spreading or shock type. Each wave of the k th kind is separated from the preceding $(k-1)$ th wave by the $M^k\{X_i^k\}$ concentration plateau (see Fig. 1c). The concentrations $\{X_i^k\}$ on the plateau are independent of the dispersion factors and can therefore be determined by calculations carried out within the framework of the ideal equilibrium model.

VI. Coherence

The coherence conditions define a special regime in the propagation of a multicomponent concentration wave in a chromatographic system in which all the concentrations of the mixture components move synchronously along the k -wave. For a two-component system, this condition has been put forward in the form of a postulate.²⁹ Later the coherence condition was formulated by Glueckauf³⁰ in order to obtain a solution in such nonlinear systems. The study of this problem showed⁴⁶ that the coherence condition holds along the characteristics.⁵⁵

The concept of coherence describes states of chromatographic systems which they tend to attain similarly to the way that closed systems tend to a state of equilibrium, while open systems with fixed boundaries and constant boundary conditions tend to attain stationary states.²²

The concept of coherence was developed by Helfferich and Klein.^{21, 35, 36, 80} It makes it possible to treat qualitatively and to calculate quantitatively the chromatograms in multicomponent chromatographic systems under arbitrary initial and boundary conditions. This concept was generalised by Helfferich.^{22, 81} Subsequently the region of its application was extended to multicomponent multiphase flows in porous media,¹⁹⁵ to multicomponent distillation processes,¹⁹⁶ and to coprecipitation and dissolution processes in multicomponent systems. Up to the present day, the concept of coherence has been justifiably applied to the dynamics of multicomponent nonlinear (sorption) systems.^{21, 22, 55, 80}

This global concept^{22, 80, 81} indicates the direction in which the development of a multicomponent system develops towards the final coherent state, which may be attained after a finite time in the ideal model or asymptotically in the presence of nonideality factors in the system. The equilibrium and stationary states of the system are then regarded as special cases.

Any multicomponent wave may be regarded as a composite one, consisting of the waves of the individual components, but, in contrast to linear systems, the multicomponent wave can not be presented as their superposition. The determination of the velocity of a multicomponent wave reduces to the calculation of the eigenvalues λ_k [from a type (20) equation]. The value λ_k characterises the velocity of a coherent k -wave, while the eigenvectors define the change in the mixture composition along such a wave.

tions coexisting at such a point in space must move in the same direction and with the same velocity.

However, the concept of coherence has a broader application, since it includes the problem of the propagation of arbitrary perturbations in open systems.^{21, 80, 81} It has been shown^{21, 22} that coherence may be defined as the state in which all the independent variables (functions) move in a synchronised regime, i.e. without a shift of their (concentration) profiles relative to one another. In mathematics it is known that 'simple waves' behave in this way.^{46, 47, 77} Thus simple waves are coherent by definition.

The principle of coherence reflects the fact that arbitrary perturbations in the system are 'resolved' (splitted) into a series of simple waves. A mathematical proof of this postulate with the aid of the method of characteristics⁴⁶ has been given by Helfferich^{22, 55} for a system of two equations of the hyperbolic type. However, it had been demonstrated previously in a mathematical study⁷⁵ that the region adjoining the region of constant states is a simple wave.

If the perturbation at the inlet to the system is smooth, then its 'resolution' into coherent waves does not occur instantaneously even in the ideal model. The time of attainment of the coherent state depends on several factors, among which the most important is the difference between the eigenvalues λ_k ($k = 1, 2, \dots$). If the lines for the individual families are almost parallel on the grid of composition paths, the resolution (the transition to the coherent state) requires a longer time interval. Furthermore, when account is taken of the nonideality factors in the system, the state of coherence may be attained only at the asymptotic stage.

VII. Description of the concentration distributions in a multicomponent Langmuir sorption system with the aid of the h -transformation

The solution of the Riemann problem is simplified if certain special functions have been found: the Riemann invariants (designated here by h)^{25, 43} or the generalised Riemann vector-invariants.^{39, 40, 43, 65} Such functions have been found for the Langmuir sorption systems (8) or for the equivalent systems (9) involving the exchange of ions with equal valences.^{21, 39, 40, 43}

The following equation is valid for the invariant h_k changing along the Γ^k path:

$$\frac{\partial h_k}{\partial \tau} + \frac{dX_i}{dY_i} \frac{\partial h_k}{\partial z} = 0 \quad \text{for all } i, j = 1, 2, \dots, m, \quad (26)$$

$$\lambda = \frac{\partial z}{\partial \tau} = \frac{dX_i}{dY_i} = \frac{dX_j}{dY_j} \quad \text{for any component } i, \quad (26a)$$

where d is the symbol of the total differential.

Eqn (26) is the fundamental differential equation of the Riemann problem.^{40, 43, 65} It describes the 'conservation law' from which follows the principal property of these invariants, which facilitates significantly the solution of the problem: only the k th Riemann invariant h_k changes along the shock or spreading wave of the k th kind, while all the remaining invariants h_i ($i \neq k$) are constant. In the monograph of Helfferich and Klein,²¹ Eqn (26a) was called the differential coherence condition.

The solution of the differential equation (26) yields the one-parameter family $X(h)$ or the Γ paths in the m -dimensional composition space $\{X_i\}$ (Fig. 1a), as well as a broken curves in the invariants space $\{h_k\}$ (Fig. 1b).

The relations for the characteristic velocities of the shock s th wave (σ_s) and the spreading k th wave (λ_k) have been derived theoretically²¹ with the aid of the concept of coherence:

$$\sigma_s = h_s^1 h_s^{m+1} Q \left(\prod_{i \neq k} h_i \right),$$

$$\lambda_k = (h_k)^2 Q \left(\prod_{i \neq k} h_i \right), \quad Q \equiv \left(\prod_i \alpha_{i1} \right), \quad (27)$$

where h_s^1 and h_s^{m+1} are the values of the invariant h_s , diminishing along the s th wave, to the left and to the right of the shock s th wave respectively (see, for example, the $M^1 M^2$ wave in Fig. 1a as well as

its image — the $N^1 N^2$ wave in Fig. 1b), $\prod_{i \neq k} h_i$ is the product

of all the cofactors h_i except h_k , h_k are the values of the invariants h_k increasing along the spreading k th wave (see, for example, the $M^2 M^{m+1}$ spreading wave in Fig. 1a and also its image — the

$N^2 N^{m+1}$ wave in Fig. 1b), and $\prod_i \alpha_{i1}$ is the product of all the

cofactors α_{i1} ($i = 1, 2, \dots, n$).

For a clear demonstration of the h -transformation, we shall return to the consideration of the geometrical interpretation of the Riemann problem.

The characteristic equation for multicomponent systems (21) involving the exchange of ions of equal valence describes the transition from the composition space $\{X_i\}$ (Fig. 1a) to the invariants space $\{h_k\}$ (Fig. 1b). The reverse transition is described by Eqn (22).^{21, 35}

The following criteria for the sharpening or spreading of the concentration k th wave, expressed in terms of the invariants h_k , are obtained from Eqns (27): if the value h_k increases along the concentration k -wave, then the velocity λ_k increases and the k -wave spreads (see the $N^2 N^{m+1}$ wave in Fig. 1b and the $M^2 M^{m+1}$ wave in Figs 1a, 1c, and 1d); if the invariant h_s decreases along the s -wave (even if we assume that it is initially diffuse), then this wave tends to become sharpened, becomes a shock wave, and subsequently moves with a velocity σ_s defined by Eqn (27).

The invariant h_k in Eqn (26), changing along the k th wave, can be found by solving Eqn (21), which relates the composition in the wave to the value of this invariant.

The simplification of the solution of the problem on the basis of the function-invariant h consists in the fact that the $M^1 \dots M^m$ in the composition space consisting of sections of the Γ^k paths (see Fig. 1a) corresponds in the invariants space $\{h_k\}$ to the $N^1 \dots N^{m+1}$, the lines in which are orthogonal (see Fig. 1b). Only the invariant h_k out of the assembly $\{h_1 \dots h_k \dots h_m\}$ changes along the k -wave. The linearity of the Γ^k composition paths in the composition space is the property of the Langmuir m -component systems (or the equivalent systems involving the exchange of ions of equal valence) which permits the orthogonalisation of the space, and this simplifies the consideration of the dynamic behaviour of these nonlinear systems. It is noteworthy that the linearity of the Γ paths in the composition space is retained along the stationary concentration waves for multicomponent Langmuir systems even in the presence of dispersion factors identical for each component.^{65, 104, 105, 197–200} This property makes it possible to obtain solutions describing the concentration profiles in the stationary waves for this case.

In the physical plane (z, τ) , the region corresponding to the Γ^k path is covered by a set of lines-characteristics λ_k^l (the dashed line in Fig. 1d) corresponding to the characteristic value λ_k . The direction of the characteristics of the k th kind in the plane (z, τ) is specified by the quantity λ_k . Since the function h_k is constant along each characteristic λ_k^l , each value of $\{X_{iQ}\}$ is represented by a point on the Γ^k path (for example, point Q on the MN line in Fig. 2). Each characteristic λ_k^Q is then a straight line in the physical plane. The family of such straight lines in the plane (z, τ) represents a simple k -wave (see Fig. 1d, the family of the lines $\lambda_2^1 \dots \lambda_2^{m+1}$, $k = 2$). If the inequality $d\lambda_k/dz > 0$ holds in the region of the simple wave, then the characteristics diverge and the k th wave spreads as a function of time. Such a wave is referred to as 'spreading'^{196, 201} or 'nonsharpening'.²¹

It has been noted in a monograph²¹ and a state of the art review²² that in the theory of chromatography the h -transformation (albeit under a different name) was first proposed by Davidson in 1949 for ion exchange but remained unnoticed.²² This transformation was proposed independently by Zhukhovitskii and coworkers^{21, 22, 202, 203} for the theory of the high-concentration gas chromatography, vacancy chromatography, and the chromatography without a carrier gas for constant partition coefficients.

As noted in the above review,²² the polynomial (h) in Eqn (21) is used in differential geometry, but for the description of the behaviour of multicomponent systems in electrodiffusion, electrophoresis, and distillation, this transformation was discovered anew. The transformation (21), based on the h -invariants, has been widely applied to systems in which the interference of the components takes place without any discrimination, i.e. the substances participating in the separation process compete under the conditions of constant relative strengths in the realisation of the function determining the given process.²² The role of such a function may be assumed by the parameter characterising the degree of occupancy of the adsorption sites in chromatography, the fraction of the void space in vacancy chromatography (or distillation), the transport of electric current in electrophoresis,³ etc. Competition between the components in the absence of discrimination then corresponds to constant binary interaction coefficients: the separation factors in chromatography, the relative volatilities in distillation, and the relative electrochemical mobilities in electrophoresis.

A computer program, permitting the calculation of both the h -transformation and of the concentration profiles on the basis of the ideal model, has been developed.⁴⁹

Studies have been performed in which the results obtained in the theory of the chromatography of multicomponent systems have been extended to systems with precipitants and with dissolution of the precipitants.^{201, 204}

A scheme for the solution of the problem of the multicomponent frontal-displacement sorption dynamics and chromatography follows from the foregoing. On the basis of the solution of the characteristic Eqn (21) using the known coordinates of the points M^1 (influent concentrations) and M^{m+1} (initial concentrations in the column) in the concentrations space, the coordinates of the corresponding points N^1 and N^{m+1} in the invariants space $\{h_k\}$ are calculated.

Next, the coordinates $\{h_k^l\}$ ($l = 1, \dots, m$) of the intermediate points N^k on the plateau between the k th and $(k+1)$ th waves are determined in the invariants space. The orthogonality of the representation of the waves in the invariants space is then employed in the calculation. Only one invariant h_k changes (from h_k^l to h_k^{m+1}) along the k th wave ($N^k N^{k+1}$) in this space [all the remaining invariants h_i ($i \neq k$) remain constant], while all the k -waves from point N^1 to point N^{m+1} are arranged in order of increasing index $k = 1, \dots, j, \dots, m$. The coordinates $\{h_k^l\}$ found are then employed to determine the coordinates $\{X_i^k\}$ of points M^k on the concentration plateau between the k th and $(k+1)$ th waves with the aid of Eqns (22).

This scheme for the calculation of concentration plateaux is used in combination with the solutions obtained for stationary waves for multicomponent Langmuir systems.^{104, 105, 198, 204} The above approach made it possible to demonstrate^{105, 198, 200} how a theoretical calculation can be used to correct and test the operation of numerical schemes for computer calculations^{98, 99} concerning problems in the theory of multicomponent sorption dynamics and chromatography.

VIII. The equivalence of multicomponent Langmuir systems and multicomponent systems with a nonuniform mobile phase velocity due to the sorption effect

The flow rate u in the material balance equation cannot remain constant if significant composition variations take place in the column, with involving net sorption and desorption steps in the molecules. This effect was first described^{205, 206} for a single component system. Different aspects of this effect, including the effect in multicomponent systems, have been investigated.^{207–218} Two reviews by Guiochon,^{213, 217} in which the results of the theory of gas chromatography with finite concentrations are discussed, are of great interest. These reviews deal briefly with problems in the solutions of systems of partial differential nonlinear equations by the method of characteristics and discuss the problems of the stability of the shock waves (concentration discontinuities).

In the separation process, net desorption steps at the rear boundary and net sorption steps at the leading boundary of the chromatographic band respectively introduce the molecules of the substance into the mobile phase and remove them from the latter. The flow rate in the region of the chromatographic band is therefore higher of the rear boundary and lower at the leading boundary.

This effect, which is significant for gas chromatography, is sometimes referred to as the 'sorption effect'²¹⁶ and its influence on the profile of the sorption band of one substance has been examined in the theory of chromatography without a carrier gas.^{203, 210, 211} The dependence of the flow rate on the concentration of the substance has been found for a one-component system.²¹⁵ The importance of the sorption effect in chromatographic separation at high concentrations has been emphasised.²¹⁴

The behaviour of the n -component sorption C system, in which account is taken of the influence of sorption effects, has been examined.^{65, 69, 198, 199} In this system the $f_i(c)$ isotherms are linear for each component, while the flow rate u is nonuniform due to the 'sorption effect':

$$f_i(c) = \gamma_i c_i; \quad \sum_{i=1}^n c_i = c_0 = \text{const}, \quad i = 1, 2, \dots, n. \quad (28)$$

It is postulated that the pressure drop in the column may be neglected and that the ideal gas law holds. The sorption effect is taken into account in gas chromatography, while in liquid chromatography it is usually neglected, although in the latter case condition (28) represents incompressibility with retention of the overall concentration c_0 of all the components. In liquid chromatography, this effect may be neglected because of the smallness of the volume changes in the sorption-desorption steps.

The Langmuir system (8) and the C system are united by one common property: in both systems, the separation factors for the i th and m th components are constant, i.e. $\alpha_{mi} = (a_m/c_m)/(a_i/c_i) = \text{const}$. The mixture components $\{c_i\}$ form the affinity sequence 1, 2, ..., n , in which the substances are numbered (and arranged) in order of decreasing affinities of the components for the sorbent:

$$\gamma_1 > \dots > \gamma_i > \dots > \gamma_n \quad \text{or} \quad \alpha_{11} < \dots < \alpha_{1i} \dots < \alpha_{1n},$$

where

$$\alpha_{1i} = \frac{\gamma_1}{\gamma_i}. \quad (29)$$

The existence of the relation (28) makes it possible to eliminate one variable (c_n) from the equations. The system of the mass balance equations then defines only $n-1$ independent functions c_i .

The invariant solutions of the system of quasi-linear material balance equations have been analysed on the basis of the ideal model.^{65, 69, 198} These solutions describe the propagation of the sorption shock and spreading concentration waves at high concentrations of the components in the multicomponent C system.

A relation for a variable flow rate u , reflecting the sorption effect, was derived for the first time for the C system by the present author.^{65, 200}

$$u = \frac{Q}{H - R/c_0} = \frac{Q}{\mu}; \quad \frac{u}{1 + \gamma_i} = \frac{Q_i}{H - R/c_0};$$

$$Q_i = \frac{Q}{1 + \gamma_i}, \quad (30)$$

where $H = \text{const}$, $R = \sum_i^n (f_i)$, and Q is the integration constant determined from the initial conditions.

Eqn (30) thus derived represents the dependence of the flowrate u on the concentrations of a mixture of m components.^{65, 198, 200} When account is taken of Eqn (30), the differential equations for the C system are identical with the mass balance equations describing the multicomponent Langmuir system (8). The relations

$$\frac{ue_i}{1 + \gamma_i} = \frac{Q_i e_i}{H - R/c_0},$$

where $e_i = (\gamma_i - \gamma_n)c_i$, play the role of multicomponent inverse Langmuir isotherms $G_i(a) = f_i^{-1}(c)$ in the mass balance equations for the C system [see Eqn (7)].^{69, 198}

The characteristic equation for the C system is formally identical with the corresponding equation for a multicomponent Langmuir system.^{65, 69, 198, 200} The separation factors (γ_m/γ_i) for the components m and i in the C system are completely analogous to the separation factors $\alpha_{mi} = \gamma_m/\gamma_i$ [see Eqn (29)]^{69, 198} used in the multicomponent theory of chromatography.²¹ The invariants μ_k/γ_1 have the same properties as the invariants $1/h_k$, where h_k are functions introduced for the Langmuir systems.²¹ All the calculations of the chromatograms for the Langmuir system based on the equilibrium model can then be carried out also for the C system using h_k and the ratio $\alpha_{1m} = \gamma_1/\gamma_m$ ($m = 1, 2, \dots, n$), taking into account the agreement between the separation factors for the two multicomponent systems considered. In the Langmuir system (8), the components also form the affinity sequence 1, 2, ..., m , in which they are arranged in order of decreasing affinity for the sorbent, namely $\alpha_{1m} > \alpha_{1i} > 1$ [see Eqn (29), $\alpha_{11} \equiv 1$], where $i < m$.

Only the invariant h_k , as well as the vector-invariant $[J_{kk}]$, varies along the characteristic (Γ^k) k -path (corresponding to a wave of the k th kind), whereas the remaining invariants h_m ($m \neq k$) and $\{J_{mk}\}$ ($m \neq k$) do not vary (Fig. 1b). The corresponding change in the invariant h_k (increase or decrease) determines the type of multicomponent k -wave (spreading or shock) in the chromatogram (see Fig. 1b; decrease of h_1 from h_1^1 to h_1^{m+1} along the M^1M^2 wave and increase of h_2 from h_2^1 to h_2^{m+1} along the M^2M^{m+1} wave).

Relations expressing λ_s (for a spreading wave) or σ_k (for a shock wave) (see Fig. 1d) in terms of the product of the Riemann invariants $h_1 \dots h_m$ (or $\mu_1 \dots \mu_m$) are valid for the characteristic velocities of the multicomponent concentration k -waves in the chromatogram.

For the multicomponent C system, the grid of composition paths in the concentration space has the same properties as for a multicomponent Langmuir system (8). An example for a two-component Langmuir system ($m = 2$) or a system with $n = 3$ is presented in Figs 1a and 2 (the concentrations c_i are then expressed

in terms of an acute-angle coordinate system). The coupling condition (28) reduces the three-dimensional concentrations space $\{c_i\}$ to the $P_1P_2P_3$ plane, where $c_i(P_i) = c_0$ (see Fig. 1a). The shock k -wave (or a stationary wave in the nonideal model) arises in the composition space if the change in the concentrations corresponding to this wave takes place in the direction opposite to that indicated in Figs 1 and 2 (i.e. if the invariant h_k or the corresponding invariant γ_1/μ_k diminishes along the k -wave — see Fig. 1b). The velocities of the shock and spreading k -waves are determined by the magnitude of the h_k -invariant in accordance with Eqn (27).²¹ A large number of examples of composition path grid for multicomponent (m -component) Langmuir systems (or the equivalent systems involving the exchange of n ions of equal valence, where $n = m + 1$) are quoted in the monograph by Helfferich and Klein.²¹ Similar path grids on the $P_1 \dots P_n$ simplex may be obtained also for the C system. The distributions of the concentrations of the components along the shock or spreading k -wave and its velocity are then described with the aid of the h_k -invariant. Examples of such calculations have been published.²⁰⁰

These data indicate the equivalence of the multicomponent sorption systems: C , where there is a sorption effect, and the Langmuir system (8). Naturally, the main result is the possibility of using for such systems a simple procedure for the calculation of the multicomponent (shock and spreading) concentration waves on the basis of the h -invariants.

IX. Multicomponent chromatographic systems with an invariant affinity sequence of the components

The nonlinear theory of sorption dynamics and chromatography may be used also in the calculation for a stoichiometric n -component system consisting of ions with $n = 3$, where all the characteristics lie in one plane (see Fig. 1a). In Figures 1–4 the characteristics of the first kind (Γ^1) are represented by continuous lines and those of the second kind (Γ^2) by dashed lines. In this case, the simplex triangle $P_1P_2P_3$ in the space of the Riemann invariants $\{h_k\}$ is transformed into the rectangle $P'_1P'_2W'P'_3$ (see Figs 1a and 1b).

Points W in Figs 1a and 1b and in Figs 2–4, at which the characteristic velocities of the k -waves coincide, are referred to as the 'watershed' points.^{21, 37, 38} The coordinates of point W for

Figure 3. A variant of the hodograph for a stoichiometric three-component system for which the equilibrium relations [of the type of the Law of Mass Action (15) for heterovalent ions] are valid. The ANW_2MB and QW_2MB routes correspond to different variants of the concentration waves (see text).

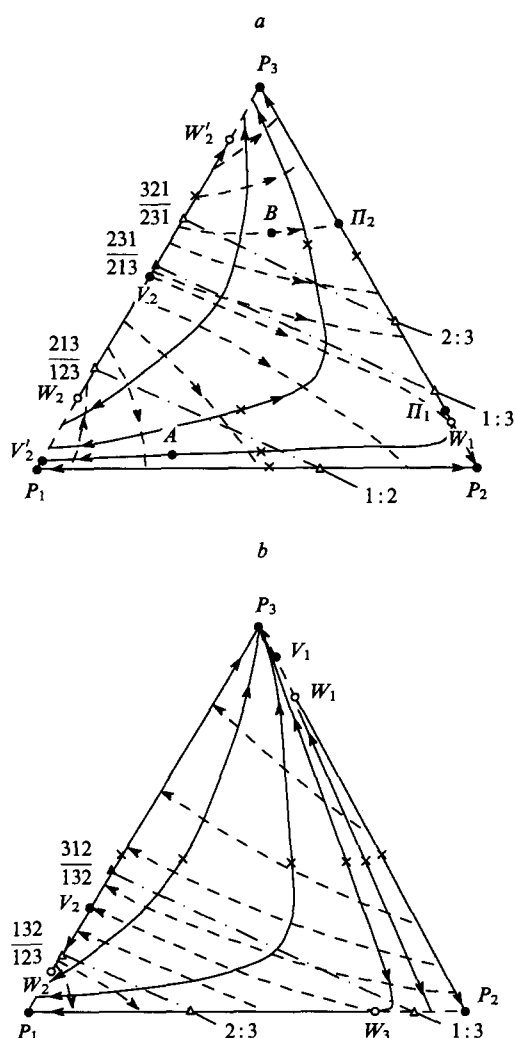

Figure 4. Variants of the hodographs obtained by numerical calculation for a stoichiometric three-component system including selectivity reversals even in a binary exchange (when the binary isotherms f_{ij} are S-shaped). (a) The presence of the inversion $i:j$ (dash-dot lines) for the 1/2, 1/3, and 2/3 components (the corresponding isotherms f_{ij} are S-shaped); (b) the presence of the inversion $i:j$ (dash-dot line) for the 1/2 components (the corresponding isotherm f_{12} is S-shaped); the crosses (x) denote the concentration points at which the wave velocity λ_k on the Γ^k paths is minimal; points V_k correspond to the points of intersection of the borders of the simplex with the Γ^k paths passing through different watershed points W within the composition region; the AP_1P_2B , $P_3V_2W_1P_2$ (a), and $P_3V_2W_3P_2$ (b) routes correspond to different variants of the concentration waves (see text).

systems with constant separation factors (8) are defined by the relation²¹

$$X_W = \frac{\alpha_{12} - 1}{\alpha_{13} - 1}.$$

The characteristics of the first kind (Γ^1) begin on the P_2P_3 side and terminate on the WP_1 segment. All the characteristics of the second kind (Γ^2) begin on the WP_3 segment and terminate on the P_1P_2 side. Each characteristic of the first kind intersects all the characteristics of the second kind and conversely. As a consequence of this, any two composition points, not located on one characteristic, may be connected by a route which initially follows Γ^1 and then Γ^2 paths, i.e. waves of the first kind and then of the second kind are formed in succession in the corresponding chromatogram. The simplex borders P_1P_2 , P_1P_3 , and P_2P_3 are

also characteristics and only they originate from the P_1 , P_2 , and P_3 corner points. There are no characteristics originating from these points within the composition region. Thus two substances cannot be absent on one side of the concentration wave and present on the other. In systems with a variable selectivity of the components, such effects may occur (see Section X).

In the case of an n -component system, the simplex gives rise to an equilateral n -gonal pyramid, but there are no fundamental differences from the case where $n = 3$.²¹

The principal rules governing the behaviour of simple (or coherent) waves may be derived from the compatibility condition (24) (for shock waves) and Eqn (26a) (for spreading waves), and also from properties associated with the continuity of the stream of molecules [see Eqns (16) and (17)]. The same rules may be obtained with the aid of the properties of the Riemann h_i -invariants and Eqn (27). However, these conclusions are valid for systems with constant separation factors α_{ij} . The rules governing the behaviour of simple waves, obtained with the aid of the velocities, are less rigorous: in this, case an invariant selectivity sequence and competitive sorption, reflected by relations (4) and (5), are needed.

In a simple wave, the species velocities u_i differ from the characteristic velocities λ_i , so that the molecules of different species pass through the propagating wave in the direction of flow or in opposition to it. This behaviour gives rise to the following effects.²¹

1. Along the wave the species velocities u_i and the concentrations X_i of all the substances change simultaneously.
2. The existence of the so called 'affinity cut'. This cut subdivides the substances in the affinity sequence $1, \dots, j, k, \dots, n$ into two groups: the high affinity group ($1, \dots, j$) and the low affinity group (k, \dots, n). The cut is designated by $j|k$. The species velocities u_i in the first group are lower and those in the second group are higher than the composition velocity (λ_i for a spreading wave or σ_i for a shock wave). The concentrations of the substances in the wave also vary in the opposite directions (if those of the substances in the first group increase then the species velocities in the second group diminish and conversely).

For an n -component (but m -variant) stoichiometric system (9), there is a possibility of $n-1$ positions of the affinity cut, namely those ranging from $1|2, \dots, n$ to $1, 2, \dots, (n-1)|n$, where the cut $k|(k+1)$ corresponds to a simple wave of the k th kind with a characteristic velocity λ_k . No concentration can vary abruptly if all others vary smoothly. One of the most important corollaries of the rules under discussion is the fact that only the substances j and k , separated by the cut $j|k$, can be present on one side of the wave and absent on the other. All other components are either present on both sides and within the wave or are altogether absent. However, two substances j and k cannot be absent from the same side of the wave, since their concentrations vary in opposite directions.

The transformation of m -component (and m -variant) Langmuir systems (9) into stoichiometric n -component (but m -variant) systems makes it possible to represent hodographs also for Langmuir systems within the space of the simplex. Fig. 2a presents a hodograph for a two-component Langmuir system with competitive sorption ($b_1, b_2 > 0$). The concentrations of the components i and j do not exceed unity and are reckoned in an acute-angle coordinate system.

Complications may arise only in the case where some of the coefficients b_i are negative. For example, the hodograph for systems with synergistic sorption, where the corresponding coefficients for one or more substances are negative ($b_i < 0$), is illustrated in Fig. 2b. As in stoichiometric systems, in such systems the initial discontinuity in concentrations splits into a chain of shock and/or spreading simple waves. Difficulties in the formation of multicomponent waves then arise. Thus Fig. 2b shows that the route along the characteristics in order of their increasing indexes, i.e. $BF^1\Gamma^2M$, is impossible between certain concentration points B (composition at the inlet to the column) and M (initial

composition in the column). In this case, the solution determining the chromatogram tends to the *BNM* route, passing partly along the envelope indicated in Fig. 2b by a dash-dot line. This route does not contain intervening plateaux. Furthermore, routes which may be referred to as metastable (for example, the *ANB* route corresponding to a single, but unstable wave) are likely on this hodograph. Small perturbations lead to the 'switching' of the metastable *ANB* route to the *AN₁B* route corresponding to two simple waves: a wave of the first kind *AN₁* and a wave of the second kind *N₁B*.²¹

In systems with invariant affinity sequence of the components the topology of the characteristics in the composition space (Fig. 3) is similar to that which occurs in systems with constant separation factors α_{ij} (Figs 1 and 2), but the characteristics are not straight lines (Figs 3, middle part of the hodograph). As a result, in systems with variable separation factors α_{ij} the route corresponding to the shock wave does not coincide with the characteristic, although it passes close to it.²¹ The deviations of the shock route are usually small, so that the characteristics may be regarded as a satisfactory approximation also to shock waves.

Problems of frontal and frontal-displacement sorption dynamics in a system with a variance $m = 2$ and with an invariant affinity sequence, in which the first component is always sorbed more effectively than the second, have been examined on the basis of the nonlinear theory of multicomponent sorption dynamics for the ideal model using hodographs with variable factors α_{ij} .²⁰⁰

All the variants of the two-component displacement chromatographs [for both convex (favourable) and concave (unfavourable) isotherms] of the components can be readily obtained with the aid of the hodograph presented in Fig. 2. Both shock and spreading waves are then obtained in the displacement chromatograms in the presence of both enhanced concentration and dilution (deconcentration) of the displaced component.

We shall consider initially the variant where both isotherms $f(c)$, of the displacing agent and the displaced component, are convex (see Fig. 2a).²⁰⁰

1. If the sorbability of the displacing agent is greater than that of the displaced component (i.e. the displacing agent is component 1 and the displaced component is component 2), then the *NMB* and *NMA* routes on the simplex $P_1P_2P_I$ correspond to the displacement regime. The displacement chromatograms corresponding to these routes have been published.²⁰⁰

2. If the sorbability of the displacing agent is lower than that of the displaced component (i.e. the displacing agent is component 2 and the displaced component is component 1), two displacement regimes, corresponding to the *MNL* and *MQS* routes, are possible. It has been noted²⁰ that in this case the displaced first component is concentrated on the plateau (C_1^*) in the intervening zone (the *MNL* and *MQS* routes respectively), but the sharp (shock) displacement wave does not arise under these conditions and two-wave displacement regimes occur: the spreading 1-wave *MN* (or *MQ*) and the shock 2-wave *ML* (or *QS*). The case of the spreading wave *NT* is an exception (see Fig. 2a, *MNT* route).

The overall character of all the types of chromatograms in the case of concave isotherm $f(c)$ consists in the fact that the concentration of the displaced component diminishes on the plateau between the concentration k -waves ($k = 1, 2$). The concentration waves may be both of the spreading and shock types in conformity with the criteria (26).

The possible variants of the calculation of the concentration waves in the displacement sorption dynamics regime for a two-component Langmuir system with different convex and concave isotherms have been examined.²⁰⁰ Tsabek⁹⁸ carried out a numerical computer calculation of two types of displacement chromatograms for two-component Langmuir isotherms. Comparison of the results with those of the present author²⁰⁰ showed that the special cases of the regimes examined in the present author's study²⁰⁰ were obtained in the numerical calculations. For other initial and boundary conditions, it is possible also to obtain other displacement regimes.²⁰⁰ Thus the results of the numerical

calculation do not always yield general conclusions about the behaviour of concentration waves in nonlinear chromatographic systems.

X. Chromatographic systems with regions including selectivity reversals of the components

We shall consider initially a system in which the ion exchange is stoichiometric and is described by the Law of Mass Action. For ideal ion exchange, this variant corresponds to the exchange of heterovalent ions, but in the general case sorption systems can also be assigned to the above systems. The stoichiometric coefficients v_i and v_s for which Eqns (15) hold can then be regarded as empirical.

For systems in which the sorption equilibrium is described by Eqns (15), it has been shown²¹ that the sorption of all the components, other than the two arbitrarily selected components k and l , diminishes if the concentration of component k with a higher affinity for the sorbent increases as a result of the decrease in the concentration of component l having a lower affinity. Thus the sorption in which the equilibrium is described by Eqns (15) is competitive. The condition of competitiveness, obtained for these systems in the monograph by Helfferich and Klein,²¹ refers to differential changes in concentration for a given mixture composition and does not eliminate the selectivity reversals arising in the system, which will be discussed below.

The characteristic equation for such systems yields $n - 1$ real roots λ_k ,²¹ which fall within the range $V_k < \lambda_k < V_{k+1}$, where

$$V_k = \frac{X_k}{Y_k}, \quad k = 1, 2, \dots, (n-1). \quad (31)$$

As in systems with a invariant affinity sequence, in the system under consideration there is an affinity cut. The condition of sorption competitiveness and the existence of the $(n - 1)$ th affinity cut for an arbitrary composition does not eliminate the reversal of selectivity. Within each region with an invariant affinity sequence, the properties of the systems (15) are the same as those of the Langmuir systems but with the difference that here the characteristics are not straight lines (see the example of Figs 3 and 4) and cannot be orthogonalised with the aid of the Riemann invariants (by the h -transformation). In this case, the path grid may be found by the numerical integration of the equation relating the concentrations of the components in the wave.^{21, 66, 200} The separation factor α_{ij} in these systems is variable and depends on the concentrations. When $v_i \neq v_j$, the separation factor varies both as a function of the partition ratio of the components and of mixture composition. If the separation factor α_{ij} varies in the range $\alpha_{ij} < 1$ to $\alpha_{ij} > 1$ course of such variation, then the components i and j change places in the sorption series. This phenomenon is in fact referred to as selectivity reversal or inversion. When the inequality $v_i < v_j$ holds, the separation factor α_{ij} is greater in the concentration range where the partition ratio Y_j/X_j greater, i.e. where there is less competition from the component (i) having a higher affinity for the sorbent. If the composition changes in the direction of a greater proportion of substances with a low affinity, then the affinity of substances with a low stoichiometric coefficient v_i increases relative to the other substances.²¹

The lines in the composition space on which the inversion of components i and j takes place (i.e. the equality $\alpha_{ij} = 1$ holds on this line) have been called^{21, 36, 37} 'reversals' and in the present review are designated by ' $i:j$ ' (the dash-dot lines in Figs 3 and 4). From the standpoint of the appearance of a possible inversion, the specification of the numbering of the substances in the sorption series has been modified.²¹ The substances are numbered in accordance with the rule

$$i < j, \quad \text{if} \quad K_{ij} > 1. \quad (32)$$

In the i/j binary system, for two arbitrary substances, the affinity of the substance with a smaller number is greater. In systems without inversion the definition (32) is equivalent to that

presented above. If inversion takes place in the system, then the composition space is divided by the reversals $i:j$ into regions where $\alpha_{ij} < 1$ and $\alpha_{ij} > 1$ (see Figs 3 and 4). For the systems (15), the reversal $j:k$ in the composition space is described by the equation of a $(n-2)$ -dimensional hyperplane parallel to the P_jP_k edge in the simplex $\{Y_i\}$ or $\{X_i\}$ (for $n = 3$, this is a straight line; see the 1:2 and 2:3 reversal lines in Fig. 3).²¹ For any two substances j and k , such a hyperplane exists $v_j \neq v_k$. There is only one hyperplane j/k of this kind, so that multiple reversal of the selectivities of components j and k does not take place. All these rules can be observed in relation to the hodograph illustrated in Fig. 3.

A sufficient condition for the existence of the reversal $j:k$ is

$$(K_{ij})^{v_k} > (K_{ik})^{v_k} \quad \text{when} \quad j < k, \quad i \neq j, k. \quad (33)$$

The system (15) has at least one reversal $j:k$ or $k:l$ if the coefficients v_i for the three components j , k , and l satisfy the condition

$$v_j, v_l > 2v_k \quad \text{when} \quad j < k < l. \quad (34)$$

It has been noted in the monograph by Helfferich and Klein²¹ that condition (34) contains no coefficients K_{ij} , so that the widely held view that there is no reversal of selectivity when $K_{1n} > K_{2n} > K_{(n-1)n}$ is erroneous. For example, a three-component system ($n = 3$) with $v_1 = 2$, $v_2 = 1$, and $v_3 = 3$ has at least one reversal regardless of the quantity K_{ij} .²¹

The influence of the reversals on the disposition of the characteristics and hence on the dynamic behaviour of chromatographic systems, described by equilibria of type (15), is not very strong owing to the existence of the following rules, which the reversals obey.

1. All the reversals are such that only neighbouring substances change places in the affinity sequence. Thus, for the reversal $j:k$, the affinity sequence changes as follows: $1, \dots, j, k, \dots, n \rightarrow 1, \dots, k, j, \dots, n$ even if j and k do not occupy neighbouring positions.

2. The reversal $j:k$ is not intersected by the characteristic with the cut j/k (for example, the Γ^1 paths in Fig. 3 intersect the reversal 2:3, while the Γ^2 paths intersect the reversal 1:2). Therefore, along any Γ^k path the compositions of groups with high and low affinities do not change. As a result, all the concentrations in the corresponding concentration wave vary monotonically.

3. Sorption remains competitive despite the reversals, so that within the limits of each region between the reversals the orientation of the characteristics and the qualitative dynamic response of the chromatographic system remain the same as in systems with invariant affinity sequence.

However, new features also appear — there is a greater number of watershed points (points W_1 , W_2 , and W_3 in Fig. 3a). Point W_2 on the P_1P_3 segment is unusual because it includes the Γ^1 and Γ^2 paths, which are tangents to the border P_1P_3 of the simplex. This property was first described by Tondeur.³⁷ In addition, the postulate that all the paths of one kind intersect all the paths of another kind, applicable to systems without inversions (cf. the hodographs in Figs 2 and 3), now ceases to be invalid.

The hodographs for systems with inversion have paths along which the velocity λ_s is constant. Such paths coincide with the reversal (the path j/k on the reversal $j:k$). For example, on Fig. 3 the reversal 1:2 coincides with the Γ^1 path and the reversal 2:3 coincides with the Γ^2 path. The concentration changes along the wave corresponding to migration along all these characteristics are not sharpened and do not become diffuse in the ideal model. Evidently, in the presence of dispersion effects in the nonideal model, such waves do become diffuse.

In contrast to systems with invariant affinity sequence in systems where a component participates in more than one reversal (for example, component 2 undergoes inversion in the reversals 1:2 and 2:3 — see Fig. 3), the initial discontinuity in concentrations may split into a larger number of concentration waves, exceeding the variance of the system (m).

Thus in Fig. 3 the ANW_2MB route from the concentration point A via the watershed point W_2 and extending to point B and intersecting two reversals gives rise to three concentration waves: AN , NW_2M , and MB . The component (in the given instance component 2) may be present when the column is filled initially (point B) and may be moved to the inlet (point A), but it is absent from the intervening concentration wave NW_2M .^{21, 200}

This variant may occur also in the case where the route runs along the Γ path, which is tangential to the border of the simplex at the watershed point W (see the concentration wave QW_2M in Fig. 3; point Q corresponds to the mixture composition at the inlet to the column).

We shall consider the properties of nonlinear chromatographic systems in the presence of static complex-formation effects when the inversion $i:j$ may arise even for the i/j binary exchange of a pair of components i and j . In this case, the binary exchange isotherm f_{ij} can have the S - or σ -shape.^{48, 66} A common feature of complex-forming systems in the presence of inversions consists in the fact that the concentration wave may be combined, i.e. may contain both discontinuous and diffuse sections.

Figs 4a and 4b present certain variants of hodographs (among those obtained by numerical integration)⁶⁶ for a system modelling the static complex-formation effects in which the multicomponent isotherms are represented by bi-Langmuir multicomponent isotherms.¹⁴⁹ The nonmonotonic variation of the wave velocity along the wave implies that the corresponding concentration wave may be partly of the shock type and partly of the spreading type — a property which is absent from the sorption systems (9) and (15).

The possible reversals for a three-component system, shown in Fig. 4a, are 1:2, 1:3, and 2:3. A hodograph of this type has been presented in a study⁴⁸ where the exchange of ions of equal valence in the presence of complex formation was considered. In this case, all three binary exchange isotherms $f_{1/2}$, $f_{1/3}$, and $f_{2/3}$ are S -shaped. The same topology of the characteristics, but this time with two reversals, was observed in the above study⁴⁸ and obtained in a theoretical investigation.⁶⁶ The binary isotherms $f_{1/3}$ and $f_{2/3}$ are then S -shaped, while the isotherm $f_{1/2}$ is convex (favourable). Other possible variants of the hodographs for a three-component system in the presence of complex formation have been quoted by the present author.⁶⁶ As for the systems (15), the hodographs for the above systems have several watershed points (cf Figs 3 and 4). There are also characteristics along the tangent to the border of the composition triangle within the composition region (cf the Γ^1 paths passing through the watershed points: through point W_1 in Fig. 4a and through point W_3 in Fig. 4b).

In the previous Section, it was noted that composition lines originating from the corner points of the simplex within the composition region are absent from the hodographs for essentially nonlinear systems. This means that on the chromatogram two components cannot be absent on one side of the wave and present on the other. For complex-forming stoichiometric systems, chromatograms of this kind are possible. For example, on the chromatogram corresponding to the $P_3V_2P_2$ route (Fig. 4b), two components i ($i = 1, 2$) are present only on one (left) side of the shock 2-wave V_2P_2 . In the usual stoichiometric systems, component 3 separates components 1 and 2 on the chromatogram, whereas on the chromatogram corresponding to the $P_3V_2P_2$ route, components 1 and 2 cannot be separated from one another (for further details on this topic, see the present author's earlier communication⁶⁶). The inversion of components 1 and 3 on the isotherm $f_{3/1}$ plays a decisive role in the formation of such a chromatogram.^{66, 200}

For the S -shaped binary isotherm $f_{1/3}$ and the convex (favourable) binary isotherms $f_{1/2}$ and $f_{2/3}$, a study has been made on the basis of qualitative considerations of the possibility of the formation of chromatograms consisting of two shock waves (see Fig. 4b):²¹⁹ the 1-wave P_3V_2 and the 2-wave V_2P_2 . The formation of displacement chromatograms of this type has been demonstrated experimentally.²²⁰

It was stated above that in the general case $n - 1$ concentration waves, separated by $n - 2$ intervening plateaux (Π_k), arise in nonlinear chromatographic n -component stoichiometric systems with invariant affinity sequence of the components. Thus, routes with a single intervening plateau Π_1 (for example, the AP_1V_2 route in Fig. 4a) are possible in three-component stoichiometric systems with complex formation.⁶⁶ Under these conditions, the two concentration waves on the chromatogram may be of the shock or spreading types partly of the shock type and partly of the spreading type. However, in the presence of inversion of the components, the route with a single intervening plateau does not always occur in chromatographic systems.

The postulate that each path of one kind intersects all the paths of another kind is invalid for such systems, so that in a number of instances one cannot move from a certain region of the simplex (the region $P_1V_2W_1P_2$ in Fig. 4a) to another region via a route including consecutively only two paths (Γ^1 and Γ^2). A variant of the route, which passes through a watershed point and contains three concentration waves and two intervening plateaux, has been proposed for such cases.³⁸

A route (for example, the $AP_1\Pi_2B$ route in Fig. 4a), corresponding to a chromatogram with three concentration waves AP_1 , $\Pi_1\Pi_2$, and Π_2B and with two intervening plateaux (Π_1 and Π_2), in which one of the components (component 1) is present during the initial filling (point B) and in the inlet zone (point A) of the chromatogram but is absent from the intervening region (segment $\Pi_1\Pi_2$), arises under these conditions. In individual instances (when the route passes along the characteristic $V_2W_3P_2$ — see Fig. 4b), the concentration of component 1 may become zero on the shock concentration 2-wave (section W_3P_2).⁶⁶

XI. Interaction of concentration waves in multicomponent chromatographic systems

The initial discontinuity in concentrations (from the influent concentration to the concentration during the initial filling of the column) in the frontal displacement multicomponent dynamic sorption problem splits into m concentration waves separated by concentration plateaux. In cyclic chromatographic processes, the column should be regenerated and for this reason yet another discontinuity concentration is created at the inlet. As a result, a further assemble (k) of concentration waves of different kinds ($k = 1, 2, \dots$) arises in the column. Thus there is a possibility of a situation where a fast wave of the k th kind catches up with a slow wave of the s th kind ($k > s$) generated during the preceding break in concentrations, whereupon the interference of two concentration (k, s)-waves of different kinds takes place. In contrast to linear systems, in the interference of waves in nonlinear systems the principle of superposition does not hold, which leads to specific results of the interaction of the waves.

If two waves of different kinds meet, a local noncoherence arises for a time, being resolved by transition to a coherent state, as in the case where a perturbation is introduced into the system. During the interference of waves, the general postulate that the noncoherent state of the wave, defined as a superposition of coherent waves, is resolved during propagation and tends to a coherent state remains valid.²¹

In a calculation for such interaction in ideal systems with constant separation factors, the Riemann invariants have been used.²¹ In the case of variable separation factors, in systems with invariant affinity sequence, the characteristics of the interaction of the concentration waves remain the same, but the Γ^k paths on the hodograph are no longer straight, which significantly complicates the quantitative calculation for the interaction of concentration waves.

It has been shown⁶⁸ that, for a three-component stoichiometric system with invariant affinity sequence of the components but with variable separation factors, there are two special cases of the interaction of concentration waves. If in the interaction of two waves in a three-component stoichiometric system the boundary

concentration plateaux are at the borders of the simplex while one of the interacting waves is of the shock type, the calculation for the interaction is carried out with the aid of only the binary isotherms f_{ij} .⁶⁸ This principle has been applied in a calculation, based on the ideal model, for a cyclic four-stage process involving preparative chromatographic multicomponent separation.⁶⁷

XII. Stationary concentration waves in multicomponent nonlinear chromatographic systems including dispersion factors

The conditions governing the appearance of stationary regimes in multicomponent sorption dynamics for Langmuir mixture isotherms (8) have been analysed^{21, 39, 40} on the basis of both the general theory of quasi-linear equations of the hyperbolic type^{46, 57} and the model of equilibrium ideal sorption dynamics and chromatography. It has been shown³⁹ that, in the case of Langmuir mixture isotherms (8), Lax's stability conditions hold for the shock waves arising under these conditions. Therefore, for certain relations between the assembly of input concentrations and their assembly in the initial stage of the filling of columns in a chromatographic system, various shock S -waves arise (where integral numbers S assume values ranging from 1 to m).

In the presence of dispersion effects in the nonideal models considered, stationary regimes governing the propagation of multicomponent concentration S -waves with a finite width, which depends on the dispersion factors and on the 'curvature' of the multicomponent sorption isotherms, correspond to the shock S -waves.

The conditions governing the attainment of stationary regimes in multicomponent chromatographic systems with invariant affinity sequence of the components are independent of the magnitude of the dispersion factors and are therefore determined on the basis of the ideal model. However, the time required for the attainment of the stationary stage in the propagation of a multicomponent concentration S -wave depends on the values of the nonideality factors. These factors lead to the spreading of the concentration S -wave, the width of which becomes constant after a time. The time needed to establish stationary regimes depends on the height equivalent to the theoretical plate (HETP) and on the 'curvature' of the multicomponent isotherm. The dispersion parameter HETP is well known and is used widely in chromatographic theory and practice. It determines the width of the concentration waves and the effectiveness of the operation of the sorption bed.

After the attainment of the stationary regime (in the asymptotic stage), a multicomponent S -wave with a fixed width propagates at a constant velocity equal to the velocity of the shock wave σ_s . This velocity is independent of dispersion effects and is determined by the concentrations on the plateaux to the left (c_i^S) and to the right (c_i^{S+1}) of the S th wave.^{20, 65, 69, 104, 105, 197–200} The methods for the determination of the concentrations on the plateaux were discussed above and examples of such calculations may be found in a number of communications.^{105, 198, 200}

In the presence of dispersion effects, the material balance equations assume the general form

$$\frac{\partial(a_i + c_i)}{\partial t} + \frac{\partial(c_i u)}{\partial z} = D_i \frac{\partial^2 c_i}{\partial z^2}, \quad i = 1, 2, \dots, m, \quad (35)$$

where D_i are the effective longitudinal dispersion coefficients for m mixture components.

This system must be supplemented by kinetic sorption effects. A reasonable approximation to the kinetic equations is provided by model phenomenological equations based on the concept of linear driving forces. For intraparticle diffusion control, the kinetic equation proposed by Glueckauf^{221, 222} for a one-component system, extended to multicomponent systems, is usually employed:

$$\frac{\partial a_i}{\partial t} = \beta_i [f_i(c) - a_i], \quad i = 1, \dots, m. \quad (36)$$

For film diffusion control, analogous phenomenological equations are employed:^{223, 224}

$$\frac{\partial a_i}{\partial t} = \zeta_i [c_i - \varphi_i(a)], \quad i = 1, 2, \dots, m. \quad (37)$$

Here $f_i(c)$ and $\varphi_i(a)$ are sorption isotherms which are reciprocal relative to one another, i.e. $f_i(c) = \varphi_i^{-1}(a)$.

The solution of the systems of differential equations (35) and (36) and (35) and (37), describing the profiles of stationary k -waves for two special types of nonlinear multicomponent chromatographic systems (L and C), has been considered.^{65, 104, 105, 197–200}

The L system is a multicomponent sorption Langmuir system (8) with constant separation factors for the components and a uniform velocity of the mobile phase u .

The C system is a system of n sorbable components in the presence of the sorption effect with linear isotherms and nonuniform flow rate u .

It has been shown on the basis of the ideal multicomponent model that the L and C systems are equivalent.^{65, 69, 198, 200}

It has been demonstrated for both systems^{65, 69, 104, 105, 197–200} that, in the case of dispersion factors identical for each component, the relation between the concentrations of the components in the stationary multicomponent S -wave is linear: for the L system

$$c_i - c_i^S = A_i^S (V - V^S), \quad \text{where} \quad A_i^S = \frac{c_i^{S+1} - c_i^S}{V^{S+1} - V^S}, \quad (38a)$$

and for the C system

$$c_i - c_i^S = B_i^S (R - R^S), \quad \text{where} \quad B_i^S = \frac{c_i^{S+1} - c_i^S}{R^{S+1} - R^S}, \quad (38b)$$

$i = 1, 2, \dots, m$.

The linear relations (38) describe the dependence of the concentrations of the components along the multicomponent concentration S -wave at the stationary stage with dispersion factors identical for each component. These relations describe a path grid in the concentration space, which coincides with the grid of the Γ^k paths for the ideal model. For a two-component model, examples of path grids of this kind are presented in Figs 1a and 2. The linear relations (38) may serve as reliable tests of the validity, convergence, and accuracy of the numerical schemes developed for the solution of nonlinear problems in multicomponent sorption dynamics (see the examples given in a number of papers^{105, 198, 200}).

In the ideal model, the parameters A_i^S and B_i^S represent the Riemann vector-invariants.^{40, 43, 65, 69, 198} A large number of examples of path grids Γ^k , including those for multicomponent systems, have been presented in the monograph by Helfferich and Klein.²¹

Accurate analytical solutions, describing the stationary multicomponent concentration waves of the S th kind for different combinations of the dispersion factors, have been obtained in the case of the L and C systems in a moving coordinate system (c, Z).^{65, 104, 105, 198–200}

1. The L system^{104, 105, 198, 200}

For equilibrium sorption dynamics, one can write

$$D_i = D \quad \text{and} \quad \frac{1}{\beta_i} = 0 \quad \left(\text{or} \quad \frac{1}{\zeta_i} = 0 \right); \quad \text{HETP} = \frac{2D}{u}.$$

For nonequilibrium (intraparticle diffusion) sorption dynamics, without allowance for longitudinal diffusion, we have

$$D_i = 0 \quad \text{and} \quad \beta_i = \beta; \quad \text{HETP} = \frac{2(1 - \sigma_S/u)\sigma_S}{\beta},$$

$$V^S \ln|E| - V^{S+1} \ln|1 - E| = \frac{2(1 - \sigma_S/u)(V^S - V^{S+1})Z}{\text{HETP}} + K_S,$$

$$V^S = 1 + \sum_i b_i c_i^S, \quad S = 1, 2, \dots, \quad Z = z - \sigma_S t. \quad (39)$$

The following expressions are used for the description of nonequilibrium (film diffusion) sorption dynamics without allowance for longitudinal dispersion:

$$D_i = 0 \quad \text{and} \quad \zeta_i = \zeta; \quad \text{HETP} = \frac{2(1 - \sigma_S/u)^2 u}{\zeta},$$

$$V^{S+1} \ln|E| - V^S \ln|1 - E| = \frac{2(1 - \sigma_S/u)(V^S - V^{S+1})Z}{\text{HETP}} - K_S,$$

$$K_S = V^S - V^{S+1},$$

$$E = E_S = \frac{c_i - c_i^S}{c_i^{S+1} - c_i^S} = \frac{V - V^S}{V^{S+1} - V^S}. \quad (40)$$

Here the distribution of the concentrations E_S along the multicomponent concentration S -wave is independent of the number i of the component ($i = 1, 2, \dots, m$) when account is taken of Eqn (38). The distribution of concentrations has been formulated in a dimensionless form and normalised, since the relation $0 \leq E \leq 1$ is valid.

A widely employed empirical parameter — the effective width Δz_S

$$\Delta z_S = \frac{\text{HETP}(V^S + V^{S+1})}{(V^S - V^{S+1})2(1 - \sigma_S/u)} \ln \left| \frac{1 - \varepsilon}{\varepsilon} \right|, \quad (41)$$

where ε is an arbitrarily selected small dimensionless quantity ($\varepsilon = 0.1$ is usually employed in practice), is applied to the description of the spreading of the wave.

2. The C system^{65, 198–200}

In the case of equilibrium multicomponent sorption dynamics, we have

$$D_i = D \quad \text{and} \quad \frac{1}{\beta_i} = 0 \quad \left(\text{or} \quad \frac{1}{\zeta_i} = 0 \right); \quad \text{HETP} = \frac{2D}{u}$$

$$\ln|E| - \ln|1 - E| = \frac{2(\sigma_S/u)(R^S - R^{S+1})Z}{c_0 \text{HETP}}. \quad (42)$$

The following relation is valid for nonequilibrium intraparticle diffusion multicomponent sorption dynamics without allowance for diffusion:

$$D_i = 0 \quad \text{and} \quad \beta_i = \beta; \quad \text{HETP} = \frac{2(1 - \sigma_S/u)\sigma_S}{\beta},$$

whilst for nonequilibrium film diffusion multicomponent sorption dynamics without allowance for longitudinal dispersion, we have

$$D_i = 0 \quad \text{and} \quad \zeta_i = \zeta; \quad \text{HETP} = \frac{2(1 - \sigma_S/u)^2 u}{\zeta},$$

$$(u^S - \sigma_S) \ln|E| - (\sigma_S - u^{S+1}) \ln|1 - E|$$

$$= \frac{2(1 - \sigma_S/u)(R^S - R^{S+1})\sigma_S Z}{c_0 \text{HETP}} + K_S,$$

$$K_S = u^{S+1} - u^S, \quad (43)$$

where u^S is the velocity on the concentration plateau to the left of the S -wave and u^{S+1} the velocity on the concentration plateau to the right of the S -wave (for the C system, the velocity u is nonuniform).

Relations for estimating the effective width of the multicomponent stationary S -wave are obtained from the distributions (42) and (43):

$$\Delta z_S = \frac{\text{HETP}c_0(u/\sigma_S)}{(R^{S+1} - R^S)} \ln \left| \frac{1 - \varepsilon}{\varepsilon} \right|, \quad (44)$$

$$\Delta z_S = \frac{\text{HETP}c_0[1 - (u^S + u^{S+1})/2\sigma_S]}{(R^{S+1} - R^S)(1 - \sigma_S/u)} \ln \left| \frac{1 - \varepsilon}{\varepsilon} \right|. \quad (45)$$

The integration constants K_S in Eqns (39), (40), (42), and (43) have been obtained from the consideration that the centre of gravity of the S -wave is zero in the moving coordinate system with $Z = z - \sigma_S t$.^{65, 104, 105, 199, 200}

It follows from Eqns (41), (44), and (45), where the denominator includes the difference $V^{S+1} - V^S$ or $R^{S+1} - R^S$, that the smaller the number of concentration jumps in the S -wave the greater its width and diffuseness.

Analytical solutions of Eqns (38) and (45) can be readily used for the analysis of the stationary stage in two-component displacement sorption dynamics of two components (or for the equivalent system involving the exchange of three ions).²⁰⁰ It follows from this analysis that the static effects of the interference of components lead to additional spreading of the concentration wave compared with its spreading in a one-component system. This additional spreading occurs in the concentration profiles of both the displacing agent and of the displaced component and is greater the greater the curvature of the sorption isotherms.

For markedly curved Langmuir isotherms for the displacing agent [large values of b_1 in Eqn (8)], it has been shown^{198, 200} that, in the displacement regime for a two-component system, the additional spreading of the displacing agent wave ($i = 1$) occurs in the region of low concentrations in the 2-wave ($S = 2$) for the intraparticle diffusion kinetic stage and in the region of high concentrations for the film diffusion kinetic stage.

It follows from Eqns (39)–(41) that, in a two-component L system with displacement of component 2 by component 1, the mutual influence of the components leads (owing to the sorption effect) to additional spreading of the concentration waves of both components compared with a one-component system.^{198, 200} In a C system, such operation of the static effect of the interference of substances is analogous to the effect which arises in the Langmuir sorption L systems. This additional spreading is greater the greater the Henry coefficient of the displaced component and the smaller the Henry coefficient of the displacing agent.^{199, 200}

XIII. Conclusion

The above analysis of the nonlinear theory of multicomponent sorption and chromatographic systems yields general conclusions about the current state of this field of study and of the trends in its development.

The application of concepts associated with the description of the behaviour of nonlinear multicomponent chromatographic systems within the framework of multicomponent concentration waves, in particular for the determination of the eigenvalues of the wave velocities, is exceptionally fruitful. Here one should employ the advances achieved in the theory of fluid and gas mechanics and also in the mathematical theory of systems of nonlinear equations of the hyperbolic type.

The theory of multicomponent nonlinear sorption dynamics and chromatography based on the ideal model has been well developed for nonlinear Langmuir systems with constant separation factors for the components.

The Riemann invariants, describing the propagation of the multicomponent concentration waves arising during the separation process, have been found. On this basis, the general characteristics of the behaviour of substances in multicomponent chromatographic systems have been obtained with allowance for interference effects. The application of the Riemann invariants on the basis of the ideal model permits not only calculations of multicomponent shock and spreading concentration waves with allowance for the effects of the interference of substances but also calculation for different forms of the interaction of multicomponent concentration waves.

Such results have been obtained with the aid of both the h -transformation and of the concept of coherence, which is of a general character and is applicable to the vast majority of nonlinear multicomponent chromatographic systems. The results have a simple and visual geometrical interpretation, which is based on the properties of the orthogonalisation of the composition space $\{c_i\}$ on transition to the invariants space $\{h_k\}$.

The application of the h -transformation, based on the properties of the Riemann invariants and developed in detail in the monograph by Helfferich and Klein,²¹ makes it possible to calculate the concentrations $\{c_i^k\}$ on the concentration plateau for the distributions corresponding to the multicomponent waves of the $(k-1)$ th and k th kinds.

The predictive power of these calculations is based on the fact that the calculated values on the concentration plateau between multicomponent waves are independent of the dispersion factors (nonideality factors). Using the criterion of the establishment of stationary regimes in concentration k -waves (defined as the decrease in the invariant h_k along such a wave), it is easy to deduce for Langmuir multicomponent systems whether such a regime is attained for the given k -wave under the specified initial and boundary conditions in the chromatography of a mixture of substances.

The concentration profiles calculated on the basis of the postulates of the ideal model are unrealistic, since they do not take into account the dispersion factors in sorption processes (although these factors always operate). Nevertheless, the ideal model yields a satisfactory first approximation, especially for the concentration distributions of spreading k -waves. In such waves, the nonlinearity factors and the factors associated with the static interference of substances, taken into account in the equations for multicomponent mixture isotherms, play the main role in the spreading of the k -waves.²¹

The solutions presented in Section XII of the present review supplement the approach based on the ideal model of the theory of multicomponent sorption dynamics and chromatography. The solutions obtained describe the stationary distributions of concentrations in a multicomponent k -wave of finite width (Δz) with allowance for the nonideality factors in the dynamic sorption process. According to these solutions, the width (Δz) of a stationary k -wave is proportional both to the HETP and the static factors arising from the interference of substances, which are related to the parameters of multicomponent sorption isotherms. The advantage of these simple analytical solutions consists in the possibility of taking into account the joint influence of the nonideality factors and the factors arising from the interference of the sorbable substances in the stationary stage of the propagation of multicomponent sorption k -waves.

More accurate results have been obtained in the numerical integration of the nonlinear multicomponent equations of sorption dynamics. However, in this case too the analytical solutions presented here [especially the linear relations (38)] can serve as reliable tests of the validity, convergence, and accuracy of the numerical schemes developed for the solution of nonlinear problems of multicomponent sorption dynamics.

Furthermore, the results based on the analytical solutions (in contrast to specific numerical solutions) make it possible to obtain general estimates of the influence of the effects of the interference of substances in nonlinear multicomponent dynamic sorption

systems.^{198–200} It follows from the analytical solutions presented here that the effects of the interference of substances lead to an additional broadening of the concentration distributions along the sorption multicomponent waves generated in the column.

For multicomponent systems with variable separation factors, especially for systems having regions with selectivity reversals of the components, the theory has not so far been adequately developed. For such systems, there is a possibility of a nontrivial chromatogram in which a specific component is present at the inlet and outlet and is absent within the multicomponent concentration distributions in the wave.

The concept of coherence,^{21, 22, 81} used to take into account the effects of the interference of substances, is fundamental in the description of the behaviour of nonlinear multicomponent dynamic systems and plays a major role in the development of a general theory of multicomponent nonlinear sorption dynamics and chromatography for multicomponent systems of a general kind. This concept facilitates the qualitative description and quantitative calculations for multicomponent systems, especially for arbitrary initial and boundary conditions. The fundamental nature of this concept extends to the description of the behaviour of a wide range of multicomponent nonlinear dynamic mass transfer, heterophase systems, such as multiphase flows in porous media,¹⁹⁵ chromatographic reactors, and nonstationary distillation.¹⁹⁶

IV. Conclusion	129

Abstract. The principal stages in a rational strategy for the investigation of reaction mechanisms are described, in which the key stage is the formulation of hypotheses at the initial stage of the study. Computer programs are examined in which hypotheses are formulated about the mechanisms of complex reactions with participation of the user. Empirical and formal-logical algorithms and programs as well as various aspects of their application are discussed. The programs are compared with those for computer-aided organic synthesis design, which are similar in their structures and algorithms. The bibliography includes 119 references.

I. A rational strategy for the mechanistic studies of catalytic reactions

Until recently, the dominant approach to the study of the mechanisms of catalytic reactions involved a method which might be called 'inductive'. Its essential feature is that it implies the following stages of the study. Initially an experiment is carried out (mainly a kinetic experiment). A mathematical description is found for the results of this experiment. The reaction mechanism is deduced from the mathematical description. A chemical content is then attributed to this scheme, abstract symbols (such as A, B, C, X, and Y) being replaced by the formulae of specific substances. The reaction mechanism is thus obtained. This approach is so deeply ingrained in the minds of many researchers that, despite the regularly held conferences devoted to the methodological problems of kinetic studies in catalysis, it has been scarcely criticised. On the other hand, the cognitive potentials of this method are extremely limited. Evidently an arbitrary number of models to describe the same experimental data may be proposed, and it is impossible to unambiguously deduce a reaction mechanism from such a description (especially in complex cases).

In practice, investigators studying reaction mechanisms in accordance with the scheme are guided initially by some hypothesis about the mechanism (there is usually only one hypothesis),

justifying and elaborating it when necessary if the experimental data do not fit within the framework of the existing ideas. Doing so, they understand that the interpretation of the kinetic curves does point out how the existing hypothesis should be modified.

Analysis of the literature on philosophy^{1–5} and the applications of computational methods and mathematical statistics in chemical kinetics^{6–10} has clearly shown that the inductive method for the investigation of reaction mechanisms is methodologically unsound. However, the crisis of the inductive method in chemical kinetics did not arise solely as a result of studies by philosophers and mathematicians, who are more skilled in logic than other researchers. The knowledge about reaction mechanisms, including catalytic reaction mechanisms, expanded significantly over several years. As this knowledge accumulated, ideas about the complexity of catalytic processes also changed. Nowadays investigators put forward much more complex mechanisms for the description of catalytic reactions than before. These mechanisms involve intermediates, which have more complex structures, and new types of elementary steps. They include a greater number of intermediates and steps, so that the kinetic models (mathematical equations) corresponding to such mechanisms have become appreciably more complex. It became clear that the path 'from the rate law to a mechanism' is no longer useful for mechanistic studies and kinetic modeling. In general this method is fruitful only in relatively simple cases.

The inductive method was replaced by the deductive method, which can be represented by the following logical sequence:

formulation of hypotheses → experiment design
→ experiment → discrimination between hypotheses
→ mechanisms not in conflict with experiment.

This method is quite natural and has found extensive applications in many branches of science. Interestingly, the American Chemical Society has recommended that papers be written according to a plan that corresponds to the stages of the investigation within the framework of the method.¹⁰ Its undoubted advantage is that the hypotheses are formulated explicitly, making it possible to estimate the width of the 'search space' and to draw conclusions about the value of the 'winning' hypothesis.

Figuratively speaking, the investigator actually addresses questions to nature. According to Polya's apt expression, 'Nature may answer Yes or No, but it whispers one answer and thunders the others; its Yes is provisional and its No is definitive'.¹¹ Thus the difference between the two methods described here is clear: in the case of 'inductive' approach, the investigator is in a search for an arbitrary 'yes', whereas, in the case of the 'deductive' method, the hypotheses for which an unambiguous 'no' is obtained are to be rejected. It is then important to know not only the hypotheses remaining after the

experimental test, but also the entire set of the initial hypotheses. The method works better if the set of hypotheses is more complete.

Several papers have been devoted to the popularisation of the deductive method.¹²⁻¹⁴ Comparison of the two strategies allowed us to conclude that the concept of a 'reaction mechanism' combines two types of information, topological and physicochemical, which are interrelated and interdependent.¹⁴

The topological information characterises the structure of the chemical reaction mechanism (the interrelation of the intermediates, reaction paths, and their coupling). The identification of the mechanism structure is based on kinetic and physicochemical methods. The structure of the mechanism can be well represented by graphs, which are widely used in chemistry in general¹⁵⁻²⁰ and in particular the theory of chemical reaction mechanisms.²¹⁻²³

The physicochemical information reflects the specific chemical content of the mechanism — the composition and structure of intermediates, their reactivities (the values of rate constants, the structures of transition states). The topological and physicochemical types of information complement one another and cannot be obtained independently; i.e., 'in general' one cannot first establish the kinetic scheme and then attribute chemical content to it.¹⁴

An important argument in favour of the idea that hypotheses must be formulated first is the multiplicity of mechanisms in catalysis. By multiplicity of mechanisms, we understand the possibility for the reaction to occur via several different mechanisms (and different intermediates) and the possibility of several such mechanisms dominating over others depending on the type of catalyst (in the case of metal-complex catalysis, on the nature of metal, its oxidation state, and even on the ligands coordinated to this metal).²⁴

For example, the reaction

may occur via three mechanisms:^{24, 25}

(1) the hydride mechanism:

(2) the alkoxide mechanism:

(3) the metallocyclic mechanism:

The hydride mechanism is more probable for Pd(0) complexes; the alkoxide mechanism is more probable for Pd(II) complexes; the metallocyclic mechanism is more probable in solutions of Pd(I) clusters.

The multiplicity of mechanisms and the increase in their complexity are best manifested in the polymerisation reactions of alkynes.²⁴ The simplest mechanism includes two steps — chain initiation and chain propagation.

Other alkyne polymerisation mechanisms are the metallocyclic mechanism

and the [2+2]-cycloaddition mechanism.

A mechanism involving several chain propagation and initiation steps is also possible:

As can be seen from the above examples, the same reactions can occur via different mechanisms. The researcher usually knows from the literature some plausible reaction pathways and uses them explicitly or implicitly as hypotheses.

II. The formulation of hypotheses on the mechanisms of catalytic reactions

The formulation of hypotheses is a creative task and cannot be fully formalised either now or in the future. However, certain elements of this procedure can be formalised. Furthermore, it is the investigator's intuition combined with the ability of a computer to execute complex algorithmic procedures that constitutes a good basis for the formulation of mechanistic hypotheses.

Three groups of hypotheses were discussed:¹⁴ (1) hypotheses about the nature of a catalyst, (2) hypotheses about elementary steps, and (3) hypotheses about the conjugation nodes. In addition, a fourth group, which combines the elements of the above three groups, was considered: hypotheses about the reaction mechanism as a whole. Each of these groups of hypotheses can serve as a basis for the design of discriminating experiments (hereafter, we shall use the term 'experiment design' in a broader sense than that adopted by the specialists in statistics).

In the case of homogeneous metal-complex catalysis, the group of hypotheses about the nature of the catalyst includes the following problems: the condition of a catalyst in solution, the existence of complexation equilibria, the specific role of solvent, the degree of nonideality of solution, the influence of the solution components on the solubility of substrates (when the reaction is a heterophase one), and the effect of the reaction medium on metal complexes. In heterogeneous catalysis, the following factors should be considered: the composition and nature of the surface, the phase composition of the catalyst, the degree and the nature of the surface nonuniformity, the adsorption of reactants and products, and the transformations of the active sites under the influence of the reaction medium.

The group of hypotheses about elementary steps of the reaction mechanism permits the discrimination between the mechanisms at the level corresponding to the discrimination between the individual steps. Here it is also essential to have a set of hypotheses which is as complete as possible.

In the complex cases of stoichiometrically ambiguous reactions, the third group of hypotheses proved very useful — the hypotheses about the conjugation nodes in the kinetic scheme of a reaction.¹³ The conjugation node is a fragment of the structure of the reaction mechanism incorporating the intermediate that is transformed by two or more steps. The form of the expression for the ratios between the rates of product formation via different routes having a conjugation node determines the structure of this node. When the reaction is far from equilibrium and the routes via which the products are formed include irreversible stages, the ratios between the product formation rates are far simpler functions of the reactant concentrations than the rates themselves or even the expressions for the selectivity. It is worthwhile analysing the conjugation nodes bearing in mind some hypothesis about the possible reaction mechanism (i.e., at the stage of designing the discriminating experiment). However, even if the general reaction mechanism is unknown, such analysis is all the same useful.¹³ Examples of analysis of conjugation nodes were discussed in several papers.^{13, 26–28}

When *a priori* information about the process is available, it is useful to formulate, before putting forward the hypotheses, the requirements that should be satisfied for all the hypothetical mechanisms. Naturally, the greater the amount of *a priori* information, the smaller the number of hypotheses which should be tested.

In this review, we restrict the consideration to the formal aspect of the problem of the formulation of hypotheses and discuss the methods of computer-aided hypothesis generation.

Numerous publications have been devoted to the problems of computer-assisted synthesis design (CASD). Investigators — users of the CASD program — usually solve the following problems: 'which reactants must be used and which reactions must be carried out to prepare a given substance in the simplest way?' and 'what can be obtained from the specified set of

substances?'.^{29–33} By the most conservative estimate about 500 original papers and several tens of reviews have been devoted to the CASD problem. Here we shall refer only to those reviews that contain a fairly complete list of references.

The CASD methods are in many respects the same as the methods for the computer generation of hypotheses about reaction mechanisms. There is also the resemblance between the algorithms of the programs. Furthermore, problems associated with the complexity of the algorithms for combinatorial search inevitably arise in both cases. In order to avoid a combinatorial explosion, particular attention is devoted to the development of effective selection criteria, which make it possible to shorten the working time of a program. However, computer generation of reaction mechanisms also has its specific features.

Firstly, in contrast to the majority of CASD algorithms, the programs designed to formulate the mechanistic hypotheses deal with elementary reactions rather than synthetic ones. At any rate, the developers of the programs for mechanism generation devote much more attention to the problem of the reactions being elementary. Secondly, the central problem which then arises is not that of the way in which the multistage synthesis can be carried out but concerns the alternative variants of the behaviour which may be expected from the chemical system when it is 'left alone' (after specifying particular conditions). Thirdly, in the computer-assisted synthesis design, use is also made of the evaluation criteria, which are inapplicable to the reaction mechanisms. These include criteria associated with the choice of a 'synthesis strategy',^{31, 34–36} and with the estimation of the cost of the synthetic steps,³⁷ the criteria characterising the similarity between intermediates and target products,^{29, 38–54} the criteria employing the complexity and similarity information-theoretic indices for the description of the complexity of the synthesis,^{55–57} etc. In certain programs, some of these criteria have been erroneously extended to the study of the mechanisms. Criteria such as the mechanistic complexity indices may be used, in principle, in the study of reaction mechanisms; however, they may not be used as evaluation criteria underlying the program and must be employed for discrimination between hypotheses if it is necessary to choose the simplest mechanism for the description of experimental observations. Otherwise the correct but more complex hypothesis may be neglected whereas sets of simpler but incorrect hypotheses would be subjected to experimental tests.

In the study of a reaction mechanism, the physicochemical criteria come to the fore. These are associated with the estimation of the chemical reactivity and are based, for example, on the calculations of electronegativity, polarisability,⁵⁸ bond energies,^{59–64} thermodynamic functions,^{65, 66} and other physicochemical quantities. In addition, use is made of criteria based on heuristic rules such as Tolman's rules,^{67–69} the restrictions the molecularity of the stages, and others. The choice of the evaluation criteria is a key factor in the development of programs for the study of reaction mechanisms, since they determine in many respects the plausibility of the results and the program execution time.

Yet another difference between the CASD programs and those for the generation of mechanisms is that the completeness of the combinatorially feasible hypotheses concerning the synthetic pathways is less important than the completeness of the hypotheses about the reaction mechanisms.

The computer programs which are being developed for the generation of reaction networks and for the study of the possible reaction routes can manipulate chemical information at a more or less general level. In some cases, the reaction is formulated in a compact form (only the transformation of the molecular fragment is described or it is simply indicated which bonds — and between which atoms — are formed or broken), whilst in others the reaction is specified in greater detail (not only the reacting fragment, but also all the reacting molecules or even the reaction conditions are specified). Depending on how detailed is the description of the reaction, one speaks of a greater or lesser degree of its generality.

For catalytic reactions, the set \mathcal{A} must be supplemented by the atoms entering into the composition of the catalyst. For example, the reaction described above takes place in the presence of the Rh(I)–HI catalytic system.^{70–72} The isomeric ensemble $EM_0 \equiv EM(\mathcal{B})$ must then include the HI and $[Rh(CO)_2I_2]^-$ species. A simplified mechanism of the methanol carbonylation reaction can be written as follows:⁷²

In this example, each of the five stages of the mechanism can be represented in a matrix form:

$$B_i + R_i = E_i, \quad i = 1, 2, \dots, 5,$$

where $B_i = E_{i-1}$ and the overall transformation can be expressed as follows

$$B(EM_0) + R = E(EM_5).$$

$$\text{Here } R = \sum_i R_i.$$

The computer program RAIN was developed for the investigation of reaction mechanisms within the framework of the Munich project.^{29, 30, 73–78} A distinctive feature of this program is the so called 'bilateral' search. The RAIN program inherited from CASD the idea of retrosynthesis,^{79, 80} in which the possibility of searching for possible starting reactants by inspecting the products (retrosearch) is employed. In RAIN, the search is carried out simultaneously in the forward and reverse directions (bilateral search). Reaction generators, which make it possible to find both the reactions and retroractions, are used in the RAIN program.⁷⁷ The reaction generators constitute, in fact, a compilation of logical rules controlling the process of formulation of a specific reaction (or retroraction). These rules are based on the combinatorial enumeration of all possible bond redistributions. The enumeration is constrained by the user's settings. Transition tables should apparently be regarded as the principal constraints. These tables, compiled for atoms of each type, restrict the number of transformations (and retrortransformations) of the valence states of atoms in the course of the generation of elementary steps. No generalised reactions of any kind are thereby used. Therefore, the RAIN program can be categorised as program of the formal-logical type.

The idea of the bilateral search is applied as follows. Isomeric ensembles of the initial species $[EM(\mathcal{B})]$ and final products $[EM(\mathcal{E})]$ are specified. The reactions and retroractions are sought for the ensembles $EM(\mathcal{B})$ and $EM(\mathcal{E})$, respectively. At some step, two (or more) intermediate isomorphous isomeric ensembles are obtained as a result of the search in different directions. In other words, the generation of reaction pathways in the direction of the products and in the direction of the initial

species should lead to isomorphous isomeric ensembles. Methods have been developed for the optimisation of the search for isomeric ensembles of molecules connecting the search tree to the retrosearch tree³⁰ on the basis of the principle of the minimum chemical distance.^{29, 30, 38–43} A chemical distance is regarded as the number of electrons which must be redistributed in order to convert one ensemble of molecules into another.

The action of this principle as an optimising factor is based on the following hypothesis. Let an ensemble of molecules be subjected to various transformations. The processes having smaller chemical distances between the reactants and products are more probable than those having greater distances. According to Ugi et al.⁷⁷ the permissible deviations from this rule are within two units of the chemical distance (one or two electrons); i.e., the reaction can sometimes choose a pathway not corresponding to the minimum structural changes, but these deviations from the general rule are not very large.

The combinatorial search in the RAIN program is limited by the user-defined constraints. In particular, apart from the transition tables, other formal constraints can be introduced: the maximum number of atoms entering into the reacting fragment of the molecule; the maximum change in bond order during the elementary reaction; the maximum number of bonds the order of which changes; the minimum size of the rings in the carbon skeletons of the molecules that contain triple or cumulated double bonds; the maximum number of charged atoms; the maximum number of covalent bonds between heteroatoms; the maximum number of rings; the maximum number of individual molecules in the intermediate ensembles of molecules, etc. (18 rules total).

The bilateral search has several drawbacks. In contrast to CASD, in the study of reaction mechanisms it is necessary to conduct the search in one (preferably forward) direction, since the intermediates formed during the reaction may interact with each other and may participate in reactions with the initial substances. It is then necessary to expand the set \mathcal{A} at each step of the generation of the possible ensemble of molecules (and hence to increase the size of the ensemble). This is impossible within the bilateral search, which, within the framework of the Dugunji–Ugi model, requires the set \mathcal{A} to be fixed and not to change during the execution of the program. According to Barone and Chanon,³² this was first mentioned by Yoneda, but the paper containing a description of his GRACE program⁸¹ does not deal with the problem of the possible expansion of the set \mathcal{A} in the course of its execution.

Like RAIN, the GRACE program belongs to the formal-logical type, but it employs a somewhat different principle of reaction generation. Yoneda put forward the idea of reaction group matrices that describe the transformations of functional groups of the molecules. Upon imposing the constraints, the GRACE program identifies the functional groups within the molecules and generates the reaction group matrices by a combinatorial-logical procedure. Then, it detects all possible combinations of the reaction group matrices from which the elementary reaction matrices may be obtained (the r -matrices of steps). Thus, as in the RAIN program, the GRACE program employs neither the library of functional group transformations nor the library of elementary reactions, which are the combinations of the functional group transformations.

In the GRACE program, the evaluation criteria are formulated by the user according to the standard scheme. The following constraints are possible:

- (1) the number of atoms (reaction centres) the valence state of which changes during the elementary reactions must not exceed 4;
- (2) the number of broken bonds (or bonds the order of which is decreased) and formed bonds (or bonds the order of which is increased) should not be greater than 3;
- (3) the molecularity of each reaction should not exceed 3;
- (4) the number of unpaired electrons on one atom should not be greater than 1;

(5) the number of atoms with unpaired electrons in one molecule should not be greater than 4;

(6) the numbers of valence electrons at the carbon and hydrogen atoms should be 4 and 1 respectively;

(7) at least one active centre on the catalyst surface must participate in each step;

(8) the hydrogen atoms must be adsorbed on the catalyst surface and cannot exist as free radicals.

The program allows the user to change any particular constraints or not use some of them at all. Apart from these constraints, an upper limit to the complexity of the elementary transformation is predefined. The quantity calculated from the r -matrix and equal to half the chemical distance was adopted as a measure of complexity. A network of elementary reactions (the reaction network) is generated in the forward direction only, which makes it possible to expand the set \mathcal{A} in the course of its growth when necessary. The execution of the program may be illustrated by the reaction network generated for the heterogeneous catalytic hydrogenation of ethene:⁸¹

Z is an active site of a catalyst.

It is of interest to note that the same set of reactions, which are formulated as transformations of ensembles of molecules, is somewhat larger by virtue of the identity of certain transformations. For example, the following two transformations constitute essentially the same reaction.

In this sense, the Dugunji-Ugi model is somewhat redundant. Indeed, if the same reaction had not been duplicated, less time would be needed for the program run. When the number of elementary steps is large, this factor plays a significant role. There are seven reactions in the example presented above. If the reactants are represented by an ensemble of molecules, then 11 transformations of such ensembles are required (i.e., 1.5 times more). The time required for the interpretation of the results proportionally increases.

The Dugunji-Ugi model was also used in Dozmorov's program.⁵⁵ Dozmorov proposed a new similarity measure, which made it possible to diminish the number of steps and intermediates generated. This similarity measure is a topological information-theoretic index which involves information components of different nature.⁸² In our opinion, the use of this characteristic as an evaluation criterion has no sufficient physical justification. Dozmorov does not report the details of the algorithm, but it appears that, as in the GRACE program, only the forward search is employed in his program, while the elementary reactions are generated by combinatorial-logical methods (i.e., it also belongs to the formal-logical type). The reaction network of the 'informationally' allowed steps of the ethene chlorination reaction, obtained with the aid of this program, is presented in Scheme 2.

Thus in all the programs of the formal-logical type, based on the Dugunji-Ugi model, similarity characteristics are used to reduce the number of 'false' solutions. In the RAIN program, the criterion is the chemical distance (of all possible transformations of the ensemble of molecules, the program selects only those corresponding to the minimum chemical distance to within an error of 2 units of the chemical distance.) In the GRACE program, the criterion is the complexity of the elementary reaction equal to half the chemical distance (the user specifies the upper limit to this quantity). In Dozmorov's program, the criterion is the information topological index, with the aid of which the program decides whether an elementary reaction is allowed or prohibited from the standpoint of information.

The MECHEM program developed by Valdés-Peréz⁸³⁻⁹² has appeared comparatively recently. Its algorithm is based on the stoichiometry principles. The initial version of the program operated not with the structural formulae of species, but with their compositions. Currently, the program also makes it possible to recognise the structures of substances. The MECHEM program belongs to the type of formal-logical programs because it does not employ any libraries of generalised reactions. The mechanisms are generated by the constrained combinatorial search for possible transformations of hypothetical intermediates. There are no reaction generators as such in the program. The 'skeleton' of the reaction mechanism is formed with further specification of the elementary steps and species. The model for the formulation of hypotheses is based on the following principles:⁸⁵

(1) The program searches for the simplest mechanisms (hypotheses) by a progressive increase in the number of steps and species. If the mechanisms with a smaller number of steps and species do not satisfy all the user-defined constraints or the condition of elemental balance, the number of species is increased or whilst the number of species is held constant the number of

Scheme 2

steps is increased. Thus the complexity of the hypotheses is characterised by the number of species and steps.

(2) The set of reaction mechanisms in which the unknown intermediates are designated by wild cards X, Y, Z, etc., is initially generated. These wild cards are then replaced by the formulae of specific substances. Their empirical formulae are evaluated from the elemental balance (in the latest version of MECHEM, an algorithm for the determination of the structures of species from their formulae is employed;⁹⁰ it is then possible to impose constraints on the species structures⁹³).

(3) The molecularity and the number of products of an elementary reaction do not exceed 2; in the same step, the same species cannot play the role of both the starting material and the product.

(4) The mechanisms are generated in such a way that each step cannot have starting materials that were not generated in the preceding steps or specified by the user as starting materials. (This and several other principles constitute the basis of the canonical representation of mechanisms⁹¹).

The user inputs the starting materials and products, the initial form of the catalyst (if it exists), and the intermediates observed. The user also inputs the constraints on the valence of each atom, the order of the appearance of the intermediates in the steps, the possibility (or impossibility) of the initial species being among the products of particular steps, the number of bonds the order of which changes, etc. A large number of heuristics, which make the algorithm more effective, are used in the program.⁸⁹

Possible mechanisms of ethane hydrogenolysis were generated with the MECHEM program.^{88, 89} The following constraints were used: (1) the overall stoichiometry is $\text{C}_2\text{H}_6 + \text{H}_2 \rightarrow 2\text{CH}_4$; (2) one catalyst active site M can form only one bond (not necessarily a single bond); (3) intermediates with a bridged structure, $\text{MCH}_2-\text{CH}_2\text{M}$ and $\text{MCH}-\text{CHM}$, are present in the reaction; (4) hydrogen is not formed in any of the steps; (5) all intermediates contain at least one catalyst site M; (6) none of the intermediates contain three carbon or metal atoms; (7) no more than three bonds are formed and broken (regardless of their order) in one step; (8) the $\text{MCH}_2-\text{CH}_2\text{M}$ intermediate must appear in the sequence of steps before the $\text{MCH}-\text{CHM}$ intermediate. Apart from these constraints, account was also taken of the need to maintain the elemental balance in each step and the condition that the valences of hydrogen and carbon atoms do not exceed 1 and 4 respectively. Among other mechanisms of the same complexity (i.e., with the same number of steps and species), the following mechanism of ethane hydrogenolysis was generated: §

1. $\text{H}_2 + 2\text{M} \rightarrow 2\text{U}$
2. $2\text{M} + \text{C}_2\text{H}_6 \rightarrow \text{U} + \text{V}$
3. $2\text{M} + \text{V} \rightarrow \text{MCH}_2-\text{CH}_2\text{M} + \text{U}$
4. $\text{M} + \text{MCH}_2-\text{CH}_2\text{M} \rightarrow \text{U} + \text{W}$
5. $2\text{W} \rightarrow \text{MCH}_2-\text{CH}_2\text{M} + \text{MCH}-\text{CHM}$
6. $\text{MCH}-\text{CHM} \rightarrow 2\text{X}$
7. $\text{U} + \text{X} \rightarrow \text{M} + \text{Y}$
8. $2\text{Y} \rightarrow \text{X} + \text{Z}$
9. $\text{U} + \text{Z} \rightarrow 2\text{M} + \text{CH}_4$

Here U, V, W, X, Y, and Z are intermediates which were interpreted by the program as HM, $\text{CH}_3-\text{CH}_2\text{M}$, CH_2-CHM , MCH, CH_2M , and CH_3M respectively. The stoichiometric numbers of steps 1–9 are 1, 1, 1, 2, 1, 1, 4, 2 and 2, respectively, with which all the intermediates vanish in the overall equation.

§ Since the program generates only unimolecular and bimolecular reactions (this is one of the principles inherent in the algorithm for the generation of a step), it is seemingly implied that 2M represents two linked active sites of the heterogeneous catalyst (M_2).

The intermediates MCH and CH_2M may be interpreted as carbyne and carbene complexes (at the time when the above investigation was carried out, the algorithm for the identification of bond orders was introduced into the program).

Generally, the MECHEM program is designed to search for hypotheses invoked to account for the results of observations (i.e., the hypotheses follow the observations). As mentioned above, another formulation of the problem is methodologically more correct: What variants of observations are to be expected? We may note that the weakest feature of this program is the concept of the selection of simplest mechanisms. It is reasonable to employ simplicity criteria at the step involving the discrimination between hypotheses and also at the instant when the experimental tests of the hypotheses have already been completed and the remaining hypotheses explain equally well the observations and agree with the background knowledge about the processes of a given type. In this case, when the future design of experiments is unclear or if it is impossible to experimentally discriminate between the hypotheses by means of the available methods, it is useful to apply criteria characterising the simplicity of the mechanism. These may be criteria based on a simple count of the number of steps and species (as in MECHEM) or more complex criteria.^{94–97}

Apart from the formal-logical methods of generating reaction networks discussed here, in many studies the reaction mechanisms have been generated by the joint application of combinatorial methods and stoichiometry,^{98–100} as well as graph theory.¹⁰¹ Computer programs were not created on the basis of these methods, nor they have been adequately documented in the literature. Methods have also been developed for 'cutting off' the mechanisms from the reaction networks that match a given overall stoichiometry.^{9, 98, 102–112} In these methods, it is postulated that all starting materials, intermediates, and final products and sometimes the equations of the steps are known. For this reason, despite the usefulness of such algorithms and programs for the study of mechanisms, their employment for the generation of hypotheses about the mechanisms of chemical reactions is extremely limited.¹⁴

2. Empirical programs

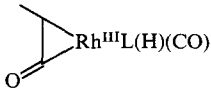

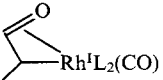

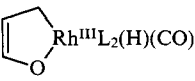

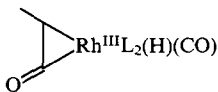

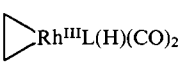

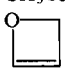

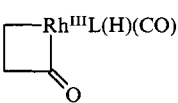

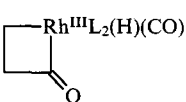

As stated above, all empirical programs are characterized by a general property: generalised reactions (transforms) are employed in them. The method used to describe the generalised reactions can be arbitrary. The general algorithm involves the recognition of molecular fragments to which particular generalised reactions (reaction templates) can be applied with subsequent generation of specific reactions and structures of substances.

One of the first empirical programs is the CAMEO program.¹¹³ At the time of writing the present review, 25 communications have already been published. Here we refer only to the first publication¹¹³ and to a review.¹¹⁴

The CAMEO program is designed to simulate the mechanisms of organic reactions. It is characteristic of the program that the search for each successive fragment to which a particular generalised reaction may be applied is performed in this program solely in the forward direction (side paths are then considered and account is taken of the interaction between the intermediates).

The starting materials and the reaction products, the reaction conditions, and also the list of modules which must be activated are initially specified. The program contains several modules, each of which is designed to describe a particular class of organic reactions. The molecules are represented in the form of special tables in which atoms and bonds are specified.¹⁰⁸ These tables contain the following information: the ordinal number of each atom, the type of each atom (C, H, ...), its coordinates on the graphical display, and the code of the charge (numbers 1, 2, and 3 stand for a cation, anion, or a radical, respectively; if the atom is neutral, then the code 0 is used); it is indicated between which atoms there are bonds and what are their orders. Each bond has a unique number. The location of the bond relative to the conventional plane of the figure is indicated. Furthermore, account is

taken of the evaluation rules, including the rules based on physicochemical principles (estimates of $\text{p}K_{\text{a}}$, ΔH_f , the HOMO–LUMO energies, heats of reaction, etc.).

The following modules were designed: reactions catalysed by bases and acids (reactions involving nucleophilic and electrophilic species) pericyclic reactions, redox reactions, free-radical reactions and chain processes, reactions of carbenoid species, reactions involving reduction by hydrides, and ‘ene’ and ‘retro-ene’ syntheses. With the aid of the CAMEO program, it is possible to determine the most probable sites of attack by active species and to estimate the comparative reactivities.

The TAMREAC program^{67–69} was designed for investigators in the field of organometallic catalysis. Unfortunately, the authors^{67–69} did not publish the details of the algorithm and it is therefore difficult to analyse the real possibilities of the program. Connectivity tables in which each atom is characterised by a number and a symbol (carbon, hydrogen, metal, arbitrary atom, arbitrary electrophilic atom, etc.) are used for the computer representation of the molecules within the framework of this program. In the tables, it is also indicated with which atoms and by what bonds the given element is linked and what is its overall charge (oxidation state). Furthermore, tables of η^2 -bonds have been introduced for the description of the η^2 -bonds with metals,

in which it is indicated between which atoms there is a multiple bond and to which atom it is coordinated. The η^3 -coordination is described with the aid of two isomeric structures:

The TAMREAC program provides for the possibility of generating elementary steps in each of which there is not more than one metal atom. The developers of the TAMREAC program systematically analysed a large number of elementary concerted reactions and constructed a well-organised library of generalised reactions. It includes the following reactions: (1) oxidation of the metal, (2) reduction of the metal, (3) reactions affording occupation of a coordination site, (4) reactions creating a vacant coordination site, (5) reactions without change in the oxidation state or the coordination number of the metal, and (6) radical reactions and one-electron transfers. The library consists of files each containing several generalised reactions, described in the form of a structural transformation of the reaction fragment.

The TAMREAC program contains an algorithm for the recognition of ligands, the number of electrons they can donate

^a The numbers of species are indicated in Table 1.

and the number of sites they can occupy. The number of valence electrons of the metal atom and its oxidation states are calculated from these data. The information obtained is used in the evaluation criteria. For example, it is ensured automatically that the number of valence electrons is within the limits specified by the user. The program also contains an algorithm for the recognition of the geometry of each complex. The developers of TAMREAC created a system of evaluation rules on the basis of which an expert assessment of the reaction plausibility is made using the data on the type of reaction (reductive elimination, migratory insertion, metallocycle formation, etc.), the coordination number of the metal, the number of valence electrons of the metal atom, and the geometry of the complex. This information, formalised in the form of evaluation matrices, is usually very useful to the investigator. However, one should understand that the data on the basis of which a conclusion is made are not sufficient. Therefore, such an estimate can be taken into account, but the possibilities of its employment within the framework of any specific study are extremely limited. Account must also be taken of the fact that the evaluation rules indicated above are usually developed exclusively on the basis of experimental observations which often lack a reliable theoretical justification. These rules are continuously revised and, generally speaking, they lack 'the strength of a law'. By studying a specific system, each investigator has ultimately the right to solve independently the problem of the need to take into account the expert recommendations. For this reason, the most acceptable variant is where the user (the investigator) is himself able to formulate the evaluation rules in accordance with various schemes proposed by the program.

The TAMREAC program was tested on a large number of specific reactions, and in a number of instances extremely inter-

esting results were obtained. For example, this program was used to generate the reaction network for the ethene hydroformylation in the system containing $\text{HRh}(\text{CO})_2\text{L}_2$ ($\text{L} = \text{PPh}_3$).⁶⁸ The starting materials were ethene, H_2 , CO, and $\text{HRh}(\text{CO})_2\text{L}_2$. It is seen from the results presented in Tables 1 and 2 that the program 'synthesised' fairly interesting by products, the search for which in a real catalytic system will help to confirm or reject some of the proposed pathways.

The KOMSIKAT program package for the investigation of the mechanisms of catalytic reactions has been developed at the Institute of Catalysis of the Siberian Division of the Russian Academy of Sciences on the basis of the Dugunji–Ugi model and the group matrix method (similar to that employed in the GRACE program⁸¹).^{59–64} In general, the ideas underlying the KOMSIKAT program are similar to those implemented in the GRACE program, but it does not use all the combinatorially possible group matrices, only those specified by the user. Therefore, this program should be categorised as an empirical program. The authors of the KOMSIKAT project extracted from literature data the characteristic structural types of elementary transformations involving the catalyst. In particular, the authors postulated that the processes occurring in the $\text{CO} + \text{H}_2$ system with participation of a metal M may be described by five basic types of elementary transformations. Table 3 presents the reaction fragments and the corresponding blocks of r -matrices (index group matrices) employed. The diagonal elements of the index group matrices characterise the changes in the number of valence electrons.

In the KOMSIKAT program, the energy criterion was used in the evaluation of reaction pathways. The reaction network was generated as follows. In the first stage, all possible ensembles of

molecules which may be obtained on the basis of the possible elementary transformations of the initial ensemble of molecules were generated. From the ensemble of molecules obtained in the first stage, only those were selected which corresponded to the maximum atomisation energy (i.e., to the most stable ensembles of molecules)¶ to within some accuracy, while the remaining ones were rejected. For each intermediate ensemble of molecules, remaining after the selection, a new set of ensembles of molecules, obtained by means of allowed elementary transformations, was found. Among them the most stable were also selected. The generation of a 'branch' of the reaction network was terminated in accordance with formal characteristics — after the isolation of the metal-catalyst in a free form (when the ensemble of molecules contained a free metal atom). As a result, the reaction network consisted of intermediate ensembles of molecules, which corresponded to the pathways leading to the transformation of their precursors into the most stable compounds. The atomisation energy was calculated by the method of interacting bonds⁶⁰ using semiempirical parameters of the bond energies of the

¶ The ensemble of molecules for which the sum of the atomisation energies of the species was greatest was regarded as the most stable. Several most stable ensembles of molecules are possible because the metal atom is not known *a priori* and only the range of the possible atomisation energies, obtained by varying the semiempirical parameters of the bond energies, is known.⁶⁰

atoms comprising the molecules in the ensemble. For bonds involving C, H, and O atoms, the parameters obtained from the experimental thermochemical data on the heats of formation of the corresponding compounds were used. Thus, the parameter $E_{C=O}$ was found from the heats of formation of aldehydes and ketones, the parameter E_{C-H} was obtained from the heats of formation of hydrocarbons and alcohols, the parameter E_{O-H} was found from the heats of formation of alcohols, etc.

At the next stage, the optimum catalyst was selected. For this purpose, the parameters E_{M-X} (E_{M-C} , E_{M-H} , E_{M-O}) characterising the metal were varied for each intermediate ensemble and each pathway in the reaction network (in each linear sequence of ensembles of molecules from the starting EM to the final one). Because the variation of the E_{M-X} parameter was organised as step-by-step procedure, the atomisation energy of each intermediate ensemble of each pathway was split into a number of values. The atomisation energy corresponding to the condition of a uniform distribution of energy over the elementary steps of the catalytic process was chosen for each ensemble. In other words, the most smoothed broken line, which corresponds to the atomisation energies of the intermediate ensembles of a pathway, was chosen (Fig. 1). The semiempirical parameters of the bond energies calculated for this broken line were compared to the tabulated values for specific metals. The metal was regarded as optimal when the tabulated parameters of the bond energies for this metal was closest to the calculated values (i.e., values obtained for the most smoothed broken line).

Thus, it follows from a comparison of the calculated parameters of the formation of ethylene glycol in the reaction between CO and H₂ in the presence of a metal catalyst and the tabulated values that the best catalysts for this reaction are Rh, Co, Ir, Ru, and V. The ranges of the optimum E_{M-X} parameters for the formation of each product of the hydrogenation of CO (methane, methanol, ethane, ethanol, acetic acid, methyl formate, and ethylene glycol) were found and the corresponding metals were determined. The optimum parameters E_{M-X} and metals (Mn, Fe, Co, Ni, Ru, and Rh) for the formation of all the C₁ and C₂ products were found from the overlap of these ranges of parameters.

Baltanas and Froment¹¹⁵ developed a program for the generation of reaction networks for the solution of specific

Figure 1. The splitting of the levels upon the variation of the E_{M-X} parameters. The optimum parameters E_{M-X} are those which correspond to the most 'smoothed' broken line, shown in the figure by a heavy line. The split levels of the atomisation energies of ensemble of molecules are shown in the dashed line corresponding to elementary steps.

problems, such as the study of catalytic hydroisomerisation and hydrocracking. Five generalised reactions, which are to be applied in succession to various species, are used in this program. These generalised reactions are designed solely for the investigation of the above catalytic processes. Species and reactions are described in terms of Boolean matrices which do not take into account the bond orders. The kinetic equations for the reaction network obtained were derived by the program. The principal disadvantage of this program is the narrow range of its applications.

Temkin's group (Lomonosov State Academy of Fine Chemical Technology, Moscow) are developing the ChemNet program for the formulation of hypotheses about the mechanisms of catalytic reactions. This program has been discussed in only a few publications, some of which are not readily available.^{14, 116} We shall, therefore, discuss it in more detail.

The first version of the program was written in the mid 1980s in FORTRAN IV, a language which has now become hopelessly obsolete.¹¹⁷ A new version, designed for modern personal computers of the IBM PC type and using the principal ideas of the old program, has been developed recently.

The list of species participating in the reaction as the reactants and system components and the list of the elementary transformations (generalised reactions) are input data. The species are specified by the user in the form of structural formulae and are transformed into records having a special format. Part of the record contains an upper triangular adjacency matrix of the atoms, while another part comprises different characteristics of atoms (charges, oxidation states, etc.), bond orders, as well as multicentre bonds. The elementary transformations are analogues of chemical reactions and describe the characteristic features of the changes occurring. The extent to which the details of the reaction are specified is decided by the user.

The more detailed the description of the elementary transformation, the shorter the list of substances to which this transformation is applicable. For example, the two elementary transformations

describe the same reaction with specification of details to different extents. The difference consists only in that, in the first case, the program 'inserts' CO into all species containing the M-C bond, whilst, in the second case, it inserts it into metal alkynyl complexes. Note that, in the first case, the program will 'insert' CO also into M-C(O) fragments until the constraints imposed on the number of atoms in the species will begin to work. The elementary transformations can be inputted both in a symbolic form and in the form when standard chemical symbols of atoms are used. If the elementary transformation is formulated in a

^a The numbers of the species are indicated in Table 1.

symbolic form, it is necessary to determine also the possible substituent of each symbol. For example, the generalised reaction

is formulated in a symbolic form. The symbols M and X must be interpreted, indicating which atoms of the metal M and which atoms X can occur in the reaction.

Upon carrying out a 'rough' generation of the reaction network, the user can alter the degree of specification of detail in the records of steps, thereby excluding the directions of attack by particular species known a priori to be implausible.

A special unique format has been developed for the description of species and elementary transformations.¹¹⁸ The substances and reactions are stored in the computer memory in the form of special codes, the description of which is outside the scope of the present review.

Several evaluation rules are used in the ChemNet program, which are recommended to the user.

1. In an elementary step, the change in the number of valence electrons and in the oxidation state of the metal atom must not exceed 2 in absolute magnitude, which agrees with Tolman's rules.¹¹⁹

2. The molecularity of the elementary reactions must not exceed 2.

3. The user specifies the maximum number of valence electrons, the maximum coordination number, and the range of the possible oxidation states for each metal atom (the quantities stored in a special file are used as default settings).

4. The user specifies the maximum number of atoms and/or the maximum numbers of atoms of a particular type (C, H, O, ...) in the products formed.

The generation of the reaction network is also constrained by the transforms which the user specifies himself or selects from the library. Furthermore, the generation of the reaction network is implicitly constrained by the degree of specification of details in the records of the transform.

After the specification of the initial species and elementary transformations (transforms), the program searches for the initial species which are regarded as candidates for participation in each

of the elementary transformations. After finding for each elementary transformation all the combinations of species to which the transformation is applicable and the new species have been stored in the computer memory, the program adds all the new substances to the list of the initial substances and repeats the entire procedure. The combinations of species and steps, tested at the preceding steps, are not examined. The process completes when each species (the starting material or the species obtained in the course of the network generation) was examined with respect to the possibility of its involvement in each elementary transformation, while new substances are not produced owing to the constraints imposed. The overall algorithm for the execution of the program can be represented by the bookkeeping scheme shown in Fig. 2.

One of the tests for the program was the synthesis of an alkynylcarboxylic acid ester in the CuCl₂–CuCl–PdCl₂–R'OH system.

The following elementary transformations were specified:

1. $MCl + ROH \rightarrow MOR + HCl$ (M = Pd, Cu; R = C)
2. $MOR + CO \rightarrow MCOOR$ (M = Pd, Cu; R = C)
3. $MCl + RC\equiv CH \rightarrow MC\equiv CR + HCl$ (M = Cu; R = C)
4. $CuC\equiv CR + Pd-Cl \rightarrow CuCl + PdC\equiv CR$ (R = C)
5. $PdC\equiv CR + CO \rightarrow Pd-C(O)-C\equiv CR$ (R = C)
6. $C-M-C \rightarrow M+C-C$ (M = Pd)
7. $M-C(O)- + C\equiv C \rightarrow M-C=C-C(O)-$ (M = Pd)
8. $M-C=CH \rightarrow C\equiv C+M-H$ (M = Pd)
9. $Pd-C(O)- + ROH \rightarrow PdH + RO-C(O)-$ (R = C)
10. $CuC+C-Pd-X \rightarrow CuX+C-Pd-C$ (X = Cl)

The following constraints were imposed: the maximum number of atoms in the conjectured species must be less than 20, the maximum oxidation state of the metal in the conjectured species is +1 for copper and +2 for palladium, and the maximum coordination numbers of copper and palladium are, respectively, 1 and 2.

The results of the generation of the reaction network are presented in Tables 4 and 5. These results may be used by the experimentalist in the discriminating experimental design.

IV. Conclusion

In conclusion, we may note that there are many computer programs, which make it possible to formulate hypotheses about the mechanisms of complex reactions and to generate reaction networks. Analysis of the programs considered makes it possible to indicate several typical disadvantages of these programs.

1. The impossibility of obtaining complete data on the transformations of the intermediates, side reactions, and by products because of the necessity for a rigid specification of the number of atoms entering into the isomeric ensemble and because of the bilateral nature of the search (RAIN, Dozmorov's program, GRACE).

2. The use of the simplicity criterion as a selection factor (MECHEM).

3. The narrowness of the range of applications (the program of Froment and Baltanas).

A feature common to the majority of the programs considered is that the key factor in the development of methods for the generation of hypotheses is the application of heuristic rules, which are used to different extents and at different stages of the execution of the programs.

1. The use of libraries of transformations (reaction generators) obtained as a result of the generalisation of the available literature data on the reactions (TAMREAC, KOMSIKAT, ChemNet, etc.).

2. The use of the more or less formalised rules for the assessment of the reaction plausibility (TAMREAC, CAMEO).

3. The use of heuristic rules for the optimisation, acceleration, and restriction of the search (RAIN, MECHEM).

4. The estimation of the thermodynamic and other characteristics, obtained by semiempirical or fully empirical methods, which in turn make it possible to assess the plausibility of individual steps or even entire reaction pathways (KOMSIKAT, the program of Froment and Baltanas, CAMEO).

In all cases, it is important for the user to know which heuristic rules are inherent in the program, what are the possibilities for their modification, and whether or not any of them can be abandoned. It is desirable to have such a possibility as regards the constraints as well.

Different levels of generalisation of the elementary reactions are employed in the empirical programs. In some programs, for example, in the ChemNet program, it is possible to apply simultaneously several levels of generalisation (i.e., reactions in which only the transformation of the fragments is characterised and reactions formulated in more detail).

Since different programs are based on different methods and heuristic rules, it is sometimes useful to combine them within the framework of a single program package. In particular, the present authors are working on the creation of a program package combining the ChemNet and KOMSIKAT programs. In our view, such a combination of programs may ensure an additional flexibility in the selection of substances for the formulation of hypotheses.

Abstract. Studies devoted to the synthesis, investigation of the properties, and chemical transformations of methylenecyclobutane are surveyed systematically. Data on the reactions of methylenecyclobutane with a broad range of reagents are presented. The bibliography includes 291 references.

I. Introduction

Methylenecyclobutane (MCB) is a side product in the production of isoprene by the catalytic cleavage of 4,4-dimethyl-1,3-dioxane,^{1,2} which makes it a potential raw material for fine organic synthesis. Due to the presence of two reactive groups, the double bond, and the cyclobutane ring in its molecule, methylenecyclobutane can undergo a variety of chemical transformations, which permits the use of this compound in small-scale chemistry (for example, in the production of pesticides, pheromones, medicinals, and perfumes).

At present, MCB is not produced as a commercial target product in any large quantities. However, it is available as a reagent. For example, 'Aldrich' offers a preparation with a MCB content not less than 92%, and 'EGA-Chemie' supplies methylenecyclobutane of > 97% purity (the remaining 3% is due to spiro(pentane)).

1. Preparation

Methylenecyclobutane **1** was first obtained by Gustavson^{3,4} in 1896 by the treatment of 2,2-di(bromomethyl)-1,3-dibromopropane [tetrabromoneopentane **2**, (X = Br)] with zinc dust in ethanol (the Gustavson method⁵). Gustavson intended to obtain spiropentane **4**, but the resulting hydrocarbon differed in its properties from spiropentane. He studied this compound and mistakenly attributed the structure of vinylcyclopropane to it.

To determine the structure of this hydrocarbon proved fairly difficult. The problem of the structure of the 'Gustavson's hydrocarbon' was ultimately solved as late as 1914 by Filipov,^{6,7} who also presented a detailed list of the papers dealing with the synthesis and properties of MCB published up to that time. The data on the debromination of tetrabromoneopentane published before 1944 are presented in a review.⁸

In subsequent years, researchers paid considerable attention to the reaction of tetrabromoneopentane with zinc.⁹⁻¹⁶ It has been shown that isomerisation occurs during the elimination of the second pair of bromine atoms from the intermediate 1,1-di(bromomethyl)cyclopropane **3**. When Zn^{2+} cations, which catalyse the rearrangement of **3**, are bound into an inactive complex, spirocyclopentane **4** is formed predominantly.¹² The influence of the nature of the halogen atom and the solvent on the reaction of tetrahaloneopentanes **2** with zinc has been studied.¹³⁻¹⁶

Further studies¹⁷⁻²⁰ have shown that the ratio between spiropentane and methylenecyclobutane depends on the nature of the metal used as the reducing agent and the acidity of the medium.

The preparative synthesis of MCB by the reduction of tetrabromoneopentane with zinc dust²¹ is most frequently mentioned in the literature.

It has been suggested that tribromoneopentyl benzenesulfonate, which is more readily available than tetrabromoneopentane, be used in the synthesis of MCB.²²

Methylenecyclobutane is formed, apart from other hydrocarbons, on reduction of trihalo-derivatives of neopentane.^{23,24}

Dehydration of 1-methylcyclobutanol gave a mixture of hydrocarbons consisting of 1-methylcyclobutene (~45%), isoprene (~35%), and MCB (~20%) in a low yield.²⁵

The pyrolysis of cyclobutylmethyl acetate **5a** at 480 °C leads to MCB in 70% yield, and the pyrolysis of the corresponding

S-methyl xanthate **5b** at 380 °C affords MCB in 65% yield.²⁶ In the thermolysis of dimethyl(cyclobutylmethyl)amine oxide **5c**, the yield of MCB reaches 95%.²⁷

R = OAc (**a**), OCS₂Me (**b**), NOME₂ (**c**)

Methylenecyclobutane can also be synthesised starting from 1,4-dibromobutane via cyclobutylidenetriphenylphosphorane²⁸ or by the thermal,²⁹ mercury-photosensitised,³⁰ or laser-induced³¹ isomerisation of spiropentane, but these reactions can hardly be regarded as preparative methods for synthesising MCB.

In the industrial production of isoprene from isobutene and formaldehyde by the Prins reaction,⁵ the still product in the column for the purification of isoprene has been found to contain some MCB.^{1,32} A method for the isolation of MCB from this mixture by fractionation has been suggested.² The specimen thus obtained contained 98.42% of MCB. To identify MCB in the fractions of C₅ hydrocarbons, gas chromatography-mass spectrometry (GCMS) has been used.³³ The liquid-vapour phase equilibria in the systems obtained in the production of isoprene and containing MCB and other hydrocarbons have been considered in a number of papers.³⁴⁻³⁷

2. Structure and physical properties of methylenecyclobutane

At present, numerous data on the geometric structure of MCB are available. In fact, NMR,³⁸⁻⁴⁹ IR,⁴⁹⁻⁵⁴ UV,^{49,55} photoelectron,⁵⁶⁻⁵⁸ mass,⁵⁹⁻⁶⁴ microwave,⁶⁵⁻⁶⁷ and Raman,^{13-16,68-70} spectra of MCB have been studied in detail. Its physical and thermodynamic characteristics have been determined.^{59,71-76}

Numerous theoretical studies have been devoted to the problems of the geometry and energetics of the MCB molecule.^{50,58,77-100} The authors of these studies used various quantum-chemical computational methods.

According to the computational and experimental data, the MCB molecule possesses conformational mobility. The energy barrier to the transition from the puckered to the planar conformation is fairly low (-0.2 kcal mol⁻¹); it is lower than that for unsubstituted cyclobutane by a factor of 4-5. This distinction is due to the lesser changes in both the angular strain and the torsional interactions which accompany the transition of MCB from the nonplanar to the planar configuration.⁹⁸

Unambiguous data concerning the value of the dihedral angle (α) in the puckered conformation (Scheme 1) are lacking. For example, a dihedral angle of 16° has been found from spin-spin coupling constants.⁴⁸ It follows from electron diffraction, microwave spectra, and quantum-chemical calculations that the angle is 21.6°,¹⁰⁰ which is lower than for unsubstituted cyclobutane, in which the angle α is 30°^{101,102} or 25°.¹⁰⁰

The C=C bond length in MCB is 1.331 Å.⁹¹ It differs little from the length of the double bond in isobutene (1.330 Å) and is shorter than this bond in ethene (1.337 Å).⁹⁰

II. Rearrangements

Whereas at ambient or low temperature MCB undergoes only conformational transformations (Scheme 1), at elevated temperatures (300-350 °C) a reversible process involving a more extensive structural rearrangement of the C-C and C-H bonds is observed. Thus, at a temperature of 332 °C partially deuteriated MCB undergoes a redistribution of deuterium atoms, which is due

to the relative ease of the homolytic cleavage of C-C bonds in the strained four-membered ring, yielding the alkylallyl biradical **6**.¹⁰³

The isomerisation of MCB via a biradical mechanism has been discussed in another study.¹⁰⁴ A quantum-mechanical calculation carried out more recently also provided evidence in support of this mechanism of the thermal rearrangement of MCB.¹⁰⁵

The rearrangement of MCB involving the *exo-endo* migration of the double bond to give 1-methylcyclobutene **7** is of considerable interest.

Like MCB, the latter compound is potentially likely to be useful in organic synthesis. The rearrangement of MCB is energetically the least favourable compared with the corresponding rearrangements of its homologues with larger rings, since the ΔH value for this reaction is fairly small (-0.54 ¹⁰⁶ and -0.9 kcal mol⁻¹¹⁰⁷). For the rearrangements of methylenecyclopentane and methylenecyclohexane, these values are -3.65 and -1.97 kcal mol⁻¹, respectively.¹⁰⁸

MCB rearranges to 1-methylcyclobutene when it is passed over Al₂O₃ at 300 °C,⁶ but, isomerisation under these conditions can also yield isoprene.¹⁰⁹ When MCB is passed over Al₂O₃ at a higher temperature (370-420 °C),¹¹⁰ the ring is cleaved to give isoprene as the main reaction product.^{109,110} The isomerisation of MCB on passing it over various heterogeneous catalysts (aluminosilicates or zeolites) in the temperature ranges 50-400 °C¹¹¹ and 350-500 °C¹¹² has been described. For all the catalysts studied, it was found that the curves for the temperature dependence of the yield of 1-methylcyclobutene pass through a maximum. When the temperature is increased further, migration of the double bond within the four-membered ring occurs, yielding 3-methylcyclobutene **8**.¹¹¹ This compound is the least stable among the three isomers **1**, **7**, and **8**.¹⁰⁹ Isomer **8** was not detected in the products of the isomerisation of MCB over Al₂O₃.¹⁰⁸

It has been shown⁶ that MCB isomerises to 1-methylcyclobutene when heated in aqueous alcohol in the presence of ZnBr₂ and Zn(OH)Br at 140 °C for several days.

Heating of MCB in dimethylacetamide for 10 min at 160 °C gave an equimolar mixture of MCB and 1-methylcyclobutene in 80% yield.¹¹³

When MCB is stirred at room temperature with metallic sodium deposited onto Al₂O₃, an equilibrium between the alkenes with the *exo*- and *endo*-arrangements of the double bond is established after several hours. The equilibrium constant *K* of reaction (3) at 20 °C is equal to 6, which implies that the reaction mixture contains 15% of MCB and 85% of 1-methylcyclobutene.^{109,114-117} As shown in another study,¹¹⁸ this process is not selective, since after its completion the reaction mixture contains 75% of 1-methylcyclobutene, 19% of MCB, 3% of spiropentane, and 3% of unidentified hydrocarbons.

The isomerisation of MCB also takes place in the presence of strong bases. The relative rates of formation of carbanions from

C₄–C₈ methylenecycloalkanes in the presence of potassium *tert*-butoxide in dimethyl sulfoxide have been reported.¹¹⁹ Kinetic studies of the isomerisation of MCB in the presence of potassium or lithium *tert*-butoxide in various solvents have been carried out.¹²⁰ A preparative procedure for the isomerisation of MCB to 1-methylcyclobutene in the Bu^tOK–DMSO catalytic system has been reported;¹²¹ however, the yield of compound **7** per unit volume of the catalyst solution did not exceed 0.1 g cm⁻³ h⁻¹. In the presence of a stronger base, lithium β-aminoethylamide, in ethylenediamine at 10–45 °C, the isomerisation proceeds more effectively (with a productivity of 4.3–4.5 g cm⁻³ h⁻¹). The equilibrium concentrations of MCB and 1-methylcyclobutene (84%–87% MCB¹²²) are virtually attained over a period of several hours.

The isomerisation of MCB [reaction (3)] in the presence of 3 mol % the rhodium hydride complex Rh(H)(CO)(PPh₃)₃ (with benzene as the solvent)¹²³ occurs much less effectively: even after 10 days the composition of the reaction mixture is far from equilibrium (the ratio between isomers **1** and **7** is 0.68 instead of 0.17). In all probability, the reaction proceeds via a π-complex of Rh(I) with MCB (see below). The isomerisation of MCB to 1-methylcyclobutene has also been observed in the presence of PdCl₂ at 100 °C in dioxane and at 22 °C in methanol.^{124, 125}

III. Formation of complexes with metals

Like other alkenes, MCB forms complexes with AgNO₃. The stability constants of some complexes of alkenes determined by GLC have been reported.^{126, 127} The formation of complexes with Ag(I) has been used in the analysis of MCB-containing mixtures of light hydrocarbons.¹²⁸

Methylenecyclobutane reacts with Pd(II) chloride or [Rh(CO)₂Cl]₂ to give π-allylic complexes.¹²⁹

The comparative stabilities of Rh(I) complexes with various alkenes have been studied.¹³⁰ The π-complex derived from MCB was found to possess an anomalously high stability, comparable with that of the Rh(I) complex of ethene.

The synthesis of a π-complex of MCB with Ni(II) (yield 61%) has also been reported.¹³¹

A trinuclear cluster-type osmium complex incorporating MCB has been described.¹³² In this complex, MCB forms a bridge between two osmium atoms via the methylenecarbon atom and also forms a π-bond with the third osmium atom.

The interaction of MCB with organotitanium,¹³³ organonickel,¹³⁴ organorhodium,¹³⁵ and organopalladium¹³⁶ compounds has also been described in the literature.

IV. Addition to the exocyclic double bond without formation of new C–C bonds

1. Reactivity

a. Cationoid intermediates

Many known transformations of MCB involve a stage in which active electrophilic species such as protons, acylium cations, etc. add to the double bond. The addition results in the tertiary carbocationic intermediate **10**, which can either combine with a nucleophile or eliminate a proton, and this governs the composition of the final reaction products (Scheme 2).

Scheme 2

The problem of the structure of the intermediate cation **10** (E = H) has attracted considerable attention and has not yet been solved. According to ¹³C NMR spectroscopy and an isotope study, at –154 °C this cation exists as the symmetrical σ-bridged methylenecyclobutanium structure **11**,^{137, 138} while from –150 to –90 °C it is an equilibrium mixture of three bicyclobutanium ions **11**, **12a**, and **12b** or delocalised 1-methylcyclopropylcarbynyl cations **13a–c** interconverting via the classical planar 1-methylcyclobutyl cation **14** (Scheme 3).

Scheme 3

The conformation of the 1-methylcyclobutyl cation **10** (E = H) in an aqueous medium at ambient temperature is unknown. Quantum-chemical calculations referring to the gaseous phase allow the existence of this cation as any of the above structures or as their equilibrium mixture.^{139–141} At the same time, since the tertiary carbocation **14** must be much more stable than the primary rearranged cations **13a–c**, one should expect that the equilibrium would be substantially shifted to the right, that is, toward the formation of the cation **14** (Scheme 3). Therefore, it is the transformations of the nonrearranged cation **10** (Scheme 2) that should determine the composition of the products of electrophilic addition to the double bond of MCB; this is in good agreement with the existing experimental data.

The relative stability of the cation **10** (E = H) can be judged by comparing the rate constants for the solvolysis of the corresponding chlorides **15–17** (80% acetone, 25 °C).¹⁴²

The above data indicate that the cation **10** (E = H) is more stable than the unsubstituted cyclobutyl cation and is less stable than the *tert*-butyl cation.

The reactivity of MCB toward electrophilic addition can be estimated by comparing the rates of the ZnCl₂-catalysed reaction of (*p*-CH₃C₆H₄)₂CHCl with various methylenecycloalkanes **18a–c**.¹⁴³

R = (p-CH₃C₆H₄)₂CH

n	3	4	5
k (arbitrary units)	1	51.1	1.03

It follows from these data that the reactivity of MCB in reaction (5) with the above electrophile is close to that of methylenecyclohexane, but is many times lower than that of methylenecyclopentane.

b. Anionoid intermediates

Another important aspect of using MCB in organic synthesis is based on its deprotonation through the action of a strong base and the subsequent transformations of the allylic carbanion **20** thus generated (Scheme 4).

The composition of the products of transformation of the carbanion **20** is determined by the direction of attack by the electrophile (E⁺), which is either on a carbon atom of the side chain or on a ring carbon atom in the allylic system. The predominance of either of these directions depends on the nature of the electrophile and on the conditions under which the reaction is carried out.¹⁴⁴

c. Free-radical intermediates

Another approach to the functionalisation of MCB is based on the radical addition to the double bond. The intermediate adduct formed in this reaction (radical **21**), like the corresponding carbocation **10** produced in the electrophilic addition to MCB (see above), does not undergo fragmentation, and the cyclobutane ring is retained in the products of its transformation.

The radicals **21**, in which R = SiMe₃, SiEt₃,^{145, 146} or MeS,¹⁴⁷ have been detected by EPR at 150–220 K. The formation of the allylic radical **22** upon photolysis of a solution of MCB in cyclopropane containing di-*tert*-butyl peroxide has also been detected by EPR.¹⁴⁸

Radical-ion species such as radical cations can also participate in reactions with MCB. The latter are formed, for example, in photoinduced¹⁴⁹ or γ-radiation-induced reactions.¹⁵⁰

2. Addition with formation of the C–O bond

The acid-catalysed hydration of MCB is among the thoroughly studied examples of electrophilic addition to the double bond of

MCB.^{151–154} The mechanism of this reaction has been described by Taft,¹⁵⁵ who has also determined its thermodynamic parameters.¹⁵⁶ The ether **23**, resulting from the addition of 1-methylcyclobutanol **24** to MCB, is formed in this reaction as a side product.

When MCB was hydrated in the presence of the KU-23(10/60) cation-exchange resin at 40 °C with an MCB:H₂O molar ratio of 2:3 and a reaction time of 8 h, the degree of MCB conversion amounted to 87.8% and the selectivity of the formation of compound **24** was 94.4% (the reaction mixture contained 3% of the ether **23**). However, by varying the hydration conditions one can direct the process to the selective formation of the ether **23**. Thus, at 40 °C, for an MCB:H₂O molar ratio of 2:1, and for a reaction time of 3 h, the selectivity of the formation of ether **23** was 96%, the degree of conversion of MCB being 92.1%.¹⁵²

The hydration of MCB under static conditions (without stirring) in the presence of the KU-23(10/60) cation-exchange resin in a batch reactor has been described.¹⁵³

Alcohols or carboxylic acids add to MCB in the presence of an acid catalyst.¹⁵⁷

R	Me	Et	Bu ⁿ		MeCO
Yield (%)	90	45	41	63	56

R	ClCH ₂ CO	FCH ₂ CO	Cl ₂ CHCO	CF ₃
Yield (%)	55	60	90	91

The reaction is carried out in hexane with MCB:ROH (or RCOOH):C₆H₁₄ ratios of 1:1:1 in the presence of sulfuric acid or HCl.

Esters derived from 1-methylcyclobutanol have found application as insecticides, acaricides, and fungicides,^{158, 159} and sugar substitutes in foodstuffs.¹⁶⁰ The 1-methylcyclobutoxy-group is incorporated in a metabolism-resistant β-lactam antibiotic possessing a high antibacterial activity.¹⁶¹

The selective addition of HOBr to MCB, affording 1-bromo-1-hydroxymethylcyclobutane in 78% yield, has been described.^{162, 163}

Hypochlorous acid also adds to MCB, but, apart from chlorohydrin, this reaction yields a diol (the ratio between these products is 3:2).¹⁶² The process is carried out in an aqueous suspension of the alkene.

3. Addition with formation of the C–N, C–S, C–Se, or C–Hal bond

The addition of hydrogen halides to MCB has been studied in detail.^{164–168} In polar solvents, hydrogen halides add in conformity with the Markovnikov rule, giving 1-halo-1-methylcyclobutane, while in the presence of a radical source in a nonpolar solvent, anti-Markovnikov addition occurs to yield bromomethylcyclobutane.^{162, 169, 170}

Hittich et al.¹⁷¹ have described the hydrofluorination of MCB, but the yield of 1-fluoro-1-methylcyclobutane **27** isolated by preparative GLC was not reported.

Acetyl nitrate adds to MCB at -20 to 0°C in the presence of acetic anhydride.¹⁷² Apart from the major product, 1-acetoxy-1-nitromethylcyclobutane **28**, the reaction yields the product **29** of the rearrangement of the intermediate cation involving ring contraction:

When NO_2BF_4 is used instead of AcONO_2 , the yield of 1,1-disubstituted cyclopropane is twice as high.¹⁷²

The interaction of MCB with the complex $\text{Me}_2\text{S} \cdot \text{SO}_3$ affords the sulfobetaine **30** as the only product in a high yield:^{173, 174}

2,4-Dinitrophenylsulfanyl chloride reacts with MCB in acetic acid at 20°C to afford predominantly the arylthiomethyl-substituted cyclobutane **31**. In addition, a small amount of compound **32** was isolated (the **31a**:**32a** ratio was 5.2:1); the overall yield of the products **31** and **32** was 88%.¹⁷⁵ At 40°C , these products are formed in a different ratio (**31a**:**32a** = 2:1):¹⁷⁶

When the reaction is carried out in chloroform, the anti-Markovnikov addition product predominates (**31a**:**32a** = 0.4:1),¹⁷⁶ while the process carried out in acetic acid in the presence of LiClO_4 affords mostly products of the interaction with the solvent (the products **31** and **32** are formed in the following yields: **31a**, 5%; **31b**, 35%; **32a**, 1%; **32b**, 12%).¹⁷⁶

Phenylselenanyl chloride interacts with MCB at -70°C in CH_2Cl_2 to give the chloromethyl derivative of cyclobutane **33** as the major product; at room temperature, compound **33** slowly isomerises to the chloride **34**.¹⁷⁷

The reaction of MCB with SeBr_4 gives the product **35** incorporating two cyclobutyl groups:¹⁷⁸

At room temperature, compound **35** is gradually dehalogenated and rearranges, affording substituted cyclopropylmethyl bromides.

The electrophilic addition of tetramethyleneselenanyl bromide to MCB gives the selenonium salt **36**.¹⁷⁹ In all probability, this reaction occurs via the intermediate bromonium ion **37**.¹⁸⁰

The formation of different products in these reactions (compounds **35** and **36**) may be due to greater steric hindrance in the selenium-containing nucleophile participating in reaction (7), which hampers the attack on the nonterminal carbon atom of the bridged cation **37**.¹⁸⁰

At -60°C , MCB can combine with SO_3 , giving the cyclic β -sultone.¹⁸¹

The chlorosulfamation of MCB yields a mixture of the products **38**–**40**. The addition is nonselective and is accompanied by partial rearrangement:¹⁸²

4. Hydrogenation

Hydrogenation under mild conditions involves the addition of hydrogen to the exocyclic double bond. Under more drastic conditions, the cyclobutane ring is cleaved and the reaction yields isopentane as the major product.⁶ The heats of hydrogenation of MCB and 1-methylcyclobutene have been reported by Turner et al.¹⁰⁷ The kinetics of the hydrogenation of MCB over platinum-containing catalysts have been studied.^{183, 184}

5. Oxidation

When MCB is treated with hydrogen peroxide in the presence of OsO_4 or in formic acid, 1-hydroxy-1-hydroxymethylcyclobutane **41** is formed in 39% and 83% yield, respectively.²¹

The highly selective dihydroxylation of MCB with hydrogen peroxide occurs in the presence of the osmium catalyst obtained from OsO_4 or $\text{Os}_3(\text{CO})_{12}$ and poly(4-vinylpyridine) or poly(4-vinylpyridine 1-oxide).¹⁸⁵

The epoxidation of MCB with 41% peracetic acid in CH_2Cl_2 in the presence of anhydrous Na_2CO_3 at room temperature gives the oxaspirohexane **42** in 45% yield.^{186, 187}

The treatment of MCB with peracetic acid in acetic acid results in a mixture consisting of the monoacetate of the diol **41** and cyclobutanecarboxylic acid, while the use of perbenzoic acid in chloroform yields a mixture of the oxaspirohexane **42** and the monobenzoate of the diol **41**.¹⁸⁸

The kinetics of the epoxidation of MCB with peroxyauric acid have been studied.¹⁸⁹ The epoxidation of MCB with atomic oxygen, generated by the Hg-sensitised photolysis of N_2O , occurs nonselectively: apart from the epoxide **42**, formylcyclobutane **43** and cyclopentanone **44** are produced.¹⁹⁰

The oxidative cleavage of MCB by potassium periodate in the presence of a catalytic amount of OsO_4 is the simplest of the known ways of preparing cyclopentanone **45**.^{191, 192}

Methylenecyclobutane is ozonised at a temperature of $-70^\circ C$ in pentane. The resulting ozonide decomposes explosively at $-20^\circ C$.¹⁹³

Cyclobutanone has been synthesised in a yield of about 70% by the ozonisation of MCB at -70 to $-80^\circ C$ in CH_2Cl_2 in the presence of pyridine.^{194, 195}

A series of MCB transformations accompanied by ring expansion and resulting finally in cyclopentanone have been described. For example, the oxidation of MCB with nitrous oxide at $300^\circ C$ and 450 atm affords cyclopentanone **44** in a low yield.¹⁹⁶ One of these processes involves the intermediate formation of the epoxide **42**, which is then allowed to react with LiI without isolation from the reaction mixture.^{197, 198}

Methylenecyclobutane can be directly converted into cyclopentanone by oxidation with oxygen in the presence of the $PdCl_2-CuCl_2$ catalytic system. The selectivity of this process depends substantially on the nature of the solvent. It occurs most selectively in benzene, the yield of cyclopentanone being 75%.¹⁹⁹

The oxidation of MCB to cyclopentanone with the complex $(MeCN)_2PdCl(NO_2)$ in CH_2Cl_2 has also been studied.²⁰⁰

The oxidation of 1-methylcyclobutene with $Tl(III)$ and $Hg(II)$ perchlorates,^{201, 202} as well as with $PdCl_2$,²⁰¹ $PdCl_2L_2$, or $PdCl(NO_2)L_2$ ($L = CD_3CN$)²⁰³ results in cyclopropyl methyl ketone **46**, the chemistry of which has been discussed in a review.²⁰⁴

The autooxidation of MCB proceeds more slowly than that of terpenes or other unsaturated alicyclic alkenes, the 2-position of the cyclobutane ring being attacked predominantly.²⁰⁵

6. Hydroboration, hydrosilylation, and hydrophosphorylation

The hydroboration of MCB with the subsequent oxidation of the resulting cyclobutylmethylborane **47** leads to cyclobutylmethanol **48**.²⁰⁶

MCB enters into the hydrosilylation reaction in the presence of a Pt catalyst immobilised on a phosphinated silica gel:²⁰⁷

The hydrophosphorylation of MCB with phosphinic acid in the presence of hydrogen peroxide in an acid medium at $50-60^\circ C$ affords cyclobutylmethylphosphinic acid **50**:²⁰⁸

The reaction of MCB with PBr_3 gives the corresponding phosphine as the only product.²⁰⁹ When the reaction is carried out in a stream of O_2 , the yield of the phosphine increases from 49% to 63%. The reaction is regiospecific and occurs via a radical mechanism.

The treatment of the phosphinidene complexes $PhPW(CO)_5$ and $MePW(CO)_5$ with exocyclic olefins affords 1-phosphaspiro[2.n]alkanes ($n = 2-5$).²¹⁰ In the case of MCB, a pentacarbonyl-tungsten complex containing the 1-phosphaspiro[2.3]-hexane ligand **51** is formed.

$R = Me$ (a), Ph (b)

V. Addition to the double bond with formation of new C–C bonds

1. Alkylation

In the presence of 20 mol % $BF_3 \cdot Et_2O$ in benzene at $7^\circ C$, MCB dimerises, giving the bicyclic dimer **52**.²¹¹

A new pathway to the synthesis of C-glycosides, which are of interest for preparing new anticancer preparations, has been suggested by Herscovici et al.^{212, 213} This method is based on the electrophilic addition of the acylated glycals **53** to MCB, catalysed by Lewis acids:

Reaction (8) was carried out at -20°C for 5 min in a $\text{C}_5\text{H}_{12}-\text{Et}_2\text{O}$ (5:1) solvent mixture. A number of workers reported^{157,214,215} the preparation of 5,7-dioxaspiro[3.5]nonane **55** by the reaction of MCB with formaldehyde catalysed by sulfuric acid or *p*-toluenesulfonic acid:

If the above reaction is carried out at 40°C in the presence of 30 mass % H_2SO_4 , the yield of compound **55** is 49%.^{157,214} The yield of 5,7-dioxaspiro[3.5]nonane can be brought to 82% with virtually complete conversion of MCB by conducting this reaction at 90°C and with a $\text{CH}_2\text{O}:\text{MCB}$ molar ratio of 2:1 in the presence of 2.5 mol % sulfuric acid and an equal volume of an extractant (hexane).²¹⁵

The methylated diol **56** has been obtained directly from MCB using methoxymethyl methyl sulfate **57** as the alkylating reagent.²¹⁶

This reaction involves the intermediate formation of the sulfate **58**, which is subjected to methanolysis and then treated with triethylamine without isolation from the solution. When the intermediate **58** is treated with an aqueous solution of NaHCO_3 , the reaction yields the alcohol **59**.²¹⁷

Similarly, 1-ethoxyethyl ethyl sulfate adds to MCB in the presence of methanol to give the adduct **60**.²¹⁸

1-(2-Ethoxyethyl)-1-methoxycyclobutane **61** has been synthesised in a similar way.²¹⁹

2. Acylation

a. Electrophilic acylation

The known instances of the electrophilic acylation of MCB involved the highly reactive cationoid reagents RCO^+X^- ($\text{X}^- = \text{SO}_3\text{F}^-$, BF_4^- , or SbF_6^-) as electrophiles. The course of the reactions of MCB with acyl tetrafluoroborates $\text{RCO}^+\text{BF}_4^-$ (Scheme 5) depends on the nature of the group R. The bulkier the group R, the larger the contribution of reactions occurring with the rearrangement of the intermediate cation **62**.²²⁰ If R is Me or Et, only the fluorinated ketone **63** is obtained. If R is Bu^t , only the rearranged product, namely, substituted tetrahydrofuran **64**, is formed. When R is Pr^n or Bu^i , mixtures of the products **63** and **64** are isolated. When water is added to the reaction mixture, the hydroxyketone **65** is produced via the hydration of the rearranged cation **66**.²²⁰

Scheme 5

(R = Bu^t , 65%–70%)

R	63 : 64 ratio
Me	100:0
Et	100:0
Pr^n	(85–75):(15–25)
Bu^i	(30–35):(70–65)
Bu^t	0:100

The composition of the products of the acylation of MCB is sensitive not only to the nature of the group R in the cationoid reagent RCO^+X^- , but also to the nature of the anion X. The solvent used also plays an important role.

When the acylation of MCB with acetyl tetrafluoroborate is carried out in the presence of acetic anhydride, 1-acetonyl-1-acetoxycyclobutane **67** is the main reaction product (Scheme 5).^{221,222}

When $\text{RCO}^+\text{BF}_4^-$ is replaced by the harder ionic reagent $\text{RCO}^+\text{SbF}_6^-$, the reaction yields the substituted tetrahydrofuran **64** as the only product, irrespective of the bulk of the group R.²²³

The acylation of MCB with $R^1CO^+BF_4^-$ in the presence of R^2CN proceeds as coupled addition of R^1CO^+ and R^2CN to the $C=C$ bond via the formation of the *N*-alkylnitrilium salt **68** (Scheme 6).²²²

Scheme 6

Depending on the reaction temperature, either the amidoketones **69** ($-30^\circ C$) or the 5,6-dihydro-1,3-oxazines **70** ($+20^\circ C$) are formed selectively. The syntheses of a number of amidoketones **69** and oxazines **70** ($R^1 = Me, Et, Pr^i, Pr^i, Bu^i$; $R^2 = Me, CH_2Cl, Ph$) in 34%–100% yields have been reported by Gridnev et al.²²⁴

In the case where acetyl fluorosulfonate, prepared in situ from AcF and SO_3 , is used in the acylation of MCB, the composition of the reaction products depends on the nature of the alcohol introduced into the system:²²⁵

It has been reported that the complex of trichloroacetonitrile with boron trichloride can be used as a chemical equivalent of the acylium cation.²²⁶ The first step of the process affords the cation **74**, which is converted in the presence of water mostly into the ketone **75** and, to some extent, into the unsaturated ketone **76**. The overall yield of the products is 91%:²²⁶

The introduction of a perfluoroacyl group into unsaturated compounds is hampered, because the perfluoroacyl cation is easily decarbonylated and, furthermore, the readily available trifluoroacetic anhydride is insufficiently electrophilic to acylate alkenes. It has been suggested that the perfluoroacylation should be carried out using the complex resulting from the addition of trifluoroacetic anhydride to a solution of dimethyl sulfide in CH_2Cl_2 saturated with BF_3 :²²⁷

b. Free-radical acylation

Only one example of the free-radical acylation of MCB is known. It is the reaction of MCB with acetaldehyde (with an AcH : MCB molar ratio of 10:1) initiated by atmospheric oxygen (at an air flow rate of $40\ h^{-1}$) in the presence of a catalytic amount of $Co(OAc)_2$ ($1.5 \times 10^{-3}\ mol\ l^{-1}$).²²⁸ Apart from the ketone **78**, acetic acid is also formed.

Reaction (9) proceeds by a chain mechanism²²⁹ involving the formation of acyl radicals, their addition to the double bond of MCB, and chain transfer by the intermediate radical adducts:

Scheme 7

3. Arylation

Only a few examples of the arylation of the MCB double bond are known. For example, in the presence of $AlBr_3$, MCB reacts with benzene, yielding 1-methyl-1-phenylcyclobutane **79**:^{211, 230}

The reaction of MCB with mesitylene in the presence of $MeCO^+BF_4^-$ affords a mixture of arylation (**80**), acylation (**63**), and coupled addition (**81**) products.²³¹

If this reaction is carried out in the presence of BF_3 , the yield of compound **80** is only 5%, and in this case extensive polymerisation of MCB is observed.²³¹

The reaction of MCB with phenol yields mostly a mixture of mono-, di-, and tri(1-methylcyclobutyl)phenols **83–85** and a small amount of the ether **82**.²³²

Depending on the reaction conditions, arylation may afford a mono- or disubstituted phenol as the major product (yield 30%–40%).¹⁵⁷

The reactions of MCB and other methylenecycloalkanes with (*p*-anisyl)phenylcarbenium tetrachloroborate have been studied.²³³

VI. Reactions with retention of the C = C bond

1. Allylic alkylation, 'ene' reactions

The allylic anion **86** prepared from MCB and butyllithium in tetramethylethylenediamine (TMEDA) reacts with methylallyl chloride **87** to give a mixture of the isomers **88** and **89** usual for allylic systems (**88**:**89** = 85:15, overall yield 90%).²³⁴

The alkylation of the allylic anion **86** with 2-bromo(methylenecyclobutane) **90** affords a more complex mixture of products,

since in this case not only the anion **86**, but also the bromide **90** are capable of reacting at two centres. The product ratios are **91**:**92**:**93** = 22:46:32, with an overall yield of 85%.

The alkylation of the anion **86** with diphenylmethyl bromide gave compounds **94** and **95** (in a 1:1 ratio) in an unexpectedly low yield (17%).²³⁵ The carboxylation of this anion with carbon dioxide proceeds with an equally low yield.²³⁶

Carbonyl compounds can also be used as the electrophilic component in the alkylation of MCB.^{236–240} Thus, Snider et al.²³⁸ have suggested a method of preparing cyclobutenylmethyl-(hydroxy)malonate from MCB and diethyl oxomalonate **98**. The reaction occurs without a solvent at 80 °C over a period of 170 h. The yield of the alkylation product **99** is 63%. Its hydrolysis followed by oxidation affords 1-cyclobutenylacetic acid **100**.²³⁹

A similar reaction with isovaleraldehyde leads to the alcohol **101** in 43% yield.²³⁸

It is noteworthy that the 'ene' reactions (10) and (11) are highly regioselective: in both cases, the addition involves exclusively the *exo*-methylene group of the allylic anion.

The selective alkylation of MCB with ketones (acetone, cyclohexanone, cycloheptanone, or camphor) at the allylic carbon atom of the cyclobutane ring can be carried out by using the novel approach described by Bubnov et al.²⁴¹ A characteristic feature of this approach is that alkylation with an electrophile (in this instance, with a ketone) is preceded by the introduction of a boron-containing group into the allylic anion **86**:

2. Metathesis (disproportionation) and cometathesis

The catalytic disproportionation of MCB in the presence of a heterogeneous rhenium-containing catalyst has been reported in a number of studies carried out mostly in the 1970s.^{242–247}

The yield of bicyclobutylidene **103** in this reaction, carried out in the liquid phase with constant removal of ethene from the reaction zone, reached 70% over a period of 4 h. The disproportionation of MCB can also be carried out in the gaseous phase over the same catalyst in a flow-type setup at 100 °C. The $\text{WCl}_6\text{--EtAlCl}_2\text{--EtOH}$, $\text{WCl}_6\text{--Bu}^n\text{Li}$, and $\text{MoO}_3/\text{Al}_2\text{O}_3$ systems turned out to be virtually inert in this reaction.

Catalytic processes involving the cometathesis of MCB with other alkenes have also been developed:^{245, 247–249}

The products of the homometathesis of MCB and $\text{CH}_2=\text{CHR}$ (which are not shown in the scheme) are also formed in reaction (12).

From a mixture of liquid products of the joint disproportionation of MCB and propene in a flow-type setup in the gaseous phase (with $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$ as the catalyst, MCB:propene = 2:1, volume rate of supply of the reactants 500 h^{-1} , 1:1 dilution with nitrogen, 20 °C), ethylenecyclobutane **104** ($\text{R} = \text{Me}$) was isolated in 20% yield.²⁴⁵

The cometathesis of MCB with 1-methylcyclobutene affords a mixture of three diene hydrocarbons (**105–107**), the yield of each depending on the reaction conditions (with $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$ modified by SnBu_4 as the catalyst and benzene as the solvent).²⁴⁸

The cometathesis of MCB and cyclopentene (CP) was carried out at low initial concentrations of the latter (MCB:CP = 9:1) in order to exclude the possibility of its polymerisation, and at temperatures between –65 and 35 °C. At 35 °C, with a CP:catalyst ratio of 10:1 by weight, and for a contact time of 1 h, the reaction gave 6-cyclobutylidenehex-1-ene **108** as the only cometathesis product (the degree of conversion of cyclopentene was 90%).²⁴⁹

VII. Cycloaddition

1. [2 + 1]-Cycloaddition

The interaction of MCB with dihalomethanes in the presence of metals such as Zn, Cd, or Cu with a CH_2Hal_2 :metal molar ratio of 1:2 in a polar solvent (DMF, dimethylacetamide,

acetonitrile, *N*-methylpyrrolidone, HMPA, formamide) results in the formation of spirohexane **109**.²⁵⁰

$\text{M} = \text{Zn, Cd, Cu}$.

Spirohexane **109** (yield 48%) has also been obtained by the cyclopropanation of MCB with diazomethane in ether at –10 °C in the presence of palladium acetylacetonate as the catalyst (1 mol% with respect to MCB).²⁵¹

Dichlorocarbene adds to MCB to give 1,1-dichlorospiro[2.3]hexane.²⁵²

Alkynylhalocarbenes also add to MCB, yielding the corresponding substituted spirohexanes **110**.²⁵³

$\text{R} = \text{Me, Pr}^n, \text{Pr}^i$.

The cyclopropanation of MCB with methyl diazoacetate, catalysed by $\text{Cu}(\text{acac})_2$ in CH_2Cl_2 , is a convenient method for preparing esters of spirohexanecarboxylic acid **111**.²⁵⁴

The addition of singlet ethoxycarbonylnitrene to MCB has been described.²⁵⁵ This reaction gives the azaspirane **112** in a moderate yield:

2. [2 + 2]-Cycloaddition

The cycloaddition to MCB of dichloroketene, generated in situ from dichloroacetyl chloride, yielded the adduct **113**.²⁵⁶ This ketone has been used in the synthesis of spiro[3.4]octa-5,7-diene **114**.²⁵⁷

The interaction of MCB with tetrachlorobutanoyl chloride in the presence of Et_3N proceeds in a similar way:²⁵⁸

3. [2 + 3]-Cycloaddition

A convenient way of synthesising spirane isoxazolidines **117** incorporating a cyclobutane ring in yields of 70% or more is based on the 1,3-dipolar cycloaddition of *N,C*-disubstituted nitrones to MCB.^{259, 260}

R = Ph, PhCO, PhNHCO, XC₆H₄NHCO (X = Br, Me, Ac, EtO).

The cycloaddition of the *N*-oxides **118** to MCB is a convenient single-stage method for the synthesis of spiro(4,5-dihydroisoxazole-5,1-cyclobutanes) **119**.^{261–263}

p-Nitrobenzenesulfonyl azide reacts with MCB via a 1,3-dipolar cycloaddition mechanism to give the triazoline intermediate **120**, which undergoes rapid rearrangement with ring expansion, affording the sulfonimide **121**. The latter is hydrolysed to give cyclopentanone:²⁶⁴

An unusual cycloaddition has been observed on irradiating MCB in benzene; equal amounts of the cyclic adducts **122** and **123** (overall yield 5%) were obtained:²⁶⁵

4. [2 + 4]-Cycloaddition

The interaction of MCB with dimethyl tetrathiooxalate occurs similarly to the Diels–Alder reaction in which MCB acts as the dienophile:²⁶⁶

An unusual example of the formation of the cyclic adduct **125** from MCB and tetrachlorothiophene dioxide has been described by Raasch.²⁶⁷

The triazine **126** reacts with MCB in a similar way (with the cleavage of the heterocyclic ring and liberation of nitrogen).²⁶⁸

Methylenecyclobutane can enter into the Diels–Alder reaction, acting as the diene.¹⁶⁴

5. [2 + 2 + 1]-Cycloaddition

The cycloaddition to MCB of alkynes bound into a complex with cobalt carbonyl (one of the coordinated CO molecules participates in the reaction) yields a mixture of the spiroketones **130** and **131** in a ratio of 1 : 1.^{269, 270}

VIII. Reactions with ring opening

The opening of the MCB ring has been observed in its reactions with hydroxyl or methyl radicals.^{271, 272}

The thermal decomposition of MCB has been studied.^{273–276} The Arrhenius parameters of this process were determined in the same investigations.

The photolysis of MCB leads to equimolar amounts of ethene and allene.^{277, 278} Vacuum UV photolysis (Xe 147.0 nm and Kr 123.6 nm) occurs less selectively.^{279, 280} Among the photolysis products, H₂, C₂H₂, C₂H₄, allene, methylethyne, vinylthyne, and buta-1,3-diene were detected.

The rearrangements of MCB accompanied by its decomposition have been discussed in a review.²⁸¹

IX. Polymerisation

The possibilities of using MCB for preparing polymers and copolymers have been examined.

Methylenecyclobutane and some of its derivatives (3-CN, 3-COOH, 3-Me-3-COOH, 3-Ph) do not polymerise in the

presence of radical initiators,^{282, 283} $\text{BF}_3 \cdot \text{Et}_2\text{O}$, or BuLi , but they form copolymers with acrylonitrile, styrene, or methyl methacrylate.²⁸²

The polymerisation of MCB on treatment with Lewis acids (AlCl_3 , TiCl_4 , SnCl_4 , or BF_3) results in a low-molecular-mass polymer (average molecular mass < 2000) having a regular structure with cyclobutane side groups.²⁸⁴

In the presence of Ziegler–Natta catalysts [AlEt_3 – $\text{Ti}(\text{OPr})_4$ or AlEt_3 – TiCl_4 – PPh_3], poly(methylenecyclobutane) is formed, the ozonisation of which yields a linear polyketone.²⁸⁵ When other catalysts were employed, polymerisation occurred with complete or partial opening of the cyclobutane rings.^{286–288}

The regioselective polymerisation of MCB and its regioselective copolymerisation with ethene occur on treatment with $[(1,2\text{-Me}_2\text{C}_5\text{H}_3)_2\text{ZrMe}]^+[\text{MeB}(\text{C}_6\text{F}_5)_3]^-$ ^{289, 290} to yield a linear polymer or copolymer 132 with methylene side groups.

132

The influence of MCB on the polymerisation of isoprene in the presence of the Ziegler–Natta catalyst $\text{Al}(\text{Bu}^i)_3$ – TiCl_4 has been studied by Sire et al.²⁹¹ It was found that an admixture of MCB in the monomer has no effect on the properties of the polymer, but substantially retards the polymerisation.

Synthesis and properties of sultines, cyclic esters of sulfinic acids

O B Bondarenko, L G Saginova, N V Zyk

Contents

I. Introduction	147
II. Methods for synthesising sultines	147
III. Properties of sultines	160

Abstract. Data on the synthesis and chemical properties of sultines, cyclic esters of sulfinic acids, are reviewed. The known methods for synthesising sultines are considered, the reaction mechanisms and stereochemistry of the compounds obtained are discussed. The chemical transformations of sultines, including photolysis, thermolysis, redox reactions, and interaction with nucleophiles, are described. The bibliography includes 109 references.

I. Introduction

Lactones of sulfinic acids, i.e., sultines, were first mentioned as early as the end of the last century.¹ However, the chemical transformations of sultines long remained little studied due to their inaccessibility. The chemistry of sultines began to develop successfully only in recent decades. Many studies on methods for the synthesis of compounds of this class and their properties were published; the interest both of synthetic chemists and theoreticians in them has grown significantly. From the theoretical viewpoint, sultines are promising as models for studying the stereochemistry of sulfur, since the S atom in them is located at a vertex of a stable pyramid and does not have identical substituents, i.e. it is a chiral centre. The asymmetry of the molecule caused by the S atom can be easily removed by oxidising the sultine to the corresponding sulfoxide.^{2,3} Owing to the existence of a rather high barrier to inversion of the sulfoxide group, the introduction of at least one substituent into the sultine ring results in the appearance of diastereomers differing in the mutual arrangement (*cis* or *trans*) of the sulfoxide group and the substituent relative to the ring plane, i.e., geometric isomerism appears. Sultines are interesting as synthons because they possess hidden (latent) bifunctionality: cleavage of the heterocycle at the S–O bond leads to the simultaneous appearance of two functional groups in the product.

Owing to the increasing interest in studies on sultines and their transformations, we have attempted to systematise the data on the compounds of this class. It is noteworthy that sultines are mentioned in several reviews devoted to sulfinic acids and their derivatives;^{4–6} however, these data are not systematic but very fragmentary and given only in outline.

II. Methods for synthesising sultines

Three main groups can be distinguished among the known methods for sultine synthesis; these groups differ in the approach used to create the sultine structure. One group of reactions involves fragmentation-cyclisation transformations of sulfones. Another group combines cyclisations of bifunctional sulfur-containing compounds, usually thiols, sulfides, or sulfoxides, in which the hydroxyl group serves as the second function. The third group, not the most common but very interesting, involves sultine ring formation reactions with simultaneous introduction of three heteroatoms into the molecule upon addition of sulfur dioxide to unsaturated molecules.

1. Rearrangements of sulfones

A number of studies of both homo- and heterolytic sulfone rearrangements, which result in sultine formation, have been described. The driving force for these reactions frequently originates from a decrease in strain in the starting structure due to an increase in the heterocycle size by one atom, as, for example, in the case of four-membered cyclic sulfones, or from the presence of a good leaving group in the molecule.

a. Reactions of sulfones involving homolytic cleavage of a C–S bond

The formation of 5-substituted 3,3-dibromo-1,2-oxathiolane 2-oxides **1** was found to occur in the radical addition of bis(tribromomethyl)sulfone to alkenes.⁷ Most probably, sultine **1** is formed through intramolecular cyclisation of radical **2**. The subsequent elimination of the very stable tribromomethyl radical is the driving force for this unusual cyclisation. Sultine **1** is formed in a low yield, the main processes being chain transfer. However, it cannot be ruled out that a decrease in the concentrations of the sulfone and alkene in solution, i.e., higher dilution, would lead to an increase in the lifetime of radical **2** and, hence, to increased probability of its cyclisation into sultine **1**.

b. Reactions of sulfones and 1,2,3-thiadiazine 1,1-dioxides via a concerted mechanism

The thermal decomposition of 3,8-diphenylnaphthothiete 1,1-dioxide **3** at 400 °C under nitrogen in the presence of 9,10-dihydroanthracene affords naphthosultine **4** in 78%–81% yield.⁸ The reaction presumably involves a step in which an intermediate (possibly, a dipolar or biradical compound) is formed, which gives sultine **4** upon subsequent cyclisation.

The role of 9,10-dihydroanthracene in this transformation is unclear; however, in its presence the decomposition of sulfone **3** stops at the stage of sultine **4**. In the absence of 9,10-dihydroanthracene, the reaction proceeds further to give the fused-ring fluorene **5** and fluorenone **6**, i.e. the same products as those from the thermolysis of sultine **4**.

Thermolysis of the unsubstituted thiete 1,1-dioxide in the gas phase at 400 °C or in a degassed benzene or cyclohexane solution at 200 °C also gives the sultine **7** in high yields (up to 90%). It is likely that this transformation involves the vinylsulfene **8** as an intermediate. This is confirmed by the fact that this reaction, in the presence of phenol, gives phenyl allylsulfonate in 15% yield.⁹

The formation of the vinylsulfene **8** and its subsequent transformation into the sultine **7** are believed to occur via a concerted mechanism.⁹ The fact that reaction of 2*H*-1,2,3-benzothiadiazine 1,1-dioxide **9** with chlorine in an anhydrous medium gives the chlorosultine **10** is considered¹⁰ to support this mechanism. It is assumed that in this case the chlorination product **11** initially formed decomposes with elimination of the very stable nitrogen molecule and formation of the vinylsulfene **12**. The latter then cyclises to the chlorosultine **10**. However, it cannot be ruled out that compound **11** gives the diazonium sulfinate **13** by heterolytic cleavage of the S–N bond. Diazo compound **13** can also eliminate a nitrogen molecule to give the same vinylsulfene **12** or be directly transformed into the chlorosultine **10**.

Clearly, the thermal decomposition of compound **9** also follows a similar scheme.¹¹

c. Reactions of sulfones involving heterolytic cleavage of the C–S bond

The rearrangement of the four-membered cyclic sulfones **14a,b** on treatment with a base, *tert*-butoxymagnesium bromide, to give the corresponding 3,5-diphenyl-1,2-oxathiolane 2-oxides **15a,b** via an ionic mechanism has been reported.^{12, 13}

Unlike the majority of transformations that result in mixtures of diastereomeric sultines, this reaction is stereospecific with respect to the phenyl substituents and stereoselective with respect to the sulfonyl group oxygen. This is explained^{12, 13} by the unique structure of the reagent, *tert*-butoxymagnesium bromide, which, together with diethyl ether as a solvent, exerts a 'cage' effect around the sulfone. It is assumed that *tert*-butoxymagnesium bromide initially abstracts a proton from the sulfone. The resulting carbanion and *tert*-butyl alcohol appear in close proximity to each other, which permits fast reprotonation of the anion before and after the rearrangement, and hence makes it possible to avoid side reactions. The above scheme reflects the stereochemical features of the reaction. The unusual cleavage of the C–S bond remote from the reaction centre formed initially is explained in terms of molecular orbital theory.

It is also interesting to note that prolonged reaction with sultine **15b**, containing *trans*-oriented phenyl substituents, results in its complete isomerisation to *cis*-3,5-diphenyl-1,2-oxathiolane (2,3-*cis*) 2-oxide **15a**. The latter is probably more thermodynamically stable, since the two bulky phenyl substituents in this compound occupy pseudo-equatorial positions.¹⁴

The synthesis of γ - and δ -sultines by the desulfurisation of the cyclic thiosulfonates **16** and **17** on treatment with tris(diethyl-amino)phosphine has been proposed.¹⁵ According to ³¹P NMR data, the reaction occurs *via* the intermediate phosphonium salt **18**.

The cyclisation of the salt **18** through one of the nucleophilic centres of the sulfinyl group, the O or S atom, accompanied by elimination of the aminophosphine sulfide molecule can give a sultine or a cyclic sulfone, respectively. The determining factor is probably the size of the resulting heterocycle. For example, the reaction with 1,2-dithiolane 1,1-dioxide **16** gives exclusively 1,2-oxathiolane 2-oxide **19**, whereas desulfurisation of 1,2-dithiane 1,1-dioxide **17** gives the sultine **20** and the sulfone **21** in a 9:1 ratio.

Braverman et al.^{2, 3, 16, 17} synthesised unsaturated γ -sultines by cyclisation of the sulfones **22** or sulfinates **23** on treatment with bromine. It is believed that the reaction begins with the electrophilic addition of bromine to the allene moiety with the formation

$R^1 = \text{Me}, \text{CH}_2\text{C}\equiv\text{CH}, \text{C}_6\text{H}_4\text{Me}$

$R^2 = \text{Bu}^t, \text{CMe}_2\text{C}\equiv\text{CH}$

of the bridged bromonium ion **24**. This allows one to explain the retention of chirality at the γ -carbon atom in the optically active sulfones **22** during subsequent nucleophilic attack by the O atom of the sulfonyl group. The subsequent transformation of intermediates **24** into sultines occurs only when the former can eliminate a stable carbocation, such as *tert*-butyl or dimethylpropargyl, and probably proceeds via an S_N1 mechanism. When there is no good leaving group, a proton is eliminated and an acyclic product **25** is formed.

The fragmentation of sulfinates **23**, unlike that of the sulfones **22**, occurs via an S_N2 mechanism in which there is nucleophilic attack by the bromide anion resulting in cyclisation to a sultine with simultaneous elimination of an alkyl bromide molecule.

It is believed that the reactions of a number of sulfones **22**, e.g. with R¹ = Me, cannot occur via the S_N2 mechanism due to steric and electronic effects of the sulfonyl group.^{2, 3, 16, 17}

A six-membered sultine, 3-methylbenzo[*c*][2.1]oxathiine 1-oxide **26**, was obtained along with the usual reaction product, the thiepine **28**, upon isomerisation of benzyl (2-cyclopropylphenyl) sulfone **27** in presence of acid.¹⁸ The formation of sultine **26** is explained by rearrangement of the benzyl α -carbocation formed initially to a β -carbocation followed by its nucleophilic stabilisation by the sulfonyl group and by elimination of the benzyl fragment.

It is to be noted that the ratio of the reaction products strongly depends on the reaction temperature, and at 20 °C one can obtain sultine **26** in up to 84% yield.

2. Cyclisation of bifunctional sulfur-containing compounds

The cyclisation of bifunctional sulfur-containing compounds is the most frequently used method for the synthesis of sultines. This group of reactions is represented by diverse transformations.

a. Oxidation of α,ω -mercaptoalcohols, disulfides and β -thiolactones

A number of syntheses of sultines by the oxidative chlorination of mercaptoalcohols in various systems have been reported. For example, benzo[*c*][1,2]oxathiine 2-oxide **30** can be obtained by treatment of β -(*o*-hydroxyphenyl)ethanethiol **29** with chlorine in glacial acetic acid.¹⁹ The mechanism of this reaction proposed by the authors is presented below.

The same method was used to synthesise 3,5-diphenyl-1,2-oxathiolane 2-oxide **15** from 3-hydroxy-1,3-diphenylpropanethiol¹² and 4-[(benzyloxycarbonyl)amino]-1,2-oxathiolane 2-oxide **31** from hydroxypropyl disulfide **32**.²⁰

However, the yields of the isomeric sultines **15a,b** and **31a,b** did not exceed 40%. It is likely that the C—O bonds in compounds **15** and **31** are weaker than the Ar—O bond in the sultine **30** and undergo extensive nucleophilic cleavage by the chloride anions present in excess. This accounts for their considerably lower yields compared with that of sultine **30**. The yield of sultine **31** could be increased to 86%–90% by maintaining the concentration of the halogen at a sufficiently low level, which is possible when *N*-bromosucinimide (NBS) or *N*-chlorosucinimide (NCS) are used as halogenating agents.

A synthesis of the simplest sultines by the cyclisation of α,ω -mercaptoalcohols on treatment with chlorine in nonpolar solvents followed by hydrolysis (see Table I) has been proposed.²¹ The authors suggest that when 2 equiv. chlorine are used in the reaction, the acyclic chlorosulfonium ion **33** is formed; the latter is transformed into the cyclic ion **34**, which then gives the sultine on treatment with 1 equivalent of water.

It should be noted that when the distance between the reacting centres increases, polymerisation prevails over cyclisation, which decreases the yields of sultines.

A preparative method for synthesising cyclic mixed anhydrides of β -sulfino-carboxylic acids **38**²² is based on oxidative chlorination of substituted β -thiolactones **35** (with chlorine or sulfonyl chloride) in acetic anhydride. It was demonstrated that β -(chlorosulfinyl)alkanoyl chlorides **36** are formed in high yields (75%–80%) for a reagent ratio $\mathbf{35} : \text{Cl}_2 : \text{Ac}_2\text{O} = 1 : 2 : 1$, and that the SOCl group is, most probably, formed due to interaction of a trichlorosulfurane intermediate with acetic anhydride. With excess acetic anhydride ($\mathbf{35} : \text{Cl}_2 : \text{Ac}_2\text{O} = 1 : 2 : 2$), sulfinyl chlorides isomerise to the cyclic sulfuranes **37**, which react with acetic anhydride to give 1,2-oxathiolan-5-one 2-oxides **38**.

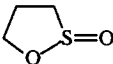

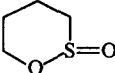

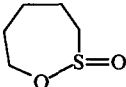

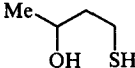

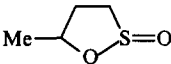

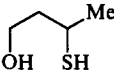

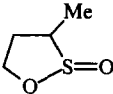

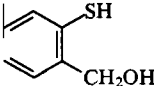

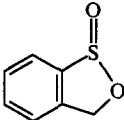

Table 1. Synthesis of the simplest sultines by chlorination of mercaptoalcohols.

Thiol	Sultone	Yield (%)
$\text{HO}(\text{CH}_2)_3\text{SH}$		90
$\text{HO}(\text{CH}_2)_4\text{SH}$		85
$\text{HO}(\text{CH}_2)_5\text{SH}$		10
		70
		70
		80

38	R ¹	R ²	R ³	Yield (%)
a	H	H	H	25–40
b	Me	H	H	73–77
c	H	Me	H	87–97
d	H	Me	Cl	100

The cyclic anhydrides **38** are highly reactive and find use in the synthesis of physiologically active compounds.

The formation of tetraphenylloxathiolanone **39** by the oxidation of the corresponding β -thiolactone **40** with *m*-chloroperbenzoic acid (MCPBA) has been reported.²³ However, the yield of the sultine obtained by this method did not exceed 18%.

The authors²³ consider that compound **39** could be formed either by the oxidation of the initial thietanone **40** to α -oxo-sulfoxide followed by its isomerisation to the sultene **41** and transformation of the latter into the sultine **39** (cf. Ref. 41) or by the oxidation of the initial thiolactone **40** to the thietanone dioxide **42**, which subsequently rearranges into the sultine **39**.

The oxidative cleavage of 3,3'-dithiodipropanol with aqueous KI-I₂ solution followed by cyclisation gave 1,2-oxathiolane 2-oxide **19** in 77% yield.²⁴ A kinetic study²⁴ allowed the following reaction mechanism to be put forward:

The attack of the disulfide-iodine complex **43** formed initially by an iodide anion cleaves the S-S bond in the disulfide. It was shown that hydroxy groups do not exert nucleophilic assistance in the cleavage, and that the cyclisation of sulfenyl iodide as well as the thiolate-iodine complex occurs in the next step. The resulting sultene **44** undergoes subsequent oxidation and hydrolysis to give 1,2-oxathiolane 2-oxide **19** as the final product. It is noteworthy that this reaction is not general. For example, 4,4'-dithiodibutanol is oxidised by an aqueous solution of iodine to give 4-sulfobutanol, possibly because the distance between the reaction centres involved in the cyclisation increases. Under the same conditions, 3,3'-dithiodipropionic acid is transformed into 3-sulfopropionic acid.

b. Cyclisation of α,ω -hydroxysulfoxides

The cyclisation of hydroxyalkyl sulfoxides in the presence of halogenating agents, such as NBS, NCS or SO₂Cl₂, results in the formation of sultines²⁵⁻²⁸ or sulfones,²⁹⁻³⁴ depending on the structure of the starting compound.

In all cases, the existence of a cyclic intermediate of type **45** is assumed,^{33,34} which can be opened at the C-O bond to give sulfones or, when R is a good leaving group, can give the corresponding sultine by cleavage of the R-S bond.

X = Cl, Br; n = 1-4

Durst and co-workers²⁶ used this approach to synthesise sultines containing from five to eight atoms in the heterocycle by reactions of *tert*-butyl ω -hydroxyalkyl sulfoxides with sulfuryl chloride.

n = 1-4

In this case, the *tert*-butyl group serves as a good leaving group. Sultines are formed in high, nearly quantitative yields for n = 1, 2 (see Table 2). When n increases, i.e., the reaction centres become more distant from each other, the probability of the cyclisation and hence the yields of the sultine decrease. The yields of sultines obtained by the cyclisation of *tert*-butyl hydroxyalkyl sulfoxides in the presence of halogenating agents (NBS, NCS, SO₂Cl₂) are given below.

Certain stereochemical features of this reaction are of interest. γ -Sultines with substituents in the ring were isolated as mixtures of diastereomers, whereas the formation of δ -sultines (six-membered heterocycles) occurs stereoselectively and results exclusively, or predominantly, in one isomer having a chair conformation with an axially oriented S=O bond and a substituent in an equatorial position.³⁵ The preference for a conformation with an axially oriented S=O bond for cyclic trimethylene sulfites and their analogues is obviously related to the anomeric effect.^{36,37}

The high selectivity of the transformations in the synthesis of δ -sultines is explained²⁶ by the isomerisation of products under the reaction conditions or during isolation, on the one hand, and by the predominant formation of some of the isomers during the reaction, on the other hand. It cannot be ruled out that this preference manifests itself at the alkoxyoxosulfonium salt formation stage, for which the conformation 46, with both substituents in equatorial positions, is the most favourable.

Attempts to synthesise β -sultines from *tert*-butyl 2-hydroxyalkyl sulfoxides failed due to their instability: at 20 °C, they eliminate sulfur dioxide in several minutes to give unsaturated compounds.^{38,39} This is probably caused by the significant strain in the four-membered ring.

It was only in the case of *tert*-butyl 2-hydroxy-1,1-dimethyl-2,2-diphenylethyl sulfoxide **47** that the corresponding sultine, 3,3-dimethyl-4,4-diphenyl-1,2-oxathietane 2-oxide **48**, which is stable at 20 °C over a period of several days, was isolated and characterised.⁴⁰

However, despite all failures to synthesise β -sultines, the generality of this method leading to heterocycles with 5 to 8 atoms in the ring and the possibility of synthesising various sultines by introducing substituents into the alkyl chain of the initial *tert*-butyl ω -hydroxyalkyl sulfoxide make this reaction a promising preparative method.

The cyclisation of 2-(benzylsulfinyl)isophthalic acid **49** gives the sultenes **50** and **51**. The latter was oxidised with MCPBA to give the corresponding sultine **52**.^{41,42} The reaction mechanism was not discussed in detail; however, it can be assumed that cyclisation of the sulfoxide in an AcOH/Ac₂O mixture probably occurs by an intramolecular Pummerer reaction followed by nucleophilic participation of the neighbouring carboxyl group.

c. Cyclisation of hydroxysulfonates

The sultine ring is also formed through the cyclisation of hydroxysulfonates in acidic media. They can be generated using various methods.

For example, Durst et al.⁴³ suggest that hydroxysulfonates can be obtained by the reduction of 1-hydroxy-1*H*,3*H*-benzo[*c*]-thiophene 2,2-dioxides **53** with sodium tetrahydroborate. Subsequent cyclisation of hydroxysulfonates gave 1*H*,4*H*-benzo-*[d]*[2,3]oxathiane 3-oxides **54**.

It is believed⁴³ that hydroxysulfinate cyclisation in acidic media involves the participation of the protonated form of sulfonic acid. The possibility of this transformation was shown for the acid hydrolysis of methyl toluene-*p*-sulfinate in H₂¹⁸O.⁴⁴

R¹ = R² = H (70%); R¹ = Me, R² = H (55%); R¹ = H, R² = Ph (79%)

The generation of a hydroxysulfinate followed by cyclisation also occurs during the metallation of the cyclic sulfone **53** with organolithium reagents. It was proposed to synthesise various sultines using functionalised lithium derivatives.^{43,45}

Messinger^{46,47} obtained hydroxysulfonates by the cleavage of γ,γ' -dioxosulfones with the cyanide anion followed by their reduction with sodium tetrahydroborate.

55a: R = *p*-ClC₆H₄ (65%), *p*-MeC₆H₄ (60%), *p*-MeOC₆H₄ (63%);

55a + **55b**: R = Ph₂CH (72%), C₁₀H₇ (42%)

It is interesting to note that upon subsequent acidification of phenyl-substituted hydroxysulfonates (R = *p*-ClC₆H₄, *p*-MeC₆H₄, or *p*-MeOC₆H₄) their cyclisation to sultines occurs stereospecifically and gives exclusively *cis*-diastereomers **55a**. It is likely that this feature of the reaction is due to steric effects of the substituents, since 5-(β -naphthyl)- and 5-(diphenylmethyl)-sultines, obtained under the same conditions, consist of a mixture of isomers **55a** + **55b**.

The alkaline cleavage of dibenzothiophene dioxide **56** in the presence of 18-crown-6 gave potassium biphenyl-2-sulfonate **57** and dipotassium 2'-hydroxybiphenyl-2-sulfinate **58**. Acidification of the mixture gave mainly biphenyl-2-sulfonic acid and the sultine **59**.⁴⁸

It is remarkable that in the absence of a crown ether, potassium biphenyl-2-sulfonate **57** is formed exclusively, i.e. only the S atom is attacked by the hydroxide ion (pathway *a*). It is assumed that the loss of reaction selectivity in the presence of the crown ether is due to the appearance of free hydroxide ions, which are more reactive than the solvated ions. This allows the hydroxide ions to attack the aromatic ring (pathway *b*) to give the dipotassium salt **58**.

The synthesis of the sultine **60** by the cyclisation of the corresponding hydroxysulfonic acid **61** on treatment with thionyl chloride or acetyl chloride has been reported.⁴⁹ The hydroxysulfonic acid **61** was obtained from benzothienobenzo-thiophenedi-sulfone **62** by nucleophilic cleavage of the C—S bond by the amine and subsequent hydrolysis.

A general method for the synthesis of 1,2-oxathiolane-5-one 2-oxides **63a-c** and 2,1-benzoxathiol-3-one 1-oxide **63d** by treatment of bis-sodium β -(hydroxysulfinyl)carboxylates **64** with oxalyl chloride according to the following scheme has been proposed:⁵⁰

Mixed anhydrides of β -sulfinocarboxylic acids **63** are unstable and can be isolated only if moisture is completely absent.

d. Cyclisation of bifunctional compounds with simultaneous introduction of a sulfur-containing group

Let us consider several examples demonstrating the syntheses of sultines by the cyclisation of bifunctional compounds involving the introduction of a sulfur-containing group.

In their study of new sulfur transfer reagents, Harpp and coworkers⁵¹ proposed the synthesis of sultines by the reactions of *N,N'*-thiobisimidazole **65a** and *N,N'*-thiobisbenzimidazole **65b** with certain diols.

Compounds of type **65a,b** are reactive toward nucleophiles containing an active hydrogen atom (OH, SH, NHR). This is explained by the protonation of the leaving group of the reagent in the first reaction step followed by its nucleophilic substitution (when it is eliminated as a neutral molecule).

The mechanism of the transformation of the diols **66** and **67** into the corresponding sultines has not been discussed;⁵¹ however, one can assume that formation of the cyclic sulfoxylate **68** occurs initially, and the latter then rearranges to the sultine **69**. Similar rearrangements are known for acyclic allyl and benzyl sulfoxylates.⁵²

The synthesis of 3-phenyl-1,2-oxathiolane 2-oxide **70** by treatment of 1,3-dibromo-1-phenylpropane with sodium 1-benzyl-1,4-dihydronicotinamide-4-sulfonate **71** has been reported.⁵³ The initial step obviously involves the formation of the sulfinic ester **72** with elimination of a bromide anion, the cyclisation of this ester then occurs by nucleophilic attack by the S atom at the C atom of the benzyl fragment. Subsequent elimination of 1-benzyl-1,4-dihydronicotinamide (BNA) yields sultine **70**.

The synthesis of γ -sultines by treatment of γ,δ -unsaturated alcohols with thionyl chloride in the presence of pyridine has been suggested.⁵⁴ In this reaction, the intermediate **73** undergoes cyclisation involving the double bond, which in this case acts as a second functional group.

It should be noted that 4-chloro-4-methyl-1,2-oxathiane 2-oxide **74** was isolated as one diastereomer with *cis*-axial orientation of the S=O group and the Cl atom.

An analogous combination of a double bond and a hydroxyl group is also present in the tricyclic alcohol **75**, which gives the sultine **76** on treatment with thionyl chloride.⁵⁵

It was shown that the result of the reaction in the rigid structure **75** is largely determined by the mutual orientation of the reaction centres — the hydroxyl group and the double bond — in the molecule and by the distance between them. Another interesting feature of the reaction should be noted: this is an unusual example of an electrophilic *exo-cis*-addition to a double bond. This conclusion was based on the spectral characteristics of the reaction product, the sultine **76**.

The reactions of unsaturated alcohols with *N*-sulfinyltoluene-*p*-sulfonamide in the presence of $\text{BF}_3 \cdot \text{OEt}_2$ gave diverse chiral six- and seven-membered mono- and bi-cyclic sultines (see Table 2).⁵⁶ The high stereoselectivity of the reaction was noted: the stereochemistry of ring annelation is determined by the configuration of the starting alcohol; in each case, the molecules of the resulting sultines contained an axially oriented $\text{S}=\text{O}$ bond and an exocyclic methylene fragment.

Alcohols **A** and **F** (see Table 2) gave the sultine **77** and the product **78**, which retained the amine residue; this did not allow

the authors⁵⁶ to make an unambiguous conclusion about the reaction mechanism.

The synthesis of dibenzoxathiine oxide **59** from *o*-hydroxybiphenyl and thionyl chloride in the presence of Lewis acids⁵⁷ can be formally assigned to the above type of reactions for the aromatic series. In this case, the second reaction step involves typical electrophilic substitution in the aromatic ring.

Table 2. Syntheses of sultines by the reaction of unsaturated alcohols with *N*-sulfinyltoluene-*p*-sulfonamide in the presence of $\text{BF}_3 \cdot \text{OEt}_2$.

Alcohol	Formula	Product	Yield (%)
A			32
B			64
C			69
D			55
E			75
F			17
G			46
H			47

3. Syntheses of sultines with participation of sulfur dioxide

We assigned reactions involving sulfur dioxide as one of the reagents to the third group of transformations resulting in the formation of the sultine ring. When considering these reactions, attention should be paid to particular features of the structure of sulfur dioxide, in the molecule of which the S atom has simultaneously a nonbonding electron pair and vacant *d*-orbitals. It is by virtue of the latter that sulfur dioxide forms charge-transfer complexes with various Lewis bases, namely, amines,⁵⁸ aromatic compounds,^{59–61} ethers, alcohols⁶² and alkenes.⁶³ Sometimes, as in the case of trimethylamine, these complexes are so stable that they can be isolated in the crystalline state.^{64,65}

a. Reactions of sulfur dioxide with 1,3-dienes

The well-known cheletropic addition of sulfur dioxide to conjugated polyenes in the presence of inhibitors of radical processes involves both the vacant *d*-orbitals and the lone electron pair of the S atom. This transformation occurs as the $[2+4][n+\pi\pi]$ cycloaddition to give five-membered cyclic sulfones, i.e. sulfonenes.⁶⁶ However, it was noted that, in some cases, an atypical mode of addition of sulfur dioxide to dienes involving the $\text{S}=\text{O}$ bond gives unstable unsaturated six-membered sultines, which undergo retrocycloaddition and rapidly decompose into the starting compounds.²⁶

For example, the formation of a kinetically controlled reaction product, the sultine **79**, in the course of $[2+4][\pi+\pi\pi]$ cycloaddition of sulfur dioxide to substituted dimethylene-tricyclohexane **80**, a reactive diene in the Diels–Alder reaction, has been reported.⁶⁷

The sultine **79**, which is unstable at room temperature, is transformed into the sultine **81** (up to 90%) by isomerisation of the tricyclic fragment into a benzene ring (pathway *a*), or into the sulfone **82** by retroaddition (pathway *b*). Heating of the sultine **81** in *o*-dichlorobenzene at 80–100 °C results in its dissociation into sulfur dioxide and *o*-quinodimethane **83** with subsequent recombination into the thermodynamically controlled product sulfone **84**, a product of [2 + 4][$n + \pi\pi$] cycloaddition. The same sulfone was obtained by isomerisation of the tricyclic fragment in compound **82**. It was also noted that the addition of diene **80** to liquid sulfur dioxide at -50 °C gave only the aromatic sultine **81**, which is probably due to the isomerisation of the sultine **79** to **81** catalysed by liquid sulfur dioxide.

The preferential formation of the sultine **69**, the product of the [2 + 4][$\pi + \pi\pi$] cycloaddition of sulfur dioxide to *o*-quinodimethane under kinetic control, together with a sulfone (in a 9 : 1 ratio) was noted.⁶⁸

In some cases, the addition of sulfur dioxide to conjugated polyenes is catalysed by Lewis acids.^{69–72} The latter form complexes with sulfur dioxide,⁷³ which then behaves with enhanced electrophilicity. The reactions occur stepwise with intermediate formation of carbocations.

For example, the reaction of cyclohexadiene with the SO₂·SbF₅ complex⁷⁴ gives the bicyclic sultine **85**. The authors⁷⁴ assume that the formation of **85** occurs through a 1,2-hydride shift in the allylic intermediate **86**.

It is interesting that the reaction with 1,3-cyclohexadiene occurs stereospecifically and gives the isomer **85** as the only product; its structure was confirmed by X-ray diffraction analysis. On the other hand, reactions of sulfur dioxide with cyclohepta- or cycloocta-1,3-dienes give complex mixtures of addition products.

b. Reactions of sulfur dioxide with cyclopropanes

The formation of the cyclic sulfinate **87** by the addition of sulfur dioxide to cyclopropyl chloride in the presence of SbF₅ was observed by Olah and co-workers⁷⁵ when attempting to obtain dicyclopropylhalogenonium ions from cyclopropyl halides. The mechanism of this transformation has not been discussed; however, it can be assumed that the first step of the reaction involves electrophilic attack on the cyclopropane ring by the SO₂·SbF₅ complex with the cleavage of the C(1)–C(2) bond to form the carbocation **88**. Subsequent intramolecular cyclisation involving an O atom of sulfur dioxide gives the sultine **89**, which eliminates an HCl molecule to give the cyclic sulfinate **87**.

Several papers^{76–81} have described the addition of sulfur dioxide to arylcyclopropanes in the presence of trifluoroacetic acid. The reaction occurs regioselectively and results exclusively in 5-aryl-1,2-oxathiolane 2-oxides **90** in good yields (Table 3).

Table 3. Synthesis of sultines by the addition of sulfur dioxide to arylcyclopropanes in the presence of trifluoroacetic acid.⁸¹

^a The diastereomers A–D are shown in Scheme 1. ^b In this case 10% of a structural isomer — 4-methyl-5-phenyl-1,2-oxathiolane 2-oxide was isolated.

A study of this reaction with a series of arylcyclopropanes substituted in the trimethylene and benzene rings indicated that it is an electrophilic reaction.

The resulting γ -sultines are mixtures of diastereomers (the addition was stereospecific only in the case of 1,1,2-triphenylcyclopropane).

It was suggested that the reaction proceeds through a step involving formation of an open carbocation according to Scheme 1.^{76–81} This is consistent with the steric requirements of the reaction products obtained. The preferential formation of isomer A in the case of *trans*-diarylcyclopropanes is explained by its thermodynamic stability arising from the fact that the bulky phenyl substituents in the latter, which are in a *cis*-position to each other, occupy the most favourable pseudo-equatorial positions in the molecule.¹⁴

The above reaction is a convenient method for obtaining 5-aryl-1,2-oxathiolane 2-oxides, which can be used as synthons in organic syntheses for the bifunctionalisation of hydrocarbons.

The photochemical addition of sulfur dioxide to certain arylcyclopropanes to give 5-aryl-1,2-oxathiolane 2-oxides **90** has also been reported.⁸² In this case, cyclopropanes containing electron-withdrawing groups in the aromatic ring were found to be reactive. *p*-Nitrophenylcyclopropane gives the sultine **90** and the cyclic sulfone **91**; the latter becomes the only reaction product in the case of the *o*-nitro isomer. It is noteworthy that, of the systems studied,⁸² a number of cyclopropanes (phenylcyclopropane, *p*-biphenylcyclopropane, 1-methyl-2-phenylcyclopropane, *p*-halophenylcyclopropanes, cyanocyclopropane, acetylcyclopropane and cyclopropanecarboxylic acid) did not undergo photochemical addition of sulfur dioxide.

R = CN, NO₂, Ac

R = *o*-, *p*-NO₂

The addition of sulfur dioxide to substituted benzvalenes to give mixtures of isomeric sultines and sulfones has been

reported.^{83,84} In the case of benzobenzvalene **92**, the sultine **93** is the main reaction product (the product ratio **93**:**94** = 3:1).

The addition of sulfur dioxide to the cyclopropyl- F_p complex **95** [where $\text{F}_p = (\eta^5\text{-C}_5\text{H}_5)\text{Fe}(\text{CO})_2$] has been reported.⁸⁵ Sulfur dioxide is usually inserted into the C–M bond of such compounds, but the reaction involving complex **95** follows a non-standard pathway with opening of the trimethylene ring and formation of the carbocation **96**, which is then transformed into the sultine **97**.

However, the reaction of the norcaradiene- F_p complex with sulfur dioxide results exclusively in the sulfone **98**. It is assumed that the reaction goes through the intermediate ion **99** having a *trans*-configuration, which makes cyclisation impossible.

c. Reactions of sulfur dioxide with organometallic compounds

Quite unexpectedly, the sultines **100** were found to be formed in reactions between sulfur dioxide and 2-alkynyl derivatives of transition metals **101**.⁸⁶ The initial electrophilic attack is at the C≡C triple bond. The scheme presented below is supported by the fact that the reaction between sulfur dioxide and the $\text{Ph}_3\text{SnCH}_2\text{C}\equiv\text{CH}$ complex gives the stable sulfinate $\text{Ph}_3\text{Sn}[\text{O}-\text{S}(\text{O})\text{CH}=\text{C}=\text{CH}_2]$, the structure of which is similar to that of intermediate **102**.

M	R	M	R
$\eta^5\text{-C}_5\text{H}_5\text{Fe}(\text{CO})_2$	Me	$\text{Mn}(\text{CO})_5$	Me
$\eta^5\text{-C}_5\text{H}_5\text{Fe}(\text{CO})_2$	Ph	$\eta^5\text{-C}_5\text{H}_5\text{Mo}(\text{CO})_3$	H
$\text{Mn}(\text{CO})_5$	H	$\eta^5\text{-C}_5\text{H}_5\text{Mo}(\text{CO})_3$	Me

Conversely, the reaction between sulfur dioxide and Grignard reagents or organolithium compounds occurs in the typical way, sulfur dioxide being inserted into the C–M bond. For example, the α,β -unsaturated γ -sultines **103** were synthesised⁸⁷ by the addition of sulfur dioxide to the Grignard reagents **104** obtained from propargyl alcohols. The hydroxysulfinate formed initially

undergoes cyclisation to the sultine **103** upon subsequent hydrolysis (see Section II.2.c).

R ¹	R ²	Yield (%)
H	Et	30
H	Ph	60
H	$\text{CH}_2\text{CH}=\text{CH}_2$	32
Ph	Et	40
Ph	Ph	24

A sultine with $\text{R}^2 = \text{H}$ was isolated in a low yield when the organoaluminium compound **105** containing a vinylic fragment was used instead of the Grignard reagent.

Durst et al.⁴³ proposed that hydroxysulfonates be obtained by adding sulfur dioxide to the previously formed dianion **106**. This approach was used to synthesise benzoxathiine oxides **107** and benzoxathiol oxides **108**.

$\text{R}^1 = \text{R}^2 = \text{H}$ (50%–70%); $\text{R}^1 = \text{R}^2 = \text{Me}$ (38%)

$\text{R}^1 = \text{R}^2 = \text{H}$; $\text{R}^1 = \text{H}, \text{R}^2 = \text{Me}$; $\text{R}^1 = \text{R}^2 = \text{Me}$

d. Electrochemical synthesis of sultines involving sulfur dioxide

In several papers on the cathodic reduction of sulfur dioxide in aprotic solvents (DMF, acetonitrile),⁸⁸⁻⁹⁰ a synthesis of five- and six-membered sultines by treatment of alkylene dihalides with the SO_2^- anion radical was proposed. The following mechanism of reaction of the latter in the presence of alkylene dihalides was assumed:

The yields of sultines or cyclic sulfones depend on the distance between the reaction centres in the alkylene dihalide. This can be demonstrated by the scheme below.

X = Cl, Br, OTs

III. Properties of sultines

The limited number of convenient methods for the synthesis of sultines has meant that their chemistry has been studied inadequately, and data on their reactions are rather fragmentary. The thermal and photochemical decomposition of sultines as well as the oxidation, reduction, and cleavage of the sultine ring by nucleophiles have been studied in more detail.

1. Thermolysis and photolysis of sultines

The thermal stability of sultines is primarily determined by the size of the heterocyclic ring, the nature and position of substituents in the ring, and to a lesser extent by other features of their structure.

For example, with rare exceptions, β -sultines are very unstable and decompose even at room temperature in several minutes with the evolution of sulfur dioxide and formation of unsaturated compounds³⁸⁻⁴⁰ (see Section II.2). This is probably a consequence of the considerable strain in the four-membered

heterocycle. The loss of sulfur dioxide occurs stereospecifically by *cis*-elimination, which was demonstrated in the formation of *cis*-stilbene **109** (> 99%).

β , γ -Unsaturated six-membered sultines — 3,6-dihydro-1,2-oxathiine 2-oxides — are unstable at temperatures above 0 °C and decompose into 1,3-dienes and sulfur dioxide.^{25, 67} The stereospecific nature of this reaction was shown for the *cis*-hydroxy-sulfoxide **110**, which gave exclusively *trans*-1-phenylbuta-1,3-diene **112** (> 99.5%) by fragmentation of the intermediate sultine **111**.

This process is characterised by extremely easy sulfur dioxide elimination: the decomposition of 3,6-dihydro-1,2-oxathiine 2-oxide into the corresponding 1,3-diene and sulfur dioxide occurs at a temperature lower by 125 °C than that required for the similar decomposition of 2,5-dihydrothiophene 1,1-dioxide.

Unlike the 3,6-dihydro-1,2-oxathiine 2-oxides already considered, benzoxathiine oxides **113** are more stable and decompose into the corresponding *o*-quinodimethanes and sulfur dioxide only at 80 °C, whereas the elimination of sulfur dioxide from the corresponding sulfones occurs only at 300 °C.^{25, 45, 67} In the absence of other dienophiles, the resulting diene once again traps the sulfur dioxide molecule to give a cyclic sulfone isomeric with the original sultine **113**.

$\text{R}^1 = \text{H}; \text{R}^2 = \text{H, Ph, Me}; \text{R}^1 = \text{R}^2 = \text{Me}.$

The ease of sulfur dioxide elimination allows one to use this reaction for generating such reactive dienes as *o*-quinodimethanes by cycloaddition in situ under mild conditions.

The fragmentation of 3,4-oxathiabicyclo[4.1.0]heptane 4-oxides **114** in boiling chloroform into a 1,4-diene and sulfur dioxide occurs stereospecifically.⁹¹ This reaction produces *cis*- and *trans*-4-phenylhexa-1,4-dienes **115a** and **115b** from sultines **114a** and **114b** with > 99.5% isomeric purity.

a: $\text{R}^1 = \text{Ph}, \text{R}^2 = \text{H}, \text{R}^3 = \text{Me};$
 b: $\text{R}^1 = \text{Ph}, \text{R}^2 = \text{Me}, \text{R}^3 = \text{H};$
 c: $\text{R}^1 = \text{R}^2 = \text{R}^3 = \text{H}$

The stereochemistry of the sulfinyl group and the mutual arrangement of substituents considerably affect the decomposition rate. It should be noted that the decomposition of sultines again occurs at a temperature 100 °C lower than that required for the decomposition of the isomeric sulfone, 3-thia-bicyclo[3.1.0]-hexane 3,3-dioxide.

All the above examples of the thermal decomposition of sultines occur apparently as concerted processes, which is suggested by the stereospecificity of the transformations and the ease (low temperatures) of sulfur dioxide elimination.

The examples of the thermal and photochemical degradation of six- and five-membered sultines described below are likely to be radical processes. The reactions occur at very high temperatures (400–900 °C), and their course significantly depends on the structure of the initial sultine and on the nature of the substituents.

For example, the thermolysis of dibenzoxathiine oxide **59** yields a mixture of dibenzofuran and dibenzothiophene in a 6 : 1 ratio.⁴⁸ The pyrolysis of dibenzothiophene 1,1-dioxide **56** gives the same products and in the same ratio, which makes it possible to assume the intermediate formation of the sultine **59**.⁹²

The thermolysis of diphenylnaphthoxathiole oxide **4** results in two cyclisation products, compounds **5** and **6**, which are formed by the interaction of radical centres with the neighbouring phenyl groups.⁷

In general, the presence of stabilising phenyl groups adjacent to the reaction centres in the molecule has a decisive effect on the thermal and photolytic transformations of sultines.

For example, the thermal decomposition of phenyl-benzoxathiol oxide **116** at 750 °C occurs by the elimination of a sulfur dioxide molecule to give a 1,3-biradical, which then rearranges to fluorene. However, the thermolysis of the unsubstituted analogue under the same conditions results in an uncharacterised mixture of degradation products.⁹³

A complete analogy between the reactions was also observed in the photolytic decomposition of the sultines **116** and **117**.⁹⁴ It was shown that the resulting 1,3-biradical **118** can also rearrange to the carbene **119**, which was identified by its reaction with methanol.

The photolysis of six-membered (**69**) and eight-membered (**120**) sultines in methanol gave a sulfone and 9,10-dihydrophe-nanthrene, respectively.

The thermolysis and photolysis of 5-phenyl-1,2-oxathiolane 2-oxides **121** are accompanied by the formation of a 1,3-biradical, in which one centre is located on the C atom of the benzyl group. This radical then recombines to give the corresponding cyclopropane. If other substituents are attached at the C(5) atom, stabilisation of the 1,3-biradical leads predominantly to isomeric alkenes.^{93, 94}

R = H (95%), Me (98%)

				Product yield (%)	
				A	B
R ¹	R ²	R ³	R ⁴		
Ph	H	H	H	100	—
Ph	Me	H	H	100	—
H	H	Me	H	37	62
H	H	Ph	H	—	†
Me	H	H	H	45	35

The addition of sulfur dioxide to benzobenzvalene, like the addition to arylcyclopropanes (see Section II.3.b), was found to be photochemically reversible. When the sultine **93** was irradiated with UV light, it evolved sulfur dioxide with the regeneration of the original benzobenzvalene **92** and formation of naphthalene in a 1 : 3 ratio.⁸⁴

This reaction is believed⁸⁴ to occur by reversible homolytic cleavage of the sultine to give the biradicals **122** and **123**. The latter, which is in a singlet state, gives benzobenzvalene **92**; alternatively, naphthalene **124** is formed by bond cleavage in the cyclopropane fragment.

The pyrolysis of the sultine **93** gives a complex mixture of products; 1*H*-indene-1-carboxaldehyde **125** and 1*H*-indene-3-carboxaldehyde **126** together with naphthalene were isolated from it in the proportion **124** : **125** : **126** : **92** = 52 : 22 : 16 : 9.5.⁹⁵ It is assumed that naphthalene is also formed due to the cleavage of the C—C bond in the intermediate biradical **123**. The formation of aldehydes in the reaction mixture was explained⁹⁵ by the generation of sulfene **127** and its subsequent cyclisation to the oxathiirane *S*-oxide **128**. In the final step, the oxathiirane *S*-oxide **128** loses a sulfur monoxide molecule to give the aldehyde **125**.

The presence of the sulfene **127** in the reaction mixture was proved by performing the pyrolysis with a tenfold excess of methyl methacrylate. This gave naphthalene (22%) and the sultine **129** (58%), the product of the 1,3-dipolar cycloaddition of the sulfene. The formation of aldehydes was not observed in this case.

The thermolysis and photolysis of the γ -sultine **39** give different products.²³ In the former case, the elimination of sulfur dioxide and carbon monoxide molecules gives tetraphenylethene, while in the latter, the intermediate is stabilised by participation of the neighbouring phenyl groups to give 9,10-diphenylphenanthrene.

† Compound **B** is the only product; yield is not reported.⁹³

The thermal transformation of the functionally-substituted γ -sultine 130 considered below leads to a mixture of *N*-allylamide and enamides owing to heterolytic bond cleavage with participation of neighbouring functional groups.⁹⁶ This decomposition is considered to involve most probably the formation of oxazolinium species 131 due to intramolecular nucleophilic attack by the amide oxygen atom at the C–O bond in the sultine ring.⁹⁶

The thermal and photolytic decomposition of six-membered saturated sultines has scarcely been studied. Only the photolysis of 6-phenyl-1,2-oxathiane 2-oxide to give the unsaturated sulfinic acid 132 has been reported.⁹⁴

2. Redox reactions of sultines

One of the most typical reactions, which is often used to prove the presence of a sulfinyl group in the compound under investigation, is the oxidation of sultines. The reaction gives sultones, cyclic esters of sulfonic acid, with characteristic frequencies at 1300–1360 cm^{-1} in their IR spectra. This distinguishes them from sultines, which unlike sultones, do not have this characteristic band in their IR spectra, and absorption is observed only at 1100–1150 cm^{-1} . (For the methods of preparation and reactions of sultones, see Ref. 97). As a rule, a 30% solution of hydrogen peroxide in glacial acetic acid^{9, 19, 48, 55, 57, 82} or MCPBA^{12, 17, 24, 26} are used as oxidants; the latter permits oxidation under mild conditions. In addition, potassium permanganate,³⁶ chromic acid⁹⁸ and potassium hydropersulfate⁸⁷ are also used for the oxidation of sultines. A few typical reactions are given below:

Unlike the oxidation of heterocycles containing an SO fragment in the ring, which can be carried out in stages, passing from sulfinyl to sulfinyl group⁴¹ and then to the sulfonyl group, the known sultine reduction reactions proceed exhaustively omitting the sultene formation stage. In this case, cleavage of the sultine ring at the S–O bond occurs leading, as a rule, to mercaptoalcohols.

The latter reaction is of interest because this is a convenient method for the bifunctionalisation of biphenyl.⁵⁷

The reduction of sultines in the presence of Raney nickel or with a great excess of lithium tetrahydroaluminate results in the total desulfurization of the compound to give the corresponding alcohol.⁵⁵

The reduction of γ - and δ -sultines with trichlorosilane in the presence of tri(*n*-propyl)amine affords symmetrical dihydroxydisulfides in high yields.⁹⁹ The reduction mechanism is unclear;

In the case of the alcoholysis of a four-membered sultone, 4-phenyl-1,2-oxathietane 2-oxide, nucleophilic attack is directed at the S atom giving hydroxysulfonate esters.³⁸

Thus, nucleophilic attack can be directed to both the C and S atoms, probably depending on the structure of the starting compounds. These data are consistent with the results obtained for sultones: the decomposition of sultones with fused aromatic rings occurs both through the cleavage of the C—O bond^{104, 105} and the S—O bond,^{106, 107} depending on their structure and reaction conditions, but, as a rule, β -sultones react with nucleophiles through the sulfur atom, while the reactions of larger-ring sultones involve the carbon atom.

The cleavage of sulfonate esters with organomagnesium compounds to give sulfoxides is well known. In the case of the cyclic esters, i.e. sultines, this cleavage results in the corresponding hydroxysulfoxides.^{48, 108}

The reactions of sultines with alkyllithium compounds proceeds in a similar way; hydroxyalkyl sulfoxides are also formed as a result of nucleophilic attack at the S atom.²⁰

R = Bu⁺CONH

Interesting data on the ability of sultines to form crystalline molecular complexes with organotin compounds (of the composition $\text{RSnCl}_3 \cdot \text{L} = 1:2$ where L is 3,5-diaryl-1,2-oxathiolane 2-oxide), which may possess biological activity, have been published.¹⁰⁹

As already mentioned, the chemistry of the sultines has not yet been adequately studied, although their presently known reactions make them rather promising reagents for use in organic synthesis. This inadequacy is partly related to the lack of convenient methods for the synthesis of sultines. Therefore, the development of new methods of synthesis of sultines and the study of their properties remain of great current interest.

Contents

I. Introduction	167
II. Synthesis of polymeric suspensions with functional groups on the particle surface	168
III. Activation of functional groups on the surface of particles of a polymeric suspension	172

Abstract. Methods for the synthesis of functional polymeric suspensions with narrow particle size distribution are analysed. Attention is concentrated on the conditions of the preparation of polymeric microspheres with aldehyde, carboxyl, epoxy, or amino groups on the surface, which possess a set of properties enabling their use for biochemical studies. Methods of modification of functional groups of the polymeric suspensions that make it possible to accomplish covalent binding of the surface groups to bioligands are considered. The bibliography includes 218 references.

I. Introduction

Aqueous suspensions containing strictly spherical polymer particles of identical diameters are usually referred to as polymeric suspensions with narrow particle size distribution (PSD).¹ Typical magnitudes of the variation coefficient (a measure of the deviation of the particle diameters from the mean value) are 1%–3% (for particles 0.1–10 μm in diameter)^{2–4} or 10%–30% (for particles with diameters smaller than 0.06 or greater than 10 μm).^{2,5}

Polymeric microspheres with a narrow PSD are used in various fields of science and engineering, for example, as calibration standards in the electron and optical microscopy and light-scattering, for counting aerosol particles, in small-angle X-ray diffraction, for counting viral particles, for determining pore sizes in filters or biological membranes, for stimulating cellular production of antibodies and their purification,^{6–9} as model colloid systems for studying their rheology,^{10,11} stability, or sedimentation¹¹ etc. In recent years, monodisperse functional suspension particles have found wide application as protein carriers in development of immunodiagnostic assays.²

The function of these assays is based on the immunochemical reaction between an antigen (a substance carrying signs of genetic information alien for a particular type of organism) and antibodies (proteins belonging to the class of immunoglobulins and produced by the cells of the organism's immune system as a

response to the appearance of the antigen) yielding an 'antigen–antibody' complex.¹² The reaction in which this complex is formed is highly immunospecific, i.e. in response to the appearance of a particular antigen, the immune system generates antibodies of a strictly specified structure capable of interacting only with this antigen. Since both an antigen and an antibody can react simultaneously with several molecules, spatial networks are produced with the antigen molecules as nodes.

The formation of network agglomerates and, therefore, the appearance of one or another type of antigens can be detected by various methods, for example, by spectrophotometry, turbidimetry, nephelometry, laser self-correlation spectroscopy, etc. The need to use special expensive equipment for the detection of 'antigen–antibody' complexes hampers wide employment of the above methods in the diagnosis of diseases. However, when antigens (or antibodies) are bound to a polymeric carrier serving only as an indicator, the complexes can be detected even by the naked eye as crowding of agglomerates of the carrier particles.

The first communication on successful use of polyvinyltoluene and polystyrene microspheres with a narrow PSD in the diagnosis of rheumatoid arthritis was published in 1956.¹³ It was reported that the interaction of antigens present in the blood serum of a patient with gamma-globulin adsorbed on the microsphere surface of a suspension resulted in the agglutination of the polymeric particles affording large agglomerates, easily discernible by the naked eye. Later, publications appeared^{14–24} dealing with the use of polystyrene and poly(methyl methacrylate) suspension particles as protein carriers for preparing diagnostic test-systems for other types of diseases.

However, the use of particles of polymeric suspensions in the development of immunodiagnostic tests has been limited by irreproducibility of the results of analysis, which is caused, as has been suggested by Yen et al.,²⁴ by the fact that on slight variations of the conditions (pH, ionic strength of the medium, temperature, etc.), the protein adsorbed on the surface of particles is desorbed to the aqueous phase; and this lowers the sensitivity of the tests and leads to nonspecific reactions with other biological objects.

Polymeric suspensions containing hydrophilic particles with surface functional groups capable of forming covalent bonds with bioligands have proved to be free of these drawbacks. Polymeric suspensions based on copolymers of methyl methacrylate (MMA), 2-hydroxyethyl methacrylate, acrylic and methacrylic (MAA) acids, acrylamide, vinylpyridine, etc. have been synthesised and used successfully for developing immuno-diagnostic tests.^{24–29}

The advantages of these suspensions over hydrophobic ones are the following:

- the absence of nonspecific adsorption of bioligands due to the high hydrophilicity of the surface of particles;
- the absence of desorption of protein molecules from the surface of microsphere due to the covalent bonding between a bioligand and functional groups of a polymeric particle;
- the possibility of covalent bonding of antigens and antibodies that are poorly sorbed on hydrophobic suspension surfaces;
- the possibility of the appearance of conditions ensuring the optimal orientation of biomolecules on microsphere surfaces, which would provide the maximum sensitivity and high specificity of the diagnostica synthesised.

The polymeric suspensions used in immunodiagnostics are classified in terms of the type of functional groups present on the surface. According to this criterion, they can be divided into two types. Suspensions, whose particles contain surface groups capable of direct interaction with amino, carboxyl, or mercapto groups of biomolecules, belong to the first type. These are, for example, chloromethyl,^{30–34} chlorosulfonyl,³¹ aldehyde,^{35–38} epoxy,³⁹ and mercapto^{40,41} groups, which react with biomolecules in an aqueous medium at moderate temperatures.

$\textcircled{\text{L}}$ — polymeric particle; P — protein

Suspensions with functional groups, which are not able to interact directly with proteins, but can form chemical bonds with them after a fairly simple activation reaction, belong to the second group. These are, for example, polymeric suspensions with carboxyl,^{2, 26, 27, 42–45} hydroxyl,^{24, 46} amino,^{24, 27} amide,^{27, 47–50} glycol,^{51, 52} and other groups. Methods of activation of these groups are considered below.

At present, numerous methods of preparation of polymeric microspheres with various functional groups on the surface have been reported (these are emulsion, suspension, dispersion, precipitation, emulsifier-free, seed, and other types of polymerisations). The choice of the method of synthesis is determined by the necessity of obtaining suspensions with a specified set of properties: particle diameter and structure, narrow size distribution, stability in physiological solutions and during storage, the presence of functional groups of a particular nature at a specified concentration on the surface of the particles. Below we survey the methods of the synthesis of functional polymeric suspensions with definite functional groups on the particle surface.

II. Synthesis of polymeric suspensions with functional groups on the particle surface

1. Synthesis of polymeric suspensions with aldehyde groups on the particle surface

Polymeric suspensions with aldehyde groups on the particle surface are obtained by homopolymerisation of unsaturated aldehydes (acrolein, formylstyrene) or by their copolymerisation with monomers of various natures.

Polymerisation of acrolein has been studied most comprehensively. Two routes of preparing polyacrolein microspheres with narrow PSD's have been reported, namely, the anionic precipitation polymerisation in an alkaline medium³⁹ and the radical emulsion polymerisation induced by γ -radiation or a redox system.⁵³

The radical emulsion polymerisation of acrolein has been carried out in an aqueous solution at a monomer concentration of 10 vol.% in the presence of poly(ethylene oxide) as an emulsifier. The process was initiated by the potassium persulfate–silver nitrate redox system and conducted in the dark at room temperature and varying acrolein concentrations. Polyacrolein microspheres 0.01–0.2 μm in diameter (depending on the acrolein concentration in the system) with a variation coefficient of less than 10% were obtained in this way. It was noted that kinetic features of the acrolein polymerisation differ substantially from those observed for hydrophobic monomers, which was accounted for⁵³ both by the high solubility of the monomer in water ($\sim 20\%$) and by intermolecular cross-linking processes occurring in polymer-monomeric particles (PMP).

The γ -radiation induced radical polymerisation was carried out in an aqueous solution containing a mixture of ionogenic (sodium dodecyl sulfate) and nonionic [poly(ethylene oxide) with a molecular weight of 100,000] surfactants at concentrations of 0%–20% and 0%–15% relative to the monomer concentration, respectively and a radiation dose of 0.4 Mrad at room temperature for 4 h. It was noted that the initial polymerisation rate obeys the first-order kinetics with respect to the monomer. The size of the particles and their PSD depend considerably on the monomer and surfactant concentrations: the particle size increases with the increase in the monomer concentration and with the decrease in the surfactant concentration. By varying the above-mentioned parameters, the authors obtained polyacrolein microspheres of a broad range of sizes (from 0.01–0.02 to 5.0 μm). Stable monodisperse microspheres were formed only when the monomer concentration did not exceed 15%.

Schlund et al.³⁹ managed to obtain polyacrolein suspensions with particle sizes ranging from 0.04 to 8.0 μm and variation coefficients of less than 10% by the precipitation homopolymerisation of acrolein in alkaline medium ($\text{pH} > 11.0$) with solution of an alkali being gradually added to an aqueous solution of acrolein, only in the presence of a specially synthesised emulsifier produced by the interaction of polyglutaraldehyde oligomers with sodium hydrogensulfite. The polymerisation was carried out for 10 h at room temperature.

It has been shown that the structure of polyacrolein depends significantly on the conditions in which the microspheres are synthesised. For example, it has been reported⁴⁰ that polymerisation of acrolein can involve both the double bond and the aldehyde group. Therefore, polyacrolein incorporates two types of repeating units:

The $x:y$ ratio depends on the method and conditions of preparation of the microspheres and varies from 4:1 for 'anionic' microspheres to 1:7 for 'emulsion' microspheres. It has been noted that the conditions in which polyacrolein suspensions are synthesised determine the concentration of functional aldehyde

groups on the surface of particles and, hence, the number of covalently bound protein molecules.

Based on spectrophotometric studies, Rembaum et al.⁴⁰ have suggested that the polyacrolein molecules synthesised by γ -radiation induced polymerisation incorporate the following structural fragments:

Due to the bifunctional character of acrolein, the polymeric chains are formed by a fairly complex mechanism and their structure is a combination of the above-presented fragments. Thus, the structure of the macromolecules and, consequently, the properties of the polymeric suspensions (particle size, PSD, concentration of aldehyde groups on the particle surface, etc.) vary over a wide range depending on the polymerisation conditions, and, hence, the process is poorly reproducible. This is especially pronounced in the case of precipitation polymerisation. Radiation-induced polymerisation has a number of advantages over the precipitation polymerisation, namely, it is better controlled and reproducible, and it yields particles with higher concentrations of reactive groups on the surface.

Poor reproducibility of the precipitation polymerisation of acrolein has also been reported in other papers.^{39,53} In addition, it was reported that particles of polyacrolein suspensions always contain a certain amount of an oligomeric product, associated with characteristic features of the precipitation polymerisation mechanism. In the course of time, these oligomeric molecules can diffuse from the particle bulk to the surface; therefore, the properties of the microspheres can change noticeably during storage.

A number of methods have been suggested to eliminate the above drawbacks which make it possible to increase considerably the chemical stability of polyacrolein microspheres, to decrease the physical adsorption of protein molecules on their surface, and to increase the yield of the target product.^{54–57} For example, the synthesis of polyacrolein suspensions in an aqueous alkaline solution in the presence of 3%–6% radical initiators with respect to the monomer, has been reported.⁵⁶ The polymerisation was carried out in two temperature regimes: at 5–35 °C for 1.5–2.5 h or at 40–90 °C for 2–3 h. The resulting polyacrolein microspheres had diameters of 0.2–6.0 μm and a narrow PSD (variation coefficient $\sim 10\%$); they were chemically more stable than the microspheres obtained by the conventional anionic precipitation polymerisation, apparently due to additional cross-linking of the polymer by radical initiators.

A similar effect has been achieved when the anionic precipitation polymerisation of acrolein has been carried out in an aqueous alkaline medium in the presence of water-soluble crown-ethers⁵⁷ at 2–38 °C and the reaction system has been kept in the presence of radical initiators [potassium persulfate, benzoyl peroxide, or azobis(isobutyronitrile) (AIBN)] at 40–90 °C. The polyacrolein suspension particles had a diameter of 0.04–6.0 μm and a variation coefficient of 14%–18%.

Polystyrene-acrolein suspensions obtained by the emulsifier-free copolymerisation of acrolein and styrene are more stable.^{35,58} The copolymerisation was carried out at various proportions of comonomers in the presence of potassium persulfate at 55 °C for 8 h in an atmosphere of nitrogen.

The copolymerisation rate has been shown to depend on the molar concentration of acrolein and is optimal at 1 : 1 molar ratio between the comonomers. The copolymeric polystyrene-acrolein particles had an average diameter of 0.25 to 0.30 μm and a variation coefficient of less than 3%. The concentration of the aldehyde groups on the surface of these microspheres exhibited linear dependence on the molar concentration of acrolein and varied from 0.08 (at 20 mol.% acrolein) to 0.17 $\mu\text{mol g}^{-1}$ (at 90 mol.% acrolein).

A similar picture has been observed in the case of the γ -radiation-induced copolymerisation of acrolein with 2-hydroxyethyl methacrylate (HEMA).³⁶ A mixture of acrolein and HEMA was dispersed in a 1% aqueous solution of polyvinyl alcohol, then the emulsion of monomers was rapidly frozen, and the radiation-induced copolymerisation was carried out at –78 °C applying a radiation dose of 1 Mrad over a period of 1 h. The resulting microspheres were thawed and purified from the remaining monomer. Depending on the copolymerisation conditions, the concentration of the comonomers, and the ratio between them, the copolymeric polyacrolein–2-hydroxyethyl methacrylate microspheres had a diameter ranging from 0.6 to 4.0 μm and a narrow PSD.

A method for preparing polymeric microspheres with aldehyde groups on the surface by the post-radiation graft polymerisation of acrolein from the gaseous phase onto stable polystyrene or poly(methyl methacrylate) particles of identical sizes serving as matrices has been described.⁵⁹

Since the conditions of the synthesis of a polymeric suspension (PS) influence essentially the properties of the modification product, the suspension particles obtained both in the presence and in the absence of an emulsifier have been used as matrices for the radiation-chemical graft polymerisation of acrolein.

Water-soluble hydroxyethylated poly(propylene glycol) [PS(F-68)] and di-*p*-tolyl-*o*-alkoxycarbonylphenylmethanol soluble in the monomer phase [PS(DTC)] were used as surfactants. In all cases, the polymerisation was initiated by potassium persulfate and conducted until the complete conversion of the monomers was achieved, which took 24 h. The particles of these polymeric suspensions proved to be stable in physiological salt solutions or during storage and had a narrow size distribution and diameters of 0.2 and 0.45 μm , respectively. The resulting polymeric suspensions were freeze-dried, and the polymer powders were used as matrices.

To determine the irradiation dose necessary for the graft copolymerisation of acrolein, the accumulation of radicals in the supporting polymer was studied by EPR. An irradiation dose of 15 Mrad was chosen at which the radical growth curves flatten out, i.e. a steady-state concentration of radicals is established.

A study of the sorption of acrolein vapour by the support particles at various acrolein vapour pressures showed that the concentration of acrolein in the particles depends appreciably on the nature of the polymer serving as the support and the surfactant used.

From the kinetic curves of acrolein sorption on the support particles, the rate constants for this process have been determined, and it has been shown that the yield of grafted polyacrolein as a function of time depends on the nature of the polymer.

An analysis of the IR spectra of the initial polymers and of those modified by polyacrolein showed that they all exhibit an absorption band in the region of 1725 cm^{-1} corresponding to vibrations of the carbonyl groups in aliphatic aldehydes. An increase in the degree of polyacrolein grafting on the polymeric matrix leads to an increase in the intensity of absorption in this region of the spectrum.

The spectra of polyacrolein-modified polymers contain an absorption band at 1100 cm^{-1} corresponding to vibrations of C–O bonds in acetals. These bonds can be formed either via polymerisation of acrolein with involvement of the carbonyl group or due to the interaction of the aldehyde groups existing in the hydrated form in the polymer produced. The latter is possible,

because free aldehyde groups exist in equilibrium with the corresponding hydrated groups, since acrolein polymers, even being dried in a high vacuum, contain certain amount of water.

To elucidate the manner in which the C—O bonds in the synthesised polymers are produced, the polymers were subjected to reaction with hydroxylamine hydrochloride. It was suggested that if the polymer incorporated free or hydrated aldehyde groups, this reaction would yield the corresponding polymeric oxime. Otherwise, if the C—O bonds are incorporated in the backbone, this reaction will not occur.

An analysis of the IR spectra showed that the reaction resulted in a decrease in the absorption intensity not only in the region of 1725 cm^{-1} , but also at 1100 cm^{-1} . The latter indicates that the C—O bonds result from the formation of cyclic acetals, which can be opened to give free aldehyde groups.

Based on the results obtained by IR spectroscopy, Bastos et al.⁵⁹ concluded that the radical polymerisation of acrolein involves mostly the vinyl group.

The amounts of free and bound CHO groups in polyacrolein are mainly determined by the conditions in which it is synthesised.

For example, the microspheres prepared by the ionic polymerisation of acrolein contain 2.9 mmol of aldehyde per g of microspheres, whereas those obtained by the radical polymerisation, for example, under the action of a radical redox system contain 12.0 mmol of aldehyde groups per g.

Calculations have shown that polyacrolein-modified microspheres obtained by the emulsifier-free polymerisation, PS(DTC) microspheres, and microspheres of the MMA—MAA copolymer contain on their surface 5.39, 4.80, and 9.34 and 8.07 mmol of aldehyde per g of grafted polyacrolein, respectively. Comparison of these results with the published data indicates that the content of aldehyde groups in the microspheres prepared by postradiation polymerisation of acrolein is twice as high as that in the microspheres prepared under conditions of basic catalysis, even in the sample with the lowest acrolein content.

Polymeric suspensions with aldehyde groups on the surface can also be synthesised by dispersion polymerisation of formylstyrene in aqueous ethanol using AIBN as the initiator and polyvinylbenzoic acid as the stabiliser.^{31, 60} The polymerisation was conducted for 24 h at 70°C . Depending on the monomer concentration, the resulting particles had a diameter of 0.5 to $2.0\text{ }\mu\text{m}$, the variation coefficient was 8%–10%, and the concentration of aldehyde groups on the particle surface was $0.1\text{--}0.2\text{ }\mu\text{mol g}^{-1}$.

A method of preparing particles with aldehyde groups on the surface involving polymerisation of glutaraldehyde has been reported.^{38, 61, 62} Polyglutaraldehyde suspensions are unstable (especially in strongly alkaline media) and have no apparent advantages over the suspensions considered above. Therefore, they have found only a limited application for marking cellular receptors.

2. Synthesis of polymeric suspensions with chloromethyl groups on the particle surface

Polymeric suspensions with chloromethyl groups on the particle surface can be obtained by precipitation^{30, 31, 63} or seeded³³ polymerisation of chloromethylstyrene and chloromethyl methacrylate. A serious drawback of this method is the high toxicity of the monomers.

The precipitation polymerisation is induced by AIBN and conducted in ethanol in the presence of a stabiliser (polyvinylbenzoic acid) at 70°C . Polymeric particles were from 0.5 to $2.0\text{ }\mu\text{m}$ in diameter (depending on the monomer concentration), with the variation coefficient being about 10%. During storage of polychloromethyl suspensions, reactive chloromethyl groups are partially hydrolysed, and, hence, properties of the suspensions changed.

The polymeric suspensions obtained by the seeded copolymerisation of chloromethylstyrene with styrene were more stable on

storage.³³ Seed polystyrene particles were obtained by the dispersion polymerisation of styrene initiated by AIBN (1 mol l^{-1}) in aqueous ethanol, 1:4 by volume, in the presence of polyacrylic acid (1 g l^{-1}) as a stabiliser. The reaction yielded seed particles with a diameter of $1.9\text{ }\mu\text{m}$ and a variation coefficient of less than 3%. The polymerisation was conducted for $\sim 10\text{ h}$ at 70°C . After that, the seed latex, styrene, chloromethylstyrene, and AIBN were mixed in a specified ratio and stirred for 24 h at 0°C , to allow the particles of seed suspension to swell, and then the polymerisation was carried out for 24 h at 70°C .

The resulting suspension particles had a diameter of $2.1\text{ }\mu\text{m}$, a variation coefficient of less than 3%, and a 'core-shell' structure. Virtually all the chloromethyl groups were located on the surface of the suspension particles.

Data concerning the use of styrene-chloromethylstyrene copolymeric suspensions in immunodiagnostics have been reported.^{64, 65}

3. Synthesis of polymeric suspensions with epoxy groups on the particle surface

Polymeric suspensions, whose particles contain epoxy groups on the surface, are mostly prepared by the emulsifier-free copolymerisation of styrene with glycidyl methacrylate. According to published data,^{66–77} the optimal conditions of the styrene copolymerisation with glycidyl methacrylate are as follows: ionic strength of the aqueous phase $0\text{--}0.02\text{ mol l}^{-1}$, concentration of potassium persulfate $0.011\text{--}0.02\text{ mol l}^{-1}$, and overall concentration of monomers $3.7 \times 10^{-3}\text{ mol l}^{-1}$. The process is carried out for 5–10 h at 65°C . Under these conditions, microspheres having an average diameter of 220–400 nm and a variation coefficient of 2%–6% are produced. During the synthesis of styrene-glycidyl methacrylate copolymeric suspensions some of the epoxy groups located on the surface of particles are lost due to hydrolysis. Nevertheless, the number of these groups on the particle surface remains sufficient for ensuring a required concentration of a bioligand by its covalent bonding.

To suppress the hydrolysis of epoxy groups during the synthesis of the suspension, it has been advised that the polymerisation be carried out with gradual introduction of the functional monomer into the polymerising system.^{39, 76} This procedure makes it possible to obtain particles with a structure of the 'core-shell' type. This is exemplified by the synthesis of particles containing a copolymer of n-butyl acrylate with butyl methacrylate as the 'core'. These particles were obtained by the emulsion copolymerisation of the monomers in the presence of sodium dodecyl sulfate and a redox system consisting of potassium persulfate and sodium thiosulfate. The process was carried out at 20°C for 20 min, after which a mixture of monomers with glycidyl methacrylate was introduced.

The resulting microspheres had diameters of 150–300 nm and a variation coefficient of $< 10\%$. According to the data obtained by Schlund et al.,³⁹ under these conditions, up to 90% of the epoxy groups are preserved and virtually all of them are distributed within a thin layer (about $150\text{ }\text{\AA}$) on the surface of the particles.

4. Synthesis of polymeric suspensions in the presence of surface active functional initiators and surfactants

The use of polyfunctional initiators and surfactants in the synthesis of polymeric suspensions with narrow PSD to be employed in immunodiagnostics has been reported. However, the use of these substances is restricted by their high prices and by the absence of a technology for their production. Azobis(bromoisocyanonitrile) 1 and di(4-chloromethylbenzoyl) peroxide 2 can be mentioned among the polyfunctional initiators which make it possible to obtain reactive functional groups, capable of forming covalent bonds with biomolecules, on the surface of suspension particles.⁷⁸

Isothiuronium salts, in particular (4-vinylphenyl)methylisothiurea hydrochloride, are used as polyfunctional emulsifiers.⁴¹

The latter compound is a cation-active emulsifier, able to copolymerise with vinylic monomers. For example, in the presence of this compound, polystyrene microspheres 0.15–0.19 μm in diameter with a variation coefficient of 2.7%, containing isothiuronium groups on the surface, have been prepared. Hydrolysis of these groups under mild conditions (pH 10–11, 25 °C, 10 min) gave mercaptogroups on the particle surface.⁴¹ It was found that the average diameter of particles or their PSD are almost constant throughout the hydrolysis.

Polymeric suspensions, whose particles contain aldehyde groups on the surface, can be prepared by modifying other functional groups. For example, the particles of polystyrene suspensions obtained in the presence of the polysaccharide dextran or ammonium glycyrrhizate as a stabiliser contain carbohydrate groups on the surface.⁷⁹ The periodate oxidation under mild conditions leads to the cleavage of the α -glycol groups and formation of reactive groups that can directly interact with the amino groups of proteins.

In both cases, the conditions for the synthesis are chosen in which polymeric suspensions with narrow PSD stable in physiological salt solutions and during storage are formed. The concentration of aldehyde groups on the surface of suspension particles is in turn determined by the concentration of the stabilising agent and the oxidation conditions.

5. Synthesis of polymeric suspensions with carboxyl groups on the particle surface

The main and most studied method for synthesis of polymeric suspensions with carboxyl groups on the surface of particles is the copolymerisation of hydrophobic monomers with various unsaturated acids (acrylic, methacrylic, itaconic, etc.) in the presence or in the absence of an emulsifier. The presence of readily dissociating carboxyl groups imparts an additional stability to the suspension particles, therefore, these microspheres are resistant to mechanical action or low temperatures (freezing).^{11, 80–83}

The distribution of the carboxyl groups between the aqueous phase, the surface, and the bulk of polymeric particles is a rather important question in the synthesis of carboxyl-containing polymeric suspensions. In a study of the emulsifier-free copolymerisation of styrene with three unsaturated acids possessing different hydrophilicities, namely, acrylic (AA), methacrylic (MAA), and itaconic (IA) acid, it has been found^{84, 85} that AA concentrates in the surface area of the particles, the more hydrophobic MAA is distributed between the bulk of microspheres and their surface, and the most hydrophilic IA mainly homopolymerises in the aqueous phase. These features of the distribution of the acrylic monomers among the phases of an emulsion system determine the properties of the suspensions obtained.

Similar information has been presented in other papers^{86, 87} devoted to the study of the distribution of carboxyl groups in the suspension particles obtained by the copolymerisation of acrylic monomers with styrene or butadiene. It was found that the functional groups are distributed between the aqueous phase, the

microsphere surface, and the microsphere bulk in a ratio of 2 : 3 : 1 in the case of acrylic acid or 0.1 : 1 : 1 when methacrylic acid is used.

Thus, it is obvious that the conventional way of conducting copolymerisation of hydrophobic monomers with unsaturated acids affords polymeric suspensions in which functional groups are distributed among various phases of the polymerisation system.

The distribution of the carboxyl groups between the surface and the bulk of the particles can be changed by gradual introduction of the functional monomer into the reaction system. It has been shown^{88, 89} that in the case where itaconic acid is added in the initial stages of the polymerisation of styrene, only 12% of itaconic acid units are located on the surface of copolymer particles, while introducing the acid at the stage where the degree of styrene conversion has already reached 80% or 95% leads to an increase in the concentration of the functional monomer on the surface to 60% or 80%, respectively.

Another method of preparing a polymeric suspension with a high concentration of a carboxyl-containing comonomer on the surface of particles consists in the seeded emulsifier-free copolymerisation of styrene and butadiene with unsaturated acids (AA, MAA, or IA),⁹⁰ with pH of the medium being varied in the course of the synthesis. In the first stage of the process carried out at low pH, all the components (including the acid), but only a portion of the main monomers, are added to the reaction system. Then the pH of the seed latex is increased, and, consequently, the carboxyl groups located near the surface of particles are ionised. In the second stage, seeded copolymerisation of the rest of the monomers is carried out.

Some authors believe that the concentration of carboxyl groups on the surface of polymeric microspheres can be increased by heating the suspension at high pH values, which ensures the migration of the ionised carboxyl groups from the particle bulk to the interface with the aqueous phase (see, for example, the paper by Okubo et al.⁹¹).

The presence of MAA or AA in the monomeric mixture leads to the formation of emulsions characterised by a higher dispersity than emulsions of hydrophobic monomers, due to a lower interfacial tension (σ_{12}). A study carried out by Okubo et al.⁹² has shown that MAA, present at a concentration of 2% with respect to styrene, diminishes the surface tension at the interface between a styrene solution of MAA and water to 22 mN m⁻¹. A dispersion analysis of styrene-methacrylate emulsions obtained with MAA concentrations being 0.2% or 3.0% with respect to styrene showed that in the former case, the emulsion of the monomers consists of drops, whose size is 1–5 μm , and in the latter case, the size of the drops varies from 0.2 to 1.0 μm .

The dispersity of the initial monomer emulsion influences the size distribution of the polymer-monomeric particles (PMP). In fact, the copolymerisation of styrene with MAA, induced by potassium persulfate and carried out at an MAA concentration in an emulsion of 0.2% with respect to styrene gives a polymeric suspension, in which 90% of the particles have an average diameter of 0.6 μm , while in the case where the MAA concentration is 3% with respect to styrene, 85% of the particles have an average diameter of 0.3 μm . When copolymerisation of styrene with MAA is carried out under the same conditions, but in the presence di-*p*-tolylalkoxycarbonylphenylmethanol (DTC), which is a water-insoluble stabiliser, polymeric suspensions with a narrower distribution of the particles of the same size were formed. These suspensions were stable in physiological salt solutions or on six-months storage.

Functional microspheres with carboxyl groups on the surface can also be synthesised by the polymerisation or copolymerisation of surface active monomers,^{93–103} for example, sodium acrylamidostearate **3**⁹³ or salts of vinylalkylcarboxylic acids **4**,⁷⁸ or surface active initiators, such as 5,5'-azobis-5-cyanopentanoic acid **5**.⁷⁸

However, these compounds have not found wide application owing to their high costs.

A new interesting method of synthesis of polymeric suspensions with carboxyl groups on the particle surface is the polymerisation of styrene in the presence of water-insoluble surfactants, whose molecules incorporate carboxyl groups. These are, for example, DTC, oligomeric peroxy esters,⁹⁴ and α -(ethoxycarbonyl)- ω -(trimethylsilyloxy)polydimethylsiloxane (PDS).⁹⁵

In the papers considered above,^{94,95} a hypothesis was put forward that the PMP are formed from drops of the monomer and that their structure is similar to that observed in the 'core-shell' type particles, whose shell is a surfactant displaced by the polymer to the interface. It was shown that the strength of the interfacial layer depends on the molecular mass of the resulting polymer, the concentration of the initiator (in this particular case, potassium persulfate), and the concentration of the surfactant.⁹⁵

The particle size distribution of particles in polymeric suspensions obtained in the presence of water-insoluble surfactants are much narrower than those observed in the presence of water-soluble surfactants. First of all, this precludes the possibility of the formation of PMP from emulsifier micelles or globules of surfactant molecules in the aqueous phase of the emulsion.

Polystyrene, poly(methyl methacrylate), polychloroprene, and polystyrene-methacrylate suspensions with narrow particle size distributions have been obtained in the presence of water-insoluble surfactants. For example, polystyrene microspheres with diameters varying from 0.2 to 0.9 μm and the content of dry substance from 8% to 33% were prepared at surfactant and potassium persulfate concentrations of 1%–4% and 0.5%–1.0% with respect to styrene, respectively. These polymeric suspensions exhibited high stabilities in physiological salt solutions during storage and have found wide application in immunochemical studies.⁹⁶

6. Synthesis of polymeric suspensions with amide groups on the surface of particles

Amide-containing polymeric suspensions are synthesised most frequently by emulsifier-free copolymerisation of styrene with amides of acrylic or methacrylic acid.^{2, 25, 104–106}

The emulsifier-free copolymerisation of styrene with acrylamide (AAM, 0.1%–0.5% with respect to styrene) at pH 9 has been studied most comprehensively.¹⁰⁶ Three stages can be distinguished in the copolymerisation process: (1) copolymerisation of the monomers in the aqueous phase yielding oligomers; (2) polymerisation of styrene within the particles formed by these oligomers; (3) copolymerisation of AAM with styrene dissolved in the aqueous phase.

Special attention in the studies of styrene copolymerisation with AAM is paid to the distribution of amide groups between the aqueous and polymeric phases (owing to the high hydrophilicity of AAM, the aqueous phase always contains a substantial quantity of the water-soluble homopolymer).^{107, 108} The particle diameters in the resulting polymeric suspensions vary from 0.2 to 0.5 μm , and the variation coefficient is less than 3%.

7. Synthesis of polymeric suspensions with hydroxyl groups on the particle surface

Polymeric suspensions with hydroxyl groups on the particle surface are synthesised by the emulsifier-free copolymerisation of

styrene with HEMA or 2-hydroxyethyl acrylate.^{106–108} An essential feature of these monomers is the absence of ionising groups in their molecules, which allows one to change hydrophilic properties of the surface of the polymeric microspheres without changing its charge. This is particularly convenient for selecting the optimal conditions for binding biomolecules.^{109–111}

Polymeric microspheres with high concentrations of surface functional groups are obtained by seeded copolymerisation with gradual introduction of a mixture of styrene and HEMA taken in a certain ratio.^{112–114} The polystyrene particles with diameters of 0.3–0.9 μm and a narrow PSD are used as the seed suspension. Polymeric suspensions with a particle size of 0.6–1.1 μm and a polydispersity coefficient of 1.0003–1.0006 are obtained in this way.

8. Synthesis of polymeric suspensions with amino groups on the particle surface

Polymerisation of functional monomers such as aminostyrene,¹¹⁵ 2-aminoethyl acrylate, 2-dimethylaminoethyl methacrylate, or allylamine⁶⁶ is a rather uncommon method for the synthesis of amine-containing polymeric suspensions. This is caused by the high cost of these monomers and by the low stability of the polymeric microspheres based on them as well as by the fact that a narrow particle size distribution is difficult to achieve due to the high hydrophilicity of the monomers.^{116–124}

Amine-containing polymeric suspensions are much more readily prepared by modifying available suspensions containing hydroxyl, chloromethyl, amide, or other groups. As an example, let us consider the synthesis of polymeric suspensions with surface amino groups by the dispersion catalytic polymerisation of *p*-aminostyrene. The polymerisation of *p*-aminostyrene is carried out in the presence of a mineral or organic acid (with pK_a below 4.76) and an organic solvent (10%–80% with respect to water), which is miscible with water and whose dielectric permeability is lower than that of water.¹¹⁵ This process yields polyaminostyrene microspheres with diameters varying from 0.6 to 10.0 μm and a narrow particle size distribution.

Polymeric microspheres with diameters of 0.2–3.5 μm and polydispersity coefficients of no more than 1.08 have also been obtained by dispersion cationic polymerisation of *p*-aminostyrene in aqueous methanol at 60 °C with a monomer:water ratio of 1:9, a concentration of cetylpyridinium bromide of 1% with respect to the monomer, and a catalyst (hydrogen chloride) concentration of 10% with respect to the monomer.

III. Activation of functional groups on the surface of particles of a polymeric suspension

The methods for activation of functional groups on the surface of particles of a polymeric suspension considered in this Section are widely applied in biochemistry and biology, in particular, to prepare sorbents for affinity chromatography.^{89, 90} However, to be suitable for preparing a highly sensitive diagnostic, these methods should comply with the following requirements:²

- to proceed quantitatively and irreversibly under as mild conditions as possible;
- not to decrease the stability of suspensions and not to influence noticeably the particle diameter and PSD;
- to have no influence on the biochemical activity of the bioligand molecules covalently bound to the functional groups on the surface of the suspension particles.

1. Methods for the activation of carboxyl groups on the particle surface

The carboxyl groups on the surface of suspension particles can react with amino groups of a biopolymer in the presence of water-soluble carbodiimides (WSC).⁸⁰ The most frequently used WSC are 1-cyclohexyl-3-[2-(*N*-methylmorpholinio)ethyl]carbodiimide toluenesulfonate **6** and 3-ethyl-1-(3-dimethylaminopropyl)carbodiimide hydrochloride **7**.

The activation reaction occurs via the following scheme:

It is carried out at a temperature of 4–6 °C and pH 6–7 for 2–4 h in the presence or absence of an inert buffer like 4-(2-hydroxyethyl)piperazin-1-yl(ethane-2-sulfonic) acid.

One of the advantages of this method for activating functional groups is its simplicity. However, since protein molecules contain both carboxyl and amino groups, inter- or intramolecular cross-linking is possible, which reduces the immunochemical activity of the bioligand.^{26, 104, 125–128}

This problem can be solved to a substantial extent by using two-stage activation: in the first stage, the carboxyl groups are converted into an active (but stable) form and the microspheres are separated from the dispersion medium containing the unchanged components, and in the second stage, the covalent binding to a bioligand is carried out.

The so-called method of 'activated esters' is among the most generally used two-stage methods for the activation of functional groups.^{2, 48, 129} In this case, the activation occurs according to the following scheme:

Apart from *N*-hydroxybenzotriazole, *N,N*-dialkylhydroxylamines and some other compounds can be used. The conditions in which the first stage of the process is conducted are similar to those described above for the 'carbodiimide' method. Following the first

stage, the suspension is purified from side products. The second step proceeds at 4 °C and pH 7–7.5 for 2–3 days, and after that, the obtained diagnostic is completely freed from impurities.

Yet another possible version of two-stage activation is the use of the Woodward reagent, namely, *N*-ethyl-5-phenylisoxazoline-3'-sulfonate.¹³⁰

In this case, the first stage is carried out at pH 8.5 and a temperature of 3 °C for 3 h, the resulting suspensions with the activated carboxyl groups on the particle surface are purified from side products and then bound to bioligands at pH 7 and a temperature of 5 °C over a period of 3 h.

Common drawbacks of the above methods are their high costs and the low stabilities during storage of the reagents used, which makes the process of binding biomolecules to the functional groups of microspheres poorly reproducible. Moreover, the biomolecules bound by these methods are arranged near the surface of polymeric particles, which may result in changes in their conformations and may decrease their biochemical activity.

Therefore, the method involving the introduction of a spacer by the reaction of carboxyl groups on suspension particles with various diamines (1,6-diaminohexane, 1,7-diaminoheptane) has gained acceptance.^{47, 131–133} In the first stage, the carboxyl groups on the microsphere surface are bound to diamine in the presence of WSC, and after that the resulting amino groups are activated by one of the methods described below.

2. Methods for the activation of hydroxyl groups

The 'cyanogen-bromide' method for the activation of hydroxyl groups consists in their interaction with cyanogen bromide in strongly alkaline media (pH 10–11) followed by the formation of bonds with amino groups of protein molecules.¹³⁴

The first two stages, (3) and (4), proceed at 25 °C over a period of 15 min, alkaline pH being maintained by the periodical addition of 2 M sodium hydroxide. Then the suspension is purified from side products, and stage (5) is carried out in a 0.1 M borate buffer at pH 8.0–8.5 and a temperature of 4 °C for 4 h. The unaffected activated hydroxyl groups are bound by adding 0.1 M glycine buffer with pH 8.5, and then the suspension is extensively purified.

This activation method is applicable only to the covalent binding of biomolecules stable in strongly alkaline media. The high toxicity of cyanogen bromide and the noticeable aggregation of polymeric microspheres during binding bioligands to the functional groups are among the drawbacks of this method.

Activation of hydroxyl groups can be carried out by using some other reagents such as tosyl chloride,² 2,2,2-trifluoroethanesulfonyl chloride^{135, 136} and carbonyldiimidazole.^{137, 138} Overleaf we present the scheme of the activation of hydroxyl groups by tosyl chloride as an example:

A fairly convenient method for the activation of hydroxyl groups is the oxidation of glycol groups, which can be readily obtained by the hydrolysis of epoxy-groups or oxidation of double bonds in polydienes (see below). Microspheres with glycol groups on the surface are obtained, as has been mentioned above, by the polymerisation of styrene in the presence of dextrans as functional surfactants.¹³⁹ The oxidation is carried out by periodic acid or periodates at room temperature at neutral pH for 30–60 min in the dark.^{50, 140, 141} Only glycols with primary or secondary hydroxyl groups enter into this reaction, which involves the cleavage of the C–C bond yielding two aldehyde groups.

The side products are removed during purification of the polymeric microspheres.

3. Methods for the activation of amide groups

Although amide groups do not interact directly with protein molecules, there are a number of methods involving polymer-analogous transformations that make it possible to convert amide-containing polymeric suspensions into microspheres with some other groups that can be easily activated.

For example, the modification of amide groups to hydrazide groups is widely used.^{27, 46} The reaction occurs at 50–80 °C in 7–10 h according to the following scheme:

The hydrazide groups formed in this reaction can be transformed either into the carboxyl groups, which need to be further activated, or into azide groups, which can directly interact with biomolecules.

The former process can be accomplished by treating the hydrazide groups with succinic anhydride.^{142, 143}

Azide-containing polymeric suspensions are obtained by diazotisation in the presence of nitrous acid at a low temperature (2–5 °C);²⁷ after that, the direct interaction of biomolecules with azide groups on the microsphere surface is possible (pH 7.0 to 9.5, duration 4 h).

It should be noted that hydrazide groups can be activated by virtue of the same methods as amino groups.

Another possible way of modification of amide-containing polymeric suspensions is the transformation of amide groups into primary amino groups under the action of sodium hypochlorite in an alkaline medium (the Hoffmann reaction^{139, 140}). The factors influencing the course of this process have been studied.^{143, 144} It was shown that, apart from the transformation of amide groups into amino groups, hydrolysis yielding carboxyl groups occurs to a substantial extent, the degree of hydrolysis increasing with increase in the temperature and decrease in the NaOCl:polyamide ratio. The following optimal conditions under which the maximum quantity of amino groups is obtained on the surface of the suspension particles were found: a ratio between the concentrations of hypochlorite and amide groups of 0.6 to 0.9, a temperature of 5–10 °C, and a duration of the process of 1–2 h. It was shown that under these conditions, the diameter of suspension particles or their PSD are virtually unchanged during modification. This method has been used for the covalent binding of enzymes to the amide groups located on the particle surface in acrylamide-styrene copolymeric suspensions (glutaraldehyde was used to activate the resulting amino groups).¹⁰⁴

The transformation of amide groups into carboxyl groups, which is frequently required for increasing the stability of microspheres, can be performed by alkaline hydrolysis under mild conditions (30 °C, 3–4 h).¹⁴⁴ The degree of hydrolysis and, consequently, the concentration of carboxyl groups on the surface of suspension particles, can vary depending on the duration of the process, and this allows one to obtain particles with various concentrations of carboxyl groups on the surface.

Finally, polymeric suspensions with hydroxyl groups on the surface can be obtained from amide-containing suspensions by hydroxymethylation. The reaction proceeds for 1 h at 50 °C and pH ≥ 12.0. In relation to the emulsifier-free copolymerisation of styrene and AAm taken in a ratio of 9:1 followed by the modification of the amide groups to the hydroxyl groups, it has been shown that this process yields stable monodisperse microspheres 220 nm in diameter containing 4.58 OH groups per nm² of the surface of particles.¹⁴⁴

4. Methods for the activation of amino groups

Since primary amino groups are highly reactive, polymeric suspensions containing these groups on the surface of microspheres are readily activated via reactions with various bifunctional compounds.

The most commonly used activation method involves reaction with glutaraldehyde, which is due to both the ease of conducting this reaction and the availability of the reagent itself. The primary amino groups react with glutaraldehyde by the following scheme:^{145, 146}

The activation can be accomplished in one or in two stages.¹⁴⁷ According to the one-stage procedure, linking a bioligand to the amino groups on the particles is carried out in the presence of an excess of glutaraldehyde. Although this method is rather simple, appreciable aggregation of polymeric microspheres due to their cross-linking is observed in the course of activation.

Preference is given to the two-stage activation. The first stage (6) involves oligomerisation of glutaric aldehyde and the reaction of the resulting oligomer with the amino groups on the surface of polymeric microspheres (7). After liberation of the suspension from side reaction products, covalent binding to bioligands is performed. The first stage is carried out at 20–25 °C in 0.01 M phosphate buffer (pH 7.0) for 1 h.²⁴ After removal of the excess of glutaraldehyde by dialysis (24 h, against a system consisting of 0.01 M phosphate buffer and 0.01 M salt buffer, pH 7.0), the molecules of a bioligand are bound to the microsphere functional groups for 5 h at 25 °C. Then the unaffected aldehyde groups on the microsphere surface are blocked with a 0.1 M solution of glycine at pH 7.0, and the resulting test-system is purified. This activation method makes it possible to avoid inter- or intramolecular cross-linking of bioligands and to prevent the functional microspheres from aggregation.²⁴

Other bifunctional compounds, for example, 1,5-difluoro-2,4-dinitrobenzene, 4,4'-difluoro-3,3'-dinitrophenyl sulfone, or 2,4-dichloro-6-methoxycarbonylmethyl sulfone, can also be used in place of glutaraldehyde.^{148, 149} Drawbacks of these methods are the high costs of the reagents and the prolonged period (4–7 days) required for covalent binding of functional groups to biomolecules.² However, the properties of the test-systems obtained by these methods are more reproducible than those of the test-systems prepared using glutaraldehyde; in the latter case, the properties of the test-systems are determined by the conditions and duration of the storage of glutaraldehyde (polymerisation is possible).

It is noteworthy that one of the possible ways of binding antibodies and enzymes incorporating polysaccharide residues to amino groups on the surface of a polymeric suspension is the treatment of the bioligand itself with periodic acid or periodates, rather than the activation of the amino groups.¹⁰⁴ The oxidation of the glycol groups of the polysaccharides incorporated in biomolecules affords reactive aldehyde groups, which can react with the amino groups on the surface of polymeric microspheres. The use of this method for binding glucose oxidase and glucose peroxidase makes it possible to retain up to 40% of their activities (compared with 10% of the activity retained when other methods, in particular the carbodiimide method, are used).¹⁰⁴

5. Methods for the modification of chloromethyl, epoxy, and aldehyde groups

In this section we consider polymer-analogous transformations involving functional groups capable of direct interaction with bioligands. These reactions are often required either to introduce an additional spacer group between a polymeric particle and a biomolecule in order to retain the biological activity of the latter, or to generate chemical groups on the surface of the suspension particles, whose reactivity is retained during the preparation and storage of microspheres (the transformation of epoxy or chloromethyl groups into aldehyde groups is an example).

Aldehyde groups are most frequently modified in order to introduce a spacer. This is achieved by conducting the reaction with diamines and the subsequent activation of the NH₂ groups with glutaraldehyde. It should be noted that the Schiff's base resulting from the interaction of a primary amino group with an aldehyde group and containing a CH=N fragment is unstable at low pH values. Therefore, it is often reduced to CH₂NH with mild reducing agents like sodium tetrahydroborate (25 °C, 30 min).^{37, 38}

Aldehyde-containing suspensions can also be modified using the reaction of aldehyde groups with amino acids (for example, with 6-amino-n-caproic acid).^{35, 150} This reaction affords carboxyl groups on the surface of the polymeric microspheres:

Chloromethyl groups are modified both in order to introduce a spacer and to suppress hydrolysis, which occurs to a substantial degree at high pH values.³¹ In the former case, the same methods as for aldehyde groups can be applied.^{28, 29, 34} The reaction is carried out in neutral or weakly alkaline media at 30–40 °C for 1–2 h.

Chloromethyl groups are rather reactive and possess pronounced electrophilic properties,³² which makes it possible to perform various polymer-analogous transformations to impart additional valuable properties to the functional microspheres, such as storage stability, hydrophilicity of the surface, etc.¹⁵¹ For this purpose, chloromethyl groups are most frequently converted into aldehyde groups. The functional groups located on the surface of the particles of a polymeric suspension are modified by treatment with iodates in an aqueous solution of chromic acid,^{117, 151–153} or by the oxidative alkylation with the sodium salt of 2-nitropropane.^{154–156}

In the latter case, sodium methoxide and 2-nitropropane are gradually added to a poly(styrene-chloromethyl) copolymeric suspension. The reaction proceeds at room temperature over a period of 2 h, and after that, the modified copolymeric microspheres are purified from the unchanged components and side products. It was shown that under these conditions almost all the chloromethyl groups are oxidised to aldehyde groups, the modification having virtually no effect on the diameter or PSD of the resulting polymeric particles. A comparison of the reactivities of the initial chloromethyl groups and the resulting aldehyde groups toward human immunoglobulin G has shown that the latter are better in binding this antibody and provide higher sensitivity of the diagnostic.

As has already been mentioned, epoxy groups can be hydrolysed, especially at low pH values. Therefore, epoxy groups are subjected to further modification with the aim of obtaining more

stable groups on the particle surface or to introduce an additional spacer group.

Owing to the high reactivity of epoxy groups, they participate in various polymer-analogous transformations.⁴⁰

For example, the hydrolysis of surface epoxy groups at 50 °C and pH 2 gives particles with glycol groups, which are readily converted thereafter into aldehyde groups by treatment with periodic acid.

It is noteworthy that up to 60% of the theoretically possible (based on the concentration of the epoxy groups on the surface of the suspension particles) number of glycol groups can be obtained by the hydrolysis, and the particle, diameter, or PSD, virtually do not change during the process: these are 440 nm and a variation coefficient of 3.9% for the starting suspension and 475 nm and a variation coefficient of 5.8% for the modified particles.

The reaction of epoxy groups with ammonium hydroxide (ammonolysis) occurs even more readily at 20 °C.

Epoxy groups on the surface of suspension particles can be converted into thiol groups by the reaction with an aqueous solution of hydrogen sulfide, which proceeds under mild conditions (20 °C, 2–4 h).

However, in this case, it was noted that the modified particles undergo substantial agglomeration (variation coefficient 15.5%).

Epoxy groups on a microsphere surface can also be modified by introducing a spacer via the reaction with diamines or amino acids (see above).

6. Methods for the preparation of polystyrene suspensions with a narrow particle-size distribution containing functional groups on the particle surface

Polystyrene suspensions have found the most extensive application in immunodiagnostic studies. This is caused by the fact that polymerisation of styrene has been most thoroughly studied and it is easy to obtain microspheres with the required diameter and a narrow PSD.^{3–5, 157–175} Here, it is expedient to consider methods for the synthesis of functional polystyrene suspensions consisting of particles with a specified diameter and a narrow PSD.

Polystyrene microspheres with hydroxyl groups on the surface are obtained in two stages: the first stage involves emulsifier-free

polymerisation of styrene initiated by potassium persulfate giving monodisperse suspensions, whose particles contain sulfate groups on the surface and which are stable in physiological salt solutions. In the second stage, the sulfate groups are converted into hydroxyl groups by the hydrolysis in alkaline media (pH 9–10, 50–70 °C, 2–5 h).^{176, 177} The resulting hydroxyl groups can be either modified further by virtue of the cyanogen-bromide method or oxidised in the presence of Ag⁺ ions (50 °C, 5 h)¹²⁷ to carboxyl groups, which are then activated. It should be noted that the hydrolysis of ionogenic sulfate groups to yield non-dissociating hydroxyl groups is accompanied by a sharp reduction in the stability of the modified microspheres due to the decrease in the electrostatic repulsion between the particles. Therefore, to prevent coagulation, non-hydrolysing sulfonate groups should be introduced.^{32, 175, 178}

The preparation of polystyrene particles with amino groups on the surface is an even more complex and cumbersome procedure.^{179, 180}

The first stage [reaction (8)] is carried out in glacial acetic acid at room temperature for 4 h, concentrated nitric acid being gradually added to the reaction mixture. The polymeric particles are then separated from the nitrating reagent by decantation and washed. The second stage (9) is carried out in ethanol; it involves the treatment with sodium dithionite at 40 °C for 2 h. The resulting polystyrene microspheres with amino groups on the surface can be activated thereafter by any of the procedures considered above. It is obvious that to be subjected to all the stages of the process, polystyrene suspensions should meet very stringent requirements for their stability, therefore, the above way of modification is applicable only to particles with cross-linked structures (copolymer of styrene with 2%–5% divinylbenzene) and diameters of no less than 0.8 μm (they can be redispersed fairly easily).²

An original method for binding bioligands to polystyrene microspheres has been suggested by Berge et al.¹³⁸ This method makes it possible to avoid any chemical effect on the surface of polystyrene particles and thus to maintain their stability. The first step of this process involves the adsorption of bovine serum albumin (BSA) onto polystyrene particles of a specified diameter with a narrow PSD; then the suspension is treated with a bifunctional compound (glutaraldehyde, diethyl adipinimidate, etc.) for the cross-linking of protein molecules and their fixation on the microsphere surface. After that, further binding of biomolecules is possible via amino or carboxyl groups of BSA.

7. Methods for the activation of polydiene microspheres

The main characteristic feature of polydiene microspheres is the presence of double bonds, which can undergo further modification.^{139, 140} However, good film-forming ability of diene polymers is responsible for the low stability of microspheres during their purification by ultrafiltration, microfiltration, or centrifugation.² Therefore, the functional polymeric suspensions are synthesised by copolymerisation of dienes (butadiene, isoprene, etc.) with various proportions of styrene.

A possible method of introducing hydroxyl groups into polydiene-styrene microspheres (for example, polyisoprene-styrene microspheres) is the oxidation of the double bonds of the polydiene by such oxidising reagents as potassium permanganate

or hydrogen peroxide.^{181, 187} The oxidation proceeds under mild conditions (pH 3–7, 5–10 °C, 30 min). The resulting glycol groups can be subjected to further activation.

The oxidation of the polybutadiene or polyisoprene double bonds to epoxy groups by their interaction with peracetic acid at reduced temperatures is of great interest.^{188, 189} It was shown that the rate and degree of epoxidation depend to a substantial extent on the polymer content in the suspension and on the concentration of peracetic acid, and does not depend on the nature of the surfactant present in the reaction system, the size of polymeric particles, or the rate of stirring. The following optimal conditions of the oxidation were found: a concentration of the polymer in the suspension of 15%–30%, a concentration of peracetic acid of 2%–3%, and a duration of the reaction of 2–3 h. Data on epoxidation of unsaturated polymers with a mixture of hydrogen peroxide and formic acid has also been reported.¹⁸⁹

Regarding the modification of polydiene microspheres, the use of thio-compounds containing mercapto groups which readily react with double bonds of polydiene microspheres, is of considerable interest. Thioglycols or thioamines are known¹⁹⁰ to be used for enhancing plastic properties of polybutadiene rubbers. In this respect, attention is attracted by the possibility of modifying polydiene microspheres by thiol compounds containing various functional groups, for example, by sulfur-containing amino acids. The modification of an artificial dispersion of SKI-3 polyisoprene by sulfur-containing amino acids has been reported.¹⁹¹ It was shown that amino acids such as cystine or cysteine, due to the presence of reactive disulfide and mercapto groups in their molecules, are capable of direct binding to partially polarised double bonds of 1,4-*cis*-polyisoprene, which occurs by an ionic mechanism.

The preparation of polymeric suspensions with amino groups on the particle surface with the aid of modification with sulfur-containing amino acids has been reported by Gritskova et al.¹⁹² They suggested a method for synthesising modified suspensions that consisted of three independent stages: the first stage involved the synthesis of seed polystyrene particles with a specified diameter and a narrow PSD, the second stage was the seed

polymerisation of isoprene, ensuring a high concentration of polyisoprene units on the surface of the particles, and in the third stage, the resulting isoprene-styrene polymeric suspensions having the 'core-shell' structure were modified by cysteine.

If all the stages of this process are conducted under controlled conditions, it is possible to obtain polymeric suspensions with diameter of particles varying over a wide range (0.1–2.0 µm), a narrow PSD (1%–5%), and a high concentration of amino groups on the particle surface.

It was shown that by varying conditions in which modification is carried out, one can control the properties of the suspensions obtained, which is particularly significant for choosing the optimal conditions for the immobilisation of protein molecules and for further application of modified suspensions in immuno-diagnostics.

* * *

Thus, the data considered above indicate that the main stage in the synthesis of functional polymeric suspensions suitable for immuno-diagnostic studies is the heterophase polymerisation. The choice of polymerisation conditions determines the stability of the suspensions, the particle diameter, and their size distribution. Functional groups on the surface of microspheres can be obtained either during the synthesis or by modifying the resulting polymeric suspensions.

Despite the fact that numerous methods for the synthesis of functional suspensions have been suggested, studies in this field are being intensely carried out.^{193–218} The purpose of the studies is to find conditions of a technologically facile method for preparing suspensions with the use of available reagents.

The work was carried out with financial support from the Russian Fundamental Research Fund (Grant No. 94-03-08987).

Abstract. The present review covers studies published over the past 15 years on the electrochemistry of hydride-forming intermetallic compounds (IMC) and alloys. Data on the discharge capacity and stability of electrode materials based on IMC and AB, AB₂, AB₃ and AB₅ type alloys and their substituted derivatives during potential cycling are classified and generalised. The problems concerning the optimisation of the elemental composition of IMC and alloys, their production and activation as well as the reasons for the degradation of electrodes based on these materials are discussed. The mathematical models suggested for describing the processes of discharge and degradation of metal hydride electrodes are analysed. The bibliography includes 149 references.

I. Introduction

It was found in the 1960s that a series of intermetallic compounds (IMC) possess the unique capability to absorb reversibly an anomalously large amount of hydrogen (up to 1.5%–2%)[†] at moderate pressures and temperatures.¹ This led to the appearance of several new fields of scientific investigations directly related to the solution of problems of hydrogen energetics and technology. The results of these studies show the possibility of developing methods, new in principle, for the preparation, storage, purification, compression and application of hydrogen in different technological processes and energy-transforming systems.^{1,2}

The present review deals with electrode materials based on hydride-forming IMC and alloys with a high sorption capacity for hydrogen. These materials are primarily intended for use in nickel–metal hydride batteries. Palladium was the first hydride-

forming element to attract the particular attention of electrochemists after studies by Nilen³ and Frumkin.^{4,5} Palladium has since been extensively used as a classical model in hydride electrochemistry, since processes of hydrogen sorption–desorption, reversible at ambient temperature but not complicated by corrosion phenomena, can be implemented only with this material. The recent commercial use of hydrides was preceded by extensive studies of a wide range of new materials, which makes it urgent to analyse and generalise the data obtained to date.

In this review we consider the main aspects of the electrochemistry of hydride-forming materials that have attracted most research attention in recent years and that we believe to be of interest to a wide circle of chemists.

II. Brief history of the discovery and use of hydride-forming intermetallic compounds

The first studies on the use of hydride-forming IMC as reversible electrodes carried out by Justi et al.⁶ for individual compounds of the Ti_{1–x}Ni_x system, and by Gutjahr et al.⁷ for a mixture of intermetallic compounds Ti₂Ni–TiNi, have demonstrated, in principle, the possibility of the cathodic storage of hydrogen using these IMC.

In 1973, the results of a study on the electrochemical behaviour of LaNi₅ were reported.⁸ This compound was found to have a discharge capacity of 200 mA h g^{–1}, which, however, was much lower than the value expected from the pressure–composition isotherm for the LaNi₅–H₂ system (360 mA h g^{–1}). In 1975, the first battery with LaNi₅ as a metal hydride cathode was patented.⁹

During the following years, the main attention of researchers was devoted to increasing the electrochemical capacity of metal hydride (MH) electrodes and to decreasing the loss of capacity in storage (self-discharge). With this purpose, IMC of the LaNi₅ type with partial replacement of lanthanum and nickel by other metals, whose electrochemical charging results in hydride phases with lower equilibrium dissociation pressures, have been studied.^{10–12}

It was found that the main difficulty in the use of such IMC as TiNi, Ti₂Ni, LaNi₅, MmNi₅ (Mm is ‘mischmetal’, i.e., a technical mixture of rare-earth metals) and their substituted derivatives as MH electrodes in batteries was the low stability of the IMC under electrochemical charge–discharge cycling conditions due to degradation processes.

[†] The content of hydrogen in these materials (v/v) is 1.5 to 2 times higher than in liquid hydrogen.

Since the early '80s, studies in the field of MH electrodes have been directed at increasing the stability of AB₃ type IMC under cycling conditions (requiring the development of multicomponent alloys maintaining the initial hexagonal structure of the CaCu₅ type),¹³ on the one hand, and at the search for electrochemically new species, i.e., IMC of the AB₃ type and the substituted derivatives,^{14,15} multicomponent Laves phases of AB₂ stoichiometry,^{16,17} hyperstoichiometric compounds of AB_{5+x},^{18,19} and AB_{2+x} types,^{17,20–22} IMC in amorphous, nanocrystalline forms and IMC films.^{23–26}

III. The main types of metal hydride electrodes

The adsorption and desorption of gaseous hydrogen on IMC are described by P – T – c diagrams, while those on MH electrodes are described by charge-discharge curves, i.e., plots of electrode potential versus the quantity of electricity passed (Q).

The charging of MH electrodes in alkaline electrolytes occurs because the electrochemical reduction of water gives hydrogen, which is then absorbed by the IMC. During discharge, hydrogen diffuses from the bulk of the IMC to the electrode surface and is oxidised. The electrochemical adsorption-desorption of hydrogen by AB_x compounds can therefore be represented by the following general equation:

A charge of one electron corresponds to each absorbed hydrogen atom, and the charge-discharge capacity (C) per unit mass (m) is determined by the equation:

$$C = \frac{Q}{m}.$$

The charge-discharge curves used for the determination of the full hydrogen capacity of electrodes (C_{eq}^0) should be recorded under equilibrium conditions, i.e., at very low charge or discharge currents. In practice, after passing a certain amount of electricity, it is necessary to disconnect the circuit and record the currentless (equilibrium) potential, and then plot graphically the dependence of the amount of electricity passed on the currentless potential. This procedure makes it possible to avoid errors related to the retardation of hydrogen diffusion into the bulk of the electrode and of other steps. In most studies, the full capacity values (C^0) were obtained under nonequilibrium conditions: first, the capacity was determined at high discharge currents (C_h), then the current was diminished (usually, tenfold), and the capacity was determined at low current (C_l). The full capacity is calculated as $C_h + C_l$.

The equilibrium potential of an MH electrode is related to the equilibrium pressure in the adsorption and desorption of hydrogen (p_{H_2}) by the Nernst equation

$$E_r = -\frac{RT}{2F} \ln p_{\text{H}_2}, \quad (1)$$

where E_r is the potential of the MH electrode relative to the reversible hydrogen electrode in the same solution. Thus, the equilibrium hydrogen pressure over the hydride phase that characterises the stability of the latter can be calculated from the potential corresponding to a plateau on equilibrium charge-discharge curves. The main requirements that should be met by MH electrodes used in current sources are high discharge capacity and cyclic stability during electrochemical charge and discharge, $S(N)$

$$S(N) = \frac{C(N)}{C^0} 100 (\%), \quad (2)$$

where $C(N)$ is the discharge capacity at the N th cycle.

Table 1 presents the currently available literature data on the studies of IMC and various alloys, i.e., AB, AB₂, AB₃, AB₅ and their substituted derivatives, as MH electrodes.

1. LaNi₅ and its substituted derivatives

LaNi₅ is an intermetallic compound which has been the most frequently studied electrochemically as an MH electrode. It is characterised by a high discharge capacity (in closed electrochemical cells), electrocatalytic activity and corrosion resistance in alkaline electrolytes. However, despite all of these advantages, LaNi₅ has a significant drawback, viz. low cyclic charge-discharge stability due to degradation processes, the mechanism of which will be considered below.

The partial replacement of Ni in LaNi₅ by Mn, Cu, Cr, Al or Co, which have higher atomic radii than that of nickel, enables the synthesis of IMC with lower equilibrium dissociation pressures of the hydride phases (< 0.098 MPa) with retention of the hexagonal type of the lattice. For example, the replacement of one nickel atom by one aluminium atom decreases p_{H_2} by almost three orders of magnitude.²⁷ Hence, MH electrodes based on such IMC have lower self-discharge due to the desorption of hydrogen as a gas under atmospheric pressure.

A comparison of $S(N)$ values and relative increases in the unit cell volume upon hydrogenation ($\Delta V/V$) showed^{13,27} that alloys, the hydrogenation of which results in insignificant volume increase, have the highest stability. Unfortunately, such alloys normally have low discharge capacity, while both of these parameters should be taken into account in the selection of MH electrode composition.

The considerable increase in the cyclic stability of LaNi₅ when alloyed with cobalt was first noted by Willems.¹³ The effect of the replacement of nickel by cobalt is enhanced when a small amount of silicon or aluminium is added^{13,34} due to the formation of a protective oxide layer on the surface. The presence of this layer, which hinders hydrogen diffusion into the bulk of the metal, increases the overvoltage of the electrochemical charge-discharge of the electrode. The addition of titanium increases the cyclic stability, but simultaneously decreases markedly the electrochemical capacity, unlike neodymium, which increases this parameter. According to the data of Sakai and co-workers³⁴, an alloy in which there is partial replacement of lanthanum by neodymium and of cobalt by aluminium, viz. La_{0.8}Nd_{0.2}Ni_{2.5}Co_{2.4}Al_{0.1}, is the most suitable MH electrode [$C^0 = 241$ mA h g⁻¹, $S(300) = 85\%$].

The partial replacement of lanthanum by zirconium and of nickel by aluminium in LaNi₅ considerably prolongs the operation time of MH electrodes. The optimum compositions correspond to the formula La_{1-x}Zr_xNi_{4.5}Al_{0.5}, where $x = 0.1 - 0.2$.³⁷

2. MmNi₅ and its substituted derivatives

The price of industrially manufactured LaNi₅ on the world market is ~\$30 US per kg.³⁹ The cost of MH electrodes can be reduced considerably if the lanthanum in the IMC is completely or partly replaced by 'mischmetal'. However, this replacement increases the dissociation pressure of the hydride phases. For example, this value is ~1.5 MPa at 298 K for MmNi₅.⁴⁰

To decrease the equilibrium pressure over the hydride phase in MmNi₅, as in the case of LaNi₅, it is necessary to partly replace nickel by such metals as aluminium or manganese.^{28,41} It was found that MmNi₅ should be alloyed not only with aluminium or manganese, but also with cobalt in order to enhance the cyclic stability of MH electrodes.^{41,43} It is remarkable that a profound effect is observed upon replacement of as little as one nickel atom by a cobalt atom, whereas the optimum replacement number for LaNi₅ is from 2 to 2.5 nickel atoms. This may be connected with the presence of Ce in the Mm.

The general criteria for selection of the IMC composition of the MmNi₅ type are the same as in the case of LaNi₅, and the optimum compositions differ only in the quantity of components added (see Table 1).

3. Nonstoichiometric intermetallic compounds AB_{5+x}

In the early 1990s, the first reports appeared^{18, 70–73} on the electrochemical behaviour of hydrogen-absorbing nonstoichiometric alloys. It was assumed^{72, 73} that a portion of the La atoms in the crystal lattice of LaNi₅ can be replaced by B atoms (one La atom is replaced by two B atoms) to form a new class of nonstoichiometric compounds AB_x, where $x > 5$.

The first compounds studied were two-phase.^{20, 74} In addition to the AB₅ phase, they contained a second, electrochemically highly reactive phase homogeneously distributed at the grain boundaries of the main alloy. This second phase contained transition metals; it was difficult to predict its composition, although it was undoubtedly determined by the thermodynamic stability of the corresponding compounds.

A detailed study¹⁸ of AB_{5.5} type IMC, such as La_{0.8}Nd_{0.2}Ni₃Co_{2.4}Si_{0.1} and La_{0.8}Nd_{0.2}Ni_{2.9}Mo_{0.1}Co_{2.4}Si_{0.1}, using scanning electron microscopy, optical microscopy, and electron microanalysis showed that cooling of homogeneous alloys resulted in the formation of grains of an AB₅ type of hydride-forming alloy, NiCo₃ (in the former case) or MoCo₃ (in the latter case) being distributed at the grain boundaries. It is likely that it is the

presence of these phases that results in a two- to threefold increase in the exchange current density of the hydrogen evolution reaction, since, according to the Brewer–Engel⁷⁵ valence bond theory, the simultaneous presence of Ni and Co or Mo and Co can cause a synergistic effect.

Such properties as the capacity and the cycling stability of two-phase and of the corresponding single-phase systems are similar, since they are determined by the main alloy. However, the discharge properties of two-phase systems are significantly better.

Later, single-phase nonstoichiometric alloys were obtained by the homogenising annealing of La(NiCu)_x alloys, where $5 \leq x \leq 6$, and their electrochemical characteristics were studied.¹⁹ It was found that an increase in x increases the annealing temperature required for obtaining single-phase samples, decreases the discharge capacity, and lengthens the activation process. However, the cyclic stability of electrodes is improved considerably: the residual discharge capacities of LaNi₄Cu and LaNi₅Cu after 400 charge-discharge cycles are 16% and 98%, respectively.

Based on measurements of the adsorption isotherms of gaseous hydrogen, a phase diagram of Cu-containing AB_x–H₂ ternary systems was plotted (Fig. 1).¹⁹ The region of coexistence of α - and β -hydride phases rapidly narrows as x increases and completely disappears at a certain 'critical' composition that approximately corresponds to the formula LaNi_{4.4}Cu. The isotherm of hydrogen sorption by this compound contains almost no horizontal plateau corresponding to the $\alpha \rightleftharpoons \beta$ transition.

4. Intermetallic compounds of AB₃ type and their substituted derivatives

The electrochemical behaviour of the IMC of the composition AB₃ has so far been studied only for the CeNi_{3–x}Co_x and YNi_{3–x}M_x systems, where $M = \text{Al, Fe, Co, Cu, Mn}$ and Cr.^{14, 15, 76–78} Increase in the cobalt content of CeNi_{3–x}Co_x increases the thermodynamic stability of the corresponding hydride phases and decreases the equilibrium dissociation pressure from 0.5×10^3 Pa for CeNi₃ to 0.2×10^3 Pa for

Figure 1. Phase diagram for Cu-containing AB_x–H₂ ternary systems.¹⁹

CeNiCo₂ at 293 K.¹⁴ The electrochemical charge–discharge processes of the IMC of this system follow the equation

Because a stable monohydride of the IMC is formed, the reversible electrochemical capacity of these MH electrodes is lower than that of LaNi₅ and MmNi₅ electrodes.

The partial replacement of Ni in YNi₃ by Al, Co, Fe, Mn, Cr, or Cu has almost no effect on the reversible electrochemical capacity but increases (except for Cr) the equilibrium dissociation pressure of the corresponding hydride phases.¹⁵

5. Ti–Ni alloys and their substituted derivatives

Ti–Ni alloys were the first materials studied as MH electrodes.^{6,7} The electrochemical charging capacity of the Ti₂Ni alloy is 425 mA h g^{−1}, which corresponds to the formation of the hydride Ti₂NiH_{2.5}. On the other hand, the discharge capacity is considerably lower (250 mA h g^{−1}), i.e. part of the hydrogen (~1 mol) is not available electrochemically. Unlike Ti₂Ni, the intermetallic compound TiNi is a totally reversible electrode with a discharge capacity of 250 mA h g^{−1}.

When equimolar amounts of TiNi and Ti₂Ni are present simultaneously, the reversible electrochemical capacity of the system increases to 320 mA h g^{−1}, which corresponds to the oxidation of ~85% of the hydrogen; the final composition of the system is Ti₂NiH_{0.5} + TiNi. It was assumed⁷ that the complete discharge of TiNiH into TiNi with simultaneous partial discharge of the Ti₂NiH_{2.5} phase occurs in the first step, and then redistribution of hydrogen between the Ti₂NiH_x phase and TiNi takes place along with its further electrochemical oxidation, i.e. the TiNi phase has a specific 'catalytic' effect on the completeness of the electrochemical discharge.

The introduction of zirconium to Ti–Ni alloys decreases the discharge capacity due to the formation of ZrNi and Zr₂Ni intermetallic compounds, which have very low discharge capacity because of the formation of hydride phases with strongly bound hydrogen states.⁶⁰ The capacity of Ti_{0.8}Zr_{0.2}Ni_x alloys is considerably higher at $x > 1$. This may be due to the formation of a hydride phase based on Zr₇Ni₁₀, whose enthalpy of formation is lower than that of a hydride phase based on ZrNi. An increase in the zirconium content in the Ti–Zr–Ni alloy results in a noticeable increase in the cyclic stability, but a greater number of activation cycles is then required for attaining the appropriate discharge capacity.

6. Metal hydride electrodes based on multicomponent Laves phases

Titanium and zirconium do not form two-component Laves phases with nickel. These phases can exist only in ternary systems with partial substitution of nickel for other metals.⁷⁹

Of two-component alloys with the AB₂ stoichiometry, ZrV₂, ZrCr₂, ZrMn₂, TiCr₂, and TiMn₂ have attracted most attention. They are characterised by the high stability of hydride phases that can be considerably decreased by replacing part of the zirconium by titanium and of the second metal by iron, cobalt, copper, nickel, or by addition of a hyperstoichiometric amount of a B-type element, or by a combination of these methods.

Alloys based on ZrV₂ with partial replacement of vanadium by nickel and of zirconium by titanium were first proposed for use in MH electrodes in a patent¹⁶ and were then studied more thoroughly by several workers.^{17,80} It was found that the content of vanadium and nickel should lie within the limits Zr._{0.1–0.6}Ni_{1.9–1.4} in order to provide optimum discharge and cyclic characteristics. The high discharge capacity of hyperstoichiometric alloys of the composition Zr(V_{0.33}Ni_{0.67})_{2.4} predetermined their choice as a base material for developing multicomponent MH electrodes with improved characteristics.¹⁷

The replacement of 12.5% to 25% of the nickel by manganese results in an increase in the discharge capacity, which is ~370 mA h g^{−1} for the Zr(V_{0.33}Ni_{0.50}Mn_{0.17})_{2.4} alloy. The partial replacement of zirconium by titanium decreases the discharge capacity, whereas the replacement of nickel by cobalt or iron somewhat increases the discharge capacity. The introduction of a small amount of aluminium to Zr–V–Ni alloys noticeably increases the cyclic stability of MH electrodes. For example, the Zr(V_{0.33}Ni_{0.67})_{2.4} alloy loses ~43% of the original capacity after 100 charge–discharge cycles, whereas the Zr(V_{0.33}Ni_{0.67})_{2.4}Al_x alloys, where $x = 0.05–0.1$, lose as little as 12–15%.

It has been shown⁵⁷ that the partial replacement of manganese by vanadium in multicomponent alloys based on a ZrNi_{1.2}Mn_{0.6}Cr_{0.2} Laves phase considerably increases the discharge capacity: from 240 mA h g^{−1} for ZrNi_{1.2}Mn_{0.6}Cr_{0.2} to 360 mA h g^{−1} for ZrNi_{1.2}Mn_{0.3}Cr_{0.2}V_{0.3}.

At present, the number of studies and patents dealing with MH electrodes based on multicomponent Laves phases of the AB₂ stoichiometry approaches that concerning multicomponent alloys of the AB₅ type based on lanthanum or the 'mischmetal' (see Table 1); this is a result not only of the acceptable exploitation characteristics of these materials but also of their lower cost.

7. Thin-film, nanocrystalline and amorphous MH electrodes

In the early 1990s, Adachi et al.⁸¹ used flash evaporation–deposition of a LaNi₅ powder onto a support to synthesise a thin, highly porous film that was stable under conditions of repeated sorption–desorption of gaseous hydrogen but possessed poor adhesion and lower sorption capacity than the bulk alloy.

Later, denser thin LaNi₅ and LaNi_{2.5}Co_{2.5} films were obtained by high-frequency spraying.^{82,83} Depending on the nature of the target and support and on spraying conditions (beam power, spraying time and support temperature), the films were either amorphous or crystalline. In the authors' opinion, the absence of a plateau on the discharge curves in alkaline solutions suggested that the adsorption of hydrogen gave only a solid solution without the formation of a new hydride phase.

The discharge characteristics listed in Table 2 for MH electrodes of this type show that a decrease in the absorption capacity occurs on passing from bulk alloy to crystalline, and further to amorphous, film. This can be ascribed to the change in the distribution of crystallographic cavities suitable for hydrogen sorption and to an increase in the strength of the crystal lattice in thin films. The cyclic electrochemical stability of LaNi_{2.5}Co_{2.5} films was found to be much higher than that of LaNi₅ films. The stability of films obtained in an atmosphere of hydrogen was higher than that of films obtained in argon, but their maximum capacity was twice as low because of the formation of a more stable protective layer on the surface.

Table 2. Discharge capacity and cyclic stability of powder and film MH electrodes.^{83,84}

Form	$C^0/\text{mA h g}^{-1}$	$S(N)\%$
LaNi₅

	160 ^a	60 (500)
LaNi_{2.5}Co_{2.5}		
Powder	240	50 (400)
Crystalline film	120	75 (500)
Amorphous film	80	75 (200)

^a Data from Ref. 84.

Thin-film LaNi_5 and $\text{LaNi}_{2.5}\text{Co}_{2.5}$ electrodes are highly active in the hydrogen evolution reaction, and the exchange currents on these electrodes are of the same order as those on the corresponding compact alloys ($\sim 10^{-4} \text{ A cm}^{-2}$).^{83,84}

Crystalline and amorphous LaNi_5 films obtained by electron-beam evaporation of lanthanum and nickel in an ultrahigh vacuum⁸⁵ have higher capacity and cyclic stability than the films obtained by high-frequency spraying.⁸³

It is unlikely that thin films would find practical use, at least in the near future. However, they are of particular interest in fundamental studies of hydrogen absorption by IMC and alloys.

It was reported recently that the structure of IMC affects the characteristics of MH electrodes.^{23–25} It was found that, as in the case of thin-film electrodes, the amorphisation of the structure of a bulk alloy decreases the discharge capacity of the MH electrodes.²⁴ Of considerable interest are nanocrystalline IMC obtained by the fusion together of the components.^{23,25} With LaNi_5 , it was found²⁵ that these electrodes possess higher discharge capacity, lower equilibrium pressure of hydride dissociation and higher cyclic stability than macrocrystalline IMC. This effect of the size of the IMC particles on the characteristics of hydrogen absorption seems unexpected, since the solubility of hydrogen in Pd-electrodes has been found to decrease with increasing dispersity of Pd when particle sizes are $\leq 10 \text{ nm}$.^{86–89} When the palladium particles are smaller than 2.5 nm, hydrogen is no longer soluble in them.

IV. The technology of the manufacture and activation of metal hydride electrodes

The successful application of compact electrode materials requires their mechanical strength against destruction during charge-discharge and their corrosion stability in electrolyte solutions to be ensured. It is also necessary to solve the problems of electrical conductivity (the contact between the IMC grains), hydrophilicity (wetting) and porosity (accessibility of the whole bulk of an electrode material to the electrolyte). Various technological approaches are used to attain the necessary characteristics.

The mechanical destruction of electrodes due to hydrogen absorption-desorption is prevented by the use of binders, viz., powders of metals (most often Cu, more rarely Ni and Co, and sometimes Au and Pt) or of polymeric organic compounds such as polytetrafluoroethylene (PTFE), polyethylene, polyvinyl alcohol, polystyrene, polyurethane, polyacrylic acid and silicones^{47,90} or combinations of metal and polymeric powders.

The fraction of metal binder in electrode materials usually ranges from 60% to 80%. It has been found for a Cu binder⁶⁵ that increasing the mass ratio, alloy:binder, increases the internal resistance of the electrode material although the discharge characteristics remain almost unchanged.

The content of a polymeric binder is normally 15%–20%. Electron microscopic studies¹⁴ of electrode materials containing polymeric binders showed that in these materials the IMC particles are enclosed in a three-dimensional framework, which, however, does not form a continuous and uniform film of the polymeric binder.

The introduction of acetylene black (up to 10%) is also recommended to improve the electric characteristics of electrode materials containing a polymeric binder,^{46,48} and the hydrophilicity should be controlled by adding hydrophilisers.⁴⁶

Electrode materials containing metal binders are activated more readily and have higher capacity and better charge-discharge reversibility^{15,33} than electrodes with polymeric binders. However, in some cases the metal binder can be oxidised at electrode discharge potentials.

At present, a technological procedure of microcapsulation of the IMC particles with copper, nickel, cobalt, iron and palladium is widely used.^{27,34,52,91–94} The metal coating (up to 20%) is applied by chemical or electrochemical deposition from solutions of the corresponding salts. A compact electrode material is then

produced from the microcapsulated IMC powder with the addition of a polymeric binder (5%–10%). These electrodes have improved discharge characteristics and longer service life.^{52,92}

It has been proposed⁹⁵ to cover the particles of IMC or a binder (coal, acetylene black) with a polymeric film by adsorption from a dilute emulsion of, for example, Teflon. The highest mechanical stability and cycling stability were shown by electrodes with 'teflonated' coal because an elastic, electrically conducting coal-Teflon framework provided a good contact between IMC grains.

A new method for modifying the surface of V-Ti alloys by sintering them with a nickel powder has been proposed.⁹⁶ The VNi_3 phase formed upon sintering is inert with respect to hydrogen, but catalytically affects hydrogen absorption-desorption in alkaline solutions and hence makes it possible to discharge an MH electrode.

All of the procedures for the manufacture of MH electrodes involve the introduction of additional components that decrease the specific capacity of an electrode material; hence, a decrease in the amount of a binder or the manufacture of binder-free electrodes are problems of current interest. In this respect, a noteworthy paper⁹⁷ reports the manufacture of electrodes that maintain their shape by the usual rolling of Zr-V-Ti-Ni-Cr alloys into the active compound without any binders or other additives, possibly due to unique physicochemical properties of these alloys.

Of particular interest are MH electrodes of amorphous alloys. They can be obtained in the form of a ribbon by very fast cooling of a melt and then used without any additional technological treatment.^{47,61,98} However, it is still unclear, for how long the properties of such materials remain unchanged.

When working with MH electrodes, it is important to obtain as high a discharge capacity as possible for the IMC used. This goal is accomplished by activating the electrodes, that is, by repeating charge-discharge cycles, the number of which depends on many factors, primarily, on the IMC composition. However, in most cases the attainable discharge capacity of an MH electrode remains lower than the sorption capacity of the corresponding IMC from the gas phase, and in some cases, satisfactory discharge curves cannot be obtained at all (e.g., for LaCo_5 ,^{84,99} CeCo_3 ,¹⁴ YCo_3 ,¹⁵ and V-Ti.⁹⁶

The following processes occur during the activation of the electrode materials: (i) the alloy particles are dispersed during the absorption-desorption of hydrogen, hence a larger area of fresh, nonoxidized surface of the material is exposed to the electrolyte; (ii) the surface oxides are reduced, dissolved, or become electrically conducting; (iii) a catalytically active metal (e.g., nickel) is accumulated on the surface; (iv) the porosity of the structure increases and access of the electrolyte to an IMC surface becomes easier.

The latter phenomenon has been investigated in several studies^{100,101} by the method of standard porosimetry of the electrode materials prepared from CeNi_3 , CeNi_2Co and ZrNi with a polymeric binder, using two measuring liquids, decane and water.

Fig. 2 presents the integral distribution curves of pore volume vs. their radii (porograms) in an initial electrode material based on ZrNi and PTFE and in the same material after prolonged cathodic polarisation in the region of hydrogen evolution. The total bulk porosity of a nonactivated Zr-Ni electrode is as low as $\sim 13\%$ and is little affected by activation. (For example, activation increases the total bulk porosity of a CeNi_3 electrode (6%–8%) by a factor of 2.5–3.¹⁰⁰) The volume of hydrophilic pores in a Zr-Ni sample is $\sim 50\%$ of the total pore volume; mixed pores occupy a considerable volume (curve 2'). The pore radii in the materials analysed varied from 10^2 to 10^4 nm and almost did not change during activation.

Figure 2. Integral distribution curves of pore volume vs. pore radius for a nonactivated (1, 1') and activated (2, 2', 3) Zr-Ni electrode plotted by measuring the evaporation of water (1, 2, 3) and decane (1', 2').¹⁰¹

Of particular interest in Fig. 2 is curve 3 obtained by measuring the evaporation of water from a Zr-Ni electrode immediately after cathodic polarisation without preliminary drying. In this case, the porosity is almost the same as that measured from decane evaporation. It is likely that during cathodic polarisation, a pressure drop arises in the bulk of the material due to intense liberation of hydrogen. As a result, the electrolyte fills even the hydrophobic pores, and this should increase the effective electrical conductivity of the material.

To decrease the number of activation cycles, IMC powders are sometimes pretreated with reducing reagents (H_3PO_2 , KBH_4)^{61,102} or with solutions of fluorides in order to convert the oxide layer into a fluoride layer.^{31,103} An unexpected enhancement of the activity of Ti-Zr-V-Ni alloys was observed upon their oxidative treatment with oxygen or after anodic polarisation in an alkali.^{17,104} This effect was explained by a change in the structure of the superficial zirconium oxide: a dense hydrogen-impermeable layer of a monoclinic modification of ZrO_2 is transformed into a tetragonal, hydrogen-permeable modification.

When Ti-Zr-V-Ni alloys are treated with a hot concentrated solution of alkali (6 M KOH or 10 M NaOH, 65–70 °C), activation occurs as a result of the modification of the surface layer (accumulation of nickel metal) and of the surface cracking due to the absorption of evolved hydrogen.⁶⁸

The modification of the surface of MH electrodes with palladium and cobalt⁹¹ facilitates activation by acceleration of the hydrogen discharge reaction, and the introduction of small amounts of rare-earth elements (La, Mm, Nd)¹⁰⁵ into ZrCrNi alloys facilitates activation due to the formation of a second, catalytically more active phase, or to a change in the structure of the surface layer.

V. Hydrogen evolution reaction on metal hydride electrodes

The cathodic polarisation of MH electrodes in electrolyte solutions results in the evolution of gaseous hydrogen along with the accumulation of dissolved hydrogen in the bulk of the electrode. The overall cathodic process includes the following steps.

1. Diffusion (convection) of the reacting species from the bulk of the solution to the electrode/solution interface

The 'b' index refers to the solution bulk, and 's' refers to the electrode/solution interface.

2. Charge transfer

3. Diffusion of the reaction products from the surface of the electrode

where H_{in} indicates an intermediate position of H atoms directly below the superficial atomic layer of the metal (near-surface hydrogen).

4. Diffusion of hydrogen into the bulk of the IMC particles

where $\text{H}_{\text{abs}}(\alpha)$ indicates hydrogen dissolved in the α -phase,

where $\text{H}_2(\beta)$ is hydrogen dissolved in the β -phase.

5. Desorption of adsorbed hydrogen

The problem of finding the slow step in such a complex process and determining the rates of separate steps is an independent current problem of electrochemical kinetics and electrocatalysis which still continues to attract attention.

The activity of MH electrodes in the hydrogen evolution reaction (HER) is mostly determined by the elemental composition of the IMC;^{14,84,106–110} it also depends on the composition and properties of the electrode material as a whole (in particular, on the nature and amount of the binder^{95,107}) and on the methods for the manufacture and pretreatment of MH electrodes.^{108,111}

The observation of the low overvoltage of hydrogen evolution on TiNi and LaNi₅ was first made by Miles¹¹² and was confirmed in several studies,^{84,106} in which the exchange currents of the HER on beads of the LaNi₅ and LaCo₅ alloys comparable to those for palladium¹¹³ were observed. The synergistic effect on passing from pure metals to IMC was rationalised in terms of the sharply defined changes in the electronic properties of the alloys when lanthanum, containing 5d-electrons, is introduced.

The electrocatalytic activity of the HER on various electrode materials prepared under similar conditions using Cu and PTFE as binders was the subject of several studies^{14,107} (Table 3). The synergistic effect was not observed, i.e., electrodes based on LaNi₅ and Raney nickel had equal activity. The partial replacement of La by Mm and of Ni by Co decreased, while alloying the IMC with Ce increased, the activity of the electrode. The addition of Nb to LaNi₅ did not result in a noticeable enhancement of its electrocatalytic activity, whereas the addition of Nb to the TiFe alloy accelerated the HER by a factor of ~30.¹¹⁰

Table 3. Electrocatalytic activity of MH electrodes in the HER.^{14,107}

IMC	Binder	$-\log(i_0/\text{A cm}^{-2})$
Ni	PTFE	5.0
LaNi ₅	PTFE	5.0
LaNi ₅	Cu	5.4
La _{0.8} Ce _{0.2} Ni ₂ Co ₃	Cu	5.4
La _{0.7} Nb _{0.3} Ni _{2.5} Co _{2.4} Cr _{0.1}	Cu	5.8
LaNi _{2.5} Co _{2.5}	Cu	5.9
MmNi _{3.5} Co _{0.7} Al _{0.8}	Cu	5.9
LaNi _{2.5} Co _{2.4} Mn _{0.1}	Cu	6.1
Mm _{0.5} La _{0.5} Ni ₂ Co ₃	Cu	6.1
CeCo ₃	PTFE	4.6
CeCo ₂ Ni	PTFE	4.0
CeCoNi ₂	PTFE	3.7
CeNi ₃	PTFE	3.2

The activity of $\text{CeNi}_{3-x}\text{Co}_x$ electrodes increased¹⁴ on increasing the Ni content of the alloy, and the exchange current density on CeNi_3 was found to be close to that on Pd.

The decrease in activity of LaNi_5 on passing from a PTFE binder to a Cu binder has not been rationalised.¹⁰⁷ This seems to be partially related to the difficulties in the determination of the actual electrode surface on which the HER occurs. For example, it was found for Ni electrodes prepared by different procedures¹¹⁴ that hydrogen overvoltage is simultaneously affected by the inherent activity of the electrode material and by the change in the area of the real surface. To separate these effects it is necessary to compare the results obtained from polarisation curves and from impedance spectroscopy.

Hydrogen evolution on palladium, its alloys and hydrogen-sorbing materials occurs according to the Volmer–Tafel scheme. The overall overvoltage of the reaction (η) is a sum of overvoltages of the Volmer reaction (η_1) and the Tafel reaction (η_2) determined from the curves of decay (or rise) of potential after switching off (or on) the polarising current (η , t -curves). The kinetics of hydrogen evolution on palladium was considered taking several rate-determining steps into account,¹¹⁵ which made it possible to describe completely the experimental polarisation η , $\log i$ -curves.

Information on the mechanism and kinetics of the HER in alkaline solutions on LaNi_5 and Ti–Ni alloys was obtained using electrodes as thin amorphous films that are more stable mechanically during hydrogen sorption-desorption than the corresponding bulk alloys.¹¹⁶ The results of quantitative processing of the η , t -curves presented in Table 4 showed that hydrogen evolution on LaNi_5 and Ti–Ni alloys occurs according to the Volmer–Tafel mechanism with comparable exchange currents of both steps. The slope of the straight regions on the η , $\log i$ -curves was 120 mV, hence, at high η the overall reaction rate is determined by the charge transfer step. The exchange current ($i_{0,\text{exp}}$) obtained by extrapolating the η , $\log i$ -dependence to $\eta = 0$ differed from that obtained by the formula

$$\frac{1}{i_0} = \frac{1}{i_{0,\text{V}}} + \frac{1}{i_{0,\text{T}}},$$

where $i_{0,\text{V}}$ and $i_{0,\text{T}}$ are the exchange currents of the Volmer and Tafel reactions, respectively.

Table 4. Kinetic parameters of the HER on various cathodes in 1 M NaOH at 303 K.¹¹⁶

Sample	Thickness /Å	Exchange current density / $\mu\text{A cm}^{-2}$			
		$i_{0,\text{V}}$	$i_{0,\text{T}}$	i_0	$i_{0,\text{exp}}$
LaNi_5	2000	3.22	0.70	0.58	1.7
	2000	3.86	0.68	0.57	
Ni	1000	—			1.4
Ni (wire)					0.45
$\text{Ni}_{0.11}\text{Ti}_{0.89}$	2000				2.1
$\text{Ni}_{0.5}\text{Ti}_{0.5}$	1500	2.46	0.93	0.67	1.7
$\text{Ni}_{0.76}\text{Ti}_{0.24}$	1500	2.76	0.15	0.81	2.6

It is evident from Table 4 that the $i_{0,\text{exp}}$ values on thin-film alloys are similar to those on a nickel film and nickel wire as well as to the values previously obtained on amorphous NiTi .¹¹⁷ Thus, the electrocatalytic activity of thin-film electrodes studied is determined by nickel, while synergism between lanthanum and nickel or titanium and nickel is not observed.

Results supporting the Volmer–Tafel mechanism for the hydrogen evolution reaction were also obtained for MH electrodes based on LaNi_5 , MmNi_5 , and $\text{MmNi}_{3.6}\text{Mn}_{0.4}\text{Al}_{0.3}\text{Co}_{0.7}$ powders.^{99,118} The $i_{0,\text{V}}/i_{0,\text{T}}$ value is, for example, ~ 9 for the $\text{MmNi}_{3.6}\text{Mn}_{0.4}\text{Al}_{0.3}\text{Co}_{0.7}$ system, which suggests a mixed character for the rate-determining step. The addition of oxides such as Co_2O_4 or RuO_2 to an electrode material markedly

accelerates the Volmer reaction and only slightly changes the rate of the Tafel reaction.

On the whole, however, the problem of the relation between the activity of IMC and its components with respect to the hydrogen evolution reaction cannot be regarded as completely solved. Solution of this problem requires the development of a procedure for the measurement and consideration of the real electrode surface area. On the other hand, the gradual change in the electronic properties of these materials on changing their composition affords a unique opportunity to reveal the fundamental problems of the nature of electrocatalytic activity.

VI. Charge-discharge processes on metal hydride electrodes

The electrochemical method of saturation of IMC with hydrogen requires much simpler equipment than that for saturation with gaseous hydrogen. However, electrochemical saturation at potentials corresponding to effective pressures above 0.098 MPa ($E_r < 0$ V) cannot be performed under equilibrium conditions due to concurrent hydrogen evolution. Thus, the effectiveness of MH electrode charging is determined by the ratio between the rates of hydrogen diffusion into the bulk of IMC particles and its desorption into the electrolyte bulk. The driving force of the sorption process is the difference between the chemical potentials of hydrogen on the surface, which is determined by the surface coverage by hydrogen, and in the bulk, which is determined by the overall fraction of occupied absorption sites.

Hydrogen sorbed by metals can exist in three different forms, namely, adsorbed hydrogen, hydrogen in a near-surface layer and dissolved hydrogen. An equilibrium is established between these forms. The quantity of near-surface hydrogen does not depend, while that of adsorbed hydrogen does depend, on the nature of the surface.¹¹⁹ The sorption of hydrogen can be accompanied by phase transitions such as the formation of hydride phases (e.g. the $\alpha \rightleftharpoons \beta$ transition in the case of the Pd electrode). No data are available on the type of isotherms of hydrogen electrochemical sorption on IMC, while the sorption isotherms on the Pd electrode differ in the α , $\alpha \rightleftharpoons \beta$, and β regions.^{1,120}

Under equilibrium conditions, the relation between the pressure of sorbed hydrogen (p_{H_2}) and the electrode potential is determined by the Nernst equation. At a cathodic polarisation, the dependence of p_{H_2} on η deviates from the Nernst equation and is determined by the mechanism of hydrogen evolution and the ratio of exchange currents of its different steps. In the case of the Volmer–Tafel mechanism, the relation between the hydrogen pressure at a certain polarisation (\bar{p}) and that at the equilibrium potential (\bar{p}_0) depends on the contribution of the overvoltage η_2 for the Tafel step by the equation¹¹³

$$\eta_2 = \frac{RT}{2F} \ln \frac{\bar{p}}{\bar{p}_0}.$$

It was found¹⁰⁸ that, after cathodic polarisation of a ZrNi electrode at potentials of hydrogen evolution followed by circuit disconnection, stationary potentials are established and maintained in the region from -0.04 to -0.008 V, depending on the polarisation potential and the composition of the solution. In addition, the passage from $\eta < -0.1$ to the -0.08 to -0.006 V range resulted in a considerable anodic current, which gradually decreased over a long period (hundreds of seconds), until converted into a cathodic current and attained the values corresponding to the rate of hydrogen evolution at the corresponding potential. An additional study showed that this does not result in dissolution of IMC components. The effects observed are evidently related to prolonged retention of hydrogen in the bulk of IMC due to hindrance of the recombination step or interphase transfer of hydrogen.^{115,121}

The amount of the hydrogen sorbed can be determined by recording the discharge curves under galvanostatic conditions, i.e., by measuring the potential versus time at constant I , or under potentiostatic conditions, by measuring the current versus time at constant E .

The process of electrochemical discharge involves the following steps:

Each of these can be the rate-determining step under certain conditions.

Metal hydride electrodes based on IMC and a binder are porous and differ considerably both from gas-diffusion porous electrodes^{136,137} and from liquid-containing porous electrodes.¹³⁸ Gas-diffusion electrodes contain pores flooded with the electrolyte and gas-filled pores, through which the gaseous reagent is transported into the bulk of the electrode to the active catalyst surface. Porous electrodes made of hydrogen-sorbing IMC do not require gas porosity. These electrodes differ from liquid-containing electrodes by the continuous supply of the reagent by diffusion from inside material particles to their outer surfaces where the electrochemical reaction occurs. Thus, porous MH electrodes should be regarded as systems with parameters distributed over the electrode thickness and over the IMC particle radius (Fig. 3).

Figure 3. A model of a porous hydrogen-sorbing electrode:¹²⁶ (1) IMC particles; (2) solution-containing pores; (3) metal current collector; (l) electrode thickness; (r) radius of an IMC particle.

Several mathematical models have been suggested for the description of experimental discharge curves. These models can be divided into two groups: in one group, the models consider hydrogen diffusion only within IMC particles (along the radius r , see Fig. 3),^{31,122–125} while in the other, models also take into account diffusion across the electrode thickness (along the coordinate l).^{126,127}

Pshenichnikov and co-workers^{122,123} proposed a model for calculating galvanostatic charge-discharge curves on an isolated spherical grain of a hydrogen-absorbing metal. Assuming that potential E is a single-valued function of the degree of surface coverage by adsorbed hydrogen, which is related to the hydrogen concentration in the bulk by the Frumkin isotherm, the authors took the nonstationary mass transfer in a unit grain into account and obtained a relation between E and the amount of electricity

Figure 4. A scheme for the variation of the hydrogen concentration in a spherical particle during discharge:³¹ (c_H) hydrogen concentration in the β -phase; (c'_H) hydrogen concentration at the interface between the α - and β -phases.

passed. By adjusting the adsorption equilibrium constant within this model, they managed to obtain qualitative agreement between the experimental and calculated data. If one assumes that the electrode consists of particles with two different radii, charge-discharge curves with two delays can be obtained. Based on this model, it was concluded that the total charging and discharging of a grain are impossible if the diffusion current is commensurate with the charging current.

It was believed^{31,124} that the quantity of ionised hydrogen is proportional to the thickness of the surface α -layer (Fig. 4) and that the rate of discharge at low discharge currents is determined by hydrogen diffusion in the α -phase. Under these conditions, the dependence of the discharge capacity (C) on the discharge current (I) has the following form:

$$C = C^0 \left\{ 1 - \left(1 + \frac{C^0 k_5}{I} \right)^{-3} \right\},$$

where C^0 is the discharge capacity (at $I \rightarrow 0$) and k_5 is the rate constant of the discharge step (5).

At high discharge currents, the rate-determining step is the electrochemical reaction occurring on the Ni-centres

and the dependence of the discharge capacity on the discharge current acquires the form

$$C = C^0 \left\{ 1 - \exp \left[-k_6 \left(\frac{C}{I} \right)^n \right] \right\}, \quad (7)$$

where n is an empirical constant and k_6 is the rate constant of reaction (6).

The model proposed was tested for a $\text{LaNi}_{4.7}\text{Al}_{0.3}$ electrode. The dependences of $\log \log [1/(1 - C/C^0)]$ on $\log(C/I)$ contained a break point at currents of ca. 1000 mA g^{-1} , which indicated a change in the discharge mechanism. The experimentally determined discharge capacities coincided with those calculated by equation (7); the k_6 value depended on the duration of the treatment of the electrode surface with a potassium fluoride solution due to changes in the composition of the surface layer.

The basic feature of yet another model¹²⁵ is the possibility of quantitative processing of step (4) as a heterogeneous chemical reaction. The authors derived equations for hydrogen diffusion in the bulk of electrodes of various shapes (plate, cylinder, sphere), which coincide with the equations obtained previously by Bucur et al.^{128,129} who theoretically described the ionisation of hydrogen dissolved in a Pd electrode. The concentration of hydrogen in the

near-surface layer (c_H^s) at low D/l^2 (where D is the diffusion coefficient of hydrogen and l is a parameter determined by the electrode size) and low discharge currents decreases linearly with increase in the discharge time (t). At high D/l^2 and/or higher discharge currents, the c_H^s value linearly depends on t only within a narrow time range. In this case, when c_H^s reaches zero (i.e., the discharge is effectively finished), the bulk of the electrode still contains a fraction (f) of the dissolved hydrogen that cannot be ionised because of the limited rate of hydrogen diffusion. The value

$$f \approx \frac{Il}{c^0 D}$$

(where c^0 is the initial concentration of the dissolved hydrogen) characterises the effectiveness of discharge. It depends on the electrode geometry and decreases in the series: plate > cylinder > sphere.

Based on the theoretically derived equation for the dependence of the electrode potential on t under galvanostatic discharge conditions, experimental discharge curves for MH electrodes made of $ZrNi_2$, $Zr(V_{0.33}Ni_{0.67})_{2.4}$ and $Zr(CrFe)_2$ were analysed and the kinetic parameters of steps (3)–(5) were calculated. They were found to depend not only on the electrode composition but also on the surface structure or the phase composition of the hydride phase.

The discharge capacity at low discharge currents is obtained by subtracting two quantities linearly dependent on the current, the first one being related to the limiting rate of hydrogen diffusion in the electrode bulk and the other to the limiting rate of hydrogen transfer from the adsorbed state, from the equilibrium capacity C ,

$$C = C^0 - \frac{Il}{aD} - C_0 \frac{I}{Fk_4 c_H^0},$$

where a is a constant depending on the electrode geometry, and k_4 is the rate constant of reaction (4). Thus, the linear C/I dependences observed at low discharge currents are analogous to those found in a previous study.¹²⁸

At high discharge currents

$$C = (C^0)^2 \frac{\pi D}{bISl^2} \left(1 - \frac{ISl}{cFk_4 c_H^0} \right)^2$$

where b and c are constants depending on the electrode geometry, and S is the surface area of the electrode.

The model described above is applicable only when the chemical potential of hydrogen (μ_H) changes continuously with changes in the concentration (c_H) in the bulk of the electrode; in particular, this is the case for amorphous films. In the case of crystalline alloys, for which the μ_H, c_H -dependences contain a plateau due to a phase transition, the model describes only single-phase regions (the starting and terminal regions) of the discharge curves.

Models based on the macrokinetics of the ionisation of the dissolved hydrogen in porous MH electrodes have also been proposed.

A theory was proposed¹²⁶ that considered a porous planar electrode of thickness l consisting of spherical IMC particles of radius r . The joint application Fick's second law and theories of slow discharge and charge-discharge of the electric double layer gave a system of equations with four dimensionless parameters determined by the characteristic times of the following processes: hydrogen diffusion in a particle; charging of the electric double layer of a porous electrode; charging of the electric double layer of a smooth electrode; and reactions of hydrogen ionisation. In the general case, an analytical solution of this system is difficult; however, numeric modelling is possible by variation of three parameters: the diffusion coefficient of hydrogen, the capacity of the electric double layer and the exchange current density.

By choice of the parameters, one can obtain the distribution of hydrogen concentration in the bulk of the particle and across the electrode thickness. When diffusion limitations prevail over ohmic limitations, the hydrogen distribution in the bulk of the electrode should play the major role. This dependence can be obtained by analytical methods.

A model was proposed¹²⁶ for the description of the discharge process by comparing the calculated and experimental potentiostatic discharge curves for an MH electrode compressed from a $CeNi_3$ powder with 20% PTFE. This model is applicable to any systems containing a phase of a reducible or oxidisable component; in particular, it was used for describing the charge-discharge behaviour of porous polyaniline electrodes under galvanostatic conditions.¹³⁰

The following drawbacks of the model proposed by Volfkovich et al.¹²⁶ should be noted: first, electrode charging is complicated by a phase transition, which can be taken into account formally only by varying the double layer capacity; second, the step of interphase transfer of hydrogen (4) is not taken into account.

Another treatment of porous systems has been proposed¹²⁷ for a cylindrical electrode consisting of spherical IMC particles. The model takes into account the diffusion of hydrogen in the bulk of IMC particles (based on Fick's second law), the charge transfer and the potential drop in the IMC particles and in the electrolyte that fills the pores. For the majority of metals the potential drop in the metal phase is low: cycling of the electrode can decrease the electrical conductivity of the powder, e.g. due to the oxidation of the surface or impairment of contacts between the particles. Because the equations obtained¹²⁷ are very complex and the model uses a great number of parameters, it is difficult to apply this model to the analysis of experimental discharge curves. Furthermore, it does not permit calculation of the kinetic parameters of reactions (3)–(5).

Thus, none of the mathematical models proposed for describing the discharge process is general, since they do not take into account all the steps of the process. The models assume that the diffusion coefficient of hydrogen (D) does not depend on its concentration in the alloy, whereas the existence of this dependence has been established experimentally.^{131,132} In addition, the models proposed do not take into account the specific nature of the $\alpha \rightleftharpoons \beta$ transition, except for the formal introduction of an infinitely large capacity corresponding to this transition.¹²⁶

VII. Corrosion of metal hydride electrodes

One of the main properties of MH electrodes required for their practical application is a sufficiently high stability during repeated electrochemical charge-discharge cycles in electrolyte solutions. As has been noted, the measure of the cyclic stability is the $S(N)$ value, which is primarily determined by the nature of the IMC and the binder, the manufacturing method, and the pretreatment of the electrode.

The high stability of AB_5 type IMC containing Al, Si, Ti and Zr is determined by a superficial oxide film formed during electrode cycling in alkaline solutions.^{13, 29, 34, 37, 117, 133, 134}

The addition of manganese to alloys, often used for decreasing the hydride dissociation pressure, impairs the corrosion stability of IMC. This is caused by the diffusion of manganese from the bulk to the surface and degradation of the alloy to give hydroxides of manganese and rare-earth elements as well as metallic nickel.^{27,33}

The increase in the plasticity of alloys on alloying $LaNi_5$ with Co decreases the rate of its dispersal and, as a consequence, decreases the newly formed surface prone to oxidation, imparting high stability to the alloy during cycling.^{135–138}

It has been shown that the corrosion stability of the intermetallic compound $LaNi_{4.5}Mn_{0.5}$ produced under diverse conditions is affected by the disruption of the atomic order within the same AB_5 crystalline system: homogenisation of the structure increases the stability of the material.³⁰

The effect of homogenising annealing or rapid cooling on the cyclic stability of $\text{MmNi}_{1.5}\text{Co}_{0.7}\text{Al}_{0.8}$ is explained⁴³ by the difference in size of IMC grains formed ($\sim 50 \mu\text{m}$ in the former case and $\sim 10 \mu\text{m}$ in the latter), assuming that a protective oxide layer can be formed not only on the particle surface, but also at the grain boundaries. In the case of the quenched alloy, the cyclic stability was found experimentally to increase with decreasing grain size.

The spectrophotometric analysis of 1 M NaOH solutions after prolonged potentiostatic polarisation of YNi_3 and YCo_3 electrodes in these solutions showed¹⁵ that the rate of yttrium dissolution from the IMC is lower by at least an order of magnitude than that from the pure metal, even at potentials much higher than the potential of the anodic boundary for total IMC dehydrogenation. Nickel and cobalt were found not to pass into solution over the whole range of potentials studied.

When an IMC of an AB_x type contacts an electrolyte, corrosion can be represented as follows:

As a result of this heterogeneous reaction, the amount of the hydrogen-sorbing compound decreases in proportion to the specific surface. Thus, the larger the IMC particles, the weaker should be the trend to decreasing capacity. The validity of this hypothesis was confirmed for $\text{LaNi}_{4.4}\text{Cu}$ electrodes produced from powders with different specific surfaces.²²

As follows from the above considerations, the disintegration of IMC grains into smaller particles during the charge-discharge process stimulates corrosion. The comminution of IMC grains is caused by the coexistence of various hydrides on the surface. These hydrides increase the volume of the unit cell to different extents; as a result, mechanical stress appears at the boundaries of hydride grains, leading to brittleness of the system and to increased local mobility of metal atoms contained in the IMC.^{13, 29}

These concepts were further developed in a study of the effect of electrode cycling on: the in situ X-ray diffraction spectra; the hydrogen concentration; the variation of the unit cell volume upon formation of α - and β -phases ($V_\beta - V_\alpha$); the variation of the overall unit cell volume upon hydride formation ($V - V_0$); and the electrode stability (Table 5).¹⁹

The ($V_\beta - V_\alpha$) and ($V - V_0$) values for the LaNi_x and $\text{LaNi}_{x-1}\text{Cu}$ electrodes decrease with an increase in the non-stoichiometry of a system, the ($V_\beta - V_\alpha$) value decreasing much more quickly. The introduction of copper into the alloy primarily affects the ($V_\beta - V_\alpha$) value. The stability of the alloys is determined by the changes in the volume of the unit cell upon formation of the β - and α -phases. An increase in ($V_\beta - V_\alpha$) enhances mechanical strain and the desintegration of the alloy particles in agreement with the results of microscopic studies.

A mathematical model of the degradation of MH electrodes has been developed²² based on the assumption that the specific surface is the main factor determining the rate of particle oxidation.

Table 5. Stability of MH electrodes and changes in unit cell volume upon hydride formation.¹⁹

Alloy	AB_x	$(V_\beta - V_\alpha)/V_0$ (%)	$(V - V_0)/V_0$ (%)	$S(400)$, (%)
LaNi_5	AB_5	21.5	22.5	15
$\text{LaNi}_{5.4}$	$\text{AB}_{5.4}$	19.9	22.0	25
LaNi_4Cu	AB_5	17.0	21.2	16
$\text{LaNi}_{4.2}\text{Cu}$	$\text{AB}_{5.2}$	13.2	19.7	62
$\text{LaNi}_{4.4}\text{Cu}$	$\text{AB}_{5.4}$	2.8	18.2	90
LaNi_3Cu	AB_6	0.0	8.5	98

For spherical particles with initial radii r_0 , the electrode capacity after cycling for a period t is

$$C_t^{1/3} = C_t(0)^{1/3} - t \left[\frac{1}{3} C_t(0)^{1/3} S_0 k_9 a_{\text{H}_2\text{O}} M_{\text{AB}_x} \right] t \quad (10)$$

where $C_t(0)$ is the electrode capacity before cycling, S_0 is the initial specific surface of the powder, $a_{\text{H}_2\text{O}}$ is the activity of water, M_{AB_x} is the IMC mass, and k_9 is the rate constant of reaction (9). If the diffusion of the water molecules is not the rate-determining step, then a linear dependence of $C_t^{1/3}$ on t should be observed. Such dependence was obtained for $\text{LaNi}_{4.4}\text{Cu}$ electrodes with three different S_0 values.²² The increase in the slope of the straight lines correlated well with the size of the alloy particles. All three straight lines intersected at one point but not at $t = 0$.

Equation (10) can be transformed into

$$C_t = C_t(0) \exp(-S_0 k_9 a_{\text{H}_2\text{O}} M_{\text{AB}_x} t) \quad (11)$$

Since $t = bN$, where b is a proportionality factor, relation (11) is analogous to the empirical equation¹³

$$C(N) = C_0 \exp\left(-\frac{N}{N^*}\right), \quad (12)$$

where C_0 is the maximum capacity, $C(N)$ is the capacity in the N th cycle, and parameter N^* reflects the rate of capacity decrease and is regarded as a stability constant. It follows from equations (11) and (12) that

$$N^* = \frac{1}{S_0 k_9 M_{\text{AB}_x}}.$$

One of the drawbacks of the model is that it does not account for the dependence of the oxidation rate on the surface state (oxidised or reduced) and on the potential. In addition, cycling gradually changes the composition of the surface layer and, hence, its protective properties.

A model including the changing discharge capacity of MH electrodes caused during cycling proposed in another study³¹ simultaneously accounts for the discharge and degradation processes. During low-current cycling, the decrease in the capacity over time should obey the following equation:

$$C(I, N) = C(0, 0) \left\{ 1 - \left[1 + \frac{C(0, 0) k_1}{I} \right]^{-3} \right\} \times \\ \times [1 - P \exp(-FN)] \exp(-K_N N), \quad (13)$$

while during high-current cycling, the following equation is obeyed:

$$C(I, N) = C(I, 0) [1 - P \exp(-kN) \exp(-k_1 N)] \\ C(I, 0) = C(0, 0) \left\{ 1 - \exp\left[-\frac{v_1 C(I, 0)^n}{I^n}\right] \right\}, \quad (14)$$

where $C(0, 0)$ is the capacity at the zeroth cycle, I is the discharge current, N is the number of galvanostatic cycles, k_1 is the rate constant of the electrochemical discharge reaction, P is the fraction of the hydrogenated alloy particles active in the cycling, k is the rate constant of the MH electrode activation, K_N is the factor of degradation of the capacity of the MH electrode equal to $S_c L \gamma^2 \Delta t$ (S_c is the fraction of corroded specific surface, L is the number of hydride particles per unit area, γ is the rate of hydride growth, and Δt is the time of corrosion during each charge-discharge cycle), v_1 is the rate of the electrochemical reaction, and n is an empirical constant.

The dependence of the discharge capacity of untreated and fluoride-treated $\text{LaNi}_{4.7}\text{Al}_{0.3}$ electrodes on the discharge current and the number of cycles were plotted, the constants were calculated by use of equations (13) and (14), and three-dimensional C, I, N -diagrams were plotted.³¹ The dependence of kinetic and corrosion characteristics on the time of treatment of

the electrodes with fluoride ions was explained by the following reactions:

leading to the accumulation of catalytically active nickel and of LaF_3 , which has better protective properties than $\text{La}(\text{OH})_3$, on the surface.

Up to the present, almost no systematic data are available on the cyclic stability of AB_3 -type IMC, where A is Ce or Y, and B is Ni or Co. For MH electrodes based on multicomponent Laves phases, only the results of electrochemical charge-discharge cycling tests have been reported (see Table 1). However, the mechanism and the nature of the accompanying degradation processes have not been considered, although, because of the different elemental composition, they would probably differ from those in the rather well-studied IMC of AB_5 type and their substituted derivatives.^{139–148}

VIII. Conclusion

To date, several countries have set up the production of nickel-metal hydride accumulators. For example, the number of such accumulators in Japan is as high as 25% of the number of nickel-cadmium current sources, and there exists a trend for a gradual displacement of the latter. This is caused both by environmental considerations and by the good specific characteristics of MH-accumulators as well as by the possibility of manufacturing them without considerable investment and with almost the same equipment. Along with small-scale MH-accumulators for portable computers, video cameras and home electronic appliances, large MH-accumulators are being developed, in particular, for electric cars.

As has been shown above, the properties of hydride-forming materials depend very strongly on their composition and change considerably on adding apparently insignificant quantities of several elements or on small changes in stoichiometry. For example, the addition of less than 2 at.% Li¹⁴⁹ or a decrease in the stoichiometric coefficient to 4.5–4.8¹⁴⁷ increases the capacity of the $\text{Mm}(\text{NiCoAlMn})_5$ electrode with respect to hydrogen, and the service life of the MH battery reaches 1000 cycles with loss of less than 10% of the initial capacity. Therefore, the problem of optimising the composition of hydride electrodes is still of current interest. From the fundamental scientific aspect, a theoretical analysis of the effect of the composition and of concentrations of particular components on the sorption properties of IMC is required. Some approaches to the problem have been reported; however, they have not been developed and generalised because primary attention was paid to extensive empirical studies aiming at the solution of applied problems.

The facts set forth above suggest that active electrochemical investigations of hydride-forming IMC have in fact led to the appearance of a new field, i.e., electrochemistry of hydrides. The particular features of these materials are the strong dependence of their properties on the amount of hydrogen sorbed and their specific electrochemical behaviour. Unfortunately, the latter has been studied insufficiently, although, judging by certain theoretical considerations and preliminary data, one can anticipate that these materials would have unusually high electrocatalytic activity and selectivity in electrochemical hydrogenation and reduction.^{78, 111, 140–142}

A detailed study of the pronounced degradation processes occurring upon hydrogen sorption can lead to a deeper insight into the nature of hydrogen embrittlement of materials, which is particularly important for the prediction of the corrosion behaviour of certain metals and alloys, for hydride materials science and electrochemical technology. Possibly cheap hydrogen-sorbing materials will be found in the future and used as gas-

separating membranes in various systems, including electrochemical ones. As yet, such membranes are most frequently made of palladium and its alloys. It has been found that when palladium is alloyed with rare-earth metals its properties as a membrane are improved.^{143, 144} It is not known at present whether similar membranes can be created using the typical IMC representatives considered above. The realisation of this possibility would drastically expand the field of use of hydrogen-sorbing IMC.

Intermetallic compounds sorbing hydrogen are interesting and promising subjects for revealing the nature of fine interactions in hydride phases. These investigations performed over a broad temperature range and using deuterium as a sorbate^{145, 146} show the most promise. It can be expected that investigations in this field will lead to the appearance of new concepts in hydride chemistry.

IX. Conclusion	222

Abstract. The published experimental data on the direct gas-phase oxidation of natural gas (methane) to methanol are surveyed. The results of kinetic modelling of the process, its mechanism, and its most characteristic features are considered. Prospects of the industrial use of the process and the most important directions for further studies are discussed. The bibliography includes 146 references.

I. Introduction

Direct oxidation of natural gas (methane) to methanol (DMTM) is a promising way of solving the problem of conversion of natural gas into more easily transportable fuels and chemicals. This process can be carried out both in the presence of a heterogeneous catalyst and under homogeneous conditions. In the latter case, pressures higher than 50 atm are needed to achieve a sufficiently high yield of the target products. The extensive literature devoted to the high-pressure gas-phase oxidation of methane,^{1–65} including numerous papers published in recent years, makes it possible to speak of a branch of science dealing with the study of the chemical fundamentals of this process and having a long-term task of developing a competitive method for the direct processing of natural gas.

Since the possibility, in principle, of obtaining valuable oxygen-containing chemical products (oxygenates) by the direct oxidation of methane had been established,^{1–3} it was reported^{4–7} that direct gas-phase oxidation of methane at high pressures can yield methanol with a high selectivity. Efforts were made to increase the yields of these products and to develop industrial processes for their production. As early as 1905, one of the first patents⁸ dealing with the catalytic oxidation of methane to oxygenates (formaldehyde, methanol, formic acid, etc) was obtained, and in 1929 and 1930 the first catalytic process carried

out at high pressures was patented.^{9, 10} At present, there are no operating industrial units for the direct oxidation of natural gas to methanol; however, during World War II more than one fourth of the annual output of formaldehyde and methanol in the USA was produced in this way.^{11, 12}

Currently, interest in this process has revived because the role of natural gas in the world energy balance has increased, because of the urgent need for environmentally clean motor fuels in leading industrial countries, and, the publication of experimental data⁶⁶ indicating the possibility of achieving a very high selectivity in the formation of methanol.⁶⁵

The problem of partial gas-phase oxidation of methane to methanol at high pressure has been considered in a number of reviews, beginning with a monograph²⁰ that summarised more than fifty years of research on the mechanism of the oxidation of hydrocarbons and ending with more up-to-date, though not fully comprehensive, reviews.^{65–67} A detailed and competent survey of the studies dealing with the DMTM problem and published before 1991 is given in a difficultly accessible publication.⁶⁸ However, the time is ripe for the analysis of all the accumulated results in terms of the modern views on the kinetics of this process in order to identify the most significant lines for further research.

We shall not consider here the numerous studies dealing with the oxidation of hydrocarbons at low pressures and with the catalytic oxidation of methane to methanol and other oxygenates, particularly since a number of detailed up-to-date reviews devoted to this problem have been published.^{69–75} The conclusions concerning the technological prospects of the direct gas-phase oxidation made in the present review retain their validity for the heterogeneous catalytic oxidation of methane, which does not afford higher yields of valuable oxygen-containing compounds than the gas-phase oxidation.

II. The current state of natural gas processing technology

The high strength of the C–H bonds in a molecule of methane, which is the main component of natural gas, substantially hampers its use in technological processes. As a rule, these processes require rather high pressures and temperatures. Therefore, until recently, only a few processes involved natural gas as a raw material. The proportions of natural gas used as a raw

V S Arutyunov, V Ya Basevich, V I Vedenev Laboratory for the Oxidation of Hydrocarbons, Semenov Institute of Chemical Physics, Russian Academy of Sciences, ul. Kosygina 4, 117977 Moscow, Russian Federation. Fax (7-095) 938 21 56. E-mail: kinet@glas.apc.org

Received 28 March 1995

Uspekhi Khimii 65 (3) 211–241 (1996); translated by ZP Bobkova

material and a motor fuel in Russia are extremely low (2.0%–2.5% and 0.5%, respectively).⁷⁶

Natural gas is used mainly in the production of synthesis gas or hydrogen. It is the possibility of producing these valuable intermediate materials that makes natural gas a very important source of various organic compounds. Among other processes, the production of chlorinated derivatives of methane, hydrogen cyanide, and ethyne are noteworthy.⁷⁷

Liquefiable components of natural gas find much more extensive applications. At present, approximately 750000 m³ of liquefied hydrocarbons per day is obtained from natural gas in the world, which constitutes about 7.3% of the overall world production of liquid hydrocarbons. In the USA, the gas condensate and other liquefied components of natural gas account for 18% of the overall production of liquid hydrocarbons and 70% of the raw material for the production of ethene and other basic petro-chemical products. In view of the current trends in the development of oil and natural gas production, liquid components of natural gas will amount to 25%–30% of the total quantity of liquid hydrocarbons produced in the USA by the late 90s.⁷⁸

Apart from liquefied hydrocarbons, motor fuels, methanol, and other oxygenates including high-octane components of motor fuels, are the target products of gas processing. However, at present there are only a few operating industrial processes in the world for the conversion of natural gas into motor fuels, based on its initial transformation into synthesis gas. It is at present the most advanced technology for producing chemicals from natural gas. However, optimistic views on the conversion of methane into synthesis gas and then into methanol or the products of the Fischer–Tropsch synthesis are difficult to justify, since synthesis gas can also be obtained from cheaper carbon-containing materials. Moreover, the high cost of these processes and a number of technological problems do not promote the maintenance of a wide interest in such conversion.

The uncertainty as regards future sources of petroleum-based raw materials and the introduction of more severe laws concerning environmental protection create a real prospect of using the enormous natural gas resources for producing traditional petro-chemical products. It would be desirable to learn how to convert this gas, which is relatively difficult to handle, into a more versatile raw material. Methanol is the most probable candidate for a raw material of this kind. Therefore, the preparation and utilization of methanol is now one of the main aspects of the research in the field of industrial chemical synthesis.⁷⁹

Despite the predicted vigorous increase in the consumption of methanol for the synthesis of *tert*-butyl methyl ether and other ethers, industrial companies still refrain from building new large plants for the production of methanol. This is mostly caused by the fear of creating excess capacities and financial stringency.⁸⁰ In our opinion, this restraint of the manufacturers is to a large extent explained by the complexity of the existing technological processes,⁸¹ by their large capital requirements, and by the fact that they are highly power-consuming and have low profitability; this results in the obvious disinclination of the manufacturers to risk large investments, taking into account the possible underemployment of industrial capacities, as was already the case in 1988–1990. This actually reflects the already existing and clearly perceptible demand for a change in the basic technological processes.

At present, substantial efforts are concentrated on the perfection of technological processes for the catalytic synthesis of hydrocarbons and alcohols from synthesis gas. However, even a breakthrough in this field can hardly change the situation fundamentally, since the energy-consuming steam reforming of methane to synthesis gas accounts for approximately 75% of the prime cost in the production of methanol.⁸² Only an increase in the degree of conversion of synthesis gas into methanol from the present-day ~25% to a level close to 100%, the abandonment of the circulation of synthesis gas, and the use of much cheaper air

instead of oxygen, could influence strongly the economic parameters of the process.⁸³ Therefore, the possibility of achieving large-scale processes based on natural gas and competitive with petroleum processing, apparently depends to a large extent on the success in the development of a technology for the direct conversion of methane without the prior production of synthesis gas.

Three promising methods for the direct conversion of natural gas into chemical products have been outlined:⁸⁴

(1) direct partial oxidation of natural gas into methanol and other oxygenates,

(2) oxidative condensation of natural gas to ethane and ethene,

(3) oxyhydrochlorination of natural gas.

Each of these methods has its own attractive features and their combination allows the production of a broad range of the most important chemical intermediate products. Hence, they supplement one another, rather than compete, though at present, the first route is certainly the most thoroughly developed and is close to practical implementation.

The development of a profitable process for producing methanol from natural gas would permit the solution of three important world-wide problems, namely, the problem of transportation, the problem of providing the chemical industry with a very valuable intermediate compound, and the problem of the mass production of environmentally clean high-octane motor fuels.

III. The main experimental data on the direct high-pressure oxidation of methane

Studies of the high-pressure gas-phase oxidation of methane and other hydrocarbons, carried out in the 1930s in order to elucidate the role of alcohols in the mechanism of the oxidation of hydrocarbons,^{4–6} which was of fundamental importance in the scientific views of that time, showed for the first time that alcohols and aldehydes can be obtained in fairly high yields directly from alkanes. It was found that methanol is formed also at atmospheric pressure under conditions including the induction period of the oxidation reaction.⁸⁵ Although under these conditions the selectivity of the formation of methanol in individual stages of the oxidation of methane can reach 20%, the overall selectivity apparently does not exceed 5%.⁸⁶ Therefore, high pressure is a prerequisite for producing methanol by the direct oxidation of methane.

In fact, the range of conditions necessary for the DMTM to be accomplished had already been roughly outlined in the 1930s. They are: high pressures (100–135 atm),^{4,5,15} moderate temperatures (400–450 °C),¹⁴ and low oxygen concentrations.^{13,14} The practically attainable selectivity of the formation of methanol (up to 60%) was determined,^{4,5} and the main kinetic features of the process, namely the decrease in the selectivity of the formation of methanol with increase in the oxygen concentration^{13,14} and high CO/CO₂ ratios in the products,³ were identified. Until now, the main aim of the studies has been to find the conditions that would permit stable high-output production of valuable compounds in sufficiently high yields, so that the process under consideration could compete successfully with other technological processes. According to estimates,⁸⁷ this requires that the selectivity of the formation of methanol (or the sum of organic products) be higher than 75%. In the majority of studies,^{4,5,19,23–26,31,39,40,46,48,60,62} for methane conversions of more than 2%, the selectivity of the formation of methanol ($S_{\text{CH}_3\text{OH}}$) did not exceed 50% (Table 1, Fig. 1). Some workers reported higher values up to 60%–65%^{27,45} or even 95%.^{28,38,41,43,66} However, an attempt to reproduce the latter results was unsuccessful,⁴⁰ and the reasons for so great a difference are still unclear.

We shall not go into the experimental details of the investigations considered. As a rule, the researchers, who carried out this process at very high pressures (thousands of atmospheres),^{23–26} used static reactors. Later, flow reactors, which are more suitable

^a Estimated by the authors.**Figure 1.** Dependence of the selectivity of the formation of methanol on the degree of conversion of methane. The symbols correspond to experimental data and the curve is the calculated plot ($P = 100$ atm, $T = 420$ °C).⁶⁴ The numerals denote the corresponding references.

for the practical realisation of the process, were mostly used. The experiments were carried out in broad pressure (1–230 atm) and temperature (300–500 °C and higher) ranges, with the reaction time t_r varying from fractions of a second to tens of minutes. More exotic cases can also be found. For example, the possibility of using the cylinder of an internal-combustion engine with a high compression ratio, operated by an electric motor, as a reactor for the DMTM has been investigated.²¹

1. The influence of pressure on the yields of the products of partial oxidation of methane

The high selectivity of the formation of methanol is the main characteristic feature of the high-pressure oxidation of rich mixtures of methane with oxygen. Water and formaldehyde are the two other main liquid products. The reaction always yields minor quantities of liquids such as ethanol (up to 1.5%–2%), acetone (up to 1%), and formic acid (up to 0.8%) (Table 2).⁶² Small amounts of higher alcohols,^{29,31,62} aldehydes,^{31,68} and organic acids^{25,29,31,68} have also been detected. When gases with high concentrations of ethane or other alkanes are oxidised, the yield of C_2 – C_3 alcohols, aldehydes, and acids may increase considerably (see Section IV). There is some evidence that the oxidation of methane also gives methyl formate.^{23,25} A GC/MS analysis of the liquid products of the partial oxidation of methane in a pilot plant³¹ has shown the presence of minor quantities (fractions per cent) of dimethyl formal, dimethyl acetal, and dimethyl ether; however, it was not established whether these compounds were formed directly in the reaction or resulted from the interaction of primary liquid products after cooling. In any case, a special attempt to detect them was unsuccessful.⁴ Repeated attempts to find hydrogen peroxide or organic peroxides in the reaction products have also given no positive results.^{4,22} Traces of these products have been found only at atmospheric pressure.⁸⁸

^a Higher homologues of these compounds have also been detected. ^b Relates to those cases where the initial gases contain no ethane or ethene or their concentration in the products is higher than the initial concentration.

The main gaseous products are carbon oxides and hydrogen, the yield of carbon monoxide at high pressures being several times larger than that of the dioxide,⁶² although carbon dioxide appears earlier than carbon monoxide.²² The yield of ethane and ethene increases with increase in temperature.

An increase in pressure intensifies the oxidation of methane by decreasing its duration or the initial temperature. For example, the pressure dependence of the delay of the self-ignition of the 8.8:1.2 methane–air mixture in the 60–113 atm range is described by the relation $\tau_1 \sim P^{-1.4}$ (Fig. 2),²² and the ten-fold increase in pressure from 5 to 50 atm in a flow reactor leads to the decrease in temperature corresponding to the complete conversion of oxygen from 500 to 400 °C⁴⁰ (Fig. 3). However, the main consequence of the application of high pressures in the oxidation of rich methane mixtures is high selectivity of the formation of methanol. The increase of pressure from 10 to 106 atm increased $S_{\text{CH}_3\text{OH}}$ by a factor of 20,⁶ and when the pressure increased from 5 to 50 atm, the temperature at which methanol begins to be detected decreased from 450 to 375 °C.⁴⁰

The results obtained by Arutyunov et al.⁶² indicate that the overall yield of liquid products of the partial oxidation of methane increases monotonically as the pressure increases up to 200 atm (Fig. 4). However, the concentrations of alcohols and acetone pass through a maximum near 150 atm (Fig. 5). Consequently, the pressure dependence of the yield of methanol has a weakly

Figure 2. Pressure dependence of the delay of self-ignition of the mixture containing 88% of methane and 12% of air ($T = 406^\circ\text{C}$).²²

defined maximum at these pressures (Fig. 6). Other data also indicate that the yield of methanol diminishes at pressures above 180 atm¹⁸ or that the selectivity of its formation decreases at pressures above 100 atm.⁶⁵

Despite the fact that the concentration of formaldehyde in the liquid oxidation products decreases monotonically with increase in pressure (Fig. 5), its yield remains approximately constant, since the overall yield of liquid products increases (Fig. 6). Thus, pressure is the crucial factor influencing the composition of liquid oxidation products, including the ratio of methanol to formaldehyde (Fig. 7).⁶² The partial oxidation of methane under very high pressures, up to 3400 atm²⁶ or higher,²³ provides no real advantages. The pressure range between 75 atm (the standard pressure in gas mains) and 100 atm may apparently be considered optimal. Since the cost of gas compression is one of the major constituents of the prime costs of the products obtained by the DMTM,⁸⁷ this conclusion is important practically.

Figure 3. Temperature dependence of the conversion of methane at different pressures (atm): (1) 5, (2) 10, (3) 20, (4) 30, (5) 50 (reported by Burch et al.⁴⁰).

Figure 4. Pressure dependence of the overall specific yield of liquid products of the oxidation of methane ($T = 400^\circ\text{C}$).⁶² Gas volumes are referred to the normal temperature and pressure (NTP).

The concentration of the main gaseous product, carbon monoxide, in the gases leaving the reactor reaches $\sim 1.5\%$ for an initial oxygen concentration of $\sim 3\%$, and remains approximately constant in the pressure range from 30 to 230 atm (Fig. 8). The concentration of carbon dioxide is several times lower and increases with pressure, which results in the corresponding decrease in the CO/CO_2 ratio.⁶² The increase in the CO_2 concentration with pressure may be partially due to the formation and subsequent decomposition of formic acid by the mechanism suggested by Vedenev et al.⁴⁷

At higher temperatures of $515\text{--}630^\circ\text{C}$, when the yield of ethane and ethene is fairly high, a pressure increase from 31 to

Figure 5. Pressure dependences of current concentrations of the main liquid products of the oxidation of methane ($T = 400^\circ\text{C}$):⁶² (1) methanol; (2) formaldehyde; (3) ethanol; (4) acetone; (5) organic acids.

Figure 8. Pressure dependences of the yields of CO (1), CO_2 (2), and of their ratio (3) ($T = 400^\circ\text{C}$).⁶²

102 atm leads to an increase in the yield of C_2 hydrocarbons from 8% to 36%; in addition, the temperature at which complete conversion of oxygen is achieved decreases by 100°C .⁵⁰

2. The influence of temperature and contact time

An increase in temperature leads to a diminution of the induction period of the reaction. As shown by Melvin,²² $\lg \tau_1$ (τ_1 is the self-ignition delay) depends linearly on $1/T$. The activation energy for

the oxidation of methane with air in mixtures having compositions from 60 : 40 to 90 : 10 at a pressure of 105 atm lies in the range of 163–188 kJ mol⁻¹.²² However, the temperature dependence of the degree of conversion of methane for a fixed length of the reactor (see Fig. 3) is clearly S-shaped, whereupon the transition from negligibly small to maximum conversion occurs within a range of not more than 20 °C,^{40,51} which reflects the critical character of the process.⁵⁸ When the temperature of the reactor walls decreases, hystereses are observed in the temperature dependences of the process parameters (heating of the mixture, conversion of methane).⁵¹

Once oxygen is entirely converted, further increase in the temperature within a certain range has apparently little influence on the yield of methanol.¹⁸ Some workers have observed^{40,51} that, at a pressure of 50 atm and above 425 °C (which is the temperature of the complete conversion of oxygen⁴⁰), the value of $S_{\text{CH}_3\text{OH}}$ already decreases monotonically (from 40% to 32% at 500 °C⁴⁰); however, according to other data,⁴⁵ the selectivity remained practically constant between 420 and 460 °C ($P = 40$ atm) or passed through a maximum at ~450 °C.^{18,59} (Fig. 9). Further increase in temperature may lead to a diminution of the yield of methanol due to both a decrease in the selectivity of its formation and the decomposition of a portion of the product already formed on contact with the reactor surface.⁴⁰ For the same reason, it is undesirable to increase the residence time of the mixture in the reactor for a longer period than is necessary for the complete conversion of oxygen at the given temperature.^{40,59} However, if the surface of the reactor is relatively inert (quartz, Pyrex, stainless steel), the variation of the residence time of the unreacted reaction mixtures within fairly broad limits has little influence on the final yield of methanol and even on the yield of formaldehyde, although the latter is less stable under these conditions.^{40,62} Attempts to increase the yield of methanol by rapid cooling of the mixture as it leaves the reactor³⁹ have given no significant advantage over the results of most other studies (Table 1).

When the temperature is increased to 500 °C or more, the composition of reaction products changes toward ethane, ethene, and small quantities of ethyne, the overall selectivity of their formation being as high as 37% at 515 °C and 100 atm.^{49,50}

The combination of high temperatures and relatively low pressures is favourable for an increased yield of formaldehyde. When the reaction was carried out at 625 °C and 5 atm, with a methane : air ratio of 1 : 5 and a contact time of 2.3 s, the yield of formaldehyde in the gas-phase oxidation of methane was raised to 3.5% ($S_{\text{CH}_2\text{O}} \approx 50\%$ for a degree of conversion of ~7%), which is even greater than in the presence of oxide catalysts.⁴⁴

Figure 9. Temperature dependences of the selectivity of the formation of the sum of useful oxygen-containing products (1, 3) and methanol (2, 4) at pressures of 184 (1, 2) and 231 atm (3, 4).¹⁸

3. The conversion of methane and oxygen in the oxidation of methane to methanol

A low concentration of oxygen in the DMTM predetermines a low degree of conversion of methane after its single passage through the reactor. In virtually all experimental studies (see Table 1, Fig. 1), the degree of conversion of methane was lower than the initial percentage of oxygen. Only Gesser et al.²⁸ and Yarlagaadda et al.,³⁸ who have achieved very high selectivities in the formation of methanol, reported methane conversions substantially higher than the initial oxygen contents. The reasons for this discrepancy are still unclear.

It has been noted⁶² that the gas-phase reaction products always contain a small amount of oxygen {~5% of its initial concentration $[\text{O}_2]_0$ on average}. Special studies made it possible to rule out trivial explanations of this fact such as that oxygen entered the system after it had left the reactor or unreliability of the analysis. The fact that the oxidation of methane stops before the oxygen is entirely consumed is difficult to explain from the theoretical viewpoint.

In one of the early studies, Newitt and Huffner⁴ stated that oxygen was fully consumed in this reaction. On the other hand, a careful analysis carried out in the study by Boomer and Thomas¹⁷ indicated that the gases leaving the reactor contain oxygen almost in all cases. The authors emphasised that the material balance of this reaction with respect to oxygen is difficult or even impossible to reconcile. A review⁶⁵ cites data⁸⁹ which state that 95% of the oxygen present in the system enters into the reaction, i.e. 5% of the oxygen remains unchanged. Finally, Bauerle et al.²⁵ presented reliable data indicating that at 100–750 atm, 250–363 °C, for reaction times of up to 900 min, and $[\text{O}_2]_0 = 10\%$, the process stops when the residual oxygen content is $(0.3–0.5)[\text{O}_2]_0$. Perhaps, the most remarkable relevant data are concerned with the existence of a limiting oxygen concentration in the oxidation of butane.⁹⁰ Appreciable amounts of unchanged oxygen have also been observed in experiments on the oxidation of methane at very high pressures of 1700–3400 atm.²⁶ In other papers, either there is no special mention of the presence of noticeable quantities of oxygen in the gas after the reaction or complete consumption of oxygen has been reported. Nevertheless, the question why the oxidation stops before all the oxygen is consumed requires an additional analysis.

4. The influence of mixture composition on the kinetics of the process and the yield of products

The kinetics and the yield of products of the DMTM are very sensitive to the composition of the mixture, especially, to the methane : oxygen ratio. As the oxygen concentration increases, the degree of methane conversion also increases, but at the same time, the selectivity of the formation of methanol rapidly diminishes.^{5,13,18,31,38,39,45,60} (Table 1, Fig. 10). Since $S_{\text{CH}_3\text{OH}}$ is governed by the methane : oxygen ratio,⁶⁰ the decrease in $[\text{CH}_4]/[\text{O}_2]$ at a constant oxygen concentration leads to diminished yields of methanol and other liquid oxidation products (Fig. 11).⁶³ The optimal proportion of oxygen in methane is about 3%–5%; however, at this concentration, the degree of conversion of methane in a single pass through the reactor is inevitably low.

An increase in the oxygen concentration has an inhibitory effect on the reaction rate. For example, the delay of the self-ignition of mixtures of methane with air at 72 or 83 atm increases with increase in the oxygen concentration²² (Fig. 12).

Dilution of the reaction mixture with nitrogen,^{40,63} helium,⁶⁰ or other inert gases does not influence the proportions of the products, if the methane : oxygen ratio remains constant. Therefore, the results are identical no matter whether oxygen or air is used as the oxidant.

Carbon dioxide and water vapour cannot apparently be regarded as being absolutely inert during the DMTM. In all probability, the oxygen incorporated in these compounds can participate in the formation of methanol or other oxygen-

Figure 10. Dependences of the selectivity of the formation of the sum of useful oxygen-containing products (1, 3, 5) and methanol (2, 4, 6) on the oxygen concentration at pressures of 141 (1, 2), 184 (3, 4), and 231 atm (5, 6).¹⁸

containing products, thus increasing their yields.¹³ However, no reliable experimental data concerning this problem have been reported. When about 75% of the methane in a $8.5CH_4 + O_2$ mixture was replaced by N_2 , CO_2 , or H_2O (at 50 atm), apart from the reduction of the reaction rate caused by the decrease in the methane concentration, the yield of methanol also diminished (by approximately 40%).⁵ This is most probably due to the decrease in the methane: oxygen ratio. The yield of formaldehyde was almost unchanged on dilution of methane with nitrogen or carbon

Figure 11. Dependences of the yields of liquid products of the partial oxidation of methane on the $[CH_4]/[O_2]$ ratio ($P = 100 \text{ atm}$, $T = 400^\circ\text{C}$):⁶³ (1) the sum of liquid oxidation products; (2) water; (3) methanol; (4) formaldehyde.

Figure 12. Dependence of the delay of the self-ignition of the mixture of methane with air at 406°C on the oxygen concentration²² at different methane pressures (atm): (1) 83.3, (2) 71.8.

dioxide; on dilution with water vapour, it increased almost two-fold, which confirms the suggestion that water plays an active role in this process.

In a study of the possibility of realising a recirculation scheme for the DMTM process, Arutyunov et al.⁶³ investigated the influence of the addition of the two main reactive gaseous products, namely, carbon monoxide and hydrogen, to the reaction system on the yield of liquid products. It was found that, if the initial concentration of these compounds does not exceed 5%, they virtually do not influence the methanol yield. However, at higher concentrations, the methanol yield may decrease by more than one half.

The influence of the addition of minor quantities of carbon dioxide (10%) or hydrogen (4%) on the DMTM process in the temperature range $400\text{--}500^\circ\text{C}$ at $P = 41 \text{ atm}$, for $CH_4:O_2:N_2 = 30:1:4$, and for a contact time of 1 s has also been investigated.⁵⁹ The addition of either of these gases caused a slight (by $\sim 10^\circ\text{C}$) decrease in the temperature of the onset of the process, but the maximum yield of methanol almost did not change.

5. Homogeneous promotion of the process

Attempts to promote the DMTM process were undertaken as early as 1921, when a number of methods for the preparation of methanol and formaldehyde from natural gas were studied. These methods are: (1) oxidation over various catalysts; (2) oxidation with ozone; (3) iodination followed by hydrolysis; (4) interaction of methane with CO_2 ; (5) synthesis of C_2H_4 from natural gas and its subsequent oxidation; (6) oxidation of methane in solution and with liquid oxidising agents.⁶⁸

In a study of the oxidation of a mixture of methane with air (3:1) at 25 atm and $300\text{--}400^\circ\text{C}$, it was found that minor quantities of HNO_3 accelerate the reaction significantly, while small amounts of $PbEt_4$ retard it.⁷ However, these additives have little influence on the composition of the products.

The possibility of initiating the partial oxidation of methane with ozone under flow conditions at $P = 1 \text{ atm}$ has been considered.⁹¹ Although ozone appreciably promotes the reaction and increases the yield of methanol, a selectivity $> 42\%$ was achieved only when the degree of conversion of methane was no more than 1%. The use of high pressures, more favourable for the formation of methanol, requires the development of effective methods for the production of ozone under these conditions.

The presence of even minor admixtures of heavier hydrocarbons in methane is well known to decrease the reaction temperature with no substantial effect on the yields of the main products. In fact, the replacement of natural gas by methane necessitated that the temperature at the beginning of the process be increased from 350 to $425\text{--}475^\circ\text{C}$,¹⁸ and the addition of 5% ethane to methane led to a 50°C decrease in the temperature.⁴⁰

Figure 13. Influence of the addition to natural gas on the concentration of methanol in the liquid oxidation products at $P = 140.6$ atm and $[O_2] = 6\%$.¹⁵

Some data indicate that the yield of methanol increases substantially in the presence of large quantities of ethane (Fig. 13).¹⁵ Unfortunately, no systematic studies on the influence of other hydrocarbons on the DMTM process have been carried out.

A decrease in the temperature of the process and an increase in the conversion of methane and the yield of methanol following the addition of 3% of ethane, propane, or isobutane have been reported ($P = 41$ atm, $CH_4:O_2:N_2 = 30:1:4$, contact time 1 s).⁵⁹ However, in view of the magnitude of this effect, it is difficult to determine unambiguously whether or not the added hydrocarbon itself acts as a source of the additionally formed methanol.

The most systematic study of the influence of promoters on the DMTM process has been carried out by Hunter et al.⁴¹ at a pressure of 10 atm. About 30 different compounds, including saturated, unsaturated, cyclic, and aromatic hydrocarbons, ethers, alcohols, ketones, aldehydes, water, peroxides, sulfur-containing compounds, and amines, were tested as promoters. Many of these promoters decrease noticeably the temperature of the process. Diethyl ether exerts the greatest influence; the addition of 3.9% of diethyl ether decreases the reaction temperature from 402 to 225 °C. Another obvious consequence of the action of some promoters is a significant increase in the yield of formaldehyde, probably at the expense of the corresponding decrease in the yield of methanol. In some cases, the selectivity of the formation of methanol or/and formaldehyde increases, compared with a system containing no promoters. However, this requires the addition of fairly large amounts of promoters, which cancels the economic prospects of thus increasing the yield of methanol in a real technological process.

6. The influence of catalysts and the material of the reactor surface

The question whether the effectiveness of the DMTM process can be significantly increased by using catalysts has remained unsolved throughout the period of its study. An investigation of the influence of certain metals and alloys on this process¹⁹ did not reveal any significant advantages of the catalytic reaction over the purely gas-phase transformation. The use of metallic reactors or catalysts at relatively low pressures favours the formation of products of the complete oxidation of methane.⁴⁰ However, at higher pressures catalysts exert no significant influence on the

selectivity of the formation of methanol. Similar conclusions were based on other data.^{41, 56}

Analysis of the results of the reactions conducted under catalytic conditions^{69–75} and in a series of recent comparative studies^{40, 41, 56} makes it possible to conclude almost unambiguously that the catalytic process has no real advantages over the gas-phase reaction carried out at high pressures.^{40, 71} The same conclusion follows from the kinetic analysis of the reaction mechanism (Section V). The only obvious positive result of using catalysts in the DMTM is the possibility of lowering the reaction temperature.

The question how the material of the reactor surface influences the stability of the products of the partial oxidation of methane is of great importance. A study of the stability of methanol in reactors made of Pyrex, stainless steel, and copper⁴⁰ has shown that, in the case of copper, methanol decomposes almost completely even at 375 °C. Stainless steel is much more inert. In a Pyrex reactor, decomposition of methanol cannot be observed even at 500 °C; nevertheless, up to 15%–18% of the methanol added to the reaction mixture decomposes, probably through being involved in the reaction.⁴⁰ Quartz and Teflon are also among the best materials for reactors used for the DMTM.⁴¹ When light paraffins are oxidised in copper or steel reactors, especially at atmospheric pressure, the yields of both alcohols and aldehydes decrease.⁹² The decomposition of methanol on some surfaces affords dimethyl ether.⁹³ Ultimately, the reactor material exerts no crucial effect on the selectivity of the formation of methanol and other organic products, because the reaction is homogeneous and the rate of diffusion of radicals to the surface at high pressures is low. The results of pilot tests indicate³¹ that the relatively low temperature of the process, which does not exceed 600 °C at the reactor outlet for an initial oxygen content of ~3%, and the low concentration of the organic acids formed can hardly create serious problems in the choice of the material of the reactor.

7. Physical initiation of the process

Attempts to use various physical methods for controlling the rate and selectivity of the DMTM have been undertaken since the 1920s. The effects of an electric discharge, radiation, and ultraviolet light on this process were then studied.¹⁵

In the 1980s, studies on the initiation of the DMTM by laser radiation were carried out in the Los Alamos National Laboratory (USA).^{94, 95} From the results obtained, one can judge that, at 450 °C, 2.04 atm, and an oxygen concentration of 11%, only the rate of the reaction could be really increased, while S_{CH_3OH} and the proportions of products do not change noticeably. However, kinetic analysis of the system showed that at elevated temperatures (530–730 °C), a pressure of 60 atm, and for the $CH_4:O_2 = 2:1$ ratio one may expect a 50% selectivity of the formation of methanol with a degree of conversion of about 25%. The time scale of the reaction (3 ms) dictated the use of a reactor with a supersonic nozzle.⁹⁴ Nevertheless, the authors were apparently unable to solve the problem of the quick removal of the heat of reaction and to achieve quick 'quenching' of the reaction products, without which a high selectivity of the formation of methanol at a relatively high oxygen concentration cannot be ensured.

Among the physical methods for stimulating the oxidation of methane, the use of an ultra-high frequency, glow discharge and thermal initiation by a heated wire have also been considered.⁹⁶ It has been shown⁹⁷ that, in a methane plasma, methane dimerises to C_2 hydrocarbons with a selectivity of more than 95% for a degree of conversion from 30% to 90%. However, the energy efficiency of this thermodynamically unfavourable process is only 0.2%–3.3%. An attempt to use an ultra-high frequency discharge for oxidising methane to methanol⁹⁸ has shown that the features of the reactor design are also significant. The introduction of methane behind the area of plasma induction allowed the yield of C_2 hydrocarbons to be significantly diminished, but the selectivity of the formation of methanol was still extremely low.

8. Cool-flame and periodic phenomena in the oxidation of methane

The existence of cool-flame and related periodic and critical phenomena has been observed in the oxidation of many hydrocarbons with various structures, including alkanes up to propane and ethane.^{20,99,100} In the vast majority of studies, cool flames have not been detected in the oxidation of methane. However, the authors of some studies have noticed phenomena that could have been interpreted as cool-flame phenomena. These situations have also been found in the high-pressure oxidation of methane to methanol.^{23,42,45} Only Vanpee¹⁰¹ and Egret et al.,¹⁰² who worked at atmospheric pressure, obtained fairly convincing experimental evidence for this phenomenon. Recently it was confirmed once again:¹⁰³ cool flames were detected in a $2\text{CH}_4 + \text{O}_2$ mixture at 650–740 Torr and about 500 °C. The dependence on time of the temperature of the reaction mixture exhibited two maxima, the temperature rise in the first one being 100–120 °C. A region of a negative temperature coefficient of the rate of oxidation of methane has been found.¹⁰⁴

Since there is a theoretical possibility of the appearance of cool-flame regimes in the high-pressure oxidation of methane,^{61,105} which may lead to the yields of products, differing fundamentally from those reached in other known oxidation regimes, we present here the published experimental data.

In a process carried out at a pressure of 3360 atm, an oxygen concentration of 8%, and an initial temperature of 262 °C in a static reactor, two temperature peaks with amplitudes of 6 and 14 °C, accompanied by corresponding pressure increases, have been observed against the background of a slow temperature rise.²³

Temperature oscillations typical of the cool-flame phenomena have been observed during the oxidation of methane in a flow reactor at 25–35 atm and an oxygen concentration not less than 5%.⁴² At oxygen concentrations of 8% or more and temperatures of about 410 °C, these oscillations were steady. An increase in the temperature to 450 °C led to a decrease in the amplitude of the oscillations and an increase in their frequency. At 475 °C, the oscillations disappeared. The amplitudes and the frequencies of the oscillations at various points along the reactor axis were very different. The maximum $S_{\text{CH}_3\text{OH}}$ was achieved at the lowest temperatures at which oscillations no longer occurred; however, the selectivity remained lower than that observed at the optimal oxygen concentrations ($\leq 3\%$). It was suggested that, under the conditions in which these oscillations occur, the process in the reactor can be controlled in order to achieve the highest selectivity.

9. The role of other factors

Among other factors which can, in principle, influence the kinetics and the yield of products of the partial oxidation of methane, one should mention the rate at which the reagents are introduced into the reactor, the conditions in their mixing, the heat transfer conditions, and features of the reactor design.

The fact that the yield of products depends substantially on the ratio between the diameter of the reactor, through which a slow (1.6 m s^{-1}) stream of methane is passed, and the diameter of the coaxial nozzle, through which oxygen is passed at a high velocity (60–300 m s^{-1}), and on the velocity of the oxygen supply through the nozzle has been reported in a patent.²⁷

There is evidence that it is necessary to ensure the maximum homogeneity of the mixture entering the reactor. For this purpose, a premixing chamber filled with Teflon turnings has been mounted before the reactor.²⁸ However, an attempt⁴⁰ to reproduce the high yields of methanol obtained by Gesser et al.²⁸ by using the same premixing device gave no noticeable positive results. The composition of the gas, the mixing conditions, as well as the reactor size and the constructional materials used^{28,40} were approximately the same and could not account for the large difference between the selectivities of the formation of methanol ($\sim 80\%$ and $\sim 40\%$, respectively). It was concluded⁴⁰ that some

slight, but perhaps significant, differences in the reactor design may account for this difference, and that the essential influence of this factor is due to the cool-flame reaction regime.

The influence of the reactor design (the way in which oxygen is supplied into the stream of methane) on the process has been studied.⁶⁰ The improvement of the conditions in the mixing of the reactants by introducing oxygen through a spiral nozzle or into a narrow zone of the reactor did not lead to a substantial increase in the yield of methanol. The best results were achieved by distributing the oxygen supply along the whole reactor.^{30,60} In this connection, it was suggested⁶⁰ that the high yields attained in some experiments reported in a patent²⁷ were due to the great distance of the flow of oxygen, before it was mixed with methane, the oxygen being injected into the reactor through a narrow coaxial nozzle, which is equivalent to a distributed supply. The best results were achieved at moderate rates of supply of oxygen. At high rates, the degree of turbulence might increase, and, hence, the mixing area might diminish, which could cause a decrease in the yield of methanol.

Theoretical calculations predict the possibility of increasing the yield of methanol by an order of magnitude by using a fundamentally different scheme for conducting the process.^{95,106} In conformity with these calculations, conducting the reaction at 730 °C with rapid quenching of the products may ensure $S_{\text{CH}_3\text{OH}} = 57\%$ with an oxygen concentration of 25%, which corresponds to a methanol yield of about 13%.¹⁰⁶

IV. High-pressure oxidation of methane homologues

Data on the oxidation of rich mixtures of methane homologues with air or oxygen at high pressures are quite scarce and are presented in a very small number of papers.^{5,6,13,15,90,107–109} Most of these papers have been considered in detail in a review.²⁰

When gases containing large proportions of higher hydrocarbons are used, the process parameters such as the pressure and the temperature needed decrease sharply. As the concentration of higher hydrocarbons grows, there is an increase in the degree of conversion of natural gas, for which the selectivity of the formation of alcohols still remains high; in addition, higher alcohols, including iso-alcohols, aldehydes, and some other compounds, are also formed.

1. Ethane

Since ethane is oxidised much more readily than methane, it follows that, as mentioned in Section III, even a slight increase in the proportion of the ethane admixture in methane (natural gas) decreases the reaction temperature by approximately 100 °C and increases the yield of alcohols (Fig. 13). The most comprehensive studies of the oxidation of ethane have been carried out by Newitt and coworkers.^{5,6,107} The oxidation of mixtures with the approximate composition $\text{C}_2\text{H}_6:\text{O}_2 = 9:1$ under static conditions at 15–100 atm,^{6,107} afforded methanol, ethanol, formaldehyde, acetaldehyde, formic acid, and acetic acid apart from carbon oxides, methane, and water. On the basis of the results obtained, it has been concluded⁶ that an increase in pressure, with approximately the same reaction time (2.5–4.5 min), leads to an increase in the yield of C_2 products (ethanol, acetaldehyde, and acetic acid) and to a decrease in the yields of methanol and formaldehyde. However, maintenance of a constant reaction time does not ensure the maximum yield of alcohols. In any case, examination of the full set of experimental data¹⁰⁷ shows (Table 3) that the maximum yields of alcohols and acetaldehyde depend only slightly on pressure, at least in the range above 50 atm. The role of pressure is more clearly manifested by an increase in the yield of acetic acid, the maximum selectivity of its formation reaching 27.2% at 100 atm, and a monotonic decrease in the yield of formaldehyde. Apparently, one can also conclude that the selectivities of the formation of ethanol and acetic acid increase as the oxygen concentration in the mixture decreases. In the oxidation of a

mixture with the composition C₂H₆:O₂:N₂ = 90:3:7 in a flow reactor at *P* = 50 atm, *T* = 360 °C, and for a contact time of 4 s, the selectivity of the formation of ethanol was 63%.⁵ When the contact time increased to 20 s, the selectivity of the formation of ethanol decreased to 14.5%, while *S*_{CH₃OH} increased from trace amounts to 7.8%. When portions of oxygen were successively added to the mixture which had already reacted, the quantities of ethanol, aldehydes, and acids formed and the quantity of methane remained virtually constant, and only the contents of methanol and carbon oxides increased monotonically.¹⁰⁷

In a more recent study,¹⁰⁸ in which the process was carried out under flow conditions at 27–37 atm, a high selectivity of the formation of alcohols (more than 70%) was also observed. However, whereas at the relatively low pressures mentioned above the ethanol:methanol ratio in the reaction products was less than unity, with increase in pressure to 90 atm this ratio increased to 6. In the experiments under consideration, the time the mixture spent in the reactor also increased from ~1 min at 15 atm to 7 min at 90 atm. Therefore, it is difficult to distinguish the influence of the linear velocity of the reactant flow in the reactor from the influence of the pressure itself. It should be noted that in another study,⁵ the opposite influence of the residence time of the mixture in the reactor has been observed: at 50 atm, the increase in the residence time from 7 to 20 s reduced the ethanol:methanol ratio from 19 to 2. It has also been reported¹⁰⁹ that this ratio increases as the oxygen concentration decreases.

2. Propane

Data on oxidation of propane at high pressures have been reported by Newitt and coworkers^{6,109} (static conditions) and Wiezevich and Frolich¹⁵ (flow conditions). These data are partly presented in Tables 4 and 5. Qualitative analysis showed that, among aldehydes, propanal and acetaldehyde are formed, among normal alcohols, methanol, ethanol, and propanol are produced, while carboxylic acids are mostly represented by acetic acid with minor amounts of propionic and formic acids.¹⁰⁹ An increase in pressure results in a substantial increase in the yields of

2-propanol, acetone, and organic acids, some reduction of the yields of aldehydes and normal alcohols, an increase in the yield of CO₂, and a decrease in the yield of CO; when the pressure is 20 atm or more, propene is no longer present in the reaction products. In addition, increase pressure appreciably diminishes the temperature of the process (Table 4) and leads to a change in the content of normal alcohols in the reaction products. The proportions of methanol and ethanol decrease with increasing pressure, while the proportion of propanol increases (Table 5). From the data presented, one can see that the most significant changes in almost all the process characteristics occur when the pressure increases to 20 atm. Further increase to 100 atm¹⁰⁹ or 200 atm¹⁵ gives no fundamental advantages, except for an increase in the yield of 2-propanol.

It is necessary to take into account the fact that the data¹⁰⁹ concerning the pressure dependences of the yields of the propane oxidation products, presented in Tables 4 and 5, have been obtained at temperatures ensuring an approximately constant rate of the process rather than under the conditions ensuring the optimal yields of the alcohols. Since according to the same study an increase in temperature increases the overall yield of normal alcohols (at 30 atm, it increases from 21% to 40% as the temperature increases from 260 to 286 °C), one should expect that, under the optimal conditions, the yield of the alcohols would be appreciably higher. As in the oxidation of methane or ethane, a decrease in the oxygen concentration in the mixture leads to an increase in the selectivity of the formation of the alcohols.¹⁰⁹ However, in the oxidation of propane, a relatively high selectivity of the formation of the alcohols (more than 30%–40%) can be achieved even for the propane:oxygen ≈ 1:1 ratio. The optimal conditions for the formation of the alcohols are ensured by the highest possible safe oxygen concentration.¹⁵

3. Butane, pentane, and heptane

There are only scattered data on the gas-phase oxidation of butane, pentane, and heptane at high pressures,^{15,90} permitting only a general idea about the expected yield of the alcohols and their proportions. The oxidation of *n*-butane, pentanes, and heptanes was studied¹⁵ using the same equipment and under approximately the same flow conditions as were used for the oxidation of propane. The following conditions are optimal for the formation of higher alcohols from alkanes: pressure from 130 to 200 atm, the lowest possible temperature, a reaction time less

Table 4. Selectivity of the formation of the products of the oxidation of the propane: air = 1:3.6 mixture (according to Newitt^{6,109}).

than 10 s in a heated reactor, and the highest possible safe concentration of oxygen.

Apart from the compounds found also in the products of the oxidation of propane, the oxidation of n-butane with oxygen at a pressure of 33–160 atm yields also butanols, their proportion increasing with increase in pressure. In general, low pressures during the oxidation of alkanes are likely to be favourable for the formation of lower alcohols and organic acids, while high pressures promote the formation of higher alcohols and aldehydes.¹⁵ In addition, increasing the pressure decreases the temperature of the process: the temperature of the oxidation of n-butane decreases from 255 to 210 °C as the pressure increases from 33 to 160 atm. The composition of the products of the gas-phase oxidation of butane differs greatly from that in its liquid-phase oxidation at high pressures, the latter yielding mostly acetic acid and ethyl methyl ketone with minor amounts of alcohols.¹¹⁰

The oxidation of a mixture of 60% n-pentane and 40% isopentane, saturated beforehand with oxygen up to its concentration of 5%–6%, gives mostly alcohols, aldehydes, acetone, and acids containing 2–3 carbon atoms. Conversely, the products of the oxidation of heptane (the fraction boiling at 70 to 97 °C and containing almost all of the heptane isomers present in the head of the petrol fraction) contained mainly hexanols and heptanols with boiling points from 140 to 180 °C. The fact that these results differ from those obtained with pentane has been tentatively attributed to the occurrence of the reaction in the liquid phase.

In another study,⁹⁰ the oxidation of n-butane, carried out at 385 °C, 3.5–12.5 atm, with reaction times from 1.0 to 4.5 s, and under turbulent flow conditions in order to minimise the transverse concentration and temperature gradients, was rapidly quenched by cooling with water. The butane and oxygen concentrations varied between 1.5 mol % and 6 mol % each, and the rest was nitrogen. The pressure dependence of the yield of useful products (alcohols, aldehydes, acetone, and acids) passed through a maximum at $P = 8.8$ atm. No appreciable variations of the ratios between various products were observed. The most surprising finding was that there are limiting oxygen concentrations for the onset and termination of the process. The reaction did not proceed if the starting oxygen concentration was less than 1.5% and stopped when the concentration of O₂ fell below this value. Although incomplete conversion of oxygen has also been noted in other studies (Section III, 3), the existence of concentration limits in the high-pressure oxidation of alkanes was pointed out in none of them. The maximum yield of useful products was achieved for an oxygen concentration of 4.5%.⁹⁰

Under the optimal conditions ($P = 8.4$ – 9.8 atm, reaction time 1.2–1.8 s, concentrations of n-butane and oxygen mixed with nitrogen 4–5% each), 20% of the hydrocarbon taken was converted into useful products. The selectivity of the formation of these products was about 50%.

4. General features of the high-pressure oxidation of alkanes

On the basis of the experimental data considered in Sections III and IV, some general conclusions concerning the features of the oxidation of methane homologues at high pressures can be drawn (Table 6).

1. In the oxidation of all the C₁–C₅ alkanes under optimal conditions, a selectivity of the formation of liquid organic products not less than 50% can be achieved.

2. An increase in the oxygen concentration reduces the selectivity of the formation of liquid organic products, but, on passing from methane to pentane, the hydrocarbon : oxygen ratio for which a high selectivity is still achieved decreases sharply (~30 for methane, ~10 for ethane, and ~1 for propane, butane, and pentane). The degree of conversion of hydrocarbons into useful products increases in the same series (up to ~2% for methane, ~5% for ethane, and ~20% for propane, butane, and pentane).

3. The pressure and the temperature optimal for the production of liquid hydrocarbons decrease monotonically in the methane–pentane series (100 atm and 450 °C for methane,

Table 6. The optimal parameters of the high-pressure oxidation of alkanes for the formation of liquid organic products (averaged published data).

Hydro-carbon	P/atm	$T/^\circ\text{C}$	$[\text{C}_n\text{H}_{2n+2}]/[\text{O}_2]$	Degree of conversion into useful products (%) ^a
CH ₄	100	450	30	2

C ₃ H ₈	20	280	1	20
C ₄ H ₁₀	9	260	1	20

^a The maximum overall selectivity of the formation of liquid organic products from all the alkanes exceeds 50%.

50 atm and 360 °C for ethane, 20 atm and 280 °C for propane, and 9 atm and 260 °C for butane). As a rule, these data correspond to a process conducted under flow conditions with a reaction time of several seconds.

4. The influence of pressure on the product composition decreases in the methane–pentane series.

V. The mechanism of the high-pressure oxidation of methane

The understanding of the mechanism and, consequently, the optimisation of the conditions in a process as complex as the oxidation of methane, which has been one of classical objects of study in chemical kinetics for decades,¹¹¹ are impossible without the creation of an adequate kinetic model. Several theories which make it possible to explain the experimentally observed characteristic features have been suggested,²⁰ however, at present, the radical-chain mechanism of the gas-phase oxidation of alkanes is generally accepted.¹¹² In view of the complexity of the methane oxidation process, one can hardly expect that a universal model, suitable for the quantitative analysis of all cases of practical interest, will be developed in the near future. Therefore, the existing quantitative models have as a rule limited applicability. In conformity with the subject of our review, we shall consider only those models which involve the modelling of the oxidation of methane at high pressures and moderate temperatures.

1. The principles of the construction of quantitative kinetic models of complex gas-phase processes

One can hardly expect that a mathematical description (kinetic model) of a complex chemical reaction will be in complete quantitative agreement with the real process. This is due to both the unavoidable inaccuracy of the kinetic parameters of a model and the errors of the real experiment. The kinetic parameters of complex models are mainly selected using the experimental rate constants for the elementary reactions, and it is desirable to have available also the results of theoretical calculations or empirical or semiempirical estimates for all the key elementary stages as well as those elementary stages, which have not been studied or have been poorly studied. The experience in modelling complex gas-phase reactions indicates that, if there is no confidence in the reliability of the available experimental rate constants for any elementary reactions or if these data deviate significantly from the theoretical estimates or calculations, the latter should be preferred.⁶⁴

Models adequately describing a whole set of reliable and noncontradictory experimental data are the most valuable. The adjustment of a model to make it describe accurately a group of results by manipulating the rate constants for individual reactions is not very promising. Kinetic analysis indicates³⁶ that the yields of products often depend strongly on the parameters of those elementary reactions in which these products are neither formed nor consumed. Moreover, a rather complex kinetic model possesses certain 'internal stability'. In some cases, several parallel pathways to the formation of particular products exist, and

attempts to attain a specified change of their yield by varying the parameters of 'obvious' reactions may fail.

2. Characteristic features of the oxidation of methane at high pressures and moderate temperatures

The rise in pressure influences the course of gas-phase reactions for several reasons. As the pressure grows, the frequency of intermolecular collisions and hence the rate of the process increase, which decreases the reaction temperature. This, in turn, leads to the possibility of the 'survival' of certain intermediates, which would decompose or undergo further transformations at a higher temperature. Pressure can also shift the equilibria of reversible reactions, and in the oxidation of hydrocarbons at moderate temperatures the most important are reactions of the type^{113, 114}

Pressure changes can also result in a redistribution of the contributions of various paths in multipath reactions (for example, in the reactions of biradicals with unsaturated hydrocarbons),¹¹⁵ in an increase in the yields of the products of radical recombination, and in the deactivation of excited molecules.¹¹¹ Finally, pressure is a critical factor for chain reactions.¹¹²

The possibility that, even at pressures of several hundreds of atmospheres, fundamentally new reaction paths may appear, due to the manifestation of the cage effect, when a short-lived molecular complex formed during the process has time to react with other reactants before it decomposes, has been discussed.¹¹⁶

At the same time, modelling of kinetic processes occurring at pressures of tens of atmospheres is facilitated in the vast majority of cases by the possibility of neglecting the pressure dependences of the rate constants for unimolecular and termolecular reactions and of using their values obtained for the infinite pressure limit.¹¹¹ The heterogeneous destruction of radicals and intermediates at these pressures is limited by the rate of their diffusion to the

surface and plays a relatively small role, which also facilitates the modelling.

Since the DMTM process occurs at moderate temperatures, its modelling is simplified, because a large number of elementary reactions requiring high activation energies as well as processes involving CH, C, C₂, and other species, formed only at high temperatures, can be excluded from the kinetic scheme. Moreover, when rich mixtures are employed, some reactions that are significant only at relatively high oxygen concentrations can also be ignored.

3. The model of the high-pressure oxidation of methane

The development of a quantitative model of the high-pressure oxidation of methane is a complicated problem in spite of the above possibilities of simplifying the kinetic scheme. Models developed for other conditions cannot be applied directly to the DMTM process; at best, they can serve as the starting point for such work. The most logical and comprehensive programme for the modelling of the DMTM has been reported by Vedenev and coworkers.^{33–37, 64} An extensive study on the modelling of the DMTM has been carried out at Trondheim University and the Norwegian Technological Institute.^{39, 68} Several other research groups have also presented their results.^{45, 54, 61, 94} Unfortunately, these publications are either difficult to obtain^{68, 94} or give no detailed description or justification.^{45, 54}

Detailed analysis and comparison of various models is beyond the scope of our review. We shall consider only the first model suggested for the DMTM process,³⁴ since it has been most fully described and tested in the modelling of a wide range of experimental results by the same workers and by other research groups.^{48, 60} In addition, the base model³⁴ and its modifications^{37, 64, 117, 118} have proved suitable for describing various processes ranging from the DMTM^{34, 37, 64} to the oxidative condensation of methane¹¹⁸ or the oxidation of methane below atmospheric pressure.¹¹⁷

The base model³⁴ (Table 7) takes into account all the main reliably established elementary reactions that play a significant

role at high pressures and moderate temperatures, including heterogeneous destruction of radicals and peroxides on the reactor surface. Some reactions, discussed in the literature but not properly justified, have not been included in the model.

a. The main stages of the process

In a kinetic analysis of a complex process, the possibility of identifying the minimum number of elementary stages necessary and sufficient to describe the process and also the identification of the elementary stages the variation of the rate constants for which influences most appreciably the process kinetics or the product composition (the rate-limiting stages), are of prime importance. This problem is solved by analysing the sensitivity of the process kinetics, the rate of product accumulation, and other characteristic features to the variation of the rate constants for individual reactions.³⁵

Analysis of the process kinetics indicates³⁵ that the rate-determining stages include the decomposition of methyl hydro-

peroxide (stage 28 in Table 7) and of hydrogen peroxide (29) and also the formation of methyl hydroperoxide (17, 18, 38, 48) and hydrogen peroxide (36, 40). All the above stages of the peroxide formation and decomposition reactions belong to the group of reactions responsible for degenerate branching. The hydrogen peroxide formation (stage 19) is not included in the set of rate-determining stages, since at low temperatures the effectiveness of branching associated with the decomposition of hydrogen peroxide is low and the effective consumption of formaldehyde, one of the main degenerate-branching agents, exerts a greater influence.

The most important quadratic chain termination reactions are stages 6, 7, and 11. Although in stage 6 two relatively inactive $\text{CH}_3\text{O}_2^\cdot$ radicals are converted into two reactive $\text{CH}_3\text{O}^\cdot$ radicals, the latter are partly converted into HO_2^\cdot radicals (the competing stages 14 and 15), which are effectively destroyed in stage 11.

Due to the rapid decomposition of methyl hydroperoxide, stage 9 is a chain propagation reaction, though formally two

other reactions also cannot be ignored. The main contribution to the formation of formaldehyde is made by stages 15 and 39, while its consumption occurs mostly via stage 19. Formaldehyde is mostly produced via independent parallel processes, primarily stage 15, rather than via a path involving the oxidation of methanol (stage 39), and the rate of its formation exceeds that of methanol. The fact that the final yield of formaldehyde in the DMTM is almost an order of magnitude lower than that of methanol (see Section III) is determined only by the higher rate of the further transformation of formaldehyde. This is properly illustrated by the experimental data,¹¹⁹ indicating that in the initial stage of the process, when the degree of conversion of methane is less than 1%, the selectivity of the formation of formaldehyde (~54%) exceeds appreciably the selectivity of the formation of methanol (~36%) but falls very rapidly as the degree of conversion of methane increases to 4%–6%, which occurs in the final stage of the DMTM process.

Hydrogen peroxide plays an important role in the process kinetics and, in particular, in the self-acceleration mechanism, despite the fact that it has not been experimentally detected in the studies on the high-pressure oxidation of methane. Hydrogen peroxide is formed mostly in stages 11, 19, 36, and 40. Carbon monoxide is formed in stages 26 and 27 and carbon dioxide is produced in stages 51–53. Certain other reactions in which CO and CO₂ are formed, in particular, the addition of HO₂ radicals to H₂CO and the addition of HCO radicals to O₂, should probably also be taken into account, although their mechanisms have not yet been reliably elucidated.

The model discussed above³⁴ has been supplemented⁶⁴ by two heterogeneous termination reactions and a set of reactions describing in more detail the kinetics of the formation and decomposition of carbon monoxide and a significant side product — formic acid. A mechanism of the formation of the latter has been suggested.⁴⁷ However, analysis has shown that allowance for this set of reactions has no appreciable influence on the kinetics of the consumption of the reactants and the formation of the remaining products.

d. Modelling of the high-pressure oxidation of ethane and methane–ethane mixtures

The quantitative models of the oxidation of the closest methane homologues suggested by various groups of researchers do not cover the region of relatively high pressures and hence they unfortunately cannot be applied directly to the analysis of the partial oxidation of methane homologues to alcohols. Therefore, Vedenev et al.¹¹⁸ have developed a preliminary model of the high-pressure oxidation of ethane based on the model of the oxidation of methane at high pressures.³⁴

The recombination of the methyl radicals

has been regarded as the main reaction yielding ethane. At pressures above 10 atm, the values corresponding to the infinite-pressure limit were used for the pressure-dependent rate constants. The reactions of all the reactive species, namely H[•], O[•], OH[•], HO₂[•], CH₃[•], CH₃O[•], and CH₃OO[•], with ethane were taken into account. The numerical values of the rate constants for these reactions were taken from the published data, except for the reactions of ethane with HO₂[•] and CH₃OO[•], the rate constants for which were calculated from the rate constants for similar reactions involving methane with allowance for the 8.4 kJ mol⁻¹ decrease in the activation energy, in conformity with the Polanyi–Semenov rule.

The formation of ethene was described by the reactions

although the latter is probably not an elementary stage. This model includes both the forward and the corresponding reverse reactions related by equilibrium constants (altogether 188 elementary stages). The model does not take into account the formation of C₃ or higher hydrocarbons.

The model under consideration¹¹⁸ makes it possible to describe quantitatively a wide range of processes, from the oxidation of methane to methanol (20–100 atm, 650–750 K) to its oxidative condensation to ethane and ethene (1–5 atm, 900–1200 K), as well as flame propagation at not very high temperatures and cool-flame phenomena during the oxidation of methane. This model was used for the kinetic analysis of the oxidation of ethane and methane–ethane mixtures at high pressures. Preliminary results indicate that, when mixtures are used, the total selectivity of the formation of alcohols (methanol and ethanol) increases substantially and reaches a maximum when the ethane concentration in methane is 30%–40%, that it is possible to retain high selectivities for high degrees of conversion of the hydrocarbon (more than 8%), and that at $P > 20$ atm the selectivity depends only slightly on pressure.

VI. Analysis of the results of kinetic modelling of the high-pressure oxidation of methane

The present-day level of experimental studies on the DMTM process is deficient in systematic combined investigations carried out within the framework of a unified programme and there are significant discrepancies between the results which are difficult to explain. Therefore theoretical analysis of the process is of particular importance. Such analysis should certainly be based on models, which describe adequately the most reliable experimental data, but, unfortunately, experimental details which would allow a direct comparison of these data with the results of kinetic analysis are not always known. In this section, we present the results of the kinetic modelling of the DMTM process based on the model developed by Vedenev et al.³⁴ (Table 7) or its modification.⁶⁴

1. Modelling of the product yields and the process time

The kinetic modelling of the consumption of oxygen and product (methanol, formaldehyde, and carbon oxides) accumulation³⁴ was performed for the experimental conditions adopted in two previous studies^{4,25} (Figs 14 and 15). The model reflects correctly

Figure 14. Kinetic curves for the consumption of oxygen (I , I') and the accumulation of methanol (2 , $2'$), formaldehyde (3 , $3'$), CO (4 , $4'$), and CO₂ (5 , $5'$) during the oxidation of methane at $T = 614$ K, $P = 100$ atm, and for $[\text{CH}_4]:[\text{O}_2] = 8.1:1.0$. Dashed lines correspond to experimental data⁴ and the continuous lines to calculations.³⁴

Figure 15. Kinetic curves for the oxidation of methane at $T = 585$ K, $P = 367$ atm, and for $[\text{CH}_4]:[\text{O}_2] = 9:1$. The designations are the same as in Fig. 14. Dashed lines correspond to experimental data,²⁵ and continuous lines to calculations.³⁴

the main features of the process: the occurrence of self-acceleration, the duration of induction periods and of the whole process, the characteristic features of the product accumulation, and their dependences on temperature, pressure, and composition of the mixture. The fact that the appreciable concentrations of hydrogen peroxide (comparable to those of methanol) predicted by the model³⁴ were not detected in the high-pressure experiments^{4,22} may be explained by its rapid decomposition on metallic surfaces.

On the basis of an extended version of the model under consideration,³⁴ the delay period of the self-ignition of methane under the conditions reported by Melvin²² has been calculated.³⁷ The resulting self-ignition delay periods exceed the experimental values by a factor of only ~ 1.5 , which must be regarded as a very close agreement. In the same study,³⁷ the experimentally observed²² increase in the delay of self-ignition with increase in the oxygen concentration in the mixture²² (see Fig. 12) was theoretically interpreted for the first time. It was shown that during the self-ignition delay period, oxygen inhibits the process, because the reaction of the alkoxyl radicals with molecular oxygen is virtually a chain termination reaction, since the reactive chain-propagating $\text{CH}_3\text{O}^\bullet$ radical is converted via this reaction into the less reactive HO_2^\bullet radical, which is destroyed rapidly.

Figs 16–18 present the main results of the modelling of the DMTM process⁶⁴ based on the extended version of the model developed by Vedenev et al.³⁴ The variation of temperature within rather wide limits, for the optimal pressure and mixture composition and virtually complete oxygen conversion $\{[\text{O}_2]/[\text{O}_2]_0 < 5\%\}$, does not influence substantially the yields of the products (Fig. 16). The selectivity of the formation and the yield of methanol pass through a weak maximum in the region of 480°C . Conversely, the selectivity of the formation of formaldehyde increases monotonically over the whole temperature range, its increase accelerating with rise in temperature. A redistribution of the reaction paths favouring the formation of formaldehyde, ethane, and ethene^{49,50} is known to occur exactly in the temperature range above 500°C .^{49,50} Since at $P > 30$ atm and $T < 500^\circ\text{C}$, the target products, that is, methanol and formaldehyde, virtually do not decompose in the reactor after the complete conversion of oxygen,⁴⁰ the temperature range $420\text{--}480^\circ\text{C}$ may be considered optimal. The significant decrease in temperature (by up to 100°C) known from the literature and due to the promoting action of higher hydrocarbons (on passing to natural gas) or to the use of catalysts does not lead to a substantial change in the proportions of the products.

An increase in the temperature is naturally accompanied by a sharp decrease in the reaction time t_r (here t_r is the time required for 95% oxygen conversion). According to an estimate, the

Figure 16. Calculated temperature dependences of some parameters of the DMTM process at $P = 100$ atm and $[\text{O}_2] = 3\%$.⁶⁴

effective activation energy $E_{\text{eff}} \approx 167$ kJ mol⁻¹. This is in good agreement with the experimental value found from the temperature dependence of the self-ignition delays (from 163 to 188 kJ mol⁻¹).²²

An increase in the oxygen concentration results primarily in an increase in the degree of conversion of methane (Fig. 17) and in heating of the mixture. The calculations were carried out for two extreme process regimes, namely isothermal and adiabatic regimes. Although significant difficulties are associated with the practical realisation of an isothermal regime at high pressures, these calculations are of undoubted interest, since they demonstrate the possibility, in principle, of improving a number of characteristics of the process, primarily, the yield of methanol, relative to the process conducted under nonisothermal conditions. At $[\text{O}_2] \leq 3\%$, when the real temperature rise does not exceed 120°C , virtually identical results are achieved in both regimes. Allowance for nonisothermal conditions affects only the

Figure 17. Calculated dependences of some parameters of the DMTM process on the initial oxygen concentration ($P = 100$ atm, $T = 420$ °C). Continuous lines correspond to the isothermal regime and dashed lines to the adiabatic regime.⁶⁴

selectivity of the formation of formaldehyde and the reaction time (Fig. 17). Both versions of the calculation confirm the experimentally observed sharp decrease in the selectivity of the formation of methanol with increase in the oxygen concentration. At the same time, the isothermal calculation indicates that the yield of methanol grows slowly and monotonically as the oxygen concentration increases. The adiabatic calculation gives a qualitatively different picture. In this case, the selectivity of the

formation of methanol drops so sharply that at $[O_2] > 5\%$ its yield also decreases. Thus, the use of mixtures with a higher concentration of oxygen to increase the yield of methanol is not expedient unless the problem of heat removal has been fully solved.

It is noteworthy that, according to the calculations, one of the initial reactants, namely oxygen, is virtually an inhibitor, since an increase in its concentration leads to a decrease in the rate of reaction (an increase in its duration). Even a substantial increase in the temperature of the gas mixture by its adiabatic heating does not balance entirely the inhibitory effect of oxygen.

The calculated pressure dependences of the yields of the main products are in good agreement with the experimental results

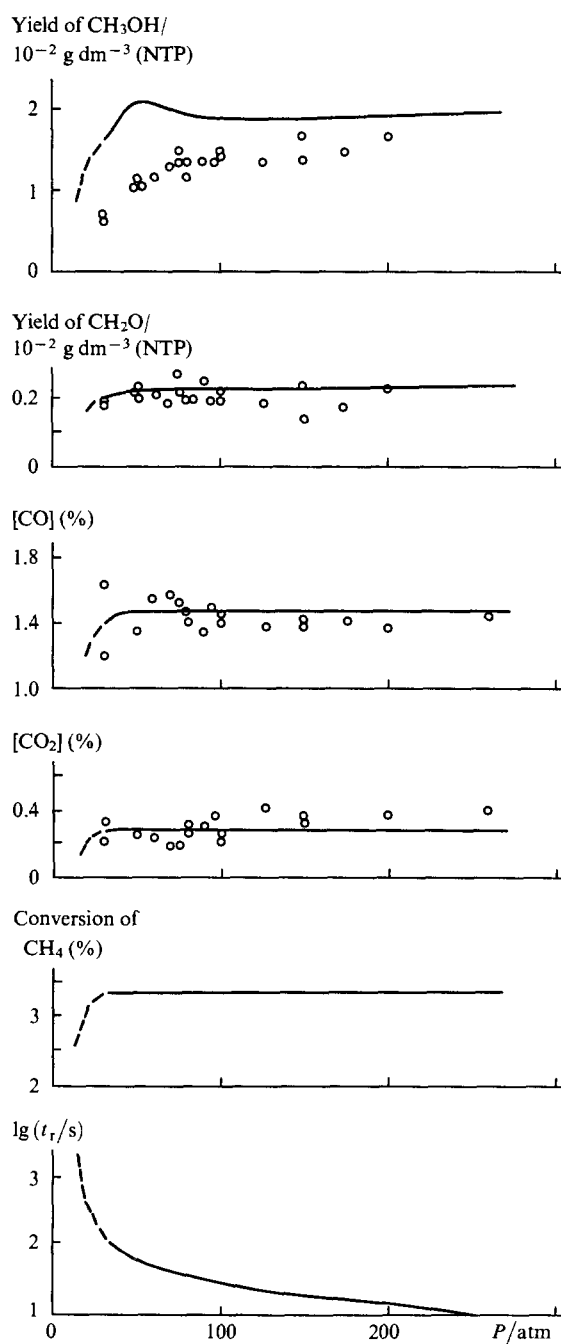

Figure 18. Calculated and experimental pressure dependences of some parameters of the DMTM process ($T = 420$ °C, $[O_2] = 3\%$). Continuous lines correspond to calculations⁶⁴ and circles correspond to experimental data.⁶²

obtained in a pilot plant⁶² (Fig. 18). According to the authors, the lower (by ~20%) yield of methanol is caused to a large extent by the imperfect separation unit, which does not exclude up to 10%–20% of the methanol formed being carried away with the gas phase.

Since the version of the model³⁴ used by Arutyunov et al.⁶⁴ (Table 7) is meant for describing processes occurring at pressures not less than 30 atm, the calculations carried out for pressures of 20 atm and especially 10 atm yield only qualitative results. Nevertheless, they reflect correctly the tendency towards a sharp decrease in the conversion of methane and in the product yields at pressures below 30 atm (see the dashed lines in Fig. 18). The sharp increase in the reaction time implies that, in this pressure region, there is a critical transition from the fast branched-chain reaction to a much slower chain-radical process.⁵⁷

Together with the experimental results, Fig. 1 presents a calculated plot of the selectivity of the formation of methanol in the DMTM against the degree of conversion of methane.⁶⁴ It is clearly seen that the vast majority of the experimental points lie near the theoretical plot.

2. The role of pressure in the critical transitions between the steady-state regimes in the oxidation of methane

As shown in the previous section, the high-pressure oxidation of methane generally occurs by a branched-chain mechanism. In the present section, we consider the results of a theoretical study of the influence of pressure on the regime in which the reaction proceeds.⁵⁷

The calculations were carried out for a mixture with the composition $\text{CH}_4 : \text{O}_2 = 9 : 1$ in the temperature range 600–750 K and the pressure range 1–100 atm. Fig. 19 shows the calculated pressure dependence of the reaction time (the time required for 95% oxygen conversion). It is clearly seen that there exists a narrow pressure range (the critical pressure P_{cr}) in which the process rate changes by several orders of magnitude. This can be caused only by a change in the reaction mechanism. The critical pressure is temperature dependent: it decreases from 6.2 atm at 600 K to 1.4 atm at 750 K (Fig. 20).

A change in the reaction mechanism should be manifested primarily by a change in the reaction kinetics. At pressures below P_{cr} , the shape of the kinetic curves is typical for nonbranched-chain reactions (more precisely, for reactions with weakly degenerate branching) (Fig. 21a). At pressures above P_{cr} , the self-acceleration of the reaction becomes much more clear-cut and the initial rate increases by a factor of approximately 10^3 (Fig. 21b).

The appearance of the critical phenomena discovered by calculations may be explained by analysing the initial stage of

Figure 19. Pressure dependence of the reaction time at $T = 650$ K.⁵⁷

Figure 20. Temperature dependence of the critical pressure.⁵⁷ The circles represent experimental¹¹⁹ temperatures of the onset of the reaction at $P = 1.5, 2$, and 3 atm.

the process³³ (Section V, 3b), where a steady-state branched-chain reaction occurs and the increase in the concentration of radicals is limited by the quadratic recombination of active centres.

In the one-centre approximation, one can easily obtain the expression

$$\frac{d[\text{CH}_3\text{OO}']}{dt} = 2k_1[\text{CH}_4]_0[\text{O}_2]_0 + \varphi[\text{CH}_3\text{OO}'] - 2k_7[\text{CH}_3\text{OO}']^2,$$

which implies that the character of the process is determined by the branching factor

$$\varphi = 2k_{17}[\text{CH}_4]_0 - k_{57},$$

Figure 21. Kinetics of the consumption of oxygen at $T = 650$ K:⁵⁷ (a) $P = 3$ atm; (b) $P = 4$ atm.

Figure 22. Kinetics of the accumulation of the methylperoxy radicals at $T = 650\text{ K}$: ⁵⁷ (a) $P = 3\text{ atm}$; (b) $P = 4\text{ atm}$.

(the numbers of the reactions and of the corresponding constants are given in Table 7).

At low pressures, $\varphi < 0$ and the concentration of the chain-propagating radicals is governed by the ratio of the rates of their generation and heterogeneous destruction. As the pressure increases, there is a transition to the region in which $\varphi > 0$, and the concentration of the propagating $\text{CH}_3\text{OO}^\bullet$ radicals is determined by the ratio of the rate of branching to the rate of their quadratic destruction. Since the rate of branching is several orders of magnitude higher than the rate of generation, the concentrations of the $\text{CH}_3\text{OO}^\bullet$ radicals at $\varphi > 0$ and $\varphi < 0$ differ from each other by approximately the same factor (Fig. 22). Figure 22 illustrates the calculations carried out using the full process scheme; however, the one-centre approximation for the initial stage of the DMTM gives the critical pressures $P_{\text{cr}}(600\text{ K}) = 6\text{ atm}$ and $P_{\text{cr}}(700\text{ K}) = 2\text{ atm}$, which are in good agreement with the values found by calculations based on the full model.⁵⁷

The calculated critical pressures correspond to the experimental plot of the temperature of the onset of reaction in the pressure range of 1.5–3 atm¹¹⁹ (Fig. 20), despite the fact that the precise value of the critical pressure may depend on certain parameters that are difficult to take into account, for example, the reactor design. From the calculations performed, it is clear that the experimental conditions influence very strongly the initial stage and, consequently, the whole oxidation process. For example, whereas at $T = 650\text{ K}$ and $P = 3\text{ atm}$ the presence of a catalyst or a change in the reactor design has a substantial influence on the process, when the pressure is increased to 4 atm (this leads to an increase in the quasi-steady-state concentration of radicals by a factor of 10^3 – 10^4) this influence can disappear almost entirely.

The results presented by Vedenev et al.⁵⁷ account for the fact that the introduction of catalysts, or homogeneous promoters, or other initiation methods (Section III) does not influence appreciably the DMTM process, carried out at sufficiently high

pressures. In fact, at $\varphi > 0$, an additional generation of radicals, even in much larger quantities than in the thermal process, cannot compete with their generation in the branched-chain reaction itself. Apparently, the fact that the use of catalysts becomes unnecessary when the oxidation of methane to formaldehyde is carried out at $P > 3\text{ atm}$ in the temperature range 873–923 K can be explained in a similar way.⁴⁴

3. Theoretical study of the possibility of the occurrence of cool-flame phenomena during the high-pressure oxidation of methane

As stated in Section V, the mechanism of the oxidation of methane is highly nonlinear, because virtually all the main chain initiation, chain propagation, chain termination, and branching reactions are nonlinear. Experimental results also indicate that, during the oxidation of methane, nonlinear phenomena can arise. These phenomena include the temperature oscillations at high pressures,⁴² the appearance of cool flames,^{101–103} and the existence of a region where the reaction rate has a negative temperature coefficient.¹⁰⁴ It is natural to assume that similar regimes may also arise in the oxidation of methane under other conditions that have not yet been studied, for example, at high pressures.

The main sign of the existence of cool flames in the oxidation of hydrocarbons is that a rapid increase in temperature is replaced by the retardation of the process before the reactants have undergone complete chemical conversion. The attainment of the peak conversion rate is usually accompanied by the luminescence of excited formaldehyde. Then the reaction either stops or, conversely accelerates again, up to the hot ignition of the mixture. Two or more cool-flame flashes can occur. In those cases where the appearance of cool flame is followed by the self-ignition of the mixture, the process includes at least two stages, namely, the cool-flame stage and the hot-ignition stage.^{99, 100}

Basevich et al.¹⁰⁵ carried out mathematical modelling of the homogeneous oxidation of methane under nonisothermal conditions, with heat removal from the reactor surface, based on the kinetic scheme for the oxidation of methane to methanol suggested previously³⁴ (Table 7).

The calculations were first carried out for conditions under which successive cool-flame oxidation and ignition have been observed experimentally in methane–oxygen mixtures.¹⁰¹ At initial temperatures $T_0 < 710\text{ K}$, the reaction does not occur for up to 700 s. In the temperature range $T_0 = 728$ – 753 K , flashes with incomplete heat evolution are observed and are followed by retardation of the reaction, which is accompanied by a temperature drop caused by the cooling of the reaction mixture by the reactor walls (Fig. 23). At $T_0 > 758\text{ K}$, ignition occurs (the arrows

Figure 23. Calculated reaction time dependences of the reaction temperature for methane–oxygen mixtures¹⁰⁵ under the following experimental conditions: $[\text{CH}_4]_0 = 67\%$, $[\text{O}_2]_0 = 33\%$, $P = 0.92\text{ atm}$. The numerals denote the initial temperatures (K).

at the ends of the curves denote a further increase in the temperature). The calculations are in fairly good agreement with the experimental results.¹⁰¹

There are almost no experimental data dealing with cool-flame phenomena under the conditions of the high-pressure oxidation of methane. Therefore, a series of calculations involving gradual transition to high pressures were performed in the modelling, so that signs of the appearance of a cool flame could be detected in each stage.¹⁰⁵ The calculations were carried out for the pressures $P_0 = 1, 1.8, 4.6, 9.2, 18.4, 70$, and 100 atm, at the constant initial temperature $T_0 = 710$ K, and at the initial concentrations $[\text{CH}_4]_0 = 67\%$ and $[\text{O}_2]_0 = 33\%$.

In the analysis of the results of modelling, a general rule was discovered: an increase in pressure leads to the self-ignition of the mixture, the ignition being achieved after progressively shorter periods. Even intense heat transfer (within the limits of reasonable heat-transfer coefficients) from the gas to the reactor walls cannot stop ignition and cause a reverse temperature variation, although it does increase the induction periods (the times required for the development of the reaction before self-ignition). However, the increase in temperature is accompanied by explicit signs of the cool-flame stage. Fig. 24 shows a typical dependence of the temperature of the mixture on reaction time. When the time scale is expressed in seconds, there are no signs of the appearance of a cool flame, and the curve can seemingly be referred to a normal self-ignition process. However, on the microsecond time scale one can see that, after $t = 4.65$ s, the increase in the temperature to 1400 K is followed by retardation of the reaction, and the next flash occurs only ~ 10 μs later. Thus, in the present case, the duration of the first stage is 4.65 s and that of the second is ~ 10 μs . Of course, it is extremely difficult to detect these two stages experimentally. The calculated kinetic curves and the time dependences of the reaction temperature under the conditions of the self-ignition of methane-oxygen mixtures at 70 atm are presented in Fig. 25. A similar $T(t)$ plot is also obtained in the absence of heat losses. Further analysis showed that similar features are also observed at low pressures, for example, under the conditions indicated in the caption to Fig. 23 (at $T \geq 750$ K), when the ignition on the time scale expressed in seconds seems to be a one-stage process.

The calculations were also carried out for $P_0 = 100$ atm and the temperatures $T_0 = 683\text{--}710$ K, but for lower oxygen contents, which is typical for the direct homogeneous oxidation of methane to methanol. It turned out that, as the oxygen content decreases, the signs of a cool flame become increasingly less clear-cut and for $[\text{O}_2] \leq 5\%$ they disappear entirely.

The elucidation of the mechanism of the appearance of cool flames and the subsequent retardation of the reaction remains the

Figure 24. Calculated reaction time dependences of the reaction temperature on time scales in terms of seconds (a) and microseconds (b) for methane-oxygen mixtures at a high pressure.¹⁰⁵ $[\text{CH}_4]_0 = 67\%$, $[\text{O}_2]_0 = 33\%$, $P = 70$ atm, $T_0 = 710$ K.

Figure 25. Calculated kinetic curves (1–5) and reaction time dependence of the reaction temperature (6) under the conditions of the self-ignition of methane-oxygen mixtures at a high pressure.¹⁰⁵ $[\text{CH}_4]_0 = 67\%$, $[\text{O}_2]_0 = 33\%$, $P = 70$ atm, $T_0 = 710$ K. The maximum concentrations corresponding to 1 on the ordinate axis (mol cm^{-3}): (1) $[\text{H}_2\text{O}_2] = 2.279 \times 10^{-6}$; (2) $[\text{CH}_3\text{OOH}] = 1.412 \times 10^{-8}$; (3) $[\text{HO}_2] = 1.619 \times 10^{-6}$; (4) $[\text{CH}_3\text{O}_2] = 2.156 \times 10^{-7}$; (5) $[\text{H}] = 1.420 \times 10^{-8}$. The maximum temperature T_{max} on curve 6 is 2273 K.

most important problem. This is a very complex nonlinear process involving critical phenomena, which is not amenable to a simple interpretation. For example, it cannot be explained by the mere shift of the equilibrium

to the left with increase in temperature, although the decomposition of the methylperoxyl radical certainly leads to a decrease in its concentration and to a change in the reaction mechanism, because in the first stage, prior to the appearance of a cool flame, branching is accomplished primarily via methyl hydroperoxide, whereas after the appearance of a cool flame, in the high-temperature region, it occurs mostly via hydrogen peroxide. Other reactions of methylperoxyl radicals are also significant in the mechanism by which a cool flame arises.

It should be emphasised that a qualitative agreement between the calculations¹⁰⁵ and the experimental results¹⁰¹ was achieved without any adjustment of the kinetic parameters of the model, except that the pressure dependences of the rate constants for some reactions were taken into account.³⁴ No attempts to attain a closer agreement with the experimental values were undertaken, because the main task was to discover whether a kinetic description of phenomena of this type is possible in principle.

4. The influence of mixing of the reactants on the product yield

In the kinetic modelling of the homogeneous oxidation of methane to methanol, the transverse and axial diffusion processes are usually neglected, for the sake of simplicity, even in the most commonly encountered case where the initial reactants, methane and an oxidant (oxygen or air), are mixed directly in the reactor. However, some workers, for example, Gesser et al.,²⁸ have noted that it is very important to achieve the homogeneity of the mixture in order to obtain a high yield of methanol. Therefore, the need arose to find out whether or not the influence of mixing on the main chemical reaction may be ignored and to identify the conditions under which this influence is insignificant. This problem has been analysed by Basevich et al.¹²⁰

A very simple flow reactor was considered in which air is supplied along an axial channel and methane is supplied along an outer coaxial channel. Then the reactants are mixed and interact to afford methanol. To simplify the complex two-dimensional problem arising during the joint consideration of the transverse (along the y axis) and axial (along the x axis) diffusion, these two types of diffusion were considered independently of each other.

In addition, the process was assumed to be isothermal, which is fairly close to the actual conditions during the oxidation of methane to methanol.

In the calculations with allowance for the transverse diffusion, two further assumptions were made:

(1) the rates of entry of the reactants via both channels are identical (isokinetic flow) and coincide with the flow rate in the reactor;

(2) the concentration gradients along the x axis are small compared with those along the y axis and may be ignored.

The initial distribution of the methane and oxygen concentrations was specified as power functions taking into account the position of the initial point in the reactor. The location of the boundary between methane and oxygen corresponded to the chosen ratio of $[\text{CH}_4]$ and $[\text{O}_2]$, and the time t determined the position x of the cross-section being considered: $x = vt$, where v is the flow rate of the gas in the reactor.

The modelling was based on the mechanism suggested by Vedenev et al.³⁴ (Table 7) with some refinements.¹²⁰ The problem under consideration is much more complex than the simple kinetic problem for a homogeneous mixture, since in this case one should take into account not only the chemical reaction but also the diffusion of all the components. Hence, a space coordinate is added to the time coordinate and the kinetic problem is solved simultaneously at all the points in space specified by the plotting step. Therefore, a number of additional expedients were used in the calculations in order to reduce the size of the kinetic scheme being processed and diminish the scale of the calculations.¹²⁰

Two extreme gas flow regimes in the reactor were considered separately. These are laminar flow (Reynolds numbers $R < 2000$), which corresponds to the normal conditions in laboratory experiments, and turbulent flow ($R > 2000$), which is more typical for industrial large-scale reactors. This large difference between the conditions in the flow of the gas mixture and hence between the mixing conditions in laboratory reactors and industrial units permanently poses the question whether data obtained in laboratory studies may be legitimately transferred to industrial plants.

The calculations were carried out for the methane–air system at a pressure of 100 atm and a temperature of 683 K in a reactor 4 cm in diameter with a central channel of variable cross-section for the air supply. Typical results of the calculation carried out for a laminar flow are presented in Fig. 26, which gives an estimate of the spatial distribution of the methane, oxygen, and methanol concentrations at various times.

In the initial moment, $t = 0$, the reactants are not mixed, the concentration of the oxidant at the reactor axis $[\text{O}_2]_0 = 20.9\%$, and the concentration of methane at the periphery $[\text{CH}_4]_0 = 100\%$. For the chosen reactor size, this corresponds to the $[\text{CH}_4]:[\text{O}_2] = 33.6:1$ ratio, typical for the DMTM process. At consecutive times of 0.93, 2.40, and 3.90 s, the concentrations of the components are affected by the diffusion of oxygen to the periphery, by the diffusion of methane to the reactor axis, and by the simultaneous chemical reaction producing methanol. The distribution of the concentrations of all the other intermediate and final products was also calculated.

From Fig. 26, it can be seen that the concentrations of the reactants do not level off over the reactor cross-section in the time interval under consideration: the methane concentration on the reactor axis ($y = 0$) at the end of the process is only 58%, and that of free oxygen is 12%. The time required for the reaction in the homogeneous mixture to be completed (that is, the time required for the consumption of 99% of the oxygen $t_r = 4.45$ s) is insufficient for the complete mixing of the reactants, i.e. $t_r < t_{\text{mix}}$, where t_{mix} is the mixing time. This accounts for the low degree of conversion η , which proved to be only 0.32%. The selectivity with respect to methanol, $S_{\text{CH}_3\text{OH}} = 47.6\%$, is also lower than that in the homogeneous mixture, in which $S_{\text{CH}_3\text{OH}} = 50.2\%$ (Table 8). In addition, during the oxidation of methane with slow molecular mixing along the whole length of the

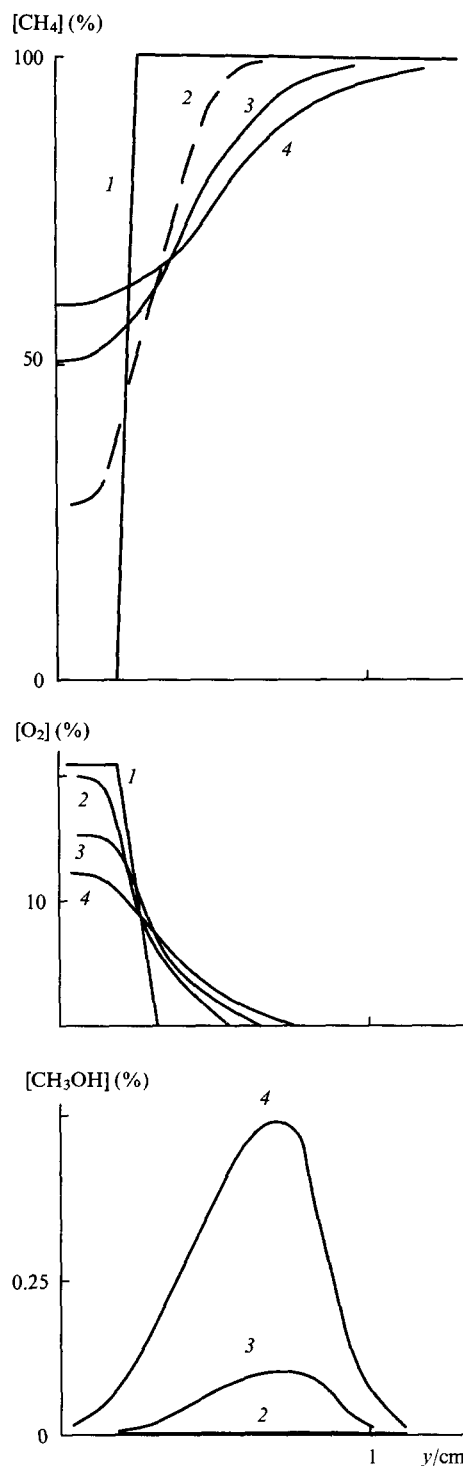

Figure 26. Concentration profiles for some components of the methane oxidation reaction in the transverse cross-section of a reactor with molecular diffusion.¹²⁰ $P = 100$ atm, $T = 683$ K, $[\text{CH}_4]:[\text{O}_2] = 33.6:1$, air as the oxidant. Time (s): (1) 0; (2) 0.93; (3) 2.40; (4) 3.90.

reactor, large volumes of the mixture with an oxygen content more than 5%, capable of self-ignition, are formed (Fig. 26), which makes the process less stable.

In the case of turbulent flow, the diffusion coefficient, which is the same for all the components, was calculated from the equation¹²¹

$$D = \varepsilon v L,$$

Table 8. Influence of the transverse diffusion of the reactants and of the conditions in the flow of gas mixture on the degree of conversion of methane and the selectivity of the formation of methanol.¹²⁰

Flow	<i>t</i> /s	[O ₂] ₀ (%)	η (%) ^a		S _{CH₃OH} (%) ^a	
			A	B	A	B
Laminar	2.27	0.52	0.86	0.19	68.2	63.0
	4.45	2.61	2.87	0.32	50.2	47.6
	6.87	4.7	5.14	2.5	39.6	33.6
Turbulent	2.27	0.52	0.86	0.89	68.2	68.7
	4.45	2.61	2.87	2.66	50.2	54.0
	6.87	4.7	5.14	5.0	39.6	41.5

^a Supply of the reactants: A — joint, B — separate.

adopting the recommended values for the degree of turbulence $\varepsilon = 0.03$ and the scale of turbulence $L = 0.35d$ (d is the reactor diameter). The calculations for a pilot unit³¹ ($d = 4.0$ cm, flow rate $v = 3$ m s⁻¹) yielded $D = 12$ cm² s⁻¹, which is greater than the molecular diffusion coefficients by three orders of magnitude.

The distribution of the concentrations in the case of turbulent diffusion at various times is shown in Fig. 27 under the same conditions as in Fig. 26. In this case, the mixing is very rapid and is

Figure 27. Concentration profiles for some components of the oxidation of methane in the transverse cross-section of a reactor with turbulent diffusion.¹²⁰ $P = 100$ atm, $T = 683$ K, $[\text{CH}_4]:[\text{O}_2] = 33.6:1$, air as the oxidant. Time (s): (1) 0; (2) 0.0015; (3) 0.014; (4) 0.029; (5) 0.9; (6) 6.3; (7) 90.

completed in less than 0.9 s. During this time, less than 1% of the final quantity of methanol is formed. After that, the reactions proceed in the resulting homogeneous mixture. In the example shown in Fig. 27, the degree of conversion is practically the same as in a homogeneous mixture (2.66%), and the selectivity with respect to methanol $S_{\text{CH}_3\text{OH}} = 54\%$ (Table 8), i.e. the case where $t_{\text{mix}} < t_r$ is realised. Thus, for turbulent diffusion, the degree of conversion is similar to the corresponding value attained in a homogeneous mixture and the selectivity is even somewhat higher. This is natural, because the duration of the chemical reaction is much greater than the characteristic time of the turbulence (frequencies from 10 to 1000 Hz). Hence, the turbulence does not influence the course of the reaction. The results obtained are in agreement with the experimental data indicating that good characteristics of the process are achieved when the reactants are quickly mixed by jets, the velocity of which is close to the velocity of sound.²⁷ For rapid turbulent mixing, mixtures capable of self-ignition exist only in the initial section of the reactor (Fig. 27); in other words, the process is more stable than that involving slow molecular mixing.

Calculations¹²⁰ have shown that, for molecular diffusion coefficients, axial diffusion has no influence on the DMTM process. When the diffusion coefficients correspond to a turbulent regime, the observed influence of axial diffusion is slight: the concentration profiles shift somewhat along the axis to the left, that is, to the entry to the reactor, and the yields of all the main products virtually do not change.

Thus, the following conclusions can be drawn:

- kinetic modelling with no allowance for diffusion under the conditions of rapid mixing provides a qualitatively correct description of the chemical process and evaluation of the product yields;
- when methane and oxygen are supplied separately, their rapid mixing ensuring that the $t_{\text{mix}} \ll t_r$ relation holds is a necessary condition for a high degree of conversion of methane and high selectivity of the formation of methanol;
- in the case of slow mixing, the process is less stable.

5. Modelling of circulation regimes in the oxidation of methane

To make the DMTM process suitable for the industrial production of methanol, one should increase the degree of conversion of natural gas, while maintaining the high selectivity of the formation of methanol. In reality, this can be achieved by conducting the process according to a circulation scheme. In this process, reactive gas-phase products (carbon monoxide and hydrogen and also nitrogen, in the case where oxidation is carried out with air) can accumulate in the circulating gases. This naturally influences the characteristics of the DMTM technological process. To elucidate the possibility of improving the characteristics of the process by using a circulation scheme, the corresponding theoretical analysis has been carried out with the aid of a special kinetic programme.¹²² The kinetic model developed by Vedenev et al.³⁴ supplemented by reactions that take more precise account of the interaction between the products formed, was used in the calculations.

The methane oxidation process with product recirculation includes three stages.

1. Methane and an oxidising agent (air or oxygen) enter the reactor, where methane is oxidised.

2. The gases leaving the reactor are cooled and the liquid phase containing the target product (methanol) is separated. As this takes place, all the unstable intermediates decompose.

3. The gaseous products are partly discarded, and the rest is mixed with fresh methane (which makes up for the lost liquid phase and for the discarded part of the gas phase) compressed to the operating pressure, heated, and injected into the reactor once again, together with the oxidising agent.

The calculations were carried out for conditions close to the optimal conditions for a flow-type process: a temperature of

713 K, a pressure of 100 atm, a reaction time corresponding to the consumption of oxygen (several seconds), and a constant oxygen concentration at the reactor inlet of 2.2%.

The relative quantity of the gas being recycled λ has the greatest influence on the course of the process involving circulation ($\lambda = 0$ means that all the gas is discarded, which corresponds to a flow regime; $\lambda = 1$ means that no gas is discarded, and stable gaseous products are accumulated in the circulating gas, while the methane concentration at the reactor inlet continuously decreases). If oxygen is used as the oxidant, even a considerable number of cycles N carried out at $\lambda = 1$ influences only slightly the initial methane concentration $[\text{CH}_4]_0$ (Fig. 28). Accordingly, the quantity of methanol formed in each cycle decreases equally slowly. The total amount of the methanol collected continuously increases, so that at $N = 30$ its overall yield $\Sigma[\text{CH}_3\text{OH}]$ reaches $\sim 30\%$. The only component that is also accumulated continuously in the circulating gas is carbon dioxide (Fig. 29); its concentration reaches 17%. The other gaseous products (carbon monoxide, hydrogen, and ethane) are accumulated much more slowly, because they are consumed during the reaction. The concentrations of these compounds after 30 cycles are 2.4, 1.2, and 0.17%, respectively.

The selectivity of the formation of methanol in the first pass under these conditions is 57.2%. As the number of cycles increases, $S_{\text{CH}_3\text{OH}}$ decreases somewhat, but for $N = 30$ it is still fairly high and amounts to 50%, so that on average $S_{\text{CH}_3\text{OH}} = 52\%$. The results obtained for $0 < \lambda < 1$ are intermediate between those observed in the flow and closed-loop (without discard) regimes.

Thus, when the circulation scheme is used, the degree of conversion in one pass virtually does not decrease, the selectivity decreases only slightly, but, in return, the overall quantities of methane being converted and methanol formed increase sharply. At $\lambda < 1$, after a fairly large number of cycles have been carried out, the system approaches a steady state in which the concentrations of the reaction products at the end of each step remain virtually constant. This corresponds to the realisation of the circulation scheme in the steady-state regime. The higher the rate of accumulation of the nonconsumable inert gases (carbon dioxide and nitrogen), the larger the proportion of the gas, which needs to be discarded (that is, the smaller the value of λ) and the smaller the number of cycles required for a steady-state to be achieved. However, the degree of conversion of the initial

Figure 28. Dependences of the initial methane concentration (1), the final current methanol concentration (2), and the overall yield of methanol (3) on the number of cycles (N) at $P = 100$ atm, $T_0 = 713$ K, $[\text{O}_2]_0 = 2.2\%$, $[\text{CH}_4]_0 = 97.8\%$.¹²²

Figure 29. Dependences of the final concentrations of CO_2 (1), CO (2), and H_2 (3) on the number of cycles (N) at $P = 100$ atm, $T_0 = 713$ K, $[\text{O}_2]_0 = 2.2\%$, $[\text{CH}_4]_0 = 97.8\%$.¹²²

methane diminishes correspondingly. The selectivity at steady-state depends on the ratio between the steady-state concentrations of methane and oxygen, which is determined by the value of λ , chosen from the standpoint of attaining the optimal yields of the products.

The DMTM circulation scheme has also been modelled for the case where air is used as the oxidising agent.¹²² The λ parameter was varied within limits ensuring a steady-state proportion of nitrogen in the working medium (up to 60%).

It may be assumed that when the circulation scheme is used, the energy expenditure is lower than in the flow regime, because in the former case the quantity of mains gas that has to be brought to the operating pressure is much smaller. However, the productivity of the reactor diminishes due to the lowering of the steady-state initial methane concentration and the decrease in the selectivity of the formation of methanol. Therefore, the optimal version of the circulation scheme should be chosen with allowance for particular technical and economic conditions including the possibility of utilising the discarded gases, for example, for heating the operating mixture, etc.

Thus, the modelling has demonstrated the possibility of implementing the circulation scheme for the oxidation of methane, in which the degree of conversion of methane increases by more than an order of magnitude with no substantial decrease in the selectivity of its formation.

VII. Technical and economic aspects of the direct oxidation of natural gas to methanol

1. Prospects for the increase in the use of methanol and other oxygenates

Methanol is among the main products of organic synthesis. The constant intense development of its production is due to the continuous extension of its applications, the main ones being the production of formaldehyde, acetic acid, solvents, ethers, and other chemicals.^{81,123} In the future, methanol may form a universal basis for organic synthesis. It is finding an increasing use in the production of high-octane components of motor fuels, primarily, of methyl *tert*-butyl ether (MTBE).¹²⁴ In the overall world consumption of methanol in 1990 (19.6 million tonnes), 40% was due to the production of formaldehyde, 45% was due to other chemical products, and 14% was accounted for by fuel components.

From 1990 to 1995, the annual increase in the demand for methanol in North America should reach 6.6%, while in the

previous five years it was only 4.3%. The major part of this increase is accounted for by the production of MTBE, necessary to meet demands associated with protection of the atmosphere against the pollutants arising during the combustion of automobile fuels. The USA demand for MTBE in 1995 should be from 15 to 30 million tonnes. However, the production of oxygenates may delay the introduction of clean fuels. Without new plants for the synthesis of methanol, North America will experience a deficit in the capacity for the production of methanol estimated as 4.7 million tonnes a year already by 1995.¹²⁵

Whereas in 1990 the producers of formaldehyde were the main users of methanol in the USA, already by 1995 from 38% to 55% of methanol will be consumed for the production of MTBE.¹²⁵ The boom in the consumption of MTBE in the USA cannot but influence the world production of MTBE and methanol, since the USA import not only MTBE but also the methanol and butane necessary for its production.⁸⁰ It is expected that in 1991–2000 the annual increase in the world consumption of methanol will be 5.6% and the increase in the consumption of MTBE will be 20%.⁸⁰ Forecasts predict that by 2001 the overall consumption of oxygenates will increase by a factor of 10 with respect to its current level¹²⁶ and the cost of their production will amount to 50 billion dollars by 2000.¹²⁷ In view of the fact that since 1995 more than 85% of the petrol used in the USA should contain oxygenates, a global deficit of oxygenates, including methanol, and a rise in their prices have been predicted.¹²⁷

Methanol is an alternative to an oil distillate fuel. There are examples of its use in power plants as a fuel for gas turbines. Boilers can also run on methanol. The main advantage of methanol over distillate fuels is that it contains no sulfur. The possible consumers of methanol are power plants, transport, food industry, metallurgy (reducing gas), and some other industries. In certain cases, it is economically favourable to produce hydrogen from methanol.¹²³

The significance of methanol as one of the most promising alternative fuels for transport has long been discussed in the literature^{128–130} [see also the proceedings of the international symposia on alcohol fuels IX ISAF, Florence (Italy), 1991; X ISAF Colorado-Springs (USA), 1993]. If full advantage is taken of the beneficial motor-fuel properties, primarily the high octane numbers, of methanol, mixtures of alcohols and petrol–methanol mixtures, these fuels become quite competitive with modern petrols.^{128, 131} Since automobiles can run on mixtures containing about 20% of methanol or other alcohols, the use of these mixtures may become an important source of the energy for transport.¹²³

The energetic efficiency of the engine specially developed to run on methanol is 30% higher than that of the analogous petrol engine.¹³¹ Its environmental advantages are particularly attractive. However, the large-scale use of methanol is impossible without a reconstruction of both the methanol-producing and oil refining industries and, most of all, of the system of distribution of automobile fuels.

As a response to the need to improve the environmental characteristics of motor fuels, the so called 'reformulated gasoline' has been developed. This fuel contains additives such as methanol, ethanol, MTBE, ETBE, mixtures of alcohols, etc., which has made it possible to increase the oxygen content in a fuel to 3.7%.¹³² Large-capacity production of MTBE already exists in many countries and its world output in 1990 amounted to 8 million tonnes (13 million tonnes has been predicted for 1995 and 25 million tonnes for 2000).¹³³ However, an important place in the concept of ecologically clean fuels is occupied by the 'fuel alcohols', that is, by mixtures of alcohols used either by themselves or as high-octane additives to motor fuels.^{132, 134} The fuel alcohols consisting of methanol to which 20%–30% of higher alcohols has been added make it possible to increase the octane number and to reduce the amount of harmful exhaust gases; their mixtures with petrols do not separate into layers in the presence of water and they are a real alternative to ethers.^{132, 134} The production of these

fuels, unlike the production of MTBE and other ethers, does not require the corresponding alkenes, which are themselves valuable products and in limited supply.¹³²

Methanol can be used to fuel an engine in a pure state, as an emulsion in hydrocarbons, or as one of the components in a separate fuel supply system. It can be preliminarily converted into CO and H₂ and into highly inflammable compounds (like dimethyl ether). Finally, it can be converted in the presence of catalysts (to obtain heat) or in fuel cells (to obtain electric energy). At present, one of the most feasible schemes for the operation of electric cars involves the catalytic conversion of methanol into hydrogen, which supplies the vehicle-borne fuel cells.¹²⁵

All the promising aspects of the development of environmentally clean transport are associated in one way or another with the use of alcohols, either directly in fuel mixtures or as intermediate compounds in the synthesis of MTBE and other ethers. This raises the problem of lowering the cost of methanol, which has so far been neglected within the framework of the traditional technology for its production via synthesis gas.⁸³

Natural gas is almost unreservedly considered to be the main raw material source for meeting the increasing demand for methanol, although a sharp increase in the use of natural gas for the production of methanol requires a thorough economic analysis.¹³⁵

2. Technical and economic estimates of the technological process for the direct oxidation of natural gas to methanol

Extensive application of a new technology for the production of methanol is impossible without serious economic prerequisites. Some economic estimates of the effectiveness of this process have been reported.^{67, 87, 136–138}

Edwards and Foster⁸⁷ have reported an economic assessment of the production of methanol by the direct catalytic partial oxidation of natural gas with an output of 2000 tonnes per day. If the selectivity of the formation of methanol is more than 77%, the direct process undoubtedly proves to be more economically viable than the traditional method. With regard to consumption of heat and hydrocarbons, the effectiveness of the direct partial oxidation of methane is also higher.¹³⁶ It has been reported⁶⁷ that methanol obtained by the direct oxidation would be 20%–30% cheaper than the product obtained by the existing methods. Some economic aspects have been discussed by Renesme et al.¹³⁸ and Crocco.¹³⁹

According to economic calculations, the cost of raw materials accounts for ~50% of the operating costs, however there exist vast reserves including the casing-head gas, oil refinery gases, and de-ethanisation gases, which now have no commercial value and are burned in flares, thus polluting the environment.

The use of gases containing substantial amounts of higher hydrocarbons would make it possible to decrease sharply the pressure and the temperature of the process. The degree of conversion of these gases in one pass can be as high as 20%, instead of 3%–4% obtained in the oxidation of methane; the efficiency may be increased further by using the circulation oxidation scheme. In addition, this process may yield valuable products, for example, iso-alcohols or aldehydes, in fairly high yields, and the isolation of these products would recoup a considerable part of the production costs.

The currently available technical solutions allow the selectivity of the formation of methanol in this process to be increased to 60% or more, and the process may therefore become nearly profitable.

3. Technological scheme for the direct oxidation of methane to methanol

The technological scheme for the DMTM is fairly simple, and this is one of its main advantages. The catalytic version of the process has been described in a paper cited above.⁸⁷ A basic scheme for a plant producing methanol by the direct gas-phase oxidation of natural gas with a productivity of 10 000 tonnes of methanol per

year, developed within the framework of the Russian state programme 'Environmentally Clean Power Engineering' has been reported.⁵⁵ The plant is meant to satisfy the local needs of the gas-industry for methanol and motor fuels. The project involves the development and the subsequent commercial production of self-contained modular units for the direct homogeneous conversion of natural gas into methanol and provides for the possibility of further transformation of methanol into a high-octane petrol.

The process makes it possible to avoid the intermediate formation of the synthesis gas, which is unfavourable from the thermodynamic standpoint, and the equipment involved is relatively simple. The project is based on a kinetic analysis^{33–37} and on the results of pilot tests on a unit with a production capacity of 100 tonnes of methanol per year.³¹ The main parameters of the process are: pressure 5–10 MPa, temperature 380–480 °C (depending on the composition of the gas), oxygen concentration 2.8%, degree of conversion of oxygen 95%–98%, yield of crude methanol 20 kg per 1000 m³ of the input gas or 0.63 kg per 1 kg of the converted gas.⁵⁵

After being compressed to an operating pressure of 5–10 MPa and heated to 380–480 °C, natural gas enters a gas-phase mixer, which also serves as the reactor. Oxygen (or air) is conveyed to the same reactor at a pressure of 10 MPa. After the reaction, the mixture is cooled in a heat exchanger and then conveyed to a condenser, in which liquid products are condensed. It then goes to an apparatus for the neutralisation of acids. After that, the liquid phase is separated from the unreacted gas in a separator. The resulting liquid product is concentrated in a fractionating column. Simultaneously, the formaldehyde formed is separated as an aqueous solution (formalin). The unchanged gases are either discharged to a gas pipeline or reenter the unit inlet. If there is an additional catalytic unit for producing petrol, the crude methanol obtained is supplied directly to the inlet of this unit. The degree of conversion of natural gas in one pass is less than 3%. Since the process yields no significant amounts of incombustible side products, the natural gas may be returned to the gas pipeline or recycled.⁵⁵

The unit is meant for the independent conversion of natural gases into crude methanol, containing more than 90% methanol, in remote gas fields where there is no developed infrastructure. It does not require a complex repair base or highly qualified personnel. The methanol produced is supposed to be consumed at site as an inhibitor of hydrate formation in the extraction and transport of natural gas and also for its direct conversion in a second unit into petrol with an octane number of 93 (3300 tonnes per year) and for other purposes. The formalin obtained as a side product also finds application in the gas fields.

In the course of the implementation of this project, a number of novel technological approaches were developed which allowed the yield of methanol to be increased by approximately 30%. The use of this technology (with the parameters already attained) in remote or relatively inaccessible oil and gas fields is at least 30% more profitable than the traditional method for the production of methanol.

As noted above, when oxygen is used as the oxidising agent, the content of incombustible impurities in the outgoing gases hardly increases and the gas can therefore be returned to the pipeline. In the case where this process is carried out just before the gas is dispensed to the consumer, the best way is to use the cheaper air as the oxidising agent.

The most significant drawback of the homogeneous partial oxidation of natural gas to methanol at high pressures is the need to maintain a low initial oxygen concentration (~3%) in order to achieve a satisfactory selectivity of the conversion of methane to methanol, and this precludes the possibility of attaining a sufficiently high degree of conversion of natural gas in a single pass through the reactor. It is therefore desirable to use a circulation scheme to increase the overall degree of conversion of natural gas.

4. The concept of small-capacity processes to meet the regional and related industrial requirements for oxygenates

At present, there are reasons for establishing a new 'sub-branch' within the structure of the gas-production industry, namely, small-capacity gas-processing chemistry, based largely on the production of methanol as the main intermediate compound. The small-capacity technological plant designed as a set of units (modular small-scale units, MSU) should be located in particular gas fields taking into account the locally available raw materials and the local needs for the hydrocarbon-based products.¹⁴⁰

Estimates indicate that the operation over a period of 10–15 years of a MSU with a production capacity of ~3000 tonnes of products per year requires that the natural gas resources in the particular deposit be at least 0.3–0.5 billion m³ and ensure a gas output of 30000 m³ per day over the whole exploitation period. The vast majority of gas fields and newly found deposits comply with these requirements.¹⁴⁰

Of the 1195 deposits of hydrocarbon gases in the C.I.S., 880 are small, their weighted average gas reserves being ~1.5 billion m³ per deposit.¹⁴¹ Connecting them to the main pipelines is unprofitable, and they also cannot be used as a source of raw materials for large-capacity chemical production. The only means of the industrial exploitation of these deposits is the processing at site of the extracted hydrocarbon raw materials by using MSU. The MSU can also be applied at condensed gas deposits, coal basins, which contain huge methane reserves, and any other hydrocarbon reserves that can be converted into the initial gaseous raw material, including biomass, the annual reproducible world resources of which are estimated as 200 billion tonnes.¹⁴⁰

The undoubted simplicity of the DMTM technological scheme,⁵⁵ compared with the traditional schemes for the production of methanol or synthetic motor fuels via synthesis gas,⁸¹ the weak dependence of the prime cost of the product on the production output, and modest demands on raw material sources are good prerequisites for the implementation of this scheme on MSU. Up to 7% of the methanol produced in our country is used to prevent the formation of gas hydrates during natural gas extraction and transportation; the expected annual demand by the gas industry for methanol in 2000 is 500 000 tonnes. The high cost of the delivery of methanol to the main gas fields, far exceeding its selling price, makes the conversion of natural gas into methanol directly in the gas fields very attractive. At the same time, these regions may be provided with motor fuels and with formaldehyde — a side product of the process.^{55, 140}

Thus, the use of MSU for the direct processing of natural gas in gas fields in order to provide the corresponding regions with methanol and motor fuels proves to be intimately connected with the technological implementation of the DMTM process. The DMTM process realised as MSU may manifest its technical and economical advantages well before it finds an application in the large-capacity chemical industry.

VIII. Promising aspects of the scientific research dealing with direct oxidation of natural gas to methanol

In many countries, large investments are made in state and private research aimed at the effective use of the abundant natural gas resources.¹⁴² The main purpose of these studies is to increase the effectiveness of the most promising processes for the production of methanol and higher hydrocarbons, which are potentially competitive with the traditional petroleum refining.

The research activity was greatly promoted by the discovery made in 1982 of catalysts ensuring high yields of ethane and ethene in the oxidative condensation of methane. In recent years, studies on the catalytic conversion of natural gas have been mostly concerned with the overcoming of kinetic barriers, which

apparently restrict the yields of C_2 hydrocarbons in the oxidative condensation of methane to $\sim 25\%$.^{75,118} This is sufficient to maintain interest in the scientific research but too low for the practical realisation of the process.

Regarding the direct gas-phase oxidation of methane to methanol, the challenge now is to reproduce on the pilot scale the high (up to 70%–80%) selectivity of the process for the fairly high (more than 5%) degrees of conversion, which have been achieved in some laboratory studies.^{28,38,41,43,45} These results, if obtained on the industrial scale, would permit the development of an undoubtedly profitable process.

Therefore, clear identification of the conditions or search for process regimes, which may lead, in principle, to such results, is a fundamental goal of the studies. In our opinion, this can be done by investigating periodic and cool-flame regimes in the oxidation of methane, in which the product yields may differ fundamentally from those obtained in other known regimes. The high degree of nonlinearity of the mechanism of the oxidation of methane (Section V) and the known data concerning the appearance of periodic phenomena, hysteresis, and cool flames during its oxidation (Section III, 8) make it possible to rely on the possibility of achieving in open reaction systems (among which are flow-type reactors¹⁴³) steady-state oxidation regimes that have not yet been investigated, or those regimes which can be stabilised artificially by means of additional physical or chemical effects. This assumption is supported by the existence of several steady-state and oscillatory regimes in the oxidation of the near homologues of methane,²⁰ including ethane.¹⁴⁴ Since in such a complex system (the oxidation of hydrocarbons is apparently among the most complex systems, if biological processes are excluded¹⁴³), a fortuitous experimental discovery of new regimes can hardly be expected, the main efforts should be concentrated on the analysis of the most realistic models (in the first place, on the stability of the regime).

The above problem is closely connected with the practically important task of analysing the stabilities of the known steady-state regimes in the case where the process is carried out in industrial-scale reactors. There are lots of reasons for the instability of a chemical process in an open system, for the appearance of non-steady-state regimes, pulsations, and oscillations, which may become dangerous. Therefore, conditions should be found in which the process would be so stable that any random fluctuation of the composition, temperature, and pressure would decay rapidly.

Yet another promising line of research is the study of the high-pressure oxidation of methane homologues, their mixtures, and the real natural gases, because the direct oxidation of gaseous hydrocarbons containing high proportions of methane homologues may provide appreciable technological and economic advantages. In our country, there are huge resources of these gases of both natural and industrial origin (ethane-containing natural gases, casing-head gases, refinery gases, de-ethanisation gases, etc.). The proportion of ethane-containing gases in the total explored gas resources is 30.5%,¹⁴⁵ and the amount of petroleum gas with high proportions of ethane, propane, and butane burned in flares every year reaches 12–15 billion m^3 .¹⁴⁶ Since raw materials account for more than 50% of the production cost,⁸⁷ the use of gases of low value with high proportions of methane homologues can enhance sharply the economic effectiveness of the process and extend the range of its feedstock.

Evidently, the study of the influence of external parameters and gas composition on the detailed composition of the products as well as the search for various methods for its correction, including the subsequent additional catalytic treatment and partial isolation of products in order to obtain mixtures of standard composition and commercial products, will be of great importance.

The development of sufficiently predictive quantitative kinetic models of the high-pressure oxidation of methane homologues

and the development of a model of the oxidation of the real natural gases based on them are also very important scientific tasks.

IX. Conclusion

Through the experimental and theoretical studies carried out for many years on the partial oxidation of methane and its homologues at high pressures, the chemical fundamentals of the direct synthesis of methanol and other oxygenates have been developed. The current level to which the technological process has been developed, its relative simplicity, its flexibility regarding production output, and its low power and capital requirements give this process in some cases real advantages over the traditional methods for the synthesis of methanol. The rapidly increasing demand of the world market for cheap methanol and other oxygenates and hence for flexible and highly-profitable methods for their production dictate the need to intensify the scientific research designed to discover the fundamental paths leading to the enhancement of the selectivity of the formation of methanol and of its yield in this process to the level of absolute profitability, to extend the range of raw materials by involving poorly utilised sources of gaseous hydrocarbons, and to develop optimal schemes for the organisation of the process.

III. The formation of complexes by tricyclic hydrophosphoranes	235
IV. The formation of complexes by tetracyclic hydrophosphoranes	236
V. Conclusion	245

Abstract. The overall results of the study of hydrophosphorane compounds as ligands for metal complex synthesis and catalysis are summarised and discussed. The principal types of coordination of hydrophosphoranes, the structure of their metallo-derivatives, and the possible mechanism of the complex formation reaction are examined. The prospects for the employment of hydrophosphoranes in modern coordination design are demonstrated. The bibliography includes 102 references.

I. Introduction

The current range of phosphorus-containing ligands is exceptionally varied and in many respects determines the progress in the field of metal complex design. Many phosphorus-containing ligands are involved in the construction of tens and perhaps hundreds of coordination compounds. Thus the Cambridge Structural Database contains information about the structures of 720 complexes based on one of the simplest organophosphorus compounds—triphenylphosphine,¹ and this does not constitute the maximum information available since new studies are being regularly published. After all, there has been no flagging of interest for more than 30 years in perhaps the most popular P, N-bidentate ligand—2-diphenylphosphinopyridine. We may also point to the outstanding range of complex chiral systems which have found application in asymmetric catalysis.^{2,3} Overall, the stream of information about the coordination compounds of phosphorus has recently assumed an avalanche-like character. Nevertheless, the notable event which occurred towards the end of the 1970s is outstanding even against this background—the introduction into practical metal complex synthesis of a fundamentally new class of phosphorus-containing ligands—hydrophosphoranes.

At first sight, the structure of hydrophosphoranes contains no potential donor centres—their phosphorus atom has no lone pair (LP) and those of the nitrogen and oxygen atoms should be involved in $p\pi-d\pi$ conjugation with the d orbitals of the phosphorus atoms. However, these compounds are in fact the most variable phosphorus-containing ligands capable of P-, N-, P,N-, P,O-, and N,N-coordination. Furthermore, many new metal complexes have been obtained precisely in the study of the reactivities of hydrophosphoranes (HP), whereupon a whole series of unusual coordination polyhedra were synthesised. Any complex reaction involving hydrophosphoranes is a nontrivial phenomenon in coordination chemistry from the standpoint both of its products and of the initial compounds. Indeed hydrophosphoranes can quite justifiably be called paradoxical ligands: they are formally incapable of binding Lewis acids but exhibit an extremely wide range of coordination possibilities.

Nowadays hydrophosphoranes constitute an independent, unique class of phosphorus-containing ligands. They have occupied this position as a result of deliberate efforts by two leading research teams: the French school under the leadership of Professor Riess, who were involved in the initiation of the coordination chemistry of hydrophosphoranes, and the American school led by Professor Lattman.

The reactivity of hydrophosphoranes has been investigated in considerable detail from the standpoint of organophosphorus chemistry and several thorough reviews have been published on this topic (see, for example, Nifant'ev and Kukhareva⁴). However, many new data concerning the formation of complexes by hydrophosphoranes have appeared since their publication and, furthermore, the data on the chemistry of hydrophosphoranes presented in these reviews are either very scanty^{5,6} or are invoked merely to illustrate certain fundamental concepts: the relation between organometallic and coordination chemistry,⁷ the characteristics of phosphoranide coordination,⁸ the characteristics of complex formation in systems with a phosphorus–nitrogen bond,⁹ and the structural characteristics of metallated phosphoranes.¹⁰ The present review is the first attempt at a systematic consideration of the coordination properties of hydrophosphoranes and of their role and position in the series of phosphorus-containing ligands. We have tried to compare the reactivities of various groups of

hydrophosphoranes, to differentiate within each group the principal types of bonding to the central atom, to discuss certain spectroscopic features (primarily ^{31}P NMR and IR spectroscopic data concerning metallo-derivatives of hydro-phosphoranes), and to indicate the prospects for the use of hydrophosphoranes in modern coordination design.

The data presented in this review have been divided into sections in accordance with the number of phosphorus-containing rings in the initial hydrophosphoranes and the nature of the junctions between them: bicyclic systems (condensed and spiro-systems) were examined initially and then tricyclic and tetracyclic systems.

II. The formation of complexes by bicyclic hydrophosphoranes

1. Processes involving bicyclic aminophosphoranes with condensed rings

Complexes of bicyclic aminophosphoranes (BAP) with condensed rings containing Rh, Pd, Ru, Mo, W, Fe, and Co are known at present. In the arrangement of the data for this part of the review, account was taken primarily of the nature of the central metal atom. An attempt was made to demonstrate strikingly the principal types of coordination of the ligands under discussion and as far as possible to reflect the history of the development of the branch of the chemistry of hydrophosphoranes considered. In view of the last factor, the discussion is initiated by considering compounds of platinum metals.

a. Rhodium complexes of bicyclic aminophosphoranes

A communication¹¹ concerning the coordination of BAP, which in historical terms proved to be the first group of ligands of a fundamentally new class, was published in 1978.

A general scheme for a possible tautomeric equilibrium involving BAP was presented¹¹ and, although only forms with pentacoordinate phosphorus **1a,b** were detected spectroscopically in solution, the presence of two donor centres — the phosphorus and nitrogen atoms in the potential phosphocane tautomers **1'a,b** — led the authors to carry out complex formation reactions with BAP.

R = H (a) (Phoran), Me (b)

It was found that compounds **1a,b** react rapidly under mild conditions with $[\text{Rh}(\text{CO})_2\text{Cl}]_2$ (P:Rh = 1:1), forming compounds **2a,b** in yields exceeding 95%.

Parameter	Compound	
	2a	2b
$\nu(\text{NH})/\text{cm}^{-1}$	3195	3178
$\nu(\text{CO})/\text{cm}^{-1}$	1991	1985
$\nu(\text{RhCl})/\text{cm}^{-1}$	290	285
$\delta_{\text{P}}/\text{ppm}$	162.0	160.8
$^1J(\text{P,Rh})/\text{Hz}$	190.5	197

Figure 1. The structure of complex **2a**.

We may note that the IR and ^{31}P NMR spectroscopic parameters [especially $\nu(\text{CO})$, $\nu(\text{RhCl})$, and the spin-spin coupling constants (SSCC) $^1J(\text{P,Rh})$] quoted for complexes **2a,b** are typical (taking into account the nature of the phosphorus centre) for mononuclear chlororhodium(I) carbonyl compounds with various chelating P,N-bidentate ligands.¹²⁻¹⁴ On the other hand, the chemical behaviour of complexes **2a,b** differs appreciably from that of the rhodium complexes with trivial phosphorus-containing ligands. Thus the formation of a 2:1 complex is not observed on interaction of compounds **1a,b** with $[\text{Rh}(\text{CO})_2\text{Cl}]_2$ in the molar proportions P:Rh = 2:1. The reactions of compound **2b** with an excess of triphenylphosphine affords *trans*- $[\text{RhCl}(\text{CO})(\text{PPh}_3)_2]$ with displacement of the P,N-bidentate ligand, but this time in the form of the initial pentacoordinate structure **1b** and not the phosphocane form **1'b**.

X-Ray diffraction study of complexes **2a,b** (Fig. 1)¹⁵ revealed distances between the rhodium atom and its nearest neighbours typical of those for chelate chlororhodium carbonyl compounds with P,N-bidentate ligands as well as normal intramolecular $\text{Cl}\cdots\text{H}-\text{N}$ hydrogen bonds. The phosphorus-nitrogen atom distances of 2.793 and 2.788 Å (for compounds **2a** and **2b** respectively), are much less than the sum of the van der Waals radii (3.4 Å). This indicates the occurrence of the intramolecular $\text{P}\cdots\text{N}$ attractive interaction.

Ethene-containing analogues of compounds **2a,b**, formed by the reaction of compounds **1a,b** with $[\text{Rh}(\text{C}_2\text{H}_4)_2\text{Cl}]_2$ in the molar proportions P:Rh = 1:1, are also known. The same reaction, but with a molar ratio of P:Rh = 2:1, leads to the cationic complexes $[\text{RhL}_2]^+\text{Cl}^-$ (L = bicyclic aminophosphorane) with a *cis*-configuration of the phosphorus atoms. We may note the presence of the $\text{N}-\text{H}\cdots\text{Cl}\cdots\text{H}-\text{N}$ hydrogen bonds between the nitrogen centres of the coordinated phosphocyclanes and the counterion.

The interaction of $[\text{Rh}(\text{CO})_2\text{Cl}]_2$ with a series of new BAP (compounds **3a-f**) was investigated subsequently.^{16,17}

Compounds **3c–f** were synthesised in a homochiral form from L-alaninol or D-ethylalaninol. The rhodium complexes $[\text{RhCl}(\text{CO})\text{L}]$ obtained from compounds **3a–f** have the same structures as complexes **2a,b** mentioned above, which follows from their ^{31}P NMR and IR spectra: $\delta_{\text{P}} = 147\text{--}161$ ppm, $^1J(\text{P,Rh}) = 180\text{--}190$ Hz; $\nu(\text{CO}) = 1995\text{--}2003$ cm^{-1} , $\nu(\text{RhCl}) = 280\text{--}300$ cm^{-1} , $\nu(\text{NH}) = 3190\text{--}3203$ cm^{-1} . One of the possible diastereoisomers of the complex based on the phosphorane **3c**, used as the catalyst of the enantioselective hydrogenation of (*Z*)- α -acetamidocinnamic acid with a chemical yield of 92% and an optical yield of 18%, has been isolated by fractional crystallisation from solution in acetonitrile.

Catalysis involving rhodium complexes of BAP merits special consideration. They are all coordination systems of the metal in a 'cradle' type, formed by the phosphocane bound as a P,N-bidentate species. The more labile nitrogen centre under these conditions is the hydrophilic NH group, capable of binding a proton in the course of the catalytic cycle. The binding of a proton is accompanied by the freeing of a coordination vacancy at the central atom. These structural features make it possible to regard the rhodium derivatives of BAP as promising metal complex catalysts. Several attempts have been made to use such compounds as catalysts. In particular, in the hydroformylation of hex-1-ene, complex **2b** ensures under comparable conditions a higher degree of conversion than $\text{RhCl}(\text{CO})(\text{PPh}_3)_2$ (85% and 52% respectively).¹⁶ The cationic systems $[\text{Rh}(\text{CO})\text{L}(\text{MeCN})]^+ \text{PF}_6^-$, obtained from compounds **2a,b** and AgPF_6 in acetonitrile, catalyse the hydrogenation of (*Z*)- α -acetamidocinnamic acid to *N*-acetylphenylalanine.¹⁸ The yield of the product was not indicated.

The hydrogenation of hex-1-ene in the presence of the ethene complex $[\text{RhCl}(\text{C}_2\text{H}_4)\text{L}]$ has been investigated in detail.¹⁹ It was shown that its activity in hydrogenation and isomerisation is somewhat superior to that of the familiar Wilkinson catalyst $\text{RhCl}(\text{PPh}_3)_3$. This applies particularly to the isomerisation process. The above feature is due to the role played by the nitrogen centre in the catalytic cycle, since the monohydride complex formed with its participation is in fact the true catalyst of the isomerisation of the alkene.

Overall, the study of the catalytic properties of the rhodium derivatives of BAP has been fragmentary and limited. Thus, in the light of the latest advances in asymmetric catalysis,³ it is evident that the hydrogenation of the prochiral precursors of aminoacids is by no means the only field where rhodium complexes with P,N-bidentate optically active ligands can be used. Apparently, this catalyst may be expected to exhibit a much higher asymmetrising activity in, for example, hydroformylation and isomerisation processes. One thing is clear, the search for a due place for BAP in modern metal complex catalysis (especially enantioselective) has only just begun and requires further efforts.

The study of the interaction of compound **1a** (Phoran) with $[\text{Rh}(\text{COD})\text{Cl}]_2$ (COD = cycloocta-1,5-diene)—a familiar precursor of active catalytic systems—is of special interest in this connection.²⁰ The reaction is monitored by IR, ^{31}P NMR, and UV spectroscopic methods.

Complex **4**, formed initially with the phosphocane coordinated as a P-monodentate species, is subsequently transformed into the unusual ionic adduct **5** with a *cis*-disposition of the phosphorus atoms in the cation, which has been characterised by X-ray diffraction. The $\nu(\text{NH})$ absorption band of a single crystal of complex **5** is in the region of 3190 cm^{-1} . Only one $\text{N}\cdots\text{H}\cdots\text{Cl}$ hydrogen bond was detected under these conditions. It is of interest that a further two forms of compound **5**, characterised by $\nu(\text{NH})$ frequencies of 3205 and 3215 cm^{-1} , have been isolated. According to the authors, the difference between the $\nu(\text{NH})$ absorption frequencies is due to the different orientations of the cation and the anion in the crystals of these forms.

The indication of the P-monodentate binding of the phosphocane in complexes **4** and **6** is of fundamental importance. However, this important conclusion appears inadequately justified. Firstly, these compounds were not isolated from the reaction mixture. Secondly, the spectroscopic data presented are clearly insufficient for a rigorous demonstration of their structure. Thus the structure of compound **6** was postulated solely on the basis of UV spectroscopic data. For complex **4**, it is possible to put forward a structure in which the coordination number (CN) of rhodium is five with a consequent apical coordination of the amino-group. Such a structure does not conflict with the spectroscopic parameters of this complex: $\delta_{\text{P}} = 140.0$ ppm, $^1J(\text{P,Rh}) = 210$ Hz; $\nu(\text{NH}) = 3140$ cm^{-1} , and $\lambda_{\text{max}} = 404$ nm. Indeed such a low $\nu(\text{NH})$ frequency is more likely to indicate direct coordination of the nitrogen centre to rhodium than the presence of the $\text{N}\cdots\text{H}\cdots\text{Cl}$ bond involving a noncoordinated amino-group.

Considerable attention has been devoted to the detailed study of the reaction of BAP with another rhodium catalyst popular in metal complex synthesis and catalysis— $[\text{Rh}(\text{CO})_2\text{Cl}]_2$. A series of chelate chlororhodium carbonyl complexes, obtained by the interaction of various BAP with this precursor, have already

been mentioned. An important discovery was made in the course of a detailed study of this process with participation of BAP such as Phoran²¹ and especially Me₄-Phoran:²² the stable dinuclear rhodium(I) complexes **7** with one chloride bridge were obtained unexpectedly.

Compound **7** was characterised by ¹H and ³¹P NMR and IR spectroscopic methods, by field desorption mass spectrometry, and by X-ray diffraction. The N—H...Cl intramolecular hydrogen bond between the nitrogen centre and the chloride ligand of the [Cl(CO)₂Rh] fragment was detected. The distance between the phosphorus and nitrogen atoms (2.705 Å) is appreciably shorter than in complexes **2a,b**, which indicates a more pronounced attractive N...P interaction in the case of complex **7**. The further reaction between complex **7** and Me₄-Phoran leads to a mononuclear complex. It is of interest that the coordination of unsubstituted Phoran is not quite so selective, since for the molar ratio P : Rh = 1 : 2 a mixture of products is formed: compound **2a**, already known, and an analogue of compound **7**, namely [Cl(CO)₂Rh(μ-Cl)Rh(CO)(Phoran)]. Attempts at a preparative separation of the latter product were unsuccessful.

A general mechanism of the interaction of BAP (L) with [Rh(CO)₂Cl]₂ has been proposed.

The dirhodium complex with one chloride bridge is a stable intermediate in this process on the way to chelate mononuclear compounds.

Study of the reactivity of complex **7** revealed an appreciable stability of the chloride bridge:²³ reactive compounds such as O₂, CO, CO₂, CS₂, CH₃I, CH₂=CH₂, and HC≡CH do not interact with compound **7** even under conditions of thermal or photochemical activation. Only Bu^tNC or activated alkynes are capable of modifying the structure of this unusual dinuclear complex.

R = CO₂Me, CO₂Bu, CF₃

In considering the structures of new rhodium compounds ¹H, ¹³C, and ³¹P NMR and IR spectroscopy and, in the case of the *tert*-butyl isocyanide derivative, ¹⁵N NMR spectroscopy were used. In the last case, direct binding of the nitrogen centre of the phosphocane to the metal was demonstrated by use of the naturally abundant ¹⁵N isotope and the INEPT method [$\delta_N = -370.0$ ppm, $^1J(N, Rh) \approx ^2J(N, P) \approx 11.8$ Hz]. This is an extremely rare and elegant experiment involving the application of ¹⁵N NMR spectroscopy to determine the nature of the coordination of the P,N-containing ligand. We may note that the study of Brun et al.²³ is the latest of a series of studies carried out over a decade and devoted to the rhodium derivatives of BAP.

Summarising, we may note that chelate P,N-bidentate coordination of BAP in the phosphocane form is characteristic of rhodium. There exists indirect evidence for the possibility of their P-monodentate binding, but this type of coordination has been established reliably only in relation to complexes of other transition metals.

b. Ruthenium and palladium compounds

We are aware of only one study²⁴ devoted to the interaction of BAP (specifically Phoran) with the ruthenium complex CpRu(CO)₂Cl.

The ionic complex **9**, which according to ¹H and ³¹P NMR spectroscopic data is in equilibrium with the neutral complex **8**, was isolated from the reaction mixture in an almost quantitative yield. The ion-exchange reaction between NaBPh₄ and compound

9 afforded an analogue of the latter complex, containing tetraphenylborate as the anion. Its deprotonation by treatment with MeLi at $-100\text{ }^{\circ}\text{C}$ leads to the amide adduct **10**, which is stable only at low temperatures, being transformed gradually at $20\text{ }^{\circ}\text{C}$ into the phosphoranide complex **11**.

The structures of complexes **8–11** have been established by means of ^1H and ^{31}P NMR and IR spectroscopy and, in the case of compounds **10** and **11**, by comparing their ^{31}P NMR spectroscopic parameters with those of the Mo- and W-containing analogues, which have been investigated in detail by X-ray diffraction. Later in this review we shall discuss further the characteristics of the phosphoranide type of binding of BAP to metals. For the moment, we may note that Vierling et al.²⁴ postulated the existence of equilibrium (even at $-100\text{ }^{\circ}\text{C}$) between complex **11** and its isomers **11'** and **11''** with P,O-bidentate or P-monodentate phosphoranide coordination.

Like ruthenium and rhodium, palladium is capable of P-monodentate and P,N-bidentate binding of BAP in the phosphocane form. In particular, the reaction between $[\text{CH}_2\text{CMeCH}_2\text{PdCl}]_2$ and Phoran (P: Pd = 1:1) affords a complex mixture of isomers.²⁵

The IR spectrum of the reaction solution contains three absorption bands at 3400 , 3280 , and 3200 cm^{-1} , corresponding to the NH group, the highest frequency band referring to the noncoordinated amino-group of complex **12**. It has been suggested that complexes **12'** and **12''** are stabilised by the formation of intramolecular hydrogen bonds. There is apparently a dynamic equilibrium between the three isomers, as a consequence of which

a poor resolution is observed in the ^{31}P NMR spectrum. On the whole, one may agree with Agbossou et al.²⁵ that a more correct description of the reaction under consideration requires additional studies.

Apart from complexes **12**, **12'**, and **12''**, the chelate cationic complex **13** is also known.

According to conductimetric data, complex **13** is an electrolyte of a type intermediate between 1:1 and 1:2. This is apparently associated with the existence of equilibrium between complex **13** and the dimer $[\text{CH}_2\text{CMeCH}_2\text{Pd}(\mu\text{-L})_2\text{PdCH}_2\text{CMeCH}_2](\text{BF}_4)_2$, in which the phosphocane ligands are of the bridging P,N-bidentate type. The high activity of complex **13** in the catalysis of the oligomerisation of butadiene is noteworthy (a mixture of C_8 , C_{12} , and C_{16} products with 100% conversion was obtained).

It has been stated²⁶ that an unstable palladium phosphoranide derivative **14** is formed.²⁶

Since the structure of complex **14** was postulated solely on the basis of ^{31}P NMR spectroscopic data, further experimental data for its confirmation appear necessary.

Summarising, we may note that the ruthenium and especially the palladium derivatives of BAP are represented by few examples and have been investigated fairly superficially. This field of BAP coordination chemistry still awaits its investigators.

c. Cobalt and iron complexes

We are aware of only one complex formation reaction between BAP and a cobalt compound, namely $[\text{Co}(\text{NO})_2\text{Cl}]_2$.^{27, 28}

According to X-ray diffraction data, although the distance between the P and N atoms in the phosphocane ring (2.978 \AA) in complex **15** is greater than in the case of the chelate rhodium complexes **2a,b**, it is again appreciably less than the sum of the van der Waals radii. By virtue of the noncoordinated peripheral amino-group, compound **15** enters into an interesting reaction with carbon dioxide, leading to the formation of the carbamate-like adduct **16**.²⁸

During storage under an argon atmosphere, complex **16** gradually loses the CO_2 group with regeneration of the initial

compound **15**. The reversible binding of CO₂ observed here models to some extent biosynthetic carboxylation processes with participation of biotin.

In contrast to the cobalt-containing complexes, the iron-containing BAP complexes have been investigated fairly widely. The first step in the study of their chemical properties already led to the discovery of the unique reversible migration of the phenyl group from phosphorus to the metal without change in the oxidation state and the coordination number of the latter.²⁹ The deprotonation of complex **17** [obtained from CpFe(CO)₂Br and Phoran], carried out for the synthesis of a phosphoranide derivative, led to the formation of complex **18** with a bicycloposphoramidite ligand.

The structure of complex **18** has been demonstrated by X-ray diffraction. The deprotonation process is reversible: the passage of gaseous HCl through a solution of complex **18** in tetrahydrofuran (THF) in the presence of NH₄PF₆ regenerates complex **17** with a 60% yield. It has been suggested that the transannular N → P interaction in the structure of complex **17** facilitates the 1,2-shift of the phenyl group attached to the P–Fe bond. Subsequently a similar reversible migration was observed²⁴ also for a homologue of Phoran (compound A), where precisely the carbon atom which had been previously linked to phosphorus was found to be bound to iron, which agrees well with the concept of a 1,2-sigmatropic shift of the aryl group.

As a result of the successful choice of the initial iron compounds, it proved possible to obtain, via a two-stage synthesis, systems with bridging P,N-bidentate binding of the phosphocane ring.^{30,31} We may note that this type of unusual coordination of BAP was observed for the first time. Complexes with the P-monodentate coordination of the ligand were obtained initially.

A weak broad ν(NH) absorption band at 3400 cm⁻¹, characteristic of a noncoordinated secondary amino-group, was observed in the IR spectrum of compound **19**. Two weak, narrow, ν(NH) bands at 3400 and 3300 cm⁻¹ were recorded for complex **20**, the presence of the latter band being tentatively attributed to the existence of intermolecular hydrogen bonds. Subsequently the

dinuclear and trinuclear iron complexes **21** and **22** were obtained from complexes **19** and **20**.

Unfortunately compounds **21** and **22** have been studied inadequately. Thus only fragment peaks were detected in their mass spectra, although an extremely mild method (chemical ionisation) was used. Nothing is said in the communication of Mordenti et al.³¹ about attempts to determine the molecular structures of compounds **21** and **22** by independent methods.

The peripheral amino-groups in complex **20** are capable of coordinating various Lewis acids, for example the proton (in the HCl–NaBPh₄–EtOH system) or BPh₃.³² In the latter case, an interesting three-centre adduct of the P–Fe–P type (compound **23**) was obtained from BAP.

The structures of compounds **20** and **23** were established by X-ray diffraction. A tetrahedral coordination of the iron atom was observed in both cases. The distances between the phosphorus and nitrogen atoms in the phosphorus-containing rings are 3.647 and 3.616 Å for compound **20** and 3.590 Å for compound **23**, which appreciably exceeds the sum of the van der Waals radii. The conformations of the phosphocane rings in compounds **20** and **23** can be described as 'chair-boat'.

The O...H–N hydrogen bond involving the amino-group of one molecule and the nitrosyl oxygen atom of another was detected in complex **20**. It had been postulated previously on the basis of IR spectroscopic data. A weak N–H...N contact was also found. These hydrogen bonds apparently actually stabilise the novel ligand conformations.

Iron phosphoranide complexes are also known. In particular, such an adduct has been detected by ³¹P NMR spectroscopy as an intermediate in the unprecedented process involving the reorganisation and migration of the allyl group from phosphorus to iron.^{34,35}

The coordination of the allyl-substituted BAP (compound **24**) leads not to a σ -allyliron complex, which might be formed as a result of the direct migration of the allyl group from phosphorus to iron, but to the σ -vinyliron compound **26** as a result of the isomerisation of this substituent accompanying the transfer process. The phosphoranide adduct **25** is stable in solution only at temperatures below 0°C . At 60°C , it is fully converted into compound **26** in 1 h. The structure of complex **26** was established by ^1H , ^{13}C , and ^{31}P NMR and IR spectroscopy. Whereas the migration of the phenyl group is known to be a reversible process, the reverse transfer of the vinyl group from iron to phosphorus is not observed even when complex **26** is treated with hydrogen chloride. It has been suggested that the phosphoranide coordination of compound **25** increases the electron density on the metal and hence its basicity, activating the insertion of iron into an allyl or vinyl C–H bond with the subsequent 1,3-shift of a proton and dissociation of the P–C bond. In fact the decrease in the $\nu(\text{CO})$ frequency by 55 cm^{-1} on passing from the cationic complex to the phosphoranide adduct **25** agrees well with an increase in electron density on the iron atom in the adduct. Thus the migration of the allyl group differs radically both from the transfer of the phenyl group (accompanied by dissociation of the P–C bond alone) and from the known *ortho*-metallation reactions (involving only the insertion of the metal in a C–H bond).

Apart from the allylphosphorane **24**, several further related BAP were used to investigate the fine details of the migration of organo groups from phosphorus to iron.³⁵

The interaction of these compounds with $\text{Cp}(\text{CO})_2\text{FeBr}$ leads in the first stage to ionic complexes and then to phosphoranide complexes.

The phosphoranide complexes exist in solution only at temperatures below 0°C . It is of interest that the iron-containing analogue of the ruthenium amide intermediate **10** has not been detected spectroscopically even at -100°C , apparently as a consequence of its short lifetime. Since the structures of the phosphoranide complexes have been discussed only on the basis of ^{31}P NMR and IR spectroscopic data, one cannot rule out the possibility of the existence in solution of their isomers with P-monodentate and P,O-bidentate coordination, analogous to the ruthenium derivatives **11** and **11'**.

An attempt to isolate the iron phosphoranide compounds led to their further reactions. The complex with a methylallyl group rearranges smoothly after refluxing in THF for 1 h into the σ -vinyliron compound (like compound **25**), while the remaining compounds form complex mixtures of products under these conditions.

Thus the study of the iron complexes has been an important stage in the development of the coordination chemistry of BAP: the P-monodentate and P,N-bidentate bridging types of binding of the phosphocane forms have been clearly demonstrated and a series of phosphoranide adducts have been characterised spectroscopically.

d. Molybdenum and tungsten compounds

Virtually all the data obtained on the formation of complexes by BAP with molybdenum and tungsten compounds refer to molybdenum complexes. There are very few tungsten adducts of BAP. In particular, the interaction of compound **3c** with $\text{M}(\text{CO})_6$ ($\text{M} = \text{Mo}, \text{W}$) at $120\text{--}150^\circ\text{C}$ for 24 h leads to the products $\text{M}(\text{CO})_5\text{L}$ with P-monodentate coordination of the phosphocane.¹⁶ The use in this process of the sterically less

hindered ligand Phoran made it possible to obtain the disubstituted compounds $M(CO)_4L_2$, but complexes of the type $M(CO)_4L$ in which the phosphocane is bound as a P,N-bidentate species have not been obtained.

Both P-monodentate and P,N-bidentate coordination has been achieved by employing more reactive molybdenum compounds initially.³⁶ All these complexes were investigated by IR and 1H , ^{13}C , and ^{31}P NMR spectroscopy, mass spectrometry, and by vapour phase osmometry.

The deprotonation of compound **27** by treatment with LiMe (ether/THF, 60 °C) leads to a molybdenum compound with P,O-bidentate phosphoranide coordination of the ligand.³⁷

28

$\delta_P = 23.8$ ppm,
 $\nu(CO) = 1925$ and 1835 cm^{-1}

This is the first example not only of the phosphoranide type coordination of BAP but also of the synthesis of a metallated phosphorane.¹⁰

It has been shown by X-ray diffraction that the P—O bond involved in the formation of a three-membered metallocycle is significantly lengthened compared with the second P—O bond (1.893 and 1.653 Å). We may note that the usual BAP geometry is retained in complex **28**: the oxygen atoms being axial and the nitrogen atoms and the phenyl group equatorial.

The first transition metal complex containing the $\overline{N-P-M}$ cyclic fragment was synthesised by the deprotonation of compound **27** with methyl lithium under mild conditions (THF, -20 °C).³⁸

29

$\delta_P = 43.9$ ppm,
 $\nu(CO) = 1945$ and 1855 cm^{-1}

According to X-ray diffraction data, the P—N bond in complex **29** is one of the longest (1.91 Å) of this type. The equatorial orientation of the oxygen atoms, unusual for trigonal-bipyramidal phosphorus, and the axial orientation of the phenyl group are also noteworthy. It is of interest that complex **29** isomerises readily to complex **28** (on heating in solution in THF to 60 °C). When hydrogen chloride was passed through a THF solution of complex **29**, an analogue of complex **27** was obtained in a quantitative yield (the counterion is the chloride anion). The tungsten analogue of compound **29** has also been obtained.

The dimeric molybdenum complex $Cp(CO)_2Mo \equiv Mo(CO)_2Cp$ has also been resorted to in order to investigate the coordination of BAP. In this case, the lack of information about its interaction with potentially chelating ligands and also the presence of the highly reactive $Mo \equiv Mo$ bond are of interest. It has been found that the reaction of this complex with Phoran leads to two main products — **30** and **31**.^{39,40}

30

31

Both substances were characterised by 1H , ^{13}C , and ^{31}P NMR and IR spectroscopy and by field desorption mass spectrometry, while complex **30** was characterised in addition by X-ray diffraction. Compound **30** was the first example of the direct substitution of a CO ligand in $Cp_2Mo_2(CO)_4$ with retention of the $Mo \equiv Mo$ bond and at the same time it was the first BAP complex where the P-monodentate coordination of the phosphocane form was confirmed by X-ray diffraction.

A methylated analogue of compound **30** — the complex $(C_5Me_5)Mo_2(CO)_3L$ — has been synthesised and investigated⁴¹ by X-ray diffraction. Its synthesis requires more severe conditions and the yield is much lower than that of compound **30**. This is associated with the large steric factor for the $\eta^5-C_5Me_5$ ligand compared with $\eta^5-C_5H_5$. The special importance of molybdenum in the coordination chemistry of BAP is noteworthy because unique phosphoranide complexes with three-membered metallocycles have in fact been obtained precisely with this metal and characterised by X-ray diffraction.

e. The adducts of BAP with BH_3

Apart from the formation of complexes between BAP and transition metal compounds, the interaction of the former with certain borane complexes has been investigated. Thus the reaction of Phoran with $BH_3 \cdot SMe_2$ affords compound **32** as the main product (for the molar ratio B : P = 2 : 1).⁴²

32

The adduct **32** was characterised reliably by spectroscopic methods: 1H , ^{11}B , and ^{31}P NMR and IR spectroscopic, as well as mass-spectrometric data have been published. The stereospecificity of the above reaction has been demonstrated because compound **32** is characterised by a *cis*-disposition of the BH_3 fragments relative to the phosphocane ring.

Special mention should be made of an unusual BAP, the bicyclic skeleton of which contains condensed benzene rings.⁴³

33

In contrast to Phoran, compound **33** exhibits a high chemical stability: it does not hydrolyse, it does not undergo deuterium exchange with D_2O in the presence of either triethylamine or toluene-*p*-sulfonic acid, and it does not react with the NaH/MeI system. The phosphorane **33** hardly interacts with $BH_3 \cdot SMe_2$. Its reaction with $BH_3 \cdot THF$ takes place in the course of a week and leads to a complex mixture of products, among which compound **34** was identified by the ^{31}P and ^{11}B NMR methods.

34

The attempt to isolate compound **34** was unsuccessful: the initial BAP was isolated in ~90% yield. Such a low reactivity of compound **33** can be accounted for by the marked delocalisation

of the lone pair of nitrogen through interaction with phosphorus and the benzene rings (all four rings are coplanar). This stabilises additionally the phosphorane structure in relation to the possible phosphocane tautomer and is also responsible for the absence of donor centres. Unfortunately we do not possess literature data on the formation of complexes between compound **33** and transition metals. In our view, it would be interesting in this instance to compare the reactivities of compound **33** and other BAP, in the first place Phoran, which would assist in a better understanding of the mechanism of the coordination of hydrophosphorane compounds.

f. The formation of BAP complexes *in situ*

There exists a nonstandard approach to the synthesis of BAP involving the interaction, under mild conditions, of the corresponding proton-donor reagent (ROH, ArOH, R₂NH) with bicyclo[3.3.0]-1-phospha-2,8-dioxa-5-azaocane in an organic solvent.^{44,45} The BAP is then characterised *in situ* without isolation from the solution.

It is surprising that this very convenient method of synthesis of a wide variety of BAP as potential ligands has been introduced only quite recently into practice in coordination synthesis. Compounds **35a,b** have been synthesised by this method in CH₂Cl₂.⁴⁶

The addition of solutions containing compounds **35a,b** to [Rh(CO)₂Cl]₂ (P/Rh = 1) led to the formation of the chelate mononuclear rhodium complexes **36a,b**.

Parameter	Compound	
	36a	36b
$\nu(\text{NH})/\text{cm}^{-1}$	3230	3148
$\nu(\text{CO})/\text{cm}^{-1}$	2012	1996
$\nu(\text{RhCl})/\text{cm}^{-1}$	294	300
$\delta_{\text{P}}/\text{ppm}$	128.3	133.5
$^1J(\text{P,Rh})/\text{Hz}$	291	262

Compounds **36a,b** are insoluble in organic solvents, except DMSO, but at 80 °C they undergo vigorous solvation followed by degradation. For this reason, the final confirmation of the structure of compounds **36a,b** was achieved by ¹³C solid-state NMR spectroscopic and ESCA methods.

The complex formation reaction between compound **35a** and Pd(COD)Cl₂ resulted in the formation of a polynuclear palladium complex with a bridging phosphocane ligand.⁴⁷

The complex was characterised in detail by IR and ³¹P and ¹³C NMR spectroscopy, ESCA, and ultracentrifugation; its nonstereoregular structure was established.

We may note an important feature—in contrast to other BAP, the coordination of compounds **35a,b** leads to complexes with a phosphite, and not phosphonite, phosphorus centre.

It is of interest that a reaction formally the reverse of the processes mentioned above had been achieved earlier.⁴⁸

The formation of the free phosphorane is treated as a result of the intracomplex oxidative addition of methanol to the N-coordinated phosphoramidite catalysed by the traces of H⁺ present in the reaction medium.

It follows from the foregoing that the BAP function either as precursors of the phosphocanes (chelating or bridging) bound via P-monodentate or P,N-bidentate linkages or as P,N- or P,O-bidentate phosphoranide ligands. In the coordination of BAP in the phosphocane form, the differentiation of P-monodentate and P,N-bidentate binding is made feasible by a reliable criterion—the absorption frequency of the NH group in the IR spectra of these complexes. Thus a wide range of vibrational frequencies (3050–3320 cm⁻¹) is characteristic of the coordinated amino-group, but the unusually high values of $\nu(\text{NH}) = 3280\text{--}3320\text{ cm}^{-1}$ are observed only in the spectra of the cationic compounds and are associated with the presence of a positive charge on the metal atom, while the anomalously low frequencies 3050–3080 cm⁻¹ are known only for [RhL₂]⁺Cl⁻, which contains strong hydrogen bonds with the counterion. On the other hand, the typical values of $\nu(\text{NH})$ are in the range 3140–3260 cm⁻¹. The free peripheral amino-group is characterised by the frequency range 3340–3400 cm⁻¹. Occasionally a decrease to 3300 cm⁻¹ is observed owing to the participation of this group in hydrogen bonds.

2. Processes with participation of hydrospirophosphoranes

a. Rhodium complexes of hydrospirophosphoranes

Hydrospirophosphoranes (HSP) constitute the most thoroughly investigated group of hydrophosphoranes,⁴⁹ but their coordination chemistry began to develop comparatively recently.^{50,51}

R = H (a), Et (b)

As in the case of BAP, the first transition metal complexes with HSP ligands were those of rhodium.

n = 4 (a), 6 (b)

It has been established that processes involving HSP are much slower than those involving organic phosphorus(III) ligands. Thus, in complex formation with the oxazahydrospirophosphorane **37a**, the residual signal of this ligand persists in the ^{31}P NMR spectrum of the reaction solution for 30 min even at 20 °C, whereas in complex formation with the aminophosphite under the same conditions the free ligand signal is recorded only at -70 °C.⁵² It follows from the ^{31}P and ^{15}N NMR data (compound **37a** with 96.4% enrichment in the ^{15}N isotope) and IR spectroscopy that the key factor in the coordination of HSP is the opening of the oxazaphospholane ring with liberation of the peripheral amino-group bound to the metal.

The polynuclear nature of these complexes, where the phosphorus-containing ligand functions as a bridging P,N-bidentate species, has been established by sedimentation analysis of solutions of compounds **38a,b** in DMSO. The elementary units of compounds **38a,b** have *trans*-orientation of the phosphorus and nitrogen centres in the coordination sphere of rhodium. This is yet another distinctive feature of the complexes based on HSP: the chlororhodium carbonyl complexes of aminophosphites and aminophosphoramidites are as a rule mononuclear with a *cis*-disposition of the phosphorus and nitrogen atoms.⁵²⁻⁵⁴

Despite thorough investigation of complexes **38a,b**, the driving force of the formation of the polynuclear structures remained unelucidated. It is also not known whether these compounds are linear or cyclic oligomers. At the present time, we are inclined to regard them as cyclooligomers, since signals due to the noncoordinated phosphorus or nitrogen centres have not been detected in the ^{31}P and ^{15}N NMR spectra.

The use of the chiral HSP **37b** and **39** in the asymmetric hydrosilylation of acetophenone by diphenylsilane [both ligands were obtained from (*R*)-2-aminobutanol] has been reported.⁵⁵

The 2L/[Rh(CO)₂Cl]₂ (L = compound **39**) catalytic system ensures an optical yield of the reaction product of 9%. Unfortunately, the use of chiral HSP in asymmetric catalysis has not received due development and only the studies concerned with the synthesis and coordination of optically active HSP with a catechol fragment have been continued.⁵⁶ This concerns the synthesis of the aminophosphite **40**, which is in equilibrium with its P(V) tautomer **40'** (this is typical for aminophosphites and aminophosphoramidites with a secondary peripheral amino-group), and also of the hydrophosphorane **41**.

The complex formation reaction between compound **40** and [Rh(CO)₂Cl]₂ (P:Rh = 1:1) leads to the formation of the dinuclear rhodium compound **42**.

It was shown that the structure of compound **42** contains the N-H...Cl intramolecular hydrogen bonds. Under the same conditions, the ligand **41** forms the mononuclear chelate complex **43**.

It exists in the form of two conformers: pseudotetrahedral and pseudosquare, which follows from ^{13}C NMR and IR spectroscopic data. The tendency of compound **43** to isomerise to the form with a *cis*-disposition of the carbonyl and amino-groups in the coordination sphere of the rhodium has been discovered.

In contrast to compound **41**, the sterically less hindered HSP **44** forms a dinuclear, and no longer a mononuclear, rhodium complex.⁵⁷

We may note that compound **45** is perhaps the most thoroughly investigated complex based on HSP: ^{31}P NMR (including the low-temperature version), ^1H NMR, ^{13}C NMR (including the version in the solid state), ^{14}N NMR, and ^{103}Rh NMR spectroscopy, IR spectroscopy, ESCA, and desorption mass spectrometry were resorted to in the consideration of its structure. The dissolution of compound **45** in acetone is accompanied by its reorganisation; fragments with a *cis*-orientation of the carbonyl and amino-groups at the rhodium atom appear in solution and ultimately a polynuclear compound with $n = 12$

(according to ultracentrifugation data) is formed.

In all probability, for the rhodium derivatives of HSP with a catechol fragment there is a definite relation between the steric factor associated with the ligand and the nature of the coordination compound: less sterically hindered ligands give rise to metal complexes with a larger number of rhodium centres.

The study⁵⁸ of the interaction of 2,2'-spirobis(1,3,2-benzodioxaphosphole) **46** with $[\text{Rh}(\text{CO})_2\text{Cl}]_2$ is of special interest because this is the only example of complex formation involving tetraoxohydrospirophosphoranes. The HSP **46** is known⁴⁹ to be in equilibrium with its tricoordinate tautomer **46'**.

The rhodium complex formed with the ligand **46'** in CH_2Cl_2 is a dimer with a rhodium coordination number of five (the rhodium coordination polyhedron is a trigonal bipyramid with an apical phosphorus atom).

The peripheral OH group is not then bound to the metal.

In the crystalline complex **47**, the phosphorus-containing ligands function as P-monodentate and P,O-bidentate species, the phosphorus centre now occupying an equatorial position. It has been suggested that the fragments

can combine into a polynuclear aggregate as a result of the bridging function of both the chloride ligands and the ligands coordinated as P,O-bidentate species.

b. Palladium and platinum derivatives of hydrospirophosphoranes

At the present time, we know of only three metal complexes of hydrospirophosphoranes. In particular, the reaction between $\text{Pd}(\text{COD})\text{Cl}_2$ and the HSP **44** gave compound **48**, which was initially described as mononuclear.⁵⁹ However, measurement of the molecular mass of this complex by ultracentrifugation revealed its hexanuclear nature.⁶⁰

The terminal positions of the chloride ligands in the structure of compound **48** have been reliably established by three independent physical methods—ESCA, IR, and X-ray emission

spectroscopy. Hence it follows that the bridging ligands in the polynuclear complex **48** are in fact the phosphorus—containing ligands.

The polynuclear metal complexes **49** and **50** have been synthesised by the reaction of the HSP **37a** with $\text{M}(\text{COD})\text{Cl}_2$ ($\text{M} = \text{Pd}, \text{Pt}$).^{47, 61}

49, 50

49: $\text{M} = \text{Pd}, n = 4$

50: $\text{M} = \text{Pt}, n = 6$

Their structures were established from ^{31}P , ^{13}C , and IR spectroscopic, ESCA, and flame-desorption mass-spectrometric data and by sedimentation analysis.

Instead of the initial hydrospirophosphorane, its amide derivative has been used⁶² in the complex formation reaction, which led unexpectedly to the formation of a phosphoramide adduct.

The information accumulated hitherto on the coordination behaviour of HSP permits the following conclusions: (1) these ligands do not tend to undergo coordination of the phosphoramide type and hence the spectroscopic parameters of their metal complexes are close to those for compounds based on organophosphorus(III) P,N-bidentate ligands—aminophosphites and aminophosphoramidites; (2) the majority of HSP complexes are polynuclear, but the available data on the molecular masses of the metal derivatives of HSP have been obtained mainly in the study of their solutions, so that direct structural investigations of solid-state specimens of these substances are needed.

III. The formation of complexes by tricyclic hydrophosphoranes

There are as yet few publications on this topic, but we are devoting to it a separate section of the present review because it is one of the most rapidly developing fields of modern coordination chemistry of hydrophosphorane compounds.

In 1990 Vannoorenberghe and Buono⁶³ reported the synthesis of the first representatives of a new group of hydrophosphoranes—tricyclic hydrophosphoranes which they called 'triquinphosphoranes'.

R = H (a), Me (b), Prⁱ (c), CH₂Ph (d)

The ³¹P NMR spectrum of a solution of compound **51a** in deuterated DMSO in the temperature range 20 to 80 °C did not reveal the presence of the potential P(III)-tautomer **51'a**.

It was shown that rapid pseudorotation is characteristic of the 'triquinphosphoranes', the difference between the conformational energies of the trigonal bipyramid (TBP) and the square pyramid (SP) being small — 2.0 ± 1.5 kcal mol⁻¹.

It is extremely significant that one nitrogen atom in the TBP is in the unusual apical position, so that it is displaced from the *pπ*-*dπ* conjugation with the phosphorus atom and is an independent donor centre. Indeed, the interaction of compound **51a** with BH₃·SMe₂ in the molar proportions P : B = 1 : 1 leads to the formation of the stable crystalline adduct **52** in 90% yield.

We may recall that the P,N-bidentate phosphoranide coordination of the BAP is also characterised by an apical nitrogen atom.

The synthesis of tricyclic hydrophosphoranes from ephedrine and compounds with condensed benzene rings has also been reported.⁶⁴ The latter hydrophosphorane is known in the form

of a stable monoborane complex, for which the structure **53** has been proposed.

However, this structure is surprising, since no hydrophosphoranes in which an equatorial nitrogen atom functions as a donor centre are known. Since the above communication⁶⁴ contains no rigorous evidence for the structure **53**, one may suppose that the compound is more likely to have a structure similar to that of the boron-containing adduct, mentioned above, with an axial orientation of the P—N—B fragment.†

Subsequently the synthesis of yet another chiral 'triquinphosphorane' **51e** (R = Et) was described.⁶⁵ Despite the use of the less reactive phosphorylating agent P(NEt₂)₃ and the fact that the reaction was carried out without a solvent, the yield of compound **51e** proved to be not less than that of compounds **51a-d**. The first transition metal complex with a tricyclic phosphorane was obtained from compound **51e**. The reaction of compound **51e** with Pd(COD)Cl₂ (P : Pd = 1 : 1) proceeds under mild conditions. According to ³¹P NMR data, phosphoranide coordination of the ligand takes place in this complex.

There is no doubt that there are satisfactory prospects for the coordination chemistry of 'triquinphosphoranes'. One can postulate that, by varying the metallic matrix and (or) the reaction conditions, it is possible to control the complex formation process involving tricyclic hydrophosphoranes and achieve not only phosphoranide coordination but also other types, for example,

IV. The formation of complexes by tetracyclic hydrophosphoranes

The synthesis of a series of polycyclic and tetraamino-substituted phosphorus compounds, two of which (cyclenPH and cyclamPH) have found applications in coordination chemistry, was reported in 1978.^{66,67}

† The P—N—B fragment in compound **53** does indeed occupy an axial position, which has been demonstrated by X-ray diffraction (personal communication by Dr Contreras).

Several years later, the structure of the hydrophosphorane cyclenPH was refined with the aid of X-ray and electron diffraction.⁶⁸ This compound has the structure of a distorted trigonal bipyramid with a large equatorial N–P–N angle (137.9° according to X-ray diffraction data) as a consequence of the small steric effect of the hydrogen atom. The anion of **54** with Li⁺ as the counterion was described in the same study, while the polymeric complex [Li(THF)cyclenP]_n was investigated by X-ray diffraction. The structure of this unusual compound merits a detailed discussion because the coordination of compound **54** to transition metals is achieved as a rule in the phosphoranide form. Furthermore cyclenPH is the first hydrophosphorane for which a direct structural comparison with the phosphoranide anion has been carried out. We may note that the linking units between the fragments in the polymer [Li(THF)cyclenP]_n are lithium cations. Despite the presence of a formal negative charge on the phosphorus atom, lithium is bound directly to the axial nitrogen atoms of two neighbouring fragments in this instance. This indicates the greater nucleophilicity of the axial nitrogen atoms compared with phosphorus. Furthermore, the axial bonds are lengthened by 0.21 Å compared with the initial cyclenPH and exceed by 0.1 Å the sum of the covalent radii. Overall, the phosphoranide ion may be described as resonance hybrid of three canonical forms:

The contribution of each of these forms is determined by the specific ligand environment at the phosphorus atom.

Although the study of the complex formation reactions of tetracyclic tetraazahydrophosphoranes (TTP) was initiated somewhat later than that of the BAP, at the present time two representatives of this group of ligands (compounds **54** and **55**) proved to be the most thoroughly investigated among hydrophosphorane ligands. The complexes of the ligands **54** and **55** will be considered simultaneously. The order in which they are described is based on the structure of the product of the coordination of the phosphorane and the type of complex-forming atom. Reactions involving the simultaneous occurrence of processes in which the hydrophosphorane structure is preserved and transformed will be discussed in one section.

1. Coordination with retention of the hydrophosphorane structure

a. Boron complexes

The pioneering communication concerning the coordination possibilities of the hydrophosphorane **54** appeared in 1983. It was found that the hydrophosphorane **54** readily reacts with diborane to form complex **56** in an almost quantitative yield.⁶⁹

Figure 2. The structure of compound **56**.

Compound **56** has a high decomposition temperature and a high stability in air, which distinguishes it favourably from the few other borane adducts constructed from the usually unstable strained phosphorus-containing structures. The monoborane complex has not even been detected: when 0.5 mol of B₂H₆ is added, the same compound (compound **56**) is formed, whilst half of the initial compound **54** remains unreacted. The difference in the behaviour of the phosphoranes cyclenPH and Phoran in relation to BH₃ is determined both by the strong macrocyclic effect, which in the case of compound **54** favours the formation of the 'closed' form, and by the presence in compound **54** of the more basic axial nitrogen atoms.

The interaction of cyclamPH with B₂H₆ was described in the same study. It proceeds less unambiguously and leads to a mixture of products, from which only two were isolated and identified: compounds **57** and **58** (in 40% and 15% yields respectively).

Both compounds can be stored in the solid state for several months without appreciable changes, but, when compound **57** is allowed to stand at room temperature in a sealed tube in solution in CD₂Cl₂, it is fully converted into compound **58** in several weeks.

The structures of complexes **56** and **58** have been demonstrated by X-ray diffraction.^{70,71} The molecule of compound **56** (Fig. 2) can be regarded as a trigonal bipyramid with a slight deviation towards a square pyramid. Lengthening of the apical P–N bonds and the shortening of the equatorial P–H and P–N bonds compared with the initial cyclenPH is observed. Although both BH₃ groups are coordinated to the apical nitrogen atoms, the B–N bonds are not located in a single plane owing to the slight helical distortion of the molecule. It was established that compound **58** exists in the form of only one of the two possible diastereoisomers, in which the P–B and N–B bonds are in the *trans*-positions relative to one another.

b. Transition metal complexes

Before beginning the consideration of transition metal complexes of cyclenPH, we may note that one or both apical nitrogen centres in the molecule of compound **54** can be easily protonated by strong acids (for example, CF₃CO₂H or HBF₄).

On the other hand, the quaternisation reaction leads only to the monoalkylated product even on treatment with an excess of MeI.⁷²

In order to synthesise N-linked metallo-derivatives of cyclenPH, a study has been made⁷³ of its interaction with ZnCl₂ and CdCl₂. On the basis of spectroscopic data, similar to those obtained for the monoprotonated and monoalkylated adducts, the following structure was attributed to the zinc (compound **59**) and cadmium (compound **60**) complexes of cyclenPH:

Attempts to isolate 1:2 compounds by treatment with an excess of zinc or cadmium chloride were unsuccessful. Both complexes give rise to derivatives on treatment with strong acids. Thus treatment of compounds **59** and **60** with one equivalent of HCl led to the formation of compounds **61** and **62**.

X-Ray diffraction of complex **61** showed that it exists in the form of a 'head to tail' dimer stabilised by two N—H...Cl hydrogen bonds.

The interaction of compound **54** with cobalt, molybdenum, manganese, iron and tungsten carbonyls and hydrides has been examined in an extensive investigation.⁷⁴ The reaction of compound **54** with HW Cp(CO)₃ proceeds as an acid-base process with formation of the salt **63**.

Its treatment with MeI leads to the replacement of the anion: MeWCp(CO)₃ and compound **64** are formed. Similarly to the reaction involving compound **54**, only fairly strong nitrogen-containing bases (in particular NEt₃) react with HW Cp(CO)₃, whereas weaker bases, for example pyridine, do not react.

Here it is appropriate to mention that all the monoprotonated nitrogen-monocoordinated cyclenPH adducts give rise to a single signal in the ¹³C NMR spectra (at room temperature) in the range 42.8–45.0 ppm. However, the low-temperature (at –76 °C) ¹³C NMR spectrum of compound **64** contains five signals. These spectroscopic features can be explained, according to Lattman et al.⁷⁴, by two different exchange processes: pseudorotation with proton transfer between the nitrogen atoms and the dissociation of the P—N bond in the P—N—H fragment accompanied by the transfer of a proton and the reduction of the P—N bond. However, the available data are insufficient for the identification of these two mechanisms, although it has been stated⁶⁶ that compound **54** undergoes pseudorotation.

The interaction of compound **54** with metal carbonyl dimers proceeds in a much more complex manner.

The salt **66** is stable in solution in THF at room temperature under an inert atmosphere, but an increase in temperature to 55 °C leads to the spontaneous loss of H₂ and CO molecules by the salt and the formation of the covalent derivative **65**. The corresponding reaction of compound **54** with [MoCp(CO)₃]₂ affords analogous products: (cyclenP)MoCp(CO)₂ **67** and (cyclenPH₂)⁺[MoCp(CO)₃][–] **68**. However, in this case even prolonged refluxing of a mixture of compounds **67** and **68** in THF does not lead to the transformation of the salt into the covalent derivative. The only product of the reaction of compound **54** with Mn₂(CO)₁₀ (refluxing in THF) which was isolated proved to be the salt (cyclenPH₂) [Mn(CO)₅].

The covalent derivative of manganese analogous to compounds **65** and **67** is apparently unstable under the reaction conditions and decomposes, while the reaction of cyclenPH with [FeCp(CO)₂]₂ does not occur at all even after prolonged refluxing in THF or dioxane.

According to Lattman et al.⁷⁴, the behaviour of compound **54** in the reaction with dinuclear transition metal carbonyls is very similar to the behaviour of phosphines under the same conditions. For example, the interaction of PR₃ with Co₂(CO)₈ leads to the initial formation of the salt [Co(CO)₃(PR₃)₂]⁺[Co(CO)₄][–], which then loses a CO molecule and is converted into Co₂(CO)₆(PR₃)₂. The structures of compounds **67**, and later⁷⁵ also of **65**, were confirmed by X-ray diffraction. Their principal feature is the presence of the three-membered ring

with a greatly lengthened P—N bond. Such compounds will be examined in greater detail in the next section.

Thus the TTP are capable of both N-monodentate and N,N-bidentate coordination to the corresponding Lewis acids. Coordination of this structural type is reflected in the length of the apical and equatorial bonds in the hydrophosphorane (the former are lengthened and the latter are shortened) and is manifested spectroscopically by a downfield shift of δ_P and an increase in the spin-spin coupling constants ¹J(P,H) in the ³¹P NMR spectra.

In a number of instances, N-monodentate and N,N-bidentate binding is accompanied by the occurrence of parallel processes leading to P,N-bidentate coordination. This is caused either by the existence of a tautomeric equilibrium (as in the case of cyclamPH) or by the nature of the initial metal complex.

2. Coordination with transformation of the hydrophosphorane structure

a. Molybdenum and tungsten complexes

The first communication concerning the use of tetracyclic hydrophosphoranes in coordination chemistry dates back to 1982.⁷⁶ A series of molybdenum and tungsten complexes obtained from cyclamPH are described in this paper and X-ray diffraction data are presented for one of them. An extensive study, in which all the aspects of the synthesis, reactivity, and structural features of these compounds are analysed in detail, was published much later (Scheme 1).⁷⁷

As stated above, cyclamPH exists as an equilibrium mixture of the closed and open forms. On addition of this mixture of the molybdenum and tungsten complexes, the equilibrium is

quantitatively displaced to the right and compounds **69** and **70** are formed respectively. According to ^{31}P NMR and conductimetric data, complex **69** exists in solution as a mixture of the covalent form **69a** (75%) and the ionic form **69b** (25%).

Only complex **69a** is present in the solid phase, which is indicated by the $\nu(\text{NH}) = 3297 \text{ cm}^{-1}$ absorption band, characteristic of a noncoordinated secondary amino-group. The conductimetric data obtained for compound **70** also indicate the absence of any appreciable amounts of the ionic product. On treatment with NaBPh_4 , complexes **69** and **70** are readily converted into compounds **71** and **72** respectively. Unfortunately, compounds **71** and **72** have been less fully characterised spectroscopically than compounds **69** and **70**. Thus, in the description of their IR spectra, the frequencies $\nu(\text{NH})$ are not indicated. Furthermore, only $\delta_{\text{P}} = 118 \text{ ppm}$ is quoted for complex **72** without an indication of the value of the spin-spin coupling constant $^1J(\text{P}, \text{W})$. The reactions of compounds **71** and **72** with MeLi lead to compounds **73** and **74** with P,N-bidentate phosphoranide coordination. Complex **73** can also be obtained

from compound **69**, but its yield is then low (20%), since in this case mainly unidentified decomposition products are formed. The transition to phosphoranide coordination is accompanied by an appreciable upfield shift of δ_P in the ^{31}P NMR spectra (by more than 170 ppm). In the IR spectra of complexes **73** and **74**, the frequencies $\nu(\text{CO})$ are reduced by $\sim 50\text{ cm}^{-1}$ compared with compounds **71** and **72** as a consequence of the decrease in the positive charge on the metal atom. The structure of compound **73** has been demonstrated by X-ray diffraction (Fig. 3). The environment of the phosphorus atom constitutes an almost regular trigonal bipyramid. Thus the N(1), P, and N(3) atoms lie virtually on a single straight line (176°), while the angles in the equatorial plane are close to 120° . The greater length of the P–N(1) bond (1.85 Å) and, conversely, the small lengths of the remaining three P–N bonds are striking. The P–Mo and N–Mo bonds have the usual lengths.

It is of interest that the structure of compound **73** shown an unusual 'negative' distortion of the trigonal-bipyramidal configuration, which means that it is not intermediate between the ideal trigonal bipyramidal and square pyramidal configurations.⁷⁷

Several studies have been devoted to the complex of cyclenPH with $\text{Mo}(\text{CO})_6$ and its reactivity.^{78–81} It was established⁷⁸ that treatment of compound **54** with the complex $\text{Mo}(\text{CO})_6$ in boiling toluene affords $\text{HcyclenPMo}(\text{CO})_5$ **75**, in which cyclenPH is linked to the metal only via the phosphorus atom.

Figure 3. The structure of complex **73** (the η^5 -C₅H₅ ring has been omitted for clarity).

$$\delta_P = 116 \text{ ppm},$$

$$\nu(\text{NH}) = 3400 \text{ cm}^{-1}$$

NMR and IR spectroscopic data indicate unambiguously the presence of a noncoordinated secondary amino-group in the structure of compound **75**. However, treatment of it with HBF_4 leads to the formation of a product with a pentacoordinate

phosphorus atom, where both axial nitrogen atoms are protonated, and not a simple ammonium salt.

The cause of such unusual reactivity was deduced with the aid of X-ray diffraction. The geometry of the phosphorus atom in compound **75** is unique: instead of the tetrahedral configuration, a distorted trigonal bipyramidal coordination obtains (Fig. 4). The Mo, N(2), and N(4) atoms are in the equatorial positions, whilst the N(1) atom is in one of the axial positions. The other axial position is occupied by the N(3) atom, which interacts with phosphorus via the lone pair. Although $P-N(3) = 2.356 \text{ \AA}$, a distance which exceeds by $\sim 0.4 \text{ \AA}$ the lengths of the axial $P-N$ bonds in other cyclenPH derivatives, it is nevertheless less than the sum of the van der Waals radii. A more important feature is that the phosphorus atom is almost in the plane of the Mo, N(2), and N(4) atoms, while the equatorial and axial $N-P-N$ angles are typical of those for other trigonal-bipyramidal derivatives of cyclenPH, in which all four nitrogen atoms form with the phosphorus atom bonds having 'normal' lengths. It is more correct to regard the 'cyclenPH' fragment as a phosphoranide zwitterion.

The reactions of compounds **75** with Lewis acids are unusually sensitive to the nature of the acid. It has been reported⁷⁹ that the interaction of compound **75** with $\text{THF} \cdot \text{BH}_3$ affords the product **77**, in which the coordination number of phosphorus is four and there is an unusual conformation of the cyclenP ring.

Figure 4. The structure of compound **75**.

The structure of compound **77** was established from ^{31}P , ^{13}C , ^{11}B , and ^1H NMR and IR spectroscopic data and was confirmed by X-ray diffraction. Treatment of complex **75** with $\text{Me}_3\text{O}^+ \text{BF}_4^-$ leads to the analogue **76**, where one of the apical nitrogen atoms is not protonated but methylated. Unfortunately, this structure has been discussed only on the basis of ^{31}P NMR spectroscopic data.

The interaction of compound **75** with $\text{CF}_3\text{SO}_3\text{Me}$ led to the formation of two products—**78** and **79**.⁸⁰

The same compounds, **78** and **79**, were isolated also after carrying out the reaction with the molar ratio $\text{75} : \text{CF}_3\text{SO}_3\text{Me} = 2 : 1$. The authors put forward two different mechanisms of the interaction of compound **75** with HBF_4 , methyl triflate, and $\text{THF} \cdot \text{BH}_3$. According to the first mechanism, the Lewis acid reacts initially with the lone pair of the second amino-group, which is followed by proton transfer. This process is analogous to the addition of alkyl halides to secondary amines.

In the case of the complex with borane, the proton transfer is unfavourable and the corresponding structure may be isolated.

The other mechanism involves the initial protonation of the second axial nitrogen atom in the *trans*-position relative to NH . This results in the immediate formation of the salt **76**.

The similarity of compound **75** to a secondary amine is also indicated by its interaction with $\text{CH}_3\text{O}_2\text{CC} \equiv \text{CCO}_2\text{CH}_3$ giving rise to compound **80**.

The structure of compound **80** was established by X-ray diffraction. Overall, the complex formation reaction between cyclenPH and Mo(CO)_6 demonstrates the ability of the 'cyclen' fragment to stabilise the trigonal bipyramidal geometry around the phosphorus atom as a result of a transannular interaction. This interaction is fairly weak and in subsequent reactions the complex may behave as a secondary amine.

The deprotonation of compound **75** by BuLi led to the formation of a phosphoranide adduct.⁸¹

We may note that the transition from the transannular $P \cdots \text{NH}$ contact in compound **75** to the direct $P-N$ bond in compound **81** is accompanied by a pronounced (96 ppm) upfield shift of the δ_P resonance signal of compound **81** compared with the

signal of complex **75**. The presence of both carbonyl ligands and of a secondary amino-group in complex **75** makes it necessary to think about the mechanism of the formation of complex **81**. It is well known that the reactions of metal carbonyls with alkyl lithium compounds lead to acyl complexes. If this reaction path is followed, the acyl complex should split off pentanal with formation of compound **81**. However, if compound **75** undergoes direct deprotonation by butyllithium with subsequent attack by the nitrogen on the metal, butane and CO are formed. Since butane was in fact isolated from the reaction mixture, the occurrence of the process via the second path was confirmed.

We have frequently noted a fundamental feature of the three-membered phosphoranide rings $P-N-M$, namely the presence in the latter of a lengthened $P-N$ bond, which, together with the negative charge of the complex ion of compound **81**, increases significantly the reactivity of the compound. Thus the addition of $ClPPh_2$ to the latter leads to a derivative with two different phosphorus atoms.

The structure of compound **82** was confirmed by IR and ^{31}P , ^{13}C and 1H NMR spectroscopic data and X-ray diffraction. Treatment of compound **81** with $H_3CO_2CC\equiv CCO_2CH_3$ also induces the dissociation of the $Mo-N$ bond, which results in the formation of the metallated enamine **83**.

Thus the reactions of tricyclic hydrophosphoranes with molybdenum and tungsten complexes take place with dissociation of the $P-H$ and $P-N$ bonds accompanied by the P -monodentate binding of the ligand in the open form. The products obtained may undergo further reactions accompanied by the transition to the P,N -bidentate (including phosphoranide) and the P -monodentate phosphoranide coordination of the ligand.

b. Iron and rhodium complexes

In contrast to the bicyclic hydrophosphoranes, TTP have not been widely employed in the coordination chemistry of iron and rhodium. Only four iron and rhodium complexes with the cyclamPH and cyclenPH ligands are known at present. The interaction of cyclamPH with $Fe(NO)_2(CO)_2$ for different ligand: metal molar ratios was investigated in the study⁷⁷ already mentioned above. It was established that the reaction proceeds with formation of monosubstituted or disubstituted products (**84** and **85**), in which the ligand is bound exclusively via the phosphorus atom.

The structures of these substances were confirmed by ^{31}P NMR and IR spectroscopic data as well as mass-spectrometric data (chemical ionisation method). Compared with the initial complex $Fe(NO)_2(CO)_2$, the IR spectra of complexes **84** and **85** exhibit a bathochromic shift of $\nu(CO)$ (for compound **84**) and $\nu(NO)$ (for compounds **84** and **85**). This finding indicates that the aminophosphoramidite ligand is a pronounced σ -donor and a weak π -acceptor, apparently owing to the strong $p\pi-d\pi$ interaction characteristic of this compound. The presence of two $\nu(NH)$ bands in the spectrum of compound **85** (3120 and 3340 cm^{-1}) may be caused, according to the authors, by intermolecular hydrogen bonds.

The synthesis of the chlororhodium carbonyl complex **86** from $[Rh(CO)_2Cl]_2$ and cyclamPH was described in the same study.

The ^{31}P NMR and IR spectroscopic characteristics of compound **86** are analogous to those of the rhodium(I) carbonyl-containing complexes with P,N -bidentate ligands already mentioned.

An attempt has been made⁷⁰ to initiate the tautomeric rearrangement of the phosphorane by treating cyclenPH with the complex $[Rh(CO)_2Cl]_2$, which was unsuccessful. However, the authors do not state what the particular result of this interaction was, so that such a claim can be treated in extremely broad terms, for example, as one implying the complete absence of the occurrence of any reaction. Nevertheless, the latter appears most improbable, since one is dealing with contact between a reactive phosphorane and a reactive rhodium substrate, particularly since cyclenPH interacts readily⁸² with $[Rh(PPh_3)_3Cl]$ with formation of compound **87**.

It was found that complex **87** reacts slowly (in two days) with methylene chloride, affording the unique rhodium complex **88** with pentacoordinate phosphorus atom and the four-membered ring $P-N-C-Rh$.

The structures of compounds **87** and **88** were established by use the ^{31}P and 1H NMR methods, while that of compound **88** was further confirmed by X-ray diffraction. The coordination

polyhedra in complex **88** are a distorted octahedron for the rhodium atom and a distorted trigonal bipyramid for the phosphorus atom. The formation of compound **88** apparently includes the oxidative addition of CH_2Cl_2 to rhodium and a subsequent rearrangement of the 'cyclenP' fragment accompanied by a change in the coordination number of phosphorus from 4 to 5 and attack by the nitrogen atom on a carbon atom with displacement of a chloride anion. It is of interest that a compound similar to compound **88** is formed in CDCl_3 immediately after the dissolution of complex **87**.

Thus the coordination of the tetracyclic hydrophosphoranes to iron and rhodium proceeds with decomposition of the hydrophosphorane structure of the ligand and by their P-monodentate (in the case of iron) or P,N-bidentate (in the case of rhodium) binding.

c. Platinum complexes

Platinum complexes are in fact most widely used in the study of the coordination possibilities of tetracyclic hydrophosphoranes. An impressive diversity of interconversions of complexes of one kind into others has been observed for these complexes. However, only cyclenPH has been used in most of these complexes; only one compound with cyclamPH is known.

The pioneering communication⁸³ published in 1987 discusses an unusual reaction between cyclenPH and *cis*- $\text{PtCl}_2(\text{PPh}_3)_2$.

The very high value of the spin-spin coupling constant $^1J(\text{P}, \text{Pt}) = 5567 \text{ Hz}$ for compound **90** (for compound **89**, it is 3672 Hz) and the anomalously low frequency $\nu(\text{Pt}-\text{Cl}) = 249 \text{ cm}^{-1}$ for complex **89** (for complex **90**, its values are 275 and 300 cm^{-1}) are noteworthy. Such a low frequency $\nu(\text{Pt}-\text{Cl})$ corresponds as a rule to a considerable lengthening of the $\text{Pt}-\text{Cl}$ bond. Indeed, X-ray diffraction of compound **89** showed that the $\text{Pt}-\text{Cl}$ distance in this compound is 2.44 \AA . The geometry of the 'cyclenP' ligand in complex **89** is of the 'usual' type: the distance from the phosphorus to the nitrogen atom in this three-membered ring is very large (1.872 \AA), whereas the length of the three other $\text{P}-\text{N}$ bonds are in the range $1.68-1.70 \text{ \AA}$. Owing to the strain in the metallocycle, all four bond angles in the plane of the platinum square deviate appreciably from 90° . We may note that lengthening of the $\text{Pt}-\text{Cl}$ bond is as a rule caused by the strong *trans*-influence of the corresponding substituent. However, the authors did not decide to account for this anomaly by the pentacoordinate state of the phosphorus atom, because the frequencies $\nu(\text{Pt}-\text{Cl})$ in complex **90** and *cis*- $\text{PtCl}_2(\text{PPh}_3)_2$ are fairly close. In their view, long $\text{Pt}-\text{Cl}$ bond and the low frequency $\nu(\text{Pt}-\text{Cl})$ may be dictated to a large extent by steric and/or electronic requirements of the three-membered metallocycle. We shall return later to the analysis of this problem.

The reaction between cyclamPH and the dinuclear compound $[\text{Pt}_2\text{Cl}_4(\text{PEt}_3)_2]$ leads to the cationic complex **91**.⁸⁴

whereas the only product of the reaction of the same platinum dimer with cyclenPH which has been isolated proved to be complex **92**.

92: $\text{X} = \text{Cl}^-$

93: $\text{X} = \text{PF}_6^-$

Analogue **93** of compound **92** was obtained by ion exchange of the latter with KPF_6 . The structures of the salts **92** and **93** are similar to the structure of complex **90**, but in the latter the chloride ligands have the *cis*-configuration. In the determination of the structures of compounds **91-93**, the ^1H , ^{13}C , ^{31}P , and ^{195}Pt NMR methods and conductimetry were used, whilst in the case of compound **91** X-ray diffraction was also employed. All the bond lengths in the first coordination sphere of the platinum atom in compound **91** are within the standard ranges of values. Unfortunately, the comparison of the complex formation reactions of cyclenPH and cyclamPH with the same metallic substrate was not developed further.

Subsequent studies were devoted to further reactions of compounds **89** and **90**. Thus their tendency towards the interconversion has been demonstrated.⁸⁵

It is noteworthy that the monoprotonated intermediate was not isolated or even detected in this reaction. Thus the interaction of compound **89** with less than two equivalents of HCl nevertheless leads to the product **90** and part of the initial complex does not react. This is apparently associated with the fact that the chloride anion is a strongly coordinating ligand, which may displace the mode of reaction towards double protonation. Consequently the use of a noncoordinating anion can ensure the isolation of the monoprotonated derivative. Indeed, the reaction of compound **89** with one equivalent of HBF_4 affords compound **94**.

The cation of compound **94** is apparently a key intermediate in the conversion of compound **89** into compound **90**. In fact, treatment of compound **94** with HCl results in the immediate formation of the diprotonated adduct **95**.

Furthermore, when a source of chloride ions (NaCl) is added to compound **94**, compounds **89** and **90** are formed. Taken all together, the interconversions of complexes **89**, **90**, **94**, and **95** can be represented by the following scheme:

Scheme 2

The structures of compounds **90** and **94** were confirmed by X-ray diffraction. The phosphorus centre in complex **90** has the configuration of a distorted trigonal bipyramid with lengthened axial P–N bonds, while that in compound **94** has a distorted tetrahedral configuration (Fig. 5). The dissociation of the P–N bond increases the phosphorus–nitrogen distance to 2.775 Å and the P(1)–Pt–N(1) angle by 28.2° compared with the analogous angle in compound **89**. The appreciable similarity of the ligand structures in compounds **89**, **90**, and **94** indicates the tendency of the 'cyclenPH' fragment to retain the trigonal bipyramidal geometry.

Systematic studies of the reactivity of compound **89** towards various nucleophiles and electrophiles were carried out subsequently.^{86,87} The results are presented in Scheme 2.

The reactions of compound **89** with Na[Co(CO)₄], NaSMe, KI, and KBr afford the substitution products **96–99** respectively. The NMR spectra of compounds **89**, **98**, and **99** are virtually identical with the exception of small differences in δ_P and $^1J(P, Pt)$. The $\nu(CO)$ frequencies in the spectrum of compound **96** are significantly lower than in those of other compounds of the type LCo(CO)₄. This indicates a markedly ionic character of the Pt–Co bond and the presence of a partial negative charge on the Co(CO)₄ group. In fact, the interaction of compound **96** with Me₃SiI leads to the formation of complex **98** and Me₃SiCo(CO)₄.

On the other hand, the reaction of compound **89** with Ph₂PCH₂PPh₂ leads to the substitution of a triphenylphosphine ligand and the attempts to displace the chloride ligand outside the coordination sphere of platinum by treatment with NaBPh₄ were unsuccessful. Treatment of compound **89** with electrophiles such as MeI and BuⁿBr also leads to compounds **98** and **99**. The exchange reactions between platinum complexes and RHal (Hal = Br, I), involving the exchange of chlorine at the platinum atom, usually proceed via oxidative addition and reductive elimination with participation of the metal atom. However, no evidence in support of this reaction mechanism was found even in a low-temperature experiment. An alternative to this mechanism may be the formation of a *N*-alkylated derivative with subsequent substitution of the halogen and the elimination of an alkyl halide. Indeed, metallation of compound **89** by MeO₃SCF₃ leads to the salt **101**, whilst its treatment with KI affords compound **98**.

Figure 5. The structure of the cation of compound **94**.

L = Co(CO)₄ (**96**),
SMe (**97**), I (**98**), Br (**99**)

Very weak electrophiles do not react with compound **89**. For example, the interaction of compound **89** and HC≡CPh does not take place even in boiling THF. However, after the addition of NaBPh₄ to the reaction mixture, compound **102** is formed. Various possible mechanisms of the formation of compound **102** have been compared.⁸⁷ According to the authors *N*-protonation takes place and is followed by the coordination of the alkyne with substitution of the chloride ion.

It follows from the scheme presented above that anionic nucleophiles substitute Cl[−], whilst neutral nucleophiles substitute PPh₃. Cationic electrophiles with noncoordinating anions attack the nitrogen atom, which leads to the dissociation of the P–N bond, whereas electrophiles with coordinating anions induce the dissociation of the Pt–N bond.

The structures of compounds **96**, **98**, and **99** have been demonstrated by X-ray diffraction.⁸⁸ The cause of the lengthening of the Pt–Cl bond and of the low $\nu(Pt-Cl)$ frequency was again discussed in this connection. The cause may not be solely the strain in the three-membered ring or solely the strong *trans*-effect of the pentacoordinate phosphorus. According to the authors, the principal difference between the structures of compounds **89** and **90** consists in the orientation of the N–P–N axis with participation of the axial nitrogen atoms: in the plane of the platinum square in compound **89** and at right angles to this square in compound **90**. It may be that in the former case the trigonal-bipyramidal phosphorus atom exerts a stronger *trans*-influence. However, the question arises of the legitimacy of such comparison, since in fact one is dealing with completely different ligands: one nitrogen centre is coordinated in compound **89**, whereas in compound **90** both axial nitrogen atoms are protonated. For this reason, the limited *trans*-influence of 'H₂cyclenP' in complex **90** does not permit conclusions concerning such influence of 'cyclenP' in compound **89**. Furthermore, in compound **90** 'H₂cyclenP' exhibits a fairly strong *trans*-influence, although not as strong as in complex **89**. Indeed, the length of the Pt–Cl bond in the *trans*-position relative to the phosphorus atom of 'H₂cyclenP' in compound **90** is 2.386 Å, whereas in compound **94** it is 2.353 Å. The Pt–Cl bond in the *trans*-position relative to the triphenyl phosphine ligand in compound **90** is shorter still (2.343 Å). The conclusion that the *trans*-influence of the pentacoordinate phosphorus atom is

greater than that of the tetracoordinate phosphorus atom follows from these data. Whereas the Pt—Cl distance in compound **94** may be regarded as 'normal' on the basis of the nature of the phosphorus centre, in compound **90** the distance is anomalously large.

It is also scarcely possible to agree with the treatment of the unusually high spin-spin coupling constant $^1J(\text{P}, \text{Pt})$ in complex **90** by Siriwardane et al.⁸⁸ In their view, the bonding σ orbital used by phosphorus to form a bond with platinum is approximately sp^2 -hybridised. It was then concluded that the high level of s character leads to a high value of $^1J(\text{P}, \text{Pt})$. However, increase in the s character of the σ -bond should inevitably lead to the shortening of the Pt—P bond. However, the Pt—P bond in compound **90** is very long (2.289 Å). Complexes of platinum with phosphites are also characterised by high spin-spin coupling constants $^1J(\text{P}, \text{Pt})$ (from 5600 to 6000 Hz) and short Pt—P bonds (~ 2.20 Å).^{89–92} Thus metallated phosphoranes exhibit a whole series of spectroscopic and structural anomalies. The characteristics established for complexes with trivial organophosphorus(III) ligands are not always confirmed in the case of pentacoordinate phosphorus. Specific syntheses of a whole series of homologous structures and a thorough spectroscopic and structural study are apparently needed for the determination of the mutual correlations.

In the latest experimental study⁹³ devoted to platinum complexes, investigation of the reactions of compound **89** with various phosphines was continued. Thus the interaction of compound **89** with $\text{Ph}_2\text{P}(\text{CH}_2)_2\text{PPh}_2$ afforded the ionic product **103**.

The ionic nature of compound **103** was established both spectroscopically and chemically: the exchange of the chloride ion for PF_6^- with formation of compound **104**, which has ^{31}P NMR characteristics almost identical with those of complex **103**, was carried out. The structure of complex **103** differs sharply from that of compound **100**. It is extremely likely that the monodentate coordination of the ligand $\text{Ph}_2\text{PCH}_2\text{PPh}_2$ is associated with its small chelate angle (73°), whereas in $\text{Ph}_2\text{P}(\text{CH}_2)_2\text{PPh}_2$ the angle is 85° . In most cases, this difference is of no fundamental importance. However, the presence of the three-membered phosphorane ring in compound **100** apparently inhibits the formation of the second small ring. As already mentioned, the attempts to coordinate the free phosphorus centre in compound **100** by treatment with NaPF_6 or NaBPh_4 were on the whole unsuccessful. This results in the formation of a mixture of adducts, which could not be separated, but the authors⁹³ nevertheless postulated the formation of complex **105**.

In support of their view, they quote only the values of δ_P for the three different phosphorus atoms and the spin-spin coupling constant $^2J(\text{P}, \text{P})$. The spin-spin coupling constant $^1J(\text{P}, \text{Pt})$ could not be determined owing to the presence of numerous signals due to impurities.

It was found that the free phosphorus centre in compound **100** can be coordinated via another path—the decomposition of the three-membered ring. This aim was achieved by a procedure already tested, by treatment with HBF_4 .

Again, as in the synthesis of compound **90**, the monoprotonated adduct could not be obtained.

The presence of the noncoordinated phosphorus atom in the structure of compound **100** raised the possibility that interaction with another metal complex would yield a heterobinuclear compound. In fact, the reaction of compound **100** with $\text{Na}[\text{Co}(\text{CO})_4]$ led to the formation of the bimetallic complex **107** with a Pt—Co bond.

The structures of compounds **106** and **107** were established by X-ray diffraction. The geometry around the phosphorus atom in compound **106** can be described as distorted trigonal bipyramidal (Fig. 6). The lengths of the axial P—N bonds not only exceed by 0.25–0.30 Å the lengths of the equatorial bonds, but they are also greater than the sum of the covalent radii. Apparently only the unusual geometry of the 'cyclenP' ring prevents the dissociation of these bonds. Both N—H groups form hydrogen bonds with the counterion.

The facts mentioned above indicate that platinum can be readily incorporated in both three- and five-membered rings simultaneously, whereas the inclusion of the metal in three- and four-membered rings is very difficult to achieve.

Figure 6. The structure of compound **106**.

On the whole, the coordination of cyclenPH to platinum leads to metallated phosphoranes with P-monodentate or P,N-bidentate binding of the ligand. On treatment with appropriate reagents, the compounds obtained can be interconverted or they can be converted into a multiplicity of different metal complexes with P,N-bidentate coordination, in which the coordination number of phosphorus is smaller. The interaction of cyclamPH and platinum has been clearly inadequately investigated. Nevertheless, the available data indicate the displacement of the $55a \rightleftharpoons 55b$ equilibrium towards the open form with P,N-bidentate binding of the ligand.

Evidently TTP are the most versatile ligands in the coordination chemistry of hydrophosphoranes. They are capable of N- and P-monodentate and N,N- and P,N-bidentate coordination, including coordination of the phosphoranide type.

The tetracyclic hydrophosphoranes can behave as amines, phosphoramidites, aminophosphoramidites, or as hydrophosphoranes proper depending on the type of Lewis acid, forming at the same time unique metal complexes. When bound to a metal, they sometimes assume the functions of the latter, interacting with reagents of different nature. However, reactions in which TTP are coordinated solely in the P-monodentate or the P,N-bidentate phosphorane form, without the occurrence of parallel reactions or without treatment by deprotonating agents, are so far unknown. The search for processes of this kind is still to be carried out.

V. Conclusion

It is seen from the data presented that considerable advances have been made in the chemistry of metallo-derivatives of hydrophosphoranes. The bicyclic and tetracyclic hydrophosphoranes were found to be the most thoroughly investigated groups of compounds, whilst a new aspect—the study of a complex formation reaction by ‘triquinphosphoranes’—has only just become outlined but promises to be continued on a duly impressive scale. At the same time the extensive coordination possibilities of hydrophosphoranes have not yet been utilised to the extent that they deserve. We may point to certain fundamental problems the solution of which we believe to be of current interest.

1. Comparison of the reactivities of various groups of hydrophosphoranes employing a specific metallic substrate and standard complex formation conditions. So far, there have been few such studies—only $[\text{Rh}(\text{CO})_2\text{Cl}]_2$ is known as a general partner in the complex formation reactions involving BAP, HSP, and TTP. The remaining platinum metals have been used to a lesser extent. Rhodium complexes have been thoroughly investigated for the BAP, while the palladium complexes have been studied very superficially and there are no examples whatever of platinum adducts. On the other hand, the platinum derivatives of the tetracyclic hydrophosphoranes have been investigated in detail, while the studies on the rhodium complexes have been fragmentary and the palladium complexes are unknown. So far, the chemistry of the HSP is in many respects the chemistry of one metal, namely of rhodium. Palladium and especially platinum have clearly not been employed adequately. Furthermore, it would be useful to investigate the interaction of a specific phosphorane with a series of analogous metal complexes, for example $\text{M}(\text{COD})\text{Cl}_2$ ($\text{M} = \text{Pd}, \text{Pt}$), $\text{M}(\text{CO})_n$, etc. This would assist in a better understanding of the mechanism of the coordination of the hydrophosphoranes. Such studies are also extremely few in number.

2. The extensive employment of all groups of hydrophosphoranes in catalysis, especially asymmetric catalysis. Nowadays this field has already been outlined—certain BAP and HSP have been involved in catalytic processes, whereas the tetracyclic hydrophosphoranes have been completely ignored by specialists in catalysis. Clearly extraordinary results may be expected for ligands with superior coordination and stereochemical properties of the kind possessed by hydrophosphoranes.

HSP with aminoacid residues,^{94,95} i.e.

may be of special interest primarily for metal complex asymmetric catalysis because these stable compounds are obtained in satisfactory yields by the direct phosphorylation of readily available chiral precursors—natural aminoacids. The authors of the present review have begun studies on the employment of such HSP in coordination design. We may also mention a novel hydrophosphorane with an unusual axial orientation of the P–H bond.⁹⁶

It is significant that an active catalyst of the oligomerisation of ethene has been obtained from this compound by treatment with KOH, NiCl_2 , and NaBH_4 .

3. The expansion of the range of hydrophosphorane ligands by resorting to new systems, for example, monocyclic hydrophosphoranes.⁹⁷

$\text{R} = \text{Me}, \text{CH}_2\text{Ph}$

Tetraoxohydrophosphoranes, on the coordination chemistry of which only one study has been published, merit more constant attention.

It is essential to state that the field of synthesis of a wide variety of BAP with additional coordination centres by the interaction of proton-donating reagents with derivatives of bicyclo[3.3.0]-1-phospha-2,8-dioxo-5-azaoctane has been developing vigorously in recent times.⁹⁸ These systems can also be regarded as promising polyfunctional ligands.

4. The study of the mechanism of complex formation reactions of hydrophosphoranes. The interaction of the tautomer having a tricoordinate phosphorus atom with a metal-containing substrate has been traditionally postulated. However, in a whole series of cases the existence of such a tautomer is doubtful. Thus NMR and IR spectroscopic studies of solutions of oxazahydrospirophosphoranes did not reveal the presence of the phosphorus(III) form.^{51,99,100} Furthermore, these HSP do not react under mild conditions with $(\text{acac})\text{Rh}(\text{CO})_2$ and $\text{BF}_3 \cdot \text{Et}_2\text{O}$, atypical of organophosphorus(III) compounds. The tautomeric equilibrium postulated for Phoran has also not been detected spectroscopically¹¹ [the phosphorus(III) isomer has been found only in the gas phase]. Finally, cyclenPH exists in the phosphorus(V) form in solution, in the solid state, and in the gas phase,⁷⁸ although a whole series of metallo-derivatives are known

where it is coordinated in the open form. On the other hand, the interaction of cyclenPH with B_2H_6 leads to a bisborane adduct with pentacoordinate phosphorus. All these facts indicate the active role of the transition metal in the complex formation reaction involving the hydrophosphorane and hence the existence of a mechanism involving the formation of a metal hydride intermediate (in accordance with the same principle as in the reactions of silanes, secondary phosphines, or hydrophosphoryl compounds).^{51, 101} At the same time, one cannot exclude from discussion the mechanism with participation of the phosphorus(III) tautomers of hydrophosphoranes. We may recall that a bisborane adduct has been obtained for Phoran, in which the latter exists in an open form let alone the fact that phosphorus(III) isomers have been detected spectroscopically for many hydrophosphoranes. Both mechanisms apparently operate, their contributions depending on the nature of the hydrophosphorane, the Lewis acid, and the reaction conditions. However, additional studies are needed to justify this view.

The interest in the employment of hydrophosphoranes in metal complex design has not weakened. A review by Lattman and co-workers, containing a brief survey of the ligand properties of cyclenPH, has been published recently.¹⁰² We believe that the current achievements in the coordination chemistry of hydrophosphoranes constitute merely a prologue to its further development.

In the preparation of the figures, the facilities of the Cambridge Structural Database (1995 release) were employed. These permit a graphical representation of molecules on the basis of the atomic coordinates of the crystals of the test compounds deposited in the Database.

Abstract. The characteristic features of the synthesis and properties of cardo polyheteroarylenes (polyarylates, aromatic polyethers, polyamides, polyimides, polyoxadiazoles, and others) are examined and surveyed. It is shown that cardo polymers containing bulky side-groups, linked via cyclic groups to the polymer main chain, have enhanced thermal characteristics combined with a satisfactory solubility. Certain aspects of the practical applications of polymers of this kind are considered. The bibliography includes 309 references.

I. Introduction

Among polymers with an enhanced thermal stability, cardo polymers occupy a special place; the term cardo polymers is applied to those containing at least one element in the repeating group which is included in the cyclic side group. The term arose from the Latin word 'cardo', meaning loop, because such cyclic side groups can be regarded as loops in relation to the backbone of the macromolecule.^{1–4}

Many years of study of the influence of chemical structure on the properties of polymers led to the idea that the asymmetry of the macromolecules, the incorporation of bridging units in the polymer chain, and the presence of bulky side substituents in the polymer chain may impart solubility in organic solvents to heat-resistant polymers, thereby facilitating their processing. An important factor in this connection is that the modification of the polymers in order to increase their solubility should not be accompanied by a decrease in their heat resistance. As will be shown in the present review, cardo polymers satisfy these requirements.

Data on the use of phenolphthalein for the synthesis of polyesters and alkyd, epoxide, phenolformaldehyde, and other polymers began to appear in patents and publications in the 1940s.^{3,5} A characteristic

feature of these polymers was that phenolphthalein was used simply as one of the diols without taking into account its specific influence on the properties of the polymers. The synthesis of high-molecular-mass polyarylates derived from phenolphthalein and various dicarboxylic acids, achieved in 1961, when attention was first directed to the specific contribution of the phthalide cardo group to the properties of the polymers, should be regarded as the start of systematic and deliberate studies on cardo polymers.^{6,7}

In subsequent years, the studies on cardo polymers developed widely.

II. Polyarylates

Data on the syntheses and the results of studies on cardo polyarylates have been published in a series of communications.^{2–4,6–89} The most useful method for their synthesis is the polycondensation of dicarboxylic acid chlorides with dihydric phenols which contain cardo groups. Depending on the structure of the initial monomers, the polycondensation process can occur under high-temperature conditions in solution, under acceptor-catalytic conditions, or by the interfacial method.^{8,10–12,14,15,49,50,55–58}

Scheme 1 presents examples of certain structures of cardo polyarylates.

Many cardo polyarylates have been synthesised successfully by the high-temperature polycondensation of the starting materials in solution in ditolylmethane, α -chloronaphthalene, Sovol (chlorinated biphenyl), nitrobenzene, etc. in the temperature range from 100 to 220 °C for ~10 h. The amount of starting materials used was 0.6–5 mol l⁻¹.^{6,7,22,23,44,59,60} The polymers were obtained in nearly quantitative yields and had high molecular masses (for example, molecular masses of the order of 60 000–100 000 are attained in the case of polyarylates derived from phenolphthalein and aromatic dicarboxylic acids).

The kinetics of the process in the temperature range from 150 to 200 °C have been investigated in relation to the high-temperature polycondensation of 9,9-bis(4-hydroxyphenyl)fluorene (phenol-fluorene) and bisphenols of the norbornane type with the chlorides of terephthalic and isophthalic acids in ditolylmethane. It was concluded that these reactions proceed in accordance with an ionic mechanism via an acylium ion.^{54,61,62} The study of the influence of the nature of the reaction medium on the results of the polycondensation of phenolphthalein and its derivatives with the chlorides of aromatic dicarboxylic acid revealed an

Scheme 1

interesting feature. It was found that the reaction medium influences significantly the formation of the supermolecular structure and the properties of the amorphous vitreous polymers of this type.^{59,60} The solvent power of the medium directs the process involving the formation of rigid macromolecules in the direction of either coiled or uncoiled conformations, as a consequence of which globular or fibrillar forms of supermolecular structures are produced. Thus, in the synthesis of the polyarylate derived from phenolphthalein and isophthalic acid in ditolylmethane, the polymer precipitates and has a globular supermolecular structure, whereas in the synthesis in solvents such as Sovol, α -chloronaphthalene, and nitrobenzene the polymer remains in solution throughout the reaction and a product with a predominantly fibrillar supermolecular structure and a better set of physicomechanical properties is formed.^{50, 59,60}

In the interfacial polycondensation of phenolphthalein anilide with terephthalic acid chloride (organic medium — benzene), where the polymer is formed at the interface between two liquid phases (the polymer is not soluble in either), the polyarylate has a distinct globular structure, whereas the polyarylate synthesised by the high-temperature polycondensation in a homogeneous medium (in α -chloronaphthalene) has a fibrillar supermolecular structure. Whereas the first polymer has a softening point of 280–285 °C, a tensile strength of 960 kgf cm⁻², a relative elongation at break of 13%, and a specific impact strength (*A*) of ~ 1 kgf cm cm⁻², the fibrillar specimen has a softening point of 315–320 °C, a tensile strength of 1000 kgf cm⁻², a relative elongation at break of 40%–50%, and a specific impact strength of 7–9 kgf cm cm⁻².⁶⁰

In the synthesis of crystallising cardo polyarylates,^{19,20,52} for example the polyarylate obtained from 9,9-bis(4-hydroxyphenyl)-10-anthrone (phenolanthrone) and terephthalic acid, the process conditions (reaction temperature, rate of heating and cooling of the reaction mass, concentration, etc.) influence not only the molecular mass of the polymer obtained but also its structure. This polymer is obtained with the highest percentage of the crystalline form

when the polycondensation is carried out at 220 °C (in Sovol, α -chloronaphthalene, and nitrobenzene). When the process is carried out at a temperature above 220 °C, polyarylates with a lower degree of order are produced. An amorphous polyarylate is obtained when the reaction is performed in Sovol at 330 °C (with rapid heating and cooling of the reaction mass). The concentration of the initial monomers should be of the order of 0.6 M under these conditions; when the concentration is raised, an amorphous polymer cannot be obtained.

A series of studies^{8,63–68} have been devoted to the characteristic features of the formation of phenolphthalein polyarylates by acceptor-catalytic polycondensation. One should note in the first place that the synthesis of polyarylates by this method is faster and proceeds under milder conditions than the synthesis by high-temperature polycondensation in solution. For example, the polycondensation of phenolphthalein with the terephthaloyl chloride in the presence of triethylamine in dichloroethane at 50 °C leads to the formation of a polymer after 5 min in a nearly quantitative yield, having a reduced (intrinsic) viscosity in tetrachloroethane of ~ 0.9 dl g⁻¹.⁶⁵ The study of the reaction of phenolphthalein with terephthaloyl chloride in the presence of triethylamine revealed the influence of the nature of the reaction medium on the acceptor-catalytic polycondensation.^{66,67} It was established that the lack of the complete solubility of the initial compounds in the reaction medium is a significant obstacle to the formation of a high-molecular-mass polymer. The molecular mass of the polymer formed is greatly influenced by the properties of the reaction medium such as its polarity and its ability to dissolve the initial reactants and the polymer. In the study of the dependence of the molecular mass of the polymer formed on the composition of the binary reaction mixture (a mixture of acetone and benzene), it was found that the polyarylate with the highest molecular mass is obtained when the reaction mixture contains 30–40 vol% of acetone.⁶⁷ In this medium, it was possible to synthesise a polyarylate

with a very high molecular mass (250 000) and with a reduced viscosity in tetrachloroethane of 10 dl g^{-1} . In general, the optimum conditions for the synthesis of polyarylates by acceptor-catalytic polyesterification in heterogeneous systems are as follows: a high solubility of the initial compounds in the reaction medium and an appreciable swellability of the polymer in a weakly polar medium, or a high polarity of the medium where the swellability of the polymer in the solvent is insignificant.^{58, 66–70}

The cardo polyarylates based on trifunctional monomers such as 2- β -hydroxyethyl-3,3-bis(4-hydroxyphenyl)phthalimidine or phenolphthalein imide can be usefully synthesised by interfacial polycondensation because it is then possible to obtain linear high-molecular-mass polyarylates with free ethoxy- or imide groups when appropriate conditions are selected.^{16, 17, 50, 70} The synthesis of the same polyarylates by high-temperature polycondensation affords insoluble three-dimensional polymers owing to the reaction of the chlorocarbonyl groups with the ethoxy- or imino-group of the lactam at high temperatures.

Oligoarylates with a branched structure and an average functionality of 2, having terminal and side alcoholic hydroxy-groups, have been obtained by the acceptor-catalytic polyesterification reaction of terephthaloyl chloride with phenolphthalein, 2- β -hydroxyethyl-3,3-bis(4-hydroxyphenyl)phthalimidine, and ethylene glycol in dioxane at 30°C in the presence of triethylamine.⁶⁴ It was shown that branched oligoarylates soluble in organic solvents may be obtained when 2- β -hydroxyethyl-3,3-bis(4-hydroxyphenyl)phthalimidine is introduced into their composition in an amount not exceeding 50 mol % of the sum of the bisphenols. An increase in the degree of branching of polyarylates entails an increase in their softening temperature. Thus, when the content of 2- β -hydroxyethyl-3,3-bis(4-hydroxyphenyl)phthalimidine in a mixture with phenolphthalein is increased from 3 to 25 mol %, the softening temperature increases from 280 to 340°C . On the other hand, when the content of the first bisphenol is up to 50 mol %, the product does not soften up to 410°C .⁶⁴

The properties of cardo polyarylates depend significantly on their chemical structure. The amorphous nature of the polyarylates with asymmetric cardo groups (for example, phthalide and acenaphthene groups) can be explained by the statistical nature of the polycondensation and the asymmetric form of the cardo groups, which lead to their different positions relative to the macromolecule.^{21, 49–51} The ability of cardo polyarylates to crystallise increases following the introduction of symmetrical cardo groups (the fluorene and anthrone groups) and when the cardo groups contain polar groups (for example, the anthrone group) and groups capable of forming hydrogen bonds [polyarylates derived from phenolphthalein imide and 2- β -hydroxyethyl-3,3-bis(4-hydroxyphenyl)phthalimidine].

Polyarylates containing cardo groups in both the bisphenol and acid fragments exhibit explicit signs of ordering. It has also been noted that the ability to crystallise is influenced significantly by the disposition of the cardo groups relative to the ester bond. Thus the phenolanthrone polyterephthalate, synthesised by high-temperature polycondensation at 220°C , is crystalline to the extent of approximately 40%, while the isomeric polyarylate derived from hydroquinone and 9,9-bis(4-carboxyphenyl)-10-anthrone and obtained under similar conditions is amorphous.^{33, 51}

The softening temperatures of a series of amorphous cardo polyarylates and, for comparison, of certain polyarylates of the noncardo type are presented in Table 1.^{29, 51, 52, 54, 72, 73} It is seen from the data presented that the cardo polyarylates have significantly higher softening temperatures (compare, for example, polymers Nos 1–3, 5, and 6 with polymers Nos 12 and 13, etc.). Comparison of polymers Nos 7 and 8 with polymer No. 19 permits the conclusion that polyarylates with a cyclic acid fragment have appreciably higher softening temperatures than polyarylates with an acyclic, 'open-chain', structure of the isomeric acid fragment.^{29, 51} Thus the softening temperatures of the polyarylates obtained from bis(4-carboxyphenyl)phthalide and acyclic dihydric phenols [1,3- and 1,4-di(4-hydroxybenzyl)benzenes] are 250 and 270°C respectively,

whereas the softening temperature of the polyarylate obtained from phenolphthalein and bis(4-carboxyphenyl)phthalide is 340°C .^{29, 51, 62}

A high heat resistance is characteristic also of carborane-containing cardo polyarylates.^{74–78} Thus the softening temperatures of the polyarylates obtained by the reaction of 1,2- and 1,7-bis(4-carboxyphenyl)carboranes with phenolphthalein, phenolfluorene, and phenolanthrone are $340–360^\circ\text{C}$. It is noteworthy that, according to X-ray diffraction data, these polyarylates have crystalline structures with low or moderate degrees of order. One can only note a tendency towards the formation of an amorphous structure on transition to polyarylates based on the *m*-carborane-containing isomer. The softening temperature of the amorphous cardo polyarylate derived from 1,2-bis(4-hydroxyphenyl)carborane and bis(4-carboxyphenyl)phthalide is also high, being 330°C .

There is no doubt that the high heat resistance of the cardo polyarylates and, incidentally, of other cardo polymers (see below) is due to the increased rigidity of the polymer chain. The cardo groups not only increase the rigidity of the main polymer chain but also loosen the structure of the polymer, diminishing thereby the interchain interaction, which ensures a high solubility of such polyarylates in many organic solvents. The majority of amorphous cardo polyarylates are readily soluble in methylene chloride, dichloroethane, chloroform, tetrachloroethane, trichloroethane, tetrahydrofuran, dioxane, cyclohexanone, nitrobenzene, and dimethylformamide, frequently with formation of highly concentrated solutions.^{3, 4, 6, 7, 51} The chemical structure of polyarylates also influences their solubility. Thus polyarylates containing groups capable of forming hydrogen bonds, for example phenolphthalein imide polyarylates, do not dissolve in chlorinated solvents but are readily soluble in dioxane, tetrahydrofuran, trichloroethane, and dimethylformamide. In contrast to polyarylates with phthalide and anthrone cardo groups, i.e.

those with cardo groups not containing the CO group, i.e.

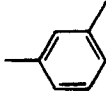

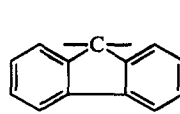

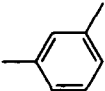

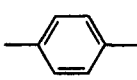

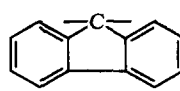

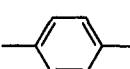

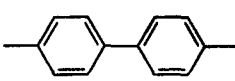

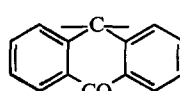

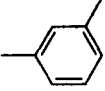

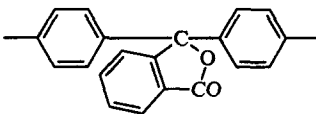

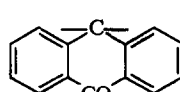

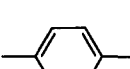

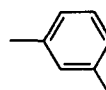

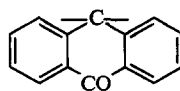

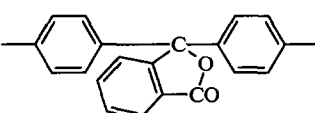

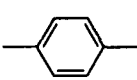

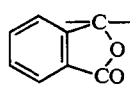

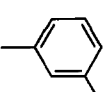

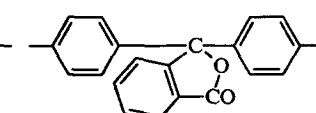

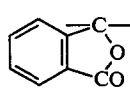

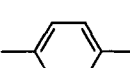

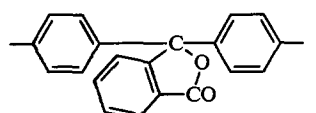

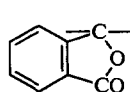

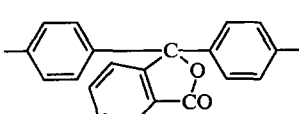

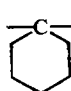

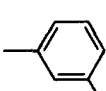

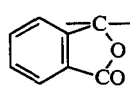

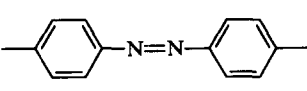

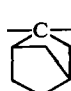

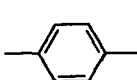

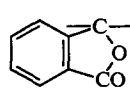

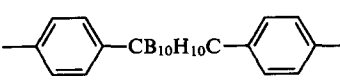

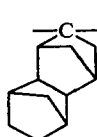

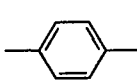

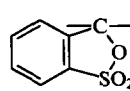

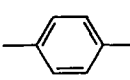

are soluble in chlorobenzene, toluene, and *o*- and *m*-xylenes.⁵¹ Carborane-containing polyarylates derived from 1,2- and 1,7-bis(4-carboxyphenyl)carboranes and 1,2-bis(4-hydroxyphenyl)carborane are readily soluble in aromatic hydrocarbons.^{76, 78} Amorphous phenolphthalein, phenolacenaphthene, and phenolanthrone polyarylates give rise to 35% solutions in chloroform, whereas phenolfluorene polyterephthalate gives only 5% solutions.⁵²

The heat resistance and solubility of cardo polyarylates are also greatly influenced by their physical state. In particular, this has been clearly established for phenolanthrone polyterephthalate, the structure of which can be deliberately altered from amorphous to crystalline by changing the conditions of its synthesis or the subsequent treatment of the finished polymer.^{21, 51, 52} Whereas the amorphous polyarylate softens at $335–365^\circ\text{C}$ and dissolves in a wide range of organic solvents, with increase in the degree of order in the structure of the polyarylate the range of solvents becomes narrower and the heat resistance increases. The crystalline polymer dissolves only in the phenol–tetrachloroethane mixture and is highly heat resistant (it does not melt before decomposition). Thus the heat resistance and solubility of cardo polyarylates can be varied specifically by varying their chemical and physical structures.

High thermal stability is characteristic of cardo polyarylates.^{36, 50, 52} Under an inert atmosphere, the temperature of the onset of decrease in the mass of phenolphthalein, phenolfluorene,

Table 1. The softening temperatures of the polyarylates

and phenolanthrone polyterephthalates is about 350–360 °C. The polymers decompose at a low rate, losing only 2%–3% of their mass before the onset of vigorous decomposition (at 460–470 °C). The chemical structure of the bisphenol does not influence significantly the temperature of the onset of the thermal decomposition of these polyarylates, which is determined mainly by the presence of the ester bond. The carborane-containing cardo polyarylates obtained by the reaction of 1,2- and 1,7-bis(4-carboxyphenyl)carboranes with phenolphthalein, phenol-fluorene, and phenolanthrone, as well as the polyarylates obtained from 1,2-bis(4-hydroxyphenyl)-carborane

and bis(4-carboxyphenyl)phthalide have the best thermal characteristics.^{74–79} The temperature of the onset of the change in their mass under an inert atmosphere and in air is 400–420 °C. After heat treatment for 3 h in air at 400 °C, these polymers give rise to large amounts of coke residues (86%–98%), whereas phenolfluorene polyterephthalate decomposes to an extent of 35% under these conditions.

The phenolphthalein, phenolfluorene, and phenolanthrone polyarylates are thermoplastic polymers. They can be processed by usual method for thermoplastic materials, which, combined with

their high thermal stability, give rise to extensive possibilities for their employment as constructional materials. By virtue of their effective dielectric properties, they can be used successfully in radio and electrical engineering. Filled materials, including antifriction materials with a low coefficient of friction and capable of working for a long time without a lubricant at high temperatures (250 °C) in a vacuum and under the conditions of high velocity gradients between the friction surfaces (sliding and roller bearings), are obtained from polyarylates.

The satisfactory solubility of cardo polyarylates in organic solvents and their compatibility with many polymers (in particular with epoxide polymers) makes it possible to convert them readily, both from solution and from mixtures, into coating films, fibrous materials, heat-resistant composite materials, and potting compounds and also permits their use as binders for reinforced plastics.^{4, 10, 14, 49–51, 80–82} In particular, a promising procedure for the conversion of cardo polyarylates, for example phenolphthalein polyterephthalate, into monolithic articles involves its combination with a reactive epoxide oligomer and subsequent moderate heating. The chemical interaction of the epoxyoligomer with the polyarylate (via a mechanism involving the 'insertion' of an oxirane ring in the ester bond⁸⁰) results in the formation of a network system having a specific set of properties and the region of mechanical usability of such compositions extends to more elevated temperatures compared with the traditional compositions based on oligoepoxides.⁸² The part of the chemically reactive heat-resistant polymer in the composition with oligoepoxides which has not reacted serves as a filler. The presence of such a high-molecular-mass chemically reactive filler reduces significantly the density of the composition and improves its strength characteristics compared with compositions containing a usual mineral filler.³⁷

The high glass points of cardo polyarylates ensure the retention at high temperatures of the effective mechanical and dielectric properties of articles made from these polymers. For example, nonoriented phenolanthrone polyterephthalate films have at 25 °C a tensile strength (σ_t) of 940 kgf cm⁻², and an elongation at break (ϵ) of 10%, whereas at 250 °C $\sigma = 470$ kgf cm⁻² and $\epsilon \leq 5\%$. After heating for 100 h at 300 °C or 500 h at 250 °C, the film retains about 50% of its initial strength. The tangent of the dielectric loss angle for this polymer hardly changes up to 250 °C; high specific volume resistivities ($\geq 1 \times 10^{15}$ Ω cm) are retained up to this temperature.^{51, 52}

At 300 °C, phenolfluorene polyterephthalate films retain more than 50% of their initial strength. The tangent of the dielectric loss angle for this polymer is 0.0025 at 220 °C.^{44, 45} Fibrous filtering materials based on phenolphthalein polyterephthalate, employed successfully for the purification of gases and liquids and for trapping aerosols, may be used up to 300 °C.^{10, 14}

Cardo polyarylates can be converted also into heat-resistant strong monolithic articles. The bending strength (σ_b) of monolithic phenolanthrone polyterephthalate reaches 1700 kgf cm⁻².⁵² The specific impact strengths of test specimens of phenolphthalein, phenolfluorene, and phenolanthrone polyterephthalates are 15–20 kgf cm cm⁻².⁴ Monolithic articles made from the polyarylates of phenolphthalein and isophthalic acid, obtained by casting under pressure, have effective physicochemical parameters (both in the initial state and after prolonged heat treatment).

Characteristic	Initial specimen	Heat-treated specimen (1000 h, 200 °C)
σ_t / kgf cm ⁻²	940	800
A / kgf cm cm ⁻²	30	70
σ_b / kgf cm ⁻²	1300	1200
H / kgf cm ⁻² ^a	1280	1250
$\tan \delta$ ^b	2×10^{-2}	2×10^{-2}

^a H is hardness. ^b $\tan \delta$ is tangent of dielectric loss angle.

Articles made from phenolphthalein polyterephthalate, filled with talc or powdered quartz, exhibit a high resistance to repeated temperature changes from –60 to 250 °C and possess satisfactory electrical insulating properties.⁸³

Cardo polyarylates are satisfactorily resistant to the action of ultraviolet and ionising radiations, retaining, for example, effective physicochemical parameters after prolonged exposure to ⁶⁰Co γ -rays in air. Cardo polyarylates with fluorene groups are more stable than polymers with phthalide groups.⁴ The partial or complete replacement of the lactone ring by a lactam ring in phenolphthalein polyarylates as well as the presence of fluorene groups in the bisphenol residues increase appreciably the resistance of the polyarylate to the action of light. The inclusion in the polymer chain of phenolphthalein polyarylates of small amounts ($\sim 1\%$) of sulfur, phosphorus, and hydroxy-groups by employing, for example, monomers such as phenolsulfophthalein, phloroglucinol, bis(4-carboxyphenyl)methylphosphine oxide, etc. promotes the formation of polyarylates with increased resistance to light-induced ageing.^{72, 84–87}

The employment of chromophore-containing monomers (the chlorides of azobenzene-3,3'-dicarboxylic and azobenzene-4,4'-dicarboxylic acids, quinizarine, alizarine, Alizarine Blue, and others) in the synthesis of cardo polyarylates led to the possibility of obtaining coloured polyarylates with different colours, the colours exhibiting a high photostability. Colours with a high photostability can be achieved even in the presence of only a small amount (0.05 mol %) of the chromophore-containing monomer in the polyarylate chain.^{49, 50, 88–91} It is also noteworthy that the introduction of even a small amount of a chromophore-containing monomer into mixed polyarylates derived from terephthalic acid and phenolphthalein greatly increases the resistance of the polymer to ultraviolet radiation.⁸⁰

Thus cardo polyarylates have enhanced thermal characteristics, satisfactory solubilities, and effective physicochemical properties.

III. Aromatic polyethers

Since the 1960s, aromatic polyethers have attracted the attention of investigators because of their high thermal stability and a number of other valuable properties.^{92–94} However, their comparatively low heat resistance is a significant disadvantage of these polymers.

The positive influence of the cardo groups on the heat resistance of polyarylates stimulated the synthesis and study of aromatic cardo polyethers.^{49, 51, 95–108}

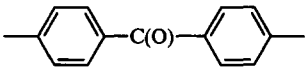

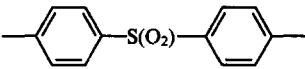

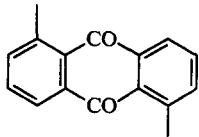

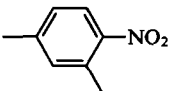

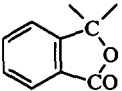

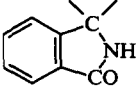

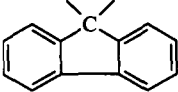

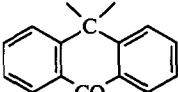

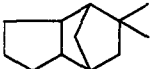

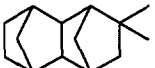

Aromatic cardo polyethers are obtained by the nucleophilic substitution reaction between phenoxides derived from bisphenols and activated aromatic dihalides (usually in dimethyl sulfoxide at 160–180 °C). Scheme 2 presents some of the structures of the polymers of this type which have been synthesised.

In the polycondensation of dihalo-derivatives with phenoxides derived from cardo bisphenols (with the exception of adamantane-containing bisphenols), only the difluoro-derivatives proved to be sufficiently reactive (for the formation of polymers with a high molecular mass). It has been suggested that the lower reactivity of the phenoxides obtained from cardo bisphenols compared with the phenoxide derived from 2,2-bis(4-hydroxyphenyl)propane is due in some cases to the greater acidity of the cardo bisphenols or the poorer solubility of the initial phenoxide in the reaction medium.^{51, 95, 99} Polyethers based on phenolphthalein contain a phthalide ring,⁹⁷ although the lactone ring of phenolphthalein is opened in alkaline media.

It has been noted that, in the polycondensation of phenolphthalein imide with bis(4-fluorophenyl) sulfone, not only the phenoxide groups but also the mobile hydrogen atom at the nitrogen atom of the lactam ring can participate in the reaction, which leads to the formation of a structured fraction.⁹⁹

A series of characteristics of the formation of cardo polyethers by the reactions of phenolphthalein and phenolfluorene with dihalobenzophenones in dimethylacetamide in the presence of potassium carbonate have been investigated.⁹⁷ It was established

Table 2. The softening temperatures (°C) of the polyethers $\text{—O—C}_6\text{H}_4\text{—R}^1\text{—C}_6\text{H}_4\text{—O—R}^2\text{—}$.

Chemical modification of polyarylene ether-ketones and polyarylene ether sulfones, including those of the cardo type, has been achieved by treating them with chromium, molybdenum, and tungsten hexacarbonyls. Polymers containing 0.7–12 mass % of the metal (0.1–1.5 of a metal atom per polymer unit) were obtained. It was noted that the polymers containing arenemetal tricarbonyl fragments in the polymer chain can be worked into articles by employing a solution (for films and coatings) and a melt (for monolithic specimens). Such polymers have effective mechanical, optical, and adhesion properties.^{109, 110}

IV. Aromatic polyketones

The use for the synthesis of polymers of cardo monomers such as bis(4-carboxyphenyl)phthalide and 2-bis(4-carboxyphenyl)-*N*-phenylphthalimide led to the possibility of synthesising cardo polyketones.^{49, 111, 112}

The study of the process characteristics showed that the polycondensation of the dicarboxylic acid with an aromatic hydrocarbon can be usefully carried out in polyphosphoric acid containing 85 mass % of phosphorus pentoxide at a concentration of the starting materials of ~0.5 M, a reaction temperature of 120–160 °C, and for a reaction time of 8–20 h. A series of polyketones of the noncardo type have also been synthesised

for comparison. Scheme 3 presents examples of the structures of the polymers obtained.

In most cases, the polyketones were obtained in high yields (the reduced viscosity in sulfuric acid was 0.40–1.60 dl g⁻¹). The molecular mass of the polyketone based on bis(4-carboxyphenyl)phthalide and diphenyl ether and having a reduced viscosity of 0.68 dl g⁻¹ was 44 000.

All the polyketones obtained were amorphous. The polyketones without cardo groups crystallise on heating above the softening temperature. The softening temperatures of the polyketones with phthalide and 2-(*N*-phenylphthalimidine) groups exceed by 60–80 °C those of the noncardo polyketones. Thus, whereas the softening temperatures of the polyketones based on diphenyl ether and bis(4-carboxyphenyl)phthalide and 2-bis(4-carboxyphenyl)-*N*-phenylphthalimide are 250 and 270 °C, the softening temperatures of the polymers based on terephthalic acid and bis(4-carboxyphenyl) ether are 190 and 185 °C respectively.

The cardo polyketones dissolve readily in organic solvents (tetrachloroethane, chloroform, methylene chloride, dimethylacetamide, *N*-methylpyrrolidone, benzyl alcohol, etc.) to form 30%–50% solutions, whereas the polyketones without cardo groups dissolve only in sulfuric acid. Colourless transparent films with a tensile strength of 690 kgf cm⁻² and an elongation at break of ~10% were obtained from 30% solutions of the cardo polyketones

Polyaryleneephthalides are also cardo polymers.¹²⁸⁻¹⁴² Polymers of this type have been synthesised by electrophilic substitution with the aid of carboxylic acid pseudochlorides (Scheme 5).¹²⁸ The polycondensation was carried out in solution in chlorinated hydrocarbons (methylene chloride, dichloroethane, etc.) or in nitrobenzene at temperatures from -70 to 140°C in the presence of Group III – V and VIII metal halides as catalysts (for example, AlCl_3 , FeCl_3 , and SbCl_5) in amounts ranging from 0.01 to 1.5 moles per acid chloride group. Certain properties of the polymers obtained in this way are presented in Table 3.¹²⁸

Scheme 5

Scheme 6

All the polymers presented in Table 3 are amorphous and readily soluble in methylene chloride, chloroform, tetrachloroethane, dimethylformamide, and other solvents. Nonoriented films with a tensile strength of 800–900 kgf cm⁻² and a relative elongation at break of 10–20% have been obtained from the first three polymers by casting from solution. Table 3 shows that polyarylenephthalides have high heat resistances and thermal stabilities.

It is noteworthy that in a number of instances the synthesis of polyarylenephthalides may be accompanied by the formation of a gel.¹²⁹

Special studies have been carried out to investigate the characteristic features of the formation of polydiphenylene-

phthalide by the polycondensation of 4-(3-chloro-3-phthalyl)-biphenyl (Scheme 6).^{130,131}

The influence of the type of solvent (chlorinated aliphatic hydrocarbons, aliphatic and aromatic nitro-compounds), temperature, reaction time, and the concentrations of the monomer and the catalyst has also been investigated. It has been noted that the polycondensation in nitro-compounds (especially in nitrobenzene) proved to be more universal and effective than in halo-derivatives, because it proceeds under the influence of catalysts of different types (ZnCl₂, AlCl₃, AlBr₃, InCl₃, SnCl₄, TiCl₄, SbCl₅, SbCl₃, SbF₃, FeCl₃) and leads to polymers with a higher molecular mass. The following are the most favourable conditions for the synthesis of polydiphenylenephthalide: monomer concentration 2–3 M, reaction temperature 100–110 °C, and SbCl₃ (7–10 mol %) or InCl₃ (3–10 mol %) as the catalyst. These ensure the selective formation of a polymer with a high molecular mass (46 000–60 000) and an intrinsic viscosity of 0.65–0.78 dl g⁻¹ (in tetrachloroethane).¹³⁰ When the polycondensation is carried out under severe conditions (in the presence of large amounts of the catalyst and at high temperatures), in some cases the quality of the polymer and the process selectivity decrease and anomalous units, for example fragments with keto-groups, arise in the macromolecules.¹³⁰

Polydiphenylenephthalide can also be obtained by precipitation polycondensation. In this case, the synthesis of the polymer proceeds in the initial stage in a homogeneous solution with subsequent segregation of the polymer in a separate phase.¹³¹ For comparison, polydiphenylenephthalide has been synthesised in two variants: by polycondensation in solution in nitrobenzene (80 °C, 10 h) and by precipitation polycondensation in dichloroethane (20 °C, 24 h) with anhydrous aluminium chloride as the catalyst. It was found that the precipitation polycondensation affords a polymer with a higher molecular mass: its η_{red} in sulfuric acid was 1.02 dl g⁻¹, whereas in the case of the polymer obtained in nitrobenzene η_{red} was 0.64 dl g⁻¹. It has also been noted that nonoriented films of the 'precipitation' polydiphenylenephthalide, obtained by moulding from a solution of the polymer in chloroform, exhibit a higher optical anisotropy than the films of the 'solution' polymer and have a degree of crystallinity of 25%–30%. The films of the 'solution' polymer are amorphous.¹³¹

The molecular mass characteristics of polydiphenylenephthalide have been investigated and the equilibrium rigidity of its macromolecules has been estimated. The length of the Kuhn segment of this polymer is 24 Å. It has been established¹³² that, in order to obtain strong films, a polymer with a molecular mass $>3 \times 10^4$ is needed. The study of the chemical stability of polyarylenephthalides showed that they exhibit a satisfactory resistance to the action of corrosive media at elevated temperatures.¹³³ The thermal stability of the phthalide ring in polyarylenephthalide is determined by the nature of the groups joining the benzene rings in the main chain. The thermal stability of polydiphenylenephthalide is higher than that of poly(oxydiphenylene)phthalide.¹³⁴

The thermal transformations of polydiphenylenephthalide and poly(diphenylene oxide)phthalide have been investigated over a wide temperature range (400–650 °C).¹³⁵ It was shown that the degradation of the polymers proceeds both via the end groups and via the phthalide ring and the hetero-bonds when such are present. The phthalide ring probably decomposes in three ways: without the evolution of carbon oxides (the formation of anthraquinone

Table 3. The properties of the polyarylenephthalides

Note. The softening temperature was determined from the thermomechanical curve obtained with a 1 kgf cm⁻² load applied to the specimen and for a heating rate of 3 K min⁻¹. The temperature of the onset of decomposition was determined from the thermogravimetric curve at a heating rate in air of 5 K min⁻¹.

^a The molecular mass of the polymer obtained by the light scattering method is 46 000.

Scheme 7

structures), with evolution of CO (the formation of compounds of the type of fluorenone), and with evolution of CO₂ (the formation of fragments of the anthracene, phenanthrene, and fluorene types), the last type of decomposition predominating. The first two reactions are accompanied by the rupture of the polymer chain, whilst the third leads to the formation of cross-linked structures.¹³⁵

Certain electrophysical properties of polyarylenephthalides have been investigated and the possibility of the thermal initiation of conduction in aromatic polymers containing readily polarisable phthalide side groups has been demonstrated.¹³⁶

Halo-substituted polyarylenephthalides have been synthesised by the Friedel-Crafts polycondensation of 3-aryl-3-chlorophthalides containing substituents in the 4-position relative to the phthalide ring. It was found that polymers containing two types of isomeric units in the polymer chain in the 4- and 7-positions can be obtained from such monomers (Scheme 7).¹³⁷

Effective thermal and physicochemical parameters are characteristic of these polymers. Thus chloro-substituted polyarylenephthalides with a characteristic viscosity in tetrachloroethane of 1.52 dl g⁻¹ have a softening temperature >450 °C, a temperature for the onset of decomposition of 450 °C, a degree of crystallinity of 30%, a tensile strength of the film of 900 kgf cm⁻², and an elongation at break of 85%.

Nitro-derivatives containing a controllable number of nitro-groups in the repeat unit (0.2–3.0 nitro-groups) have been obtained by nitrating polydiphenylenephthalide with potassium nitrate in

nitric acid or with nitric acid in sulfuric acid.^{138–140} It was found that the trinitro derivatives of polydiphenylenephthalide contain nitro-groups in the 6-position in the phthalide ring and in the 2- and 2'-positions in the biphenylene unit. They are soluble in nitrobenzene, dimethylformamide, dimethylacetamide, *N*-methylpyrrolidone, and cyclohexanone. The nitro-derivatives containing less than one nitro-group per repeat unit of the monomer are soluble in tetrachloroethane, aniline, and benzonitrile. The polymers containing more than one nitro-group per repeat unit are soluble in tetrahydrofuran, 1-chloro-2,3-epoxypropane, and dimethyl sulfoxide, in contrast to the initial polymer. Strong elastic films may be obtained from solutions of the polymers containing up to two nitro-groups in the repeat unit. The decomposition temperatures in air of nitro-substituted polyphenylenephthalides containing 0.2–2.6 nitro-groups in the repeat unit are in the range 320–340 °C. These polymers do not soften before they decompose.¹⁴⁰

VII. Aromatic polyamides

The use of aromatic diamines and dicarboxylic acid chlorides with cardo groups for the synthesis of polyamides made it possible to obtain cardo polyamides.^{2–4, 12, 27, 37, 38, 49, 76, 77, 127, 143–169} Scheme 8 presents examples of such polymers. The study of the characteristic features of the formation of cardo polyamides showed that satisfactory results are obtained when the low-temperature polycondensation is carried out in aprotic solvents

Scheme 8

(dimethylacetamide, *N*-methylpyrrolidone) at -10 to -30 °C for 15–60 min and at reactant concentrations of 0.6–0.7 M. The reaction is carried out by adding the solid acid chloride to a solution of the diamine.^{27, 143–147, 154} The optimum polycondensation conditions for the polyamide based on 9,10-bis-(4-aminophenyl)-anthracene are as follows: temperature 20 °C, reaction time 2 h, solvent — 2:1 (vol %) *N*-methylpyrrolidone–hexamethylphosphoramide mixture, concentration of monomers 0.25 M, and concentration of LiCl 5% (relative to the solvent).¹⁵²

Electron microscope study of the films and pressed anilinephthalein polyamides, obtained by low-temperature polycondensation in solution, showed that such polymers contain supramolecular 500–1000 Å globular formations.¹⁴⁶ The majority of the cardo polyamides synthesised have an amorphous structure, although some of them exhibit a tendency towards ordered structures. This is characteristic of, for example, the polyamide based on anilinephthalein and terephthalic acid or bis(4-carboxyphenyl)phthalide and anilinefluorene polyterephthalamides and polyisophthalamides.^{146, 147, 154}

When the fluorene cardo group with a dicarboxylic acid residue is introduced into the polyamide, the products are polyamides which show no tendency to crystallise.¹⁵⁴ According to the results of thermomechanical tests, the cardo polyamides derived from aliphatic dicarboxylic acids have comparatively low softening temperatures (210–240 °C),^{147, 154} exceeding somewhat the melting points of the widely familiar crystalline polyamides based on hexamethylenediamine and adipic and sebacic acids. Table 4 presents the softening temperatures (determined by the thermomechanical method) of a series of aromatic cardo polyamides.^{27, 147, 152, 155, 161, 162, 164}

These polymers have a high heat resistance, which changes little on passing from isophthalic polyamides to the polyamides of terephthalic, biphenyl-4,4'-dicarboxylic, and carborane-dicarboxylic acids, or on replacement of the anilinephthalein residues in the repeat unit by anilinephthalein imide. An appreciable decrease in heat resistance is observed when bis(4-carboxyphenyl) ether residues are introduced into the polyamide, which is apparently due to the decreased rigidity of the main polymer chain owing to the presence of bridging units (oxygen atoms) in the hinge positions. The polyamide derived from 9,10-bis(4-amino-phenyl)anthracene and bis(4-carboxyphenyl)phthalide as well as the copolymers of terephthalamide with diphenylanthracene and anilinefluorene, which do not soften up to the decomposition point, have exceptionally high heat resistances.¹⁵² It is noteworthy that the softening temperature of cardo polyamides are always higher than those of the corresponding cardo polyarylates.^{148, 151}

The thermal and thermooxidative degradation of cardo polyamides has been investigated.^{146, 147, 149, 150, 164} The temperature of the onset of mass decrease of these polymers is in the range 360–450 °C. It has been shown that the thermal stabilities of the cardo polyamides depend to some extent on the nature of the cardo group, whereas those of the polyarylates are limited mainly by the stability of the ester bond. Polyterephthalamides with anthrone and fluorene groups exhibit a higher stability than the polymers with phthalide groups. The study of the thermal degradation of anilinephthalein and anilinefluorene polyterephthalamides showed that the decomposition of these polymers begins at temperatures above 350 °C; the hydrolytic decomposition predominates at 350–400 °C, whereas the contribution of the homolytic decomposition increases above 400 °C. The homolytic

Table 4. The softening temperatures of the aromatic cardo polyamides $\text{—NH—C}_6\text{H}_4\text{—R}^1\text{—C}_6\text{H}_4\text{—NHOC—R}^2\text{—CO—}$.

		400			380

decomposition of the amide bond is accompanied mainly by cross-linking processes in the polymers, which lead to the formation of tertiary amide and amine fragments in the polymeric structures.¹⁴⁹ The thermal oxidation of these polymers hardly differs from their thermal decomposition.¹⁴⁹ At temperatures preceding the decrease in the mass of the polymers (up to 350 °C), branching and cross-linking processes develop. During the isothermal heating of aromatic cardo polyamides at 300 °C in air and in vacuo for 3 h, no decrease in the mass and no appreciable impairment of the properties of these materials are observed.¹⁴⁷ According to the results of dynamic thermogravimetric analysis in air at a heating rate of 4–4.5 K min⁻¹, the temperatures of the onset of mass loss for a polyterephthalamide of anilinephthalein, anilinephthalimidine, and anilinefluorene and the polyamide obtained from anilinefluorene and 9,9-bis(4-carboxyphenyl)fluorene are 400, 390, 405, and 410 °C respectively.^{147, 154}

Thermogravimetric study of the carborane-containing polyamides obtained from 1,2- and 1,7-bis(4-carboxyphenyl)-carboranes, anilinefluorene, and anilinephthalein showed that the principal difference in the nature of the degradation of these polymers and of the usual aromatic cardo polyamides consists in a lower rate of decomposition, while the temperature ranges of vigorous decomposition are comparatively the same. At the same temperature, the decrease in the mass of carborane-containing polyamides is 3–5 times less than for the usual aromatic polyamides.¹⁶³

The use of cardo monomers for the synthesis of polyamides not only leads to the formation of heat-resistant and thermostable polymers but also greatly improves their solubility. In contrast to the majority of aromatic polyamides, sparingly soluble in organic solvents and soluble predominantly in solutions of inorganic salts in amide solvents,¹⁷⁰ cardo polyamides dissolve readily in dimethylformamide, dimethylacetamide, methylpyrrolidone, dimethyl sulfoxide, benzyl alcohol, and cresol with formation of highly concentrated solutions (in excess of 400 g l⁻¹).^{4, 147} Cardo polyamides dissolve in an unusual manner in cyclohexanone.¹⁵⁴ Whereas cardo polyamides with phthalide groups dissolve readily in cyclohexanone (this applies even to polyterephthalamide), anilinefluorene polyterephthalamide is almost insoluble in this solvent, while solutions of anilinefluorene polyisophthalamide are unstable, which is believed to be caused by the tendency of this amide to acquire an ordered structure. Anilinefluorene polyterephthalamide, which precipitates from solution in dimethylformamide, also exhibits a tendency towards ordering on standing at room temperature. This property of the chains can be suppressed by synthesising mixed polyamides derived from anilinefluorene and terephthalic and isophthalic acids with a molar ratio of the latter of 85:15. When the fluorene cardo group with a dicarboxylic acid residue is introduced into the polyamide, the products are also polyamides which do not exhibit a tendency towards ordering and which are readily soluble in cyclohexanone.¹⁵⁴ The study of solutions of anilinephthalein polyterephthalamide in dimethylformamide showed that such solutions are stable over a wide range of temperatures and compositions.¹⁶⁷

Films with satisfactory strength parameters (tensile strength of 800–1500 kgf cm⁻², elongation at break 20%–70%) are obtained by moulding cardo polyamides from solutions.^{4, 27, 49, 147, 154} Polyamide films, for example, anilinefluorene polyterephthalamide films, exhibit a high resistance to ultraviolet light and radiation. Thus the strength of a film made from this polyamide remains unchanged after exposure to ⁶⁰Co γ-rays in vacuo at a dose of 20 000 Mrad; 60% of the strength is retained on irradiation in air at a dose of 3500 Mrad.^{154, 166} The strength characteristics of the anilinefluorene polyterephthalamide film remain unchanged also after subsequent irradiation with UV light and electrons (50 MGy), while the relative elongation and the heat resistance increase.¹⁵⁸

Aromatic cardo polyamides exhibit a satisfactory chemical stability.^{146, 147} Thus the molecular mass of anilinephthalein polyisophthalamide hardly changes after being kept for 40 h at room temperature in concentrated sulfuric acid or in a 40% sodium

hydroxide solution. Films of this polyamide retain their strength and elasticity after heating in water for 4 h at 200 °C. The polymer is resistant to the action of boiling dimethylformamide and dimethylacetamide.

Cardo polyamides have satisfactory electrical characteristics, similar to those of other polyamides. Their stability is much higher by virtue of their high heat resistance.⁴ Highly heat-resistant monolithic articles with effective mechanical and antifriction properties can be obtained by pressing filled and unfilled cardo polyamides.^{4, 147}

A number of studies^{153, 156, 157} of the matrix polycondensation of the cardo polyanilinephthalein- and cardo polyanilinefluorene-terephthalamides with less rigid chains in a medium comprising the macromolecules of rigid-chain poly-*p*-phenyleneterephthalamide or polyphenylenebenzimidazoleterephthalamide have been carried out in order to be able to regulate the structures of cardo polyamides and hence their properties and to obtain polymer–polymer compositions. Thus blends of aromatic polyamides obtained by low-temperature polycondensation in solution of terephthaloyl chloride with anilinefluorene (cardo polyamide 1) on a rigid-chain poly-*p*-phenyleneterephthalamide matrix (matrix 2) and by the retrosynthesis of poly-*p*-phenyleneterephthalamide (polyamide 2) on a polyanilineterephthalamide matrix (matrix 1) have been investigated.^{156, 157} Interesting results have been obtained in the synthesis of polyamide 1 on matrix 2. The matrix polyanilinefluorene-terephthalamide has the highest coefficient of friction at elevated temperatures and the lowest intensity of linear wear of its specimens (obtained by compression pressing), amounting to 2 × 10⁻¹⁰, which is five times smaller than for specimens of matrix poly-*p*-phenyleneterephthalamide (retrosynthesis) and is smaller by a factor of two than for a mechanical mixture of polyamides 1 and 2. In contrast to polymer blends, obtained by retrosynthesis or by mechanical mixing of polyamides 1 and 2, this polymer blend could not be separated quantitatively into the corresponding homopolymers by extraction with *N*-methylpyrrolidone. The content of polyamide 1, which is as it were 'encapsulated' in matrix 2, is 55%. These data indicate a definite influence of the method of synthesis of the polymer systems on their properties and also the possibility of employing such aromatic polyamides for the creation of antifriction materials with improved properties.¹⁵⁷

The regulation of the properties of the polymers by varying the previous history of their synthesis, carried out in the presence of a matrix comprising one of the blend components, has also been demonstrated in relation to polymer blends of polyphenylenebenzimidazoleterephthalamide and polyanilinefluorene-terephthalamide.¹⁵³ It was found that, depending on the structure of the polymer, the structure of the matrix can exert both disordering and ordering effects on the other polymer. This makes it possible not only to alter the mechanical properties of the films but also to obtain films from blends containing a large amount of the polymer which does not itself form films (in the given instance, this is polyphenylenebenzimidazoleterephthalamide, which is insoluble in organic solvents and has a high softening temperature).

The possibility of the formation of linear-network polymer systems based on a cardo polyamide and unsaturated cardo amides in which the linear cardo polyamide is enclosed in a network polymer matrix has been demonstrated.¹⁶⁸ In particular, the possibility of the polymerisation of amorphous and high-melting ($T_m > 350$ °C) crystalline unsaturated cardo amides (for example, anilinefluorene bisacrylamide) in a matrix comprising the amorphous heat-resistant anilinefluorene polyterephthalamide has been investigated. Films were cast from solutions in dimethylformamide containing both the unsaturated bisamides and the polyamide. It was found that anilinefluorene and anilinephthalein bisacrylamides can be satisfactorily blended with the polyamide and that, when the crystalline anilinefluorene bisacrylamide is blended with the cardo polyamide, it becomes amorphous. The crystalline anilinefluorene bisacrylamide does not itself polymerise in bulk up to 350 °C, but, when it is introduced into a matrix comprising a heat-resistant cardo polyamide in an amount of 10–100 mass %, it passes

to the amorphous state and polymerises effectively with formation of a network polymer in air at 250 °C in the course of 5 h. Such network systems, filled with amorphous cardo polymers, exhibit a high strength and heat resistance.¹⁶⁸

Heat-resistant compositions based on cardo polyamides and oligoepoxides have also been described. It has been observed that at elevated temperatures epoxide compounds interact with aromatic cardo polyamides via a mechanism involving the 'insertion' of a fragment of an oxirane ring in the amide bond,^{80, 81, 126, 127, 169} giving rise to three-dimensional polymer systems.

VIII. Polyimides

The cardo principle has been used successfully also for the synthesis of polymers with a cyclochain structure. In particular, cardo polyimides are the first representatives of heterocyclic cardo polymers. Numerous studies have been devoted to their synthesis and investigation (see, for example, Refs 2–4, 49, 146, and 171–269). Cardo diamines such as anilinephthalide, anilinephthalimide, anilinefluorene, anilineanthrone, anilinecyclohexane, and also the dianhydride of bis(3,4-dicarboxyphenyl)phthalide combined with various aromatic, aliphatic, and aliphatic-aromatic diamines as well as the dianhydrides of tetracarboxylic acids have been used as the starting materials for the synthesis of cardo polyimides.

It is noteworthy that the ready solubility of cardo polyimides has led to the possibility of their synthesis by different procedures: by the two-stage polycyclisation of tetracarboxylic acid dianhydrides and diamines^{2–4, 49, 146, 174–177, 201, 210–213, 218–220, 223, 228, 250, 258, 262, 263, 265} with thermal and catalytic imidisation of polyamidoacids, by a single-stage polycyclisation in solution both in the presence of catalysts and without them (see, for example, Refs 2–4, 49, 146, 171–173, 178–183, 211–214, 217, 222, 223, 225, 250, 258, 261, 263), by the reaction of tetracarboxylic acid dichloride diesters and diamines,^{2–4, 49, 183–185, 200, 211, 261} and by the polycyclisation of tetracarboxylic acid dianhydrides and trimethylsilyl derivatives of diamines.^{211, 216, 258}

In the two-stage polycondensation, the first stage (the formation of polyamidoacids) is carried out under the conditions of low-temperature polycondensation in solution of solvents such as dimethylacetamide, dimethyl sulfoxide, *N*-methylpyrrolidone, etc. The study of the kinetics of the formation of cardo polyamidoacids from anilinefluorene and a number of dianhydrides in *N*-methylpyrrolidone^{201, 262} showed that, in terms of decreasing reactivity, the dianhydrides can be arranged in the series presented in Scheme 9, the most reactive dianhydride being to a large extent involved in side reactions with the solvent or the impurities present in it. The rate of reaction increases on passing from a less polar solvent (dioxane) to a more polar one (methylpyrrolidone).²⁰¹ The formation of polyamidoacids involving the carboxy-groups arising on opening of the anhydride ring was found to be autocatalytic.^{211, 262} This made it possible to develop catalytic procedures for the synthesis of polyamidoacids and polyimides in the presence of carboxylic acids.

The catalytic method is extremely effective in the reactions of relatively unreactive diamines [for example bis(4-aminophenyl) sulfone] and tetracarboxylic acid dianhydrides [for example, bis(3,4-dicarboxyphenyl) ether].

In the synthesis of polyimides, account must be taken of the reversibility of the formation of polyamidoacids.^{69, 70, 211, 217–219} The reversibility is manifested particularly strongly in the thermal cyclisation of polyamidoacids, which leads to a sharp decrease in the molecular mass of the polymer in the initial instant of the cyclisation process. However, as the end groups accumulate, the resynthesis of the polyimides as a result of the condensation of the fragments formed via the terminal anhydride and amino-groups assumes an increasing importance. A mechanism has been proposed for the thermal imidisation of polyamidoacids (Scheme 10), taking into account the occurrence of consecutive-parallel cyclisation reactions of the *o*-carboxyamido units, their decomposition, and the condensation of the resulting fragments, i.e. this process must be described not by one but by at least three rate constants. The difficulties in the synthesis of polyimides associated with the instability of polyamidoacids and the reversibility of the imidisation stage can to some extent be overcome by carrying out the polycyclisation in the presence of catalytic systems^{174, 211, 262} such as mixtures of acetic anhydride with various tertiary amines, alkali metal acetates, silazanes, mixtures of chlorotrimethylsilane with tertiary amines, etc. By virtue of the mild temperatures (20–100 °C) at which the catalytic cyclisation takes place, it is possible to obtain linear soluble polyimides with a reactive group, for example the cardo polyimides derived from benzophenone-3,3',4,4'-tetracarboxylic acid, which are cross-linked via the ketogroup if synthesised by other methods. One should also note that polymers with extremely high molecular masses (up to 200 000) can be obtained by the chemical cyclisation of polyamidoacids, whereas thermal cyclodehydration affords polyimides with a molecular mass of ~20 000.

Scheme 10

The formation of polyamidoacids may be avoided by employing as starting materials tetracarboxylic acid dichloride diesters and diamines or tetracarboxylic acid dianhydrides and bis-(trimethylsilyl) derivatives of diamines. Stable alkyl and silyl esters of polyamidoacids are then obtained at an intermediate stage, as shown in Scheme 11.

Scheme 9

The cyclisation of polyamidoesters, which are hydrolytically more stable than polyamidoacids, leads to polyimides with higher molecular masses than those obtained by the cyclodehydration of the corresponding polyamidoacids. High-molecular-mass polyimides (molecular mass in the range 100 000–140 000) are formed on cyclisation of polyamidoesters in solution (for example, in nitrobenzene and sulfolane) at 210 °C and also on chemical cyclisation, which can be achieved directly in the film.

The solubility of cardo polyimides was a precondition for the development of a fundamentally new method of their synthesis — one-step high-temperature polycyclisation in an organic solvent (nitrobenzene, sulfolane, *p*-nitrotoluene, α -chloronaphthalene, cresol, etc.).^{2–4, 49, 171–173, 178–182, 211, 217, 222} An equimolecular mixture of the starting materials in a solvent is heated rapidly to 200–210 °C in an inert gas stream and is maintained at this temperature for a specified time (3–10 h). The growth of the polymer chain (the formation of the polyamidoacid) and intramolecular cyclisation take place almost simultaneously. The one-step polycyclisation in the presence of acid catalysts proved extremely successful.^{49, 181, 182, 211–214} In this case, it is possible either to decrease significantly the reaction time (down to 1–3 h), with formation of polymers with extremely high molecular masses under these conditions, or to carry out the process at lower temperatures (140–160 °C).

Carboxylic acids (for example benzoic acid) are effective catalysts also in the synthesis of high-molecular-mass polyimides from monomers with a reduced reactivity such as the dianhydride of naphthalene-1,4,5,8-tetracarboxylic acid.²¹⁴

Since, as mentioned above, the formation reaction of polyimides is reversible, it follows that in order to obtain high-molecular-mass polyimides, it is necessary to remove from the reaction sphere, as fully as possible, the water evolved during cyclisation, which is achieved by raising the reaction temperature, by carrying out the reaction in an inert gas stream, by binding the water with chemical reagents, etc. The simplicity of the one-step polycyclisation, its ready reproducibility, and the possibility of obtaining polyimides with a high molecular mass, which contain virtually no defective *o*-carboxamide units, makes it possible to regard this method as promising for the synthesis of a wide variety of polyimides.²¹¹

In the synthesis of copolyimides, one must not forget that their formation reaction is reversible. There is also no doubt that one must take into account the involvement of polyimides in exchange reactions at elevated temperatures, in the first place aminolysis.^{70, 216, 223–225, 244, 246, 247, 258} It has been shown that the formation of the microstructures of copolyimides may depend on three factors: the ratio of the reactivities of the comonomers, the rate of introduction of the intermonomer into the reaction vessel, and the occurrence or nonoccurrence of exchange reactions.

In the two-stage method of synthesis, the foundation of the microstructure of copolyimides is laid in the stage involving the formation of copolyamidoacids. Such a microstructure may be

retained or damaged in the subsequent cyclisation. Since in the two-stage method of synthesis the polyamidoacids are formed close to room temperature, the exchange reactions are then virtually ruled out. For this reason, the formation of the copolyamidoacid microstructure is determined by the ratio of the rates of the interactions of the intermonomer with the comonomers, which depend on their reactivities and on the rate at which the intermonomer is introduced into the reaction. The formation of block copolyamidoacids when there is a significant difference between the reactivities of the comonomers is observed when the intermonomer is introduced into the reaction zone comparatively slowly, for example when it is added in the solid state (frequently in portions). On the other hand, in the synthesis of the copolyamidoacid by the rapid mixing of dianhydrides and diamines, statistical copolymers are produced.

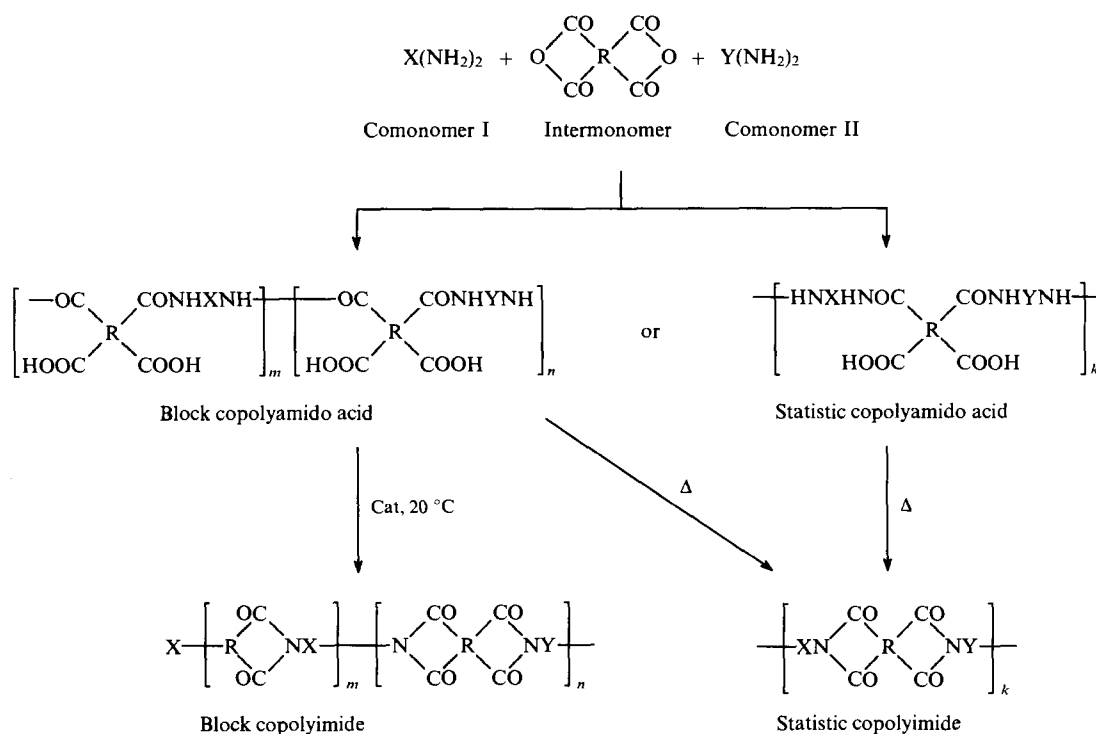

The microstructure of the copolyimides based on copolyamidoacids may be regulated by varying the cyclisation conditions. In the cyclisation under the influence of chemical reagents, occurring under mild conditions and not complicated by degradative or exchange reactions, the microstructure of the copolymer formed is identical with that of the corresponding copolyamidoacid. In thermal cyclisation, accompanied by exchange reactions, predominantly statistical copolyimides are formed from both block copolyamidoacids and from statistical copolyamidoacids.

A detailed study of the one-step copolycondensation showed that in this method of synthesis the copolymer microstructure depends on the relative reactivities of the comonomers, the differences between the reactivities of the functional groups of the intermonomer, the rate at which the intermonomer is introduced into the reaction, and the resistance of the imide rings to destructive exchange reactions and is in many respects determined by the ratio of the rates of the main polymer formation reaction and the exchange reactions, in the first place aminolysis.^{70, 216, 223, 225, 258} When aliphatic and aromatic diamines (for example, hexamethylenediamine and anilinefluorene) are used as the comonomers, while the intermonomer is the dianhydride of bis(3,4-dicarboxyphenyl) ether, statistical copolyimides are obtained owing to the occurrence of effective aminolysis. The increase in the rate of formation of the polymer when the much more reactive pyromellitic dianhydride is used permits the formation of a copolyimide with a block structure. The microstructure of copoly(naphthoylene imide), which is more resistant to aminolysis, can be altered deliberately by varying the reaction conditions. Statistical copolyimides are obtained when the starting materials and the catalyst (benzoic acid) are introduced simultaneously into the reaction, whilst in the case where the intermonomer is added slowly together with the catalyst to a solution of a mixture of diamines, the product is a copolyimide with a block structure. Scheme 12 presents the overall mechanism of the formation of copolyimides by the one-step and two-stage methods.

The use of siloxane-containing diamines, together with cardo diamines, for the synthesis of copolyimides makes it possible to obtain high-molecular-mass siloxane-containing copolyimides with different numbers of dimethylsiloxane fragments in the repeat unit (Scheme 13). Such copolyimides have been synthesised by the low-temperature polycondensation of tetracarboxylic acid dianhydrides and diamines in solution with subsequent cyclodehydration of the copolyamidoacids in the presence of chemical reagents under conditions promoting the initial formation of siloxane-amidoacid and then arylene-amidoacid fragments.¹⁹⁸

The presence of a cardo group in rigid-chain polymers such as polyimides affects primarily their solubility.^{2–4, 46, 49, 173, 175, 176, 179, 186, 187, 211, 263, 270} Many cardo polyimides are readily soluble in organic solvents: dimethylformamide, dimethylacetamide, methylpyrrolidone, dimethyl sulfoxide, hexafluoroisopropyl alcohol, sulfolane, chloroform, methylene chloride, tetrachloroethane, phenol, *m*-cresol, nitrobenzene, etc., while individual polyimides are soluble in dioxane and cyclohexanone. Among the cardo groups investigated, the asymmetric phthalide and phthalimidine groups impart the highest solubility to polymers. Their introduction

Scheme 12

X = alkylene or arylene, Y = arylene (cardo)

Scheme 13

$n = 1, 29, 39, 99$

increases the solubility of even the polyimides with a most rigid chain such as polypyromellitimide and poly(1,4,5,8-naphthoylene imide). The solubility of cardo polyimides is influenced appreciably also by the structure of the tetracarboxylic acid dianhydride. It has been found that the different groups entering into the composition of the main chain of the polymer can be arranged in a sequence, in terms of their influence on solubility, in which each successive group expands the range of the solvents for the polymer (Scheme 14).²¹¹ Polyimides containing cardo groups in both the dianhydride and diamine components, (for example, phthalide or phthalide and fluorene) are more soluble than the polyimides containing only one such group in the elementary unit. (In particular,

the former acquire solubility in cyclohexanone.¹⁸⁶) The presence of the phthalide cardo group solubilises adamantane-containing polyimides based on the dianhydride of bis(3,4-dicarboxyphenyl)-phthalide, while their analogues based on the dianhydrides of pyromellitic and benzophenone-3,3',4,4'-tetracarboxylic acids are insoluble.²³⁴ The synthesis of cardo copolyimides has led to extensive possibilities for the variation of solubility. In particular, the formation of copolyimides is an effective method of imparting solubility to polyimides derived from naphthalenetetracarboxylic acid.^{70, 225}

The effect of solvent antagonism has been observed for certain cardo polyimides. Such antagonists are dimethylformamide, dimethyl sulfoxide, dimethylacetamide, and methylpyrrolidone, on the one hand, and methylene chloride, chloroform, and tetrachloroethane, on the other.^{211, 263} Thus the polyimide derived from anilinefluorene and bis(3,4-dicarboxyphenyl) ether does not dissolve in a 1:1 (vol %) dimethylformamide–chloroform mixture, but is readily soluble in each of these solvents. This effect is manifested even more strikingly in anilinephthalene poly(naphthoylene imide), which is insoluble in nitrobenzene–methylpyrrolidone mixtures with different proportions of the individual solvents.

The majority of cardo polyimides are amorphous, but some of them tend to crystallise, which exerts a considerable influence on their solubility. Thus anilinefluorene and anilineanthrone polypyromellitimides and poly(naphthoylene imides) are weakly crystallising polymers which are insoluble in organic solvents (in contrast to the corresponding polyimides with phthalide groups).²¹¹

The ready solubility of cardo polyimides in organic solvents has led to the possibility of investigating their molecular mass characteristics and the determination of their constants in the Mark–Kuhn–Houwink equation (Table 5).^{195, 202, 205, 211, 230, 263, 268}

$$[\eta] = KM_w^\alpha$$

A number of studies^{167, 233, 235} have been devoted to the investigation of solutions of cardo polyimides in greater depth. Thus the study of solutions and gels of anilinephthalene polypyromellitimide in dimethylformamide showed that solutions of the polyimide lose their stability after a time, become turbid, and

are converted into a gel, which can be explained by the poor thermodynamic affinity of the polyimide for dimethylformamide. It follows from X-ray diffraction and polarised light scattering data that the polyimide gels contain both isotropic and anisotropic regions having approximately the same dimensions ($\sim 400 - 600$ nm).¹⁶⁷ The second virial coefficients of solutions of the polyimide derived from anilinephthalein and bis(3,4-dicarboxyphenyl) ether in *N*-methylpyrrolidone, dimethyl sulfoxide, chloroform, THF, and dimethylformamide have been determined.

It has been shown that the molecular masses of this polymer in various solvents are virtually identical, which indicates the absence of association.²³³ The phase diagram for solutions of cardo polypyromellitimides and poly(naphthoylene imides) with fluorene, phthalide, and anthrone groups in fused antimony trichloride has been investigated. The formation of spherulites of anilinefluorene polypyromellitimide and anilinefluorene poly(naphthoylene imide) solutions and of nonordered anisotropic rods has been established for the anilinephthalein pyromellitimide system in antimony trichloride. The results indicate the possibility of the crystallisation of cardo polypyromellitimides and cardo poly(naphthoylene imides) in antimony trichloride on phase separation of their solutions, which leads to new possibilities for the regulation of the properties of these polymers.²³⁵

Table 6 (see over) presents the softening temperatures of a series of cardo polyimides.^{211, 265} It is seen from these data that polymers with three and five condensed rings in the dianhydride residue have the highest heat resistance, which is significantly higher than that of the polyimides with phthalimidine groups having similar chemical structures (cf, for example, polymers Nos 1 and 10, 5 and 4, or 6, 7, and 8).

Scheme 15 presents examples of the structures of aliphatic-aromatic and aromatic cardo copolyimides.^{49, 214, 216, 223, 225, 258} Their heat resistance may be varied within wide limits ($160 - 500$ °C) by varying the chemical structures and microstructures of the copolymers. The softening temperatures of the aliphatic-aromatic polyimides increase consistently with increase in the cardo diamine proportion in the macromolecule and on passing to polyimides with six-membered imide rings.

Like other aromatic polyimides, aromatic cardo polyimides have high thermal stability.^{164, 179, 187, 191 - 193, 211, 250, 265} Polyimides with anthrone and fluorene groups are the most thermostable, the onset of decrease in their mass being observed at $500 - 520$ °C. They retain 70% of their mass on heating to 900 °C under an inert atmosphere. The cardo groups in polyimides with anthrone and fluorene groups are stable virtually up to the same temperatures as the imide ring, whereas in the polyimides with phthalide and especially with cyclohexylidene groups, destruction affects primarily the cardo groups. According to the results of dynamic thermogravimetric analysis (heating rate 4.5 K min⁻¹), the polyimides with phthalide groups begin to decompose in air at

450–490 °C. Saturation of the polymer chain by fragments with a large number of condensed rings in the system and replacement of the five-membered phthalimide groups by the six-membered naphthoylene imide groups increase the thermal stability of the cardo polyimides. On heating in helium (heating rate 5 K min⁻¹), the 'coke' residues from carborane-containing anilinefluorene cardo polyimides with 1,7- and 1,2-bis(3,4-dicarboxyphenyl)-carboranes amount to 92% and 80% respectively.²⁶⁵

The pyrolysis of the cardo polyimide obtained from anilinefluorene and the dianhydride of benzophenone-3,3',4,4'-tetracarboxylic acid has been investigated in the temperature range from 450 to 3000 °C.^{249, 253, 266} It was noted that thermochemical transformations begin in the polymer at a temperature above 450 °C. In argon, destructive processes take place most vigorously at 550–650 °C (with a 20–22% mass loss). At 700–750 °C, the formation of the polyimide coke residue, containing 92.5% carbon, is largely complete. It was of interest to note that, in contrast to a series of the usual polypyromellitimides, heat treatment of the cardo polyimide up to 3000 °C leaves a residue of up to 0.75% of the nitrogen forming part of the composition of condensed six-membered rings. As a result of pyrolysis, the electrical resistance of the system decreases by 12–13 orders of magnitude. The carbon materials thus obtained have a high mechanical strength, a low coefficient of friction, and, in contrast to graphite, a very low porosity. It was established that the electrical conductivity of the polyimide-based carbon materials may be increased still further by their thermal decomposition in various metal (copper, nickel, zinc, and iron) formates.²⁵¹

The ability of soluble cardo polyimides to form charge-transfer complexes with low-molecular-mass (*N*-methylcarbazole) and high-molecular-mass (poly-*N*-vinylcarbazole) electron donors has been noted; in the latter case, a very distinct cooperative polymeric effect is observed.²⁵²

The radiolysis of anilinephthalein polypyromellitimide on prolonged γ -irradiation in vacuo has been investigated.²⁵⁴ The high radiation stability of this polymer was demonstrated. The radiation-induced electrical conductivities of certain copolyimides have been studied in the course of their irradiation in vacuo by electron pulses

with an energy of 65 keV. It was established that the macrostructure (block or statistical) of the copolyimide exerts a definite influence on the electrical conductivity.²⁵⁶

The high heat resistance, thermal stability, radiation resistance, and chemical stability of cardo polyimides, as well as the possibility of working many of them in the 'cyclised' form makes them promising for practical use in the manufacture of various articles designed for prolonged use at temperatures above 200 °C.

Virtually colourless strong films (tensile strength 1000–1100 kgf cm⁻², elongation at break 40%–70%), the electrical properties of which in the temperature range 20–300 °C are not inferior to the familiar Kapton H film, are obtained from solutions of cardo polyimides by casting.²¹¹ The study of the optical properties of polyimide films obtained from anilinefluorene and bis(3,4-dicarboxyphenyl) ether showed that they exhibit a high optical transmittance at 500 nm (81%–87%) and are thermophotoradiation-resistant. After heat treatment at temperatures up to 300 °C or after UV irradiation at a dose equivalent to a 300 h exposure to sunlight, the optical transmittance of the film diminishes by only 1%–3%.¹⁵⁸

The cardo polyimide based on anilinefluorene and bis(3,4-dicarboxyphenyl) ether (PIR-2 brand) has been used successfully for the preparation and attachment by adhesive at room temperature of resistance strain gauges for the measurement of static deformations, operating over a wide temperature range (from –190 to 300 °C). A series of cardo polyimides can be worked in the fused state into strong plastics for various purposes. Thus the compressive strength of PIR-2 plastics is 1800 kgf cm⁻² and their modulus of elasticity is 2.2×10^4 kgf cm⁻².²¹¹ The strengths and moduli of elasticity on compression of plastics made from a series of cardo copolyimides reach 1400–2100 and $(1.7 \text{ to } 2.2) \times 10^4$ kgf cm⁻² respectively, the strength characteristics remaining virtually unimpaired after preliminary heating of the plastics to 200–240 °C.²²³ Monolithic plastics with an impact strength of 15 kgf cm cm⁻² and a bending strength of 700–1000 kgf cm⁻² have been moulded from cardo copoly(naphthoylene imides) by the hot pressing method.²²⁵

The satisfactory solubility of cardo polyimides and their compatibility with many polymers and oligomers, for example, with phenolformaldehyde and epoxide polymers, ensured their approval as heat-resistant fibre-forming materials, as binders for reinforced plastics, as coatings, and as adhesives.^{126, 127, 211, 264} In particular, the modification of epoxide oligomers by cardo polyimides leads to the formation of cross-linked polymer systems superior as regards heat resistance, strength, and other properties to materials obtained with the aid of the usual hardening agents for epoxide oligomers. For example, the use of polyimide–epoxide compositions as binders for reinforced carbon plastics proved successful. The compressive strength of such plastics is 2900–4200 kgf cm⁻² at 20 °C and remains virtually unchanged up to 250 °C.²⁶⁴

A linear-network system, in which the linear amorphous cardo polyimide is enclosed in a network polymer matrix, has been obtained by the polymerisation at 200–250 °C of anilinefluorene bisacrylamide in a matrix comprising a cardo polyimide based on anilinefluorene and bis(3,4-dicarboxyphenyl) ether. This system has a high strength and heat resistance.¹⁶⁸

The high thermal stability of the imide rings combined with the valuable physicomechanical properties of the materials based on linear polyimides made it desirable to develop methods of synthesis of thermoreactive polyimides based on reactive oligomers having comparatively low softening temperatures. By imparting thermoreactive properties to polyimides, the possibilities for their processing into various materials are expanded. In particular, thermoreactive polymers containing imide rings have been synthesised from the dianhydrides of tetracarboxylic acids and the corresponding diamines with subsequent blocking of the terminal amino-groups by the acrylic or methacrylic acid chlorides in the oligomeric amidoacid stage (Scheme 16a) or the oligoimide stage (Scheme 16b).²⁰⁶ A series of studies have been devoted to the preparation and study of certain oligomeric cardo imides with terminal unsaturated acrylamide and methacrylamide

groups.^{49, 168, 203, 204, 206, 207, 211, 245, 259} They have been obtained in quantitative yields and with a specified degree of polymerisation.

Unsaturated oligoimides obtained from cardo diamines and having terminal acrylamide and methacrylamide groups are amorphous substances readily soluble in dimethylformamide, dimethylacetamide, and tetrachloroethane with formation of concentrated solutions. Their softening temperatures can be regulated by varying the nature of the cardo group and the degree of polymerisation of the oligomer. Thus, when the degree of polymerisation of the oligoimide obtained from anilinephthalein and benzophenone-3,3',4,4'-tetracarboxylic acid and having terminal acrylamide groups is increased from 3 to 10, its softening temperature increases from 210 to 280 °C, remaining at the same time appreciably lower than the softening temperature of the corresponding high-molecular-mass linear polyimide (380 °C).

Cross-linked insoluble polymers which do not soften up to the onset of thermal destruction have been obtained by the thermal polymerisation in bulk of unsaturated cardo oligoimides in air at 250–310 °C. The thermal destruction develops vigorously only at temperatures above 400 °C.²⁰⁶ Glass fibre-reinforced plastics with a low porosity and a high bending strength (4000–5000 kgf cm⁻²) both at room and elevated temperatures have been prepared from solutions of unsaturated anilinefluorene- and anilineanthrone-benzophenone-3,3',4,4'-tetracarboxylic acid oligoimides in *N*-methylpyrrolidone.²⁵⁹

The above unsaturated oligoimides have been used successfully to prepare copolymers with monomers such as *N*-vinylpyrrolidone, *N*-phenylmaleimide, and the bismaleimides obtained from various aliphatic diamines, the oligomers being readily soluble in such monomers.^{49, 207, 211, 259} It was established that the cross-linked copolymers are formed at lower temperatures than the corresponding cross-linked homopolyimides. Thus the use of *N*-vinylpyrrolidone makes it possible to reduce the polymerisation temperature by 50–80 °C.²⁰⁷ The cross-linked copolymers obtained in up to 90% yields by thermal polymerisation at 200–250 °C have high heat resistances and chemical and thermal

stabilities.^{207, 211, 259} Such copolymers begin to undergo deformation only at temperatures above 300 °C, and, according to dynamic thermogravimetric data, the onset of decrease in their mass in air is in the temperature range from 350 to 400 °C. The cross-linked copolymers of unsaturated polyoligoimides as well as the corresponding network homopolyimides undergo hardly any change in their mass on being kept for a week in sulfuric and nitric acids, 25% ammonia, and 10, 20, and 40% solutions of sodium hydroxide. In this respect, they are superior to their linear analogues, which undergo appreciable destruction under the conditions indicated.

The satisfactory solubility of the unsaturated cardo oligoimides in a monomer such as *N*-phenylmaleimide makes it possible to obtain from them (without using an inert solvent as a binder) reinforced plastics (using organic and glass fibres) having a high mechanical strength both in the initial state and after prolonged maintenance at elevated temperatures. For example, the glass fibre-reinforced plastic based on the cross-linked copolymers of *N*-phenylmaleimide and the anilinefluorene-benzophenone-3,3',4,4'-tetracarboxylic acid cardo oligoimide with terminal acrylamide groups and $n = 5$ (Scheme 16) has tensile strengths of 15500 and 15000 kgf cm⁻² and bending strengths of 8500 and 14000 kgf cm⁻² at room temperature and 250 °C.²¹¹

The cross-linked copolymers based on the unsaturated oligoimides considered and the bismaleimides obtained from aliphatic diamines have interesting properties. These are solid, transparent, heat-resistant substances which do not undergo deformation up to the onset of thermal decomposition (the temperature of which in air is 400–450 °C according to thermogravimetric data). They have effective mechanical properties. At room temperature, the above substances have a compressive strength of 2000 kgf cm⁻² and a modulus of elasticity on compression in the temperature range from 180 to 300 °C of $(4-7) \times 10^3$ kgf cm⁻² which shows that such copolymers exhibit properties similar to those of leather over a wide range of elevated

Scheme 16

temperatures. This makes it possible to regard them as promising materials for high-temperature hermetic seals.^{211, 259, 260}

Network cardo polymers of the polyaminoimide type^{49, 208, 209, 260} have been synthesised by the interaction of *N,N'*-hexa-, octa-, nona-, deca-, and dodecamethylenebismaleimides with cardo diamines (anilinefluorene, anilinephthalein). The process may be regulated by varying the conditions under which it is carried out (temperature, reaction time, proportions of starting materials, addition of a catalyst and initiator) and by regulating the contribution of each of the two main reactions: migration polymerisation (addition of amino-groups to double bonds) and three-dimensional copolymerisation (via carbon-carbon double bonds). The density of the three-dimensional polymer network and the length of the fragments between its nodes change under these conditions. Network cardo polyimides of this type are solid monolithic materials insoluble in organic solvents and characterised by a valuable set of physicochemical properties: high heat resistances and chemical and thermal stabilities, and effective physicomechanical parameters.

We shall deal with yet another type of cardo polyimides, the so called functional cardo polyimides containing in their polymer chains free functional groups, which in a number of instances impart specific properties to the polyimides and give rise to the possibility of their further chemical modification.²⁶⁹

Thus the synthesis of cardo polyimides with free hydroxy-groups [the dianhydrides of bis(3,4-dicarboxyphenyl)methanol and cardo diamines were used as the starting materials] has been achieved. Copolyimides with benzimidazole rings, containing a free reactive NH group, in the main chain have been obtained by the polycondensation of various tetracarboxylic acid dianhydrides with a mixture of a cardo diamine and 5(6)-amino-2(4-aminophenyl)benzimidazole. Aromatic polyimides with reactive quinuclidine cardo groups have been synthesised by the reaction of various tetracarboxylic acid dianhydrides with 3,3-bis(4-

aminophenyl)quinuclidine. Polyimides with functional groups are readily soluble in organic solvents and have satisfactory heat resistances, thermal stabilities, and dielectric characteristics as well as enhanced adhesive properties and they form strong transparent films. The possibility of modifying epoxide oligomers by polyimides derived from bis(3,4-dicarboxyphenyl)methanol has been demonstrated. Such modification afforded cross-linked polymer systems with heat resistances and mechanical strengths superior to those of the epoxide oligomers hardened by the traditional methods. The presence of quinuclidine fragments in the polyimides gives rise to prospects for their employment as catalytic systems and for their further chemical modification at the tertiary nitrogen atoms of the quinuclidine ring system.

IX. Poly-1,3,4-oxadiazoles

The introduction of cardo groups also into polymers with a cyclochain structure such as poly-1,3,4-oxadiazoles has been successful.^{2-4, 12, 49, 76, 77, 186, 270-296} The high heat resistances and thermal stabilities of aromatic polyoxadiazoles together with the comparatively ready availability of the initial compounds (dicarboxylic acids and their derivatives) used for their synthesis are responsible for the interest in these polymers.²⁹⁷⁻³⁰⁰ However, aromatic polyoxadiazoles are in the main high-melting polymers insoluble in organic solvents. This limits the possibilities for the comprehensive investigation of such polymers and in many cases their practical applications.

Bis(4-carboxyphenyl)phthalide and its derivatives (the acid chloride and dihydrazide) containing a central carbon atom in the polar cyclic side group²⁷⁰⁻²⁷⁵ and also 2-[3,3-bis(4-carboxyphenyl)]-*N*-phenylphthalimidine and its derivatives containing *N*-phenyl-2-phthalimidine cardo groups²⁹³ were selected as the starting materials for the synthesis of cardo polyoxadiazoles.

The polymers were synthesised by a two-stage polycyclisation method in which low-temperature polycondensation was employed in the first stage in order to produce a polyhydrazide with its subsequent cyclisation and by one-step polycyclisation in polyphosphoric acid (Scheme 17).

The ready solubility of the polyhydrazides based on bis(4-carboxyphenyl)phthalide and its derivatives owing to the presence of phthalide cardo groups permits their successful synthesis by low-temperature polycondensation not only in hexamethylphosphoramide, normally employed in the synthesis of aromatic polyhydrazides, but also in other organic solvents (*N*-methylpyrrolidone, dimethylacetamide).²⁷¹ Admittedly, polyhydrazides with a high molecular mass ($\eta_{\text{red}} = 2 \times 10 \text{ dl g}^{-1}$ in dimethylformamide) are obtained only in hexamethylphosphoramide apparently as a result of the much smaller tendency of this solvent (compared with dimethylacetamide and *N*-methylpyrrolidone) to undergo side reactions with acid chlorides.

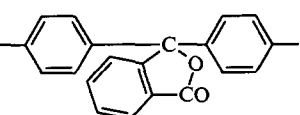

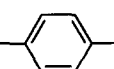

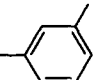

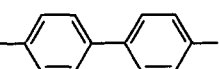

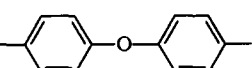

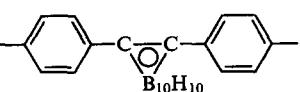

The thermal cyclodehydration of the polyhydrazide based on bis(4-carboxyphenyl)phthalide, like that of the polyhydrazides of aromatic dicarboxylic acids, requires extremely severe conditions as regards temperature in order to attain high degrees of cyclisation: prolonged (of the order of 30 h) heat treatment of the polymer at 300 °C *in vacuo* is needed. If the cyclodehydration of cardo polyhydrazides is carried out by treatment with the dimethylformamide-sulfur trioxide or dimethylacetamide-sulfur trioxide complex, it is possible to reduce the temperature (to 100 °C) and the reaction time (to 5 h).^{49, 270, 271, 275}

The characteristic features of the formation of cardo polyoxadiazoles by one-step polycondensation in polyphosphoric acid have been investigated in detail.^{49, 271, 275, 281} It was found that a side reaction involving the lactone ring takes place, leading to the

formation of an insoluble cross-linked polymer, together with the growth of the polymer chain, in the one-step polycyclisation of the dihydrazide of bis(4-carboxyphenyl)phthalide in polyphosphoric acid and also in the interaction of bis(4-carboxyphenyl)phthalide with hydrazine sulfate. The side reaction may be avoided if the polyoxadiazole is synthesised from bis(4-carboxyphenyl)phthalide and its dihydrazide or the dihydrazides of other aromatic dicarboxylic acids, or from the dihydrazide of bis(4-carboxyphenyl)phthalide and various aromatic dicarboxylic acids.

A series of characteristics of the formation of polyoxadiazoles have been investigated in relation to the reaction of bis(4-carboxyphenyl)phthalide with its dihydrazide. It was established that the results of the polycondensation (yield and molecular mass of the polymer) and the possibility of the occurrence of side reactions are greatly influenced by the ratio of the starting materials, the reaction temperature, the reaction time, the concentration of the starting materials, and the content of phosphorus pentoxide in polyphosphoric acid. Thus a soluble polymer with a high molecular mass is obtained for the equimolecular ratio of the starting materials. An excess of the acid gives rise to a decrease in molecular mass, while an excess of the dihydrazide leads to the formation of an insoluble polymer as a result of the side reaction involving the lactone ring. When the process is carried out at 140 °C, it is desirable to continue it over a period of 5 h. Polymers with the highest molecular mass are obtained when the concentration of the starting materials is approximately 0.3 mole per kilogram of phosphoric acid. The molecular mass of polyoxadiazole depends greatly on the concentration of phosphorus pentoxide in polyphosphoric acid, increasing significantly with increase in the content of the pentoxide from 82% to 86%. However, polycondensation in polyphosphoric acid containing about 84% of

Table 7. The properties of the cardo polyoxadiazoles

R	Temperature/ °C		Mechanical properties of nonoriented films

	360	400	1200	10
	400	430	2400	75
	340	430	1400	100
	335	420	—	—

^a σ_t is tensile strength of the film. ^b ε is relative elongation at break.

phosphorus pentoxide is preferable on technological grounds. Mixed polyhydrazides and polyoxadiazoles were obtained when one of the initial components was replaced by the corresponding derivative of an aromatic dicarboxylic acid such as isophthalic, terephthalic, and biphenyl-4,4'-dicarboxylic acids, bis(4-carboxyphenyl) ether, benzophenone-4,4'-dicarboxylic acid, or 1,2- and 1,7-bis(4-carboxyphenyl)carboranes.

All three methods of synthesis (thermal dehydration, chemical dehydration in the presence of the dimethylformamide-sulfur trioxide complex, and one-step polycyclisation in polyphosphoric acid) can be used successfully for the synthesis of cardo polyoxadiazoles. However, polymers with a high molecular mass (up to 300 000) are obtained when the process is carried out in polyphosphoric acid.^{49, 271, 275}

The homopolymers and copolymers of 1,3,4-oxadiazoles with *N*-phenyl-2,2-phthalimidine cardo groups have been synthesised successfully by one-step polycondensation in polyphosphoric acid.²⁹³ In this case, the polyoxadiazoles were obtained by the interaction of salts of hydrazine or dicarboxylic acid dihydrazides with 2-[3,3'-bis(4-carboxyphenyl)]-*N*-phenylphthalimidine. The presence of the *N*-phenyl-2,2-phthalimidine group in the initial monomer (in contrast to the phthalide group) rules out the occurrence of undesirable side reactions during synthesis. The synthesis of polyoxadiazoles from hydrazine sulfate involves the formation of polymeric adducts with sulfuric acid having high heat resistances and thermal stabilities and satisfactory solubilities even in solvents such as acetone, THF, ethyl methyl ketone, dioxane, and cyclohexanone.

Table 7 presents some properties of a series of cardo polyoxadiazoles with phthalide groups which have been obtained.^{49, 271, 275} These polymers have high heat resistances and thermal stabilities. Thus the softening temperatures of polyoxadiazoles are from 340 to 400 °C. According to thermogravimetric data (heating rate 5 K min⁻¹), these polymers begin to decompose in air at 400–430 °C. Cardo polyoxadiazoles are resistant to the action of water and corrosive media at room temperature and to the action of water at 100 °C.^{271, 291} Comparison of the thermomechanical curves for the polyoxadiazole derived from bis(4-carboxyphenyl)phthalide and the noncardo poly-2,5-(4,4'-diphenylene oxide)-1,3,4-oxadiazole in the amorphous state revealed the influence of the cardo group on the heat resistance of polymers of this type: the softening temperature of the cardo polymer exceeds by approximately 150 °C that for the noncardo polyoxadiazole.^{49, 271}

Among various polyoxadiazoles with phthalide groups, poly 2,5-(4,4'-diphenylphthalide)-1,3,4-oxadiazole has the highest solubility. It is soluble in methylene chloride, tetrachloroethane, dimethylacetamide, hexamethylphosphoramide, pyridine, benzyl alcohol, methylpyrrolidone, etc. The solubility of cardo polyoxadiazoles gives rise to the possibility of obtaining different articles from them by moulding from solution. Strong transparent films, with effective physicochemical and dielectric properties both at room and elevated temperatures, are formed from solutions of cardo polyoxadiazoles.^{271, 275} Thus the strength of films of the homopolyoxadiazole obtained from bis(4-carboxyphenyl)phthalide is 1000 kgf cm⁻² after heating at 250 °C for 500 h and 400 kgf cm⁻² after heating at 300 °C for 1000 h (the initial strength is 1200 kgf cm⁻²). At 20 °C and a frequency of 5000 Hz, the specific volume resistivity of this polymer is 6×10^{15} Ω cm, while the tangent of the dielectric loss angle is 3.2×10^{-2} ; at 300 °C, these parameters are respectively 10^{13} Ω cm and 2.0×10^{-2} .

The solubility of cardo polyoxadiazoles made it possible to investigate for the first time the hydrodynamic properties, polydispersity, and the molecular mass characteristics of cyclochain polymers of this type.^{178, 179, 270, 271, 282, 287} For the cardo polyoxadiazole obtained from bis(4-carboxyphenyl)phthalide in dimethylacetamide and THF, the Mark-Houwink equations are $[\eta] = 7.74 \times 10^{-4} M^{0.57}$ and $[\eta] = 4.00 \times 10^{-4} M^{0.66}$ respectively. The polydispersity coefficient for this polymer, synthesised by one-step polycyclisation in polyphosphoric acid, is 3.0–3.1.^{270, 278, 279}

Polyoxadiazoles containing phthalide rings in the side chain have an amorphous structure regardless of the method of synthesis, whereas the familiar poly-1,3,4-oxadiazoles, synthesised in two stages, have a crystalline structure.²⁷⁵ The radiation stability of the polyoxadiazole based on bis(4-carboxyphenyl)phthalide is fairly high and is superior to that of poly(ethylene terephthalate) and polycarbonate.²⁸⁸

The use in the synthesis of cardo polyoxadiazoles of phosphorus-containing monomers such as bis(4-carboxyphenoxymethyl)-methylphosphine oxide, bis(4-carboxyphenyl)methylphosphine oxide, and bis(1-carboxy-3,5-dichloro-4-phenoxy-methyl)methylphosphine oxide together with bis(4-carboxyphenyl)phthalide and its hydrazide made it possible to obtain phosphorus-containing cardo polyoxadiazoles with a satisfactory solubility, high heat resistance and thermal stability, effective adhesive properties, and an enhanced resistance to combustion.^{285, 294, 295}

Cardo polyoxadiazoles may be of interest for the electrical engineering industry, machine building, aircraft construction, and other industries employing materials in units and constructions designed for prolonged use at 200–300 °C. They have been used in the form of powders and solutions for the preparation of glass fibre-reinforced and carbon plastics, moulding materials, films, coatings, adhesives, filtering materials, including materials of the membrane type, and heat- and atmosphere-resistant anticorrosion coatings. Table 8 presents certain data on the properties of the moulding

Table 8. The properties of the 'Niplon 1' polyoxadiazole.

materials and glass fibre-reinforced and carbon plastics based on the 'Niplon 1' cardo poly-1,3,4-oxadiazole.^{301, 302}

The data presented above show that cardo polyoxadiazoles have a set of valuable properties and are promising for practical employment.

* * *

Summarising the foregoing, one should note that the 'cardo' principle has been justified in a series of different types of polymers: polyarylates, aromatic polyethers, polyamides, polyarylene-phthalides, epoxide polymers, polyheteroarylenes with a cyclochain structure (polyimides, polyoxadiazoles, polybenzoxazoles,³⁰³⁻³⁰⁸ polybenzimidazoles³⁰⁹) etc. A characteristic feature of the cardo polymers, distinguishing them from their noncardo analogues, is a combination of an enhanced heat resistance with a satisfactory solubility in organic solvents whilst retaining other valuable properties characteristic of the particular type of polymer to which they belong. This makes the employment of such polymers for practical purposes undoubtedly promising.

As shown above, the properties of cardo polymers depend on their chemical and physical structures and can be altered deliberately by varying the latter, including a transition from polymers of one class to another. For example, the heat resistances and the operating temperatures of cardo polymers and the materials based on them increase on passing from aromatic polyethers to polyarylates and aromatic polyamides and polyimides.

The solubility of cardo polymers in readily available organic solvents made it possible to investigate a series of common features of the formation of polymers with a cyclochain structure, which had not been possible previously owing to the insolubility of these polymers. The solubility of cardo polymers and their satisfactory compatibility with various monomers, oligomers, and polymers has also led to unlimited possibilities for the creation of new polymers in a matrix comprising cardo polymers and hence the creation of new valuable polymer systems.

Abstract. Published data on the activity and selectivity of titanium-containing catalysts of esterification and transesterification reactions are surveyed. The influence of the nature of ligands and of the composition of the medium on the activity of catalysts is shown. The selectivity of the catalysis is considered from the viewpoint of information transmission theory. The bibliography includes 61 references.

I. Introduction

The esterification of carboxylic acids has been studied for 130 years. This reaction may be considered to be a classical topic of physical organic chemistry. Its investigation is associated with such names as Berthelot, Ostwald, Menshutkin, Guldberg, Waage, and others.¹ Esterification and transesterification reactions occupy an important place in industrial organic synthesis; they are widely used for the production of solvents, perfumes, polymers, and plasticisers.

Esterification reactions are traditionally catalysed by strong protic acids, which are active and cheap catalysts, although not free from certain drawbacks. Among these drawbacks one should note the low selectivity of protic acids caused by their ability to accelerate many side reactions, the necessity to neutralize the catalyst and to purify substantial amounts of effluent, and corrosion of the equipment.^{2,3} This has stimulated the search for new catalysts for esterification and transesterification; a broad range of organic and inorganic compounds of various metals have been proposed as these catalysts, and titanium compounds occupy a special place among them. The high activity and selectivity of titanium-containing catalysts, their good solubility, and the absence of acidic effluent, which causes corrosion, are the reasons why these catalysts are frequently used in industry. Titanium compounds are used as catalysts for the synthesis of ester-based plasticisers, mostly dioctyl phthalate^{3–5} and poly(alkylene terephthalates) — the polymers that have found application in the production of synthetic fibres, films, and structural materials.^{5–8}

In the present review, attention is concentrated on the titanium-containing catalysts used in the preparation of poly(alkylene terephthalates) (PATP) by the esterification of terephthalic acid with ethylene glycol, butane-1,4-diol, and other diols, by the transesterification of dimethyl terephthalate (DMT) with diols, and by the so-called polycondensation.

The latter reaction can also be regarded as transesterification in which one polymeric molecule acts as the ester and another one acts as the alcohol. It should be noted that the general rules of catalysis with titanium compounds manifested in these reactions are also valid for many other esterification and transesterification reactions.

Our review mostly deals with the activity and selectivity of titanium-containing catalysts. The problems of kinetics and mechanisms of the reactions are considered only in relation to the discussion of particular data on activity and selectivity. We also present nontraditional approaches to the mechanism of the catalytic action of titanium compounds based on the use of control and information theories.

II. The main groups of titanium-containing catalysts

It has not been our aim to consider the numerous patents in which the application of various titanium compounds as catalysts for esterification and transesterification is described. These data have been reported previously.^{2–7,9} We shall restrict ourselves to the classification of the catalysts according to their chemical composition. In conformity with this principle, titanium-containing catalysts can be divided into organic, inorganic, mixed, and complex catalysts.

Compounds containing a Ti—OR bond (R is an organic radical) are usually referred to as organic catalysts. Among them, tetraalkyl titanates (alkyl orthotitanates or titanium alkoxides) Ti(OR)₄, where R = Et, Prⁱ, Bu, are most frequently used. Some other titanium compounds have also been suggested as catalysts. For example, titanium salts of aromatic or aliphatic

carboxylic or dicarboxylic acids (formates, benzoates, oxalates), titanium polyacrylates and polymethacrylates, titanates of the general formula $Ti[O(CH_2CH_2O)_nH]_4$, where $n = 2, 3, 4$, obtained by the interaction of butyl orthotitanate with the corresponding diol, bis(chelate)bis(hydroxyalkoxy)titanates, and bis(chelate)bis-(oligoether)titanates, where the chelate is the residue of a chelating compound such as acetylacetone, dibenzoylmethane, 8-hydroxyquinoline, or ethyl salicylate. It has been shown that various oligotitanates, for example, compounds of the formula $RO[Ti(OR)_2O]_nR$, where $n = 2-20$, $R = H$, Et and/or Pr^i and/or Bu, can also be used.

Among inorganic titanium-containing catalysts, hexafluorotitanates $M_x(TiF_6)_y$, where M is an alkali metal, alkaline earth metal, zinc, antimony, or ammonium, are noteworthy. Data concerning the use of titanium oxides and hydroxides, orthotitanium acid and its salts have also been reported.

Organic compounds that incorporate, apart from oxygen (the Ti—O bond), atoms of other metals or other elements, such as halogens, Si, S, P, or N, belong to mixed titanium-containing catalysts. Metal hexaalkyl orthotitanates $MH[Ti(OR)_6]$ and $M'[Ti(OR)_6]$, where M is an alkali metal, M' is an alkaline earth metal, and R is C_1-C_6 alkyl residue, are examples of this type of compounds. The use of titanium salts of aromatic thiols (thioxine, dimercaptobenzene, etc.) and compounds of the formula $M_x[TiO_2 \cdot (C_2O_4)_2]_y$, where M is an alkali metal, alkaline earth metal, Sb, Sn, Zn, Pb, or Co has also been reported.

In recent years, complex catalytic systems consisting of several catalysts or containing one catalyst with functional additives have found wide application. This direction is very promising, since it appreciably widens the possibility of controlling the activity and selectivity of catalysts. Both organic and inorganic titanium compounds can serve as the main components of the complex catalysts for esterification and transesterification reactions. For example, catalytic systems based on tetraalkyl titanates and containing carboxylic acids, their salts, alkoxides of Group 3, 4, and 5 elements, organic compounds of sulfur, tin, bismuth, and antimony have been suggested.

Among inorganic titanium-containing catalysts with additives, mixtures of titanium metal with titanium hydrides and zinc acetate, mixtures of alkali and alkaline earth metal hexafluorotitanates with Li, Ca, Pb, Zn, and Mn salts of aliphatic carboxylic acids are noteworthy.

The above data illustrate the great diversity of titanium-containing catalysts for esterification and transesterification

III. The activity of titanium-containing catalysts

1. Comparison of the activities of titanium-containing and other catalysts

The higher catalytic activity of titanium compounds compared with similar compounds of other metals is manifested, for example, in the alcoholysis of alkyl benzoates.^{10,11} Some of the results obtained are presented in Table 1.

As can be seen from Table 1, compounds of transition metals of the titanium and vanadium subgroups are the most active. The activation energy of the alcoholysis in the presence of Ti compounds (46.9 kJ mol^{-1}) is lower than that in the presence of other metal derivatives by a factor of almost two ($84-105 \text{ kJ mol}^{-1}$).

Tetrabutyl titanate (TBT), as a catalyst of the reactions of heptanol with benzoic acid and methyl benzoate, i.e. esterification and transesterification reactions, is superior to Zn, Mn, and Co compounds.¹²

The catalytic activity of dibutyl tin dilaurate, dibutyltin diphenoxide, dibutyltin oxide, and tetraphenyltin in the transesterification of 4-hydroxybutyl benzoate at 167°C , was two orders of magnitude lower than that of TBT,¹³ the composition of organotin compounds having only slight influence on their catalytic activity.

Table 1. The activity of various catalysts in the alcoholysis of methyl benzoate with heptanol at 200°C .¹⁰

Catalyst	Concentration of the catalyst (mol %)	Rate constant/ min^{-1}
$Ti(OBu)_4$	0.0190	1.0×10^{-2}
$Zr(Pr^iO)_4$	0.0200	3.0×10^{-3}
$Nb(OEt)_5$	0.0189	2.4×10^{-3}
$Ta(OEt)_5$	0.0203	5.7×10^{-3}
$B(OBu)_3$	0.0231	3.0×10^{-4}
$Al(Pr^iO)_3$	0.0193	2.0×10^{-4}
$Sb(OBu)_3$	0.0220	0.9×10^{-4}
$As(OBu)_3$	0.0203	0.8×10^{-4}

The influence of the nature of catalyst on the kinetics of the reaction of dimethyl terephthalate with butane-1,4-diol at a temperature of $175-225^\circ\text{C}$ and a catalyst content of $0.16\%-0.17\%$ has been studied.¹⁴ The rate of transesterification was monitored by following the liberation of methanol. In the series of catalysts $Co(OAc)_2$, $Mn(OAc)_2$, and $Ti(OPr^i)_4$, the latter exhibited the highest activity.

The kinetics of this reaction were studied at a DMT: butane-1,4-diol molar ratio of $1:2.2$, a catalyst content of 5×10^{-4} moles per mole of DMT, and temperatures of $160-240^\circ\text{C}$ in the presence of zinc acetate, lead oxide, and TBT.¹⁵ The highest degree of conversion, 98% after 4 h, was achieved with the titanium catalyst, while in the presence of PbO , it was 83% and with zinc acetate it was 75%.

It is known^{7,16} that in the transesterification of DMT with ethylene glycol, titanium compounds exhibit lower catalytic activity than zinc, manganese, and cobalt acetates, which are usually employed in industrial processes.

The data presented imply that the activity of a catalyst in transesterification depends on the number of methylene units in the diol.

A number of papers have been devoted to the comparison of catalytic activities of various metal compounds in polycondensation in relation to the synthesis of poly(ethylene terephthalate) (PETP). Refler et al.¹⁷ have studied the catalytic activity of metal butoxides in polycondensation in a thin layer of the polymer melt. At 280°C and a catalyst content of 3×10^{-4} moles per mole of bis(hydroxyethyl) terephthalate, metals can be arranged in the following series in terms of their catalytic activities (rate constants, $\text{g mmol}^{-1} \text{s}^{-1}$, and degrees of polymerisation are given in parentheses): $Zn (2.5, 105) < Al (2.6, 99) < Ge (4.6, 114) \ll Ti (6.4, 175) < Sn (7.9, 202)$. In the polycondensation of oligo(ethylene terephthalates), titanium derivatives are also more active catalysts than manganese or antimony compounds.

While analysing the data on the activity of catalysts for esterification and transesterification, one should take into account the fact that equilibrium constants of the reactions under consideration are low and are of the order of unity.¹⁸ Therefore, the reverse reaction can substantially influence the rates of esterification and transesterification. In order to obtain data on the catalytic activity, independent of the reverse reaction, initial reaction rates should be measured or the process be conducted under conditions in which the reaction is virtually irreversible owing to the quick removal of the reaction products from the reaction zone. When esterification or transesterification reactions involve low-molecular-mass compounds, the realisation of these conditions is not difficult. A different situation occurs in the syntheses of polymers, especially when they are conducted in highly viscous media. For example, melt polycondensation of oligo(butylene terephthalate) used in the production of poly(butylene terephthalate) proceeds in a system in which the viscosity increases during the reaction to $5000-10000 \text{ Pa s}$.

The rate of the removal of the low-molecular-mass product, namely, butane-1,4-diol, from the reaction mixture in such systems may be low and comparable with the rate of the chemical transformation.

Thus, to compare the activities of polycondensation catalysts, one should take into account that the observed rate of the process may be determined not only by the rate of the chemical reaction, which is influenced by the catalyst, but also by the velocity of mass transfer. The latter depends on the thickness of the melt layer or on the interfacial area, which is a function of the intensity of stirring, composition of the reaction mixture, the temperature, and the degree of bubble-formation. Correct determination of the catalytic activity, based on the kinetics of polycondensation, requires that the above factors be taken into account in the mathematical model used for the calculations. The problems of mathematical modelling of the processes of the production of poly(alkylene terephthalates) have been considered by Adorova and Kuznetsov.¹⁸

In collaboration with Kuznetsov, we developed a procedure for studying the kinetics of polycondensation of oligo(alkylene terephthalates) convenient for the determination of the activity and the selectivity of a catalyst. In this case, the viscosity of the reaction medium is the most sensitive indication of the occurrence of polycondensation; it sharply increases in the course of the process. The change in the viscosity can be conveniently monitored by the increase in the power consumed in stirring the reaction melt. The power of an electric motor with mild [responsive] characteristics is directly related to the speed of the stirrer rotation, which can be easily measured. During the reaction the number of revolutions [per unit time] of the stirrer diminishes, the dependence of this value on the number-average degree of polymerisation of the product formed being nearly linear. It is notable that the rotation speed of a stirrer depends appreciably on the material of the reactor, in this particular case, on the kind of glass. This effect, which has been noted previously,¹⁹ is probably due to the fact that the properties of the reactor material influence the adhesion of the polymer melt to the reactor walls and, hence, the processes of bubble and foam formation. These processes determine to a large degree the liquid-to-vapour interfacial area, through which the low-molecular-mass product of polycondensation is transferred. The effect observed indicates once again that mass transfer contributes significantly to the macrokinetic features of the polycondensation in the synthesis of poly(alkylene terephthalates).

The experimentally observed dependence of the number-average degree of polymerisation on the reaction time was treated using a mathematical model that took into account the following processes: (1) the formation of the ester bond via interaction of two terminal hydroxyalkoxycarbonyl groups or hydroxyalkoxycarbonyl and carboxyl groups; (2) side reactions yielding tetrahydrofuran and carboxyl groups (see below); and (3) the mass transfer of the diol and water liberated during the formation of the ester bond. The calculated rate constants for reactions (1) served as a measure of the activity of the catalysts studied, and the rate constants for reactions (2) served as a measure of their selectivity.

2. Catalytic activities of various titanium compounds.

The effect of the medium

Several studies have been devoted to the influence of the nature of ligands (fragments) on the catalytic activity of titanium compounds. An evaluation of the activity of various titanium compounds in the esterification of 2-ethylhexyl hydrogen phthalate with an excess of 2-ethylhexanol at 170–175 °C and at a catalyst concentration of 0.01 mol kg⁻¹ has shown that there is no substantial difference between the catalytic activities of the following compounds: titanium sulfate, titanium acetate, titanium dichlorodiacetate, titanium tetrachloride, TBT, tetra-2-ethylhexyl titanate, poly(butyl titanate), triethanolamine titanate, tributoxo titanium butyl hydrogen phthalate, and a complex of butyl levulinate with TBT.²⁰ Ortho- and metatitanic acids were found

Table 2. Catalytic activity of titanium compounds in the alcoholysis of methyl benzoate with heptanol at 200 °C.¹⁰

Catalyst	Concentration of catalyst (mol %)	Initial heptanol : methyl benzoate ratio/mol mol ⁻¹	Rate constant/10 ⁻² min ⁻¹
Ti(C ₇ H ₁₅ O) ₄	0.020	21.50	0.96
Ti(CF ₃ CH ₂ O) ₄	0.021	20.30	1.01
Ti(C ₂ H ₅ OC ₂ H ₄ O) ₄	0.021	20.26	1.04
Ti(C ₄ H ₉ O) ₄	0.020	20.17	0.83
Ti(C ₆ H ₅ O) ₄	0.019	20.18	1.03
Ti(Cl-C ₆ H ₃ Cl-O) ₄	0.019	19.47	1.06

to be somewhat less active, and the catalytic action of titanium dioxide was much weaker. It is natural to attribute the low activities of the latter titanium-containing catalysts to their poor solubilities in the reaction medium.

The catalytic activities of various alkoxy and aryloxy titanium derivatives of the general formula Ti(OR)₄ in the transesterification of methyl benzoate with heptanol have been compared (Table 2).^{10, 21}

One can see that the nature of the organic radical does not influence significantly the reaction rate constant, which remains almost invariable even when twelve electronegative fluorine atoms or an aryl group are introduced into the catalyst molecule. Judging from the ability of alkoxy and aryloxy titanium derivatives to undergo quick radical exchange reactions, the results obtained were rationalised¹⁰ in the following way: in the presence of excess heptanol, the alcohol and the catalyst undergo a quick exchange reaction giving tetraheptyl titanate. This was confirmed by NMR data. Therefore, alcoholysis reactions conducted in the presence of various titanium-containing compounds are characterised by nearly identical rate constants.

The formation of complexes and the radical exchange during the interaction of tetraalkyl titanates with esters and alcohols, as well as the formation of various complexes, have been reported.^{22, 23} It should be noted that in the general case, exchange reactions of the type

do not necessarily proceed up to the complete conversion of the initial tetraalkyl titanate to Ti(OR²)₄. The position of the equilibrium is determined by the composition of the reaction mixture and by the equilibrium constant of the reaction. For example, in the TBT–*n*-heptanol system at 20 °C, the degree of conversion is 0.65, which corresponds to an equilibrium constant of 3.4.²³ In conformity with our data obtained by gas chromatography, in the transesterification of DMT with butanediol, 1.5–2 moles of butanol per mole of the catalyst (TBT) is liberated. These data imply that there is in principle the possibility of a substantial influence of the nature of the ligands in titanium-containing catalysts on their activities. Obviously, this effect should be most pronounced in the case of bulky and/or chelate-forming ligands, whose exchange may be hampered due to thermodynamic or kinetic restrictions. This is in agreement with published data.^{24–26}

The catalytic activities of TBT and chelated titanium derivatives in the esterification of phthalic anhydride can differ by an order of magnitude.^{25, 26} Bis(acetylacetonato)dibutoxytitanium exhibited the highest esterification catalytic activity in a 2-ethylhexanol medium, and TBT was the most active when the process was carried out in di(2-ethylhexyl) phthalate.

In general, the rates of esterification and trans-esterification reactions, accelerated by titanium-containing catalysts, are appreciably influenced by the composition of the

reaction medium.^{12, 26–28} This effect cannot be reduced to nonspecific solvation, which is measured in terms of the dielectric permeability of the medium. It is likely that the influence of the medium is mostly determined by the ability of titanium-containing catalysts to enter into various reactions with the components of the medium including the reagents.

For example, in a study of the esterification of 2-ethylhexyl hydrogen phthalate (monoester) to dioctyl phthalate (diester), it has been found²⁸ that in the medium of the monoester, TBT exhibits virtually no catalytic activity. In fact, in the beginning of the process, when the concentration of the monoester in the reaction medium is high and the concentration of the diester is low, an increase in the TBT concentration does not lead to any noticeable increase in reaction rate, which almost does not differ from the rate of esterification in the absence of the catalyst. As the reaction proceeds and the monoester content in the mixture decreases, the influence of TBT on the rate of the process increases appreciably. These data are supported by the results of Lemman et al.,^{27, 29} who found that when 2-ethylhexyl hydrogen phthalate or dioctyl phthalate instead of 2-ethylhexanol are used as solvents, the rate of the catalytic esterification of phthalic anhydride decreases in the following sequence: diester > 2-ethylhexanol > monoester. These experimental data were interpreted with a mathematical model, which made allowance for the reactions of TBT with the carboxyl group of the monoester, the hydroxyl group of the alcohol, and the ester group of the diester, that is, with all the main components of the reaction medium.²⁸ In addition, the effects of interaction between neighbouring ligands and the ligands of the inner and outer coordination spheres were taken into account.

3. The influence of additives and impurities on the catalytic activities of titanium-containing catalysts

The synthesis of PATP and other esterification and transesterification reactions are often carried out in the presence of titanium-containing catalysts mixed with other compounds. The question of how these additives influence the activity of titanium-containing catalysts is of interest both for the practice and for the theory of catalysis. Very little information concerning this problem has been published in the literature; therefore, the information provided by patent descriptions merits attention. An analysis of the latter has shown⁹ that the use of complex titanium-containing catalytic systems may be favourable for both increase in the catalytic activity and improvement of the properties of the products obtained, for example, complex polyesters.

Ca, La, Zr, Co, Zn, Cd, Mg, Hg, Ge, Sn, and Sb derivatives, silver carboxylates, aromatic thiols, aliphatic and aromatic sulfonic acids, and their salts have been suggested as additives that increase the activity of titanium-containing catalysts.⁹

The problem of the influence of free carboxyl groups and water deserves particular attention, since they are virtually always present in the reaction mixtures. It should be noted that published data on this problem are somewhat contradictory. Despite the fact that carboxylic acids themselves are catalysts of alcoholysis, their influence on the activity of titanium-containing catalysts in esterification and transesterification is ambiguous. The addition of a small amount of adipic acid to TBT accelerates transesterification of its dimethyl ester with diethylene glycol.³⁰

The maximum rate constant was achieved at a concentration of COOH groups of 0.96 mol % with respect to dimethyl adipate. In some patents, carboxylic and dicarboxylic acids have been offered as activators for titanium-containing catalysts in the synthesis of PATP.⁹ This made it possible to obtain polyesters with increased molecular weights.

However, a study of the synthesis of poly(butylene terephthalate) using model compounds in the presence of TBT at 150 and 167 °C has shown that benzoic acid deactivates the catalyst.³¹ 4-Hydroxybutyl benzoate (HBB) was used as a model compound with a terminal hydroxyl group, benzoic acid (BA) was taken as a model compound with a terminal carboxyl group, and 1,4-butylene dibenzoate (BDB) was used as a model polymer. Attention was concentrated on the reactions modelling the polymer chain growth, namely, polycondensation (1) and direct esterification (2).

The results obtained in the experiments with various concentrations of the reactants and TBT led the authors to the following conclusions. Benzoic acid behaves as an inhibitor, if it is introduced in the reaction mixture together with TBT, or as a catalyst in the absence of TBT. In conformity with the coordination mechanism suggested for the catalytic reaction involving TBT, the inhibiting action of BA is caused by the formation of its adduct with the titanium-containing catalyst; this adduct is more stable than the adducts of titanium-containing catalysts with HBB or BDB. The existence of a stable Ti–BA adduct at room temperature in chloroform was confirmed by IR spectroscopy. However, the spectroscopic study provided no evidence supporting the existence of a product of addition of HBB to TBT under the experimental conditions. Based on the suggested mechanism, kinetic equations for calculating the rates of the formation of BDB and consumption of BA were derived. The calculated data proved to be close to the experimental results. It was also found that the stability of the BA–TBT adduct decreases appreciably with an increase in the temperature (the equilibrium constant for the adduct formation decreases by a factor of more than three as the temperature increases from 150 to 167 °C). Consequently, the inhibitory influence of BA is weaker at higher temperatures. The inhibitory effect of carboxyl groups on catalytic transesterification in the presence of titanium-containing catalysts is much less pronounced than that in the case of zinc-, manganese-, and cobalt-containing catalysts.¹²

The influence of water on the activity of titanium-containing catalysts has not been fully elucidated. Many organic compounds of titanium are known³² to be rapidly hydrolysed in the presence of even traces of water to give oligotitanates.

In a study of the kinetics of the transesterification of DMT with ethylene glycol,³³ it has been found that the activity of titanium-containing catalysts depends only slightly on the

added water. This is due to the low stability of aqueous complexes of titanium compounds, which are converted to polymeric derivatives of the following structure:

Ioda³³ managed to show experimentally that the catalytic activity of these compounds is nearly identical to that of the initial TBT.

An attempt has been made³⁴ to study the influence of the degree of preliminary hydrolysis of TBT on its catalytic activity in the esterification of phthalic anhydride with octanol. When the water:TBT molar ratio increased to 1.22:1 (which corresponded to a degree of TBT hydrolysis of 60%), the activity of the compound resulting from the hydrolysis became somewhat higher than the activity of the initial TBT. Further increase in the water:TBT molar ratio and in the degree of hydrolysis led to a monotonic diminution of the reaction rate, due to the decrease in the solubility of the TBT hydrolysis products. An analysis of the TBT hydrolysis products by IR and NMR spectroscopy and a comparison of their catalytic activities have shown that the products of TBT hydrolysis having a mainly linear structure are the most active. The increased catalytic activity of linear polytitanates is believed to be caused by the fact that they are more stable in the reaction medium than TBT, which incorporates reactive alkoxy groups.³⁴

There are patents describing the use of oligotitanates as effective catalysts for the synthesis of PATP.⁹ However, a study of the reversible reactions (1) and (2) has shown that water exerts an inhibiting influence on transesterification in the presence of TBT.³⁵ It was suggested that interaction of the catalyst with water and butane-1,4-diol affords catalytically inactive titanium derivatives. It was assumed that the active catalyst, water, and the inactive form of the titanium-containing catalyst exist in an equilibrium. Assuming that TBT is not capable of self-association under the reaction conditions and that most of the butoxy groups in its molecule have been substituted by alkoxy groups, Pilati et al.³⁵ has derived an equation for calculating the initial reaction rates at various initial ratios of the reactants. The results of these calculations are in good agreement with experimental data.

The above information indicates that the contradictory character of the data on the influence of carboxylic acids and water on the activity of titanium-containing catalysts is associated with the ability of the latter to enter into various reactions with these compounds.

IV. The selectivity of titanium-containing catalysts

The esterification and transesterification processes are accompanied, as a rule, by side reactions. First of all, there are various reactions of dehydration of alcohols and diols yielding ethers, including cyclic ones, aldehydes, and unsaturated compounds.³⁻⁷ For example, usual products of the synthesis of PETP are diethylene glycol, 1,4-dioxane, formaldehyde, acetaldehyde, cyclic compounds, and some other compounds.⁷ The major contributions are made by processes giving acetaldehyde and diethylene glycol and by the thermal degradation of the polymer.

The major side products in the synthesis of poly(butylene terephthalate) are tetrahydrofuran, water, and acids. A TLC analysis of the products of the transesterification of DMT with 1,4-butanediol has shown that when titanium-containing catalysts or acetates of certain metals are used, no di(4-hydroxybutyl) ether is detected among the reaction products.³⁶ This was confirmed by NMR spectroscopy. Since THF is the main side product in the

synthesis of poly(butylene terephthalate), the extent of its formation can serve as a measure of catalyst selectivity. Let us consider this problem in more detail.

Studies of a number of reactions involving model compounds and the real process³⁷⁻⁴¹ led to the conclusion that during the esterification of terephthalic acid or transesterification of DMT with butane-1,4-diol at 160–225 °C, THF can result from the dehydration of butane-1,4-diol

or from the cyclisation of the terminal hydroxybutylene groups.

THF has also been detected by thin-layer chromatography among the products formed in the synthesis of poly(butylene terephthalate) without a catalyst.⁴² In addition, as shown by IR spectroscopy, the polymeric product incorporates carboxyl groups. Based on these data, it was suggested that THF is produced via reaction (4). The same conclusion was drawn by Radas and Hall,³⁷ who have found THF in the products of polycondensation of bis-hydroxybutyl terephthalate in the presence of various titanium- or tin-containing catalysts.

In a kinetic study,¹⁴ it has been shown that in the transesterification of DMT with butane-1,4-diol at a diol:DMT molar ratio > 2 in the presence of titanium isopropoxide at 175–225 °C, THF is formed mainly via reaction (3). The rate of the accumulation of THF varies only slightly with increase in the degree of the conversion of the monomers, because the number of terminal carboxyl groups, which catalyse dehydration of butane-1,4-diol, increases simultaneously with the decrease in the diol concentration. In the late stages of the polycondensation, the formation of THF from the terminal hydroxybutylene groups is likely to prevail.

It is logical to raise the question of the role of titanium-containing catalysts in the formation of THF via reactions (3) and (4). Analysis of the published data provides no unambiguous answer to the question whether or not titanium-containing catalysts accelerate the dehydration of butane-1,4-diol. It has been reported³⁷ that the heating of butane-1,4-diol at 210 °C for 8 h without a catalyst does not produce THF. According to another study,³⁸ butane-1,4-diol is dehydrated over a period of 4–5 h at 180–190 °C, THF being formed both without any added compounds and in the presence of TBT, benzoic acid, THF itself, or water. The reaction has a clear-cut induction period, which allowed it to be described as an autocatalytic reaction.³⁸ However, in our opinion, the attempt to attribute a catalytic influence to water or THF is dubious, especially in view of the fact that no substantial influence of added water or THF on the rate of dehydration of butane-1,4-diol was observed. The formation of THF on prolonged heating of butane-1,4-diol at 180 °C in the presence of various esterification and transesterification catalysts, including TBT, has been found by Moller et al.⁴³

The general consensus of researchers on the influence of acidic additives is that acids are active catalysts of this reaction. For example, butane-1,4-diol is easily converted to THF on heating to 160–185 °C in the presence of orthophosphoric, benzoic, terephthalic, or hydrochloric acid.^{9, 37, 38}

There are virtually no published data on the acceleration of reaction (4) by titanium-containing catalysts. Only Pilati et al.,³⁸ who have studied cyclisation of a model compound, namely, 4-hydroxybutyl benzoate, at 160–190 °C,

have shown that this reaction is not accelerated by acids and that catalysts used in the synthesis of PATP, including TBT, exert no influence on it.

The data presented indicate that there is no clear-cut catalytic influence of titanium-containing catalysts on the side reactions proceeding during the synthesis of poly(butylene terephthalate), which points to high selectivity of these catalysts. As regards their selectivity, titanium-containing catalysts of many esterification and transesterification reactions are superior not only to strong protic acids, but also to other metal-containing catalysts. This conclusion is in agreement with the results of a kinetic study¹⁵ of the transesterification of DMT with butane-1,4-diol in the presence of various metal-containing catalysts in which TBT proved to be the most selective. A similar conclusion has been drawn by Suvaram et al.,⁴⁵ who have studied this reaction carried out at 220 °C and at a catalyst content of 0.1% by mass with respect to DMT. Titanium isopropoxide, phenoxide, diisopropoxyacetate, and triethanolamine, calcium acetate, and antimony(III) oxide were used as the catalysts. It was found that in the presence of traditional catalysts for transesterification, for example calcium acetate, THF is formed in a high yield. Titanium-containing catalysts were much more selective, the best results being achieved with titanium isopropoxide. It has been shown⁴⁶ that the rate of the formation of a side product, namely diethylene glycol, during the synthesis of PETP in the presence of titanium-containing catalysts is lower than in the presence of antimony trioxide, which is frequently used as the catalyst.

In the patent literature, there is much information concerning highly selective catalysts for the synthesis of PATP based on titanium derivatives with added tin, antimony, germanium, lead, calcium, zinc, and manganese derivatives or amides of monocarboxylic acids, sulfonic acids, and phosphoric acid.⁹ There are data concerning high selectivity of titanium-containing catalysts in other esterification and transesterification reactions. For example, TBT does not catalyze the side reaction of octanol dehydration during the esterification of phthalic anhydride with this alcohol.⁴⁷

V. The activity and the selectivity of titanium-containing catalysts from the viewpoint of the theory of information transmission

The optimal catalyst should possess high activity and selectivity. The experimental data that refer mainly to enzymes, as well as to some chemical catalysts, indicate that it is possible to combine these characteristics in a single catalytic system. This possibility has been theoretically justified based on a cybernetic approach to catalysis developed in a number of studies.^{8,9,48} The use of this approach made it possible to explain the remarkable activity and selectivity of titanium-containing catalysts for esterification and transesterification reactions.

According to the concept outlined by Siling,⁸ a reaction system is regarded as being an object under control, a catalyst is considered to be a control device, and the rate of the reaction is taken to be a controlled parameter. The catalyst points to a reaction pathway that differs substantially from the noncatalytic one or, more precisely, it 'pilots' the reaction system along this pathway.

Any control is based on information transmission. In this case, one may speak of the information transmission from the catalyst to the reactants. The catalyst-reactant interactions serve here as the material basis for the information transmission. From the standpoint of statistical information theory,⁸ the activity of a catalyst is largely determined by the diversity of these interactions.

To accomplish the main reaction, a catalyst should transmit particular information to the reactants. The information is transmitted along a communication channel as signals with the use of a certain code. In this particular case, the reaction system itself serves as the communication channel, a separate interaction of the catalyst with a reactant acts as a signal, and the space and time sequence of the interactions, which ensures the occurrence of the main reaction, is the code.

The information transmission along a communication channel is almost inevitably accompanied by errors (noise). This may be manifested, for example, as the omission of a necessary interaction, as the replacement of a necessary interaction by another one, or as the appearance of an 'excessive' interaction. Whereas the transmission of the nonperturbed information ensures the occurrence of the main reaction, the noise can be responsible for the side reactions. Thus, the problem of selectivity can be solved by using the theory of the information transmission along a channel with noise.⁴⁹ It should be noted that such a consideration will refer to the selectivity of the catalytic reaction, which does not always coincide with the selectivity of the overall process, first of all, due to the contribution of noncatalytic reactions.

The rate of the information transmission along channels with noise can be represented as jV , where V is the rate of the signal transmission, and j is the average information content of one signal. The latter value is a function of the probability of the appearance of errors in the signal transmission. The appearance of noise leads to the loss of information, and consequently j diminishes. As the probability of the appearance of errors decreases, j increases, and so does the rate of the information transmission. The highest possible rate of the information transmission for a particular channel with noise is referred to as the capacity of a communication channel.

If the amount of information transmitted in a unit time (I) is smaller than the channel capacity (C), then, in conformity with the Shannon theorem, there exists a way of presenting the information (coding), which makes it possible to transmit a message without delay and with a minor error. In the case where $I > C$, no way of coding that would provide high reliability and transmission of the message without delay can be chosen; however, as the coding becomes more perfect, the unreliability of the information transmission would decrease approaching the $I = C$ value, and the transmission rate would tend to C .

The Shannon theorem, as applied to catalysis, makes it possible to identify some general features concerning the reaction selectivity. First, it follows from the theorem that a selectivity as high as desired can in principle be achieved. It is known that this possibility is most fully realised in enzymic catalysis, though chemical catalysts that ensure the selective course of certain reactions also exist. One may believe that in these cases, the condition $I < C$ is met.

Regarding the relationship between activity and selectivity in a series of catalysts of the same type, one may assume from general considerations that the selectivity and the activity would vary, as a rule, in opposite directions, because transmission of a large amount of information is associated with a larger probability of an error. However, from the theorem it follows that this is not always true, and the relationship between activity and selectivity is determined by the manner in which the $I - C$ value varies over the given series of catalysts. In a series of catalysts for which $I < C$, there exists in principle the possibility of coding which ensures that high selectivity of the catalysts is retained as their activity increases. In a series of catalysts with $I > C$, limiting selectivity decreases as the $I - C$ difference increases. If, in this series, the channel capacity varies slightly and the activity grows with an increase in the amount of information transmitted, then selectivity and activity of the catalysts will vary in the opposing directions.

Thus, theoretical consideration indicates that different relationships between activity and selectivity in a series of single-type

catalysts are possible. This is consistent with experimental data (see, for example, the books by Golodets⁵⁰ and Gates et al.⁵¹).

In the context of information theory, the selectivity of a catalyst can be increased in the following ways.

(1) By increasing the capacity of the communication channel. With the average information content of one catalyst-reactant interaction being constant, the C value is determined by the number of the interactions in unit time. Therefore, high selectivity can be reached in those systems in which many fast interactions occur. Such situations are observed in enzymic catalysis,⁵²⁻⁵⁴ which is one of the reasons why in this case the condition $I < C$ is satisfied. It is believed that it is the set of adsorption or other additional interactions of an enzyme with substrates that predetermines the high substrate specificity observed in the enzymic catalysis.

(2) By a decrease in the bulk of the information transmitted. The amount of information can be relatively small in the case where the reaction involves the cleavage and formation of a small number of bonds, and consequently, a great diversity of the catalyst-reactant interactions is not required. It has been noted⁵⁵ that one enzyme does not catalyse, as a rule, complex transformations involving cleavage and formation of many bonds. This requires a set of enzymes, each of them accelerating a relatively simple chemical transformation.

(3) By perfecting the coding procedure. According to information theory, correct transmission of messages along a channel with noise is favoured by connecting signals in long blocks. This way of coding is manifested in the catalysis as synchronous (concerted) reaction mechanisms, where the cleavage and the formation of bonds occur synchronously in a single activation complex.⁵⁶⁻⁵⁸ Mechanisms of this type are frequently realised in enzymic catalysis.

It can be seen that all the main factors contributing to the selectivity of catalysis from the viewpoint of information transmission are manifested in enzymic reactions. For our purposes, it is necessary to note the important role of the diversity of fast catalyst-reactant interactions, which ensures high channel capacity and effectiveness of coding.

Considering titanium-containing compounds in this context, one may suggest that the high activity and the high selectivity of these catalysts in esterification and transesterification reactions are caused by two main factors.

The first of them is the great diversity of the catalyst-reactant interactions. In fact, titanium is known to be capable of interacting with various oxygen-containing ligands.^{32, 59, 60} Furthermore, tetraalkyl titanates tend to undergo exchange reactions at the Ti-O bond in which one oxygen-containing ligand is substituted by another. For example, in a tetraalkyl titanate-DMT-diols-oligo(alkylene terephthalate) system, a large number of coordination and exchange interactions occur leading to the appearance of the fifth and the sixth ligands at the titanium atom and to the complete or partial substitution of the OR groups by the molecules of the reactants and giving a wide range of mixed complexes and chelate-type derivatives. It is noteworthy that in the systems under consideration, information is transmitted not only via the interaction of titanium with the reactants or the components of the medium, but also via the formation of hydrogen bonds between these compounds and inner-sphere ligands (the interaction of ligands of the inner and outer coordination spheres and its role in catalysis have been considered in a number of studies.^{8, 23, 28, 58, 61}). Of course, not all these interactions are stages of the catalytic process; moreover, some of them may retard the reaction (see for example, the paper by Siling et al.²⁸). Nevertheless, it is the great diversity of the catalyst-reactant interactions that ensures the transmission of a large bulk of information from titanium-containing catalysts to the reactants. This diversity is a characteristic feature of complex catalytic systems based on titanium compounds.

High rates of the coordination and exchange reactions are the second factor. In fact, the high rate of exchange of alkoxyl radicals

in the case of titanium alkoxides has been confirmed by NMR.^{10, 22, 23} In terms of the rate of these reactions, metals can be arranged in the following sequence $Ti > Sb > As$.

The concept developed above is consistent with the fact that virtually all the titanium-containing catalysts suggested for esterification and transesterification are compounds with Ti-O bonds, which are prone to undergo a variety of fast reactions with the reactants, rather than compounds with Ti-C bonds.

As can be seen from the presented data, the application of information transmission theory to the problem of catalyst selectivity gives results consistent with the experimental data. In our opinion, the informational approach to catalysis has also a predictive ability. For example, one can speak of the design of an effective catalytic system, in which primary importance is assigned to the diversity and the rate of the interactions of the catalyst with the reactants. These interactions can be not only direct, but also indirect (with the participation of ligands of the outer coordination sphere).

* * *

This review covers studies published in the last 10-15 years and demonstrates the prospects of using complex catalytic systems based on titanium derivatives for esterification and transesterification reactions. Study of these catalysts may also prove to be fruitful in elucidating the general features of the homogeneous catalysis.

Abstract. The review deals with aspects of the modelling of the compositions and properties of inorganic compounds with tetrahedral anions on the basis of crystal-chemical information. One of the possible algorithms employing crystal-chemical data for the modelling of the compositions, structures, and properties of new compounds is proposed on the basis of the structures of six structural types (glaserite, β - K_2SO_4 , bredigite, palmierite, NASICON, and whitlockite). The likely usefulness of such data for the solution of various problems in materials science is demonstrated. The bibliography includes 208 references.

I. Introduction

Solid state chemistry is the science of chemical phenomena in solid materials observed during their preparation, heat treatment, use, ageing, and regeneration. This branch of chemistry is also concerned with the development of theoretical foundations for the synthesis of solid materials. Progress in many branches of science and engineering is determined by the development of new materials with a set of special properties. The methods of solid state chemistry have been devised to accelerate fundamental research involving the search for and development of new materials.

At the present stage of development, solid state chemistry faces a task concerned with the transition from the consideration of individual aspects of the structures, reactivities, and properties of materials with specified structures, properties, and compositions to the determination of the dependences of their properties on structure and the development of procedures for the construction of such materials based on scientific principles. This problem can be partly solved on the basis of crystal-chemical data and the theory of the electronic structure of solids and crystal lattice defects.

The employment of crystal-chemical data is of interest both for fundamental research — the understanding of the relations between the chemical compositions, structures, and properties of

compounds — and for applied studies — the search for new materials with special and practically important properties (phosphors, chemical sensors, superconductors, catalysts, semiconductors, piezo- and ferro-electric materials, solid electrolytes, materials for the storage of information, etc.). The consideration of problems in materials science from the structure–property–composition standpoint makes it possible to achieve the specific syntheses of compounds and materials having specified physicochemical characteristics. However, problems in materials science have hitherto been usually solved by empirical methods. Such an approach retards the development of procedures for the synthesis of compounds possessing a set of predetermined parameters.

The structures of a large number of inorganic compounds (more than 15000) have now been established. New studies concerned with the determination of the crystal structures of inorganic phases have mainly refined the assignment of a particular compound to a structural type already known. When the chemical composition of a compound becomes more complex, its subcell usually increases or becomes distorted, but the overall order in the alternation of cations and anions remains unchanged.

As an example, we shall consider the ideal structure of the natural mineral glaserite $\text{K}_3\text{Na}(\text{SO}_4)_2$ [space group (sp.gr.) $P\bar{3}m1$, $a = 5.680 \text{ \AA}$, $c = 7.309 \text{ \AA}$].¹ Following substitution in accordance with the scheme

the compounds $\text{K}_3\text{R}(\text{EO}_4)_2$ ($\text{R}^{3+} = \text{rare earth, Y; E}^{5+} = \text{P, As, V}$) with a glaserite-like structure are formed.^{2–4} Depending on the set of cations, different distortions of the ideal structure arise in the crystals — from trigonal in $\text{K}_3\text{R}(\text{PO}_4)_2$ ($\text{R} = \text{Sc, Lu}$)^{5,6} to monoclinic in $\text{R}_3\text{Nd}(\text{PO}_4)_2$.⁷ The characteristic features of such distortions have been discussed in a review.⁸ Here we shall only note that the unit cell in lutetium and scandium compounds increases by a factor of 3 and in neodymium compounds by a factor of 2. A twofold increase in the size of the unit cell has been observed also in $\text{K}_2\text{MR}(\text{PO}_4)_2$ ($\text{M} = \text{Rb, Cs}$).⁹

Within the framework of the β - K_2SO_4 structural type ($Pnam$, $a = 7.456 \text{ \AA}$, $b = 10.08 \text{ \AA}$, $c = 5.776 \text{ \AA}$),¹⁰ substitutions also occur, for example in accordance with the scheme

with formation of the compounds $\text{NaR}(\text{EO}_4)_2$.^{11–15} They are subdivided into nine structural types,¹⁶ each of them characterised by a different volume of the unit cell and a different space group. On passing from the ideal β - K_2SO_4

structure to structures of the type $\text{Na}_3\text{R}(\text{EO}_4)_2$, the volume of the unit cell increases by a factor of 1–6.¹⁶ For other types of substitution, for example

the size of the unit cell remains unchanged, as in KBaPO_4 ($Pnam$, $a = 7.709 \text{ \AA}$, $b = 5.663 \text{ \AA}$, $c = 9.972 \text{ \AA}$),¹⁷ or increases, as in $\beta\text{-CaNaPO}_4$ ($Pn2_1a$, $a = 20.397 \text{ \AA}$, $b = 5.412 \text{ \AA}$, $c = 9.161 \text{ \AA}$),¹⁸ depending on the radii of the cations forming part of the composition of the compounds.

In the examples quoted, the number of atoms in the subcell does not change and all the cationic sites are fully occupied, but it is possible to quote examples of structures in which some of the cationic sites may be vacant. For example, in the structures of $\text{Ca}_5(\text{PO}_4)_2\text{SiO}_4$,¹⁹ $\text{Cd}_5(\text{PO}_4)_2\text{EO}_4$ ($\text{E} = \text{Ge}, \text{Si}$),²⁰ $\text{NaCd}_4(\text{PO}_4)_3$,²¹ and $\alpha\text{-Ca}_3(\text{EO}_4)_2$,²² which are similar to that of $\beta\text{-K}_2\text{SO}_4$, one of the sites is partly occupied. The vacant sites in the crystal lattice may be occupied by additionally introduced cations and it is then possible to calculate theoretically the limiting compositions of the phases.

The stability of a structure with a partly occupied site (or sites) permits the existence of a lattice with a fully vacant site, i.e. it is possible to 'remove' from the lattice a calculated number of cations at non structure-forming sites and predict the limiting composition of the new phases. Consequently the formation and occupation of vacancies in the crystal lattice make it possible to model new compounds within wide composition ranges.

The arsenates, vanadates, and phosphates having the general formula $\text{M}_3(\text{EO}_4)_2$ ($\text{M} = \text{Sr}, \text{Ba}; \text{E} = \text{As}, \text{V}, \text{P}$)^{24–27} and the molybdates $\text{M}_5\text{R}(\text{MoO}_4)_4$ ($\text{M} = \text{Rb}, \text{K}, \text{R} = \text{rare earth}$)^{28–32} crystallise in the structural type of the natural mineral palmierite $\text{K}_2\text{Pb}(\text{SO}_4)_2$ ($R\bar{3}m$, $a = 5.49 \text{ \AA}$, $c = 20.83 \text{ \AA}$).²³ In most cases, these compounds retain the trigonal palmierite-like unit cell. A decrease of symmetry to monoclinic has been observed for some of them.³¹ We emphasise that, among the numerous palmierite-like structures, there are no representatives with vacancies in the cationic sublattice.

As regards the modelling of new compounds with specified structures and properties, the NASICON (Na Super Ionic Conductor) structural type is of undoubted interest.³³ Compounds having the general formula $\text{A}_x\text{M}_2(\text{EO}_4)_3$, where A is a monovalent or divalent cation (Li^+ , Na^+ , K^+ , Ag^+ , Cu^+ , Ca^{2+} , Sr^{2+} , Ba^{2+} , Cu^{2+}), M is a divalent (Mg), trivalent ($\text{Sc}, \text{V}, \text{In}, \text{Cr}, \text{Fe}$), tetravalent (Ti, Zr), or pentavalent (Nb, Ta) cation, and $\text{E} = \text{Si}, \text{Ge}, \text{P}, \text{or As}$, and $0 \leq x \leq 4$, belong to this structural type.^{34–38} In compounds of this class, the occupation of some of the cationic sites may vary from 1 [$x = 4$, $\text{Na}_4\text{Zr}_2(\text{EO}_4)_3$, $\text{E} = \text{Ge}, \text{Si}$]^{39,40} to 0 [$x = 0$, $\text{Sc}_2(\text{MoO}_4)_3$].⁴¹ Depending on the set of cations, the symmetry of the unit cell varies from trigonal to monoclinic. It is also possible to quote examples of other isostructural classes of compounds with garnet,⁴² perovskite,⁴³ bredigite,⁴⁴ eulythine,⁴⁵ and whitlockite⁴⁶ structures, in which some cations are substituted by others with retention of the overall architecture of the structure.

Many of the phases listed above were initially synthesised and only then assigned to a particular structural type, but most of them could be predicted within the framework of a definite structural type. All the necessary preconditions required for this purpose were in fact available, namely the crystal structures and radii of the cations were known^{47,48} (in the present review the cationic radii quoted by Shannon⁴⁸ are used).

II. The use of crystal-chemical data for the construction of compounds with specified structures and properties

One example of the use of crystal-chemical data for the preparation of compounds in which the metal atoms would be in an unusual valence state is the synthesis of the $\text{La}_2\text{LiFeO}_6$ oxide phase containing Fe(V) cations.⁴⁹ The synthesis of this

compound became possible by the creation of the necessary structural preconditions promoting the existence of the $t_{2g}^3e_g^0$ electronic configuration of the iron atoms. Demazeau et al.⁴⁹ stabilised the 'unusual' iron(V) valence state by introducing lithium cations, which strengthen the $\text{Fe}-\text{O}$ bond by means of the six weakly competing $\text{Li}-\text{O}$ bonds in the octahedron of the perovskite structural type.

Another example is the synthesis of the K_2NaPdF_6 fluoride phase.⁵⁰ The authors stabilised the palladium (III) ion in the $t_{2g}^6e_g^1$ electronic configuration, which is intermediate between the stable $t_{2g}^6e_g^0$ [Pd(IV)] and $t_{2g}^5e_g^2$ [Pd(II)] configurations, by the deformation of the elpasolite (K_2NaAlF_6) structural type. In the K_2NaPdF_6 lattice, the [PdF_6] octahedra are extended compared with the [AlF_6] octahedra, which also promotes stabilisation of the $t_{2g}^6e_g^1$ state.

After the discovery by Bednorz and Muller⁵¹ of high-temperature superconductivity (HTSC) in the compounds $\text{La}_{2-x}\text{Ba}_x\text{CuO}_4$ with a perovskite-like structure, crystal-chemical data became the basis of the search for subsequent generations of materials with higher critical temperatures (T_c) of the transition to the superconducting state. The structures of the superconducting phases have been examined in detail in a number of reviews.^{52–54} By selecting the ionic radii and the oxidation states of the cations within the framework of the perovskite structural type, the copper-containing superconducting oxide materials $\text{Bi}_2\text{Sr}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_{2n+4}$,^{55,56} $\text{Ti}_2\text{Ba}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_{2n+4+\delta}$,^{57,58} $\text{Pb}_2\text{Sr}_2\text{R}_x\text{Cu}_3\text{O}_{8+\delta}$ ($\text{R} = \text{rare earth}, \text{Y}; \text{M} = \text{Ca}, \text{Sr}$),⁵⁹ and $\text{HgBa}_2\text{CuO}_{4+\delta}$ (see Ref. 60) were in fact synthesised. The conductivity in these phases is ensured by the two-dimensional (CuO_2) layers.

Many superconducting compounds have the composition $\text{A}_m\text{M}_2\text{R}_{n-1}\text{Cu}_n\text{O}_x$, where $\text{A} = \text{Bi}, \text{Ti}, \text{Pb}, \text{or Hg}$, $\text{M} = \text{Ba or Sr}$, $\text{R} = \text{Ca or rare earth}$, and $m = 1$ or 2 . They are made up of (AO), (MO), (BO), and (CuO_2) layers alternating along the c axis of the unit cell. An increase in the number of (CuO_2) layers in one block of the structure (usually to three) leads to an increase in the critical temperature T_c . The problem of the synthesis of multilayered structures of the 'puff pastry' type arose in this connection. This can be achieved by means of a layer-by-layer arrangement of the 'dielectric' blocks and CuO_2 layers. However, a necessary condition for the formation of such structures is that the distances in different layers are commensurate. This is particularly important for the (CuO_2) and (MO) layers, where the ratio $d_{\text{M-O}}:d_{\text{Cu-O}}$ must be approximately equal to $\sqrt{2}$.⁷⁴ In the layered HTSC cuprates, where the distance $d_{\text{Cu-O}}$ varies from 1.9 to 1.98 \AA , the distance $d_{\text{M-O}}$ should be 2.69–2.80 \AA , i.e. the cations M may be Ba^{2+} , Sr^{2+} , and La^{3+} . Such crystal-chemical preconditions served as a basis for the construction of the mercury-containing compounds $\text{HgBaRCu}_2\text{O}_{6+\delta}$ ($\text{R} = \text{rare earth}$)⁶¹ and of superconductors of a new class⁶⁰ with the record-breaking critical temperatures $T_c = 135\text{--}164 \text{ K}$.

The dimensions of the polyhedra in the structure make it possible to predict the positions of the cations in the lattice and their mobilities. Thus, in the case of superionic conductors with the NASICON structure,^{33,62–64} it is possible to show on the basis of structural information that decrease in the size of the structure-forming cation (M) hinders the migration of the mobile sodium ions within the channels of the structural framework. The corresponding weakening of ionic conductivity has been observed experimentally on passing from $\text{Na}_3\text{Zr}_2(\text{SiO}_4)_2\text{PO}_4$ ($\sigma_{300^\circ\text{C}} = 0.2 \Omega^{-1} \text{ cm}^{-1}$)^{33,62} to $\text{Na}_3\text{MgZr}(\text{PO}_4)_3$ ($\sigma_{300^\circ\text{C}} = 0.16 \Omega^{-1} \text{ cm}^{-1}$) and $\text{Na}_3\text{MnZr}(\text{PO}_4)_3$ ($\sigma_{300^\circ\text{C}} = 5.5 \times 10^{-4} \Omega^{-1} \text{ cm}^{-1}$).³⁸ The radii of the structure-forming cations with $\text{CN} = 6(r_{\text{VI}})$ are 0.72 \AA for Zr^{4+} , 0.83 \AA for Mn^{2+} , and 0.72 \AA for Mg^{2+} . On substitution of the tetravalent cation by a divalent one, the channels within the structure decrease with a corresponding diminution of conductivity. An analogous increase in conductivity is observed in $\text{Na}_3\text{M}_2(\text{PO}_4)_3$ on increase in the radius of the cation M .

Cation	$r_{VI}/\text{\AA}$	$\sigma_{570} \text{ } ^\circ\text{C}/\Omega^{-1} \text{ cm}^{-1}$	Ref.
Cr^{3+}	0.615	7.8×10^{-3}	65
Fe^{3+}	0.645	9.8×10^{-3}	65
Sc^{3+}	0.745	5.0×10^{-2}	66

It follows from the examples presented that information about the dimensions of the channels makes it possible to alter deliberately the conductivity in structures of the NASICON type. Thus the analysis of vacancies made it possible to discover channels in which the sodium cations migrated from their narrowest sites.^{67–69} Later a similar scheme was also proposed in other investigations.^{70–72}

A structure of the NASICON type has a high capacity in relation to metal cations. This promotes the formation of a large number of compounds of this structural type having different compositions but identical structures. In the lattice of the NASICON type with the crystal-chemical formula $A'M_2(EO)_4$ ($E = \text{P, As, Si, Ge}$), heterovalent and isovalent substitutions can be carried out at the A' , A , M , and E sites. The occupations of the A' and A sites may vary from 1 [in $\text{Na}_4\text{Zr}_2(\text{EO}_4)_3$]^{39, 40} to 0 [in $\text{Sc}_2(\text{MoO}_4)_3$].⁴¹ Monovalent [Li, Na, K, Cu ; $A'M_2(\text{PO}_4)_3$],^{35–38, 73–78} divalent [Ca, Sr, Ba, Cu ; $A_{0.5}M_2(\text{PO}_4)_3$],^{79–82} and trivalent [Ln ; $A_{1/3}M_2(\text{PO}_4)_3$]⁸³ cations can enter these positions. Tetravalent ($\text{Zr, Hf, Ti, Ge, Sn}$)^{39, 40, 74–86} and trivalent [$\text{Sc, Cr, Fe, Ga, V, In}$; $A_1M(\text{PO}_4)_3$]^{65, 67, 68, 80, 87–89} cations can enter the M positions. These positions can also be occupied by cations with different valences, for example divalent and trivalent [$M^{II} = \text{Mg, Zn}$; $M^{III} = \text{Sc, Cr}$; $\text{Na}_{2x}M_{2x}\text{Sc}_{2-2x}(\text{PO}_4)_3$, $\text{Na}_{3+x}\text{Cr}_{2-x}\text{Mg}_x(\text{PO}_4)_3$],^{37, 90} trivalent and tetravalent [$M^{III} = \text{Cr, Fe, Ga, In, Ti}$; $M^{IV} = \text{Ti, Zr}$; $A^{II}M^{III}M^{IV}(\text{PO}_4)_3$],^{79, 80} as well as tetravalent and pentavalent [$\text{Nb}^V\text{Ti}^{IV}(\text{PO}_4)_3$ and $\text{Nb}^V\text{Nb}^{IV}(\text{PO}_4)_3$]^{34, 91} cations. The compositions of the compounds listed above have been modelled on the basis of crystal-chemical data. The introduction of cations with different sizes and in different oxidation states influences appreciably the mobility of the type A cations in the three-dimensional cavity framework.^{65, 66, 92} The latter fact is important for the preparation of solid electrolytes with specified electrophysical characteristics.

The ability of the $\{[M_2(\text{EO}_4)]^p\}_{3\infty}$ framework to retain the cations of one element in different oxidation states at an A site (for example Cu^+ (see Refs 93–95) and Cu^{2+} (see Ref. 82)) promotes the occurrence of reversible redox reactions ($\text{Cu}^{2+} + e \rightleftharpoons \text{Cu}^+$),⁹⁶ which is a precondition for the application of these materials as catalysts, for example in the dehydrogenation of butanol.⁹⁷

Yet another example of the synthesis of compounds with a specified structure by means of isovalent substitution based on crystal-chemical data is the synthesis of the compounds $M_2M'R(\text{PO}_4)_2$ having structures analogous to that of glaserite with $M-M'$ combinations: potassium–rubidium, potassium–cesium, and rubidium–cesium.^{6, 9, 98} In conformity with the crystal-chemical formula of the glaserite-like structure $X^{[12]}Y_2^{[10]}M^{[6]}(\text{EO}_4)_2$, the chemical composition of the compounds was chosen in such a way that the number of alkali metal cations with a larger radius is two times smaller than that of the alkali metal cations with a smaller radius. This relation was established on the basis of the number of $X^{[12]}$ and $2Y^{[10]}$ sites in the glaserite type structure.¹ According to the results of structural analysis, the alkali metal cation with the larger radius in the glaserite-type structure occupies the more capacious $X^{[12]}$ site. Depending on the set of alkali metal cations, different types of distortions of the glaserite structure occur in the compounds under discussion.

Analysis of the dimensions of the polyhedra and of their number in the $\beta\text{-Ca}_3(\text{PO}_4)_2$ structure,⁹⁹ which belongs to the structural type of the mineral whitlockite $\text{Ca}_{18.19}\text{Mg}_{1.17}\text{Fe}_{0.83}\text{H}_{1.62}(\text{PO}_4)_{14}$,⁴⁶ made it possible to model the new compounds $\text{Ca}_9(\text{PO}_4)_7$ ($R^{3+} = \text{Ln, Y, Bi, Sc, Cr, Fe, In}$),^{100–103}

$\text{Ca}_{10}\text{M}(\text{PO}_4)_7$ ($M = \text{Li, Na, K, Cu}$),^{104, 105} and $\text{Ca}_9\text{MgM}(\text{PO}_4)_7$ ($M = \text{Li, Na, K}$)¹⁰⁶ and to predict a wide region corresponding to the ternary phosphates in the $\text{Ca}_3(\text{PO}_4)_2\text{--RPO}_4\text{--M}_3\text{PO}_4$ systems.¹⁰⁷ Cations with different dimensions and oxidation states (from +1 to +4) form part of the composition of the whitlockite-type crystal lattice.

Analysis of whitlockite like structures made it possible to predict the occurrence of reversible redox reactions. Such reactions proceed without the destruction of the crystal lattice but with a change in the oxidation state of the transition metal cation. The reduction reaction is accompanied by the incorporation of a proton in the crystal lattice, while the oxidation reaction involves its elimination.^{108–110} The corresponding reactions proceed in accordance with the following schemes:

The materials in the crystal lattice of which reversible redox reactions take place may be used as catalysts,^{111–115} intermediates for the two-stage oxidation of hydrogen,^{116, 117} and sensors.¹¹⁸

Crystal chemistry makes it possible to interpret successfully and to predict the formation of different phases in oxide systems exhibiting a complex polymorphism. Such compounds have valuable practical properties (luminescent, magnetic, ferro-elastic, piezo- and ferro-electric, and catalytic), which are often successfully combined in a single material. The properties of such complex systems cannot be always predicted, but the use of crystal-chemical data makes it possible to solve successfully certain controversial problems.¹¹⁹

The $\text{Ca}_3(\text{PO}_4)_2\text{--Ca}_2\text{SiO}_4$ system is important in the processing of natural phosphate raw material and in the metallurgy of converter slags. The experimental data obtained by different authors^{120–124} concerning the regions of existence of individual phases in the system are extremely contradictory and it has been possible to interpret them correctly only by employing data on the structures of the individual phases of the system.¹²⁵ Furthermore, crystal-chemical data made it possible to justify on a scientific basis the use of various additives in the formation of a charge for the preparation of phosphate fertilisers with the maximum solubility in 2% citric acid solution^{110, 125–130} and hence to avoid additional studies concerning the search for the optimum charge composition.

The examples quoted demonstrate that crystal-chemical data can be used effectively for the prediction of the compositions of new compounds with specified physicochemical properties.

III. Construction of compounds with a new composition

In the modelling of new phases on the basis of crystal-chemical data, analysis of the dimensions of the occupied and vacant polyhedra and of their number is important in the first stage. The outcome of such analysis is the crystal-chemical formula of an individual structure or structural type on the basis of which the composition of the possible phases may be predicted by means of iso- or hetero-valent substitutions, taking into account the formal valences and dimensions of the cations. In addition, the dimensions of the ions and polyhedra in this structure make it possible to predict the positions of the atoms in the lattices.

The characteristic features of the structures of a series of structural types with tetrahedral anions, which will be used for the modelling of the compositions of compounds with specified structures and properties, are discussed below. The generalised data, obtained as a result of such analysis, provide an algorithm for the modelling of new compounds and their properties.

1. The glaserite $K_3Na(SO_4)_2$ structural type

The glaserite structural type is common among inorganic salts with tetrahedral anions. Two types of columns directed along the $\bar{3}$ axis are differentiated in the glaserite crystal lattice (Figs 1 and 2): cationic (C) and mixed cationic-anionic (A). The A column is made up of alternating (EO_4) tetrahedra and YO_{10} polyhedra: $\dots - YO_{10} - EO_4 - YO_{10} - \dots$ (Fig. 1). The cation in the Y position is surrounded by ten oxygen atoms: four of these are close (three belong to the face of a single tetrahedron, the fourth apical oxygen — on the $\bar{3}$ axis — belongs to another tetrahedron), while six are remote (the edges of three tetrahedra are disposed along the equator) (Fig. 3b). The coordination number of this site can be formulated as $Y^{[4+6]}$.

The C columns in the glaserite-like structures are made up of octahedra and dodecahedra: $\dots - MO_6 - XO_{12} - MO_6 - \dots$. The atom at the M site is surrounded by six oxygen atoms (one atom each from the six tetrahedra) and its coordination number can be formulated as $M^{[6]}$ (Fig. 3d). The atom at the X site is surrounded by six nearest oxygen atoms (one oxygen atom each from the six tetrahedra) and six more remote apical oxygen atoms and its coordination number can be specified as $X^{[6+6]}$ (Fig. 3a). The crystal-chemical formula for glaserite-like structures can be written as $X^{[6+6]}Y_2^{[4+6]}M^{[6]}(EO_4)_2$. The cations K^+ in the $K_3Na(SO_4)_2$ structure occupy the large $X^{[6+6]}$

and $Y^{[4+6]}$ polyhedra, whilst the cations Na occupy the $M^{[6]}$ polyhedra.

The two neighbouring cationic-anionic type A columns in the glaserite-like structures have different orientations of the EO_4 tetrahedra along the $\bar{3}$ axis [with the apical oxygen atoms pointing downwards or upwards (Fig. 1)]. Each type C column is surrounded by three type A columns, in which the tetrahedra are oriented in such a way that the apical oxygen atoms are directed downwards, and by three columns with tetrahedra in which the apical oxygen atoms are directed upwards (Fig. 2). The greatest amount of information about the positions of the tetrahedra and the cations is contained in the projection of the glaserite-like structure on to the $(1\bar{1}1)$ plane. Henceforth we shall compare layers which are arranged around this plane. The glaserite structure can be constructed from such layers, two neighbouring layers being displaced relative to one another by $1/2$ of a translation along the c axis, while two neighbouring A columns in the layer have the opposite orientations of the tetrahedra (Fig. 1).

It follows from the analysis of the surroundings of the $X^{[12]}$, $Y^{[10]}$, and $M^{[6]}$ sites that in a glaserite-like structure¹ with the composition $M_3M'(EO_4)_2$ there are three large polyhedra ($X^{[12]} + 2Y^{[10]}$) and one small polyhedron ($M^{[6]}$). This structural type is characteristic of salts in which the large cation:small cation ratio is 3:1. This ratio as well as the dimensions of the cations

Figure 1. The layers in the $K_3Na(SO_4)_2$ and $\beta-K_2SO_4$ structural types.

(a) $K_3Na(SO_4)_2$; (b) $\beta-K_2SO_4$; (c) $\beta-Ca_2SiO_4$; (d) $Ca_3Mg(SiO_4)_2$; (e) $Ca_5(PO_4)_2SiO_4$; (f) $6Ca_2SiO_4 \cdot Ca_3(PO_4)_2$; (g) $\alpha-Ca_3(PO_4)_2$.

Sites: (1) $M = Na^+$ or Mg^{2+} cations; (2) $X = Ca^{2+}$ or K^+ cations; (3) and (4) $Y = Ca^{2+}$ or K^+ cations.

(a) $K_3Na(SO_4)_2$; (b) $\beta-K_2SO_4$; (c) $\beta-Ca_2SiO_4$; (d) $Ca_3Mg(SiO_4)_2$; (e) $Ca_5(PO_4)_2SiO_4$; (f) $6Ca_2SiO_4 \cdot Ca_3(PO_4)_2$. The unit cells are differentiated.¹²⁵

are of fundamental importance in the formation of a glaserite-like structure. If the $K_3Na(SO_4)_2$ structure is adopted as a basis, then the difference Δr between the radii of potassium [$r_{XII}(K) = 1.64 \text{ \AA}$] and sodium [$r_{VI}(Na) = 1.02 \text{ \AA}$] is approximately 0.6 \AA . In this case, an ideal arrangement is achieved. When this difference is altered (a set of other cations is adopted), the structure is distorted (Table 1). It may be metastable ($\Delta r = 0$) when the radii of the cations at the X, Y, and M sites are identical, as happens, for example, in $\alpha-Ca_2SiO_4$ (see Ref. 131) and $\alpha'-Ca_3(PO_4)_2$.¹³² These two phases crystallise in the glaserite-like structural type and exist only at high temperatures. Under the usual conditions, they crystallise in the $\beta-K_2SO_4$ structural type,¹⁰ which will be described below.

Figure 3. The $X^{[6+6]}$ (a), $Y^{[4+6]}$ (b), $X^{[6+3]}$ (c), and $M^{[6]}$ (d) polyhedra in the glaserite, palmierite, and $\beta-K_2SO_4$ structural types.¹¹⁰

With increase in the difference Δr , the symmetry of the cell may be reduced to monoclinic,² as happens, for example, in $Rb_3Sc(PO_4)_2$ [$r_{XII}(Rb^+) = 1.72 \text{ \AA}$, $r_{IX}(Sc^{3+}) = 0.745 \text{ \AA}$]. In this case, Δr has the maximum value of 0.97 \AA among those known for glaserite-like phases. The minimum value $\Delta r = 0.59 \text{ \AA}$ is observed for $BaNaPO_4$.¹³⁴ In the $Ca_3Mg(SiO_4)_2$ (merwinite) crystal lattice,¹³³ the positions of the tetrahedra are the same, apart from small rotations, as in the glaserite-like structure (Fig. 1). The Mg^{2+} cations occupy the M site, while the Ca^{2+} cations occupy the X and Y sites. Thus the partial replacement of Ca^{2+} by Mg^{2+} in calcium α -silicate leads to the formation of a stable glaserite-like structure.

The glaserite structural type is stable for compounds in which the difference between the radii of the cations occupying the M and X(Y) sites is in the range $0.59 \leq \Delta r \leq 0.89 \text{ \AA}$. With decrease in this difference, metastable glaserite-like structures or compounds crystallising in the $\beta-K_2SO_4$ structural type are formed.¹⁰ The upper limit can apparently reach 0.98 \AA . However, these data are unreliable, since the $Rb_3Sc(PO_4)_2$ structure, for which $\Delta r = 0.98 \text{ \AA}$, has not been investigated. In the case of cations with a small radius, characterised by an octahedral environment, the above difference Δr gives rise to the formation of the glaserite structural type. With increase in its radius, the small cation tends to increase the size of its coordination polyhedron and hence to alter the structural type. This conclusion can be well illustrated for compounds of the $K_3R(PO_4)_2$ series. Thus $K_3Lu(PO_4)_2$ (see Ref. 5) belongs to the glaserite structural type, whilst $K_3Nd(PO_4)_2$ (see Ref. 7) belongs to the $\beta-K_2SO_4$ structural type. According to Kalinin's data,² the glaserite structural type is stable for compounds with $R = Gd - Lu$.

It follows from the analysis of the distances in the polyhedra of the glaserite-like phases that the large cation:small cation ratio may also be 1:1. Thus a small cation, for example, sodium can also enter the $X^{[6+6]}$ position. Such a position of sodium (at the X and M sites) has been found in the crystal structures of $KNaSO_4$ (see Ref. 1) and $BaNaPO_4$.¹³⁴ Compounds with a

^a The crystal structure has been determined.

similar composition have been found among tungstates and molybdates, for example MR(EO₄)₂ with M^I = K or Rb and R^{III} = Al, Sc, Fe, Cr, or In.¹³⁵ Thus the formation of the crystal lattice in the structural type under discussion depends both on the ratio of the radii of the cations and on their number.

Having at one's disposal data on the structure of K₃Na(SO₄)₂ and knowing the radii of the cations, it is possible to predict the compositions of a series of compounds which may crystallise in the glaserite structural type. Thus, the substitution of SO₄²⁻ by MoO₄²⁻, EO₄³⁻ (E = P, V, As), and EO₄⁴⁻ (E = Si, Ge) and the selection of the corresponding cations in order to maintain electroneutrality may be expected to result in the formation of the compounds M₃Na(MoO₄)₂, M₃R(EO₄)₂ (M' = K, Rb; R = Ln, Y, Sc; E = P, V, As), M₃M(SiO₄)₂ (M' = Ba, Sr, Pb; M = Mg, Cu) and BaCa₂Mg(SiO₄)₂. Some of them have been described above. The characteristic features of the structures and the physicochemical properties of some of the glaserite-like phases have been described in detail.^{2-6, 8, 9, 79, 135}

2. The β-K₂SO₄ structural type

The β-K₂SO₄ structure is made up of cationic (C) and anionic (A) columns (Fig. 1)¹⁰ similar to the columns in the glaserite structure. In the type A column (...-EO₄-YO₁₀-EO₄-...), the coordination polyhedra are retained, whilst in the type C column (...-XO₉-XO₉-...) they are changed.

The cationic column in β-K₂SO₄ (see Ref. 10) is surrounded by four type A columns with a single orientation of the tetrahedron and by two such columns with a different orientation (Fig. 2). This results in the formation of a structure in which layers with a single orientation of the tetrahedra alternate with layers having tetrahedra with the opposite orientation (Fig. 1). In contrast to glaserite, in the structure of which two neighbouring tetrahedra from two type A columns always have the opposite orientations, in the β-K₂SO₄ structure the two neighbouring tetrahedra can have both identical or opposite orientations of the tetrahedra along the *c* axis of the unit cell (Fig. 1), i.e. on passing from glaserite to β-K₂SO₄ the orientation of some of the tetrahedra is reversed. As a result of the rotation of the tetrahedra, the unit cell symmetry is reduced from trigonal to orthorhombic, while the environment of the Y site in the A column is retained (Fig. 3*b*). The rotation of the tetrahedra in no way affects the positions of the E and Y sites on the threefold 'pseudoaxis', while the X site is displaced from this 'pseudoaxis'. The coordination numbers of the X and M sites in the C column are changed. These sites in the β-K₂SO₄ structure become equivalent and the immediate octahedral (as in glaserite) arrangement of the surrounding oxygen atoms from six tetrahedra is retained for these sites. When account is taken of the three more remote apical oxygen atoms, the coordination number of these sites (X and M) becomes nine — X^[6+3] (Fig. 3*c*). The crystal-chemical formula of the β-K₂SO₄ structural type is X^[6+3]Y^[4+6]EO₄.

It follows from the analysis of the X—O and Y—O distances in the XO₉ and YO₁₀ polyhedra that the β-K₂SO₄ structural type is more stable for cations with similar radii. Iso- and hetero-valent substitutions in the cationic and anionic sublattices of the β-K₂SO₄ structure may lead to compounds having different compositions. After the substitution of SO₄²⁻ by EO₄²⁻ (E^{VI} = Mo, W), EO₄³⁻ (E^V = P, V, As), and EO₄⁴⁻ (E = Si, Ge), it is necessary to select cations such that the ratio of their radii differs little from unity (Table 2). The formation of the β-K₂SO₄ structural type is promoted by cations tending to achieve an octahedral environment. The latter is associated with the fact that the X site in the most immediate environment must have six oxygen atoms (a distorted octahedron) and the long X—O distances in this octahedron promote the incorporation in the latter of cations with a radius greater than 0.9 Å.

β-Ca₂SiO₄ is constructed similarly to β-K₂SO₄.¹³⁶ The substitution of potassium by calcium and of SO₄²⁻ by SiO₄⁴⁻ is accompanied by a monoclinic distortion of the ideal β-K₂SO₄ structure. As can be seen from Fig. 2, on passing from β-K₂SO₄ to β-Ca₂SiO₄, the tetrahedra rotate and the reflection plane disappears. Owing to the rotation of the tetrahedra, eight oxygen atoms (one each from the six tetrahedra and two apical oxygen atoms) located at a distance of 2.36–2.80 Å, and a further one oxygen atom, separated by a distance of 3.25 Å, enter the first coordination spheres of the Ca²⁺ ions occupying the X sites. The coordination number of this site can be formulated as X^[8+1]. Furthermore, the rotation of the tetrahedra alters the immediate environment of the metal atom at the Y site: six oxygen atoms are accommodated in the first coordination sphere at distances of 2.30–2.75 Å, whilst the other four oxygen atoms, which build up the Y polyhedron to a decahedron, form the second coordination sphere with distances *d*_{Y-O} = 2.98–3.30 Å. The rotations of the tetrahedra also bring the two apical oxygen atoms closer to the Y site (*d*_{Ca-O} = 3.48 and 3.56 Å). In β-K₂SO₄ they are separated by more than 4 Å. The coordination polyhedron of the Ca²⁺ cations at the Y site in the β-Ca₂SiO₄ structure can be formulated as Y^[6+4+2], whereupon the crystal-chemical formula assumes the form X^[8+1]Y^[6+4+2]EO₄. The idealised formula is X^[9]Y^[10]EO₄, as in the β-K₂SO₄ structure. The layers in the two structures are similar (Fig. 1).

The γ-, β-, α_L-, α_H- and α-polymorphic modifications have been observed for Ca₂SiO₄.¹³⁷ The characteristic features of the structures of the polymorphic calcium orthosilicate modifications have been described in detail.^{131, 138, 139} The α_H-Ca₂SiO₄ phase is isostructural with α'-Sr₂SiO₃¹³⁹ and α'-Sr_{1.9}Ba_{0.1}SiO₄.¹⁴⁰ and has a structure of the undistorted β-K₂SO₄ type. The α_L-Ca₂SiO₄ structure is intermediate between β-Ca₂SiO₄ and β-K₂SO₄ and is apparently constructed similarly to the calcium silicophosphate 6Ca₂SiO₄·Ca₃(PO₄)₂ with partially ordered layers.¹⁴¹ The α_H-Ca₂SiO₄ structure is similar to the undistorted β-K₂SO₄ structure. According to

Table 2. X-Ray diffraction characteristics of certain phases based on the β -K₂SO₄ structure.

^a The crystal structure has been determined.

Kozak et al.¹³¹ the $\alpha'_H \rightarrow \alpha$ polymorphic transition can occur as a result of the jump of the 'small' Si⁴⁺ cation from its tetrahedron to a neighbouring vacant tetrahedron, which ultimately appears as rotation of the tetrahedra. As a result of such a jump, the structure of α -Ca₂SiO₄ corresponds to that of the ideal glaserite. The cationic positions are fully occupied in the crystal lattices of all the polymorphic modifications of calcium silicates.

In the β -K₂SO₄ structural type, substitutions in both cationic and anionic components are possible. For example, the compound β -K₂PO₃F, isostructural with β -K₂SO₄, has been synthesised.¹⁰ The structures of compounds with vacancies in the cationic sublattice, for example the calcium silicophosphates formed in the Ca₂SiO₄-Ca₃(PO₄)₂ system, have been described.^{19, 22, 141}

Two crystal structures have been determined for calcium silicophosphates: 6Ca₂SiO₄·Ca₃(EO₄)₂ (see Ref. 141) and Ca₅(PO₄)₂SiO₄.¹⁹ The 6Ca₂SiO₄·Ca₃(PO₄)₂ structure belongs to the β -K₂SO₄ structural type. Four-layer fragments along the [010] direction can be differentiated in it (Figs 1 and 2). Three layers are the same as in the β -Ca₂SiO₄ structure, whilst the fourth layer differs little from the layer in β -K₂SO₄. A similar alternation of distorted and undistorted (weakly distorted) layers has been found in Cd₅(PO₄)₂EO₄ (E = Si, Ge),²⁰ Cd₄Na(PO₄)₃,²¹ and α -Ca₃(PO₄)₂.²² We may note that the Y sites in the undistorted layer of these structures are vacant. Taking into account the latter factor, one may claim that the Y sites in the 6Ca₂SiO₄·Ca₃(PO₄)₂ structure are half-occupied in one layer (Fig. 1), while in the remaining layers they are still fully occupied (Fig. 2). This structure can be obtained by the alternation of the three occupied layers and one layer with a half-occupied site. The coordination numbers of the Y site vary from 7 to 10, whilst those of the X site are 7 and 8.

The structure of silicocamotite Ca₅(PO₄)₂SiO₄ can also be built up by alternating the layers (two with a occupied Y site and one with an vacant Y site) (Figs 1 and 2).¹⁹ The two occupied layers resemble in this instance the analogous layers in β -Ca₂SiO₄, while the layer with an vacant Y site corresponds to the layer in the β -K₂SO₄ structure. Appreciable rotation and shifts of the tetrahedra from the ideal sites are observed in the occupied layers, whereas in the vacant layer the vacancies in the

type A column promote the 'ideal' arrangement of the tetrahedra.

The maximum distortion of the type β -K₂SO₄ lattice is observed in α -Ca₃(PO₄)₂.²² An ordered occupation of the Y sites in type A columns occurs in this structure (Fig. 2). The tetrahedra in this structure are intermediate between the ideal positions in the β -K₂SO₄ and the glaserite structures. This is manifested also in the coordination numbers of calcium, which vary from 6 to 10. The intermediate structure α -Ca₃(PO₄)₂ has also been confirmed by the arrangement of the cations in the type C column, where some of the calcium cations are located virtually on the threefold 'pseudoaxis', whilst the others are arranged as in β -K₂SO₄ (Fig. 1).

At a temperature above 1723 K, the α -Ca₃(PO₄)₂ phase undergoes a transition to the α' -modification.¹³² One may postulate that this modification is built up on the basis of the glaserite and not the β -K₂SO₄ structure. This conclusion was confirmed by the fact that a continuous series of solid solutions is formed at high temperatures (>1723 K) between α -Ca₂SiO₄ and α' -Ca₃(PO₄)₂,¹²⁰⁻¹²³ which is possible only when the components of the system are isostructural.

It follows from the data presented that the β -K₂SO₄ structural type is more stable also in the presence of vacancies in the cationic sublattice. These vacancies are present only in the mixed anionic-cationic column (the Y site).^{22, 141} The maximum number of vacancies occurs in α -Ca₃(PO₄)₂.²² In the α -Ca₃(PO₄)₂ lattice, the Y site is half-occupied. In the compounds Cd₄Na(PO₄)₃ (see Ref. 21) and Cd₅(PO₄)₂EO₄ (E = Si, Ge),²⁰ there is an intermediate occupation of the Y site, as in the case of Ca₅(PO₄)₂SiO₄.¹⁹ The different degrees of occupation of the Y sites in these phases are clearly reflected by their crystal-chemical formulae: X₂Y□(PO₄)₂ and X₃Y₂□(EO₄)₃.

With increase in the number of vacancies in the crystal lattice, the distortion of the type β -K₂SO₄ structure increases and in the silicophosphates the following features are observed: (1) the layers in which the Y sites are vacant or are partly occupied correspond to the ideal layers in β -K₂SO₄ (Figs 1 and 2); (2) neighbouring layers with fully occupied Y sites are distorted owing to the rotation of the tetrahedra. The individuality of the cation exerts a lesser influence on the crystal lattice. Thus Cd₄Na(PO₄)₃ (see Ref. 21) and Ca₅(PO₄)₂SiO₄ (see Ref. 19) have identical structures although they have different

sets of cations, but the degree of occupation of the Y sites is the same.

The distortion of the type β -K₂SO₄ structure is mainly associated with the rotation of the tetrahedra, which has been confirmed by luminescence spectroscopic studies of solid solutions in the MNaPO–Na₂Eu(PO₄)₂ (M = Ca, Sr) systems.^{142, 143} The authors note that the broadening of the lines in the luminescence spectra is associated with the rotation of the PO₄^{3–} tetrahedra without change in the cationic sublattice. The X-ray diffraction patterns of solid solutions in the MNaPO–Na₂Eu(PO₄)₂ (M = Ca, Sr) system are identical. On the other hand, three (for M = Ca) and two (for M = Sr) composition ranges with identical spectra have been differentiated in the luminescence spectra of these solid solutions.

Heterovalent substitution in accordance with the scheme

leads to the formation of the compounds M'MPO₄ (rhenanites). There are data on the crystal structures of the compounds γ -, β -, and α -NaSrVO₄,¹⁴⁴ NaBaPO₄,^{134, 135} KBaPO₄,^{17, 146} TlBePO₄,¹⁴⁷ and β -CaNaPO₄.¹⁸ Only the crystal structures of KBaPO₄ and β -CaNaPO₄ are of the β -K₂SO₄ type. In these structures, the alkali metal cations occupy the Y site, while the alkaline earth metal cations occupy the X site (Fig. 4). In the β -CaNaPO₄ structure, the type A column contains three different PO₄^{3–} tetrahedra. This increases the parameter *a* by a factor of three compared with that in β -K₂SO₄. As a result of the rotations of the tetrahedra in this structure, the coordination numbers of the Y and X sites change. In the β -CaNaPO₄ structure, the sodium cation is surrounded by six oxygen atoms in the immediate vicinity (up to 2.8 Å) or by ten oxygen atoms when more remote ones (up to 3.3 Å) are taken into account. The *d*_{Ca–O} distances in the cationic C column are 2.39–2.79 Å. The coordination polyhedron consists of eight oxygen atoms.

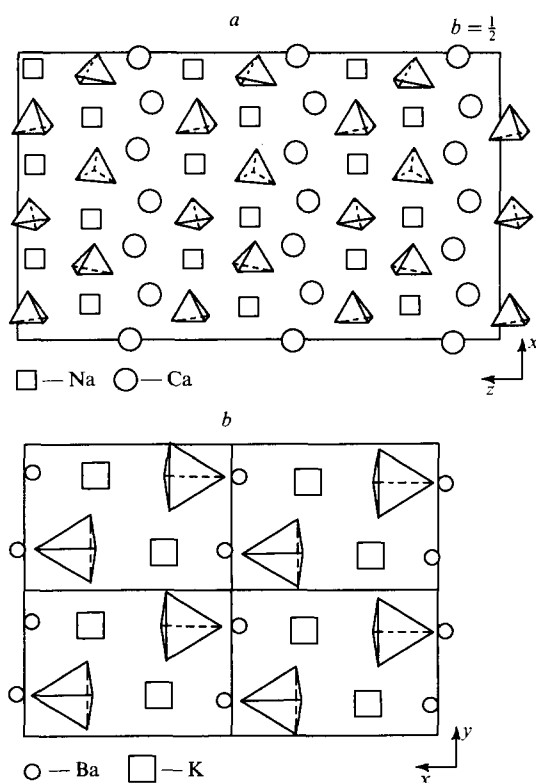

Figure 4. The layers in the β -CaNaPO₄ (a)¹⁸ and BaKPO₄ (b)¹⁷ structures.

As noted above, a large group of compounds with the composition Na₃R(EO₄)₂ (R = rare earth; E = P, V, As) crystallises in the β -K₂SO₄ structural type. Eight varieties of this structural family are distinguished (Fig. 5).¹⁶

The cations alternate in the same sequence in the compounds Na₃R(EO₄)₂. The lanthanide and sodium cations occupy the X site in an ordered manner (...–Na–R–Na–...). The Y site is occupied by sodium cations. Depending on the set of elements in the compounds, the crystal lattice is subjected to different distortions induced by the rotation of the EO₄ tetrahedra. The coordination polyhedra of the cations change as a result of the rotation of the tetrahedra (6–7 for Na, 6–8 for R). The rotation of the tetrahedra is induced by the tendency of sodium and lanthanide cations to assume smaller and larger coordination numbers respectively than those 'inherent' in the ideal β -K₂SO₄ structure.

It is noteworthy that the distortions of the crystal lattice in the compounds Na₃R(EO₄)₂ become more pronounced with increase in Δr (Table 2). For Na₃R(PO₄)₂ with R = Tm, Yb, or Lu, the structural type under discussion does not occur owing to the tendency of the lanthanide cations at the end of the series to acquire an environment comprising six oxygen atoms. The high-temperature modifications of Na₃R(PO₄)₂ (R = Tm–Lu)¹⁴⁸ crystallise similarly to the NASICON structural type.⁷³

Figure 5. The regions of existence of the Na₃R(EO₄)₂ modifications, where E = P (a), V (b), As (c).¹⁶

The β - K_2SO_4 structural type is very common among phosphates, silicates, arsenates, and vanadates. The existence of a β - K_2SO_4 type structure with and without vacancies gives rise to extensive possibilities for substitution in the cationic and anionic groups without a reconstructive rearrangement of the structure. The compositions of compounds with the β - K_2SO_4 structure may include monovalent, divalent, and trivalent cations. Thus, one may expect the formation of the silicates $MRSiO_4$ ($M = Na, K$), the phosphates $MCa_4(PO_4)_3$ ($M = Na, K$), and other phases. Laborious studies on phase diagrams are not needed in this instance. For example, the existence of the compounds $NaPbPO_4$, $NaPb_4(PO_4)_3$, $AgPbPO_4$, and $AgPb_4(PO_4)_3$ could have been postulated also without studying the phase diagrams for the Na_3PO_4 - $Pb_3(PO_4)_2$ and Ag_3PO_4 - $Pb_3(PO_4)_2$ system.¹⁴⁹ Querton et al.¹⁴⁹ assigned the compounds $MPbPO_4$ ($M = Na, Ag$) and $MPb_4(PO_4)_3$ which they synthesised, to the β - K_2SO_4 and apatite structural types with vacancies respectively, but the unit cell parameters of all the compounds synthesised do not differ from the analogous parameters for potassium sulfate. Apparently the assignment of the compounds $MPb_4(PO_4)_3$ to the apatite and not the β - K_2SO_4 structural type should be regarded as erroneous, since, in view of the lack of $MPb_4(PO_4)_3$ single crystals, it was impossible to carry out a full X-ray diffraction study of these compounds.

As mentioned above, the β - K_2SO_4 structural type is stable for the compounds in which heterotypical cations (two or more) have similar radii. Such a structure obtains for the compounds $Na_3R(PO_4)_2$ ($R = La-Ho$),^{13,14} $CaNaPO_4$,¹⁸ and $KBaPO_4$.¹⁷ With increase in the difference between the radii of heterotypical cations, the glaserite-like structure, of the kind occurring, for example, in $BaNaPO_4$ (see Ref. 134) and $KNaSO_4$,¹ or the olivine structure, as in $NaMnPO_4$ (see Ref. 150) and $NaB^{II}PO_4$ ($B^{II} = Co, Fe, Mn, Gd$),¹⁵¹ becomes more stable. The features noted above, must be taken into account in modelling the compounds within the framework of the β - K_2SO_4 structural type.

3. The bredigite structural type

In the analysis of the structures of various modifications of $Na_3R(EO_4)_2$, there are difficulties in the assignment of the compounds to the β - E_2SO_4 or glaserite structural types. This applies particularly to compounds with large unit cells (Table 2). In such compounds, the tetrahedra have appreciably rotated away compared with the ideal arrangement. Some of them occupy, as it were, an intermediate position between their positions in glaserite and β - K_2SO_4 . For an appropriate selection of the cations, one can apparently expect the formation of a phase with a 'mixed' (glaserite and β - K_2SO_4) arrangement of the tetrahedra. The compositions of such compounds should include small ($<0.8 \text{ \AA}$), medium ($\sim 1 \text{ \AA}$), and large ($>1.2 \text{ \AA}$) cations.

Analysis of the literature data showed that such a compound does indeed exist and its composition corresponds to the general formula $(Ca, Ba, Mn)Ca_{13}Mg_2(SiO_4)_8$ (the mineral bredigite). The crystal structure of $Ca_{26.9}Ba_{0.6}Mg_{3.6}Mn_{0.9}(SiO_4)_{16}$ has been determined (space group $Pmch$, $a = 10.909 \text{ \AA}$, $b = 18.34 \text{ \AA}$, $c = 6.739 \text{ \AA}$, $Z = 2$).⁴⁴ The projections of the ideal and real structures of bredigite are presented in Fig. 6. This structure is made up of type A and C columns, as in β - K_2SO_4 and glaserite discussed above. The ideal crystal-chemical formula of the bredigite structural type, i.e. $X^{[12]}X_2^{[9]}Y_4^{[10]}M^{[6]}(EO_4)_4$ includes the polyhedra of the glaserite and β - K_2SO_4 structures in proportions of 1:2.

In the $Ca_{26.9}Ba_{0.6}Mg_{3.6}Mn_{0.9}(SiO_4)_{16}$ structure, there are two sets of independent sites, two sites in each set, namely $X^{[12]}$ and $X^{[9]}$ in one set and $Y^{[10]}$ and $M^{[6]}$ in the other. The cations are distributed among the sites in the following manner:⁴⁴ $X(1) = 0.707Ca^{2+} + 0.293Ba^{2+}$; $M(1) = 0.93Mg^{2+} + 0.07Mn^{2+}$; $Y(1) = 0.88Ca^{2+} + 0.12Mg^{2+}$. The remaining sites are occupied by calcium cations only. Owing to the rotations of the tetrahedra (Fig. 6), in the real structure the coordination

Figure 6. Projections of the bredigite structure on to the xy plane. Ideal (a) and real (b) arrangements.⁴⁴

numbers of the sites are smaller than in the ideal structure. However, when account is taken of the longer distances, they correspond to the coordination numbers of the sites in the ideal structure.

It has been established that the bredigite structure occurs also for the solid solutions in the range $(Ca_{1.8}Mg_{0.2})SiO_4$ - $(Ca_{1.7}Mg_{0.3})SiO_4$.^{19,152} If the formulae of the compounds $(Ca_{1.8}Mg_{0.2})SiO_4$ ¹⁹ and $(Ca_{1.7}Mg_{0.3})SiO_4$ (see Ref. 152) are adjusted to the composition reflecting the ideal crystal-chemical formula, they become $Ca_{7.2}Mg_{0.8}(SiO_4)_4$ and $Ca_{6.8}Mg_{1.2}(SiO_4)_4$. In the solid solutions between these phases, the $M^{[6]}$ site and one of the $Y^{[9]}$ sites are statistically occupied by magnesium and calcium cations. The remaining sites, $X^{[12]}$ and $Y^{[10]}$, are occupied by calcium cations only. The compound $Ca_7Mg(SiO_4)_4$ corresponds to the ideal formula of the bredigite structure (without a statistical occupation of the sites).

When account is taken of the dimensions of the X, Y, and M polyhedra, one may expect the formation of the compound $BaCa_6Mg(SiO_4)_4$, in which the cations occupy the following sites: $X^{[12]}$ by Ba^{2+} , $Y^{[10]}$ and $X^{[9]}$ by Ca^{2+} , and $M^{[6]}$ by Mg^{2+} . Apparently the ideal structure is not produced in this case. In order to obtain the ideal structure of the bredigite type, it is more likely to be useful to employ the compounds $K_3R(PO_4)_2$ (the compounds with $R = Sc$ or Lu have the ideal glaserite structure)^{5,6} and $KBaPO_4$ (with a structure of the β - K_2SO_4 type)⁷ or $BaNaPO_4$ (glaserite structural type)¹³⁴ and $KBaPO_4$ (type β - K_2SO_4 structure).¹⁷ In this case, one may expect the formation of the $Ba_2K_5R(PO_4)_4$ ($R = Lu, Sc$) and $Ba_4K_2Na_2(PO_4)_4$ phases respectively. In the latter compound,

the second sodium cation may occupy one of the Y sites together with Ba, as in the case of BaNaPO₄.¹³⁴

The modelling of the phases based on the bredigite structure examined above is important for the synthesis of compounds with the required physicochemical properties. Firstly, the combination of two structures with different coordination polyhedra into one structure makes it possible to introduce various cations into a lattice of this kind. The problem of the synthesis of multifunctional materials is thus solved. Secondly, the successive alternation of polyhedra of different structures makes it possible to increase the distances between like cations, preventing thereby their interaction, which may improve the physicochemical characteristics of the materials. The latter is important in the synthesis of phosphors and diamagnetic materials with cations having magnetic properties.

4. The palmierite K₂Pb(SO₄)₂ structural type

In contrast to α -Ca₃(PO₄)₂ (β -K₂SO₄ structural type), the phosphates of divalent elements with large radii, namely M₃(PO₄)₂ (M = Sr, Ba, Pb),^{26,153} Pb₄(PO₄)₂CrO₄,¹⁵⁴ and also the molybdate K₂Pb(MoO₄)¹⁵⁵ crystallise in the structural type corresponding to the natural mineral palmierite K₂Pb(SO₄)₂.²³ Barium and strontium vanadates and arsenates also belong to this structural type.^{25–27}

In the K₂Pb(SO₄)₂ structure, the potassium cation occupies the YO₁₀ decahedron, while the lead cation occupies the XO₁₂ dodecahedron. The XO₁₂ coordination polyhedron is formed by the edges of six tetrahedra (Fig. 3a). The X–O distances are divided into two types: six short distances (2.83–2.85 Å) form an appreciably extended (along the $\bar{3}$ axis) trigonal antiprism, while six long ones (3.4–3.5 Å to the apical oxygen atoms) are located in the equatorial plane of the antiprism. The symmetry of this polyhedron is $\bar{3}2/m$. XO₁₂ is adjoined below and above (along the $\bar{3}$ axis) by two YO₁₀ polyhedra (Fig. 7). They have triangular faces in common with the antiprism. The YO₁₀ polyhedron is formed by three edges of three tetrahedra (equatorial plane), three oxygen atoms in three other tetrahedra (at distances of ~ 3 Å), and one (apical) oxygen atom on the threefold axis (Figs 3b and 7).

Overall, the palmierite structure is made up of ...–YO₁₀–XO₁₂–YO₁₀–EO₄–EO₄–... columns and its crystal-chemical formula is X^[12]Y₂^[10](EO₄)₂. The Sr²⁺, Ba²⁺, and Pb³⁺ ions occupy the large XO₁₂ and YO₁₀ polyhedra.

At first sight, the existence of the double molybdates M₅R(MoO₄)₄ (M = K, Rb; R = rare earth, Bi, Y, Al, Fe), crystallising in the palmierite structural type, appears unusual. Such compounds have been found in the study of the M₂MoO₄–R₂(MoO₄)₃ systems.^{28,29} It follows from crystal-chemical data that the X sites may be occupied also by small cations. To a first approximation, their coordination number is then six (the nearest six oxygen atoms). As a result of the ease of the rotation of the tetrahedra, coordination numbers different from those in the ideal structure may occur in the palmierite-like structure. For example, the phase transition in Pb₃(PO₄)₂ is accompanied by an increase in the symmetry from monoclinic to trigonal at 473 K.¹⁵⁴

The mobility of the tetrahedra in the palmierite-like structure promotes the formation of coordination polyhedra characteristic of the given trivalent cation. For this reason, the compounds M₅R(MoO₄)₄ are formed for the entire series of lanthanide, bismuth, iron, and aluminum cations.^{28–32,155–161} Analogous tungstates are formed only for M = K or Rb and R = Bi, La, or In.^{162–165} An intrinsic distortion of the ideal palmierite structure, precisely characteristic of the given compound, occurs in each case (Table 3).

With the aid of the crystal-chemical formula X^[6+6]Y₂^[9+1](EO₄)₂ and the characteristics of the environment of the X site, one may predict the compositions of the M₅R(MoO₄)₄ phases, bypassing the laborious investigation of phase diagrams. Taking into account the fact that palmierite-like structures include large and small cations or only large cations, one may expect that isovalent or heterovalent substitutions would entail the formation of the following phases: M'₄NaR(MoO₄)₄ (M' = K, Rb); SrBa₂(PO₄)₂; BaSr₂(PO₄)₂; M'MR(PO₄)₂ (M' = K, Rb; M = Sr, Ba; R = Ln, Y, Bi, Fe, Al); M₂R(SiO₄)₂ (M = Sr, Ba; R = Ce, Zr, Hf); M₂RPO₄SiO₄ (M = Sr, Ba; R = Ln, Fe, Al, Bi, Y); M'MRPO₄SiO₄ (M' = Sr, Ba; M = K, Rb; R = Ce, Zr, Hf). A series of compounds having similar compositions and structures had been synthesised earlier, for example, Sr₄(PO₄)₂CrO₄,¹⁶⁶ Ba₃(TaO₄)₂,¹⁶⁷ M₂M(EO₄)₂

Figure 7. Projection of the structure of palmierite K₅Sm(MoO₄)₄ on to the xy plane: (a) 0.10 ≤ z ≤ 0.44, (b) xz.¹⁵⁶

^a The crystal structure has been determined.

($E = \text{S, Cr}$),^{168–170} $\text{K}_5\text{R}(\text{SO}_4)_4$ ($R = \text{Ln}$),¹⁷¹ $\text{M}_8\text{Th}(\text{MoO}_4)_6$,¹⁷² and $\text{K}_3(\text{MoO}_4)(\text{ReO}_4)$.¹⁷³

In the case of both palmierite and other structural types, an important factor in the prediction of such phases is the estimation of their crystal lattice energies. An estimate of this kind can be achieved provided that the coordinates and the 'effective' charges of the atoms are known.

5. The NASICON structural type

The NASICON structural type occurs for cations with small radii (Sc^{3+} , Fe^{3+} , Cr^{3+} , V^{3+} , Mg^{2+} , Zr^{4+} , Ti^{4+} , Nb^{4+} , Nb^{5+}) accommodated in the (RO_6) octahedra. A three-dimensional skeletal composition made up of RO_6 octahedra, sharing their vertices with the EO_4 tetrahedra, is characteristic of structures of this class (Fig. 8). A framework of this kind was first described by Abrahams and Bernstein.¹⁷⁴ Subsequently, as the structures of other representatives of this family were determined, the characteristic features of its structure were refined.^{33–41, 62, 68–73, 95} At present, there are more than 400 publications on the structures and properties of compounds of this class. Many of them are devoted to the elucidation of the mechanism of ionic conduction on the basis of crystal-chemical data.

The formula $\text{M}_n\text{R}_2(\text{EO}_4)_3$, where $0 \leq n \leq 4$, describes all the possible compounds with the NASICON structure.⁴¹ The NASICON-like phases are based on the three-dimensional framework $\{[\text{R}_2(\text{EO}_4)_3]^{p-}\}_{3\infty}$ where $E = \text{P, Si, S, Mo, As, W, Se, or Ge}$. The sodium cation is usually employed as the vacancy-filling cation (M), but it can be replaced by Li^+ and Cu^+ or by Cu^{2+} , Ca^{2+} , Sr^{2+} , and Ba^{2+} .

The structural framework is threaded by channels of two types, *I* and *II*, along the c axis of the unit cell (Fig. 8). The zigzag network of type *III* channels passes at right angles to them along the $[010]$ direction. Channels *III* intersect channels *I* and *II*, forming a three-dimensional cavity framework. The channels have variable widths, the cross-sections of the narrowest sites being 1.0 Å for type *I* channels, 1.1 Å for type *II* channels, and 0.9 Å for type *III* channels. Cations with radii of 1.2–1.4 Å can be placed in the wide spaces within the channels (at the intersection of channels *III* with channels *I* and of channels *II* with channels *III*). In the above cavities, it was possible to differentiate two sites — $M(1)$ and $M(2)$ (Fig. 9).

If the space group $R\bar{3}c$ is adopted as the basis (the highest symmetry for the compounds under discussion), then in this case the sixfold $M(1)$ site is an extended antiprism with distances of ~ 2.6 Å to the nearest six oxygen atoms (the other six oxygen atoms are separated by long distances of ~ 3.7 Å). The eightfold $M(2)$ site is surrounded by eight oxygen atoms at distances of ~ 2.47 – 2.89 Å and two oxygen atoms at distances of ~ 3.25 Å.

It follows from the analysis of the cross-sections of the channels that a cation with a radius of ~ 1 Å (for example, Na) can migrate through them. During the migration of sodium cations from the $M(1)$ site to the $M(2)$ site, the narrowest places are at the $A-B-C$ and $A-B-D$ faces (Fig. 9b).¹⁷⁵ When account is taken of the thermal displacements of the oxygen

**Figure 8.** The framework of the $\text{Sc}_2(\text{MoO}_4)_3$ structure.⁴¹

Figure 9. The NASICON structural type: (a) surroundings of the M(1) and M(2) sites; (b) the free space bounded by the common faces of the M(1)O₆ and M(2)O₈ polyhedra in the α -Na₃Sc₂(PO₄)₃ structure.¹⁷⁵

atoms, particularly with increase in temperature, the sodium cations ($r_{V1} = 1.02 \text{ \AA}$) can migrate from one site to the other without any obstacles. This fact is indeed the reason for the appearance of superionic conduction in compounds of this class.^{33, 38, 65, 66} The mobility of sodium cations has been confirmed experimentally by the distribution of their electron density within the conduction channels observed even at 60 °C in α -Na₃Sc₂(PO₄)₃ (Fig. 10).⁶⁷

It follows from the analysis of the number of polyhedra and their surroundings that the crystal-chemical formula of the NASICON structural type is $M(1)^{[6]}M(2)^{[8]}R_2^{[6]}(EO_4)_3$. A necessary condition for the occurrence of the structural type under discussion is the small size ($<0.8 \text{ \AA}$) of the cations R. Their valence should be in the range $2 \leq p \leq 5$. Phases with valences of 2 and 5 have not been described in the literature.

Figure 10. Distribution of the electron density of the sodium atoms in the conduction channels of the α -Na₃Sc₂(PO₄)₃ structure (60 °C).⁶⁷

However, phases with 'formal' valences of 2.5 ($2R = Cr^{3+} + Mg^{2+}$)³⁷ and 4.5 ($2R = Nb^{5+} + Ti^{4+}$)³⁴ are known. The additional atoms M can be accommodated at the M(1) and M(2) sites. Structures with fully occupied M(1) and M(2) sites [Na₄Zr₂(EO₄)₃ (E = Si, Ge),^{39, 40} Na_{4.5}R_{1.5}(PO₄)₃ or Na₃R(PO₄)₂ (R = Tm, Yb, Lu)¹⁴⁸], structures in which only the M(1) sites are occupied [NaR₂(PO₄)₃, R = Ti, Zr]^{62, 73}, structures in which only the M(2) sites are occupied (jointly with the vacancies) [Cu^ITi₂(PO₄)₃ (see Ref. 95)] and the low-temperature Na₃Sc₂(PO₄)₃ (see Ref. 68)], structures with a statistical occupation of the M(1) and M(2) sites (jointly with the vacancies) [the high-temperature Na₃Sc₂(PO₄)₃ (see Ref. 67)], and structures with fully vacant M(1) and M(2) sites [R₂(EO₄)₃ (R = Sc, Fe; E = Mo, S),^{41, 176, 178} MM'(PO₄)₃ (M = Mo, Nb; M' = Ti, Zr),¹⁷⁹ and NbTi(PO₄)₃ (see Ref. 34)] have been found.

Depending on the set of cations, the ideal trigonal unit cell may be distorted to an orthorhombic or monoclinic cell. Examples of certain compounds of the structural type under consideration are presented in Table 4. As can be seen from the Table 4, different distortions of the unit cell occur even for a set of the same cations. The symmetry of the cell is appreciably influenced by the distribution of the cations among the structural sites. A highly symmetrical cell is characteristic of compounds with an occupied M(1) site. In this case, an appreciable cationic conductivity occurs at a temperature above 500 K. When the M(2) site is fully occupied, the cationic conductivity even appears at room temperature.⁶²

^a The crystal structure has been determined.

Detailed information about the structure of compounds of the NASICON type made it possible to synthesise, with the aid of isovalent and heterovalent substitutions in the cationic and anionic sublattices, new superionic materials with low temperatures of the onset of ionic conduction, for example, $\text{Na}_{3+x}\text{Cr}_{2-y}\text{Mg}_z(\text{PO}_4)_3$,³⁷ $\text{Na}_{1+x}\text{Zr}_2\text{Si}_x\text{P}_{3-x}\text{O}_{12}$,⁶² $\text{NbTi}(\text{PO}_4)_3$,³⁴ $\text{Na}_{1+x}\text{Zr}_{2-x}\text{In}_x(\text{PO}_4)_3$,⁷² $\text{HZr}_2(\text{PO}_4)_3$,¹⁸⁰ $\text{Cu}_{0.5}^{\text{II}}\text{Ti}_2(\text{PO}_4)_3$,⁸² $\text{Na}_{2x}\text{M}_{2-x}\text{Sc}_{2-2x}(\text{MoO}_4)_3$ ($\text{M} = \text{Zn}, \text{Cd}, \text{Mg}$),⁹⁰ $\text{Cu}^{\text{I}}\text{Zr}_2(\text{PO}_4)_3$,⁹³ $\text{H}_{0.5}\text{Cu}_{0.5}^{\text{I}}\text{Zr}_2(\text{PO}_4)_3$,⁹⁶ and many others.

It follows from the data presented above that the NASICON structural type is based on the $\{[\text{R}_2(\text{EO}_4)_3]^{p-}\}_{3\infty}$ three-dimensional framework. Other atoms can be introduced into such a framework by means of substitution or insertion with formation of new phases. A framework of a similar kind has been encountered also in compounds of other classes belonging to the garnet $\text{Ca}_3\text{Zr}_2(\text{Si},\text{AlO}_{12})$ ⁴² and langbeinite $\text{K}_2\text{Mg}_2(\text{SO}_4)_3$ (see Ref. 182) structural types. The crystal-chemical analysis of the $\{[\text{R}_2(\text{EO}_4)_3]^{p-}\}_{3\infty}$ framework for these structural types has been described in detail.¹⁸³

6. The whitlockite structural type

The low-temperature β -modification of calcium orthophosphate is isostructural with the natural mineral whitlockite ($R3c$, $Z = 3$) $\text{Ca}_{18.19}\text{Mg}_{1.17}\text{Fe}_{0.83}\text{H}_{1.62}(\text{PO}_4)_{14}$.⁴⁶ Projections of this $\beta\text{-Ca}_3(\text{PO}_4)_2$ structure with the highest information content are presented in Fig. 11. This structure is made up of isolated EO_4^{3-} tetrahedra, which bind the MO_n polyhedra into a three-dimensional framework via common vertices. Along the c axis in the structure, it is possible to differentiate two types of columns — A and B. In the type B column, the MO_8 polyhedra, containing calcium cations at the M(1), M(2), and M(3) sites and two tetrahedra alternate consecutively $[\text{M}(1)\text{O}_8 - \text{M}(3)\text{O}_8 - \text{M}(2)\text{O}_8 - \text{PO}_4 - \text{PO}_4 - \dots]$. The type A column (along the 3 axis) consists of a sequence of polyhedra and cavities $\dots - \text{PO}_4 - \text{M}(4)\text{O}_{15} - \text{M}(5)\text{O}_6 - \text{M}(6)\text{O}_{10} - \dots$ (Fig. 12). The M(4) site in this column is vacant or partly occupied, while the M(6) site is always vacant.

The unit cell of $\beta\text{-Ca}_3(\text{PO}_4)_2$ contains 21 formula units.⁹⁹ In conformity with the stoichiometric formula of the compound, there are 63Ca^{2+} cations and 42PO_4^{3-} tetrahedra per unit cell. The $R3c$ symmetry presupposes the occupation of 66 sites (three 18-fold and two sixfold) by calcium cations. Consequently three cationic vacancies (\square) are present in the unit cell.

Figure 11. The layers in the $\beta\text{-Ca}_3(\text{PO}_4)_2$ structure: (a) layer with type B columns ($y = -0.25$); (b) layer with type A and B columns ($y = 0$).¹⁰³

Figure 12. Fragment of a type B column in the $\text{Ca}_9\text{Fe}(\text{PO}_4)_7$ structure. Certain interatomic distances are indicated.¹⁰⁹

The composition of the unit cell is reflected by the formula $\text{Ca}_3\square_3(\text{PO}_4)_{42}$ ($Z = 1$) and its crystal-chemical analogue $\text{Ca}(1)_{18}^{[8]}\text{Ca}(2)_{18}^{[8]}\text{Ca}(3)_{18}^{[8]}\text{Ca}(4)_{18}^{[9]}\square_3^{[9]}\text{Ca}(5)_{18}^{[6]}(\text{PO}_4)_{42}$ where \square is a vacancy at the M(4) site. Having differentiated the calcium atoms with similar environments at the 18-fold M(1), M(2), and M(3) sites, we obtain the formula $\text{Ca}_{54}\text{Ca}_6\text{Ca}_3\square_3(\text{PO}_4)_{42}$ ($Z = 1$) or, in an abbreviated form $\text{Ca}_9\text{CaCa}_{0.5}\square_{0.5}(\text{PO}_4)_7$ ($Z = 6$).

The M(4) site is half-filled by calcium cations in $\beta\text{-Ca}_3(\text{PO}_4)_2$.⁹⁹ It is not structure-forming and theoretically may be both entirely free ($6\square$) or fully occupied (6M). The boundary conditions (number of vacancies) make it possible to model phases with specified compositions.

The postulated compositions of the new compounds have been calculated taking into account the heterovalent substitutions of the Ca^{2+} cations by M^+ , R^{3+} , and R^{4+} .^{100–106, 108, 110} Different substitution schemes with formation or population of vacancies were used for the modelling of the compositions of the compounds:

- (1) $9\text{Ca}^{2+} + 3\square = 6\text{R}^{3+} + 6\square$, $\text{Ca}_3(\text{PO}_4)_2\text{-RPO}_4$ section, limiting composition $\text{Ca}_9\text{R}\square(\text{PO}_4)_7$ ($Z = 6$);^{100–103, 108}
- (2) $3\text{Ca}^{2+} + 3\square = 6\text{M}^+$, $\text{Ca}_3(\text{PO}_4)_2\text{-M}_3\text{PO}_4$ section, limiting composition $\text{Ca}_{10}\text{M}(\text{PO}_4)_7$ ($\text{M} = \text{Si}, \text{Na}, \text{K}, \text{Cu}^{105}$) ($Z = 6$); (3) $9\text{Ca}^{2+} + 3\square = 6\text{Mg}^{2+} + 6\text{M}^+$, limiting composition $\text{Ca}_9\text{MgM}(\text{PO}_4)_7$ ($\text{M} = \text{Li}, \text{Na}, \text{K}$) ($Z = 6$);¹⁰⁶
- (4) $9\text{Ca}^{2+} + 3\square = 3\text{R}^{3+} + 9\text{Na}^+$, $\text{Ca}_3(\text{PO}_4)_2\text{-Na}_3\text{R}(\text{PO}_4)_2$ section, limiting composition $\text{C}_{18}\text{Na}_3\text{R}(\text{PO}_4)_{14}$ ($Z = 3$);^{107, 184, 185}
- (5) $6\text{Ca}^{2+} + 3\square = 3\text{R}^{4+} + 6\square$, $\text{Ca}_3(\text{PO}_4)_2\text{-R}_3(\text{PO}_4)_4$ section, limiting composition $\text{Ca}_{19}\text{R}\square_2(\text{PO}_4)_{14}$ ($\text{R} = \text{Ce}$) ($Z = 3$).¹⁰⁸

Variable-composition phases with whitlockite-like structures are formed between $\text{Ca}_3(\text{PO}_4)_2$ and the limiting compositions.^{101, 103, 104, 107, 108, 160, 161} This predetermines the existence of phases within the $\text{Ca}_3(\text{PO}_4)_2$ – $\text{Ca}_{10}\text{Na}(\text{PO}_4)_7$ – $\text{Ca}_{18}\text{Na}_3\text{R}(\text{PO}_4)_{14}$ – $\text{Ca}_9\text{R}(\text{PO}_4)_7$ tetragon.¹⁰⁷

It follows from the analysis of the interatomic distances in the polyhedra of the whitlockite-type structure that the lanthanide elements should occupy the M(1)–M(3) sites, whilst the cations with $r < 0.8 \text{ \AA}$ should occupy the octahedral M(5) site.¹¹⁰ There is sufficient space within the M(4)O₁₅ cavity to accommodate cations with a radius of $\sim 1.5 \text{ \AA}$ (Na, K) but not enough to accommodate rubidium and caesium cations (Fig. 12). The Na and K cations can occupy different sites along the threefold axis in the M(4)O₁₅ cavity which are restricted by the distances to the O(12) and O(33) oxygen atoms.

The choice of the most suitable distribution of cations among the structural sites in the model compounds has been made taking into account the calculated Madelung constants.¹⁸⁶ Trivalent and tetravalent cations are most probably accommodated at the M(1) and M(2) sites, while monovalent cations are at the M(4) sites. Subsequent studies on the structures of $\text{Ca}_{10}\text{Na}(\text{PO}_4)_7$,¹⁰⁴ $\text{Ca}_9\text{Fe}(\text{PO}_4)_7$,^{109†} and $\text{Ca}_9\text{Eu}(\text{PO}_4)_7$ (see Refs 188, 189) confirmed these calculations.

It is noteworthy that, in contrast to the glaserite, palmierite, β -K₂SO₄, and NASICON structural types examined above, the whitlockite-like crystal structure is not distorted after the insertion or substitution of cations in it (Table 5). The architecture of the whitlockite-type structure remains unchanged after the introduction into the lattice of cations having different dimensions and oxidation states. The stability of this structure predetermines the occurrence of reversible redox reactions without the destruction of the structure.^{108–110}

Together with substitutions in the cationic lattice of a whitlockite-like structure, one can achieve substitution also in the anionic component, for example in accordance with the scheme

with retention of the number of vacancies, or in accordance with the scheme

with occupation of the vacancies in the structure. For trivalent cations with $r < 0.8 \text{ \AA}$, the formula describing the limiting composition with six cations at the M(5) site is $\text{Ca}_{19}\text{R}_2(\text{PO}_4)_{12}(\text{SiO}_4)_2$, whilst for cations with $r > 0.8 \text{ \AA}$ the formula is $\text{Ca}_7\text{R}_4(\text{SiO}_4)_{14}$; intermediate compounds have the compositions $\text{Ca}_{15}\text{R}_6(\text{PO}_4)_8(\text{SiO}_4)_6$ and $\text{Ca}_9\text{R}_{12}(\text{PO}_4)_2(\text{SiO}_4)_{12}$ with full occupation of one or two 18-fold sites by the cations of the trivalent element. The limiting composition of compounds with a small trivalent cation (R') at the M(5) site and a large cation (R) at the M(1)–M(3) sites is described by the formula $\text{Ca}_4\text{R}'_2\text{R}_{14}(\text{SiO}_4)_{14}$. In this case, when the M(5) site is occupied by the Mg^{2+} cation, the limiting composition is $\text{Ca}_5\text{Mg}_2\text{R}_{14}(\text{SiO}_4)_{14}$. The possibility of the existence of silicates and silicophosphates with a whitlockite-type structure is confirmed indirectly by the mineral cerite $(\text{Ce, La, Nd, Ca})_9(\text{Fe, Mg, Al})(\text{SiO}_4)_6(\text{SiO}_3\text{OH})(\text{OH})_3$,¹⁸⁷ which is isostructural with whitlockite.

Thus the data on the whitlockite structural type made it possible to calculate theoretically for the first time a wide range corresponding to the existence of variable-composition phases in the $\text{Ca}_3(\text{PO}_4)_2$ – Na_3PO_4 – RPO_4 ternary system¹⁰⁷ and the compositions of the individual compounds. This region is located within the $\text{Ca}_3(\text{PO}_4)_2$ – $\text{Ca}_{10}\text{Na}(\text{PO}_4)_7$ – $\text{Ca}_{18}\text{Na}_3\text{R}(\text{PO}_4)_{14}$ – $\text{Ca}_9\text{R}(\text{PO}_4)_7$ tetragon.

†The full structural data have been published by B I Lazoryak, V A Morozov, A A Belik, S S Krasnov, V Sh Shekhtman. *J. Solid State Chem.*, **121**, 1(1966).

^a The crystal structure has been determined

IV. The structures and physicochemical properties of the materials

In the search for new or improved known materials with specified properties, synthetic chemists must either estimate theoretically or postulate the properties which the newly formed compounds will have. Known prototypes are most often used for such purposes and more rarely, data on the structure of the solid material. Certain possibilities for the prediction of properties on the basis of crystal-chemical data will be considered in this section. We shall deal with certain approaches to the solution of problems of this kind.

Since the 1960s, a vigorous search for laser materials and phosphors has been prosecuted. Some of them have found applications in engineering. One of the most important characteristics of such materials is the lifetime (τ) of the excited state and the quantum yield. These two characteristics are interrelated. An increase in the concentration of the activator in the matrix is usually accompanied by a decrease in the lifetime and an increase in the quantum yield. According to the data of Hong and Chinn,⁷ the optimum ratio of these parameters is observed for materials containing isolated NdO_x polyhedra, which prevent the Nd–Nd interaction and hence the concentration-induced quenching, and in which the polyhedron surrounding Nd^{3+} has no centre of inversion, since the intensity of the emission is largely associated with electric dipole transitions.

In laser materials with a high Nd^{3+} concentration ($> 10^{21} \text{ cm}^{-3}$, when the condition of 'localness' does not hold),¹⁹⁵ the Nd^{3+} – Nd^{3+} distances are 4.65–6.66 Å. As can be seen from the data presented in Table 6, the lifetime of the metastable levels for isostructural compounds, for example for $\text{M}_2\text{B}(\text{MoO}_4)_4$, increases with increasing Nd^{3+} – Nd^{3+} distance. However, such a dependence cannot be traced for the entire series of compounds presented in Table 6 because the symmetry of the surroundings of the activator ion changes in these phases. Thus the Nd^{3+} – Nd^{3+} distances in the $\text{K}_3\text{Nd}(\text{PO}_4)_2$ (see Ref. 7) and $\text{Na}_3\text{Nd}(\text{PO}_4)_2$ (see Ref. 13) structures, based on β -K₂SO₄,

Table 6. The lifetimes of the excited state (τ) and the Nd–Nd distances in certain laser materials.

^a The values τ for the maximum (max) and minimum (min) Nd³⁺ concentrations are quoted; ^b the lifetime of the metastable level has not been quoted ¹³ for Na₃Nd(PO₄)₂.

differ little (Table 6) and the lifetime of the metastable Na₃Nd(PO₄)₂ level is probably the same as for K₃Nd(PO₄)₂.

Crystal-chemical analysis makes it possible to estimate the laser characteristics of the compounds postulated. The structural type of bredigite, the structure of which contains fragments of the glaserite and β -K₂SO₄ structural types, should be promising in this connection. The insertion of glaserite columns between type β -K₂SO₄ columns would increase the Nd³⁺–Nd³⁺ distance by a factor of 2 and the latter, would amount to 9 Å on average. The neodymium concentration would diminish by a factor of 2 and would be $2 \times 10^{21} \text{ cm}^{-3}$ [in Na₃Nd(PO₄)₂, the Nd³⁺ concentration is $4 \times 10^{21} \text{ cm}^{-3}$]. In the postulated compound M₃Na₃NdR(PO₄)₄ (M = K, Rb; R = Lu, Sc), the minimum distance between the Nd atoms (5.4 Å) may be achieved only in the C column (Fig. 1). The lifetime of this compound would be $\sim 100 \mu\text{s}$, as for NdP₅O₁₄.¹⁹⁶ This conclusion is based on the fact that, as in NdP₅O₁₄, the two neighbouring Nd polyhedra in M₃Na₃NdR(PO₄)₄ do not have a common tetrahedron linking them and are separated by two tetrahedra or the NaO_x polyhedron.

The lifetimes of glaserite-like phases containing neodymium atoms may be estimated similarly. For example, the compound K₂NaNd(PO₄)₂ [obtainable by the heterovalent substitution $\text{K}^+ + 2\text{SO}_4^{2-} = \text{Nd}^{3+} + 2\text{PO}_4^{3-}$ in K₃Na(SO₄)₂] may serve as a laser material. Regardless of which of the polyhedra (X^[6+6] or Y^[4+6]) is occupied by Nd³⁺ cations, the minimum Nd³⁺–Nd³⁺ distances in the postulated phase would be determined by the X–X or Y–Y distances. These distances are the same and amount to 5.68 Å in glaserite itself. Two neighbouring (X or Y) polyhedra in K₂NaNd(PO₄)₂ are linked together by an edge of the tetrahedron, as in M₅Nd(MoO₄)₄. These data suggest that the lifetime of the metastable level in the compound K₂NaNd(PO₄)₂ would be of the same order of magnitude as in M₅Nd(MoO₄)₄. It follows from the data presented that, by using crystal-chemical ideas, it is possible to estimate to a first approximation the characteristics of laser materials.

In optical materials, the luminescence (lasing) line width depends on the number of activator cations, their surroundings, and the quality of the crystals. The smaller the difference between the surroundings of the activator cations, the smaller the half-width of the emission lines. Despite this, dilution is used to diminish the concentration-induced quenching in laser materials. For this purpose, Nd³⁺ cations are substituted by La³⁺, Lu³⁺, Y³⁺, or Bi³⁺ cations. The correct choice of the diluent cation can be achieved only by taking into account crystal-chemical data. For example, in order to reduce the concentration-induced quenching in M₅Nd(MoO₄)₄, it is more promising to substitute Nd³⁺ by La³⁺ and not by Y³⁺, Lu³⁺,

or Bi³⁺, which have surroundings in the palmierite-like matrix different from those of Nd³⁺.³¹

The luminescence line width of the lanthanide cation in M₅R(MoO₄)₄ (R = rare earth) is appreciably increased owing to the presence of several RO_x polyhedra in close proximity.³² When a second trivalent element (diluent) is introduced into such a material, the line width increases appreciably, which impairs the optical characteristics of the material. A similar effect is observed also in the Na₃Nd_{1-x}R_x(PO₄)₂ (R³⁺ = Gd, Lu, Y) solid solutions. The surroundings of Nd³⁺ and R³⁺ in these phases are different.¹⁶

Apart from crystal-chemical data, in selecting diluent cations it is useful to employ in certain cases other structure-sensitive methods, for example optical data may be employed. This extremely sensitive method makes it possible to determine the number of active centres and the limits of existence of the phases of two structurally similar compounds. In certain cases this method is the only one suitable for the elucidation of the regions of homogeneity. For example, in the study of the solid solutions in the Na₃Eu(PO₄)₂–K₃Eu(PO₄)₂, Na₃Gd(PO₄)₂–R₃Gd(PO₄)₂,²⁰¹ NaCaPO₄–Na₃Eu(PO₄)₂, NaSrPO₄–Na₃Eu(PO₄)₂,¹⁴² and Ca₃(PO₄)₂–Na₃R(PO₄)₂ (R = Nd, Eu, Er) solid solutions,¹⁸⁵ only the luminescence method made it possible to discover the limits of existence of the solid solutions. The X-ray powder diffraction analysis of a mixture of compounds with similar structures entails a large error in this case or altogether fails to distinguish them.

It has been established that the number of nonequivalent Eu³⁺ sites in the Na₃Eu(PO₄)₂–K₃Eu(PO₄) solid solutions²⁰¹ is the same as in the corresponding initial compounds. There are six such nonequivalent sites in Na₃Eu(PO₄)₂ and one in E₃Eu(PO₄)₂ (Fig. 13). It follows from the experimental determinations of the regions of homogeneity^{142,185,201} that the substitution of cations in the crystal lattice is accompanied by slight changes in the surroundings of the R³⁺ ions, which cannot be predicted solely on the basis of crystal-chemical data or be determined by X-ray diffraction.

Analysis of the geometry of the polyhedra and of their relative positions in the β -K₂SO₄ and glaserite structures made it possible to postulate initially the composition and then also to synthesise effective phosphors with lanthanide elements^{141,202–206} characterised by a long lifetime and a high luminescence intensity. In the search for such materials, various structural types were considered and the compositions of the compounds were modelled within the framework of a single structural type. For example, the introduction of Ce³⁺ and Tb³⁺ cations into a type β -K₂SO₄ matrix increased the quantum yield as a result of energy transfer from Ce³⁺ to Tb³⁺.^{203–205}

The ability of the tetrahedra to rotate readily, noted in the β -K₂SO₄ structural type, and the occurrence of low-temperature phase transitions in compounds of this type have been used by Elouadi et al.²⁰⁷ to predict the possible ferroelectric and piezoelectric transitions in the compounds MM'PO₄ (M = Na⁺, K⁺; M' = Ca²⁺, Zn²⁺, Sr²⁺, Ba²⁺, Pb²⁺). It has been established experimentally that such transitions occur in the temperature range 585–1470 K.²⁰⁷

In a study of the structure of the low-temperature modification of Na₃Sc₂(PO₄)₃, it has been found⁶⁸ that sodium occupies two close sites in the M(2) polyhedron with an 'effective' distance of 1.28 Å. The occupations of these sites differ by a factor of 1.7. Such non equivalence of the site occupations in the M(2) polyhedron is equivalent to the existence in the structure of a system of uncompensated dipoles,⁶⁸ the presence of which suggests ferroelectric properties [it has been established experimentally⁶⁶ that α -Na₃Sc₂(PO₄)₃ is a ferroelectric substance up to 333 K].

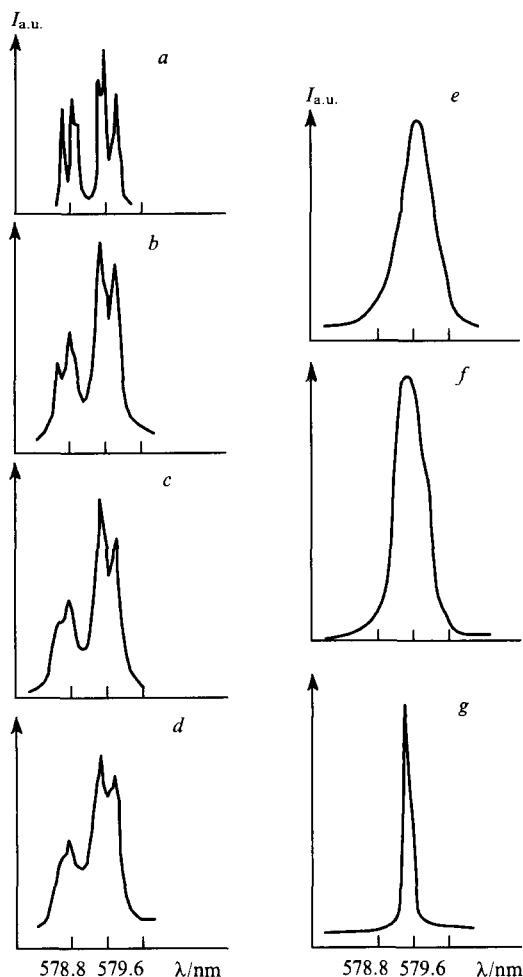

Figure 13. Luminescence spectra of Eu^{3+} in the region of the transition $^5D_0 \rightarrow ^7F_0$ in $\text{Na}_{3-x}\text{K}_x\text{Eu}(\text{PO}_4)_2$: (a) $x = 0$; (b) $x = 0.15$; (c) $x = 0.4$; (d) $x = 0.6$; (e) $x = 1$; (f) $x = 1.5$; (g) $x = 3$.²⁰¹

V. Conclusion

It follows from the data presented in this review that crystal chemistry constitutes an effective instrument for the modelling of the compositions of new compounds with a specified structure, for the prediction of new materials with specified properties, for the modification and improvement of the properties of materials, and for the correct interpretation of experimental data concerning the regions of existence of the initial phases and their polymorphic transitions.

Furthermore, reliable information about the structure of a solid makes it possible to estimate the crystal lattice energies of known and model phases, to establish the symmetry and the coordination environment of the cations in the compounds, to determine the geometrical characteristics of the polyhedra in the structure and their relative positions, to determine or estimate the cation-cation and cation-anion distances in the model phases, to introduce chemical elements with different dimensions and oxidation states into the crystal lattice of the structure in order to obtain materials with the required properties, and to deform the structure in order to improve the properties or obtain materials with unusual properties (for example, oxide superconductors).

However, at the present time crystal-chemical data are used effectively only for the interpretation of experimental data and to only a very slight extent (excluding the search for superconducting materials) for the prediction of the compositions of materials and their properties. The reason

for this is the lack of a well-founded algorithm for the application of the crystal-chemical data accumulated hitherto (due to the fact that the relevant studies have been shared between synthetic and structural chemists).

At the present time, problems in materials science are mainly considered from the composition-structure-property standpoint. Such a scheme includes the following components: (1) empirical search for the compound; (2) the study of its structure; (3) the study of its properties. On the other hand, the structure-property-composition scheme proposed in the present review includes the following components: (1) analysis of the structures of the compounds or classes of compounds; (2) prediction of the possible properties; (3) prediction of the compositions of the compounds with the necessary properties; (4) synthesis of the predicted compounds; (5) test of the properties; (6) refinement of the structure (if necessary). At the present level of development of solid state chemistry and information science, this approach is quite realistic. It makes it possible to shorten the time required to search for the necessary compositions of the compounds or phases and also to reduce the extent to which the equipment is used and to diminish the expenditure on the search stages. The structures of a large number of inorganic compounds have now been established; there exists a data bank for the structures of many inorganic phases; the radii of the cations in fluoride and oxide phases have been determined fairly reliably.^{47, 48}

On the basis of the crystal-chemical analysis of structures belonging to different structural types and containing tetrahedral anions described above, the following algorithm may be proposed for the search for compounds with specified structures and properties.

1. Determination of the projections, layers, or fragments of the structure with the greatest information content for the differentiation of the occupied and free polyhedra and channels.
2. Analysis of the symmetry and the geometrical characteristics of the differentiated polyhedra in the structure (structural types) in order to introduce into the latter new cations by means of isovalent or heterovalent substitution.
3. Establishment of a general crystal-chemical formula taking into account the occupied, free, and partly occupied sites.
4. Modelling of the compositions of the possible compounds by means of isovalent or heterovalent substitutions in the cationic or anionic sublattice taking into account the formal valences and dimensions of the atoms and polyhedra.
5. Comparison of blocks of different structural types in order to achieve their arrangement for the formation of a new structural type (made up of two or several fragments of different structural types) in which the distances between the cations are specified.

6. Estimation of the crystal lattice energy change following the introduction of additional atoms into the basic structure or structural type.

7. Prediction and estimation of the possible properties taking into account the characteristics of the structure.

Depending on the tasks faced by the synthetic chemist, some of the items may be omitted or they may change places, but items 1-4 and 7 are in all cases fundamental for the specific design of new compounds based on crystal-chemical data.

Only one of the possible aspects of the construction of compounds (geometrical and spatial factors) has been considered in the present review. Problems concerning the distortion of crystal lattices, the changes in symmetry, the distribution of cations and electron density in the structure, energetic aspects, and others have been considered only occasionally, mainly for the understanding of the transition from the model to a specific compound. There is no doubt that, in the solution of a problem as complex as the modelling of the compositions, structures, and properties of new phases, many approaches exist which have not been mentioned in this review, for example the methods of energetic crystal chemistry.²⁰⁸

The tautomerism of heterocyclic thiols. Five-membered heterocycles

E D Shtefan, V Yu Vvedenskii

Contents

I. Introduction	307
II. Furan-, thiophene- and selenophene-thiols	307
III. 5-Mercaptopyrazoles	307
IV. Imidazolethiones and 1,3-oxazole-2-thiones	308
V. Thiazole-2-thiones	308
VI. 1,3,4-Oxadiazolethiones and 1,3,4-thia(selena)diazolethiones	308

Abstract. Data on the tautomerism of five-membered heterocyclic thiols and its effect on the behaviour of these compounds in different chemical reactions are surveyed. The bibliography includes 113 references.

I. Introduction

The tautomerism possible in heterocyclic thiols imparts a considerable diversity to their properties compared with those of aromatic thiols. Consequently, the investigation of the effect of tautomerism on the mechanism of the reactions of these compounds is interesting. In the present review, we attempted to combine the results of spectroscopic studies with selected data on the reactivity of five-membered heterocyclic thiols, namely, data directly concerned with the tautomeric nature of the latter. It is to be noted that there is a series of reviews and general monographs on the tautomerism itself,¹ as well as on the chemistry of certain classes of heterocyclic compounds,^{2–7} which to a certain extent deal with the problems under consideration. However, new experimental data have been published recently and need to be surveyed. The new data have served as a basis for the consideration of particular types of thiols in this review.

II. Furan-, thiophene- and selenophene-thiols

Unlike the hydroxy derivatives that mostly occur as oxo-forms, furan- and thiophene-thiols exist, according to all spectroscopic and other physicochemical characteristics, as mercapto-compounds.^{5,6,8–12} The only report¹³ that 2-mercaptoselenophene occurs in the thione form has been disproved.¹⁴

At the same time, the tautomeric nature of these compounds was never doubted. Besides the thione structure of mercapto-aldehydes (see the review of Litvinov et al.¹⁵) and the ketonic structure of the corresponding heterocyclic hydroxy derivatives (see, for example, Gronovitz's review¹⁶), the most important evidence for the tautomeric nature of heterocyclic thiols was the extreme lability of the thiols of the thiophene and, particularly, the furan series. The corresponding selenols are even more labile. Some of them have only recently been characterised by spectroscopic methods.^{17,18} A common reason for the lability of the heterocyclic thiols and selenols proved to be associated with their tautomerism. Analysis of the auto-transformation products has shown these compounds to be dimers, which are most probably formed by the addition of the chalcogenols to their own tautomeric forms.^{14,16,17–22}

X = O, S, Se; Y = S, Se

This reaction is catalysed by triethylamine and phenylhydrazine (in the latter case, the hydrazones Y = N–NHPh of the dimeric products are formed).

III. 5-Mercaptopyrazoles

Mercaptopyrazoles represent an unusual example of compounds where tautomerism can be detected directly by spectroscopic methods.²³

The equilibrium position depends strongly on the solvent. In aprotic media, the $[NH]:[SH]$ ratio increases with increase in the polarity of the medium. For example, the concentration of the NH-form of 5-mercapto-1,4-dimethyl-pyrazole in dioxane is close to zero, in THF it is about 5%, and in DMSO it is as high as 70%. In alcohols, the amount of the NH-form increases with increase in their ability to form hydrogen bonds. Depending on the nature of the substituent in the 4-position, intramolecular hydrogen bonds stabilise one or the other tautomer. It is the thiol form in the case of the carbonyl group, and the thione in the case of the phenylazo group.

R = H, Me, Ph

It is interesting to note that no traces of the possible third tautomer (C—H) have been found.

Only the SH-forms of 3-mercapto-1-methyl- and 5-mercapto-1-methyl-pyrazoles have been detected in their photoelectron spectra in nonpolar solvents.²⁴

IV. Imidazolethiones and 1,3-oxazole-2-thiones

The ^{15}N NMR spectra of 2-mercapto-1-methyl-imidazole indicate that in a polar solvent (DMSO) this compound exists only in the thioamide form, while in chloroform the presence of a small amount (2%) of iminothiol form is observed.^{25,26} The additional stabilisation of the thioamide form in DMSO is caused presumably by formation of hydrogen bonds with the solvent. The prevalence of the thioamide form is also corroborated by UV,²⁷ ^{13}C NMR,²⁸ and photoelectron spectroscopy,²⁹ quadrupole resonance,³⁰ and acidity constant measurements.³¹ Polarographic studies have shown that 2-mercapto-1-methylimidazole occurs in the thione form in aqueous solution at $pH < 6$, while at $pH > 6$ it forms thiolates.³²

The IR spectrum of 1-methylimidazole-2-thione, obtained by Ettlinger as early as 1950,³³ is identical with that of the corresponding imidazolone; this is convincing evidence in favour of the thione structure.³⁴ An unexpected result was obtained by Spanish investigators.³⁵ According to their IR and Raman spectroscopic data, in the crystalline phase imidazolethione actually exists as the pure thiol. This conclusion probably requires additional proof.

Both the sulfur and nitrogen atoms can serve as the reaction centres in the nucleophilic addition of imidazolethiones to an activated acetylenic bond.^{36,37}

Data obtained by several investigators^{29,31,38-41} have shown that the IR spectra of a series of oxazole-2-thiones provide no grounds for doubts about their thione nature.

An MNDO calculation also confirms that the thione form predominates over the thiol form. The difference between the enthalpies of formation of these two forms is 43.96 kJ mol⁻¹ when $R^1 = R^2 = H$.⁴²

V. Thiazole-2-thiones

The first evidence for the thione structure of thiazolethione and its methyl derivatives was obtained by Ettlinger from IR spectra which were indistinguishable from those of thiazolones.³³ These data were confirmed in later studies.^{29,31,35,43-46} Sheinker, Postovskii, and Voronina supposed⁴³ that the thione form predominates both in the condensed phase and in solution (dioxane). This was confirmed by the comparison of the spectra of compounds 1 and 2.

In addition, Flett has noted⁴⁴ that the NH vibration bands in the 3430 cm⁻¹ region in the spectrum of a solid sample disappeared in a CCl₄ solution. Hence it was concluded that 4-methylthiazole-2-thione exists in the crystalline form as thioamide complexes with hydrogen bonds.

The evidence for the thione structure of 4-indolyl-2-mercaptothiazole is, firstly, the absence of SH-group absorption bands in the IR spectra, and, secondly, the presence of a maximum at 332 nm in the UV spectrum, disappearing in an alkaline medium.⁴⁵

According to the MNDO calculation, the difference between the enthalpies of formation of the thione and thiol forms of the unsubstituted potential mercaptothiazole is 56.82 kJ mol⁻¹, which is evidence in favour of the thione form.⁴²

In an alkaline medium, the nucleophilic centre in the mercaptothiazole molecule is the exocyclic sulfur atom. For example, sodium thiazolethiolates react with thiophosgene to give trithiocarbonates.⁴⁷

VI. 1,3,4-Oxadiazolethiones and 1,3,4-thia(selena)diazolethiones

In 1956, Ainsworth obtained a series of substituted oxadiazolethiones.⁴⁸

R = Alk, Ar, Het.

Their thione structures were confirmed by IR spectroscopic data.⁴⁸ Later studies^{49,50} gave the same result.

In 1958, Ainsworth⁵¹ found that the IR spectrum of 2-mercapto-5-phenyl-1,3,4-thiadiazole was identical with that of the corresponding oxadiazolethione; hence, this compound also exists in the thione form. A similar conclusion was also reached recently by Indian investigators⁵² who studied 5-substituted 2-mercapto-1,3,4-thiadiazoles. In the ¹H NMR spectra of these compounds, the chemical shift (δ) of the NH proton is about 5.2–5.5 ppm. There are no SH absorption bands (2500 to 2600 cm⁻¹) in the IR spectrum of the thione **3** in the condensed state.⁵³

In the system

the equilibrium is significantly shifted towards the thione form, which has been confirmed by spectroscopic methods: IR (the absence of the SH-group absorption band), ¹H NMR [δ (NH) = 12–14 ppm], and ¹³C NMR spectroscopy [δ (C=S) = 188 ppm].^{54,55} Only in the IR spectrum of a concentrated chloroform solution, has a weak absorption of the SH group (2560 cm⁻¹) been detected, which may indicate the coexistence of two tautomeric forms.

The absorption bands corresponding to the SH group were not found in the IR spectrum of 2,2'-azo-1,3,4-thiadiazole-5-thione **5**.⁵⁶

According to the data of Arvidsson and Sandström,⁵⁷ the hydrazones **6** and **7** have very similar UV spectra, differing markedly from that of the *S*-methylated compound **8**; this fact undoubtedly proves the thione structure of these compounds.

The structures of some potential thiols and selenols of thia- and selenodiazoles were studied by ¹³C NMR spectroscopy.⁵⁸ It was found that, on oxidation of these compounds to disulfides and diselenides respectively, the chemical shifts of the carbon atoms change significantly: the C(2) signal is shifted upfield (by about 30 ppm) and the C(5) signal is shifted downfield (by 10 ppm).

Bearing in mind that disulfides and diselenides should be good models for thiol and selenol tautomerism, these data suggest that the thione and selenone structures are preferred.

VII. 5-Mercapto-1,3,4-thiadiazole-2-thiones and 1,2,4-thiadiazole-3,5-dithione

The IR spectra of 2,5-dimercapto-1,3,4-thiadiazole **9**⁴³

contain a distinct absorption band in the region of 2489 cm⁻¹ (corresponding to the SH group) and intense bands in the range 2860–3067 cm⁻¹, indicating the presence of the NH group. Hence it was concluded that compound **9** has a mixed thione-thiol structure, i.e. form **9b** predominates.

Later, Thorn⁵⁹ undertook a detailed study of the absorption spectra of compound **9** and a series of its methyl derivatives **10**–**14** (Scheme 1).

Compound	9	10	11	12	13	14
λ_{\max} /nm	335	318	288	333	320	324
	260	235	—	260	243	268

Analysis of the UV spectra revealed a striking similarity of the absorption maxima of compounds **9**, **12**, and **14** that appeared to show unambiguously that they have the dithione structure. However, this conclusion was not confirmed by IR spectra. In all the spectra except that of compound **11**, there is a band at 1475–1508 cm⁻¹, which has been assigned to the thioamide fragment. However, for all the compounds except compound **14**, the band at 1415–1435 cm⁻¹, which should be assigned to the iminothiol group, is also detected. Furthermore, in the spectra of compounds **9** and **12** bands in the thiol region (2590 cm⁻¹ and 2555 cm⁻¹ respectively) were detected. To account for this discrepancy between the IR and UV spectroscopic data, Thorn assumed⁵⁹ that compounds **9** and **12** exist in a mixed form in a concentrated chloroform solution (i.e. under the conditions of the recording of the IR spectra) while the dithione form prevails in dilute alcoholic solution used for UV spectroscopy. Stanovnik and Tišler⁶⁰ suggested a 'monomercapto-monodipolar' structure for compound **9**. Later, the presence of at least one thiol group was established⁶¹ by IR spectroscopy, this group being deprotonated on formation of complexes with metals.

Zaidi et al.⁶² have noted the presence of a 'weak' absorption band (at about 2490 cm⁻¹) due to the thiol group, in contrast to the 'medium' bands at 3060 cm⁻¹ and 2875 cm⁻¹ corresponding to the N–H bond. They suggested that structure **9b** should be discounted, because the band due to the SH group is too weak compared with that of the NH group; thus, 2,5-dimercapto-1,3,4-thiadiazole exists mainly in the dithione form, which is in equilibrium with a small amount of the thiol form. However, in the next paper⁶³ a modified view was expressed: here the SH

bands were classified as 'medium', and the NH bands — as 'strong'. This has two possible explanations. Firstly, the authors⁶³ may have been influenced by their own results on the structures of complexes of compound **9** with transition metals, where the ligand is in the thione-thiolate form **9b**. Secondly, the important study by Anthony et al.⁶⁴ was published a year earlier. They used for the first time ¹³C NMR spectroscopy of chloroform solutions in order to solve this problem. The chemical shifts of the two carbon atoms in the rings of compounds **15**–**17** were found to differ significantly (186–188 ppm and 144–154 ppm), while in the symmetrical dithione **14** the shift is 180 ppm. This fact proves reliably the presence of structure **9b**. In the IR spectra of compound **15**, bands at 2560 cm⁻¹ and 930–933 cm⁻¹ were detected, disappearing on its oxidation with iodine to the disulfide **16**. They were assigned to S–H stretching and C–S–H deformation vibrations.

R = Ph, Me

Mercaptothiones do not yield N-adducts in the reaction with thiophosgene, but form trithiocarbonates.^{47,64}

R = Me, Ar

Unsubstituted mercaptothiadiazolethione reacts with dibromoalkanes in the presence of bases to form various macroheterocyclic compounds.⁶⁵ The final product composition depends strongly on the reaction conditions and the selection of the initial reactants. For example, by using dibromomethane with one equivalent of alkali (KOH), it is possible to obtain trithiathiadiazolinophanetrithione **18**, i.e. the product of the reaction at both S and N atoms. With two equivalents of alkali, tetrathiathiadiazolophane **19** can be produced.

Depending on the conditions, the reaction with 2,3,4,6-tetra-O-acetyl-α-D-glucopyranosyl bromide [α-acetobromoglucose, (Ac)₄GlBr] leads to S,S'- or S,N-bisglycosides.⁶⁶

The S,N-adduct is formed either *via* the stepwise glycosidation of compound **20** by one and then by another mole of (Ac)₄GlBr, or by the glycosidation of the mercury salt of **20**, or by the transglycosidation of the S,S'-adduct in the presence of HgBr₂.

In the case of 1,2,4-thiadiazole-3,5-dithione, the IR spectroscopic data seem to be in favour of the dithione structure.⁶⁷

The intense absorption at 3010 cm⁻¹ and 2830 cm⁻¹ is due to the NH group, while the SH band in the 2600 cm⁻¹ region is absent.

VIII. 1,2,4-Triazolethiones

In 1959, Reynolds and VanAllan⁶⁸ compared the UV spectra of potential mercaptotriazoles and their S-methyl and S-acyl-derivatives and concluded that the thione form predominates. This conclusion was confirmed^{29, 69–71} by means of the IR and NMR spectroscopy of 3-mercapto-1,2,4-triazoles having various substituents in the 4- and 5-positions. In the IR spectrum of 4-amino-1,2,4-triazole-3,5-dithione, SH bands are absent, but there are bands at 1333 cm⁻¹ and 1519 cm⁻¹, which can be assigned to the C=S and HN–C=S fragments respectively. The latter two bands disappear on alkylation of the dithione with methyl iodide.⁷² According to X-ray diffraction data,⁷³ 4-amino-3-hydrazino-5-mercapto-1,2,4-triazole crystallises in the thione form.

At the same time, the IR and ¹H NMR spectra of 5-ferrocenyl-4-phenyl-1,2,4-triazole-3-thiol indicate that it is more likely to exist as a mixture of tautomers.⁷⁴ The same conclusion has been made for 4-amino-5-mercaptotriazoles and the Schiff's bases derived from them. In the IR spectra of these compounds, there is a weak absorption in the 2480–2550 cm⁻¹ region, which can be assigned to the thiol group. In addition, the thiol proton with a chemical shift of about 8.5–8.8 ppm was detected in the ¹H NMR spectra, together with the NH-group protons.^{75,76} Furthermore, the bold hypothesis has been put forward⁷⁷ that the absence of signals in the thiol region of the IR spectra of 4-amino-5-mercaptotriazoles does not necessarily indicate the absence of the thiol form, since the S–H bond usually has a very weak absorption.

A zwitter-ionic structure has been proposed for 3-hydrazino-5-mercapto-1,2,4-triazole on the basis of crystallographic data.⁷⁸

Thus, the C–S bond length is 0.174 nm, which is, of course, closer to that of the single bond and not the double bond.

In 1,2,4-triazolethiones, both the sulfur and nitrogen atoms can act as nucleophilic centres, depending on the nature of the attacking reagent and on the reaction conditions (Scheme 2).^{79–83}

The introduction of an arylamino group into the 5-position does not change the mode of nucleophilic substitution reactions.⁸⁴

Scheme 2

$R = p\text{-XC}_6\text{H}_4$, $X = \text{H, Cl, OEt}$;

$Y = \text{CN, } \alpha\text{-Py}$;

$\text{NR}_2^1 = \text{N} \begin{array}{c} \diagup \diagdown \\ \text{C} \quad \text{O} \end{array}$, etc.;

$R^2 = \text{H, Ph, C}_6\text{H}_4\text{NO}_2\text{-}p, \text{CONH}_2, \text{COOH, CH}_2\text{COOH}$

Regardless of the nature of the substituents in the 4- and 5-positions, cyanoethylation occurs at the nitrogen atom^{72, 85–87} with one exception:⁷²

On the other hand, compounds of the HalCH_2R type usually react at the sulfur atom.^{79, 81–85, 87–89}

The situation is changed if the aryl substituent is present in the 1- or 2-position. In the case of 1-phenyl-1,2,4-triazole-3-thione, cyanoethylation at the sulfur atom takes place, while alkylation of 2-phenyl-1,2,4-triazole-3-thione by β -chloropropionitrile can occur at a nitrogen atom.⁹⁰

$R = \text{CH}_2\text{CH}_2\text{CN, CH}_2\text{CH}_2\text{COOH, CH}_2\text{Ph}$

$R' = \text{CH}_2\text{CH}_2\text{COOH, CH}_2\text{Ph}$

The mechanism of the cyanoethylation reaction is believed to begin (in all cases) with the attack of the reagent on the sulfur atom, since it carries a greater negative charge. However, this is followed by transcyanoethylation with the participation of a second reagent molecule. This is based on quantum-chemical calculations of the charge distribution in the triazolethione molecules by Hückel's MO method.⁹⁰

The acylation of 4,5-disubstituted triazole-3-thiones with benzoyl and cinnamoyl chlorides yields ultimately C–N-products; however, when phenyl substituents are present in both positions and the reaction is carried out in an alkaline medium, it is possible to isolate C–S-derivatives, which are, however, readily transacylated on heating.^{86, 87}

Under ethyne pressure in the presence of alkali, 1,2,4-triazolethiones give S-vinyl derivatives. Further vinylation at the nitrogen is possible when catalysts (cuprous chloride, cadmium acetate) are used.^{91–93} The formation of divinyl products also occurs in the case of various substituted ethynes.^{94, 95}

However, initial N-vinylation takes place in this case.

IX. Tetrazolethiones

In 1958, Lieber et al.⁹⁶ reported the absence of bands corresponding to SH groups in the IR spectra of aryltetrazolethiones. The absorptions in the $1470\text{--}1500\text{ cm}^{-1}$ and $1338\text{--}1359\text{ cm}^{-1}$ regions were assigned to the N=C=S and C=S fragments respectively. The UV spectra of methyl- and benzyl-thiotetrazoles differed from those of mercapto-derivatives, resembling more closely the spectra of non-tautomeric tetrazoles,⁹⁷ which also constituted evidence in favour of the thione structure.

Kauer and Sheppard concluded that the UV and IR spectra of arylmercaptotetrazoles did not correspond to those of aryltetrazole systems.⁹⁸ However, the question of the position of the proton remained unsolved, and it was suggested that arylmercaptotetrazoles may exist (at least in the solid state or in weakly polar solvents) as hydrogen-bonded dimers.

Fairly definite results have been obtained by means of ^{13}C NMR spectroscopy.^{29, 58, 99–101} The chemical shift of the carbon atom in substituted tetrazolethiones was shown to be 163–165 ppm (depending on the substituent and the solvent), while in the *S*-derivatives (sulfides, disulfides, etc.) this value is lower by 8–18 ppm. Thus, the thione structure of the compounds under consideration is confirmed. According to ^{15}N NMR spectra,¹⁰² most tetrazolethiones have the 2H-structure; however, Stefaniak¹⁰³ believes 4*H*-tetrazole-5-thione to be the dominant structure.

From the chemical viewpoint, the properties of tetrazolethiones are similar to those of triazolethiones. For example, they undergo pyridylethylation⁸⁰ and aminomethylation¹⁰⁴ at the nitrogen atom adjacent to the thione group. At the same time, tetrazolethiones are more prone to form sulfides than triazolethiones in reactions with α,β -unsaturated carbonyl compounds and in the cyanoethylation reaction.^{99, 105, 106} Addition occurs at the nitrogen atom in presence of triethylamine and at the sulfur atom in an alkaline medium. The sulfides formed can rearrange into C–N-adducts. Moreover, a special experiment involving the use of ^1H NMR spectroscopy showed the C–S-adduct to be the intermediate in the reaction catalysed by triethylamine.

The mode of acylation depends on both the nature of the substituent in the ring and on the acyl halide structure.^{100, 107, 108} For example, sodium 1-phenyltetrazole-5-thiolate gives a mixture of products of the acylation at the sulfur atom and the nitrogen atom in the 4-position, the fraction of the latter decreasing with increase in the bulk of the substituent R.

The yields of compounds **23** and **24** are equal for $\text{R} = \text{Me}$, while for $\text{R} = \text{Bu}^t$ the C–N-adduct is not formed. In 1-alkyltetrazolethiones not only the nitrogen atom at the 4-position but also the nitrogen atom at the 2-position undergoes acylation, and a mixture of three products is formed. Arenesulfonyl chlorides, benzoyl chloride, and compounds containing the $\text{Hal}-\text{C}(\text{sp}^3)$ bond react at the sulfur atom. Only one exception is known.

Arylsulfonyl chlorides react with tetrazolethiones in ether in the presence of pyridine to give disulfides.¹⁰⁹

Diazomethane reacts with 1-methyltetrazole-5-thione to give a mixture of *S*-methyl- and 4-*N*-methyl-derivatives,¹⁰¹ while oxiranes give spirocyclic 1,3-oxathiolanes.¹¹⁰

The thione structure was assigned¹¹¹ to 1,2,3,4-tetrazole-5-thione on the basis of the absence of absorption at $2500-2600\text{ cm}^{-1}$ in the IR spectrum.

In alkaline medium, this compound is alkylated and acylated at the sulfur atom.^{100, 111–113}

* * *

Comparative analysis of the structures of tautomeric five-membered heterocyclic thiols leads to the following conclusions. The thione form predominates in all azoles having the mercapto-group between two heteroatoms, as happens, for instance, in imidazole-2-thione, thiadiazole-2-thione, and tetrazolethione. 5-Mercaptothiadiazole-2-thione is an exception; it contains a thiol group, unlike, for example, 1,2,4-thiadiazole-3,5-dithione. On the other hand, if the above condition is not fulfilled and at least one of the 'neighbours' of the mercapto group is a carbon atom, the predominance of the thiol form may be expected. Among such compounds are furan-, thiophene-, and selenophene-thiols, mercaptopyrazoles, as well as 3-mercaptoisothiazoles **25**, 5-mercaptoisoxazoles **26**, and 4-mercapto-1,2,3-triazoles **27**, which have not been considered here (see the review of Elguero et al.¹).

As to the characteristic features of the chemical properties of the compounds considered, one may note that the predominance of one or another tautomeric form does not often determine the regioselectivity of the reaction. The alkylation of azolethiones with alkyl halides at the sulfur atom and the autothiolation of furan-, thiophene-, and selenophene-thiols may be given as examples.

The reactivity of metal β -diketonates in the thermal decomposition reaction

E I Tsyganova, L M Dyagileva

Contents

I. Introduction	315
II. The influence of the nature of the metal and the ligand on the volatility of metal β -diketonates	315
III. Kinetics of the thermal decomposition of metal β -diketonates	319
IV. Conclusion	325

Abstract. Characteristic features of the thermal decomposition of Group I–IV metal β -diketonates are surveyed and analysed. A systematic account is given of data concerning the influence of the nature of the metal and of the substituent in the β -diketone on the volatility of the metal β -diketonates and the kinetics and mechanism of their thermal decomposition. The bibliography includes 95 references.

I. Introduction

Metal β -diketonates are a class of compounds which have been quite adequately investigated.^{1–5} The syntheses and properties of the β -diketonates of virtually all the metals in the Periodic System and the structures of the complexes^{6–8} have been described in the literature and the nature of the bond in the chelate ring has been examined.^{9, 10}

Metal β -diketonates constitute a convenient model for the study of theoretical problems in the chemistry of coordination compounds and possess a series of properties of practical value which are responsible for their wide-ranging application as catalysts in oxidation, addition, and polymerisation processes,^{11, 12} for the separation of mixtures of lanthanides,^{13, 14} and for the preparation of metallic and oxide coatings.^{15–26} Interest in the β -diketonates has again grown in recent years because, by virtue of their volatility and resistance to oxidation, they proved convenient starting compounds for the introduction of metals into high-temperature superconducting films by deposition from the gas phase.^{27–36}

The volatility and thermal stability of the β -diketonates are fundamental factors in their use in the technology of the preparation of films. However, there are no data in the literature on the analysis of the thermal stability of these compounds.

The aim of the present review is to give a systematic account of the literature data and the authors own studies on the volatility and kinetics of the thermal decomposition of Group I–VIII metal β -diketonates, to discover the common features of the influence of

the nature of the metal and the ligand on the volatility and on the kinetic and activation parameters of the thermal decomposition and on its mechanism.

II. The influence of the nature of the metal and the ligand on the volatility of metal β -diketonates

Vapour pressure is one of the most important physicochemical characteristics of pure compounds. Metal β -diketonates exhibit an enhanced volatility at temperatures in the range 373–573 K. Various methods are used nowadays to measure the vapour pressures of metal β -diketonates: the isotenoscope, membrane, and spectrophotometric methods, the flow method, and the Knudsen effusion method. The advantages and disadvantages of each of the above methods have been analysed in monographs.^{37–39}

There have been fairly numerous studies on the vapour pressures of metal β -diketonates.^{40–70} However, their results are contradictory. The establishment of the general characteristics of the influence of the nature of the metal and the ligand on the volatility of metal β -diketonates is therefore of undoubted interest.

There are quantitative data on the vapour pressures of metal β -diketonates mainly for Group II–IV and VIII metals, metals of the 3d series, and also the lanthanides and actinides.^{41–65}

The results of vapour pressure measurements on metal β -diketonates obtained by the isotenoscope,^{40–42, 51–55} spectrophotometric,^{56, 57} membrane,^{58, 59} effusion,⁶⁰ and flow⁶¹ methods have been analysed in a review by Igumenov et al.⁴³ Appreciable discrepancies between the experimental vapour pressures obtained by different methods have been noted.^{41, 52, 57, 61} It has been concluded that, in the study of fairly volatile and thermally stable β -diketonates, the static method with a membrane null-manometer is the most reliable.⁴³

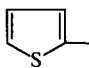

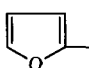

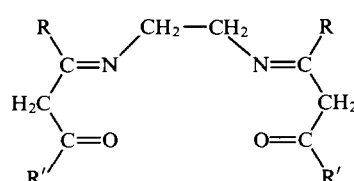

Table 1 presents the conventional designations of the metal β -diketonates investigated and Table 2 lists the thermodynamic parameters of their evaporation process obtained by the static method. All the compounds investigated exist in the gas phase as monomers and the thermodynamic parameters obtained refer to heterogeneous processes of the type $A(\text{solid, liq.}) \rightleftharpoons A(\text{gas})$. The authors of the above review⁴³ believe that the enthalpies of sublimation of the β -diketonates in the range 83.6 to 104.5 kJ mol^{–1}^{58, 59} are more reliable than the values in the range 12.5–58.5 kJ mol^{–1} established by Berg and his coworkers.^{40–42}

The volatility of chelates of the type

n = oxidation state of the metal,

may be influenced by the end groups R and R', the nature of the metal and of the donor atoms X and Y, the stoichiometry of the complexes, and the crystal lattice structure.⁴³

It has been noted⁶⁷ that the replacement of a hydrogen atom by alkyl groups diminishes the volatility of the complexes.

Among the Group I metal complexes, the volatility of copper(II) β -diketonates with fixed donor atoms (X = Y = O; X = O, Y = N) but different groups R and R' has been investigated (Table 2).^{2, 48, 68, 69}

The following series based on the variation of the volatility of copper(II) complexes was obtained:

It was shown that the introduction of the CF₃ and C₃F₇ groups into the ligand increases the volatility of the copper complexes. The replacement of both groups R and R' in Cu(acac)₂ by *tert*-butyl groups increases the volatility slightly, but the thermal stability of the complex rises sharply.⁴⁸ The presence of aromatic, heterocyclic, and ether groups lowers the volatility of the complexes drastically.² Comparison of the

Table 2. The coefficients in the equation for the temperature variation of the vapour pressure, $\lg P = B - A/T$ (at $P \times 1.33$ GPa), and the thermodynamic parameters of the vaporisation of metal β -diketonates.

volatilities of Cu(tfacac)₂ and Cu(fod)₂ shows that an increase in the length of the fluorinated chain hardly affects the volatility of the complexes.⁴⁸

In the case of the N and O donor atoms, the dependence of the volatility on the nature of R and R' remains the same as before.

It is essential to note the conventional nature of the series presented, since, depending on the temperature range in which the comparison is carried out, the relative volatilities of adjacent complexes may change. Only comparison of experimental $P-T$ curves can yield a concrete answer to the question of the greater or lower volatility of a complex in a particular temperature range.

Among Group II metal β -diketonates, the volatility of calcium,⁴⁴ strontium,⁴⁴ and barium⁴⁵ β -diketonates has been investigated. It was established that the volatility of the calcium compounds at temperatures below 400 K varies as follows:⁴⁴

In the temperature range 430–520 K, the series assumes a different form:

Thus the introduction of the *tert*-butyl group into the calcium compounds increases the volatility of the complexes to a greater extent than the introduction of the trifluoromethyl group.

For the strontium compounds⁴⁴ in the temperature range from 430 to 500 K, the change in the volatility of Sr(tfacac)₂ is greater than for Sr(ptfacac)₂. At temperatures below 430 K and above 500 K, the opposite relation holds.

In terms of their volatilities, the β -diketonates can be arranged in the following series:⁴⁵

As in the case of copper β -diketonates, the volatility of the barium compounds increases following the introduction of the trifluoromethyl group into the ligand molecule. The introduction of the *tert*-butyl group lowers the volatility of these compounds. The lowest volatility is that of Ba(dpm)₂, which contains two *tert*-butyl groups. Here it was noted that the volatilities of Ba(dpm)₂ synthesised at different times differ significantly. A decrease in the volatility of Ba(dpm)₂ during its storage has been observed.⁴⁵

It has been shown⁷⁰ that, according to mass-spectrometric data, Ba(dpm)₂ exists as a trimer in the gas phase and that its thermolysis is preceded by its depolymerisation. During the storage of Ba(dpm)₂ or Ba(dpm)₂ · 2H₂O, the complex decomposes slowly with formation of Hdpm or the diketone Bu'-CO-CH=CH-CO-Bu'. It is therefore recommended that Ba(dpm)₂ be stored in vacuo.

We shall consider how the nature of the metal influences the volatility of the isotypical calcium, strontium, and barium β -diketonates.

The volatility of the complexes M(tfacac)₂ (M = Ca, Sr, Ba) increases with increase in the atomic number of the metal: Ca < Sr < Ba. For the complexes M(ptfacac)₂, the above series is reversed: Ca > Sr ≈ Ba. The same trend has been observed for M(dpm)₂: Ca > Ba.

Thus in the series of Group II metal β -diketonates we see no common trends in the variation of the volatility with the atomic number of the metal for different ligands.

Among the Group III metal diketones, the variation of the volatility of the aluminium,⁴³ gallium,⁴³ indium,⁴³ scandium,^{43, 50} yttrium,⁴⁶ and the lanthanide and actinide^{50, 56, 60–64, 66} β -diketonates has been investigated.

For aluminium β -diketonates, the series based on increasing volatility has the following form:⁴³

The influence of the end groups has been clearly traced for the aluminium compounds. The introduction of the CF₃ group into the ligand of the chelate increases sharply the volatility of the complex. The joint presence of the *tert*-butyl and trifluoromethyl groups reduces the volatility of the complex compared with Al(tfacac)₃. Thus, in the case of the aluminium complexes, as for the copper and barium complexes, the trifluoromethyl group increases while the *tert*-butyl group diminishes the vapour pressure of the chelate.

A successive decrease in volatility with increase in the atomic number of the metal has been observed for the compounds M(tfacac)₃ (M = Al, Ga, In).⁴³

In terms of their volatilities, scandium β -diketonates can be arranged in the following sequence:^{43, 50, 56}

The chelates with *tert*-butyl substituents proved to be more volatile than those with the trifluoromethyl substituents (although one should bear in mind that data obtained by different workers were compared). The following dependence of the volatility of the β -diketonates on the nature of the ligand has been established for yttrium β -diketonates:⁴⁶

The volatility of yttrium β -diketonates increases in proportion to the number of fluorine atoms introduced into the ligand molecule: in the series of fluorine-substituted acetylacetonates, the hexafluoroacetylacetonates have the highest vapour pressure. The greater volatility of the complexes with fluorine-containing ligands compared with their analogues without fluorine has been attributed to the mutual repulsion of the strongly electronegative terminal fluorine atoms and the corresponding decrease in the extent of van der Waals interactions.

The following series based on the variation of volatility has been observed for M(dpm)₃ (M = Sc, Y, La):⁵⁰

Evidently, the volatility of the chelate diminishes with increase in the atomic number of the metal, as in the aluminium subgroup.⁴³

The variation of the volatility of lanthanide β -diketonates Ln(dpm)₃ (Ln = La, Ce, Pr, Nd, Pm, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu) has been investigated.^{50, 62} A monotonic increase in the volatility of Ln(dpm)₃ with increase in molecular mass and with some decrease in the size of the molecule has been observed.

Konstantinov et al.⁵⁰ attribute this to the different degrees of association of the compounds in the condensed phase. It is suggested that, on passing to lighter elements, the concentration of the involatile dimeric molecules in the melt increases and the vapour pressure of the monomeric molecules over the melt diminishes. With increase in the temperature of the melt and hence with increase in the degree of dissociation of the dimeric molecules in the melt, the volatilities of different $\text{Ln}(\text{dpm})_3$ are similar and they become indistinguishable as regards their ability to evaporate.

It has been shown for the actinides⁶² that the compounds $\text{M}(\text{fod})_3$ are more volatile than $\text{M}(\text{dpm})_3$, the nature of the metal having a greater influence than that of the radicals.

The influence of the nature of the metal on the volatility of Group IV metal acetylacetonates is insignificant.⁶⁶

The influence of the nature of the ligand substituent on the volatility of Group V metal β -diketonates has been investigated for bismuth.⁷¹ It was shown that, depending on the type of substituent, the volatility of the complexes diminishes in the sequence

We observe a rare instance of a decrease in volatility following the introduction of the trifluoromethyl group into the ligand.

Factual data on the volatility of Group VIII metal (Pt, Pd, Ir, Rh) β -diketonates have been treated systematically by Igumenov et al.⁴⁹ The usual sequence based on the variation of volatility was observed for rhodium and iridium:

A greater volatility of the iridium complexes compared with the rhodium complexes was observed.⁴⁹ The following sequence based on the variation of volatility was established for platinum(II) chelates:

Igumenov et al.⁴⁹ note that all the octahedral platinum(IV) chelates, even dimeric ones, have appreciably higher vapour pressures than the isoligand pseudosquare platinum(II) chelates. It was shown that *trans*- $\text{Pt}(\text{tfacac})_2$ occupies a special place among platinum(II) β -diketonates. Its volatility is lower than that of *cis*- $\text{Pt}(\text{tfacac})_2$ and even that of $\text{Pt}(\text{dpm})_2$. This is one of the few experimental confirmations of a decrease in volatility after the introduction of the CF_3 group into the ligand.

The introduction of the trifluoromethyl group into the ligand in nickel(II) complexes led to a significant increase in the vapour pressure.⁷²

The study of the volatility of the trifluoroacetylacetonates of the metals in the first transition series (Sc, V, Cr, Fe, Co) led to the conclusion that the volatility decreases with increase in the atomic number of the element. It was noted in this connection that the influence of the nature of the metal on the volatility of the complexes for fixed groups R and R' is insignificant.^{43, 68}

Igumenov et al.⁴⁹ observed a decrease in the thermodynamic parameters characterising the sublimation and evaporation of the β -diketonates after the introduction of the CF_3 group into the ligand. The decrease in ΔH°_f , which should entail a sharp increase in the vapour pressure, is compensated by the corresponding decrease in ΔS°_f . Analysis of the data for compounds belonging to one group in the Periodic System shows a decrease in the absolute values of the thermodynamic parameters with increase in the atomic number of the metal.

Analysis of the data presented above for metal β -diketonates shows that the decisive factor in the volatility of the chelates is the nature of the ligand. In terms of their influence on the volatility, the factors considered can be arranged as follows:⁴³

(1) the influence of the nature of the terminal R and R' groups of the ligand;

(2) the influence of the nature of the metal within the groups of the Periodic System;

(3) the influence of the nature of the metal within the periods of the Periodic System.

The fact that the volatility of copper, calcium, strontium, barium, yttrium, aluminium, gallium, indium, nickel, palladium, iridium, and platinum β -diketonates increases following the introduction of trifluoromethyl groups into the β -diketone and diminishes after the introduction of *tert*-butyl groups into the latter may be regarded as established. A decrease in the volatility after the introduction of CF_3 groups has been observed only for calcium (at 430–520 K), scandium, and bismuth β -diketonates and the *trans*-isomer of $\text{Pt}(\text{tfacac})_2$.

General trends in the variation of the volatility of the β -diketonates as a function of the atomic number of the metal have not been noted. A decrease in volatility with increase in the atomic number of the metal has been observed in the calcium subgroup for the complexes $\text{M}(\text{ptfacac})_2$ and $\text{M}(\text{dpm})_2$ (M = Ca, Sr, Ba), in the aluminium subgroup for the complexes $\text{M}(\text{tfacac})_3$ (M = Al, Ga, In), in the scandium subgroup for the complexes $\text{M}(\text{dpm})_3$ (M = Sc, V, La), and in the group of metals of the first transition series (Sc, V, Cr, Fe, Co) for the $\text{M}(\text{tfacac})_n$ complexes. On the other hand, an increase in volatility with increase in the atomic number of the metal has been observed for the compounds $\text{M}(\text{tfacac})_2$ (M = Ca, Sr, Ba) and $\text{M}(\text{dpm})_3$ (M = lanthanides).

It is at present impossible to establish an unambiguous correlation between the thermodynamic data and the structural parameters of metal β -diketonates because these compounds have been little investigated.⁴³

III. Kinetics of the thermal decomposition of metal β -diketonates

In the present review an attempt is made to treat systematically the available literature data concerning the influence of the nature of the metal and the substituent on the kinetics and mechanism of the gas-phase pyrolysis of substituted metal β -diketonates. The thermal decomposition of the β -diketonates can occur both in the gas and solid phases. In the case of the gas-phase thermal decomposition of metal β -diketonates, the rate constant for the thermal decomposition serves as a measure of reactivity. In the solid-phase decomposition investigated by differential thermal analysis (DTA), the comparison of the reactivities was based on the temperatures of the onset of decomposition, while in the case of the solid-phase decomposition, investigated by the kinetic method, it was based on the initial rates of thermal decomposition.

1. Thermal decomposition of Group I metal β -diketonates

Among Group I metal β -diketonates, the kinetics of the thermal decomposition of copper(II) β -diketonates have been described in greatest detail.^{73–78} The kinetics of the thermal decomposition of copper(II) complexes have been studied by static,⁷³ flow,⁷⁴ and mass-spectrometric⁷⁵ methods. The experimental conditions and the activation parameters for the thermal decomposition are presented in Table 3.

The gas-phase pyrolysis of $\text{Cu}(\text{acac})_2$ under static conditions in vacuo is homogeneous-heterogeneous in character and is described satisfactorily by a first-order kinetic equation.⁷³ The acceleration of the thermal decomposition in the presence of oxygen has been noted.

Mass-spectrometric analysis led to the detection of the following components in the products of the total thermal decomposition at 573 K (in mol %): acetone (22.3), ethene (carbon monoxide) (38.0), ethyl methyl ketone (0.3), CO_2 (36.2), and H_2O (3.2). This product composition indicates appreciable degradation of acetylacetone, which is formed in the initial stages of the thermal decomposition. The splitting off of the ligand is observed at temperatures close to that of the onset of

Table 3. Kinetic parameters of the gas-phase pyrolysis of copper(II) β -diketonates obtained by a flow method ⁷⁴ (A — pro-exponential factor).

Compound	Temperature range/K	lg A	$E/\text{kJ mol}^{-1}$
Cu(acac) ₂ ^a	536–613	7.48 ± 0.98	115.4 ± 10.8
Cu(acac) ₂	553–723	7.16 ± 0.65	58.7 ± 6.2
Cu(tfacac) ₂	473–673	7.15 ± 0.48	46.9 ± 4.5
Cu(hfen) ₂	473–723	7.07 ± 0.35	45.9 ± 5.4

Cu(dfh) ₂	453–593	6.28 ± 0.45	31.8 ± 8.2
Cu(dpm) ₂ ^b	423–823	13.176	155.5 ± 7.1

^a Data obtained by a static method.⁷³ ^b Data obtained by the mass-spectrometric method.⁷⁵

decomposition.⁷⁷ The ligand Hdpm is also formed in the initial stages of the pyrolysis of Cu(dpm)₂.

It has been established⁷⁹ that acetylacetone has a higher thermal stability than that of the chelate complexes based on it. The M–O bond energy in acetylacetonates is 160–280 kJ mol^{−1}. The M–O bond is the least stable in the chelate molecule.⁷⁹

The kinetics of the thermal decomposition of fluorine-substituted copper β -diketonates in an open system have been investigated in a stream of helium at temperatures in the range 453–723 K in a reactor the walls of which were lined with metallic copper having a constant catalytic activity (Table 3).⁷⁴

Analysis of the dependence of the maximum rate of growth of the metallic copper film under dynamic deposition conditions enabled Mazurenko et al.⁷⁴ to conclude that the rate-limiting stage of the thermal decomposition of fluorine-substituted copper(II) β -diketonates is the decomposition of the adsorption complex. A linear dependence of the energy characteristics of the thermal dissociation process on the electronic structure of the coordination unit of the β -diketonate complexes has been observed. Thus, following the enhancement of the electron-accepting properties of the α -substituent, a decrease in the activation energy and an increase in the rate constants for the thermal decomposition of copper(II) β -diketonates have been observed in the sequence

Cu(acac)₂ has the highest kinetic stability in the thermal decomposition reaction. An increase in the number of fluorine atoms in the β -diketone leads to a successive increase in the thermal decomposition rate constant. Thus at 553 K the rate constant for the thermal decomposition of Cu(acac)₂ is accordingly smaller than those for the thermal decomposition of the fluorine-substituted analogues.

The greater thermal stability of Cu(acac)₂ compared with the substituted β -diketonates has been attributed⁷⁸ to the fact that the contribution of ring conjugation in copper(II) β -diketonates is greater than in the chelates of other metals by virtue of the π -bonding ($p\pi-d\pi$) nature of the Cu–O bond. The alkyl substituents in these chelates exhibit a hyperconjugation effect, which disrupts the resonance in ring-conjugated systems.

It was not possible to reach a conclusion about the comparative stabilities of Cu(acac)₂ and Cu(dpm)₂, since the thermal decomposition rate constants were obtained under different experimental conditions^{73,75} and may refer to different rate-limiting stages.

A kinetic analysis of the thermal decomposition of copper(II) β -diketonates in vacuo and under an inert atmosphere, based on the results of thermogravimetric analysis, has been published.⁷⁶ In terms of the apparent activation energies, the compounds can be arranged in the following sequences [the values of E (kJ mol^{−1}) are given in brackets]:

(a) under an inert atmosphere:

(b) in vacuo:

However, no conclusions concerning the comparative thermal stabilities of the copper(II) β -diketonates can be reached on the basis of these series, since the pre-exponential factor in the rate constant equation is unknown.

The thermal stability of Na(acac) has been investigated by the DTA method⁷⁸ relative to the thermal stabilities of the acetylacetonates of divalent and trivalent metals: Cu(II), Ni(II), Co(II), Cr(III), Fe(III), Co(III), and Mn(III). It was shown that all the compounds M(acac)_n investigated decompose in the temperature range from 423 to 673 K. In terms of the thermal stabilities of their acetylacetonates, the metals can be arranged in the following sequence:

The principal gaseous products of the decomposition of M(acac)_n [M = Co(II), Co(III), Al(III), Fe(III)] are acetone and carbon dioxide. In the case of Na(I) and Cr(III), methane appears in the thermal decomposition products on raising the temperature. The principal product of the thermal decomposition of copper(II) and manganese(III) acetylacetonates is acetylacetone over the entire temperature range.

The thermal decomposition of three types of chelate complexes of dimethylgold(III) having the general formula Me₂Au(R–CX–CH–CO–R'), where X = O, NH, or S and R and R' = Me, Bu^t, or CF₃ in various combinations, has been investigated by the DTA method⁷⁹ in the solid and gaseous states. Thermolysis of all types of chelates proceeds in the same way regardless of the nature of the donor atoms and the type of substituents R and R' in the ligand.

The complexes containing the *tert*-butyl group exhibit the highest thermal stability. The introduction of the CF₃ group into the β -diketonate complexes leads to an appreciable decrease in their thermal stability, while, conversely, the introduction of CF₃ groups into the β -iminoketonates increases the thermal stability of the complex.

The decisive factor governing the variation of the thermal stability of the complexes in the condensed state is not the type of substituents R and R' but the nature of the donor atoms in the ligand. The introduction of sulfur atoms into the chelate ring leads to a sharp decrease in the thermal stability of the dimethylgold(III) complexes.

It has been established that, in the series of dimethylgold(III) chelates investigated, the thermal stability increases as a function of the chelate unit in the following sequence:

The thermal stability of the β -diketonate complexes in the gas-phase decomposition is analogous to their stability in the solid-phase decomposition.

When the CF₃ group is introduced into the chelate ligand, the series of the thermal stabilities of the gaseous β -iminoketonates is reversed.

The principal volatile products of the thermal decomposition of the compounds investigated are the free β -diketonates, β -iminoketonates, HL, CH₄, C₂H₆, and MeL (L = ligand). The presence of this set of products indicates the occurrence of competing rearrangements of the thermally excited species with opening of the chelate ring.

In the interaction of the β -diketonates with deuterium, the ketones $R-CO-CDMe-CO-R'$ and monosubstituted deuteriated β -diketonates were detected in the reaction products. Deuteriated metal-containing products were not found. Appreciable temperature-dependent deuteriation of the molecules of the complexes has been observed for the β -iminoketonates. Mainly monosubstituted deuteriated metal-containing products are formed, whereas in the case of the free β -iminoketonates, disubstituted molecules were detected, which confirms the above hypothesis of the initial opening of the chelate ring in the thermally excited molecule with subsequent decomposition via different paths.

2. Thermal decomposition of Group II metal β -diketonates

The following thermal stability series has been obtained from the results of the study of the relative reactivities of divalent Group II metal acetylacetonates:⁸⁰

The size of the alkyl substituent in beryllium β -diketonates has little effect of the stability of the complexes. Among Group II metal compounds fluorine-substituted calcium and strontium β -diketonates have been investigated in greatest detail.⁴⁴ The thermal decomposition of these compounds takes place in the gas phase and is described by a first-order kinetic equation (Table 4). From 1.5 to 6.0 moles of gaseous products are evolved per mole of the decomposed chelate. The complexes $Ca(dpm)_2$ and $Ca(acac)_2$ undergo the greatest and smallest degradation respectively. The main product of the thermal decomposition of calcium acetylacetonate is acetone, the content of which diminishes with increasing degree of conversion of the reactant. The first decomposition stage is the opening of the chelate ring with subsequent dissociation of the C-C bonds.⁴⁴ In terms of their kinetic stabilities, the calcium compounds can be arranged in the following sequence:

Table 4. Kinetic and activation parameters for the gas-phase pyrolysis of Group II–V metal β -diketonates (the initial pressures of the reactants were 50–200 GPa).

^a Pyrolysis in the solid phase. ^b Calculated from the initial rates of pyrolysis.

The thermal stability of the compound $Ca(dpm)_2$ is highest. The introduction of trifluoromethyl groups diminishes significantly the thermal stability of the calcium chelates.

Comparison of the kinetic parameters of the thermal decomposition of the strontium compounds shows that the complex $Sr(tfacac)_2$ is much more stable than $Sr(ptfacac)_2$. A considerable amount of trifluoromethane is present in the products of the decomposition of fluorinated strontium chelates.

Comparison of calcium and strontium β -diketonates containing isotypical ligands shows that the calcium compounds have a higher thermal stability than the corresponding strontium compounds. The difference between the thermal stabilities of the β -diketonates $M(tfacac)_2$ is smaller than in the case of $M(ptfacac)_2$. The thermal decomposition of the strontium compounds is retarded in the presence of oxygen, whereas the decomposition of the calcium chelates is accelerated under these conditions.⁴⁴ The rate constant for the thermal decomposition process diminishes with increase in the heterogeneous factor S/V (S is the surface area of the reactor and V its volume). This indicates a complex homogeneous-heterogeneous character of the thermal decomposition of the chelates, the main products of which are carbon oxides (for both low and high degrees of conversion) (Table 5).

The decomposition of barium β -diketonates takes place both in the solid and gas phases (Table 4).^{45, 73} The pyrolysis of barium acetylacetonate proceeds topochemically in the solid phase and is accompanied by the formation of both solid and gaseous products.⁷³ The composition of the solid phase has the empirical formula $BaC_{3.6}H_{6.06}O_{1.91}$. More extensive degradation of barium acetylacetonate to the carbide BaC_2 takes place in the presence of oxygen, the initial rate of thermal decomposition remaining unchanged. The following substances were detected among the products of the total pyrolysis of barium acetylacetonate at 573 K (mol %): acetone (86.6), ethanol (0.8), ethene (carbon monoxide) (9.3), ethyl methyl ketone (0.2), carbon dioxide (1.0), water (2.1).

The thermal decomposition of the fluorine-substituted barium β -diketonates takes place in the gas phase and is described satisfactorily by the kinetic equation for a first-order reaction.⁴⁵ The kinetic stability of barium β -diketonates in the thermal decomposition reaction varies in the following series:

The influence of oxygen on the rate of the thermal decomposition of fluorine-substituted barium β -diketonates is specific and is determined by the nature of the ligand.⁴⁵ In the thermal decomposition of $Ba(ptfacac)_2$ and $Ba(dpm)_2$, a decrease in the rate constant to a minimum value in the presence of 30%–50% of added oxygen is observed. In the case of $Ba(hfacac)_2$, the addition of oxygen hardly affects the rate, whereas an appreciable increase in the rate constant is observed for $Ba(tfacac)_2$. As in the case of the analogous calcium and strontium compounds, a decrease in the decomposition rate constant with an increase in the heterogeneous factor is likewise observed for the barium chelates.⁴⁵

The main products of the thermal decomposition of all the barium compounds investigated, in both the initial and final decomposition stages, were CO and CO₂, the content of which decreases on passing from the $Ba(hfacac)_2$ to the $Ba(dpm)_2$ complexes in the following series of ligands:

The amount of the main ligand in the total pyrolysis products does not exceed 0.2%–1.4% for all the compounds investigated, which indicates its far-reaching degradation (Table 6). The trends in the variation of the contents of other products are determined by the nature of the initial ligand and by the degree of decomposition.

Comparison of the thermal stabilities of the Group II metal β -diketonates $M(tfacac)_2$ ($M = Ca, Sr, Ba$) shows that the kinetic

stability of these compounds in the thermal decomposition reaction falls with increase in the atomic number of the metal:^{44, 45}

For the complexes $\text{M}(\text{ptfacac})_2$ ($\text{M} = \text{Ca}, \text{Sr}, \text{Ba}$), the kinetic stability series assumes the following form:

A study has been devoted to the radiation-induced thermal decomposition of zinc and cadmium acetylacetonates.⁸¹ Zinc acetylacetonate is thermally less stable than cadmium acetylacetonate. The decomposition curves are S-shaped and, after the sigmoid section, there are long linear sections on the curves. The activation energies corresponding to the sigmoid and linear sections of the decomposition curves have been found.

3. Thermal decomposition of Group III metal β -diketonates

The thermal stability of aluminium β -diketonates, investigated by the DTA method, decreases in the following series:⁴³

As for copper,⁷⁴ calcium,⁴⁴ strontium,⁴⁴ and barium⁴⁵ β -diketonates, the introduction of the trifluoromethyl group into the ligand decreases and the introduction of the *tert*-butyl group increases the thermal stability of the aluminium complexes. In the Al, Ga, and In group, a successive decrease in the thermal stability of the trifluoroacetylacetonate complexes with increase in the atomic number of the element is observed.⁴³

The study of the thermal decomposition of aluminium acetylacetonate in the gas phase, which we carried out by the manometric method, showed that, at temperatures in the range 657–723 K, the degree of decomposition of the reactant is independent of the initial pressure in the range from 130 to 200 GPa. The kinetic decomposition curves at low temperatures are autocatalytic in character, which is induced by the aluminium oxide formed. With increase in the decomposition temperature, the autocatalytic character of the curves vanishes as a consequence of the high rates of decomposition. The first-order rate constant calculated for 723 K is $4.1 \times 10^{-1} \text{ s}^{-1}$. The activation energy for the overall process, calculated by the method involving the transformation of the kinetic curve, is 68.1 kJ mol^{-1} . The primary product of the gas-phase decomposition is acetylacetone, which decomposes to acetone and carbon dioxide. The following substances have been found (mol%) among the products of the total pyrolysis of aluminium acetylacetonate at 673 K: acetylacetone (0.3), diacetyl (0.17), carbon dioxide (33.81), butane (9.54), methane (1.49), dimethylfuran (0.35), acetone (44.67), carbon monoxide (6.90), ketene (0.84), hydrogen (1.54), and unidentified products (0.7). The addition of oxygen accelerates the decomposition.

The trifluoroacetylacetonate chelates of other trivalent metals can be arranged in the following sequence in terms of their thermal stability:⁶⁸

The thermal decomposition of yttrium acetylacetonate takes place in the solid phase similarly to that of the barium analogue.⁷³ The gaseous products of the total pyrolysis of yttrium acetylacetonate at 573 K have the following composition (mol %): acetone (80.0), ethanol (0.4), ethene (carbon monoxide) (8.7), ethyl methyl ketone (0.2), carbon dioxide (1.0), water (0.4). On the other hand, the decomposition of the fluorine-substituted yttrium β -diketonates takes place in the gas phase in accordance with the kinetic law for a first-order reaction (Table 4).⁴⁶ From 2 to 8 moles of volatile products are evolved per mole of the compound decomposed depending on the temperature and the nature of the ligand. The ligand in the complex $\text{Y}(\text{tfacac})_3$ undergoes degradation to the greatest extent, whilst those in the complexes $\text{Y}(\text{dpm})_3$ and $\text{Y}(\text{tfacac})_3$ are least degraded. The kinetic stability of yttrium β -diketonates diminishes in the sequence

This sequence agrees well with the inductive influence of the *tert*-butyl and trifluoromethyl groups on the reaction centre. The electron-donating *tert*-butyl groups strengthen the Y–O bond, which leads to a greater thermal stability of the compounds $\text{Y}(\text{dpm})_3$ and $\text{Y}(\text{ptfacac})_3$ compared with the fluorine-substituted analogues $\text{Y}(\text{tfacac})_3$ and $\text{Y}(\text{hfacac})_3$, in which the strongly electron-accepting CF_3 groups weaken the Y–O bond. Thus the introduction of fluorine atoms into the ligands of the yttrium chelates not only increases the volatility but also diminishes the thermal stability of the complexes.

Evidence indicating a homogeneous-heterogeneous thermal decomposition of yttrium complexes as well as the accelerating effect of oxygen on the rate of thermal decomposition has been observed. The thermal decomposition of yttrium complexes is accompanied by far-reaching degradation of the ligands with formation of a wide range of products, including fluorine-containing hydrocarbons (Table 6).

Among the lanthanide derivatives, the kinetics of the thermal decomposition have been investigated only for the complex $\text{Pr}(\text{ptfacac})_3$ (Table 4).⁴⁷ The thermal decomposition of the praseodymium complex in vacuo takes place in the gas phase and is described satisfactorily by the kinetic equation for a first-order reaction. About 4 moles of gaseous products are evolved per mole of the compound decomposed, the main products being CO and CO₂, which indicates a far-reaching degradation of the ligand (Table 6).

4. Thermal decomposition of Group IV – VII metal β -diketonates

The kinetic and activation parameters of the gas-phase thermal decomposition of titanium, vanadium, and vanadyl acetylacetonates in vacuo have been investigated.^{82,83} The acetylacetonate derivatives of trivalent and tetravalent vanadium have comparable reactivities (Table 4). On the other hand, the replacement of the central metal atom has a much greater influence on the thermal stability of the acetylacetonates than the oxidation state of the metal. The thermal stabilities of the compounds investigated diminish in the sequence

The complex homogeneous-heterogeneous character of the decomposition reactions of these compounds has been demonstrated. As in the case of the barium,⁴⁵ calcium,⁴⁴ and strontium⁴⁴ chelates, a decrease in the rate constant for the thermal decomposition of vanadium acetylacetonate is observed with increase in the surface area, whereas the nature of the surface does not influence the rate of the process. The principal volatile products of the thermal decomposition of vanadium acetylacetonate at 703 K and for low degrees of decomposition were (in moles per mole of the reactant decomposed): acetone (2.0), carbon dioxide (2.5), carbon monoxide (1.2), xylene (0.14), hydrogen (0.11), butene (0.29), and an unidentified product (with m/e 86) (0.02). Similar products have been detected also in the decomposition of vanadyl acetylacetonate. The set of kinetic and analytical data indicates the preferential operation of an intramolecular pathway leading to the decomposition of these compounds. However, the influence of the addition of substances which might serve as initiators of a radical process (acetone, oxygen) indicates indirectly a small contribution of the radical decomposition path. Thus the addition of acetone and oxygen increases the rate constants for the decomposition of vanadium and vanadyl acetylacetonates. The same trends have been observed in the pyrolysis of the copper,^{73–75} yttrium,⁴⁶ barium,⁴⁵ calcium,⁴⁴ strontium,⁴⁴ and aluminium⁴³ chelates. The formation of the acetylacetonyl radical has also been postulated in the pyrolysis of the metal chelates.⁸⁴

The thermal decomposition of zirconium acetylacetonate has been investigated by the DTA method under an inert atmosphere at temperatures from 293 to 773 K.²¹ The process takes place in two stages. In the first stage (453 K), the displacement of two chelate ligands as a result of coordination polymerisation and the formation of an intermediate polymeric product are observed; in the second stage (623 K), zirconium dioxide in the cubic modification is formed. In contrast to the acetylacetonate derivative, the decomposition of the complex $\text{Zr}(\text{ptfacac})_4$ takes place in one stage. It involves the dissociation of the bonds within the chelate ligand with formation of volatile low-molecular-mass products. This decomposition path is associated with the absence of α -hydrogen atoms from the side chains, which would lead to the possibility of the radical recombination of the carbon chains. On further heating, zirconium dioxide passes from the cubic to the pure monoclinic form.

The thermal decomposition of the bismuth chelates $\text{Bi}(\text{tfacac})_3$, $\text{Bi}(\text{hfacac})_3$, and $\text{Bi}(\text{ptfacac})_3$ in the vapour and solid phase has been investigated in helium and oxygen streams.⁷¹ The most characteristic gas-phase products of the thermolysis of the bismuth chelate vapours were the β -diketonates and their fragments. The complex $\text{Bi}(\text{ptfacac})_3$ decomposing at a temperature above 573 K, showed the highest thermal stability. This complex shows a smaller tendency to form oligomers owing to the steric hindrance generated by the bulky substituents in the ligands within the octahedral bismuth complex. The increase in the steric factor as a result of the replacement of the Bu^t groups by MeOCMe_2 rules out almost completely the possibility of dimerisation of the molecules.

Comparison of the thermal stabilities of chromium(III) and manganese(III) acetylacetonates and their alkyl and fluorine-

substituted derivatives, carried out by the DTA method in terms of the initial decomposition temperatures, shows that the chromium chelates are more stable than the manganese chelates.⁸⁰ The pyrolytic decomposition of the β -diketonates of manganese(III) in an unstable oxidation state is accompanied by the transition of the central metal ion from the trivalent to the divalent state and the liberation of the ligand. It has been suggested that this process proceeds via a radical mechanism.⁸⁰

5. Thermal decomposition of Group VIII metal β -diketonates

The thermal stability of iron(III), cobalt(II), cobalt(III), and nickel(II) β -diketonates in the solid phase has been investigated by the DTA method.⁸⁰ The thermal stability of divalent metal acetylacetonates increases on passing from cobalt to nickel: $\text{Co}(\text{acac})_2 < \text{Ni}(\text{acac})_2$. The thermal stability of the chelate nickel acetylacetonate complexes with bulky alkyl substituents increases in the sequence

This agrees with the increase in the number of carbon atoms in the alkyl substituents. A similar sequence has been observed also for cobalt(II) chelates. The thermal stability of these chelates depends on the electron-donating effect of the alkyl group, which increases the basicity of the ligand oxygen atom and this increases the strength of the $\text{M}-\text{O}$ bond. At room temperature, the alkyl derivatives of cobalt(II) and nickel(II) have a polymeric octahedral structure. An increase in temperature favours the formation of chelates with a square planar structure in the liquid phase. This tendency intensifies with increase in the bulk of the alkyl substituents owing to steric hindrance. Near the temperature of the onset of decomposition, the axial $\text{M}-\text{O}$ bond in cobalt(II) and nickel(II) β -diketonates is weakened, whilst the equatorial bond is strengthened. If one considers the decomposition of metal β -diketonates with the dissociation of the equatorial $\text{M}-\text{O}$ bond, then the β -diketonates with less bulky alkyl substituents, which favour the formation of a polymeric hexacoordinate structure, should be less stable.

The influence of the structure of the compound on the thermal properties of the nickel complexes $\text{Ni}(\text{acac})_2$, $\text{Ni}(\text{dpm})_2$, $\text{Ni}(\text{acim})_2$, and $\text{Ni}(\text{tfacim})_2$ has been traced.⁷² The introduction of the trifluoromethyl group into the ligand instead of the methyl group increases the thermal stability of the nickel acetylacetonate complexes and decreases the stability of the imino-derivatives. The thermal decomposition of the β -diketonate derivatives of nickel proceeds via a mechanism involving an intramolecular rearrangement with evolution of the free β -diketonates into the gas phase. A second decomposition path with formation of a ligand radical operates for the ketoiminate complexes, the contribution of this path increasing with temperature. In the presence of hydrogen, the main products of the decomposition of all the nickel(II) complexes investigated are the free ligands.

Iron(III) acetylacetonates and alkylacetylacetonates are more stable than the analogous cobalt(III) compounds. The thermal stability of cobalt(III) β -diketonates increases in the sequence

A similar trend has also been observed for iron(III) β -diketonates, which is consistent with the increasing bulk of the alkyl substituent. The pyrolytic decomposition of cobalt(III) and iron(III) (an unstable oxidation state of the metal) β -diketonates is accompanied by the transition of the central metal ion from the trivalent to the divalent state and the liberation of the ligand. It has been suggested that the decomposition of these compounds proceeds via a radical path.

The characteristic features of the thermal decomposition of palladium, iridium, rhodium, and platinum β -diketonates have

been examined.^{49, 80, 85} The dependence of the thermal stability of the β -diketonates of these metals on the type of substituents in the ligand is weak.⁴⁹ One can only confirm fairly unambiguously the ability, frequently noted above, of the *tert*-butyl group to increase somewhat the thermal stability of the complex. It has been noted for palladium(II) β -diketonates that the unsubstituted acetylacetonates have a higher thermal stability than the acetylacetonates with bulky alkyl groups.⁸⁰ The palladium complexes are characterised by a larger contribution of the ring conjugation than other metal chelates by virtue of the π -bonding ($p\pi-d\pi$) nature of the M—O bond. The alkyl substituents in these ligands exhibit hyperconjugation, which disrupts the resonance in the ring-conjugated systems and this increases the contribution of π -bonding in the M—O bond. Problems concerning the influence of substituents in the *cis*- and *trans*-positions in rhodium complexes with asymmetric substitution in a planar chelate ring have been examined on the basis of IR and NMR spectroscopic data.^{86, 87} The inductive effect of the alkyl substituents on the free energy of the gas-phase oxidation of ruthenium β -diketonates has been studied: $\text{Ru}(\text{acac})_3$, $\text{Ru}(\text{dprm})_3$, $\text{Ru}(\text{dbtm})_3$, $\text{Ru}(\text{dibtm})_3$, and $\text{Ru}(\text{divm})_3$.⁸⁸ It was shown that it varies from $-200.6 \text{ kJ mol}^{-1}$ for the complexes with methyl substituents to $-150.5 \text{ kJ mol}^{-1}$ for the complexes with *tert*-butyl substituents. The one-electron oxidation energy varies from -79.4 to $-66.9 \text{ kJ mol}^{-1}$ and is not correlated with the size of the alkyl substituent.⁸⁸ The replacement of one of the donor oxygen atoms by nitrogen in the palladium, iridium, rhodium, and platinum complexes leads to an increase in the gas-phase thermal stability of the complexes. The products of the thermal decomposition of these compounds contain considerable amounts of the noncoordinated ligand molecules.⁸⁵

IV. Conclusion

The above analysis of the literature data concerning the influence of the nature of the metal and the substituents in the β -diketone on the volatility and thermal stability of metal β -diketonates shows that the volatility of the complexes depends to a large extent on the nature of the substituent in the β -diketone, while their thermal stability is determined both by the nature of the metal and that of the substituent in the ligand.

Unambiguous rules governing the variation of volatility and thermal stability as a function of the atomic number of the metal have not been established. The kinetic stability of the metal β -diketonate complexes $\text{M}(\text{tfacac})_n$ [$\text{M} = \text{Ca}, \text{Sr}$ or Ba ($n = 2$) and Al, Ga , or In ($n = 3$)] decreases successively in the thermal decomposition reaction with increase in the atomic number of the metal: $\text{Ca} > \text{Sr} > \text{Ba}$, $\text{Al} > \text{Ga} > \text{In}$.

The parallel variation of the volatility and thermal stability of the complexes $\text{M}(\text{tfacac})_3$ ($\text{M} = \text{Al}, \text{Ga}, \text{In}$) has been observed. The volatility of these compounds diminishes with increase in the atomic number of the element, which is associated with the characteristic features of the electronic structures of these compounds.⁸⁹ For $\text{M}(\text{tfacac})_2$ ($\text{M} = \text{Ca}, \text{Sr}, \text{Ba}$), the opposite variation of this kind is observed: the volatility of the complexes increases with increase in the atomic number of the metal. The variation of the thermal stability with increasing atomic number of the metal presented above does not hold for the complexes $\text{M}(\text{tfacac})_3$ ($\text{M} = \text{Sr}, \text{Cr}, \text{Mn}, \text{Fe}$). Their thermal stability and volatility vary in the following series of metals respectively:

A clear-cut dependence of the thermal stability on the atomic number also does not occur for the acetylacetonate complexes of monovalent, divalent, and trivalent metals. The thermal stability of the complexes is influenced not only by the energy of the M—O bond, determined by the nature of the metal, but also by the steric structure of the complexes, the possibility of the formation of

oligomers, and the phase in which the thermal decomposition takes place. The rate of the gas-phase pyrolysis is determined by the type of reaction — homogeneous, heterogeneous, and homogeneous–heterogeneous — and also by the type of the rate-limiting stage.

In the study of the kinetics of the thermal decomposition of fluorine-substituted calcium, strontium, and barium β -diketonates, the decrease in the rate constant for the thermal decomposition of the chelate with increase in the surface area of the reactor can be clearly traced, whilst in other cases it is rarely manifested. This may be associated with the retardation of the rate-limiting stage of the thermal decomposition — the conversion of the bidentate ligand into a monodentate one with subsequent splitting off of the free ligand.

A general rule is the increase, frequently emphasised in the literature, in volatility and the decrease in the thermal stability of the metal β -diketonates after the introduction of the trifluoromethyl group into the ligand. On the other hand, the introduction of the *tert*-butyl group decreases the volatility of the complex and increases its thermal stability.

The influence of chain length of the alkyl substituents in the β -diketone on the thermal stability of the chelates is determined by the structure of the complexes. The thermal stability of the cobalt(II), cobalt(III), iron(III), and nickel(II) complexes, which have polymeric octahedral structure at room temperature, increases with increase in the length of the alkyl group. This is associated with the electron-donating effect of the alkyl group, which strengthens the M—O bond. Among the palladium(II) and copper(II) complexes, which have a square planar structure, the acetylacetonate derivatives are more stable than the derivatives with alkyl substituents. This has been attributed to the hyperconjugation effect of the alkyl substituents, which disrupts the resonance in the ring-conjugated system of the chelate. A common feature of the thermal decomposition of the metal β -diketonates investigated is its acceleration in oxygen and also the complex and homogeneous–heterogeneous character of the process.⁹⁰

The principal aspects of the gas-phase thermal decomposition of metal β -diketonates have been examined.^{91–95}

The characteristic features of the mechanism of the thermal decomposition of the chelates are determined by the presence of two reaction centres — the M—O bond and the γ -CH proton. It has been suggested that the first stage of the thermal decomposition of the β -diketonates is the opening of the ring and the conversion of the bidentate ligand into a monodentate one. This is followed by decomposition via different paths:

(a) intramolecular decomposition with formation of the free ligand and low molecular mass products:

$n > m$;

(b) decomposition with homolytic dissociation of the metal–ligand bonds and the formation of the ligand radical L^\cdot :

(c) decomposition with far-reaching degradation of the organic component of the complex, which results in the formation of both low molecular mass and radical products:

$x, y \geq 0$;

(d) decomposition with dissociation of the C—O bonds and the formation of gaseous products having the general formula $\text{R}^1\text{C}(\text{O})\text{CH}_k\text{CR}^2$ (where $k = 0, 2$):

$k = 0; n > m$;

(e) decomposition with formation of a cyclic diketone as a result of the intramolecular interaction of the opened chelate rings of two ligands:

$L = \text{Hacac}$, $n = 3, 4$.

Depending on the type of terminal substituents in the ligand and on the nature of the central metal atom, a particular decomposition path operates. The thermal decomposition can proceed via one of the paths enumerated or simultaneously via several.

Path (a) is the main one in the thermal decomposition of the complexes $\text{Cu}(\text{dpm})_2$, $\text{Ru}(\text{acac})_2$, and $\text{Zr}(\text{tfacac})_4$. Thermolysis of the vapours of palladium β -diketonates takes place simultaneously via paths (a) and (b). With increase in temperature, path (b) becomes dominant. Path (c) operates in the thermolysis of the vapours of the complexes $\text{Ru}(\text{tfacac})_3$ and $\text{Y}(\text{dpm})_3$. Both the free ligand and its radical are absent from the products of the thermal decomposition of the $\text{Ru}(\text{tfacac})_3$ vapour, the main bulk of the latter comprising the CO , CO_2 , H_2O , and HF molecules and the CF_3 radical. Complexes for which the thermal stability is higher than that of the ligand decompose via path (c).⁹⁵ The threshold decomposition temperature of these complexes is $763 \pm 283 \text{ K}$.

The thermolysis of $\text{Ba}(\text{dpm})_2$ takes place simultaneously via paths (a), (c), and (d) and includes in addition the depolymerisation reaction of the molecules and the oligomeric composition of the gas phase does not then correspond to the composition of the condensed phase. Thus the complex exists in the form $\text{Ba}_4(\text{dpm})_3$ in the condensed phase, whilst in the gas phase it is present as a mixture of trimers, dimers, and monomers.

The thermal decomposition of the complexes $\text{Al}(\text{acac})_3$, $\text{Sc}(\text{acac})_3$, and $\text{Hf}(\text{acac})_3$ proceeds simultaneously via paths (a), (c), and (d) near the threshold temperature, whereas the thermal decomposition of $\text{Mg}(\text{acac})_2$ takes place via paths (a) and (c).⁹⁵

A scheme for the thermal decomposition of the $\text{Al}(\text{acac})_3$ and $\text{Sc}(\text{acac})_3$ vapours is presented below (the postulated species are indicated in square brackets).

$M = \text{Sc, Al}$; $L = \text{C}_5\text{H}_7\text{O}_2$.

Each of the thermal decomposition paths operates in a particular temperature range ΔT .

The path leading to the formation of the $(\text{C}_5\text{H}_6\text{O})_2$ species as a result of the cyclic dimerisation of two ligands coordinated as monodentate species on dissociation of the carbon-oxygen (enolic) bonds with migration of a hydrogen atom from the methyl group to the enolic oxygen atom of a neighbouring ligand has been demonstrated. The cyclic diketone formed eliminates ketene CH_2CO and is converted into the more stable 3,5-dimethylphenol.

On the basis of this scheme, one can postulate a path leading to the formation of metal oxides in the condensed phase.

$M = \text{Al, Sc}$;

$M = \text{Hf}$, $L = \text{C}_5\text{H}_7\text{O}_2$.

The existence of path (c) for aluminium and scandium acetylacetonates constitutes experimental confirmation that the thermal decomposition is preceded by a stage involving the thermal excitation of the molecules, in which the coordination of the ligands changes from bidentate to monodentate (in terms of the isolated molecules approximation).⁹⁵

Paths (d) and (e) are characteristic of thermal decomposition processes leading to the formation of oxides in the condensed phase as a result of intramolecular reactions.

In virtually all cases, the presence of oxygen diminishes the threshold decomposition temperature of the β -diketonates and increases the rate of reaction.^{90, 95} Under these conditions, there is an appreciable increase in the fraction of simple molecular thermolysis products such as CO_2 , CO , and H_2O . The influence of oxygen on the thermal decomposition process can be exerted in two ways.⁹⁵ If the reaction proceeds via path (a) with formation of the free ligand, then oxygen participates quantitatively in the reaction at the stage involving the oxidation of the free ligand. As a rule, this occurs at a higher temperature than the temperature of the onset of decomposition of the complex. On the other hand, if the thermal decomposition takes place via path (b) or (d), virtually all the gaseous products are oxidised immediately after the threshold temperature has been exceeded. Paths (c) and (e) do not then operate in the presence of oxygen. A similar situation is observed also on path (c).

The influence of hydrogen on the thermal decomposition of the metal β -diketonate vapours depends on the nature of the metal and the ligand.⁹⁵ In the case of the $\text{Ru}(\text{acac})_3$, $\text{Zr}(\text{tfacac})_4$, $\text{Sc}(\text{acac})_3$, and $\text{Al}(\text{acac})_3$ vapours, the threshold temperature increases by 283–353 K and the rate of thermal decomposition falls, whereas the threshold temperature decreases for $\text{Ru}(\text{tfacac})_3$. Such different effects of hydrogen on the kinetics of the thermal decomposition process can be accounted for by the specific interaction of the hydrogen adsorbed on the surface with the molecules of the complex. Hydrogen does not influence appreciably the composition of the gaseous products and the path followed in the thermal decomposition of metal β -diketonates.

Thus the kinetics, the thermal decomposition path, and the composition of the condensed phase are determined by the nature of the metal and the ligand in the complex and by the decomposition temperature.

Abstract. Data on the catalytic methods for the reduction of β -ketoacids and their esters to the corresponding optically active hydroxyacids and hydroxyesters with the aid of enzymes and chiral heterogeneous and metal complex catalysts are surveyed. The application of optically active hydroxyesters as chiral synthons and monomers for the synthesis of biodegradable polymers is examined. Procedures for increasing the optical purity of the products are outlined on the basis of an analysis of the literature data and the author's own results. The bibliography includes 151 references.

I. Introduction

Optically active carboxylic hydroxyacids and their esters are key intermediates in the biosynthesis and metabolism of aliphatic acids, which are widely distributed in biological systems. A number of chiral lower homologues of hydroxyacids are used as chiral synthons in asymmetric syntheses of natural products and medicinal preparations. The efforts of many investigators have therefore been directed towards the search for new effective methods of synthesis of the most important α - and β -hydroxyacids and their esters and to the improvement of the already known procedures for their synthesis by the enzymic reduction of ketoacids^{1,2} or by the hydrogenation of the keto-group with the aid of chiral heterogeneous and homogeneous catalysts.^{3,4}

Optically active hydroxyacid esters have also attracted special attention as promising chiral monomers for the synthesis on an industrial scale of biodegradable polymers, for example of the type Biopol (Zeneca Company, Great Britain).

Despite the interest shown in the development of methods of synthesis of chiral β -hydroxyacids and their esters, publications giving a compilation of data on the methods of synthesis of these compounds together with their critical assessment are so far lacking in the literature, although the increasing number of

publications has led to an urgent need for such a survey. In the present review, an attempt is made to fill this gap. Studies carried out during the last ten years are mainly analysed. The analysis considers principally the most thoroughly developed methods: the reduction of ketoacids and their esters by the enzymic procedure and with the aid of heterogeneous metallic catalysts modified by optically active compounds. Less attention has been devoted in the literature to the application of highly effective chiral metal complex hydrogenation catalysts and one can only hope for a development of this aspect in the future.

II. Optically active biodegradable polymers based on β -hydroxyesters

Optically active polycondensation polymers are known to have higher melting points (softening temperatures), higher degrees of crystallinity, and better mechanical properties than racemic polymers by virtue of the stereoregularity of their structure. For example, the optically active polylactide

is significantly superior to the corresponding polymer based on the racemate as regards characteristics such as crystallinity, melting point (< 449 K), and insolubility in a number of solvents, these characteristics improving with increase in the optical purity of the polymer.^{5,6}

Polycondensation polymers based on carboxylic β -hydroxyacids and their esters, which participate in the metabolism of a number of microorganisms and decompose when acted upon by soil bacteria, have aroused particular interest. These polymers constitute an ideal environmentally clean material for the manufacture of polymeric articles because they decompose biologically in waste after use.

An optically active polycondensation polymer is formed from (*R*)-(-)- β -hydroxybutyric acid (HBA) or its esters when they are acted upon by a number of microorganisms. It can also be obtained by reducing ketoacids or the corresponding esters in the presence of enzymes and heterogeneous or metal complex catalysts.^{7,8} In a number of papers published after the first communication about the synthesis of poly(hydroxybutyric acids) (PHBA) from HBA,⁹ the properties of this lipid-like

polymer are examined¹⁰ (the microbiological preparation of PHBA has been surveyed¹¹).

The polymer PHBA, accumulating in the cells of bacteria of a particular species, serves as an energy storage material and plays the same role as starch in plants.^{12,13} The polymer, containing on average 138 000 units, can be isolated from the bacterial mass in the form of hydrophobic 0.5 μm grains. A polymer with a molecular mass from 60 000 to 1 000 000 (100–10 000 HBA units) can be formed, for example, when the system is acted upon by hydroxybutanolate-Co-A-polymerase. The PHBA–PHVA copolymer is formed from a mixture of HBA and β -hydroxyvaleric acid (HVA).

PHBA can be obtained by the usual fermentation methods using laboratory equipment.¹⁴ Cell material containing up to 70% of PHBA is obtained by the fermentation of a 24% aqueous solution of fructose acted upon by *Bacto Nutrient Broth* (Difco). Pure PHBA is isolated by extracting the biomass in a Soxhlet extractor with chloroform and is precipitated by adding ether. This laborious procedure involves filtration for many hours and treatment of the solutions, which requires the consumption of large amounts of solvents. For example, 5 litres of acetone has to be consumed in order to obtain 35 g of PHBA.

The polymer obtained, consisting of (R)-(–)-HBA units, has a 'head to tail' linear structure.¹²

The polyester, namely poly(ethyl β -hydroxybutyrate) (PEHB), is a crystalline substance with a right-handed helical structure^{15,16} and weak optical activity. This polymer exhibits a positive Cotton effect at a wavelength of 215 nm (in ethanol).^{13,14}

In solution in chloroform and dichloroacetic acid, the PEHB structure is analogous to that of proteins (helix–coil). For certain proportions of the solvents, maintaining or loosening the helical structure of the polymer (dichloroacetic acid and ethylene dichloride), there is a sharp jump in optical activity. A similar jump, corresponding to the helix–coil transition at 351 K, is also observed as the temperature is increased (Fig. 1). With increase in molecular mass, the melting point rises from 350 to 473 K. The polymer is insoluble in water, methanol, and dimethylformamide (DMF).

Thermal instability and sensitivity to the action of acids and bases are characteristic of PEHB. It is thermoplastic and may be used in the form of films, fibres, etc. A valuable property of this polymer is its susceptibility to biodegradation. The PEHB–PEHV copolymers, which began to be produced by British companies (ICI, Zeneca, Marlborough Biopolymers Ltd) in 1986, are of considerable interest.⁷

Figure 1. Dependence of the specific rotation $[\alpha]_{365}^{25}$ of the PEHB polymer on the solvent composition in the dichloroacetic acid (DCA)–methylene dichloride (EDC) system (1) and on temperature in the 76:24 DCA:EDC mixture (2) according to the data of Marchesault et al.¹²

Publicity announcements in the scientific and popular chemical literature of the 1980s convey the sensational nature of the discovery of these new polymers: 'Artificial polymeric materials from bacteria',¹⁷ 'A new procedure for the development of polymers based on bacteria',¹⁸ 'Back to nature — the beginning of a new era of biopolymers',¹⁸ etc. The (R)-EHB–(R)-EHV copolymer with different monomer ratios can be obtained in yields up to 80% by the controlled fermentation of glucose or fructose by the bacteria *Alcaligenes eutrophus*,^{19,20} *Hydrogenomonas eutropha*,²⁰ or *Bacto Nutrient Broth*.¹⁴

By depolymerising the copolymer produced, for example, by ICI under the name Biopol TM, it is possible to obtain in a high chemical yield (γ) the corresponding monomeric optically pure esters and, after their hydrolysis, also the optically pure β -hydroxyacids.^{20–22} For this purpose, the crude cell material, containing up to 70% of PEHB, is treated with $\text{Ti}(\text{OEt})_4$ in ethanol and heated for 2 h at 388–433 K. The mixture is filtered, the solvent eliminated, and the product, (R)-(–)-EHB 1, is distilled. The yield is 75%. The acid (R)-(–)-HBA 2 is obtained by the hydrolysis of EHB with 1 M KOH at 273 K.

The chemical yields and specific rotations of the optically pure β -hydroxyacids and their esters obtained in this way are presented below in Table 1.

Table 1. Optical characteristics of certain β -hydroxyacids and their esters.

Com-pound	T_b /K (P /Pa)	T_m /K	$[\alpha]_D^{25}$ a/deg	γ (%) (OY) ^b	Ref.
1	353 (2100)	—	–43.2 (c 5, chloroform)	90	20–22
2	358–360 (10)	315–317	–24.5 (c 5, chloroform)	93	20–22
5	—	316–319	–25.0 (c 6, water)	(98)	19, 28
3	363 (2000)	—	–34.5 (c 5, chloroform)	65	20–22
4	333 (20)	—	–19.0 (c 2.7, chloroform)	94	1

^a Here and henceforth this formulation means that the specific rotation $[\alpha]_D^{25}$ has been measured at the given temperature and wavelength (589 nm, Na D-line) in the solvent indicated (chloroform, water, etc.) at a concentration c expressed as the number of grams of the compound under consideration (1 g of EHB, 5 g of HBA, etc.) in 100 ml of the solution in a layer 1 dm thick. ^b OY is the optical yield (%) defined as

$$\text{OY} = \frac{[R] - [S]}{[R] + [S]} 100.$$

Optically pure (R)-(–)- and (S)-(+)-HBA have been obtained by the resolution of the racemic acid via the quinine and strychnine salts.²¹ The configuration of the acid (S)-(+)-HBA is genetically linked to that of (S)-(+)-lactic acid:

β -Hydroxyacid esters are unstable: during storage at room temperature, they give rise to oligomers, this tendency increasing in the series of esters $\text{Pr}^i < \text{Et} < \text{Me}$. Since the oligomerisation is catalysed by alkalies and acids, the ester to be stored must be carefully purified. The usual acetoacetic ester contains admixtures of dehydroacetic acid, methyl 3-acetoxypropionate, and diketene, which influence significantly the catalytic asymmetric hydrogenation of the ester.²³ For this reason, it is best to store EHB specimens in the form of the PEHB polymer or to convert HBA into the silyl ester **4**:^{1, 14, 24–28}

The Fluka Company has suggested that the polymer (*R*)-PHBA be used as the starting material for the preparation of (*R*)-HBA **5** (Table 1)^{19, 28} and (*R*)- β -butyrolactone.^{14, 25, 26}

III. β -Hydroxyacid esters as chiral synthons

The molecules of β -hydroxyacids are extremely reactive, which makes it possible to obtain from them a wide variety of optically active derivatives and chiral synthons used in the synthesis of a number of medicinal preparations.^{29, 30} Certain examples of the successful use of optically active hydroxyacids as chiral synthons for the preparation of a number of chiral initial compounds are presented below.³¹

R = OTs, Br

The Andeno Company used PPL lipase for the kinetic resolution of the racemic glycidyl butyrate:³²

Antibiotics containing the β -lactam group belong to an important class of medicinal preparations. In the synthesis of carbapenem **6** and penem **7**, the key intermediate is the azetidinone **8**, which is synthesised in two ways.

Thus the Kanegafuchi Company (Japan)³³ uses enzymic reduction in the synthesis of β -EHB, while the Tagasago Company (Japan)³² employs the chiral ruthenium complex [Ru-BINAP] [BINAP = 2,2'-bis(diphenylphosphino)-1,1'-binaphthyl]³⁴ in the reduction stage. In the latter case the azetidinone is obtained with $OY = 98\%$ and $de = 95\%$.†

† The symbol de denotes an excess of the diastereoisomer and ee denotes an excess of the enantiomer, both expressed as percentages.

The acid (*R*)-HBA is used to synthesise a number of medicinal preparations. The depolymerisation of PHBA opens an easy path to the formation of the chiral synthon EHB, HBA, and a PHBA degradation product — the diol (*R*)-MeCH(OH)CH₂CH₂OH.¹⁴ (*R*)- and (*S*)-2-Hydroxyglutaric acids have also become readily available. (*R*)-Isobutyl lactate is produced by the BASF Company. Carbomycin B,³⁵ (*R,R*)-pyrenophorin,³⁶ gramimycin A₁,³⁷ sulcatol,² lavandulol,³⁸ colletodiol,³⁷ and recifeiolid³⁹ belong to the class of medicinal preparations the structures of which contain a fragment of the chiral (*R*)-EHB molecule. (*R*)- β -Hydroxyiso-butyric acid, produced by the Kanegafuchi Company by the microbiological oxidation of isobutyric acid, can be used to synthesise the inhibitor captopril⁴⁰ via (*R*)- β -acetylmercaptoisobutyric acid, produced by the Andeno Company,⁴¹ while its enantiomer, (*S*)- β -hydroxyisobutyric acid, is used in the synthesis of phytol — a fragment of the vitamin E molecule.^{42, 43}

IV. Enzymic synthesis of β -hydroxyacids and β -hydroxyesters

The bank of chiral natural optically active hydroxyacids consists of an extremely limited number of compounds: (*R*)- and (*S*)-lactic, (*R,R*)-(+)-tartaric, (*S*)-malic, and (*S*)-mandelic acids and their esters. The enzymic and catalytic asymmetric syntheses of these compounds therefore constitute an important source of chiral β -hydroxyesters. β -Hydroxyacids and β -hydroxyesters in the enantiomeric form are synthesised as follows:

by the kinetic resolution of the racemate with participation of a chiral auxiliary compound;⁴⁴

by the depolymerisation of polyhydroxyesters or polyhydroxyacids;^{14, 45}

by the microbiological reduction of ketoesters with the aid of enzymes;¹⁴

by the catalytic hydrogenation of ketoesters on modified metallic catalysts;^{3, 4, 46}

by the catalytic hydrogenation of ketoesters on chiral complex catalysts.⁴⁷

The last three methods are of greatest interest.

The enzymic reduction of ketoesters to optically active hydroxyesters was first achieved with the aid of baker's yeast in 1918.⁴⁸ Although data^{2,49} indicating a high effectiveness of this method were not subsequently confirmed,⁵⁰ its improvement made it possible to achieve an optical yield of EHB up to 85% and above,⁴⁵ while in a bioreactor (with continuous introduction of the substrate and aeration) the yield was up to 96%.⁵¹ The method was developed further^{52,53} and acquired preparative value mainly as a result of the studies by Seebach.^{45,54} It proved possible to employ the reduction of ketoesters with the aid of baker's yeast (*Saccharomyces cerevisiae*) in practical organic synthesis.^{32,51,54,55}

High OY values for the products are usually attained when the concentration of the substrate in the fermenting solution does not exceed 0.1%,⁵¹ while the reaction time is 30–130 h. Under these conditions, the productivity of the process is 20–70 mg dm⁻³ h⁻¹. However, the need to employ large volumes of solutions, the long reaction time, the high consumption of sucrose (or another organic reducing agent — a hydrogen donor), the instability of the bacterial strain, the impossibility of the repeated employment of the reducing system, as well as the complexity of the isolation of the product prevent the wide scale employment of this method.^{56,57} Furthermore, the selectivity of the enzymic reaction depends on a number of factors, such as the nature of the enzyme, the structure of the substrate molecule, and the reaction conditions.^{58,59} For example, ketovalerate is reduced less effectively than ketobutyrate.^{58,59}

According to the standard method for the reduction of acetoacetic ester [ethyl acetoacetate (EAA)] with the aid of baker's yeast,⁴⁵ the synthesis of 24 g of EHB from 40 g of EAA requires the consumption of 600 g of sucrose and 200 g of yeast and a vessel with a volume up to 5 litres has to be used. The reaction time is 134 h with a process productivity of 0.068 g dm⁻³ h⁻¹. The final product, (S)-(+)-EHB, is obtained in 59%–71% yield with OY = 85%. A similar method is used to obtain BuHB (OY = 90%).¹⁴ The optical yield of HBA may be increased to 97% after several recrystallisations of the derivative EHB 3,5-dinitrobenzoate.⁶⁰ The optically pure EHB obtained had $[\alpha]_D = +43.5^\circ$ (c 1, chloroform). The optical purity of EHB can be determined from the ¹⁹F NMR spectrum of the ester comprising the Mosher reagent.⁶¹

An improvement in the method for the reduction of EAA also makes it possible to increase the optical yield of EHB to 95%. This is attained by the slow introduction of EAA into the fermenting solution under aerobic conditions.⁵¹ The replacement of 5%–15% of sucrose in the fermenting solution by ethanol, glucose, fructose, glycerol, or mannitol⁶² also helps to increase the OY of the hydroxyester.

Keeping the yeast in 5% aqueous ethanol for four days before use in the reaction helps to activate it and to raise the optical yield of the product to 95.9%.^{63–65} According to the method of Ehrler et al.,⁶⁶ a suspension of 125 g of baker's yeast in 1 litre of 5% aqueous ethanol is stirred at 303 K for 4 days,

after which 5 g of EAA is added. After 2–3 days, the reaction comes to an end (it is monitored with the aid of gas–liquid chromatography). The mixture is centrifuged and the filtrate is repeatedly extracted with ether for 4 days and the extract is vacuum distilled. EHB is obtained in 70% yield with OY = 94% and $[\alpha]_D = +40.9^\circ$ (c 1, chloroform). Unfortunately this method does not yield satisfactory results when applied to other substrates, such as ketovalerate and fluorine-containing ketoesters. Only 2-formylbutanoate could be reduced to (S)-2-hydroxymethylbutanoate HOCH₂CH(Et)COOEt in 70% yield with OY = 95.5%. This product is an important chiral synthon analogous to the Roche acid HOCH₂CH(Me)COOH.⁶⁷ According to the data published by the Hoffmann La Roche Company, the latter product can be obtained with the aid of *Streptomyces griseus* with OY not exceeding 86.3%.⁶⁸

A strain of the *Halobacterium halobium* bacteria reduces EAA to (S)-(+)-EHB with OY = 44%–76%, but the chemical yield of the product is low and the reduction is accompanied by hydrolysis of the ester to the acid. Hydrolysis of the racemic ester EHB with the aid of the above strain leads to (R)-(-)-EHB with OY = 88%.⁶⁹

The reduction of ketoesters with the aid of the thermophilic bacteria *Thermoanaerobium brockii* (*Th.b.*) is carried out in the usual laboratory apparatus or in a bioreactor⁷⁰ by a procedure similar to that used in the case of yeast. However, this strain is sensitive to atmospheric oxygen and the reduction must be carried out under an argon atmosphere. In contrast to yeast, the strain reduces ethyl ketovalerate effectively to the β-hydroxyester (OY = 93%–97%).

Depending on the nature of the microorganism and the structure of the substrate molecule, products with the (R)- or (S)-configuration can be obtained by reduction of the ketoesters. Table 2 presents comparative data obtained for different substrates with the aid of baker's yeast and a strain of *Th.b.*⁷¹ As can be seen, in certain cases the *Th.b.* strain is more effective than baker's yeast and, furthermore, it is possible to obtain the other enantiomer of the hydroxyester.

Both enantiomers of the hydroxyacid may be obtained by reducing the ketoacid in the presence of NADH (reduced β-nicotinamide-adenine dinucleotide), bound to poly(ethylene glycol) in a membrane reactor.^{72,73} The reduction of ketoesters in a nonaqueous medium (in solution in isopropyl hexadecanoate) by a suspension of a mixture of Asolectine phospholipids produced by the Fluka Company and yeast proceeds rather effectively (Table 3).⁷⁴

Other examples of the influence of the structure of the substrate molecule and of the introduction of aromatic substituents or aromatic hexahydro-substituents into the ketoester XCOCH₂COOR on the configuration of the enantiomers and diastereoisomers obtained⁷⁵ are presented in Table 4.

Apart from the asymmetric enzymic reduction of ketoesters to obtain optically active hydroxyesters from hydroxyacids, it is also possible to employ the enantioselective kinetic conversion of the hydroxyester racemate by the enzyme. Thus the DSM

Andeno Company has used successfully the lipase from *Pseudomonas fluorescens* for the kinetic resolution of the ester.²⁴ The product PhOCH(Et)COOEt is formed with OY = 99% and a conversion of 57%.²⁸

Examples of the effective enantioselective resolution of other racemic hydroxyacids and hydroxyesters are known: thus, on treatment with *Candida rugosa*, the acid HOCH₂CH(Me)COOH affords the (*R*)-product;⁷⁹ on treatment with chymotrypsin, the (*R*)-product is formed from PhCH(OH)CH₂COOEt with OY = 98%;⁸⁰ EtC(Me)(OH)COOMe is hydrolysed by esterase with formation of the (*S*)-product (OY = 98%);⁸¹ the product of the conversion of MeCH(OH)CH(Me)COOEt by yeast has the (2*R*,3*S*)-configuration (*de* = 86% and OY = 96%);⁸² the asymmetric resolution of the PhCH₂CH(OH)CH(Me)COOEt racemate on treatment with *P. farinosa* leads to the (2*R*,3*S*)-product with OY = 99%.⁸³

β -Hydroxyesters can be obtained by reversible transesterification. The acid anhydride is used as the reversible acylating agent. When acted upon by PS lipase, it gives rise to the (*R*)-acid PhCH₂CH₂CH(OH)COOH **9** in 39% yield and with OY = 99%.³²

The synthesis of chlorine- and fluorine-containing hydroxyesters by the reduction of the corresponding ketoesters effected by baker's yeast is of interest.⁷⁶

Crystallisation of the product **9** from methylcyclohexane increases OY to 98%. The optical yield of the (*R*)-(+)-ester **11** on crystallisation from a pentane-ether mixture can be raised to 98%. The ester **11** has a configuration which is the opposite of that of the product **10**, whence it follows that, in conformity with Prelog's rule, the CF₃ group should have the same seniority as the methyl group.

In conclusion, one should note that a number of companies have achieved the enzymic synthesis of optically active hydroxyesters. Thus the Kanegafuchi Company produces (*R*)- β -hydroxyisobutyric acid by the microbiological oxidation of *n*-butyric acid³² or by the fermentation of isobutyric and methacrylic acids by a strain of *C. rugosa*. The cost of (*S*)-(+)-MHB and (*R*)-(-)-MHB is US\$ 2.5 per gram. According to the catalogue of the Aldrich Company, (*R*)-(-)-EHB with $[\alpha]_D = -46^\circ$ (*c* 1, chloroform) is sold at a price of US\$ 9 per gram, whilst the price of the racemate is smaller by a factor of 20.⁸⁴

The synthesis of β -hydroxyacids and β -hydroxyesters by the depolymerisation of PHBA and PEHB was examined above in Section III.

V. Synthesis of β -hydroxyesters by the hydrogenation of ketoesters on heterogeneous dissymmetric catalysts

The asymmetrising activity of copper, nickel, and platinum catalysts deposited on crystals of optically active quartz in the asymmetric decomposition of racemic butan-2-ol was first observed by Schwab and coworkers.^{85,86} Terent'ev and Klabunovskii⁸⁷ extended the studies on catalysts of this type to other reactions. The enantioselectivity of such catalysts was low, the optical yield not exceeding 1%. Akabori and Izumi³ suggested that palladium based on the fibroin of natural silk fibres be used as the catalyst for the asymmetric hydrogenation of the C=C bond in the prochiral precursors of amino acids. Its effectiveness was fairly high (for example, OY = 35.5% in the hydrogenation of azlactone), but there are no literature data on the reproducibility of these results. Nevertheless, the studies carried out have demonstrated the important role of complex formation in asymmetric catalysis and served as a stimulus for the development of dissymmetric metallic catalysts of new types. Among the latter, we may mention the skeletal Raney nickel catalyst and catalysts modified by optically active amino acids or hydroxyacids, which readily form complexes on the surface of the metal. As a result of the modification, centres for enantioselective hydrogenation arise on the surface of the metallic catalysts.

The choice of acetoacetic acid esters [methyl acetoacetate (MAA)³ and ethyl acetoacetate (EAA)⁴] proved successful. Methods for the preparation of effective catalysts have been developed in relation to these substrates and the characteristic

features of asymmetric hydrogenation have been investigated. Almost 20 years of research were required to increase the *OY* in this reaction from 10%–15% to 90%–94%.

The achievements in this field have been surveyed in a series of monographs^{3,4,87,88} and reviews.^{89–93} Factors influencing the enantioselectivity of catalysts for the hydrogenation of β -ketoesters will be examined below and procedures for increasing the optical purity of the hydroxyesters formed will be outlined.

The effectiveness of the modified metallic catalysts[†] depends significantly not only on the stereochemical properties of the modifying agent and the substrate but also on the state of the catalyst surface, its genesis, the nature of the salts used to prepare the initial catalyst mass, the conditions in its reduction, the degree of crystallinity of the catalyst, the size of the crystallites, the nature of their size distribution, and the adsorption and complex-forming capacities of the metallic catalyst in relation to the molecules of the modifying agent and the substrate (product).

According to Balandin's theory of hydrogenation,⁹⁴ the effectiveness of the hydrogenation depends significantly on the hydrogen pressure. Since the modification of the catalyst alters its activity usually by diminishing it, the reaction has to be carried out at elevated temperatures and pressures. The complexity of the dependence of *OY* in the MAA and EAA hydrogenation reactions on the hydrogen pressure (*P*) has been examined.⁹⁵ In the hydrogenation of EAA on Ru–SiO₂–TA, the optical yield *OY* increases with increase in *P*, but, after the attainment of a pressure of 7 MPa, it ceases to vary.⁹⁶ On the RCo–TA catalyst, the optical yield initially increases with increase in *P* to 2 MPa and then remains constant up to *P* = 8 MPa.⁹⁷ On RNi–TA, the optical yield is independent of hydrogen pressure in the range 5–10 MPa.⁹⁸ When EAA is hydrogenated in the vapour phase on HNi–TA,^{99,100} a zero order of the reaction with respect to hydrogen is observed in the pressure range 10–14 MPa (*OY* = 17.8%).

The enantioselectivity of the hydrogenation of MAA on deposited Ni–SiO₂–TA and Ni–SiO₂–TA–NaBr catalysts depends significantly on the reaction conditions (hydrogen pressure, MAA concentration, nature of the solvent). The experiments have been performed¹⁰¹ both in the kinetic region (stirring rate 500–800 revolutions per minute), where the rate of reaction and *OY* are independent of the stirring rate and are proportional to the amount of the catalyst, and in the diffusion region in a rocking autoclave with a MAA:Ni = 8 ratio. When the experiments were carried out in the kinetic region on Ni–SiO₂–TA, the optical yield of the (–)-MHB formed fell from 50% to 30%–35% with increase in hydrogen pressure, while on Ni–SiO₂–TA–NaBr it hardly changed. Evidently, treatment of the catalyst with NaBr imparts to it an increased enantioselectivity and stability. In the diffusion region, *OY* was 38%–40% and hardly changed as the pressure increased from 1.0 to 8.0 MPa, which agrees with the data of Lippart et al.⁹⁸ An increase in *OY* when the reaction is carried out in the kinetic region can be achieved by reducing *P* and by increasing the MAA concentration in EtOAc (Fig. 2). A similar picture is also observed when MeOH and THF are used as the solvent.

It is noteworthy that such effectiveness is attained only at low pressures (0.2–1.0 MPa) and only in the initial stages of the reaction (for degrees of conversion up to 15%). It is not stated in the above communication¹⁰¹ whether a similar variation is retained at higher conversions. Data concerning the variation of

Figure 2. The influence of the MAA concentration in EtOAc on *OY* in the MAA hydrogenation reaction on the Ni–SiO₂–TA catalyst at pressures of 6.0 MPa (1) and 1.0 MPa (2) and on the Ni–SiO₂–TA–NaBr catalyst at a pressure of 1.0 MPa (3). Degree of conversion 15%.¹⁰¹

OY during the reaction are also lacking. Nevertheless the practical value of the proposed methods for increasing the enantioselectivity of the process depends precisely on this factor.

The substrate:catalyst ratio is also important. The maximum optical yield in the hydrogenation of EAA at pressures of 0.1 and 10 MPa has been achieved⁹⁸ for the ratio EAA:Ni = 10–20. The independence of *OY* on the degree of conversion was also noted. This shows that, under the given conditions, the reaction is a kinetically controlled process and the product does not racemise during its occurrence.

In certain cases, *OY* varied as a function of the degree of conversion and the nature of the solvent simultaneously with the variation of the overall rate of reaction *w* due to the inhibition of the latter by its product.

The antiparallel variation of *OY* and *w* during the reaction has been noted.^{95,102} Thus *OY* decreased with increase in the rate of hydrogenation of MAA on RNi–TA.¹⁰² The optical yield also changed with increase in the degree of conversion:¹⁰³ it reached 56.4% for a conversion of 10% and then fell.

According to Balandin's theory of hydrogenation,⁹⁴ the product may inhibit the reaction if the adsorption coefficients of the substrate and the product differ greatly. Chernysheva and coworkers^{104,105} showed for the first time that the addition of (–)-EHB to a solution of EAA inhibits the enantioselective hydrogenation of the latter on RNi–TA and lowers *OY* as a result of the preferential adsorption of (–)-EHB on the selective centres. According to the data of Chernysheva and coworkers,^{104,105} the ratio of the adsorption coefficients of (–)-EHB and EAA is 3:2. As a consequence of this, *OY* decreases, as can be seen from Fig. 3, where the results of Chernysheva et al.¹⁰⁴ are compared with those of Nitta et al.¹⁰⁶

The relative adsorption coefficients were calculated¹⁰⁴ by the equation⁹⁴

$$\frac{1}{w} = \frac{b_2/b_1}{kC_2/C_1} + \frac{1}{k},$$

where *b*₁ and *b*₂ are the relative adsorption coefficients and *C*₁ and *C*₂ are the concentrations of EAA and EHB respectively.

When the reaction is inhibited by the EHB racemate, *b*₂:*b*₁ = 1:2. It follows from the data of Chernysheva et al.¹⁰⁴ that the degree of adsorption of (–)-EHB on the selective centres exceeds that of (+)-EHB. The introduction into the EAA solution of other strongly adsorbed substances, for example catalyst poisons such as pyridine, thiophene, or amines, exerts a strong inhibiting effect on the enantioselective reaction, the effectiveness of the additives increasing in the sequence (+)-EHB < (–)-EHB < pyridine < thiophene.¹⁰⁴

For example, the addition of pyridine in the initial stage of the hydrogenation of EAA (for degrees of conversion up to

†The following notation has been adopted in the literature: RM = skeletal metallic catalyst of the Raney type; M–TA = catalyst modified by (*R,R*)-tartaric acid (TA); M–SiO₂–TA = deposited metallic catalyst modified by TA; M–SiO₂–TA–NaBr = catalyst modified by TA with added NaBr; HM = catalyst obtained by reducing the metal oxide in a stream of hydrogen.

Figure 3. Dependence of OY on the concentrations of the additives in the hydrogenation reactions of EAA on $RNi-TA$ (1)¹⁰⁴ and of MAA on $Ni-SiO_2-TA$ (2)¹⁰⁶. The additives are $(-)$ -EHB in the first case and $(-)$ -MHB in the second.

5%–10%) increases OY as a result of the preferential adsorption of this inhibitor on the nonselective centres which were not protected in the modification by the adsorbed TA. Afterwards, as the degree of conversion increases, OY falls almost to zero. In the hydrogenation of EAA on the $HNi-TA$ catalysts, the addition of pyridine and butylamine increases OY in the initial stage of the reaction from 11% to 17% and 50% respectively.⁹⁹ After the introduction of pyridine or thiophene, the optical yield for $y = 10\%$ increased from 7% to 12% and from 2.5% to 11.5% respectively.¹⁰⁵ Chernysheva and coworkers^{104,105} determined the optical yields polarimetrically, taking into account the change in the specific rotation of EHB for low degrees of conversion ($y \leq 7\%$):

$$\lg [\alpha]_D = 1.55 - 0.2 \lg y.$$

A significant increase in OY in the hydrogenation of MAA¹⁰¹ was achieved by adding unsaturated compounds, which are hydrogenated preferentially on nonselective centres. The fraction of enantioselective centres on which MAA is hydrogenated increases under these conditions (Fig. 4).

The addition of benzene, which is not hydrogenated under these conditions, also ensures an appreciable increase in OY .

Figure 4. The influence of added benzene (1), cyclohexene (2), and ethyl acetate (3) on the optical yield of $(-)$ -MHB in the hydrogenation of MAA on $Ni-SiO_2-TA$ (pressure 1.0 MPa, degree of conversion 15%).¹⁰¹

However, its use as a solvent in the hydrogenation of MAA lowers OY , apparently as a result of the displacement of TA from the modified centres of nickel.

A complex pattern in the variation of OY in the hydrogenation of MAA on $RNi-TA$ catalysts prepared by different procedures (the 1:1 $Ni-Al$ alloy was leached with a 20% $NaOH$ solution at different temperatures in the range 278–353 K) has been noted.¹⁰³ When the reaction was carried out on the most active catalyst, a flat maximum ($OY = 18\%$) was observed on the curve relating OY to the degree of conversion at $y = 70\%$, whereas in the case where less active catalysts were employed the maximum optical yield (45%–50%) was attained at $y = 25\%$.

Table 5. Chemical and phase composition of the $RNi-TA$ catalysts.¹⁰⁵

Composition (%)	Alloy specimen			Catalyst specimen

^a Cr + Ti.

The variation of OY with y is influenced by the chemical and phase compositions of the initial $Ni-Al$ alloys (Table 5).¹⁰⁵ A decrease in the nickel content, i.e. an increase in the content of the intermetallic compound $NiAl_3$ in the alloy, promotes a more complete removal of aluminium in the leaching of the alloy (cf. the catalyst specimens 1–3 in Fig. 5), which should apparently increase OY in the hydrogenation of EAA for low degrees of conversion ($y = 10\%$ –30%). However, as can be seen from Fig. 5, the dependence of OY on y is complex and for this reason comparison of the enantioselectivities of different catalysts only for low degrees of conversion, as was done,

Figure 5. Dependence of the optical yield OY (1, 2, 3) and of the rate of hydrogenation of EAA w (1', 2', 3') on the degree of conversion y on specimens of the $RNi-TA$ catalyst obtained from alloys with different initial compositions¹⁰⁵ (Table 4): (1, 1') specimen 1; (2, 2') specimen 2; (3, 3') specimen 3.

for example, by Nitta et al.,¹⁰¹ is clearly inadequate: it is necessary to follow the variation of OY over the entire range of y .

The nature of the dependence of OY on y is also influenced by the strength of the bond between hydrogen and the catalyst surface. Catalysts obtained from $NiAl_3$ are known to contain a greater amount of weakly bound hydrogen than catalysts prepared from alloys in which the intermetallic compound Ni_2Al_3 predominates (specimen 3).^{104, 105} A higher optical yield is attained on the latter.

Another way of increasing OY is by controlling the degree of dispersion of the catalyst metal on the carrier surface. As was shown for the first time by Klabunovskii and coworkers,^{4, 107} the quantity OY in the hydrogenation of EAA on the $Ru-SiO_2-TA$ catalysts depends significantly on the degree of crystallinity of ruthenium. The optical yield increases with increase in the catalyst reduction time and attains its maximum value for an average size of the crystallites of 4.5 nm. On the catalyst with 8.0 nm crystallites, the enantioselectivity of the hydrogenation reaction diminishes (Fig. 6).

Figure 6. The influence of the metal content in the $Ru-SiO_2-TA$ catalyst on its asymmetrising capacity — on $[\alpha]_D$ for the product — in the EAA hydrogenation reaction. The preliminary catalyst reduction times were 0.5 h (1) and 5 h (2). Points *a*, *b*, and *c* on curve 1 correspond to ruthenium crystallite sizes of 1.6, 4.5, and 8.0 nm respectively.⁴

The important role of the size of the crystallites and of their size distribution was confirmed in a study of the enantioselective hydrogenation of MAA on the $Ni-SiO_2-TA$ catalyst.¹⁰⁸ By varying the conditions in the preparation of the catalyst, it was possible to achieve a narrow peak in the size distribution of nickel crystallites on the surface. $Ni-TA$ catalysts (without a carrier) of different composition were investigated:¹⁰⁹ nickel boride ($Ni-B$), nickel phosphide ($Ni-P$), Raney nickel (RNi), and nickel black obtained by the decomposition of nickel formate (DNi) or by the reduction of NiO (HNi). The $HNi-TA$ ($OY = 56.2\%$), $DNi-TA$ (42.3%), and $RNi-TA$ (26.7%) catalysts exhibited the highest enantioselectivity. On the $Ni-B$ and $Ni-P$ catalysts, the optical yield did not exceed 3–5%. Their low enantioselectivity was attributed to the cryptocrystallinity of the Ni phase (it is X-ray amorphous) and also to the strong adsorption of TA .¹¹⁰ After the modification of the $Ni-B$ catalyst by tartaric acid, the latter was adsorbed in an amount of $4.9 \times 10^{-3} \text{ mmol g}^{-1}$, which is 9 times greater than on RNi . Careful washing of the $Ni-B-TA$ catalyst and its treatment with a solution of alkali led to the removal of boron from the surface and to a decrease in the TA content on the surface to $0.5 \times 10^{-3} \text{ mmol g}^{-1}$. As a result, the optical yield in the hydrogenation of MAA increased to 26.7%, while the $Ni-B-TA$ catalyst was virtually converted into $HNi-TA$ as a result of the liberation of part of the surface.

According to the data of Nitta et al.,¹⁰⁹ the adsorption of tartaric acid on the catalyst surface in an amount exceeding that required for the specific modification of the surface does not influence significantly the enantioselectivity. This conclusion conflicts with data^{99, 100} indicating a linear increase in OY with increase in the fraction of the TA dianion on the DNi surface.

The increase in the size of the nickel crystallites from 6 to 20 nm increases OY from 36.1% to 54.9%.¹¹¹ This can be accounted for with the aid of a stereochemical model of the catalytically active centre,⁴ according to which the accommodation of the catalytic complex on the surface of the enantioselective catalyst requires fairly large crystalline formations (faces, planes). This view is confirmed also by data¹¹⁰ according to which the reduction of NiO leads to the formation of cryptocrystalline, almost amorphous, nickel, which does not exhibit enantioselectivity after modification.

The high effectiveness of the coarsely crystalline $TNi-TA$ specimens¹⁰⁹ is attributed to the presence in this catalyst of impurities remaining after the decomposition of the formate. These data also agree with the previously proposed model⁴ and confirm the influence of the crystallinity of the metal on its enantioselectivity. Since cryptocrystalline nickel catalysts are ineffective in asymmetric hydrogenation, in order to increase the enantioselectivity of the MAA hydrogenation reaction it is desirable to produce a catalyst with relatively large crystallites having uniform dimensions.^{108, 110–115}

It had been noted earlier⁴ that aluminium oxide is relatively unsuitable as a carrier for asymmetric hydrogenation. Thus the $Ru-Al_2O_3-TA$ catalyst did not exhibit enantioselectivity in the hydrogenation of EAA, whereas $Ru-SiO_2-TA$ had a weak activity. This can be explained by the fact that ruthenium interacts much more strongly with Al_2O_3 than with SiO_2 . However, by varying the conditions in the formation of the catalyst, it was also possible to obtain enantioselective catalytic systems when Al_2O_3 was used as the carrier, for example $Ni-Al_2O_3-TA$ and $Ni-Co-Al_2O_3-TA$ with a metal content of 20%.¹¹⁶ These catalysts were reduced at 773 K and EAA was hydrogenated at 393–408 K and a pressure of 10–12 MPa. The optical yield on the first catalyst was 76.0% and that on the second was 62.6%. Such relatively high values of OY can be due to the presence on the nickel surface of incompletely reduced residues of the metal salts, which decrease the fraction of the small crystallites. The reduction of the catalyst under mild conditions (for example at a reduced partial pressure of hydrogen) increases the ratio of large crystallites and their enantioselectivity.

The formation of small nickel crystallites can be prevented by introducing into the catalyst mass (nickel and aluminium hydroxides), before its deposition, a certain number of Fe^{3+} ions, which weaken the interaction between nickel and the carrier.¹¹⁷ Thus the introduction of up to 10% of Fe^{3+} increases the enantioselectivity of the $Ni-Al_2O_3-TA$ catalyst in the hydrogenation of MAA, increasing OY from 18% to 38%, i.e. making the effectiveness of the catalyst comparable to that of $Ni-SiO_2-TA$. On the other hand, the addition of Fe^{3+} in the preparation of $Ni-SiO_2$ lowers both the optical and the chemical yields of the MAA hydrogenation product (Fig. 7). The introduction of a palladium salt has a similar effect.¹¹¹ It is noteworthy that the promoting effect of Fe^{3+} is manifested only when Al_2O_3 is used as the carrier: in this case, the increase in the $Fe:(Fe + Ni)$ ratio to 10% increases OY from 16% to 38%, whereas the addition of iron in the preparation of the $Ni-SiO_2-TA$ catalyst lowers OY from 30% to 10%.¹¹⁷

The use of a mixed carrier instead of silica gel (the $Ni-Al_2O_3-SiO_2-TA$ catalyst) lowers OY from 49.7% to 18.3%, although the size of the crystallites increases under these conditions from 8 to 24 nm. One should note in this connection that the nickel catalyst on a zeolite (1:5), obtained by impregnation, is less effective in the hydrogenation of MAA. The optical yield attained on this catalyst is 7.3%, whereas on the

Figure 7. Dependence of *OY* in the MAA hydrogenation reaction on the iron content in the Ni-Fe-Al₂O₃-TA (1) and Ni-Fe-SiO₂-TA (2) catalysts.¹¹⁷

Ni-zeolite-TA catalyst, obtained by joint deposition, *OY* = 45.6%.¹⁰⁸

In order to investigate the role of the size of the crystallites at a constant surface coverage,¹¹⁸ the Ni₃(OH)₄Si₂O₅ system was prepared on the basis of chrysotile — a layered silicate.¹¹⁹ Its reduction in a stream of hydrogen afforded the 59.4% Ni-SiO₂ catalyst with a constant degree of surface coverage and a uniform dispersity, which could be regulated by varying the reduction conditions. An increase in the temperature of the reduction of Ni-chrysotile helped to increase the size of the crystallites (\bar{D}) and in the temperature range 673–973 K \bar{D} varied from 4 to 11 nm, while *OY* in the hydrogenation of MAA reached 40% (Fig. 8). The nature of the initial nickel salt, used in the preparation of Ni-chrysotile, influenced significantly the size of the crystallites and *OY*.¹²⁰

Vedenyapin et al.¹²¹ investigated the influence of platinum metals, introduced into various metallic catalysts, on the enantioselectivity of the latter. The TA-modified palladium catalyst did not exhibit an activity in the enantioselective hydrogenation of EAA. The introduction of even 5% of palladium into the RCu-TA catalyst, capable of promoting enantioselective hydrogenation albeit with a low effectiveness, led to a decrease in *OY* from 9% to 1%.¹²¹

The 10% (Ni-Pd)-aerosil and 10% (Ni-Pd)-Al₂O₃ catalysts were obtained by impregnating the carriers with solutions of the appropriate salts.¹²² The catalysts were dried and reduced at 630 K in a H₂-He stream. Catalysts of another

Figure 8. Dependence of the enantioselectivity of the Ni-SiO₂-TA catalyst, obtained from Ni-chrysotile, in the MAA hydrogenation reaction (333 K, 10 MPa) on the average size of the crystallites (\bar{D}) (1, 3) and the influence of the temperature of the reduction of the catalysts on \bar{D} (2, 4): (1, 2) initial salt Ni(NO₃)₂·6H₂O; (3, 4) initial salt NiCl₂·6H₂O (according to the data of Nitta and coworkers^{119, 120}).

series were prepared by impregnating Ni-SiO₂ with a PdCl₂ solution. The modification was carried out with a 5% TA solution at pH 5. Similar results in the hydrogenation of EAA were obtained on the catalysts of both series: the optical yield was 7%–9% for an overall rate of reaction of 0.1 mmol min⁻¹ (g catalyst)⁻¹.

The modification of the RNi-Ru catalyst obtained by leaching ternary Ni-Ru-Al alloys containing 70% of aluminium was achieved by employing a 2% solution of TA at pH 4.5.¹²³ With increase in the ruthenium content, *OY* decreased. According to the data of Vedenyapin et al.,¹²³ the introduction of palladium or ruthenium as additives into nickel or copper catalysts does not promote the enantioselective hydrogenation of EAA. A similar picture was observed when the DNi-TA catalyst, obtained by decomposing nickel formate, was employed.¹¹⁰ The addition of 15% of palladium lowered the optical yield in the MAA hydrogenation reaction from 50% to zero. After the introduction of palladium, the amount of TA adsorbed by the catalyst during its modification diminished from 0.01 to 0.001 mmol (g Ni)⁻¹ as a consequence of the displacement of TA from the surface by palladium. Thus, in conformity with the data of Nitta et al.,¹¹¹ the high effectiveness of nickel catalysts alloyed with 1% of platinum metals, observed by Orito and coworkers,^{124–128} can be accounted for by the influence of these additives on the formation of the catalyst surface and primarily on the crystallinity of nickel.

Orito and coworkers^{124–128} showed that the 1:1 nickel catalyst on kieselguhr (Kg), alloyed with 1% of noble metals and modified with (*R,R*)-TA, exhibits an exceptionally high enantioselectivity in the hydrogenation of MAA to MHB. The optical yield of MHB reached¹²⁷ 99.4% on the Ni-Pd-Kg catalyst. However, Orito and coworkers^{124–128} determined the values of *OY* polarimetrically and adopted $[\alpha]_D = +20.9^\circ$ for the optically pure MHB. Since it was later established⁴⁶ that the specific rotation of MHB is 22.95° and not 20.9°, the highest values of *OY* in the above investigations should have been 79.0%–90.5%, which are also extremely high parameters. The importance of the results obtained led us to describe here the methods for the preparation of the catalyst and for carrying out experiments on the hydrogenation of MAA.¹²⁴

Kieselguhr [manufactured by the National Chemical Laboratory for Industry (Japan)] was introduced, without additional purification,§ into a solution of nickel nitrate and a platinum metal salt in an amount such that the ratios Ni:Pt:Kg = 100:1:100 were attained. The mixture was allowed to stand for 1 h and was then treated with a solution of sodium carbonate. The precipitate was thoroughly washed and dried for 24 h at 383 K. The 3 g catalyst specimen was heated by a quartz lamp in a stream of H₂ (7 dm³ h⁻¹) up to 573 K for 1 h, after which it was cooled and added to a 100 ml of a 1.5% aqueous solution of (*R,R*)-TA at pH 4.1 bubbled with nitrogen, reducing the temperature of the solution gradually to 358 K. The catalyst was then centrifuged and washed initially twice with water (with 25 ml in each case) and then with methanol and the solvent in which the hydrogenation was to be carried out. The reaction was performed in an autoclave with stirring at a pressure of 6–8 MPa and with a substrate:catalyst \approx 14:1 ratio. The reaction temperature was raised from 293 K to the specified level at a rate of 0.7 K min⁻¹. When the absorption of hydrogen was completed, the catalyst was filtered off and the product distilled.

The compilation in Table 6 presents the maximum optical yields of MHB under different conditions.¶ By carrying out the reaction in THF and by adding small amounts of carboxylic

§Personal communication by Prof. Orito.

¶The optical yields obtained by Orito and coworkers^{124–128} and presented in Table 6 were corrected in accordance with the new value of the specific rotation of MHB $[\alpha]_D = 22.95^\circ$.

was added. ^e Catalyst composition Ni:Ru = 100:1. ^f 0.05 g of HCOOH was added. ^g 0.5 g of benzoic acid was added. ^h Catalyst composition Ni:Ru:Kg = 100:3:100. ⁱ Catalyst composition Ni:Ru = 100:1. Modification conditions: pH 4.5, 293 K. Samples: 0.2 g of the catalyst, 41 ml of EAA. The hydrogenation was carried out at 333 K (according to the data of Klabunovskii and Vedenyapin⁴).

acids into the reaction mixture, the OY for the product is increased by 6%–10%.

The method of synthesis of MHB with OY up to 90.6%, in which the modification with tartaric acid is carried out at pH 4.3–4.5 (0.68–0.72 g of NaOH on 1.5 g of TA) at 357 K, was developed for the Ni–Pd–Kg catalyst. Before the reaction, the catalyst (2.3 g sample) must be heated for 4 h in THF without stirring, having added 1.5% of acetic acid, at 382 K and a pressure of 5.5 MPa (experiment No. 10). The reaction mixture (MAA in 44 ml of THF to which 1 ml of AcOH has been added) is kept initially without stirring for 1 h at the same temperature and pressure and is then stirred for 10–20 h. The optical yield of the MHB thus obtained reaches a maximum value of 90.6% (experiment No. 11). Instead of acetic acid, formic or benzoic acid may be added. The optical yield of the product increases if the added monocarboxylic acid has a pK_1 lower than that of the modifying agent — tartaric acid ($pK_1 = 2.89$).

It follows from Table 6 that the alloying of the nickel catalyst with platinum metals increases significantly the enantioselectivity and the overall rate of the reaction. The deposited Ni–Ru–Kg catalyst is more effective (OY = 50%) than the Raney RNi–Ru catalyst without a carrier, on which OY is 4% and 17% respectively in the MAA and EAA hydrogenation reactions.⁴

An increase in the temperature of the modifying TA solution from 293 to 353–363 K helps to increase the optical yield of MHB. When the reaction is carried out in alcohols, OY diminishes but the overall rate of reaction increases. The best solvent has proved to be THF and ethyl acetate with added acids (acetic, formic, or benzoic). The antiparallel variation of OY and the overall rate of reaction, observed earlier by Orito and coworkers,^{124–128} was confirmed.⁴ Among the carriers investigated (activated charcoal, aluminium oxide, silica gel, kieselguhr), best results were obtained with kieselguhr.

Unfortunately there are no literature data on the reproducibility of the results of the studies by Orito and coworkers.^{124–128} Nevertheless, a question arises concerning the reason for the high enantioselectivity of nickel catalysts alloyed with other metals and especially concerning the role of kieselguhr as the carrier. Bimetallic catalysts based on nickel and copper with added platinum metals (ruthenium and palladium) did not exhibit an appreciable enantioselectivity in the EAA hydrogenation reaction.^{4,123}

Nitta et al.¹¹¹ investigated in detail modified nickel catalysts on carriers, including kieselguhr. They exhibited a high enantioselectivity, but kieselguhr as a carrier had no special properties. Apparently the addition of platinum or palladium at the nickel catalyst preparation stage promotes a more complete reduction of nickel and the formation at nickel crystallites of optimum size.¹¹¹ The NiO reduction process is influenced significantly by Cl[−] and Br[−] anions. The addition of PdCl₂ to the initial NiO–SiO₂ system promotes the reduction of NiO but has little influence on the enantioselectivity.¹¹¹

Contrary to the data of Orito and coworkers,^{124–128} the deposition of nickel on kieselguhr of the Shimalite brand or on Al₂O₃ with subsequent modification by (*R,R*)-tartaric acid did not make it possible to attain a value of OY in the MAA hydrogenation reaction in excess of 54–68% even in the presence of a high metal content on the carrier.¹²⁹ Similar optical yields were also obtained when nickel was deposited on TiO₂ (70%) and ZrO₂ (68%). The reactions were carried out at a pressure of 9 MPa and a temperature of 393 K.¹²⁹

The higher values of OY attained by Orito and coworkers^{124–128} can apparently be partly accounted for by the high nickel content on the carrier (50%), which actually converts the deposited catalyst into nickel black, and also by the specially favourable conditions in the formation of the catalyst created by the addition of platinum metals. It is also possible

Table 7. Conditions in the preparation of the Ni–SiO₂–TA catalysts for the hydrogenation of MAA (Ni : SiO₂ = 1 : 1).

that the kieselguhr employed in the above studies contained promoting admixtures.

Nitta et al.¹¹¹ concluded that the high effectiveness of the nickel catalysts under discussion^{124–128} may be accounted for by the special conditions in their formation. According to Nitta et al.,¹¹¹ the introduction of 1% of palladium into the Ni–SiO₂ catalyst in the stage involving the reduction of the NiCO₃–SiO₂ system promotes the reduction of the salt, a decrease in the process temperature, and the formation of larger nickel crystallites. Nitta et al.¹¹¹ attempted to reproduce the data of Orito and coworkers.^{124–128} The Ni–SiO₂ catalytic systems were prepared by three methods differing in the conditions in the deposition of the catalyst and its reduction. The influence of the introduction of palladium into the catalysts on the formation and enantioselectivity of the catalysts and the role of kieselguhr as the carrier were also investigated.

Table 7 presents the conditions for the preparation of the nickel catalysts described by Nitta et al.¹¹¹ and for comparison the conditions quoted by Orito et al.¹²⁴ Nitta et al.¹¹¹ used silica gel (60–200 mesh) with a specific surface of 600 m² g^{−1} and kieselguhr with a specific surface of 5.7 m² g^{−1} supplied by the Yoneyama Yakuhin Company. The suspension of the carrier was impregnated with a solution of nickel nitrate and precipitated with a solution of sodium carbonate at 348 K. After drying (383 K), the catalysts were reduced in a stream of hydrogen for 1 h at 773 K. In order to obtain the Ni–Pd–SiO₂ system, PdCl₂ was added to the catalyst mass before its reduction (Ni : Pd : carrier = 100 : 1 : 100).¹¹¹ As can be seen from Table 7, methods A, B, and C differ in the severity of the conditions during the deposition and treatment of the catalyst mass. The catalyst obtained by method C contained an excess of NiCO₃. Method A is distinguished by milder conditions, similar to those adopted by Orito and coworkers.^{124–128} Method B affords a deposit containing less effectively reducible Ni(OH)₂, the reduction of which even in the presence of palladium gives rise to larger crystallites.¹¹⁵ Depending on the composition of the initial mixture, the catalysts differ significantly in their enantioselectivity in the MAA hydrogenation reaction in EtOAc at 333 K and a pressure of 1 MPa. It was shown¹¹¹ that nickel catalysts with added palladium, deposited on silica gel or kieselguhr, are usually less effective than the catalysts without such an additive, which conflicts with the data of Orito et al.¹²⁴ Admittedly, the introduction of palladium into the catalyst obtained by method A promoted some increase in enantioselectivity as a consequence of the increase in the average size of the nickel crystallites (Table 8).

The use of kieselguhr did not increase but actually somewhat diminished *OY* even when the modification was carried out by the method of Orito et al.¹²⁴ at pH 4.1. The reaction rates on all the Ni–SiO₂–TA catalysts were similar and amounted to 0.4–0.8 mmol min^{−1} (g Ni)^{−1}. The introduction of palladium decreased somewhat the average size of the crystallites, which increased the rate of reaction but did not increase *OY*, whereas, according to the data of Orito et al.,¹²⁴ the catalysts on kieselguhr with added palladium are more active [the rate of

reaction is 2.5–8.7 mmol min^{−1} (g Ni)^{−1}] and enantioselective (*OY* = 63.8%–89.1%). Thus, contrary to the data of Orito and coworkers,^{124–128} the introduction of palladium and the use of kieselguhr as the carrier did not lead to the formation of specially effective catalysts.¹¹¹

Table 8. The influence of the method of preparation of the catalyst, the nature of the carrier, the reduction temperature (*T_r*), and added palladium on the enantioselectivity of the catalysts for the hydrogenation of MAA to (−)-MHB (according to the data of Nitta et al.¹¹¹).

^a See Table 7. ^b Ni : Pd : carrier = 100 : 1 : 100; modification by (R,R)-tartaric acid at pH 5.1. ^c Modification carried out at pH 4.1. ^d Experiment No. 7 in Table 6. ^e Experiment No. 10 in Table 6.

With increase in the fraction of NiCO₃ in the catalyst mass above 25% there is an increase in the specific surface and in the average size of the nickel crystallites (from 5 to 18 nm). *OY* passes through a maximum corresponding to the catalyst obtained from the catalyst mass containing 37% of NiCO₃ and reduced at 773 K. The increase in the fraction of NiCO₃ to 58% makes it possible to lower the reduction temperature to 573 K. This leads to an increase in \bar{D} to 15 nm, which promotes an increase in *OY*. Hence it follows that the enantioselective hydrogenation is a structure-sensitive reaction and may be used as a method for the monitoring of the size distribution of the nickel crystallites. Fig. 9 presents the variations of the catalytic activity and the optical yield in the MAA hydrogenation reaction on Ni–SiO₂ with the fraction of NiCO₃ in the catalyst mass. The size of the nickel crystallites is related, in its turn, to this quantity.

Studies have shown^{114,115} that the formation of the catalyst is greatly influenced by the additives, the nature of the initial salts, and the reduction conditions. The high effectiveness of the bimetallic catalysts deposited on kieselguhr may therefore be

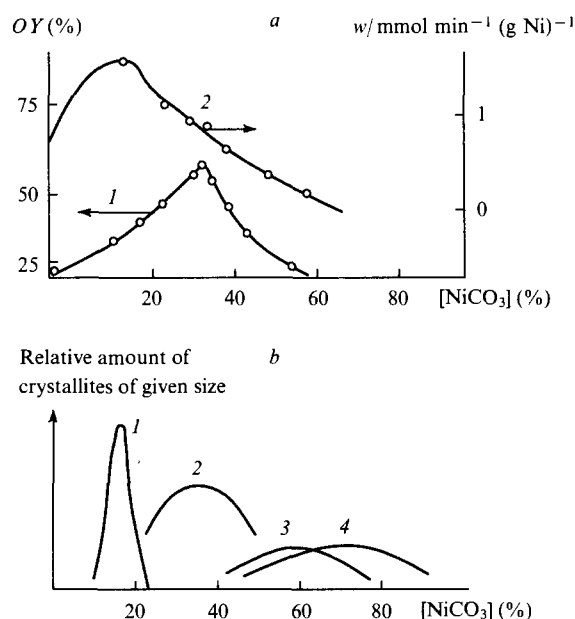

Figure 9. The influence of the NiCO_3 content in the initial catalyst mass (catalyst reduction temperature 673 K) on the optical yield of MHB (1) and the catalytic activity (w) of $\text{Ni-SiO}_2\text{-TA}$ (2) in the MAA hydrogenation reaction (a) and also on the average size of the nickel crystallites (b). Curves 1–4 (b) correspond to $\bar{D} = 3.5, 8.0, 16.0$, and 18.0 nm respectively (according to the data of Nitta et al.^{114, 115}).

caused by the precise influence of these factors on the formation of the structure of the catalyst surfaces and primarily on the size of the nickel crystallites.^{106, 108, 109, 113–115}

The introduction of palladium into the catalyst apparently affects the degree of reduction of nickel, which occurs in this case at lower temperatures. This influence depends greatly on the nature of the initial salts: the presence of palladium promotes the reduction of NiCO_3 , formed on precipitation with sodium carbonate, but has little effect on the reduction of Ni(OH)_2 . The presence of the carrier accelerates the conversion of part of NiCO_3 into Ni(OH)_2 , but the reduction of the hydroxide requires more severe conditions.

As already mentioned,^{124–128} the addition of AcOH increases significantly OY in the hydrogenation of MAA on Ni-Pd-Kg . The addition of certain salts into the modifying TA solution also helps to increase OY, the nature of the anion playing an important role. NaBr proved to be the most effective modifying additive to RNi-TA .⁴⁶

High concentrations of halide salts in the modifying TA solution have a negative effect on the rate of reaction and on OY,¹¹⁸ but the addition of NaI (or KI) at very low concentrations tends to increase the optical yield. It has been found that NaI reduces OY sharply at a concentration of just 0.002%, whereas NaBr is effective even at concentrations higher by a factor of 100. This is associated with the fact that the iodide is adsorbed on nickel much more strongly than the bromide. Thus the anion affects OY no less strongly than the cation.⁴⁶

The nature of the cation is important in the leaching of the Ni-Al alloy and in the establishment of a suitable pH of the modifying tartaric acid solution. Best results were achieved when Na^+ ions were employed: at a NaBr concentration of 8% and a TA concentration of 1%, the optical yield in the hydrogenation of MAA was 70.2%. Li^+ and Rb^+ ions hardly affect OY. The cations are coordinated to the oxygen in TA and MAA adsorbed on nickel, sodium and potassium participating in the octahedral coordination, which intensifies the template effect in the stereochemical interaction of TA with MAA (and MHB). The anions are by themselves incapable of showing the

template effect, particularly at high salt concentrations, their function consisting in fixing the appropriate amounts of the cation on the catalyst surface, needed for coordination to the TA–MAA (MHB) complex. The influence of NaBr is also manifested by the fact that the salt is a weak poison for the nickel catalysts. It blocks the most active centres on the nickel surface, intensifying thereby the enantioselective effect of the modified centres.

According to Nitta et al.,¹¹¹ the introduction of chlorides or bromides into the catalyst mass during the formation of deposited catalysts promotes an increase in OY by virtue of the increase in \bar{D} , but the overall rate of reaction decreases under these conditions. The addition of the salts NiCl_2 , NaCl , FeCl_2 , and NaBr or of the acids HCl or HBr to the catalyst mass prepared by method A increases OY from 36.1% to 49.7%–57.5%. With increase in \bar{D} (from 13 to 20–30 nm), a narrower size distribution of the nickel crystallites is obtained.¹¹¹

The increase in OY after the addition of NiCl_2 is of interest. The introduction of 29.8% of this salt into the catalyst mass, prepared by methods A, B, or C, diminishes sharply the specific surface of the reduced nickel (the reduction was carried out at 623 K for 1 h), which indicates an increase in \bar{D} . Depending on the method employed, OY increases from 36.1% to 54.9% (A), from 19.3% to 51.0% (B), and from 39.4% to 53.2% (C) respectively. The sharp diminution in the specific surface indicates not only the growth of \bar{D} but also the presence on the surface of chloride residues, which hinder the adsorption of hydrogen. At the same time, the Cl^- ions remaining on the catalyst after its reduction may act as a promoting additive, i.e. may behave similarly to NaBr in the modifying solution.⁴⁶

The RNi-TA-NaBr catalyst was obtained by leaching the 42:58 Na-Al alloy at 373 K.⁴⁶ The catalyst was washed 15 times with portions of deionised water and was modified in 1% (*R,R*)-TA solution containing 10 g of NaBr at 373 K in the course of 1 h. After the modification, the catalyst was again washed with water and methanol. MAA was hydrogenated in an $\text{EtCOOMe} + 0.2$ ml AcOH solution at a pressure of 9 MPa and a temperature of 373 K. The rate of reaction was $0.2 \text{ mmol min}^{-1} (\text{g Ni})^{-1}$. A threefold repetition of the modification procedure increased OY from 83.1% to 88.6%. Under the same conditions but without the addition of NaBr and AcOH, OY was 31.2%. The introduction of NaBr at a concentration of $0.01\text{--}0.04 \text{ mmol (g Ni)}^{-1}$ did not affect the degree of adsorption of TA on nickel and the optical yield increased in proportion to the NaBr concentration. This has been attributed⁴⁶ to the presence on the surface of the modified catalyst of two types of centres:⁴ selective centres, modified by TA, on which the (–)-enantiomer is formed, and nonselective centres on which the MHB racemate is produced.

This method also has its negative aspects: as stated above, NaBr diminishes the activity of the nonselective centres and lowers the overall rate of reaction. In order to compensate for this negative effect, it is necessary to increase the reaction pressure and temperature and this entails a decrease in regioselectivity and the appearance of side products, in particular the ester $\text{MeCH(CH}_2\text{COOMe)OCOCH}_2\text{CH(OH)Me}$. The behaviour of the deposited nickel catalyst is somewhat different from that of the Raney catalysts. The presence of residual amounts of Cl^- ions in the Ni-SiO_2 catalyst imparts stability to the latter in repeated hydrogenation. On the other hand, the Ni-SiO_2 (1:1) catalyst modified by TA with added NaBr is not quite so effective¹¹¹ as RNi .⁴⁶ The modification by NaBr increases OY in the MAA hydrogenation reaction from 36.1% to 46.0%, but, after repeated hydrogenation on the same portion of the catalyst, OY fell to 11.0%, while the catalyst promoted by the addition of NiCl_2 to the catalyst mass before reduction retained its stability in three consecutive experiments ($y = 90\%$, 79%, and 81% for $\text{OY} = 52.7\%$, 55.0%, and 54.9% respectively). This can be explained not only by the presence of

residual amounts of the halogen on the nickel surface but also by a more uniform size distribution of the nickel crystallites. Promotion by halides (nickel chloride) of the initial catalyst mass increases the degree of reduction of NiO to the metal.¹¹¹ This effect is manifested to a particularly notable extent in the reduction of the catalyst mass obtained by method B and containing Ni(OH)₂, which is reduced with difficulty as a consequence of the strong interaction with the carrier.¹¹⁷ As a result of this, the catalyst obtained has a higher activity but a lower enantioselectivity.

The low enantioselectivity of the Ni–Al₂O₃ catalysts, in the preparation of which NaOH is used to precipitate the hydroxides, can be accounted for by the strong interaction of the metal with the carrier and the formation of Ni–Al compounds on the surface. However, similar catalysts formed under mild conditions, which rule out the formation of small nickel crystallites, have the same enantioselectivity as Ni–SiO₂.¹¹⁶

A series of studies by Izumi and coworkers^{3, 46, 92} were devoted to the development of methods for increasing the enantioselectivity of the RNi–TA catalysts in the MAA hydrogenation reaction. With increase in the temperature of the leaching of the Ni–Al alloy, the optical activity of the product increases as a result of the decrease in the residual amount of aluminium present in the catalyst as aluminium hydroxide. The OH groups present in TA and Al(OH)₃ compete with one another for the formation of hydrogen bonds with MAA, reducing thereby OY. The elimination or blocking of the aluminium-enriched nickel centres increases the fraction of dissymmetric centres and increases OY. This view is confirmed by the fact that the nickel catalyst, obtained by the reduction of NiO in a stream of hydrogen at 523 K and modified with a 1% solution of TA at 358 K and pH 4.1, exhibits a higher enantioselectivity than the RNi–TA Raney catalyst. The hydrogenation of MAA in solution in EtCOOMe at a pressure of 1 MPa and a temperature of 393 K leads to the formation of (R)-(–)-MHB with OY = 81.7%, whereas the optical yield on RNi–TA under the same conditions is only 44%.⁴⁶

The fraction of nonselective centres on the nickel surface may be diminished by the ultrasonic treatment of the catalyst, which induces the selective disruption of the more active centres not protected by the modifying agent, tartaric acid.¹³⁰ Such treatment makes it possible to increase not only OY but also the overall activity of the catalyst, i.e. to eliminate the disadvantage characteristic of RNi catalyst modified by TA in the presence of NaBr (as already stated, the adsorption of this salt increases OY, but decreases significantly the overall catalytic activity).

Table 9. Hydrogenation of the methyl esters of ketoacids on the RNi–TA–NaBr catalyst treated with ultrasound and the untreated catalyst (according to the data of Tai et al.¹³⁰).

Compound hydrogenated	Treatment of a catalyst ^a	$w/\text{mmol min}^{-1}$ (g catalyst) ^{–1}	OY (%)
MeCOCH ₂ COOMe	+	18.0	86
	–	9.0	80
n-C ₇ H ₁₅ COCH ₂ COOMe	+	1.3	89
	–	0.3	83
n-C ₉ H ₁₉ COCH ₂ COOMe	+	0.9	91
	–	0.2	86
n-C ₁₁ H ₂₃ COCH ₂ COOMe	+	0.9	94
	–	0.2	86

Note. Reaction conditions: solvent — EtCOOMe, pressure 1 MPa, temperature 373 K.

^a + — with treatment by ultrasound, – — without treatment by ultrasound.

The overall rate of hydrogenation after the ultrasonic treatment of the catalyst increases by a factor of 2–4, while OY increases to 86%–94% (Table 9). This is the maximum optical yield attained hitherto on modified RNi–TA–NaBr catalysts. After such treatment, the catalyst becomes stable and can be used to obtain the optically active (R)-(–)-MHB on a large scale. Thus it has been possible to hydrogenate 10 kg of MAA, dissolved in 100 dm³ of EtCOOMe, on 190 g of the ultrasonically treated RNi–TA–NaBr catalyst after 18 h. The optical yield of (–)-MHB in this reaction, carried out at a pressure of 10 MPa and a temperature of 373 K, was 81%.

Optically pure 100% MHB can be obtained by crystallising a MHB derivative — the dibenzylammonium salt of HBA.¹³⁰ For this purpose, (–)-MHB with an excess of the enantiomer (OY = 83%) is hydrolysed in a 1:1 MeOH–H₂O mixture. The sodium salt is passed through a column with Amberlite IR-120 and the resulting acid (–)-HBA is converted into the dicyclohexylammonium¹³¹ or dibenzylammonium salt,¹³⁰ which is then crystallised. This leads to the formation of the optically pure (OY = 98%–100%) acid (R)-(–)-HBA in a high yield (Table 10).

Table 10. Preparation of optically pure carboxylic β -hydroxyacids by the hydrogenation of the methyl esters of the β -ketoacids Me(CH₂)_nCOCH₂COOMe on the RNi–TA–NaBr catalyst after three crystallisations of the dicyclohexylammonium salts of the acids from acetonitrile (according to the data of Tai and coworkers^{131, 135, 136}).

<i>n</i>	OY for hydroxyester (%) ^a	Consumption of acetonitrile /ml (gram salt) ^{–1}	β -Hydroxyacid	
			yield (%)	OY (%) ^b
0	86	7.0	52	98
6	87	11.5	50.5	98
8	88	18.0	73.5	100
10	85	19.0	72.1	100
12	87	24.5	75.1	98

^a Before crystallisation. ^b After crystallisation.

An important practical problem concerns the possibility of the repeated use of the RNi–TA–NaBr catalysts. It has been shown that RNi–TA–NaBr introduced into a solid matrix of vulcanised silicone rubber containing oxime groups (KE-441 produced by the Shin Etsu Chemical Company) can be used repeatedly, up to 30 times, in the hydrogenation of MAA to (–)-MHB.^{132, 133} The optical yield on a single catalyst specimen (9 MPa, 373 K) is maintained at the level of 58%–62% and there is no significant decrease in enantioselectivity.¹³⁴ The usual catalyst without a matrix is somewhat more enantioselective but is less stable and OY has already decreased from 76% to 28% by the third experiment. The stability of the catalyst inserted into a silicone matrix is ensured by the binding of the nickel to the oxime groups of the polymer, which are converted into amino-groups during the reaction.¹³⁴ Treatment with a solution of pyridine or MePrNH^{100, 104} therefore also makes it possible to obtain a stable catalyst on one portion of which up to 10 consecutive hydrogenations can be performed with only a slight decrease in OY (from 80% to 73%).¹³⁴

Processes in which the optical yield is not less than 80% while the preparation of the catalyst and the process technology are fairly simple are of practical interest. These requirements are satisfied by modified metallic catalysts. The industrial production of chiral hydroxyesters and glycols with OY up to 90% can be achieved on modified nickel catalysts.

The high effectiveness of the RNi–TA–NaBr catalysts has been used to synthesise practically important optically active β -hydroxyacids, which are common in biological systems. (R)-(–)-3-Hydroxydecanoic acid forms part of the composition

of growth factors, 3-hydroxytetradecanoic acid is the principal aliphatic acid in 'lipid A' in endotoxin,¹³⁵ the choline ester of 3-acetoxyhexadecanoic acid, known as pahutoxin, is one of the components of fish poison,^{131,136} while 3-hydroxyoctadecanoic acid is a component of the antitumour preparation emposatin. All these compounds have been obtained in high optical yields by the hydrogenation of the corresponding ketoacids on RNi-TA-NaBr at a pressure of 9.5 MPa and a temperature of 373 K in solution in $\text{EtCOOMe} + \text{AcOH}$. After 2–3 recrystallisations of the dicyclohexylammonium or dibenzylammonium salts, obtained from the esters of the corresponding hydroxyacids,^{131,137} it is possible to obtain the optically pure acids in high yields. The nickel catalyst is also used in the synthesis of the hydroxyester which is an intermediate in the synthesis of tetrahydrolipostatin produced by the Hoffmann-LaRoche Company.¹³⁸

β -Hydroxyesters and β -glycols, for example ethyl β -hydroxybutyrate and pentane-(2*R*,4*R*)- and -(2*S*,4*S*)-diols, are produced industrially on the RNi-TA-NaBr catalysts. The optical yield of the diol reaches 87%, while after the crystallisation of its derivative it becomes 100%.¹³⁹ This is used in the synthesis of the chiral diphosphine Skewphos [(*R,R*)-2,4-bis(diphenylphosphino)pentane].¹⁴⁰

Modified nickel catalysts for asymmetric hydrogenation are produced by the Wako Pure Chemistry,¹⁴¹ Kawaken Pure Chemistry, and Degussa Companies (RNi-TA-NiBr)¹³⁸ and by the Heraeus Company (HNi-TA-NaBr).^{138,142}

VI. Synthesis of optically active β -hydroxyesters by the hydrogenation of ketoesters on metal complex catalysts with chiral ligands

Chiral rhodium–diphosphine complexes are highly effective chiral catalysts on which it is possible to hydrogenate dehydroamino acids to optically active amino acids with OY close to 100%.¹⁴³ Under certain conditions, ketones can also be reduced on these catalysts.^{143,144} The presence of the COOR group in the molecule facilitates reduction and hydroxyesters are formed from α - and β -ketoesters with high values of OY .¹⁴⁵ The ketoesters are particularly effectively reduced on chiral rhodium and ruthenium complexes.¹⁴⁶ The methyl acetoacetate is reduced

to MHB with $OY = 71\%$ when acted upon by the complex $[\text{Rh-CAMP}]$ [$\text{CAMP} = (R)$ -cyclohexyl-*o*-methoxyphenylmethylphosphine].¹⁴⁷ The rhodium complex with the chiral diphosphine BINAP,^{47,148} produced by the method of Takaya et al.,¹⁴⁹ exhibits a very high enantioselectivity. MAA is hydrogenated at pressures of 1.0 or 1.12 MPa and a temperature of 298 K for 48 h.^{150,151} The (*R*)-(-)- β -hydroxyester with $OY = 99\%$ is formed from methyl β -ketovalerate in solution in 1:1 $\text{MeOH-CH}_2\text{Cl}_2$ in the presence of the complex $[\text{Rh-BINAP}]$, and the optically pure (*R*)-(-)-hydroxyvaleric acid can be obtained by its hydrolysis.

The use of phospholanes as chiral ligands in rhodium complexes proved to be relatively ineffective: the optical yield did not exceed 27% in the reduction of MAA at a pressure of 2 MPa and a temperature of 298 K.¹⁵¹

VII. Conclusion

In conclusion, the three methods of synthesis of β -hydroxyesters examined above should be compared from the standpoint of their practical applicability. Table 11 presents the main characteristics of the processes involving the reduction of β -ketobutyrate, acted upon by baker's yeast, on a Raney nickel catalyst modified by (*R,R*)-tartaric acid with added NaBr, and in the presence of a chiral ruthenium complex containing a chiral ligand, the diphosphine BINAP.³² As can be seen, all three methods ensure a high effectiveness of the process. The optical yield is 85%–99%. We shall now consider their disadvantages.

Despite the high enantioselectivity (in the best instances), the possibilities for wide scale application of the enzymic reduction of ketoesters are limited by the low productivity of the process, by the need to employ large volumes of solutions, by the low concentration of the product in solution, by the need for additional purification (filtration, extraction), by the long duration of the process, and by the instability of the enzyme. This is a single-use process which cannot be carried out under flow or cyclic conditions and the reducing agents are not regenerated.

The employment of a metal complex catalyst ensures an extremely high effectiveness and productivity, the turnover number for the reaction on such a catalyst being very high. The process can be performed at room temperature. However, the cost of the catalyst and of the chiral ligand is high and they cannot be regenerated.

Table 11. Comparative characteristics of various methods for the synthesis of β -hydroxybutyrate by the reduction of β -ketoesters.

Characteristic	Enzymic reduction ^a	Heterogeneous-catalytic process RNi-TA-NaBr	Metal complex catalysis Ru-BINAP
Substrate and its sample/g	EAA, 40	MAA, 40	MAA, 40

Productivity/g (litre solution) ⁻¹ h ⁻¹	0.07	40	12
Possibility of repeated use of catalyst	none	5–30 times	none

^a Standard method.⁴⁵

The somewhat reduced enantioselectivity of the heterogeneous catalyst modified by tartaric acid (the maximum optical yield attained so far is 94%) is compensated by the high productivity of the process, the possibility of the repeated employment of the catalyst (up to 30 times in certain cases), the ease of its separation from the product, and the low cost and ease of preparation of the catalyst. The heterogeneous catalyst can be readily prepared in large amounts and it can be usefully employed in the large-scale production of the chiral β -hydroxybutyrate with an optical yield of about 90%, particularly if it is proposed to carry out further purification of the product by the crystallisation of its derivatives.

Overall, chemical methods have clear advantages over enzymic procedures, which constitutes an important stimulus for the improvement of the latter. There is no doubt that further search for effective catalytic systems, both heterogeneous and metal complex, is needed.

VII. Conclusion	352

Abstracts. The methods of preparation and physicochemical and mechanical properties of gradient interpenetrating polymer networks (IPN) are examined. The results of studies on the viscoelastic properties as well as the strength and other mechanical characteristics in layers of gradient IPN are presented. The properties of the usual and gradient IPN of the same chemical nature are compared. Data are presented on the layer-by-layer variation of the thermodynamic compatibility of the components in gradient IPN. The bibliography includes 64 references.

I. Introduction

One aspect of the chemistry of macromolecular compounds which is of current interest is the modification of finished polymers and preparation of materials based on them. From this standpoint, the study of mixtures and blends of linear polymers (interpenetrating polymer networks) is promising, since one can vary indefinitely the structures and properties of polymeric materials obtained on the basis of such systems. Interpenetrating polymer networks (IPN) are polymer–polymer compositions consisting of two or more three-dimensional polymers (or of network and linear polymers) in which the individual networks are not chemically linked but are indistinguishable owing to the mechanical intertwining of the chains determined by the conditions of the synthesis.

Interpenetrating polymer networks are obtained by modifying polymers with a three-dimensional structure. Since the appearance of the term ‘interpenetrating polymer network’¹ much time has elapsed, but the principal studies in this field began in the 1980s^{13–17} and have continued up to the present time.

L M Sergeeva, L A Gorbach Division of Thermoreactive and Thermoplastic Polymers, Institute of the Chemistry of Macromolecular Compounds, National Academy of Sciences of Ukraine, Khar'kovskoe shosse, 48, 253160 Kiev, Ukraine. Fax (7-044) 552 40 64. Tel. (7-044) 559 47 95 (L M Sergeeva).

There are two monographs and several review articles^{2–12} in which the methods of preparation, the nomenclature, and the structure and properties of IPN of different types are considered. Analysis of the literature shows that gradient IPN are some of the most interesting and promising polymers. Sperling,⁴ Sergeeva and Lipatov,¹⁰ and Sergeeva¹¹ have considered gradient IPN very briefly.

Gradient IPN are mixtures of three-dimensional polymers (or mixtures of a three-dimensional and a linear polymer), the concentrations of the components in which vary along the cross-section of the specimen. Gradient IPN constitute the basis for the synthesis of promising polymeric materials used, for example, in medicine, optoelectronics, wave optics, and instrument making, for vibration- and sound-proofing, and in other fields. The volume characteristics of polymeric materials based on IPN may remain unchanged. However, the overall characteristics of the composite are improved.

II. Methods of preparation and layer-by-layer analysis of the compositions of gradient interpenetrating polymer networks

The first studies involving the preparation and investigation of gradient IPN were associated with the search for and development of materials for medicine.^{13–17} The interpenetrating polymer networks used for such purposes can be obtained only by the successive hardening method. This method consists of the following procedures: in the first stage, the preformed polymer (the first component) is kept in a monomer, which subsequently polymerises with formation of a second polymer. Swelling is interrupted at a certain stage, before the attainment of equilibrium, after which the second polymer is obtained, its concentration in the matrix polymer varying perpendicular to the surface as a consequence of the slowness of the swelling and diffusion processes in the matrix network. This results in the formation of an IPN, the properties of which differ both from those of the individual polymers and from the properties of the IPN of the same chemical nature but obtained by the successive hardening method under equilibrium conditions.

Since in the preparation of gradient IPN there is a stage involving the nonequilibrium swelling of the matrix network in the monomers, problems arise, associated with the influence of various factors on the rate of diffusion of the monomers into the matrix network and hence with the distribution of the second

Received 27 March 1995

Uspekhi Khimii 65 (4) 367–376 (1996); translated by A K Grzybowski

polymer through the thickness of the matrix. In order to investigate the nature of the distribution of the polymers entering into the composition of the IPN as a function of thickness, use is made as a rule of the layer-by-layer elemental analysis. In the gradient IPN based on polystyrene (PS) and polyacrylonitrile (PAN) (with ethylene dimethacrylate as the cross-linking agent),¹³ PS served as the matrix network and PAN was concentrated in the surface layer of PS with a definite concentration gradient. In order to establish the nature of the distribution of PAN in PS, layers 0.05 mm thick were removed and their nitrogen content assayed chemically. It was shown that the highest content of PAN (~50%) occurs near the surface of the specimen of the gradient IPN. The concentration of PAN near the surface is also confirmed by the finding that the specimens of the test IPN are more resistant to the action of hydrocarbons, for example benzene, in contrast to pure PS.¹³ It has been suggested that the diffusion of the monomer into the matrix network in the test specimen generally obeys Fick's law, although there are certain deviations.¹⁴ For systems such as poly(methyl methacrylate)–polymethacrylate, the layer-by-layer methods of chemical analysis proved unsuitable, since both polymers contain the same elements.

The rate of diffusion of the monomers during the preparation of gradient IPN and the subsequent distribution of the polymers probably depend on the monomer concentration in the solvent (if such is used), on the concentration of the cross-linking agent, and other factors. These problems have been examined in detail in a study of the gradient IPN based on polyester urethanes (PU) and cross-linked polyacrylamide (PAA).¹⁵ The polyester urethanes were obtained by a two-stage method from diphenylmethane diisocyanate and poly(propylene glycol) using diaminoethane as the lengthening agent. The polyester urethane contained rigid domains — physical cross-links forming a network. The IPN specimens were obtained by swelling PU plates in a solution containing acrylamide (AA), a cross-linking agent (tetraethylene glycol dimethacrylate), and an initiator. This was followed by the polymerisation of the AA. The overall amount of the PAA was determined from the difference between the masses of the initial PU film and that obtained after its saturation by the PAA. It has been shown for this system that an increase in the monomer concentration in the swelling mixture leads to a steady increase in the PAA concentration in the IPN, although the dependence of its content on the AA concentration in solution is nonlinear. Naturally, an increase in the PAA content in the IPN leads subsequently to an increase in the degree of swelling of the specimen in water. An increase in the initiator concentration in the AA solution also leads to an increase in the PAA content in the IPN, but only up to a certain limit, beyond which the influence of the initiator concentration is insignificant. The change in the concentration of the cross-linking agent influences non-monotonically the PAA content in the IPN: there is an optimum concentration ensuring the maximum PAA content, but the capacity of the IPN for swelling in water decreases monotonically under these conditions.

The concentration of the monomer and its distribution in the matrix network are naturally to a large extent determined by the duration of the swelling of the initial network in the monomer. Thus, the influence of the swelling time (from 5 to 30 min) on the PAA content in the IPN has been investigated for the PU–PAA system.¹⁶

It has been established that the dependence of the fraction of PAA in the IPN ($\omega = W_{\text{PAA}}/W_{\text{IPN}}$) on the swelling time is described by the equation

$$\omega_t = \omega_\infty(1 - e^{-kt}),$$

where ω_t and ω_∞ are respectively the fractions of PAA in the IPN during polymerisation after swelling for a time t and after equilibrium swelling.

Apart from varying the swelling time, other procedures may be used to set up a concentration gradient along the thickness of the IPN layer, for example one can employ cross-linking agents with a higher molecular mass or the diffusion of the cross-linking agent.¹⁶ The latter method can be described as follows: the matrix network is kept in the monomer solution with the initiator until the attainment of equilibrium, after which the swollen matrix network is placed for a time in a solution of the cross-linking agent. It was found that, when this procedure is employed, the fraction of PAA in the IPN based on PU and PAA is independent of the time during which the swollen PU is kept in the solution of the cross-linking agent.

The Fourier transform IR spectroscopic method¹⁶ makes it possible to obtain more accurate information about the nature of the distribution of polymers in gradient IPN based on PU and PAA compared with chemical analysis.^{14,15} It has been established¹⁶ that, when the partial swelling method is employed (the method involving different exposure times), PAA concentrates mainly at the surface of the specimen (the depth of penetration by PAA does not exceed 10 μm). The PAA concentration gradient along the thickness has also been observed in the preparation of IPN after the attainment of the equilibrium swelling of the matrix network in the monomer, but it is not quite so distinct as in the previous case. Finally, the diffusion of the cross-linking agent and the variation of its molecular mass have virtually the same influence on the PAA concentration gradient in PU.

Like the usual IPN, 'direct' and 'reverse' gradient IPN may be synthesised. The system based on poly(methyl methacrylate) (PMMA) and poly(chloroethyl acrylate) (PCEA) have been obtained in two ways.¹⁷ In the first case, the PMMA obtained beforehand was swollen in chloroethyl acrylate (CEA) and the CEA was then polymerised. The initiator was fluorobutyl ether from petrol and the cross-linking agent was ethylene glycol dimethacrylate. In the second case, PCEA was swollen in methyl methacrylate (MMA) and the latter was subsequently polymerised. Gradient IPN containing 30 mass % of PCA in a PMMA matrix and up to 50 mass % of PMMA in a PCEA matrix were obtained in this way. In order to determine the profile of the concentration gradient (in the present instance of chlorine) in the test system, chemical analysis was employed, as in certain other gradient IPN.

Fig. 1 presents the gradient in the distribution of PCEA in specimens obtained by the first method. Evidently the PCEA content decreases sharply on moving away from the surface, particularly when its concentration in the gradient IPN is low whereupon the main bulk of PCEA concentrates at the surface of the specimen.

It is noteworthy that in the usual IPN (Fig. 1, curve 4) i.e. those obtained by the successive hardening method under the conditions of the equilibrium swelling of the matrix network in the monomer, the PCEA concentration does not change on moving away from the surface of the specimen. This conflicts with data obtained for the PU–PAA system,¹⁴ where a concentration gradient with respect to the thickness was established even for the usual IPN. It is most likely that this may be induced by the time during which the PU specimens are kept in PAA, before the start of the polymerisation, being insufficient.

For specimens of the second series, the PMMA content does not diminish quite so sharply (judging from the growth in the PCEA content with increasing thickness) on moving away from the specimen surface.

Gradient IPN based on PU and polyacrylate copolymers have been obtained^{18,19} by a method involving the swelling of a preformed network PU without attaining the equilibrium distribution of the diffusants and subsequent photopolymerisation of the reactants. The composition of the components in the layers was determined by comparing the glass points (T_g) of the

Figure 1. Distribution of PCEA and PMMA in specimens of gradient polymers (1–3) and IPN (4–7) with a PMMA matrix (a) and a PCEA matrix (b) for different PCEA and PMMA contents. c_{PCEA} (mass %): (1) 10; (2) 20; (3) and (4) 30; c_{PMMA} (mass %): (5) 10; (6) 30; (7) 50; L/L_0 = relative thickness of the specimen.

usual IPN and gradient IPN of the same nature and also by elemental analysis.^{20–33}

Free-radical initiation was used in the studies described above to obtain the second polymer with a concentration gradient in the first polymer-matrix. The use of polycondensation appears at first sight impractical, since the reaction can occur during the swelling process. After the attainment of equilibrium, the reactants must then be present in the matrix in almost equivalent proportions for the formation of a high-molecular-mass condensation polymer. Nevertheless, it has been shown³⁴ that polycondensation can be used extremely successfully for the preparation of gradient IPN. For this purpose, one of the reactants is initially kept in the preformed polymer-matrix and the matrix is then placed in the second reactant or its solution. Diffusion and the polycondensation reaction between the reactants take place simultaneously under these conditions. Such a process may be referred to as diffusion-controlled polycondensation occurring in the matrix in the mixing zone of the two components.

A gradient IPN, the matrix of which consisted of the 2-hydroxyethyl methacrylate–*N*-vinylpyrrolidone copolymer while the polymer with a concentration gradient was polyurethane based on a diol or a triol and 1,6-diisocyanato-2,4,4(2,2,4)-trimethylhexane, was obtained in this way.

III. Thermodynamic compatibility of the components in layers of gradient interpenetrating polymer networks

At a certain stage during the formation of the IPN, a microphase separation of the components begins as a consequence of thermodynamic incompatibility caused by the formation of heterogeneous three-dimensional structures.^{3,20–22} The phase separation conditions are determined both by the composition of the IPN and by the rate of formation of the two networks. Apparently, the separation in each layer of the gradient IPN occurs to different extents, since the component ratio undergoes continuous layer-by-layer variation. It is noteworthy that the microphase separation is not completed in the IPN formed, which results in the formation of nonequilibrium 'frozen structures', which are nevertheless kinetically stable.^{3,10}

The thermodynamic parameters which make it possible to infer the compatibility of the components in layers at different distances from the surface of the specimens have been estimated²³ in relation to the gradient IPN based on polyurethane and cross-linked poly(butyl methacrylate). The changes in the free energy of mixing of the network components Δg_x were estimated by analysing the isotherms for the sorption of benzene vapour by the IPN specimens. Fig. 2 presents the variation of Δg_x in IPN layers on moving away from the specimen surface (from the first to the fourth layer). Evidently, Δg_x is positive, so that the components are incompatible, as in the majority of the usual IPN.^{3,24,31–36} The absolute value of Δg_x depends on the depth of the layer in the specimen. This fact is due not only to changes in the composition of the networks as the core of the specimen is approached but also to changes in the phase separation conditions in each layer of the IPN produced.

The different degrees of compatibility of the components in the IPN layers influence the structure formed and at the same time the properties of the component as a whole. Each layer in a gradient IPN can be regarded as an independent two-phase IPN with a different phase composition.²³ By considering each phase arising during the incomplete phase separation as an independent quasi-equilibrium IPN,²⁴ the authors²³ estimated the compositions and ratio for these phases. For this purpose, they used Fox's equation,²⁵ proposed for compatible polymer blends, and the glass points obtained by the dilatometric method both for the individual networks and for the networks in the layers of the gradient IPN. In the gradient IPN based on polyurethane, T_g refers to one of the phases enriched in PU or the copolymer. The volume fractions of PU in the PU-enriched phase and of the copolymer in the copolymer-enriched phase were calculated from the corresponding glass points in the IPN and in the layers of the gradient IPN.

Figure 2. Variation of the free energy of mixing of the components in the layers of gradient IPN.

Analysis of the data obtained led to the conclusion that, as a consequence of the incomplete separation, two phases are formed in the layers of the gradient IPN, the composition of which depends on the phase separation conditions in each layer. As a result of the variation of the composition (and hence of the thermodynamic compatibility of both networks), the degree of segregation in each layer is different from that for the usual IPN having the same composition.²³

Thus gradient IPN are multicomponent systems, the properties of which are determined by the presence not only of the composition gradient but also of the phase composition gradient and the phase ratio in the microphase systems.

IV. Relaxation properties and transition temperatures

A considerable proportion of the studies on gradient IPN have been devoted to dynamic mechanical properties. Information about the transition temperatures and the compatibility of the components in the test systems can be obtained from these data. Thus two transition temperatures have been observed for the IPN based on PMMA and PCEA (PMMA matrix)¹⁷ in a study of the temperature dependence of the modulus of dynamic losses: one at 263 K, corresponding to PCEA, and the other at 383 K, corresponding to PMMA. This indicates unambiguously the occurrence of phase separation and the incompatibility of the components in the IPN.

However, a single transition in the region between the glass points T_g of the corresponding homopolymers has been observed for the same IPN but with a PCEA matrix. The transition temperature shifts to 323 K at a PMMA concentration up to 50%, which constitutes evidence, according to Martin et al.,¹⁷ in favour of the absence of phase separation. As will be shown below, the latter conclusion is hardly legitimate.

The mechanical relaxation properties of a polymer with a composition gradient have been modelled for a qualitative estimation of the influence of the change in composition on the viscoelastic properties of a polymeric specimen with a glass

point gradient.²⁶ A system consisting of eleven plates, differing in the glass points by a known number of degrees determined by the gradient, was adopted as the model gradient material for this purpose.

Fig. 3 presents the calculated temperature variations of the real component of the complex modulus of shear ($\lg G'$) of the model gradient material, the layers of the material being deformed in parallel. The presence of a glass point gradient leads to the appearance of characteristic temperature variations, which are less steep the higher the gradient. At the same time, with increase in the temperature gradient, the height of the maximum of the tangent of the angle of mechanical losses ($\tan \delta$) decreases, becomes broader, and shifts by 8–10° into the low-temperature region compared with the position of the $\tan \delta$ maximum corresponding to a high glass point. It was also established that, in the formation of the specimen in the direction coinciding with the direction of the gradient (i.e. for the consecutive deformation of the layers), the nature of the temperature dependences of $\lg G'$ and $\tan \delta$ is predetermined by the properties of the components having low glass points. However, the $\tan \delta$ maxima for the gradient materials are shifted towards higher temperatures by 5–7° relative to the $\tan \delta$ maximum corresponding to the 'lowest temperature' component and the changes in the height of the maxima are slight.

The theoretical data obtained led to the conclusion²⁶ that the temperature range of the transition state of the gradient materials expands significantly, increasing with increase in the temperature gradient. An important feature of materials of this kind is the anisotropy of the properties in different directions, which is manifested most strikingly in limiting cases where the direction of the deformation is parallel or perpendicular to the direction of the gradient.

Experimental studies^{18,19} have confirmed to some extent the above theoretical conclusions. Gradient IPN based on PU with a network structure and the copolymer of butyl methacrylate with triethylene glycol dimethacrylate¹⁸ or oligo(carbonate-methacrylate)¹⁹ were obtained. The usual IPN having the same composition were also obtained for comparison.

Fig. 4 presents the temperature variations of $\tan \delta$ for the usual IPN based on PU and the butyl methacrylate-oligo(carbonate-methacrylate) copolymer and also for their components.¹⁹ Similar variations have also been obtained for another IPN of a similar chemical nature.¹⁸ Evidently the $\tan \delta$ maximum is observed at 248 K for PU and at 366 K for the copolymer. For the IPN with 10 mass % of the copolymer, the temperature dependence is characterised by the occurrence of the relaxation α -transition, corresponding to the acrylate

Figure 3. Calculated temperature variation of $\lg G'$ (a) and $\tan \delta$ (b) for a gradient model ($n = 11$) with different T_g gradients $[(dT_g/dx)/K]$: (1) <20; (2) 20; (3) 50; (4) 70 with parallel deformation of the components.

Figure 4. Temperature variations of $\tan \delta$ for PU, the copolymer, and the IPN based on them with different component ratios: (1) PU; (2) copolymer; (3)–(6) IPN containing 10, 20, 30, and 40 mass % of the copolymer respectively.

component, and is manifested by a distinct shoulder on the descending branch of the curve in the temperature range 273–303 K (Fig. 4, curve 3). With increase in the fraction of the copolymer in the IPN, the relaxation maximum corresponding to the copolymer is manifested more distinctly and the temperature range where this transition occurs shifts, with increase in the copolymer concentration in the IPN, towards the temperature range of the relaxation α -transition of the initial copolymer (Fig. 4, curves 2–6).

The nature of curves 3–6 in Fig. 4 shows that the IPN are two-phase systems in which both components form continuous phases.²⁷ The expansion of the temperature range of the α -transition of the copolymer indicates the generation of an extensive interfacial region in the IPN during the formation of the acrylate network under these conditions.

Calculation of the segregation coefficients of the components (α) by the method proposed by Rosovitskii and Lipatov²⁸ showed that α for all the IPN is in the range from 0.3 to 0.5 and tends to fall with increase in the fraction of the copolymer in the IPN, i.e. the degree of segregation of the components diminishes.

Thus the usual IPN are two-phase systems. However, the observed shift of the $\tan \delta$ maximum along the temperature scale for the copolymer in the IPN compared with its position in the individual network and also its broadening indicate an incomplete phase separation of the components in the formation of the IPN. This confirms data indicating the thermodynamic incompatibility of the components in the IPN of the same chemical nature.

The gradient IPN-1 IPN-2 with different copolymer contents, 30% and 15% respectively, have been investigated layer-by-layer, both along the copolymer concentration gradient and at right angles to it.¹⁹ Fig. 5 presents the temperature variations of $\tan \delta$ for specimens obtained sections at right angles to the concentration gradient. Analysis of the family of curves and their shape as well as the intensity and relative positions on the temperature scale of the maxima corresponding to PU and the copolymer led the authors¹⁹ to the conclusion that, firstly, a copolymer distribution gradient is indeed observed as one moves away from the surface of the specimen and, secondly, the continuity of both phases in the gradient IPN-1 containing a greater amount of the copolymer is observed at a greater distance from the specimen surface than for IPN-2.

The average concentrations of the copolymer in the layers of the gradient IPN were calculated from the observed linear dependence of the glass point of the copolymer (T_g is the temperature corresponding to the high-temperature $\tan \delta$ maximum) on composition for the usual IPN. Thus the first three layers in IPN-1 contained 38.6, 26.9, and 15.3% of the copolymer, while the contents of the copolymer in the first and second layers in IPN-2 were respectively 38.6 and 10.6 mass %, i.e., for a greater average concentration of the copolymer in the specimen, a more uniform distribution with respect to the depth in the specimen is observed.

The study of the viscoelastic properties of sections obtained along the copolymer concentration gradient revealed certain differences (Fig. 6).^{18,19} For specimens representing a complete section through the gradient system (Fig. 6, curves 2), a

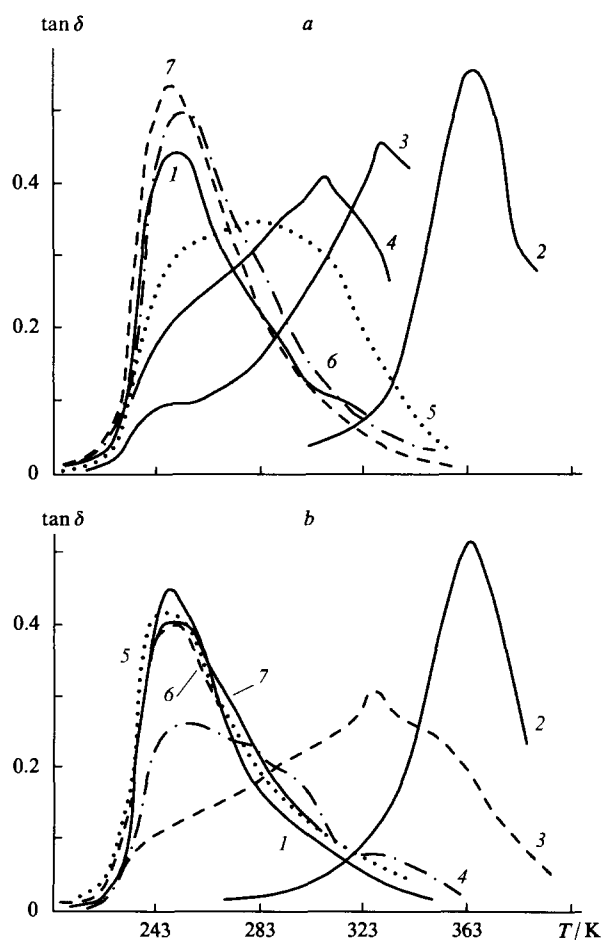

Figure 5. Temperature variations of $\tan \delta$ obtained for perpendicular sections through gradient IPN-1 (a) and IPN-2 (b): (1) PU; (2) copolymer; (3)–(7) the first, second, third, fourth, and fifth sections respectively.

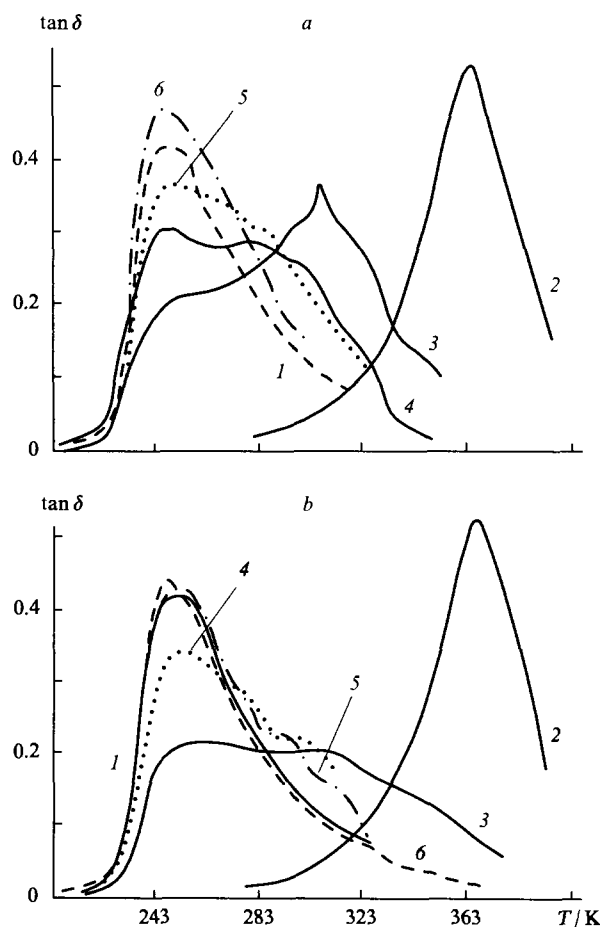

Figure 6. Temperature variations of $\tan \delta$ for specimens obtained from longitudinal sections of gradient IPN-1 (a) and IPN-2 (b): (1) PU; (2) copolymer; (3)–(6) the first, second, third, and fourth sections respectively.

maximum is observed in the range 233–363 K. For IPN-1, the maximum is observed at 308 K in the region corresponding to the transition in the copolymer, while in the region of the relaxation α -transition in PU there is a distinct shoulder. A single broad maximum in the form of a plateau, overlapping the region of the relaxation transitions in both components, is observed for IPN-2.

The presence of broad maxima on the $\tan \delta$ – T curves is probably not a result of the compatibility of the components in the IPN but indicates a superposition of a large number of relaxation maxima in layers with gradually varying compositions.¹⁸ These data agree with the results of modelling²⁶ and also account for the appearance of a single but broad transition for the PMMA–PCEA system, which has been erroneously regarded¹⁷ as evidence for the compatibility of the components.

The damping properties of the gradient and the usual IPN based on PU and the butyl methacrylate–oligo(carbonate-methacrylate) copolymer have been compared¹⁹ on the basis of the analysis of dynamic mechanical spectroscopic data for these systems. One of the integral parameters characterising the ability of a material to scatter mechanical energy is known^{29,30} to be the area under the curve describing the temperature variation of the imaginary component of the complex modulus of elasticity ($S_{E''-T}$), which is determined by the intensity and width of the temperature range of the relaxation transition. For all the test specimens, this parameter has been calculated by the method of trapezia on a computer. For specimens of the usual IPN, the values of this parameter have been calculated assuming additivity.¹⁹

Examination of the results revealed that in general the damping properties of the IPN investigated are superior to those of the initial components (the $S_{E''-T}$ for the IPN are higher). For gradient IPN specimens sliced at right angles to the copolymer concentration gradient, $S_{E''-T}$ diminishes with decrease in the concentration of the copolymer, whereas for sections along the $S_{E''-T}$ gradient the values of $S_{E''-T}$ actually increase with decrease in the copolymer concentration, i.e. the anisotropy of the properties is observed, which confirms the conclusions reached by Lipatov et al.²⁶

Furthermore, it was found that the variation of the damping properties of the usual and gradient IPN is not the same for chemically similar IPN specimens: thus the damping characteristics of the gradient IPN based on PU and the butyl methacrylate–ethylene glycol dimethacrylate copolymer¹⁸ are superior to those of the usual IPN, whereas the opposite picture is observed for the IPN based on the same PU and the butyl methacrylate–oligo(carbonate-methacrylate) copolymer.¹⁹

Thus analysis of the results of the study of the relaxation characteristics of the usual and gradient IPN indicates a significant difference between their viscoelastic properties. Furthermore, the results of the modelling agree satisfactorily with the experimental data.

V. Mechanical properties of gradient interpenetrating polymer networks

The strength characteristics of gradient IPN have been investigated in some studies. Thus, in a study of the IPN based on PMMA and PCEA, Martin et al.¹⁷ established that the gradient IPN differ from the usual IPN and the homopolymers by a higher decomposition energy and that the deformation of gradient IPN with a PMMA matrix and 30 mass % of PCEA increased by an order of magnitude on decomposition compared with the pure PMMA, while the strength of the IPN with a PCEA matrix and 50 mass % of PMMA is 10–15 times higher than that of PCEA.

The study of the mechanical characteristics of gradient IPN based on PMMA and methyl methacrylate (MMA) showed¹³ that, whereas pure PMMA decomposes (at 373 K) on 2% extension, the gradient IPN containing ~10 mass % of MMA

Figure 7. Stress–deformation curves for a gradient polymer (1), IPN (2), and a statistical methyl methacrylate–methyl acrylate copolymer (3).

breaks after 10% extension. The introduction of 19 mass % of MMA leads to the disruption of the IPN specimen only after 80% extension. Fig. 7 presents the stress–deformation relations for PMMA–MMA specimens obtained in the form of a gradient polymer, an IPN obtained by successive hardening, and a statistical copolymer.¹³ Evidently, the gradient polymer is subjected to the highest stress at rupture and the area under the stress–deformation curve is greatest for this polymer.

Comparative study of the mechanical properties of the usual and gradient PU-based IPN and the butyl methacrylate–triethylene glycol dimethacrylate copolymer (for the same component ratios) showed (Fig. 8) that the highest strength parameters are observed for the gradient IPN:¹⁸ the area under the stress–deformation curve increases and so does Young's modulus (the slope of the initial section of curve 3 is greater than that of curve 2).

Thus when a gradient of the concentrations of the components is established in a polymeric material, there is a tendency towards an improvement in its mechanical properties. Several hypotheses have been put forward to account for these phenomena.^{13,17} According to one of them, a gradient IPN is regarded as an assembly of an infinite multiplicity of layers, the compositions and moduli of elasticity of which vary monotonically on moving away from the surface the bulk of the specimen. On deformation of the specimen, all the layers are stretched to the same extent and the stress in each layer corresponds to its modulus. Such distribution of stresses promotes the development of plastic deformation, and not brittle rupture, and leads to an increase in the elongations at rupture and rupture energies.

Figure 8. Stress–deformation curves for polyurethane (1), a usual IPN containing 33.7 mass % of the butyl methacrylate–triethylene glycol dimethacrylate copolymer (2), and a gradient IPN containing 33.7 mass % of the copolymer (3).

Another hypothesis attributes the increase in the strength of gradient IPN to a decrease in the defectiveness of the surface layers. One can postulate that the introduction of an elastomer into the surface layer of a 'rigid' matrix inhibits the growth of cracks and increases thereby the stress necessary to initiate cracks. The study of the morphology of the specimens confirmed that the presence of an elastic shell can increase the stress corresponding to the formation of 'cracks'.¹⁷ The near-surface layers (after the rupture of the specimen) proved to be smoother than the internal regions of the specimen.

In order to confirm or reject the hypotheses proposed, further studies involving the use of a wider range of gradient IPN are needed.

VI. The use of the principle governing the formation of gradient interpenetrating polymer networks for the preparation of gradient lenses and other polymeric materials

Polymers with nonlinear optical properties have found extensive application in engineering at the present time,^{35,36} in particular a series of polymeric materials based on IPN with nonlinear optical characteristics have been obtained.^{37–39} These have definite advantages over both inorganic materials and polymers of other classes.^{38,39} Studies on the creation of gradient or graded-index lenses — light-focussing elements based on transparent materials with a parabolic distribution of the refractive index — are of interest in this connection.^{40–51} Such lenses have been used successfully in optoelectronics and wave optics (adjusting devices, light beam dividers), in instrument making, and medical engineering.

In most of the studies, the synthesis of graded-index lenses is accompanied by the formation of gradient IPN. The possibility of obtaining graded-index lenses from gradient polymers was first pointed out by Ohtsuka.⁴⁰ For this purpose, methyl methacrylate was allowed to diffuse into a cylindrical gel matrix consisting of a diallyl isophthalate (DAIP) prepolymer (70 mass % of the monomer + a mixture of linear and cross-linked polymers), the refractive index of methyl methacrylate being lower than that of DAIP. The distribution of the refractive index generated during the diffusion process was 'fixed' by additional polymerisation. Refractive index differences $\Delta n_D \approx \pm 0.04$ were then obtained, which is appreciably beyond the possibilities of the diffusion technology in inorganic glasses.⁴²

A similar polymer system has been used^{41,42,44} to obtain light-focussing elements (LFE). The physicochemical processes constituting the basis of the preparation of such elements were investigated in detail. Exchange diffusion processes in the DAIP–MMA system were examined using Fick's equation. The influence of various parameters (diffusion time, temperature, diffusant concentration, etc.) on the variation of the refractive index in the LFE was analysed.

Thus it has been established⁴¹ that the variation of the diffusion coefficient with the diffusant concentration does not alter significantly the optimum diffusion conditions and in many instances impairs the distribution of n_D compared with the case in which there is a constant diffusion coefficient. In order to create the maximum change in n_D along the LFE cross-section, it has been suggested⁴⁰ that a polymerisation initiator (benzoyl peroxide) be added to the diffusant (MMA). Bearing in mind that Fick's equation cannot be used to calculate the n_D profile under conditions where polymerisation reactions take place, the authors⁴¹ suggested that account be taken of the cessation of the diffusion of some of the MMA and DAIP molecules. They modified a series of equations for the calculation of the diffusion coefficient and calculated the changes in the MMA and DAIP concentrations during the preparation of the LFE and also the variation of the n_D profile along the specimen cross-section.

It was noted⁴¹ that the use of monomers capable of forming a network in the early stages of the polymerisation is very important from the standpoint of the n_D distribution obtained. In the study of the influence of temperature on the variation of the n_D distribution along the LFE cross-section, it was shown that, up to certain temperatures, the polymerisation reaction has an insignificant influence on the n_D profile, but at high temperatures, for example at 353 K, the influence of polymerisation is reflected in a change in the distribution of n_D after only 20 min. In the preparation of polymeric LFE, account must also be taken of the disappearance of the n_D gradient along the LFE cross-section and its subsequent restoration.⁴¹

An important conclusion reached by Marturunkakul et al.³⁹ and Ohtsuka⁴⁰ is that it is essential to select systems capable of increasing sharply the rate of polymerisation after the attainment of a specified degree of conversion. This property, called the gel effect, is characteristic of many vinyl monomers during their radical block polymerisation. The gel effect plays an important role in the formation of gradient lenses from gradient IPN based on DAIP and MMA⁴⁴ and on styrene–triethylene glycol dimethacrylate (TGDM)–MMA.^{43,45,50} A characteristic feature of the latter system is that, at a certain instant after the beginning of the diffusion of MMA into the polymerised matrix consisting of styrene and TGDM, rapid spontaneous copolymerisation of the matrix monomers and the diffusant up to virtually complete conversion takes place. After the diffusion process has ceased, the n_D profile generated at the given instant is fixed.

The problem is how to make sure that the fixation of the distribution of n_D should occur at the instant when it is closest to the ideal form^{43,48} because one then rules out the separate stage involving the fixation of the distribution of the refractive index established during the diffusion process (characteristic of other systems⁴⁸), in which it is difficult to avoid the diffusion-induced impairment of the distribution of n_D .

A mathematical model has been proposed^{43,45} for the establishment of the n_D distribution profile and the following conclusion was reached on the basis of the analysis of the results of the modelling of the diffusion and copolymerisation processes in the styrene–TGDM–MMA system: if the chosen amount of initiator and the temperature are such that the gel effect begins for a distribution n_D close to that given by the expression

$$n_D(r) = n_0 \operatorname{sech}(\alpha r) \simeq n_0 \left(1 - \frac{\alpha^2 r^2}{2} \right),$$

where n_0 is the refractive index along the axis of the lens, r is the radius of the graded-index lens and α is the distribution constant, then the distribution is preserved and the gradient lens obtained is of good optical quality. The results of the modelling have been confirmed experimentally and the optimum conditions for the preparation of polymeric gradient elements based on the copolymer of styrene with TGDM and MMA have been proposed.^{43,45}

Further study of the molecular diffusional exchange in the DAIP–maleic anhydride (matrix)–MMA (penetrant) system established the occurrence of diffusional anomalies⁵² when specimens having different diameters are employed. It was established that a disk model for the description of the molecular diffusional exchange in the system investigated is applicable to specimens having diameters between 5 and 12 mm. On the other hand, for specimens with larger diameters (from 12 to 30 mm), a sharpening of the diffusion was, as it were, observed and in addition the experimental refractive index distribution (RID) curves differed from the Fick RID.^{53,54} Hui et al.⁵⁴ put forward ideas according to which the volume fraction of the penetrant on the surface may increase to an equilibrium value, the rate of change of the volume fraction of the penetrant (at any point on the surface) being determined by

the rate of deformation of the creep, which depends on the osmotic pressure arising in the polymer during swelling. Here it has been suggested that the longitudinal viscosity diminishes exponentially with increase in the concentration of the penetrant. Bukhbinder et al.⁵² suggested that the concentration of the penetrant at the boundary increases fairly slowly, so that for short times (diffusion into specimens having small diameters) conditions are not attained under which there is a sharp decrease in viscosity accompanied by an abrupt increase in the diffusion coefficient. Thus the mechanism of the diffusion in specimens with small diameters is close to the Fick mechanism, whereas, on passing to specimens with a large diameter (an increase in the diffusion time), the equilibrium concentration reaches the threshold value. After the attainment of the threshold value, there is a sharp jump in the diffusion coefficient and a front begins to be formed on the RID curves. This front can be regarded as the moving boundary of the penetrant, which is equivalent to a decrease in the effective diameter of the specimen as a function of time. The proposed explanation for the diffusional anomaly is supported by the fact that a large change in n_D along the cross-section, virtually equal to the theoretical change, can be attained in large-diameter specimens, in contrast to specimens with a small diameter. Thus a reasonable explanation of the observed diffusional anomaly has been found and an interesting conclusion has been reached: the geometrical factor (the change in the dimensions of the specimens) is important in the preparation of graded-index lenses with a specified RID.

The possibility of using gradient IPN of different nature for the preparation of polymers with hard external, soft internal, and intermediate zones and with a continuously varying composition has been demonstrated.⁵⁵

In order to obtain materials with a surface susceptible to hydration, which can replace protective coatings in arteriovenous shunts, a gradient IPN based on oxyethylene methacrylate monomers and a silicone rubber has been employed.⁵⁶

The possibility of forming grains from hydrogels, the surface layer of which consists of a gradient IPN acting as a membrane permitting the regulation of the migration of the water-soluble medicinal substances absorbed by the grains, has been demonstrated in relation to gradient IPN based on polyurethane and cross-linked polymers consisting of 2-hydroxyethyl methacrylate and *N*-vinylpyrrolidone.^{34, 57–59} This makes it possible to create new forms of long-acting medicinal preparations.

Gradient IPN are promising for the preparation of vibration- and sound-proofing materials.^{4, 18} It is possible to apply the principle governing the formation of gradient IPN in other fields as well. Thus, the use of IPN as adhesives, especially for polymeric substrates, is promising. It has been shown⁵⁹ that in this instance an adhesion junction consisting of a gradient IPN is formed. The authors used the IPN based on polyurethane and the MMA–triethylene glycol dimethacrylate (TEGDM) copolymer for glueing vulcanised natural rubber (NR) to poly(vinyl chloride) (PVC). It was established that, as a consequence of the diffusion of the MMA and TEGDM monomers into the polymeric materials and subsequent hardening of the composition, two gradient IPN are formed: a three-component gradient IPN consisting of natural rubber, PU, and the copolymer is produced at the interface with natural rubber, whilst a three-component IPN, consisting of PVC, PU, and the copolymer, is formed at the interface with PVC. The thickness of the transitional layer at the interface with natural rubber reaches 30 μm , while that at the interface with PVC reaches 20 μm . The thickness of the transitional layers as well as the adhesive strength can be regulated by varying the duration of contact between the unhardened composition with natural rubber and PVC and also by employing different procedures for the preparation of the IPN-adhesive, namely by employing the

Figure 9. Dependence of the strength of a complex capron filament in the presence of an IPN in its surface layer at 373 K.

prepolymerisation MMA or the simultaneous mixing of the components and subsequent hardening of the composition.

It has been shown⁶⁰ that the method for the preparation of gradient IPN for the improvement of the physicochemical characteristics of synthetic fibres and organic plastics based on the latter is promising. This has been demonstrated in relation to polyamide fibres, which were swollen for different times in an alcoholic solution of a phenol-formaldehyde oligomer containing a hardening agent with subsequent hardening of the binder. This resulted in the formation in the surface layer of the fibre of a gradient IPN, the matrix of which is the polyamide, while the hardened phenol-formaldehyde layer is distributed in it with a certain concentration gradient. Physicochemical study of the fibres obtained showed that the modified fibres are more effectively wetted by solutions of the phenolic oligomer and that their heat resistance is improved: the temperature of the onset of degradation increases to 373 K and the mass loss in the temperature range 373–473 K is smaller by a factor of 2 than for the initial fibres. The strength properties of the fibres at room and elevated temperatures also increase under these conditions. The strength of the hardened oligomer in the surface layer of the fibres (Fig. 9) varies non-monotonically. The curve has two maxima in the regions where the contents of the IPN are 1.8–4.5 and 22 mass%. The breaking stress on compression of organic phenoplastics, obtained from the modified fibres, is 50% greater than for the plastics obtained from the initial fibres, i.e. the application of the method for the preparation of gradient IPN is promising for the preparation of organic plastics with improved physicochemical characteristics.

VII. Conclusion

The preparation of gradient IPN is a promising procedure for the specific modification of the surface layers of monomers with a three-dimensional structure, which makes it possible to impart to them new characteristics — to improve the optical and mechanical properties of composites based on them, to alter the relaxation behaviour, etc.

Variation of the degree of thermodynamic compatibility of the matrix network with the monomer or polymer diffusing in it and the conditions governing the diffusion process (diffusion time and temperature) makes it possible to regulate specifically the thickness of the layer with a composition gradient and at the same time to obtain polymeric composites with specified characteristics.

The number of gradient IPN obtained and investigated hitherto is unfortunately small. However, a series of materials based on IPN of this type have already found quite definite applications in various branches of engineering and biomedicine.

As is frequently the case, the studies on the preparation and practical employment of the gradient IPN have outstripped those on the mechanism of their formation, structure, and the relation between structure and physicochemical properties. Furthermore, during the formation of gradient IPN, there is a change not only in the ratio of the components in the layers but also in the formation conditions, in particular phase separation conditions in the layers of gradient IPN, which should alter the morphological characteristics and the properties of these layers compared with the IPN obtained by the usual methods.

Studies along these lines have only just begun. The available information about the layer-by-layer variation of the morphology in gradient IPN is limited. It is of interest to obtain multicomponent IPN with a composition gradient and to investigate their formation and properties. Analysis of the available data on gradient IPN does not as yet permit definite conclusions about the causes of their different properties. It may be that, for a certain change in the formation conditions, it is possible to obtain a particular gradient for the same polymer system. All the problems noted here and others listed above require further investigations in order to be able to create new gradient systems. The synthesis of gradient IPN leads to new prospects for the preparation of polymeric materials and it is so far difficult to predict what diverse combinations of properties these systems will possess. In addition, further studies on gradient IPN as well as other types of IPN are extremely important from the standpoint of the theory of the formation of multicomponent polymer systems and the principles governing the preparation of composite polymeric materials from them.

In conclusion, one should note that the synthesis of gradient IPN is only one of the ways of obtaining gradient polymeric materials. There are also other procedures. Recent investigations,⁶¹⁻⁶⁴ in which a fundamentally new aspect of the creation of gradient polymeric materials from network copolymers has been developed, are particularly interesting. In order to obtain other polymeric materials, in which the modulus of elasticity varies smoothly within the boundaries of one specimen in a specified direction (in the absence of transitional layers and interfaces), an approach based on the creation of dense-network structures containing bulky rigid nodes connected by flexible linear chains with a controllable length has been employed. The creation of such structures has been demonstrated experimentally in the synthesis of network polyisocyanurates, in which the role of the node was assumed by isocyanurate rings with the aromatic rings adjoining them and the role of the internodal fragment was assumed by fairly short but flexible organosilicon chains^{61,62} or short chains based on the oligomeric tetrahydrofuran-epoxypropane copolymer.⁶⁴ This resulted in the formation of materials in which the modulus of elasticity varies smoothly within a single specimen in the specified direction from 4.5 MPa to 2.0 GPa, i.e. a smooth transition from a rubber to a plastic has been achieved. The following conclusion is of fundamental importance: despite the fact that the range of moduli for the materials synthesised overlaps the values characteristic of the region corresponding to the transition from the vitreous to the highly elastic state, the materials obtained exhibit elastic and not viscoelastic properties, behaving, for example, as glasses or rubbers.⁶⁴ Studies on these lines are being vigorously prosecuted.

This review has been written in the course of studies carried out with the support of the International Scientific Fund (grant UAZ 000).

Interaction of bleomycin and its oligonucleotide derivatives with nucleic acids

D S Sergeev, V F Zarytova

Contents

I. Introduction	355
II. Binding of bleomycin to nucleic acids	356
III. Cleavage of nucleic acids by bleomycin	363
IV. Bleomycin derivatives of oligonucleotides. Synthesis and site-specific cleavage of DNA	369

Abstract. Various aspects of interaction of the antitumour glycopeptide antibiotic bleomycin with nucleic acids are considered. Data on equilibrium binding parameters obtained by various physicochemical methods have been collected and compared. The contribution of N- and C-terminal domains of the glycopeptide molecule to the binding with DNA and sequence specificity of DNA cleavage are discussed. Data on a recently created new class of compounds — bleomycin–oligonucleotide conjugates — are presented. These compounds, like antibiotics, possess DNA-cleaving activity (also in a catalytic manner) together with high selectivity towards a selected nucleotide sequence. The bibliography includes 267 references.

I. Introduction

1. A brief review of the bleomycin antibiotics family

The discovery and pioneering studies on the family of bleomycin antibiotics date back to 1963 when a group of Japanese investigators headed by Umezawa detected a substance possessing a high antibiotic activity in the culture fluid of the mutant strain of the soil bacterium *Streptomyces verticillus*. Just three years later, in 1966, a wide range of structurally related compounds, given common name of bleomycins, were isolated.^{1,2} Owing to their beneficial therapeutic effects, these compounds have found wide use in the clinical practice as valuable pharmaceutical drugs endowed with both antibacterial and, even more important, antitumour activities.^{3–8} The major area for clinical application of bleomycins is in the chemotherapy of malignant tumours, particularly of lymphomas and squamous carcinomas.^{9–12} Along with their high antitumour activity, bleomycins are characterized by relatively low toxicity and lack of immunodepressive action which makes them helpful tools in combined chemotherapy.^{13,14} Applications of bleomycins in clinical oncology have been described in numerous reviews and special publications.^{13–20}

Simultaneously with practical applications of bleomycin antibiotics, in-depth studies into their actions on the cell were

under way. It turned out that the main target for bleomycin antibiotic action in the cell is DNA.^{21,22} Bleomycin has a number of actions coupled to DNA degradation, namely, the loss by animal and bacterial cells of their ability to form colonies,⁵ inhibition of DNA synthesis,^{6,23} chromosomal aberrations,²⁴ intracellular DNA degradation to acid-soluble products,²⁵ and DNA dissociation from the membrane complex.²⁶ These findings prompted extensive research concerned with bleomycin interactions with DNA with special emphasis on its binding to DNA, action mechanisms, cofactors required, etc. Recent studies have demonstrated that bleomycin can also cleave RNA. This important discovery gave a strong impetus to further studies into the action mechanisms of bleomycin and the basis for its biological activities.

To date, a great body of information on this antibiotic has been accumulated in the literature. Some of the data concerning the nature of bleomycin interactions with DNA are presented in this review.

2. Functional domains of bleomycin

Since the initial isolation of individual bleomycins, intensive studies have taken place with the aim of establishing the structure, the elucidation of which required a vast variety of chemical and physicochemical methods including NMR spectroscopy and X-ray analysis. For general features, this work was completed by 1972.²⁷ In 1978, the bleomycin structure was finally elucidated;²⁸ total chemical synthesis of bleomycin A₂ was carried out in 1982.²⁹

Bleomycins are glycopeptides with a molecular mass of about 1500 Da. The fragment of the molecule (termed as bleomycinic acid) common to all bleomycins consists of pyrimidoblamincic acid, β -hydroxyhistidine, 4-amino-3-hydroxy-2-methylpentanoic acid, threonine, 2'-(2-aminoethyl)-2,4'-bithiazole-4-carboxylic acid linked by peptide bonds, and a carbohydrate moiety containing 3-(O-carbamoyl)-D-mannose and L-gulose attached to the hydroxyl group of β -hydroxyhistidine. The structures of bleomycin (Blm) and C-terminal amines of the most commonly occurring bleomycins are given below. Individual bleomycins differ from one another by the terminal amine bound to the carboxyl group of the bithiazole residue. Bleomycinic acid (Blm–OH) represents a compound with OH instead of NHX. Depending on the composition of their terminal amines, bleomycins are divided into two subgroups: A and B. Group A bleomycins carry in their terminal amine both primary and secondary amino groups with the exception of bleomycins A₁ and A₂; group B bleomycins have guanidinium groups. Studies on bleomycin carried out abroad were largely performed on bleomycin A₂ and bleomycin B₂, a mixture of bleomycins A₂ (60%–65%), bleomycin B₂ (30%) and minor components (B₄, A₅, etc.). In our country, bleomycin A₅ is routinely used in clinical practice and in laboratory studies.

$\text{NH}(\text{CH}_2)_3\text{NH}(\text{CH}_2)_3\text{N}(\text{CH}_2)_4$	Bleomycin BAPP	(Blm-BAPP)

In parallel with the determination of the bleomycin structure, general concepts of molecular mechanisms of their biological activity were developed. It was found, in particular, that bleomycin can interact with DNA and form strong noncovalent complexes with it.^{30–34} Bleomycin can also form complexes with metal ions and cause DNA degradation in the presence of Fe(II) ions and molecular oxygen.^{35–37} Based on these findings, the bleomycin molecule was conventionally divided into domains in accordance with their specific function.^{38–40} Pyrimidinobis(2-aminopropyl)amine and β-hydroxyhistidine are involved in the metal-binding domain. The primary and secondary amino groups present in this domain provide for the formation of a tight complex with many transient metals.^{41–44} The bithiazole residue and the C-terminal amine responsible for the binding to DNA are termed 'the DNA-binding domain'. 4-Amino-3-hydroxy-2-methylpentanoic acid and threonine determine the reciprocal arrangement of these two domains needed for the tight binding and effective cleavage of DNA. Finally, the disaccharide favours the binding of molecular oxygen which, in turn, is necessary for oxidative cleavage of DNA.^{45,46}

II. Binding of bleomycin to nucleic acids

1. Parameters of equilibrium binding

An assumption that bleomycin binds to DNA was made as long ago as 1969^{30,33} and the first evidence for the binding of tritium-labelled bleomycin A₂ to *E. coli* DNA was obtained a year thereafter.³⁴ However, systematic studies of this process employing physicochemical methods were begun only in the late 1970s. The discovery of quenching of bleomycin fluorescence in the binding of the antibiotic to DNA was a boon for experimenters.³⁸ Being light-excited at the wavelength of 300 nm, bleomycins produce two emission bands with maxima at 353 and 405 nm. Light with a wavelength of 353 nm is emitted by the bithiazole residue and exceeds in intensity the emission of the 4-aminopyrimidine ring at 405 nm. Addition of calf thymus DNA to bleomycin solutions

results in significant (up to 50%) quenching of the fluorescence at 353 nm. This finding made it possible to quantify both bound and free bleomycin and to calculate, at variable concentrations of DNA, the apparent equilibrium binding constant, K_{app} , and the number of DNA nucleotides per bound molecule of the antibiotic, n . The K_{app} and n values were also determined using equilibrium dialysis,^{47–49} gel filtration⁴⁹ and circular dichroism spectroscopy (CD).^{50–52} The values of K_{app} and n determined by different methods are summarized in Table 1.

As can be seen from Table 1, the binding constants determined by different authors for metal-free bleomycin A₂ vary from 10^5 to $10^6 \text{ dm}^3 \text{ mol}^{-1}$. The number of DNA base pairs per bound antibiotic molecule also varies significantly in different studies, being equal, on average, to 3–10 pairs. The lower values cited in the most recent papers^{52,55} appear to be far more reliable. An increase in ionic strength does not affect the K_{app} values but increases the n value, thereby decreasing the number of accessible binding sites.^{38,54} Interestingly, bleomycin binding to homogenous DNA of poly(dG)·poly(dC) and poly(dA)·poly(dT) appears to be stronger than that to heterogeneous DNA, and parameter n ⁴⁹ is greater in the former case. The binding of bleomycin to the bivalent copper ion slightly decreases the binding constant but increases the number of accessible binding sites.^{49,57} At the same time, the binding constant for the bleomycin–Fe(III) complex is twice as high as that for bleomycin itself, while the number of accessible binding sites is the same in both cases.⁵⁶ Bleomycin complexes with Co(III) are characterized by K_{app} of 10^5 to $10^7 \text{ dm}^3 \text{ mol}^{-1}$ depending on the nature of the chelated ligand.^{50,59} An increase in ionic strength strongly decreases the constant of binding of bleomycin–copper and cobalt complexes to DNA without any change in the number of base pairs per bound molecule,^{48,59} thus suggesting that electrostatic interactions have a role in this process.

Evidence concerning the parameters of bleomycin binding to RNA is very sparse in the current literature except for a study,⁶¹ in which K_{app} and n values for bleomycin binding to yeast phenylalanine tRNA were determined by the fluorescence quenching method. The parameters of binding to this tRNA are close to those for DNA ($K_{\text{app}} = 0.86 \times 10^5 \text{ dm}^3 \text{ mol}^{-1}$ and $n = 25$ in 5 mmol dm^{-3} phosphate buffer pH 7.0).

Most of the data listed in Table 1 were obtained using the method of quenching the fluorescence of bithiazole rings. This widely used procedure, which has a number of indisputable advantages (simplicity, rapidity, etc.), also has some limitations. Firstly, the quantum yield of this fluorescence is rather low (ca. 0.01).³⁸ Chelation of the metal ion leads to a further decrease in bleomycin fluorescence,^{54,57} which imposes certain restrictions on the accuracy of the experimental results. Secondly, according to recent data,⁵⁵ upon excitation by light with a wavelength of 300 nm, the intensity of bleomycin fluorescence decreases significantly with time due to the decay or phototransformation of the bithiazole residue that has been neglected in earlier studies. Finally, bleomycin fluorescence is effectively quenched not only by double-stranded DNA (binding data are given in Table 1) but also by single-stranded DNA and RNA.^{54,57} However, it is known that neither single-stranded DNA nor RNA protect double-stranded DNA from bleomycin action.^{62–65} Apparently, the mode of bleomycin fluorescence quenching by these substrates depends on the binding type and affinity. The fact that, after incubation under identical conditions and subsequent dialysis,³⁴ the amount of tritium-labelled bleomycin on double-stranded *E. coli* DNA exceeds 30-fold that on ribosomal RNA, provides additional evidence that fluorescence quenching does not indicate strong binding. Moreover, the fluorescence quenching itself depends, in turn, on the composition of DNA: poly(dG)- and poly(dG)·poly(dC) sequences quench the fluorescence to a greater extent.^{54,57} Presumably, the K_{app} and n values listed in Table 1 are mean values for different binding sites displaying different affinity.

^a Where two values are indicated, the former corresponds to strong binding, and the latter to weak binding.

^b F is fluorescence quenching; E is equilibrium dialysis; G is gel filtration; CD is circular dichroism spectroscopy.

^c Bleomycin is a mixture of bleomycin A₂ (60%–70%), bleomycin B₂ (30%) and minor components (bleomycin A₅, bleomycin B₄, demethylbleomycin A₂, etc.) used as a chemotherapeutic drug.

^d Tripeptide S:

^e Acetyldipeptide:

Another method of using the fluorescence quenching technique for a determination of the parameters of bleomycin binding to DNA has been described by Sakai et al.⁵⁸ In this study, the fluorescence was excited at a wavelength of 260 nm (not 300 nm) as usual. This made it possible to increase the difference between the fluorescence of DNA-bound and free bleomycin and thus to increase the sensitivity of the method, as a result of which two binding constants could be obtained for bleomycin binding to poly(dA) · poly(dT). One of them, which reflects the binding of one molecule of the antibiotic per 10 base pairs, corresponds to stronger binding and is equal to $(7-9) \times 10^6 \text{ dm}^3 \text{ mol}^{-1}$, whereas the other one, which reflects the binding of one bleomycin molecule per 1.5 base pairs, is $5 \times 10^4 \text{ dm}^3 \text{ mol}^{-1}$. The existence of different binding sites was also demonstrated by applying the method of equilibrium dialysis to tritium-labelled bleomycin A₂ and its copper complex.⁴⁹ The difference between K_{app}^1 and K_{app}^2 determined for calf thymus DNA appeared to be insignificant (6.8×10^5 and $2.5 \times 10^5 \text{ dm}^3 \text{ mol}^{-1}$). A greater difference between the binding constants was observed when bleomycin A₂ was bound to the homopolynucleotides poly(dG) · poly(dC) and poly(dA) · poly(dT) (Table 1).

Hence, the parameters of equilibrium binding obtained by various methods suggest a significant affinity of bleomycin and its metal complexes for double-stranded DNA. Strong binding of the antibiotic to the double helix precedes a cascade of events resulting in oxidative degradation of the DNA chain.^{41,66}

2. The role of domains in binding

a. The role of the bithiazole residue and C-terminal amine in bleomycin binding to DNA

Historically, NMR spectroscopy was the first and the most informative method to shed some light on the involvement of certain parts of the bleomycin molecule in the binding to DNA. Bleomycin interaction with calf thymus DNA was accompanied, first of all, by broadening and changes in the intensity of the signals in the ¹H NMR spectrum of the bithiazole residue and the dimethylsulfonium group, thus suggesting the strongest binding of these fragments of the bleomycin A₂ molecule to DNA.³⁸ The phenomenon of quenching bithiazole ring fluorescence detected by Horwitz et al. also argues for the interaction of the bithiazole residue with DNA. This pioneering study was followed by a vast series of NMR investigations into interactions of bleomycin A₂ and its derivatives with poly(dA) · poly(dT).^{40,58,60,67-71} It was

found that significant spectral changes were observed only in the binding of bleomycin to double-stranded DNA, being maximal for the signals for the aromatic protons of the bithiazole residue, which upon interaction with poly(dA) · poly(dT) broadened and shifted upfield. An upfield shift was also noted for adjacent protons: CH₃–S⁺ and CH₂–S⁺ of the terminal amine, CH₂–N of the 2'-substituent of the bithiazole residue, and CH(CH₃)CO of methylpentanoic acid.⁶⁷

C-Terminal fragment Blm-A₅

Similar results were obtained in the study of binding of bleomycin and its metal complexes to short duplex fragments of DNA.^{52,72-75}

The use of the nuclear Overhauser effect (NOE technique) made it possible to detect complex formation between bleomycin containing a Zn(II) or Fe(II) ion in the metal-binding domain, and DNA.⁶⁸ In this case, bleomycin acts as a spacer between DNA and the metal ion. The general changes in the chemical shifts for the protons of bleomycin during the formation of such a complex virtually represent overall changes produced by chelation of the

metal ion and its binding to DNA.⁴⁰ The signals for the protons of the N-terminal fragment of the molecule comprising β -hydroxy-histidine and disaccharide change only upon their interaction with the metal; those in the C-terminal dipeptide, only during the binding to DNA, whereas the signals for the protons of 4-amino-3-hydroxy-2-methylpentanoic acid and threonine are equally sensitive to the both interactions.

The same research group studied the binding of C-terminal fragment of bleomycin A₂, C-terminal fragments of Blm-A₂ (acetyldipeptide, tripeptide S, tetrapeptide S) and Blm-A₅, to DNA. The nature of changes in the signals for bithiazole ring and terminal amine protons was identical for both the entire bleomycin molecule and its C-terminal fragments.^{58,60,67,69} Thus, the NMR spectroscopy data suggest that the C-terminal fragment of the bleomycin molecule containing 2'-(2-aminoethyl)-2,4'-bithiazole-4-carboxylic acid and the terminal amine binds to DNA to a greater degree and apparently determines the strength of binding.

This conclusion was supported by the data obtained by equilibrium methods. The parameters of binding of tripeptide S and acetyldipeptide to DNA practically coincide with those for bleomycin A₂ (Table 1).^{38,47,55,58,60} An attempt was made⁵⁵ to establish a correlation between the values of binding constants for the C-terminal fragments of bleomycin A₂ and their increasing lengths, beginning with the dipeptide fragment. The latter plays a crucial role in the binding; L-threonine increases the binding constant by a factor of 2, while 4-amino-3-hydroxy-3-methylpentanoic acid and β -hydroxyhistidine have no effect on the magnitude of the binding constant.

This finding is consistent with the ability of bleomycin C-terminal fragments to inhibit DNA cleavage by the complete antibiotic.^{76,77} Unlike other inhibitors, C-terminal fragments diminish the cleavage proportionally to each cleavage site, i.e., the inhibition is competitive.⁷⁶ It is necessary to mention in this connection that bleomycin analogues devoid of the bithiazole residue or C-terminal amine cleave DNA far less effectively than the bleomycin itself.^{78–81} At the same time, they can chelate the iron ion and effectively oxidise some organic substrates, e.g., *cis*-olefins.⁷⁸

b. The role of electrostatic interactions in bleomycin binding to DNA As can be seen from Table 1, the parameters of bleomycin binding to DNA depend on ionic strength, thus implicating electrostatic interactions between bleomycin and DNA. An increase in ionic strength also leads to a loss of the upper threshold of fluorescence quenching.⁵⁴ Similarly, an increase in ionic strength from 10 to 150 mmol dm⁻³ strongly attenuates the changes in the chemical shift of the aromatic protons H(5) and H(5') of the bithiazole residue and methyl CH₃-S⁺ protons of bleomycin A₂ interacting with poly(dA)·poly(dT). Under these conditions, the changes in the chemical shifts of protons CH₂-N of the substituent at position 2', of bithiazole and CH₂-S⁺ of the C-terminal amine, are completely suppressed. No changes in the ¹H NMR spectrum of bleomycin added to DNA are observed at an ionic strength of 1.0 mol dm⁻³.⁷¹

It should be noted that the bleomycin molecule (devoid of the terminal amine) has several ionogenic groups at its N-terminus: a secondary NH group of β -aminoalanine within the structure of the pyrimidoblaminc acid ($pK_a = 2.7–2.9$), an N(1) atom of the imidazole ring of β -hydroxyhistidine ($pK_a = 4.7–4.9$) and a primary NH₂ group of β -aminoalanine ($pK_a = 7.3–7.7$).^{27,82,83}

The structure of the N-terminal fragment of Blm is given below (the ionogenic groups within the pH range of 2–8 are marked with asterisks).

This indicates that the positive charge of the bleomycin molecule at pH 7.5 is mainly localised at the C-terminal amine which provides for electrostatic interactions with the negatively charged DNA backbone.

Evidence for this assumption can be derived from the following data.

1. Bleomycinic acid bearing a negative charge at its C-end only weakly cleaves DNA.^{57,63,84}

2. The extent of fluorescence quenching upon binding to DNA increases in the following order: bleomycinic acid (negatively charged C-end), bleomycin B₁ (neutral C-end), bleomycin A₂ (positively charged C-end).^{54,57}

3. Demethylbleomycin A₂ and deglycobleomycin A₁ with neutral C-terminal fragments cleave DNA much more weakly than does bleomycin A₂.^{69,70,81,84} No changes in the NMR spectrum of demethylbleomycin A₂ were found upon its interaction with DNA.^{69,70}

4. The copper complex of demethylbleomycin A₂ (1×10^{-4} mol dm⁻³) does not cause any unfolding of the supercoiled plasmid DNA, whereas the copper complex of bleomycin A₂ provides its effective unfolding.⁸⁵

At the same time, there is evidence that the positive charge at the N-end of the bleomycin molecule influences the binding of bleomycin to DNA. Acetylation of the primary amino group of β -aminoalanine gives acetylbleomycin A₂, whose N-end is neutral at pH 6.8. Virtually no changes in the NMR spectrum of this derivative occur in its interaction with poly(dA)·poly(dT).⁶⁹ The appearance of a positive charge at the N-end of the bleomycin A₂ molecule at pH < 7 (6.8 and 4.5) results in a higher upfield shift of bithiazole proton signals; however, this does not affect the shift of proton signals in the N-terminal fragment of the bleomycin molecule upon its interaction with DNA.⁷¹ Chelation of the metal ion, e.g., Cu(II) or Fe(III), which also provokes the appearance of a positive charge in the N-terminal fragment of the antibiotic molecule,⁸³ only weakly reflects on the value of the binding constant.^{49,56,57} However, the appearance of an extra charge at the C-end of the bleomycin A₅ molecule increases the degree of fluorescence quenching and affinity of the antibiotic for DNA.^{54,57}

The results presented above testify to the fact that electrostatic interactions are a necessary prerequisite for bleomycin binding to DNA. A crucial role in providing strong binding to DNA is played by the positive charge at the C-terminal amine.

c. Interaction of the N-terminal fragment of the bleomycin molecule with DNA

In late 1970s, a definite concept was formed concerning the relationship between the structure of the bleomycin molecule and its biological activity, namely, that the C-terminal fragment of the antibiotic binds to DNA, while its N-end chelates the metal (iron) ion which interacts with molecular oxygen, eventually resulting in DNA decay.^{38–40} According to this concept, the interaction between the metal-binding domain and DNA was thought to be very weak. However, the ¹H NMR spectra of the bleomycin N-terminal fragment and the Zn(II)-bleomycin complex reveal small, though persistent changes upon their interaction with poly(dA)·poly(dT).⁴⁰ These changes are even more pronounced in the case of the CO-Fe(II)Blm-A₂ complex binding to DNA. In parallel with the broadening and upfield shift of signals for the protons of the bithiazole residue and the terminal amine, the signals for the aromatic protons of β -hydroxyhistidine also tend to

broaden considerably with a small shift towards the higher field. The fact that the signals for the pyrimidine methyl protons also shift upfield (by 0.08 ppm)⁸⁶ is also suggestive of interactions between the N-terminal fragment of the bleomycin molecule and the DNA backbone.

¹H NMR data on the binding of bleomycin to short oligonucleotide duplexes provide support for the interaction of the metal-binding domain with the double helix.^{52,73–75} The most interesting results were obtained in the study in which the binding of bleomycin A₅ to the 8-meric duplex d(CGCTAGGCG)₂ was analysed⁷⁵ using the NOE technique. The authors succeeded in establishing intermolecular interactions between the protons of the α -CH₂-group of β -hydroxyhistidine and H(4') of the deoxyribose C(7) residue. The formation of a hydrogen bond between the NH₂ group of β -aminoalanine and the oxygen atom of the ribose–phosphate backbone in the oligonucleotide chain was also postulated in this study.

EPR data provide additional support in favour of the metal-binding domain interaction with DNA. Thus, the interaction of the NO–Fe(II)Blm complex with calf thymus DNA was accompanied by marked spectral shifts indicating changes in the Fe(II) microenvironment.^{45,87,88} Evidence for direct interaction of the metal-binding domain with DNA can be derived from changes in the EPR spectrum of 'activated bleomycin' [HOO–Fe(III)Blm] upon its binding to the double helix.⁸⁹ The binding to DNA converts the Fe(III)Blm complex from the high spin ($g = 4.3$) to the low spin state ($g = 2.45, 2.18, 1.89$). In this case, native double-stranded DNA stabilises the low spin state with a greater efficiency than the denatured one.⁸⁹

Characteristic changes in EPR spectra are produced upon addition of DNA to the O₂–Co(II)Blm–A₂ complex which mimics the active O₂–Fe(II)Blm–A₂ complex.^{90,91} This may be due to the alteration of the oxygen molecule orientation relative to the plane containing the cobalt ion. Recent studies⁹² on this complex revealed significant restrictions in the orientation of the O–O bond, which is almost perpendicular to the main axis of the DNA helix.

Figure 1. The structure of the site of the bleomycin molecule that chelates the copper ion (a)^{93,94} and the hypothetical position of the plane containing a metal ion relative to the axis of the DNA helix (b).^{96,97}

Conclusive evidence in favour of tight contacts of the metal-binding domain and DNA is the displacement of ligand L from the coordination sphere of the L–Fe(III)Blm complex (where L is the ligand of the N₃[–], S₂O₃^{2–} or SCN[–] type).⁵¹

The influence of the positive charge of the bleomycin N-terminal fragment on its binding to DNA can also be regarded as evidence of interaction of the metal-binding domain with DNA. In this context, mention should be made of the study⁸⁵ in which chelation of the Cu(II) ion by bleomycin A₂ produced qualitative changes in the binding of the antibiotic to supercoiled plasmid DNA. Whereas metal-free bleomycin A₂ is practically incapable of unfolding such DNA under conditions excluding DNA cleavage, its copper-containing counterpart effectively eliminates the coils in the DNA superhelix. It should be noted also that Cu(II) and Fe(III) complexes of bleomycin bind to DNA at different rates which also points to the involvement of the bleomycin N-terminal fragment in the binding to the polymer.⁴⁸

The application of the EPR method to oriented DNA fibres provides valuable information on the position of the metal-binding domain relative to the axis of the DNA double helix. As is known, the nitrogen atoms in the N-terminal moiety of the bleomycin molecule which chelate copper or iron ions, viz., the nitrogen atom of the secondary amino group of β -aminoalanine, the N(1) atom of pyrimidine, the N(1) atom of imidazole, and the nitrogen atom of β -hydroxyhistidine forming a peptide bond,^{39,93,94} lie in one plane with the metal ion (Fig. 1). For the bleomycin molecule bound to DNA, the angle Ψ between the normal (perpendicular) to this plane and the axis of the DNA helix has been found to be 15° for the Cu(II)Blm complex, with rotational freedom of the normal around one of the axes lying in the plane of base pairs of $\pm 80^\circ$.⁹⁵ However, recent studies using the same model gave different results, namely, the angle between the normal and the axis of the DNA helix is 25° with deviations in the range of $\pm 30^\circ$.⁹⁶ This is consistent with the earlier data for the Fe(III)Blm complex bound to oriented DNA fibres (the Ψ value for this model is 15–30° with variations of $\pm 26^\circ$).⁹⁷

Thus, the great body of experimental evidence testifies to tight contacts of the bleomycin N-terminal fragment with DNA. These contacts are manifested also in the influence of the metal-binding domain on the specificity of DNA cleavage (see below).

3. Models of bleomycin binding to DNA

The data obtained by physicochemical methods suggest that the interaction of bleomycin with DNA involves both the metal-binding domain and the C-terminal fragment of the antibiotic molecule. It is the latter, which contains the bithiazole residue and the terminal amine and is especially tightly bound to DNA, that is responsible for the binding to the polymer. We have already noted that electrostatic interactions between the positively charged terminal amine and the negatively charged sugar–phosphate backbone contribute to the binding of bleomycin to DNA. However, there exist other interactions that can also play a role in the binding of bithiazole rings to DNA. The three hypotheses postulating the nature of this binding are as follows: the intercalation model, the partial intercalation model and binding in the minor groove of DNA.

Both heterocyclic rings of the bleomycin bithiazole fragment lie in the same plane⁹⁸ and can theoretically intercalate between the base pairs of DNA. First experimental evidence for intercalation binding of bleomycin was obtained in 1979.⁴⁷ It was found that bleomycin A₂ and its C-terminal fragment, tripeptide S, cause the unfolding of covalently closed circular double-stranded DNA and increase the length of short rod-like DNA molecules as determined by their orientation time in an electric field. Moreover, they favour parallel arrangement of the bithiazole rings and base pairs as evidenced by linear dichroism data.⁴⁷ Changes of this kind usually occur in intercalation binding.⁹⁹ Metal complexes of bleomycin reveal a similar capacity upon their binding to DNA.

It has already been mentioned that the copper-containing complex of bleomycin A₂ can produce the relaxation of supercoiled DNA.⁸⁵ According to Povirk et al.,⁴⁸ the length of short-chain DNA (150 base pairs) increases by 0.46 nm upon binding to the Cu(II)Blm molecule. For the Fe(III)Blm complex, this value is equal to 0.32 nm, and for Blm, 0.31 nm;⁴⁷ such elongation is characteristic of typical intercalators.^{99,100} At the same time, the copper-containing complex of the bleomycin analogue phleomycin, whose thiazole ring is partially reduced,¹⁰¹ does not produce any elongation of DNA upon binding.⁴⁸ It follows, therefore, that DNA elongation can only be achieved in the case of a planar chromophore.

In 1981, Lin and Grollman¹⁰² proposed, on the basis of NMR data, a model for complete intercalation binding of the bleomycin C-terminal fragment to dinucleotides. In this study, the greatest changes in the chemical shift (0.4 ppm) were observed for aromatic protons of the bithiazole residue upon binding to pdG-dC. According to this model, the bithiazole residue is 'stacked' to base pairs in such a way that its aromatic protons appear to be oriented towards the minor groove of DNA. Theoretical calculations confirmed the indisputable energetic superiority of the proposed intercalation model for binding of the terminal positively charged amine in the minor groove of DNA.¹⁰³

In a recent work by Wu et al.,⁷⁴ two-dimensional NMR was used to study the interaction of the cobalt-containing bleomycin A₂ complex with the 10-meric DNA-duplex d(CCAGGCCTGG)₂. It was found that the bithiazole residue intercalate between GC pairs corresponding to positions C(6) and C(7). In this case, the upfield shifts of the signals for bithiazole protons were 0.9 and 0.61 ppm for H(5') and H(5''), respectively.

However, the model of complete intercalation binding does not agree with numerous experimental data. Thus, the angle of unfolding of supercoiled DNA upon its binding to the bleomycin molecule is 12°,⁴⁷ whereas for the majority of intercalators it constitutes 17–26°.¹⁰⁰ Bleomycin interaction with sonicated DNA did not increase significantly the solution viscosity and, correspondingly, the length of the DNA chain,³⁸ which is in conflict with the results reported by Povirk et al.⁴⁷ Moreover, viscosimetric data for the binding of the bleomycin C-terminal fragment to calf thymus DNA suggest that the length of the DNA molecules decreases slightly.¹⁰⁴ Laser scattering data point to the length reduction of short rod-like DNAs upon their interaction with the antibiotic.¹⁰⁵

Incorporation of spin labels into bleomycin molecules is a convenient tool for determining the parameters of their binding to DNA.^{106,107} The EPR spectrum of such a label (2,2,6,6-tetramethyl-1-piperidine-*N*-oxide) incorporated at position 4 or 2' of bithiazole, practically did not change upon its interaction with DNA which is hardly likely in the case of complete intercalation binding.¹⁰⁴

Changes in the ¹H NMR spectrum of bleomycin upon its binding to poly(dA)·poly(dT) are also incompatible with the

complete intercalation model. Although the most pronounced changes are observed for the signals of bithiazole ring protons (their maximum upfield shift is 0.1–0.2 ppm),^{38,40,67,69–71} for typical intercalators this varies from 0.4 to 1.0 ppm.^{108,109} It should be noted also that the shift strongly depends on temperature, ranging from 0.02 to 0.05 ppm at 20 °C up to 0.1–0.2 ppm at temperatures just below the melting temperature for poly(dA)·poly(dT) (50–60 °C)^{67,69,71} and thus cannot be explained within the framework of the complete intercalation model.

There are a number of publications dedicated to the analysis of interactions of bleomycin and its metal complexes with oligonucleotide duplexes using the NMR method.^{52,72–75} Most of the data obtained are also contrary to the complete intercalation model. Hiroaki et al.⁵² studied the binding of bleomycin to the duplex d(CCCCAGCTGGGG)₂ possessing a single site for the antibiotic-induced cleavage (underlined). The signals from non-exchangeable protons of the bithiazole residue and the bleomycin terminal amine displayed a characteristic shift towards higher field (0.15 to 0.2 ppm), however, without any changes in the chemical shifts of signals for imino protons and phosphorus nuclei of the oligonucleotide in the vicinity to the binding site. On the other hand, it is known that intercalating molecules produce significant changes in the chemical shifts of signals for these nuclei.^{110,111} A somewhat greater upfield shift of the signals for bithiazole protons (0.2–0.4 ppm) was observed upon the interaction of the antibiotic with the duplex d(CGCGCG)₂.^{72,73} In this case the temperature dependence of the chemical shifts characteristic for poly(dA)·poly(dT) was not observed, apparently, due to the stronger binding of bleomycin to GC sequences. The use of the NOE technique makes it possible to establish the intercalation type of binding.¹¹² The presence of cross-peaks along the whole length of the 8-meric duplex d(CGCTAGCG)₂ chain upon its interaction with bleomycin A₅ is suggestive of the non-intercalating type of antibiotic binding.⁷⁵

In order to rationalise the experimental data in favour of intercalation and against it, an attempt was made to interpret them in terms of the hypothesis of partial intercalation of bithiazole rings proposed as early as in 1976.¹¹³ According to this hypothesis, one of the bithiazole rings is inserted between the DNA bases, thereby producing a local bending in the helix. Its effect on the length and, correspondingly, hydrodynamic properties of DNA may be very different¹¹⁴ as evidenced by viscosimetric^{38,104} and laser scattering data.¹⁰⁵ This model provides an explanation for relatively small changes in the chemical shift of bithiazole proton signals as well as for temperature dependence of the chemical shift magnitude. A rise in temperature up to values just below the melting temperature for DNA chains causes local denaturation of the helix, thereby facilitating the incorporation of the bithiazole residue between the base pairs and enhancing the upfield shift of the signals for the protons.⁷¹ A decrease in ionic strength, which causes destabilisation of the double helix, would also favour partial intercalation of the bithiazole residue and, as a consequence, more intensive fluorescence quenching and changes in the chemical shift.^{54,71}

Evidence for the improbability of complete intercalation of bithiazole rings into the DNA double helix can be derived from experiments with analogues of the C-terminal fragment of bleomycin A₂.

According to ^1H NMR data, the removal of the aliphatic substituent from position 2' of the 2,4'-bithiazole derivative enhances the ability of bithiazole rings to intercalate and increases the binding constants for poly(dA)·poly(dT).^{58,69} At the same time, the substitution of the aliphatic chain at position 2' by an aromatic ring (thiazole or benzene) strongly changes the characteristics of bithiazole analogue binding to DNA, thus permitting their intercalation. Changes in the chemical shifts (by 0.5–0.8 ppm) produced by such analogues upon their binding to DNA are far more pronounced than those for bleomycin.^{58,69,115,116} In contrast to bleomycin, its analogues increase the viscosity of DNA solutions¹¹⁶ and cause effective unfolding and folding (positive supercoiling) of covalently bound circular DNA.⁷⁷ Moreover, they display a far greater affinity for DNA and are more potent competitive inhibitors of DNA cleavage.⁷⁷ Thus, despite its inability to undergo complete intercalation binding to DNA, the bithiazole residue can partly incorporate between the base pairs, the most accessible loci for such binding being the sites of local injuries to the double-helical structure (transition regions between denatured and native states of the DNA helix, bends and breaks on the helix, protrusions formed by an extra base, etc.).

Yet another model for bleomycin binding to DNA also provides a satisfactory explanation for the available experimental data. According to this model, the terminal amine and bithiazole rings of bleomycin bind in the minor groove of DNA. This model, which was first proposed in 1986,¹¹⁷ is based on the structural similarity of the bleomycin C-terminal fragment and netropsin and the fluorescent dye Hoechst 33258, both of which bind in the minor groove of DNA. In favour of this model are experiments in which changes in site-specificity and efficiency of DNA cleavage by bleomycin were studied in the presence of ligands tightly bound to DNA. Thus, distamycin A, which binds to the sites enriched with AT sequences in the minor groove of DNA, can inhibit DNA cleavage at sequences GT and GA by increasing the cleavage selectivity at GC sequences.^{118–120} By contrast, actinomycin D binding to GC sequences and blocking the minor groove of DNA by its peptide rings around the binding sites (by 5–6 base pairs)¹²¹ produces an opposite effect: cleavage at GT and GA sequences increases, while that at sequences GC decreases. Covalent attachment of aflatoxin B to the N(7) atom of guanine or of mitomycin C to the O(6) atom of guanine in the major groove of DNA has practically no influence on the specificity or efficiency of DNA cleavage by bleomycin.¹²² The presence of bulky glycosyloxy-methyl residues in the major groove of DNA of the wild-type phage T4 also has insignificant effect on the specificity and efficiency of cleavage.¹²³ In addition, bleomycin displays a similar affinity for both glycosylated and nonglycosylated DNA of phage T4.¹²⁴ A crucial role in the antibiotic affinity for DNA is played by the nucleotide composition of DNA, particularly by the presence of guanine and the 5'-guanine–pyrimidine-3' sequence. Thus, G- and GC-enriched DNA sequences quench bithiazole ring fluorescence far more effectively,^{54,57} whereas poly- and oligonucleotides carrying sequences GC and GT appear to be the most effective inhibitors of the SV40 DNA cleavage by the antibiotic.^{63,64} The value of the constant for bleomycin binding to poly(dG)·poly(dC) exceeds those for binding to poly(dI)·poly(dC) and poly(dA)·poly(dT) (3- and 5-fold, respectively).¹²⁴ It should be noted that the minor groove of the double helix of poly(dG)·poly(dC) contains a 2-amino group of guanine which is absent in inosine or adenine. The crucial role of this amino group in strong binding of bleomycin was confirmed by experiments with anthramycin-modified DNA. This antibiotic, being localised in the minor groove, can form a covalent bond with the 2-amino group of guanine without any appreciable effect on the B-form of DNA.¹²⁵ Treatment of DNA with anthramycin results in strong inhibition of DNA cleavage by bleomycin at sequences GC and GT.¹²⁴ On the basis of these data, Kuwahara and Suguira¹²⁴ proposed a model for bleomycin binding to the 6-meric duplex d(ATGCCA)·d(TGGCAT) possessing a site for effective cleavage (underlined). The terminal amine and the bithiazole residue are arranged along

the DNA minor groove in the direction from the 5'- to the 3'-end relative to the chain to be cleaved. The binding occurs owing to electrostatic interactions and hydrogen bond formation between the 2-amino group of guanine and the nitrogen of the thiazole ring and/or oxygen of the carboxamide group. The bleomycin binding site comprises two to three base pairs which is in keeping with the data on DNA protection from cleavage by DNase I.¹²⁶

Two-dimensional NMR data also testify to the possibility of bleomycin binding in the minor groove of the double helix. Of particular interest in this respect are the results⁷⁵ which in many features provide support for the earlier hypothesis.¹²⁶ In this study, the NOE technique was used to establish the interactions between the protons of the zinc-containing bleomycin A₅ complex and the protons of the 8-meric duplex d(CGCTAGCG)₂ localised in the minor groove of the double helix. On the basis of the data obtained by molecular dynamics methods, a hypothetical spatial model of the complex was calculated. According to the calculations, the bleomycin A₅ molecule is localised in the minor groove, overlapping 4–5 base pairs. The complex is stabilised by hydrogen bonds between the amino groups of the C-terminal fragment of spermidine and the oxygen atoms of the phosphate group and the deoxyribose cycle, between the nitrogen atom of the thiazole ring and the 2-amino group of guanine as well as between the primary amino group of β -aminoalanine and the oxygen atom of the sugar–phosphate backbone. The authors of this model state, however, that this structural model is not unique: a considerable upfield shift of the signals for bithiazole protons by 0.18 ppm [H(5)] and 0.52 ppm [H(5')] and for the imino protons of GC- and AT-pairs corresponding to positions G(2) and T(4) suggests partial intercalation of the bithiazole rings.⁷⁵

Thus, there is no experimental evidence thus far allowing an unequivocal identification of the binding mode (complete or partial intercalation or binding in the minor groove) characteristic of bleomycin. It is quite probable that these binding modes are characteristic of different structures in the DNA double helix. Nevertheless, it is certain that the C-terminal fragment of the bleomycin molecule provides the binding of the antibiotic to DNA by 'anchoring' the rest of the molecule which interacts with the polymer upon oxidative cleavage of the sugar–phosphate backbone. Whatever the mode of C-terminal fragment binding, the mechanism of DNA oxidation (see below) implies the closest approximation of the bleomycin metal-binding domain to the minor groove of the DNA double helix.

III. Cleavage of nucleic acids by bleomycin

1. The mechanism of DNA cleavage

Degradation of DNA by treatment with bleomycin eventually resulting in the cleavage of the sugar–phosphate backbone was discovered as early as 1969;^{30–33} however, the mechanism of action underlying this process has long remained obscure. The first theoretical speculations on the putative mechanism of DNA cleavage were made in 1973, and bleomycin was considered to be a hydrolytic enzyme.^{113,127} Shortly thereafter, cofactors essential for the antibiotic activity were identified. In 1975, it was found that molecular oxygen favours the DNA degradation by bleomycin.¹²⁸ In the same period it was shown that Fe(II) and Fe(III) ions stimulate the DNA cleavage by bleomycin in the presence of 2-mercaptoethanol;^{129,130} these two cofactors favouring DNA degradation were distinguished as being the most essential ones.^{35–37} According to nuclear absorption data,¹³⁰ the previously observed degradation of DNA upon treatment with bleomycin was due to the constant presence of trace amounts of iron ions in the reaction mixture. The discovery that iron atoms and molecular oxygen are essential for DNA degradation was immediately followed by a hypothesis suggesting a free radical mechanism for this process.^{37,56,130–132} Indeed, the Fe(II)Blm complex can generate $\cdot\text{OH}$ radicals^{133,134} that can interact with DNA. The enzyme superoxide dismutase converting the $\text{O}_2^{\cdot-}$ ion into O_2 and H_2O_2 inhibits DNA cleavage under the action of

bleomycin.^{37,135,136} A correlation exists between the biological activity of bleomycin analogues and the amount of 'OH radicals generated by them.¹³² However, it turned out soon afterwards that *tert*-butylphenylnitron and dimethylsulfoxide, which act as 'traps' for 'OH radicals, do not inhibit the cleavage of DNA. Moreover, the efficiency of 'OH radical production by the Fe(II)Blm complex is 40 times lower than in the Fe(II)-H₂O₂ system.¹³⁷ Another group of investigators¹³⁶ succeeded in demonstrating that inhibition of DNA cleavage by superoxide dismutase is not related to the reduced amount of O₂^{•-} ions but is rather due to the association of the enzyme with DNA.

An alternative explanation for the bleomycin action mechanism is the formation of the so-called 'activated bleomycin' which causes direct oxidative degradation of DNA.^{89,138,139} Electron spectroscopy and EPR data as well as the use of the Mössbauer effect made it possible to propose the following scheme for DNA cleavage by bleomycin with participation of the iron ion and molecular oxygen (Scheme 1).⁸⁹

The Fe(II)Blm complex formed in the first stage rapidly interacts with molecular oxygen. In this complex the bivalent iron atom undergoes oxidation, giving rise to the O₂^{•-}-Fe(III)Blm complex. The formation of 'activated bleomycin' requires an extra

electron which is provided either by the reducing agent present in the solution or by an additional Fe(II)Blm molecule undergoing disproportionation.¹³⁹

'Activated bleomycin' can oxidise organic substrates and DNA to form a Fe(III)Blm complex which can be reactivated by peroxy compounds.^{89,138-142}

According to recent mass-spectrometry data, the structure of 'activated bleomycin' corresponds to the peroxy complex of the ferric ion, HOO-Fe(III)Blm.¹⁴³ This scheme, which depicts the bleomycin activity in the presence of iron ions and molecular oxygen, was confirmed experimentally and developed further.

Intensive studies of the mechanism of action of bleomycin led by late 1980s to the establishment of all the main stages of bleomycin activation and pathways of oxidative degradation of DNA. These were documented in detail in reviews and publications.^{41,66,144,145} Therefore, in this review we give only a brief description of the main pathways of DNA oxidation by bleomycin.

Activated bleomycin induces oxidation at position 4' of a carbon atom of the deoxyribose ring¹⁴⁶⁻¹⁴⁸ which is accompanied by the splitting of the H(4') atom and the formation of a 4'-radical (Scheme 2). The oxidation is the limiting step in the chain of subsequent conversions as unequivocally follows from the isotope effect produced by substitution of the hydrogen atom for deuterium or tritium (the rate of the end product formation is 2-7 and 7-12 times less, respectively).¹⁴⁸⁻¹⁵⁰

Further conversions of the 4'-radical proceed in two different ways (*a* and *b* in Scheme 2).⁶⁶ Under aerobic conditions (pathway *a*), an addition of molecular oxygen may occur, resulting in the formation of a 4'-peroxy radical.¹⁴⁶ The subsequent scission of the C(3')-C(4') bond results in the elimination of the base-substituted propenal and cleavage of the sugar-phosphate backbone of DNA, 5'-phosphate and 3'-phosphoglycollate being formed at the site of the chain scission.^{146,151,152}

Pathway *b* is associated with hydroxylation at position 4',¹⁴⁷ apparently as a result of oxidation of the 4'-radical to a carbocation and subsequent attachment of water.¹⁵³ Under physiological conditions, the hydroxylation results in the elimination of the free base without any scission of the DNA chain.^{119, 147, 153–157} Under alkaline conditions β -elimination occurs, which results in the cleavage of the sugar–phosphate backbone and the formation of 5'-phosphate at the cleavage site. The oxidised deoxyribose residue is further converted into 2,4-dihydroxycyclopentenone which remains covalently bound to the 3'-phosphate group. If alkaline treatment is carried out in the presence of hydrazine, 3'-pyridazine is formed; treatment with alkylamines yields 3'-phosphate.¹⁵⁶

Under normal conditions (e.g., at atmospheric pressure of O₂) DNA oxidation by bleomycin results in the formation of approximately equal amounts of free bases and their propenal derivatives,¹⁵⁸ i.e., both pathways of the 4'-radical conversion are possible. Under anaerobic conditions only free bases are formed.^{148, 158} Under O₂ pressure of 3 atm, the ratio of base-propenal derivatives to free bases is 7;¹⁴⁸ at 4 atm this is equal to 10.¹⁵⁹

The high selectivity of bleomycin action with respect to oxidation of deoxyribose is worth noting. As it has been mentioned above, bleomycin can only slowly generate OH radicals.¹³⁷ Chromatomass-spectrometry data¹⁶⁰ demonstrate that treatment of DNA with the Fe(II)Blm complex in the presence of molecular oxygen and a reducing agent is practically unaccompanied by the formation of side products of DNA oxidation (as distinct from the products of the 4'-radical conversion). In particular, the major side product, 8-hydroxyguanine, constitutes only 2%–3% of the total amount of the bases and their propenal derivatives formed in the process.^{160, 161}

2. Specificity and efficiency of DNA cleavage by bleomycin

a. Effect of the primary sequence

Elaboration by Maxam and Gilbert in 1977¹⁶² of a convenient method for identifying the sequences of long-chain DNAs gave a strong impetus to a series of investigations of the sequence specificity of DNA cleavage by bleomycin and related compounds. It turned out that bleomycin displays marked specificity towards dinucleotide sequences carrying guanine at the 5'-end.^{163, 164} In this case deoxyribose of the second nucleotide undergoes oxidative degradation. The most preferred sequences for the cleavage are GT and GC; sequences GA, AT and GG are less susceptible to degradation. This finding correlates with the amount of liberated free bases: T > C \gg A > G.^{37, 164, 165} Soon it was noted, however, that identical dinucleotide sequences are cleaved to a different degree. It was hypothesised that the specificity of DNA cleavage by bleomycin is determined by DNA sequences larger than dinucleotides.^{166, 167} Mirabelli et al.¹⁶⁸ found that pyrimidine present at the 5'-end of the GC sequence enhances the cleavage.¹⁶⁸ Statistical analysis of the sequence specificity of the bleomycin-induced cleavage confirmed that the base preceding the purine–pyrimidine sequence has a certain influence on the extent of cleavage.¹⁶⁹ Thymine enhances, whereas adenine diminishes, the cleavage in the sequences GT, GC, AT, and AC.

b. Effect of the double helix structure on bleomycin-induced cleavage

Despite the conclusions of Mirabelli et al.¹⁶⁸ (which further received experimental support) one cannot explain the difference in the DNA cleavage at different sites by the effect of the primary sequence alone. Lloyd et al.¹⁷⁰ demonstrated that bleomycin induces single- and double-strand scissions at a limited number of sites in bacteriophage PM2 DNA. Some of these sites, if present in DNA in a supercoiled form, were cleaved to a greater extent.^{171, 172} The specificity of cleavage of the linear pBR 322 DNA differed from that of the supercoiled DNA, the extent of cleavage being greater for the latter.¹⁷³ It is known that the supercoiled DNA of plasmid *ColE1* is cleaved 1.5 times more

effectively than the relaxed form.⁴⁷ It was noted also that SV40 DNA contained regions which, by virtue of their secondary structure, were preferentially cleaved by bleomycin.¹⁷⁴ Interestingly, the intracellular DNA is cleaved by the antibiotic at the same preferential cleavage sites as the purified DNA.

The influence of structure on the cleavage efficiency manifests itself in the interaction of bleomycin with the modified DNA. Thus, covalent attachment of mitomycin C¹²² or *cis*-diaminodichloroplatinum(II)¹⁷⁵ in the major groove of DNA enhances the bleomycin-induced cleavage. *cis*-Diaminodichloroplatinum(II) also influences the specificity of cleavage,^{175, 176} apparently due to alterations in the structure of the DNA double helix resulting from intrastrand cross-links. Of special interest are recent findings testifying to the enhancement of the bleomycin effect:¹²⁰ distamycin A strongly (about 100-fold) enhances the bleomycin-induced cleavage of DNA at certain GC-rich sequences. Other compounds bound in the minor groove, such as Hoechst 33258, berenyl, 4',6'-diamidino-2-phenylindol, only slightly increase the efficiency of DNA cleavage by the antibiotic. Presumably, the significant enhancement of DNA cleavage is associated with structural changes in the double helix upon binding of distamycin A.¹²⁰

The presence of a protruding base has a strong effect on the specificity of the bleomycin-induced cleavage by directing its action to nucleotides located in close proximity to the given base.¹⁷⁷ It is quite probable that this effect is due to the ability of bithiazole rings to intercalate into sites with a distorted secondary structure.⁷¹

Convincing evidence for the sensitivity of the antibiotic to even minor changes in the target DNA structure was obtained in the studies by Murray et al.¹⁷⁸ when the cleavage of two virtually identical sequences in the human genome was compared. Substitution of 11 bases in a 340-meric double-stranded fragment produced significant changes in the mode of cleavage. Statistical analysis revealed that some of these changes may be attributed to the direct effect of the substituting base, whereas the changes in the cleavage at other sites located at a distance of 2–12 nucleotides from the substitution site result from structural changes in the substituted DNA.

The effect of the double helix structure on the bleomycin-induced cleavage of DNA is also manifested in DNA methylation. Enzymatic methylation of cytosine residues at position 5 diminishes the extent of cleavage in the vicinity of such sites. The protective effect is observed even at a distance of 14 nucleotides from the methylation site for DNA duplexes having the lengths from 100 to 400 base pairs.¹⁷⁹ This may be associated with local changes in the DNA structure, since it is known that methylation of cytidine facilitates the B–Z transition, the major conformational change in DNA.¹⁸⁰ Further studies with poly(dG)·poly(dC) and poly(dG)·poly(dC^{Me}) revealed that the B–Z transition induced by increasing the salt concentration strongly inhibited the cleavage of these polynucleotides by bleomycin. This finding indicates that the Z-form of DNA is conformationally unprofitable for the manifestation of the antibiotic activity. Additional evidence can be derived from circular dichroism data. In the presence of bleomycin, the B–Z transition needs a far greater ionic strength for its realisation which indicates that bleomycin predominantly binds to and stabilises the B-form of DNA.¹²³

Methylation of cytidine has a different inhibiting action on DNA cleavage by various bleomycins. Demethylbleomycin A₂ and bleomycin B₂ are less sensitive to the presence of 5-methylcytidine than bleomycin A₂ and bleomycin BAPP. At the same time, methylation of adenosine at the N(6) atom diminishes the DNA cleavage by the above-mentioned bleomycins.¹²³ In another study, a self-complementary dodecanucleotide methylated at one of its cytidine residues was used as a target. Long et al.¹⁸¹ showed that the efficiency of oxidation of methylated and nonmethylated oligonucleotides appeared to be the same, but the ratio of liberated free bases and their propenal derivatives was different. In case of the methylated dodecanucleotide, the amount of

liberated free bases was 1.5 times as great as that with the nonmethylated one; hence, the 4'-radical tended to be more susceptible to hydroxylation than to the interaction with molecular oxygen.

The effect of the polynucleotide secondary structure on the efficiency and specificity of the bleomycin-induced cleavage is especially pronounced in the case of cleavage of RNA.

3. Cleavage of RNA by bleomycin

Early studies dating back to the mid 1970s repeatedly demonstrated that RNA was resistant to the action of bleomycin.^{34, 182, 183} In RNA-DNA hybrids, the cleavage affected only the DNA chain.^{159, 184, 185} Cleavage of DNA by bleomycin was not inhibited even by a great excess of RNA.^{62-65, 186}

This generally accepted viewpoint was dispelled in 1989 when it was demonstrated that approximately three molecules of Fe(III)Blm bind to one molecule of yeast phenylalanine tRNA with an equilibrium binding constant of $0.86 \times 10^5 \text{ dm}^3 \text{ mol}^{-1}$. The cleavage occurred at three separate sites with low efficiency [5%–10% for 0.3 mmol dm^{-3} Fe(II)Blm and 3 mmol dm^{-3} tRNA as calculated per nucleotide] and resulted in the formation of free adenine and uracyl.⁶¹ This pioneering study was followed by a number of publications^{65, 187-195} dealing with various aspects of bleomycin interaction with RNA, particularly with a comparison of RNA and DNA cleavage patterns. In both cases the cleavage occurs due to oxidation of the sugar-phosphate backbone¹⁹¹ with iron ions and molecular oxygen (or peroxy compounds) as necessary cofactors.^{191, 194} The presence of reducing agents, such as ascorbate or 2-mercaptoethanol favours the RNA cleavage. A chromatographic analysis of oligonucleotide degradation products and data on electrophoretic mobility in polyacrylamide gel of degradation products of long-chain RNA testify to the formation, at the cleavage site, of 3'-phosphoglycollate and 5'-phosphate.^{191, 194} However, in contrast with DNA, the cleavage of RNA results in the liberation of free bases alone.^{61, 65, 191, 194} In all probability, the detachment of the H(4') atom of ribose triggers a chain of events resulting in the cleavage of the RNA chain.^{190, 192, 194}

The specificity and efficiency of RNA cleavage by bleomycin differ essentially from those for DNA. Firstly, RNA cleavage is more selective at a lesser number of sites. Secondly, the efficiency of the bleomycin-induced cleavage varies considerably for different RNA molecules. Some RNAs are cleaved even by micromolar concentrations of bleomycin, whereas other RNAs are resistant to even very high (0.3 mmol dm^{-3}) concentrations of the antibiotic.^{61, 194}

Bleomycin splits both single- and double-stranded fragments in RNA. However, the cleavage is especially efficient in those parts of the RNA molecule where the single-stranded structure transforms into the double-stranded one and vice versa. Interestingly, the sequence specificity typical of DNA cleavage is not observed in this case. The available data suggest that the bleomycin molecule predominantly cleaves GU sites in RNA,^{65, 188-190, 191, 193, 194} however, by no means all these sites undergo cleavage, while the intensity of cleavage for each GU site may vary considerably. It may thus be concluded that the specificity of RNA cleavage by bleomycin depends not so much on the primary sequence but is rather determined by peculiarities of the secondary or tertiary structure of the polymer molecule. The resistance of some RNA molecules to the effect of bleomycin and the lability of other molecules indicate a crucial role of certain spatial structures in the realization of effective cleavage.

The sensitivity of bleomycin to the structure of the substrate to be cleaved is likely to be manifested in its interaction with RNA. As has been mentioned, bleomycin preferentially cleaves the B-form of DNA. It is known also that the A-form of the double helix exists in RNA. The difference in sizes between the major and minor grooves and the conformation of the carbohydrate residue may be the reason for 'non-recognition' and, as a consequence, of 'non-cleavage' of RNA. Nevertheless, at definite sites, e.g., at the sites of the helix transition from the double-stranded to the single-stranded

structure and vice versa, structures may be formed that represent suitable targets for the cleavage by bleomycin. These structures may resemble the B-form of DNA. An important role in this process is played by the size of the minor groove and the position of the 4' hydrogen atom in it. It may also be assumed that such sites favour stronger binding of the antibiotic, presumably due to the possibility of intercalation of the bithiazole residue.^{71, 177} The low incidence of such sites accounts for the low number of RNA cleavage sites, which results in higher selectivity in RNA cleavage, than for DNA.¹⁹⁴

A spectacular proof of the significance of the spatial structure in effective cleavage of the double helix is given in the study by Holmes and Hecht.¹⁹³ These authors showed that DNA, which represented a copy of histidine tRNA of *Bacillus subtilis*, had one major cleavage site that coincided with the single cleavage site for this tRNA.

4. The role of domains in determining the specificity of bleomycin action in DNA cleavage

Immediately after the discovery of sequence-specific DNA cleavage by bleomycin, a question arose as to the nature of this specificity. By then, it had already been established that the C-terminal fragment of the antibiotic molecule is responsible for the binding to DNA.^{38, 39, 47} The fact that various bleomycins cleave DNA in a similar way^{196, 197} suggests that the terminal amine does not contribute at all to the specificity of bleomycin action. For this reason, the preferential cleavage of certain DNA sequences was attributed to the specificity of bithiazole residue binding, particularly during intercalation.¹⁶⁴ However, an increasing body of experimental evidence argues against this hypothesis.

Thus, phleomycin (B) having one reduced bond in the bithiazole residue¹⁰¹ and, correspondingly, incapable of intercalation, displays the same site specificity.^{48, 167, 197} Bleomycin with a phototransformed bithiazole residue (the 4,4' bond between the thiazole rings instead of the 2,4' bond) (A) has a site specificity that is practically identical with that of natural bleomycin.^{198, 199}

On the other hand, according to the most recent data, a certain role in sequence specificity of DNA cleavage is played by the metal-binding domain. Thus, cleavage of the self-complementary dodecanucleotide CGCTTTAAAGCG by bleomycin occurs at GC sequences (underlined), the C(3) residue being cleaved to the greatest extent.¹¹⁹ Removal of the disaccharide residue (deglycobleomycin, D) or the carbamoyl group of D-mannose (decarbamoylbleomycin, C) from the bleomycin molecule does not influence the sequence specificity of cleavage of this oligonucleotide. However, the predominant site for such cleavage is residue C(11).^{200, 201} According to the data reported by Oppenheimer et al.,²⁰² the carbamoyl group of D-mannose may become involved in the chelation of the iron ion in the metal-binding domain of bleomycin. Its removal may affect the coordination sphere of the metal as follows from NMR data.²⁰³ Hence, the change of the site of preferential cleavage of the dodecanucleotide seems to be due to the alterations in the metal-binding domains of deglyco- and decarbamoylbleomycin.

Experimental proof for the dependence of the geometry of the metal-binding domain on the sequence specificity of DNA cleavage has been presented.²⁰⁴ The degradation of three restriction fragments of DNA under the action of various bleomycin derivatives has been studied. Bleomycin B₂, deglycobleomycin A₂ (D), and isobleomycin A₂ (E) having a carbamoyl group at position 2 of D-mannose²⁰⁵ (in the case of natural bleomycin this group is at position 3) displayed a sequence specificity identical with that of bleomycin A₂. At the same time, in the case of epibleomycin A₂, which differs from bleomycin A₂ in the configuration at the chiral carbon atom of the substituent at position 2 of the pyrimidine ring (marked with an asterisk) and, consequently, in the orientation of the propionamide residue relative to the metal-binding domain,²⁰⁶ the mode of DNA cleavage changed significantly. Epibleomycin A₂ effectively cleaved guanosine at sequence TG, this cleavage mode being

non-typical of natural bleomycin. The percentage of cleaved CT and GG sequences was also higher in this case; sequences AT, TT, TC, and GC were cleaved to a lesser extent. Decarbamoylbleomycin A₂ (C) did not cleave sequences AA, AC, or CT at all, though they are weakly cleaved by bleomycin A₂. With bleomycinic acid, not only the cleavage of DNA was by 35% weaker than with bleomycin A₂ but the sequence specificity of the cleavage also changed. The main cleavable sequences were GT and GA (but not GT and GC); for CT, the percentage of cleavage was also relatively high.²⁰⁴

The nature of the chelated metal (Cu, Co, Mn) has also certain influence on the specificity of the antibiotic action.^{59, 207–209} In the presence of dithiothreitol, the Cu(II)Bln complex can effectively

cleave DNA, the site specificity for such cleavage being different from that for Fe(II)Bln. The difference in the specificity of DNA cleavage by the Fe(II)- and Cu(II)-complexes of bleomycin was especially apparent when the 127-meric double-stranded fragment of SV40 DNA was used.²⁰⁷ Unfortunately, no data on the efficiency of cleavage of specific dinucleotide sequences were given. It is interesting to note that the cleavage of DNA by the Cu(II)-deglycobleomycin complex is more effective than by the Cu(II)-decarbamoylbleomycin complex, whereas for Fe(II)-dependent cleavage an inverse dependence is observed.²⁰⁰ Noteworthy, the isobleomycin A₂-Fe(II) complex effectively cleaves DNA,²⁰⁴ whereas the isobleomycin A₂-Cu(II) complex is fully inactive.²⁰⁷

Upon irradiation with UV-light, the specificity of DNA cleavage by bleomycin complexes containing trivalent cobalt differs from that by Fe-containing bleomycin complexes.^{59, 208} A statistical analysis of sequence specificity of Co(III)-bleomycin complexes is also absent in these studies. What is evident from these experiments, is that sequences GT and GA are preferably cleaved, while sequence GC is cleaved less effectively.

Valuable information on the nature of sequence specificity of the bleomycin action can be derived from the studies of bleomycins with a significantly modified structure. One such work²¹⁰ describes the synthesis of deglycodemethylbleomycin A₂ analogues (see below) carrying glycine residues (Gly)_n (where $n=0-2$ and 4) instead of threonine, and gives an analysis of their cleaving capacity. It turned out that the sequence specificity of such analogues differs only slightly from that of the natural antibiotic. However, the efficiency of cleavage was much lower than with the natural deglycodemethylbleomycin A₂. Thus, the analogue with $n=0$ hardly cleaved DNA, whereas the level of DNA degradation by the analogues with $n=1$ and 2 possessing the maximum efficiency was comparable with that characteristic of the natural antibiotic at 10–20-fold higher concentrations.^{188, 210}

It was thus concluded that the metal-binding domain plays a decisive role in the sequence specificity of DNA cleavage. However, this definite conclusion is appropriate only in case of a mechanistic approach to the consideration of the bleomycin molecule as was the case in the late 1970s: the C-terminal fragment specifically binds to DNA and the change in the length of the spacer between this fragment and the cleaving (metal-binding) domain would alter the specificity of cleavage. If this does not take place, the situation is reversed, namely, the metal-binding domain determines the specificity of cleavage, and the C-terminal fragment defines the affinity for DNA.

As noted above, bleomycin is highly sensitive to the structure of the substrate to be cleaved. High selectivity of oxidation of C(4') of deoxyribose evidences the fine adjustment of the bleomycin molecule to the double helix conformation. It may thus be assumed that any alteration in the spacer leads to an unprofitable (with regard to cleavage) positioning of the metal-binding domain, resulting in self-degradation (but not oxidation) of DNA. Alternatively, instead of additional stabilisation of binding due to electrostatic interactions, the unfavourable localisation of the metal-binding domain may decrease the affinity of the modified antibiotic for the polymer which can also be the reason for the low cleavage efficiency. And, finally, in all previous speculations the threonine residue was regarded only as a constitutive component of the spacer, which does not take part in binding or determining the sequence specificity of the cleavage. However, one must not rule out the possibility that the free OH group can form intra- or intermolecular hydrogen bonds and thus contribute to the sequence specificity of the bleomycin action.

It is known that the bleomycin analogue tallysomycin²¹¹ having additional OH groups in the aliphatic chain at position 2' of the bithiazole residue and the aminosugar tallose attached to one of those OH groups induce the formation of single-strand scissions less effectively than bleomycin and differ from the latter in sequence specificity.^{173, 212, 213} Thus, the cleavage of supercoiled DNA of bacteriophage PM2 by tallysomycin proceeds 5–10 times

less effectively than that by bleomycin.^{53, 214} Furthermore, tallysomylin cleaves GA sequences far more effectively,^{166, 167, 197} GT and GA sequences being preferential for this antibiotic.¹⁶⁸ This finding points to the role of the bleomycin C-terminal fragment in determining the specificity and efficiency of DNA cleavage.

Convincing evidence of the ability of the bleomycin C-terminal fragment to determine sequence specificity has been given in the studies carried out by Japanese investigators.^{215, 216} These authors performed the chemical synthesis of a bleomycin metal-binding domain analogue, in which the 4-aminopyrimidine ring was substituted by methoxypyridine, the disaccharide residue was substituted by a *tert*-butyl group, and the carbamoylmethyl residue in the 2-substituent of pyrimidine was missing. In the presence of iron ions, this compound activated molecular oxygen and oxidised low molecular weight organic substrates with an efficiency comparable with that of the natural antibiotic.^{215, 216} Attachment to this compound of the C-terminal fragment of bleomycin A₂ [Blm-PYLM(6)] was accompanied by the appearance of the DNA-cleaving activity^{217, 218} despite significant changes in the metal-binding domain. These studies received further development, culminating in the synthesis of a molecule comprising the metal-binding domain, 4-aminopentanoic acid as a spacer and a distamycin A residue instead of the C-terminal tripeptide S.²¹⁹ This synthetic molecule effectively cleaved DNA (relative to natural bleomycin), the maximum degree of cleavage being observed in the regions enriched with AT sequences, to which distamycin A binds especially strongly.²²⁰ No specificity to GT and

GC sequences was observed, which is characteristic of bleomycin-induced cleavage.

Studies by Hamamichi et al.²²¹ provided valuable information as to whether the C- or the N-terminal fragment of the antibiotic molecule determines the sequence specificity of bleomycin action. To this end, the authors synthesised and assayed DNA-cleaving agents (analogues of natural deglycodemethylbleomycin A₂) containing, instead of one of the thiazole rings (A or B), its biosynthetic precursor, *S*-methyl-L-cysteine).²²²

It turned out that such analogues cleave supercoiled covalently closed and linear double-stranded DNA less effectively than natural deglycobleomycin A₂. No discernible sequence specificity was observed in the cleavage of 5'- or 3'-labelled linear double-stranded DNA. Thus, the synthetic analogues cleave DNA statistically in contrast with sequence-specific cleavage by the natural antibiotic. This study is a sound argument in favour of the determining role of the bithiazole residue in sequence specificity of the bleomycin action, the bi- (but not mono-) thiazole fragment being the crucial factor.²²²

Another recent study of the role of bleomycin N- and C-terminal fragments in the recognition of definite DNA sequences²²³ concerned the synthesis of molecules containing both DNA-binding and DNA-cleaving groups. As the DNA-binding group the C-terminal fragment of bleomycin A₂, or demethylbleomycin A₂ carrying a bithiazole residue and a terminal amine, was used. The DNA-cleaving group, EDTA (ethylenediaminetetraacetic acid), was attached to the bithiazole residue by an amide bond. If the bithiazole fragment in the bleomycin molecule is the critical factor determining the direction of the antibiotic action, such molecules will cleave DNA in the vicinity of guanine-pyrimidine sequences. However, no appreciable sequence specificity of DNA cleavage characteristic of bleomycin was noted in these model compounds.²²³ One serious pitfall of this study is that its authors did not provide any experimental proof for the binding of their synthetic model

compounds to DNA. This is an important circumstance if one takes into consideration that synthetic compounds cleave DNA far less effectively (approximately 10-fold) than natural bleomycin. The efficiency of DNA cleavage by EDTA-containing compounds is comparable with that for EDTA. It can thus be assumed that at the concentration of the analogues of $100 \mu\text{mol dm}^{-3}$ that had been used to demonstrate the sequence specificity of the antibiotic action, the degradation of DNA is predominantly effected by diffusing $\cdot\text{OH}$ radicals generated by the reagent molecules not bound to DNA. In this case, the conclusion made by the authors in favour of the determining role of the bleomycin N-terminal fragment in sequence specificity appears to lack sufficient experimental justification.

Yet another detail worth noting is important for the correct understanding of the nature of sequence specificity. According to Otsuka et al.,²¹⁹ cleavage by a bleomycin analogue containing distamycin A occurred at sites enriched with AT sequences, i.e., at sites responsible for the binding of distamycin A. This provides evidence of the spatial proximity of the metal-binding domain to the DNA-binding fragment in the bleomycin molecule. Molecular models for this compound suggest the existence of a bend in the residue linking distamycin A and a metal-binding site providing for such cleavage. Presumably, a similar situation takes place in the binding and cleavage of DNA by natural bleomycin; in this case, site-specific recognition of DNA may be effected by both C- and N-terminal fragments of the antibiotic molecule.

However, the data available do not provide any unambiguous conclusion on the nature of the sequence-specific effect of bleomycin. Many of these data and, particularly, the model of binding in the minor groove of DNA, point to the important role of the bleomycin C-terminal fragment in the specific recognition of DNA. Nevertheless, one should not rule out that the C-terminal fragment alone cannot induce either the sequence-specific binding or cleavage of DNA. There are strong grounds for believing that the metal-binding domain plays an important role in preferential recognition of the dinucleotide sequence to be cleaved. It is not excluded that an important role in this process is played by the matching of the sizes of the metal-binding domain and the minor groove. Apparently, the residues of threonine and 4-amino-3-oxy-2-methylpentanoic acid providing correct spatial orientation of N- and C-terminal fragments, also contribute to the specificity of the bleomycin action. It follows from these data that adequate interpretation of the nature of such site specificity is possible if one takes into consideration all the three structural elements, such as affinity for the cleavage site provided predominantly by the C-terminal fragment, microvariations in DNA structure determining the size of the minor groove and the optimal position of the deoxyribose C(4')–H bond for oxidation by the iron hydroperoxide complex as well as the possibility of fixing the orientation of the metal-binding domain needed for the attack through the connecting group and/or due to the interaction of the bleomycin N-terminal fragment with the double helix of DNA. To this can be added the necessity of penetration of the oxygen molecule to the chelated iron ion provided by the disaccharide which may form a hydrophobic pocket and the important role of the reducing agent in generating 'activated bleomycin'. The elucidation of these factors will undoubtedly shed more light on the nature of site specificity of bleomycin.

5. Correlation between the affinity and efficiency of cleavage

Cleavage of DNA by bleomycin is preceded by the binding of the antibiotic to the polymer. This raises the following questions: Do cleavage and binding sites coincide? How many base pairs does bleomycin cover upon binding? Is the cleavage efficiency determined exclusively by the bleomycin affinity for the given site or are other factors also involved? Some recent results provide answers to these questions. In particular, studies^{126, 224–226} describe DNA cleavage by different endonucleases in the absence and in the presence of bleomycin and phleomycin complexes with Co(III). The mode of DNA cleavage by DNAase I and micrococcal

nuclease changed considerably in the presence of bleomycin, showing a distinct protective effect at definite regions on the radiograms. These regions comprised, as a rule, a site for the cleavage by the Fe(II)Blm complex. In this case, one bleomycin molecule 'covered' from 3 to 5 adjacent base pairs from the endonuclease action^{126, 225} which agreed well the earlier observations.¹²⁴ Nightingale and Fox¹²⁶ even made an attempt to validate, on the basis of nuclease hydrolysis inhibition data, the orientation of arrangement of the bleomycin molecule at the binding-cleavage site 5'...ACGT...3', stipulating that one antibiotic molecule 'covers' three base pairs. The authors assumed that bleomycin encompasses sequence 5'-CGT-3', i.e., its molecule is positioned at the 5'-end of the chain relative to the base to be cleaved. Another interesting finding of this study is that the sites with alternating (AT)_n sequences, where $n = 3$, are cleaved by bleomycin with almost the same efficiency as GT sequences. At the same time, the Co(III)Blm complex does not protect these sites from the DNAase I action. In other words, these sites are characterized by efficient cleavage at a relatively weak binding. At the (AT)_n sites, the cleavage affected only the AT (but not TA) sequences. (AAT)_n, (ATT)_n, (TTA)_n, (TAA)_n, A_n·T_n and some individual AT sites did not practically undergo cleavage. It was assumed that the observed phenomenon is due to an unusual alternating conformation of the B-form in sequences (AT)_n, where the turn of the helix at 5'-TA-3' is greater than at 5'-AT-3'.²²⁷ It is probable also that changes in the normal B-form of DNA are due to the low ionic strength of the buffer solution used for the cleavage.^{126, 225, 226}

Thus, there exists a certain dependence between the strong binding of bleomycin to DNA and the efficient cleavage of the latter. An important factor is the presence of guanine in the nucleotide sequence. The efficiency of cleavage depends, to a large extent, on the local structure of the double helix which must be in conformation B (but not Z or A). Obviously, the cleavage is more efficient in alternating purine–pyrimidine sequences as can be evidenced from preferential cleavage of guanine–pyrimidine (relative to guanine–purine) and thymine–purine–pyrimidine (relative to adenine–purine–pyrimidine) sequences, and efficient cleavage of (AT)_n. Summing up, one may conclude that the efficiency of cleavage depends not only on the strength of binding but also on DNA structure. Therefore, the cleavage of DNA by bleomycin can be used as a sensitive method for determining microvariations in the double helix structure.

IV. Bleomycin derivatives of oligonucleotides. Synthesis and site-specific cleavage of DNA

As noted above (see Section I), owing to its relatively low toxicity, bleomycin has found wide use in treating squamous tumours both separately or in combination with other chemotherapeutic drugs. Nevertheless, the application of this antibiotic is restricted due to its damaging action on certain tissues, in which the content of a bleomycin-inactivating enzyme is low. One of the most common side effects produced by this antibiotic is pulmonary fibrosis.^{13, 15, 228} Among other ways to enhance the specificity of therapeutic actions of this drug is to increase its selectivity towards specific nucleic acids. The inherent specificity of natural bleomycin towards dinucleotide sequences prevents it from distinguishing various nucleic acid molecules or different sites of the same macromolecule. The enhancement of specificity of the bleomycin action can be achieved through its attachment to the oligonucleotide exemplified in Scheme 3. In this scheme, the sites of hypothetical cleavage of the DNA chain are marked by arrows. This approach, which was first suggested in the 1960s^{229, 230} and is widely used now^{231–235} permits spatial approximation of bleomycin and the preselected nucleic acid region and thus ensures its directed chemical modification. Such an approach is now widely used in routine studies.^{231–235}

A broad spectrum of reactive oligonucleotide derivatives have been created by now that carry alkylating or photoreactive groups, platinum complexes capable of coordinating target heterocycles,

Scheme 3

and groups catalysing oxidative degradation of target nucleic acids.^{231, 235} The latter can chelate transient metals; their interaction with molecular oxygen can catalytically generate active oxygen-containing species which degrade DNA. There exist natural compounds (among those is the antitumour antibiotic bleomycin) which cause destruction of DNA in the same way. From the data presented in Sections I–III, one may conclude that oligonucleotides carrying the residue of this antibiotic should be effective site-specific reagents able to 'switch-off' the function of definite genes. However, taking into account the complex nature of bleomycin, which has several nucleophilic centres, special efforts will be necessary in order to obtain its oligonucleotide derivatives.

1. Synthesis and properties of bleomycin derivatives of mono- and oligonucleotides

When constructing bleomycin derivatives of oligonucleotides suitable for site-specific degradation of target DNA, it is necessary to preserve both the ability of the antibiotic to cleave the DNA of an oligonucleotide fragment to form complementary complexes.

To meet these requirements, the antibiotic was attached to an oligonucleotide at the 5'- or 3'-terminal phosphate group preactivated with triphenylphosphine-2,2'-dipyridyl disulfide in the presence of 4-*N,N*-dimethylaminopyridine-1-oxide (DMAPO) (Scheme 4). It is known that the phosphate group in the thus obtained zwitterion derivative readily reacts with aliphatic amino groups.²³⁶ Bleomycin A₅ contains several such groups. The amino groups in the metal-binding domain essential for the DNA-cleaving activity of the antibiotic were protected by chelation with the copper ion, thus directing the attachment to the amino groups of the spermidine residue at the C-terminal fragment of the bleomycin molecule. The successful use of the copper-containing bleomycin complex for selective acylation of the C-terminal amine was documented in earlier studies.²³⁷ In order to avoid the attachment of two oligonucleotide molecules to one antibiotic molecule, the latter was taken in a 10-fold excess.

Analysis of electronic absorption spectra revealed the presence in the synthetic compounds of both the oligonucleotide fragment and the bleomycin residue, the contribution of each component to the total spectrum being commensurate with the binding of one antibiotic molecule to one oligonucleotide molecule.^{238, 239}

The structure of bleomycin-oligonucleotide derivatives was finally established in ¹³C NMR studies.²⁴⁰ It was found that the linkage of the terminal phosphate group of the oligonucleotide involves the spermidine primary amino group in bleomycin A₅ (see Scheme 4).

As has been mentioned above (see Table 1), bleomycin can form relatively stable complexes ($K_b = 10^5 \text{ dm}^3 \text{ mol}^{-1}$) with double-stranded DNA. Moreover, being bound to DNA, this antibiotic stabilises the structure of the double helix. Thus, the melting temperature for calf thymus DNA in the presence of bleomycin

Scheme 4

risers by 4 °C.¹⁰⁴ Attachment of bleomycin to an oligonucleotide should stabilise the complementary complex formed thereby. Indeed, the melting temperature for a complex of tetradecanucleotide pd(TGTTTGGCGAAGGA) with the bleomycin derivative of the complementary heptanucleotide, Blm-A₅-pd(CCAAACA), is 33 °C which is 11 °C higher than that for the analogous complex formed by the original heptanucleotide.^{238, 239} This is an important point in the realisation of the targeted complementary action, since the efficiency of this action on DNA depends, in a large measure, on the stability of the complementary complex formed by target DNA and the reagent.²⁴¹

The next step in this direction was to investigate the DNA-cleaving activity of bleomycin derivatives of oligonucleotides.

2. Site-specific cleavage of a single-stranded fragment of DNA by bleomycin derivatives of oligonucleotides

In a study by Sergeev et al.,²⁴² a 302-meric DNA fragment representing a copy of the RNA fragment of the tick-borne encephalitis virus was used to examine the site specificity of oligonucleotide derivatives of bleomycin. Two oligonucleotide reagents carrying a bleomycin A₅ residue at their 5'-ends were complementary to sequence 261–274 which is predominantly located in the single-stranded hairpin (the Blm-A₅ residue attached to 5'-phosphate is marked by an asterisk) (Scheme 5).^{243, 244}

Cleavage of the 302-meric DNA target was studied using polyacrylamide gel electrophoresis. This approach allows one to separate the degradation products from the original DNA target and to determine (with an accuracy of one base) the site where the target has been cleaved. The latter is achieved by comparing electrophoretic mobilities of degradation products of the target by the reagent with electrophoretic mobilities of the products of statistical degradation of the target at one or two types of bases using the procedure described by Maxam and Gilbert in 1979.¹⁶²

The results of electrophoretic analysis suggest that under conditions of complementary complex formation, both oligonucleotide reagents induce scissions at the GT sequences of the target closest to the antibiotic residue, i.e., at T(272) and T(277) (Fig. 2). The cleavage proceeds with high efficiency and selectivity. By illustration, when the shorter, 12-meric reagent is used at a concentration of 1×10^{-5} mol dm⁻³, direct breaks (without an additional alkaline treatment, Scheme 2, pathway *a*) occur at sequences T(272) and T(277) in 70% of the DNA target.

Figure 2. The results of analysis of degradation products of a 302-meric 3'-³²P-labelled DNA target by 12- and 14-meric oligonucleotide reagents. Lanes 1 and 5, is statistical cleavage of the DNA target at purine residues;¹⁶² lanes 2–4, is the 12-meric reagent (1×10^{-7} , 1×10^{-6} and 1×10^{-5} mol dm⁻³, respectively); lanes 6–8, is cleavage by a 14-meric reagent (5×10^{-6} mol dm⁻³) for 1, 3 and 6 h, respectively; lane 9, is the DNA target incubated in the absence of the reagents; lanes 10–12, is cleavage by a 12-meric reagent (5×10^{-6} mol dm⁻³) for 1, 3 and 6 h, respectively.

This cleavage is determined by site-specific binding of the oligonucleotide fragment of the reagents to the complementary sequence of the DNA fragment. This becomes obvious when analysing the DNA cleavage by bleomycin and its oligonucleotide derivative whose nucleotide sequence is devoid of the complementary binding site at the preselected fragment. It was shown that (i) both reagents cleave the DNA target with lower efficiency than do complementary reagents and at multiple positions and (ii) T(272) and T(277) are not the preferential sites for the cleavage.²⁴²

Evidence for the necessity of complementary complex formation for effective degradation of the DNA target is presented in Scheme 6 (the main cleavage sites are marked by arrows).²³⁹ The 14-meric DNA target is effectively cleaved by the 7-meric oligonucleotide reagent Blm-A₅-pd(CCAAACA) [Scheme 6 *a* (1)]. In the presence of a tetranucleotide complementary to the target, this reagent loses its ability to form a complementary complex with the target and does not practically cleave it [Scheme 6 *a* (2)].

Complementary oligonucleotide reagents of various lengths are characterised by different positional directionality of cleavage. Thus, for a 6-meric reagent, the main cleavage sites are T(5) and T(3) [Scheme 6 *b* (1)]; those for a 7-meric reagent are G(7), T(5), and T(3) [Scheme 6 *b* (2)], while those for a 8-meric reagent are C(8) and T(5) [Scheme 6 *b* (3)]. It is interesting to note that when 7- and 8-meric reagents are used, the target is directly cleaved at the

nucleotide closest to bleomycin which is involved in the formation of a complementary complex with the reagent (at residues G(7) and C(8), respectively). In the case of a 6-meric reagent, the adjacent nucleotide [residue G(6)] does not undergo cleavage, while residue T(5) is cleaved. Nucleotide G(6) remains intact both when 7- and 8-meric reagents are used (Scheme 6b).²³⁹ Apparently, under these conditions, the specificity determined by the moiety of the oligonucleotide reagents is superimposed on the specificity of the antibiotic itself, for which the cleavage at sequence TG is not typical (see Section III).

Thus, the alteration in the length of the oligonucleotide moiety of the reagent changes the site-direction of the DNA cleavage, indicating a site-specific mode of action of the covalently attached bleomycin residue.

3. Degradation of a double-stranded DNA target by bleomycin derivatives of oligonucleotides within the triplex structure

One of the versions of the complementary targeted modification is the use of reactive oligonucleotide derivatives capable of attacking selected sites of a double-stranded DNA by forming a ternary complex.^{235, 247} Oligonucleotides containing alkylating^{246, 247} or photoreactive groups,²⁴⁸ as well as groups with a redox mechanism of action,^{249, 250} have been used. The bleomycin A₅ residue, which has demonstrated effective cleavage of a DNA target within a duplex structure was assayed as the reactive group.²⁵¹

The DNA target for the study of the oligonucleotide reagent action within the ternary complex was selected in accordance with the following demands. First, the target had to contain a region of homopurine and homopyrimidine sequences necessary for the ternary complex formation. Second, a stable ternary complex should be formed at neutral pH values, since bleomycin effectively cleaves DNA in the pH range of 7–9.^{37, 62, 63} If these conditions are fulfilled, stable ternary T·AT complexes are formed.^{252, 253} Third, the fragment involved in the formation of the complex with the reagent must be flanked by sequences which could serve as targets for the action of the bleomycin residue during the complex formation. Since bleomycin predominantly cleaves DNA at sequences GT, GC, AT, and GA at deoxyribose, the second nucleotide (Section III), a 30-meric double-stranded target (Scheme 7) was selected (the cleavage sites are marked by arrows whose length is proportional to the cleavage intensity).

Under conditions of ternary complex formation, 5'- and 3'-bleomycin derivatives of the 16-meric oligothymidylate induce the cleavage of the target. Both reagents cleave DNA at both chains in the vicinity of the antibiotic residue upon binding of the third chain

(reagent), which is parallel to purine-rich (triplex I) and antiparallel to pyrimidine-rich (triplex II) sequences. This is in agreement with the literature data^{249, 250} for the cleavage of double-stranded DNA by EDTA- and 1,10-phenanthroline-containing oligonucleotide reagents which form a ternary complex with DNA.

Cleavage of a pyrimidine-rich chain by a 3'-bleomycin derivative of hexadecathymidylate occurs both in the vicinity of the 5'-end of the oligo(T)-track due to the formation of a ternary complex and around the 3'-end of the chain (Scheme 7). The latter cleavage occurs at sites C(30), C(28) and T(26) of the GC and GT sequences that are preferential for the binding and cleavage by the bleomycin itself (Section III). At a 5-fold excess of the reagent (relative to the target), this cleavage may be due to the ability of the bleomycin residue to bind to a double-stranded DNA without the formation of a triplex by the oligonucleotide moiety of the reagent. To check this hypothesis, a DNA target was cleaved by a 5'-bleomycin derivative of a 16-meric oligonucleotide, Blm-A₅—pd(CAGCGGGATGGAACAC), which a priori is incapable to form a ternary complex with the target. In this case, the purine-rich chain is cleaved only insignificantly (by 6%), whereas the pyrimidine-rich chain, as in the case of bleomycin derivatives of hexadecathymidylate, is cleaved at the 3'-end at sites C(30), C(28), and T(26) (16%). This suggests that the action of a 5-fold excess of 5'- and 3'-bleomycin derivatives of hexadecathymidylate on the double-stranded DNA target can be both site-specific due to the targeted attachment of the oligonucleotide in the ternary complex formation and nonspecific when the bleomycin residue binds to double-stranded DNA.

Comparing the total extent of cleavage of the double-stranded DNA target by bleomycin-containing reagents (Table 2), one may conclude that for both 5'- and 3'-bleomycin derivatives of hexadecathymidylate, site-specific cleavage associated with the ternary complex formation prevails over nonspecific ones.

Table 2. Total extent of cleavage of a 30-meric double-stranded DNA target by bleomycin derivatives of oligonucleotides.

Reagent	Total extent of cleavage (%)	
	Purine-rich chain	Pyrimidine-rich chain
Blm-A ₅ –p(dT) ₁₆	25	47
(dT) ₁₆ p–Blm-A ₅	35	36
Blm-A ₅ –pd(CAGCGGGATGCAACAC) ^a	6	16

^a Does not form a ternary complex with the DNA target.

4. Catalytic degradation of a DNA target by an oligonucleotide derivative of bleomycin

The advantage of applying groups with a redox-type mechanism of action [Fe(III)–EDTA, metalloporphyrins or Cu(II)–1,10-phenanthroline] over alkylating or photoreactive groups for the site-specific DNA modification is their ability to produce catalytically active oxygen-containing species and thus exert manifold action on the DNA target.^{254–256} The glycopeptide antibiotic bleomycin is an illustrious representative of compounds with a redox mechanism of action. Cyclic oxidation–reduction of the iron ion chelated in the metal-binding domain of bleomycin by molecular oxygen and some reducing agent results in multiple production of ‘activated bleomycin’ and, as a consequence, in catalytic oxidation of organic substrates.^{56, 257, 258} In the process of oxygen reduction, bleomycin acts as an enzyme with the iron ion as a cofactor.^{56, 259} Recent studies²⁶⁰ provide evidence that in the presence of ascorbate one molecule of bleomycin can catalyse the reduction of 4.7 molecules of oxygen. The main advantage of bleomycin as a reactive group for the site-specific cleavage of DNA is its ability to oxidise catalytically not only low molecular weight substrates but also DNA.^{201, 261}

It has already been noted that all the redox groups used for site-specific modification of DNA can reduce molecular oxygen catalytically. However, the capability of these groups to cause multiple degradation of DNA within the structure of the oligonucleotide reagent has not yet been realised. One of the reasons for this is an accidental damage to nucleotide residues by reactive oxygen-containing species generated by these reagents. The analysis by chromatomass spectrometry revealed the presence of a greater number of modified bases (compared to the number of direct cleavages) after treatment of DNA with Fe(III)–EDTA and Cu(II)–1,10-phenanthroline complexes.^{262, 263} Similarly, a great deal of modified bases (primarily, guanine) are formed upon treatment of DNA with metalloporphyrins.²⁵⁶

Modification of bases does not lead to direct cleavage of the DNA chain. Moreover, many modified bases, particularly 8-hydroxyguanine and 8-hydroxyadenine, the major products of ·OH radical interaction with purine heterocycles, are stable under alkaline conditions and even treatment with piperidine does not result in the cleavage of the sugar–phosphate backbone at these sites. Such hidden modifications mask the catalytic activity of the above-mentioned reagents.

The mechanism of effective degradation of DNA by bleomycin differs essentially from that by redox groups. Under physiological conditions, bleomycin-induced selective oxidation of the C(4′) atom of deoxyribose leads with equal probability either to direct cleavage of the DNA chain or to the formation of a base-labile site (Section III). For this antibiotic, modification of nucleotides is only a minor reaction.^{160, 161} Thus, the yield of the major side product of the reaction, 8-hydroxyguanosine, constitutes 2%–5% of the amount of oxidised deoxyribose.¹⁶⁰ Thus, bleomycin oxidises nucleotide residues with a far greater selectivity than its redox analogues.

Bleomycin does not form covalent linkages with DNA following oxidation of deoxyribose but it can bind to a new site in DNA, and after reduction of the iron ion in the active centre it

can again oxidise the sugar–phosphate backbone. Analysis of extended DNA revealed that one antibiotic molecule stimulates the formation of several molecules of free heterocyclic bases or propenal derivatives.²⁶¹ The ability of one bleomycin molecule to induce degradation of several DNA molecules has been demonstrated for oligonucleotides used as targets.²⁰¹

In order to examine the ability of the bleomycin residue within the structure of the oligonucleotide conjugate to cleave DNA catalytically, a model with an equimolar target: reagent ratio (Scheme 8 *a*) and 10-fold excess of the target relative to the reagent (Scheme 8 *b*) was used. The cleavage sites in the scheme are marked by arrows.²⁶⁴

Scheme 8

It is known that bleomycin more effectively cleaves double-stranded DNA than single-stranded DNA.^{167, 265–267} This circumstance considered, a model comprising a 14-meric DNA target, a 5′-bleomycin derivative of a heptanucleotide, and a heptanucleotide complementary to the 3′-end of the target was chosen.

The catalytic activity of the bleomycin residue covalently bound to the oligonucleotide, can be manifested (depending on the experimental conditions) in a damage to several DNA target molecules by one reagent molecule or in repeated attacks on the same target by the complementary complex.

a. Repeated cleavage of a 14-meric DNA target by an oligonucleotide derivative of bleomycin

Interaction of an oligonucleotide derivative of bleomycin with the tetradecanucleotide at their equimolar ratio (Scheme 8 *a*) results in a practically complete (80%) degradation of the target. This is accompanied by the formation of a broad range of degradation products and modification of sites T(3)–T(5) remote from the site of covalent attachment of the antibiotic. At the same time, with a 10-fold excess of the target, the modification predominantly occurs at G(7) (Scheme 8 *b*). This result can be interpreted in terms of catalytic properties of the bleomycin residue, which under conditions of an equimolar reagent: target ratio can be manifested in repeated action on the DNA target. Analysis of the time dependence of the tetradecanucleotide degradation at 20 °C revealed that the target is primarily attacked at position G(7) (Fig. 3). This is followed by accumulation of shorter fragments formed upon the destruction of sites T(5), T(4) and T(3). The amount of the degradation product at position G(7) does not increase any longer but decreases with time. A similar situation is observed when the cleavage occurs at position G(9). These findings provide direct evidence in favour of repeated exposure of the DNA target to the antibiotic action.

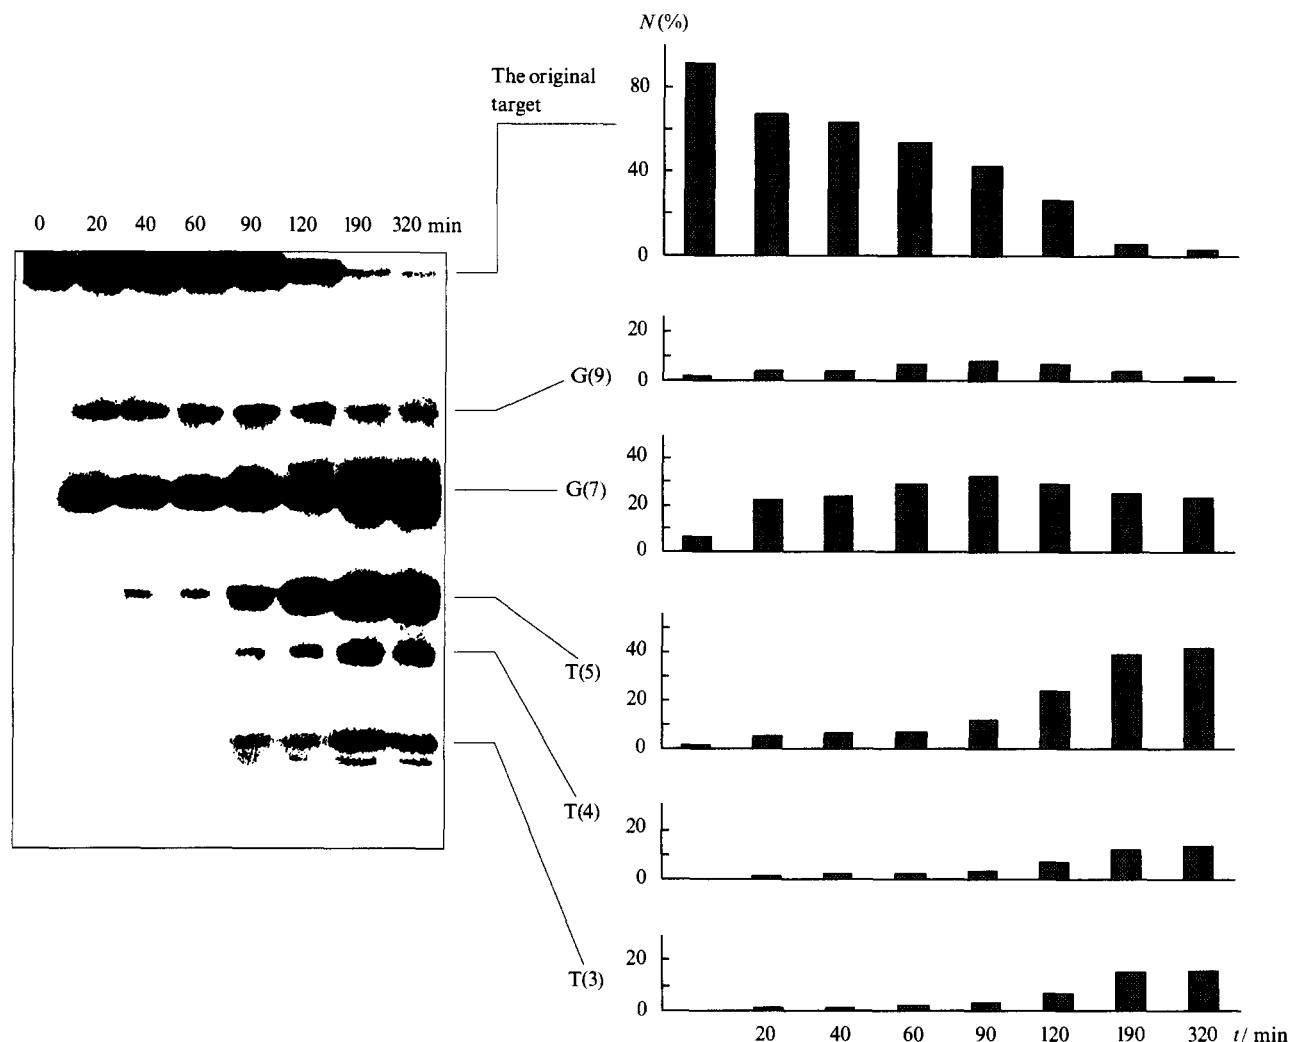

Figure 3. Time dependence of the cleavage of the 14-meric DNA target by the oligonucleotide reagent (see Scheme 8 a) (electrophoretic and densitometric data). Oligonucleotide concentration is 1×10^{-5} mol dm $^{-3}$; N is the concentration of the product in the reaction mixture.

b. Degradation of several target molecules by one reagent molecule

In order to manifest the catalytic activity, the oligonucleotide derivative of bleomycin has to attack one target molecule after another. This will require an excess of the target and selection of conditions enabling both ready dissociation of the complementary reagent–target complex and, simultaneously, the stability needed for efficient modification. Fig. 4 illustrates the cleavage of the DNA target by the reagent at different temperatures and under conditions when the reagent concentration is 10 times less than that of the target and the heptanucleotide. The cleavage of the target is a maximum in the temperature range of 25–35 °C which includes the melting temperature for the reagent–target complex ($T_{m.p.} = 33$ °C). Under these conditions, the reagent readily dissociates from the complementary complex, thereby enabling its transfer from one target molecule to another. At the same time, about half of the reagent molecules remain within the complementary complex. An increase in temperature sharply decreases the degree of cleavage, apparently, due to the decrease in the concentration of the complementary reagent–target complex. Lowering of temperature also diminishes the degree of the target cleavage, which can be attributed to nonoptimal conditions for the manifestation by the reagent of its catalytic activity. It has been established that at temperatures around 30 °C, about 20% of the target undergoes direct cleavage, while subsequent treatment with piperidine reveal an additional 10% of sites that are labile under alkaline conditions.²⁶⁴

Degradation of about 30% of the tetradecanucleotide by the oligonucleotide reagent and in the presence of a 10-fold excess of the target testifies to the fact that one reagent molecule can attack, on average, three target molecules. Restricted efficiency of the reagent action in the presence of a sufficient amount of iron ions,

Figure 4. The total extent of cleavage (α) of 14-meric target DNA (1×10^{-5} mol dm $^{-3}$) by the oligonucleotide reagent (1×10^{-6} mol dm $^{-3}$) in the presence of heptanucleotide (1×10^{-5} mol dm $^{-3}$) (see Scheme 8 b) at different temperatures, according to densitometric analytical data.

reducing agents, and molecular oxygen may be attributed either to the degradation of its oligonucleotide moiety or to the degradation of the antibiotic itself. To elucidate possible reasons for the restriction of the catalytic activity, synthesis of the 5'-³²P-labelled reagent and cleavage of the nonlabelled target DNA were carried out under conditions of 10-fold target excess (Scheme 8b). Electrophoretic analysis data indicate that catalytic degradation of the target is accompanied by significant degradation of the oligonucleotide reagent.²⁶⁴ Removal of the bleomycin residue from the reagent after termination of the reaction gave rise to a nonmodified oligonucleotide. Hence, the restriction of the reagent catalytic activity is associated with the destruction of bleomycin itself.

Thus, chemical attachment of the antibiotic to the oligonucleotide makes it possible to direct it to a preselected site of one of nucleic acids and thus to increase markedly the selectivity of its action on all these acids. The method described of covalent attachment of bleomycin to the oligonucleotide^{238,239} makes it possible to preserve not only the ability of the antibiotic to cleave DNA, but also its capacity for catalytic cleavage characteristic of free bleomycin.
