Drastic hydrolysis of **122** afforded 2,3-diacetyl-amino-2,3-dideoxy-D-mannose **123** whose structure was corroborated by mass spectrometry of the corresponding diacetylaminodialditol acetate. Fragmentation of this derivative proceeds by the same pathway as that of the alditol obtained from the *gluco*-analogue. The parameters of the NMR spectra of the diaminuronic acid residue present in the acetate of the trisaccharide **122** confirmed its structure: the ^{13}C NMR spectrum contained signals of C(2) and C(3) carrying NH groups at 52.3 and 52.5 ppm, and the coupling constant values of the ring protons in the ^1H NMR spectrum were consistent with the *manno*-series ($J_{2,3} = 3.9$, $J_{3,4} \approx J_{4,5} = 9.8$ Hz). Finally, the absolute configuration of the diacetylaminodideoxyhexose obtained from PS was confirmed by direct comparison with a synthetic sample of 2,3-diacetyl-amino-2,3-dideoxy-D-mannose.¹⁴³

The third isomer of diaminuronic acids of this series, a derivative of 2,3-diacetyl-amino-2,3-dideoxy-L-guluronic acid **124** containing an *N*-acetimidoyl group, was found in PS of several subtypes of *Pseudomonas aeruginosa* O3^{140,143} and *Pseudomonas aeruginosa* immunotype 7.^{143,144} Some of these PS also contained a residue of 2,3-diamino-2,3-dideoxy-mannuronic acid that posed some problems while establishing the structure of the *gulo*-isomer, since interpretation of the NMR spectra of fragments containing both isomeric diaminuronic acids was quite complicated.

The structure of 2,3-diacetyl-amino-2,3-dideoxy-L-guluronic acid in PS of *Pseudomonas aeruginosa* O3 was established using the same scheme as for its *gluco*- and *manno*-analogues. After detection in the IR and NMR spectra of PS of signals for carboxy groups, the polysaccharide was subjected to solvolysis with liquid HF and subsequent treatment as described above. This resulted in a derivative of the trisaccharide **125** containing residues of diaminouronic acids with the *manno*- and *gulo*-configurations that was corroborated by NMR spectroscopy.

Regretfully, not only the derivative of the diaminoguluronic acid itself but also the product of its reduction, 2,3-diacetyl-amino-2,3-dideoxy-L-gulose, appeared to be rather unstable in acid media. The latter also failed to be isolated and identified. For this reason the structure and the configuration of the diaminoguluronic acid was established by analysis of the complex NMR spectra of the trisaccharide derivative **125** and its acetate **126** (their composition was confirmed by mass spectrometry) using special versions of NMR spectroscopy. It was found that, in addition to the carboxy group, the novel monosaccharide contains two acetamino groups at C(2) and C(3) and has the *gulo*-configuration as evidenced by the coupling constant values for the ring protons in the ^1H NMR spectrum ($J_{2,3} = 4.5$, $J_{3,4} = 3.0$ and $J_{4,5} = 3.0$ Hz). This configuration was finally corroborated by comparison of signals of the carbon atoms belonging to the residue of the acid **124** in the ^{13}C NMR spectrum of the derivative **125** with the spectral characteristics of synthetic samples of all isomeric 2,3-diacetyl-amino-2,3-dideoxyhexoses.¹⁴⁵ This configuration was also established for the oligosaccharide **127**, one of the intermediate products of selective cleavage of PS from *Pseudomonas aeruginosa* immunotype 7, during the analysis of the NMR spectra.¹⁴⁴

The absolute L-configuration of diaminoguluronic acid was evident from the specific optical rotation of the oligosaccharide **125**. It was finally confirmed by analysis of the ^{13}C NMR spectrum of the trisaccharide **127** using the dependence of the glycosylation effects on the absolute configuration of the neighbouring monosaccharide units. A negative β -effect of glycosylation (0.9 ppm) on C(3) of the diaminomannuronic acid (for which the D-configuration had been established previously) attached to the diaminoguluronic acid residue in **127** by the α -glycosidic bond at position C(4) demonstrated, unambiguously, the L-configuration of 2,3-diacetyl-amino-2,3-dideoxyguluronic acid.

Recently, the fourth isomer of diaminodideoxyhexuronic acids, 2,3-diacetyl-amino-2,3-dideoxy-D-galacturonic acid (**128**), was identified. This acid is a component of O-antigenic PS of the Gram-negative bacteria *Bordetella bronchiseptica* and *Bordetella parapertussis*.¹⁴⁶ Both PS are homopolysaccharides built up of diaminogalacturonic acid residues, the immunochemical difference between the antigens being exclusively due to variations in the structure of the core of the corresponding LPS. The structure of the novel monosaccharide was established without any difficulty by a non-destructive method using NMR spectroscopy. The

presence of signals of the carboxy group (175 ppm) and of C(2) and C(3) bearing amino groups (46.6 and 49.1 ppm) in the ^{13}C NMR spectra and the coupling constant values for the ring protons in the ^1H NMR spectrum characteristic of the *galacto*-series ($J_{2,3} = 10.8$, $J_{3,4} = 3.0$ and $J_{4,5} = 3.0$ Hz), fully confirmed the structure of 2,3-diacetyl-amino-2,3-dideoxygalacturonic acid. The absolute D-configuration was evident from the specific optical rotation of the PS.

Recently, the first representative of 2,4-diamino-2,4-dideoxyuronic acids has been identified. 2,4-Diacetyl-amino-2,4-dideoxy-D-glucuronic acid **129** was found in O-specific PS of *Thiobacillus* IFO 14570.¹⁴⁷ The structure of this PS was established by a non-destructive method using a complex analysis of PS with the help of several versions of NMR spectroscopy, including NOE measurements. This study is an excellent demonstration of contemporary structural analysis of a structurally complex PS using NMR spectroscopy alone. Signals of the diaminoglucuronic acid residue identified in the two-dimensional heteronuclear ^1H - ^{13}C NMR spectrum corroborated the structure of the molecular skeleton: the ^{13}C NMR spectrum contained a signal at 173.0 ppm [COOH group at C(6)] and signals at 55.3 and 56.5 ppm [the carbon atoms at C(2) and C(4) containing NHAc substituents]. Large coupling constant values for the ring protons in the ^1H NMR spectrum (9–10 Hz) showed the *gluco*-configuration of the acid **129**, and the data obtained during NOE measurements proved the D-configuration.

To the above statements concerning hexuronic acids it must be added that sometimes these monosaccharides are present in PS as amides. This fact may have a considerable influence on the immunochemical specificity of the whole biopolymer, since amides, in contrast to the parent acids, are neutral and their presence alters the distribution of charged groups along the polysaccharide chain. In this context, identification of a uronic acid amide and its localisation in the chain are integral parts of structural analysis of O-antigenic PS.

Up to the present, both unsubstituted glycuronamides and more complex compounds of this series with the carboxy group amidated, e.g., by an amino acid, have been found in PS (see Section 5).

Unsubstituted amides of uronic acids were detected in polysaccharides of various classes. For the first time, they were found in PS of several serotypes of *Pseudomonas aeruginosa*,¹²⁸ which contain 2-acetyl-amino-2-deoxy-D-galacturonamide. More recently, this same hexuronamide was detected in PS of *Shigella dysenteriae* 7¹⁰⁵ and *Vibrio anguillarum*.¹⁰⁷

Since identification of unsubstituted hexuronic acids is now being carried out by a non-destructive method on the basis of NMR spectra, and the spectra of the acid and its amide differ insignificantly, the presence of an amide group is usually established by the pH dependence of the position of the H(5) signal in the ^1H NMR spectrum: for an amide the chemical shift of this signal does not depend on pH, while in case of an acid the signal is shifted down-field with a decrease in pH (due to the effect of the adjacent carboxy group).¹⁴⁸ Thus, it was shown that the PS chain

of *Shigella dysenteriae* 7 contains two adjacent units, 2-acetylamino-2-deoxy-D-galacturonic acid and its amide: with a drop in pH from 9 to 1 the signal of H(5) of the acid residue is shifted from 4.40 to 4.63 ppm, whereas the chemical shift of the amide signal remains unchanged.

In conclusion, it should be noted that amidation of hexuronic acid residues in the PS chain may also be non-stoichiometric. In this case the same PS may comprise both a free acid and its amide, their quantitative ratio being different for PS of related serotypes or subtypes. This phenomenon was studied for several subtypes of PS of *Pseudomonas aeruginosa* O4 containing residues of both 2-deoxy-2-formylamino-D-galacturonic acid and its amide. By using anion-exchange and reversed-phase chromatography for separation of the trisaccharide fragments obtained from PS after solvolysis with liquid HF and study of the pH dependence of their ^1H NMR spectra, it was found that the degree of amidation of this uronic acid in subgroups O4a,4b, O4a,4d and O4a,4c is 10%, 20% and 0%, respectively.¹⁴⁸ Derivatives of more complex amides of uronic acids containing 'non-carbohydrate substituents' will be considered in Section 5.

9. Glycosonic acids

Glycosonic acids are α -keto acids of the carbohydrate series. These acidic monosaccharides which have a peculiar structure are found in various PS of microbial origin; however, the main source of glycosonic acids is extracellular and capsular PS. The chain of natural glycosonic acids may comprise 5 to 9 carbon atoms; some of those acids contain deoxy units and amino groups.

Most widespread representative of glycosonic acids in the microbial world is 3-deoxy-D-manno-octulosonic acid (KDO), an indispensable component of the inner core of all Gram-negative bacteria.¹⁴⁹ This acid, like some hexulosonic acids as well, was found in capsular PS of *Klebsiella* and some other bacteria (see review⁶).

In the present review we shall restrict our consideration to only some representatives of this class of acidic monosaccharides detected in O-antigenic PS of Gram-negative bacteria. Of those, most widespread is 5-amino-3,5-dideoxy-D-glycero-D-galactononulosonic acid **130** more commonly known as neuraminic acid. Derivatives of this acid having the common name of sialic acids are especially widely distributed in carbohydrate-containing biopolymers of animal tissues where they enter into the carbohydrate chains of glycoproteins and glycolipids and play a crucial role in the determination of specific biological properties and conversions of these biopolymers.¹⁵⁰

Residues of neuraminic acid and other glycosonic acids are present in the PS chain in the pyranose form **130** and have a deoxy unit adjacent to the anomeric centre. Derivatives of neuraminic acid are distinguished by high acid lability and are destroyed during hydrolysis of the carbohydrate-containing biopolymer. Perhaps, for this particular reason, derivatives of neuraminic acid were first identified in O-antigenic PS not long ago.

So far, *N*-acetyl derivatives of neuraminic acid have been found in O-antigenic PS of several bacteria: *Salmonella arizonae*,^{151, 152} *Citrobacter freundii*,¹⁵² *Escherichia coli*,¹⁵²⁻¹⁵⁶ *Hafnia alvei*^{152, 157} and *Vibrio cholerae*.¹⁵⁸ They are also present in some extracellular PS. One of such polysaccharides, the long known colaminic acid, is a homopolysaccharide composed of residues of *N*-acetylneuraminic acid.¹⁵⁹

Because of the wide occurrence of neuraminic acid derivatives in glycoproteins and glycolipids, their chemical properties and spectroscopic characteristics have been studied in great detail and are comprehensively discussed in reviews.^{150, 160} In this connec-

tion, identification of a neuraminic acid residue (or its derivatives) in O-antigenic PS is now being achieved by a non-destructive method based on the NMR spectroscopic analysis of the PS itself or of its oligosaccharide fragments.

Recently, another two structurally unique representatives of aminodeoxynonulosonic acids have been identified in O-antigenic PS. Derivatives of one of them, 5,7-diamino-3,5,7,9-tetradeoxy-L-glycero-L-manno-nonulosonic acid **131** (pseudaminic acid), were detected in PS of several serotypes of *Pseudomonas aeruginosa*,¹⁶¹⁻¹⁶³ *Shigella boydii* 7^{161, 162, 164} and *Vibrio cholerae* O2.¹⁶⁵

In the monosaccharides of these PS (with the exception of *V. cholerae* PS) the amino group at C(5) is acetylated, while the amino group at C(7) carries a formyl group or a residue of 3-hydroxybutyric acid. In the case of *V. cholerae* PS, the monosaccharide contains an acetylated amino group at C(7) and an acetimidoyl group at the amino group at C(5).

Originally, the presence in these PS of a pseudaminic acid residue was established by a qualitative reaction for *N*-acetylneuraminic acid with the resorcinol reagent.¹⁶⁶ Furthermore, the ^{13}C NMR spectra of the fragments obtained by acid hydrolysis of PS contained signals characteristic of a 3-deoxyaldulosonic acid.

In view of the high lability of pseudaminic acid derivatives towards acids, the establishment of their structure met considerable difficulties. The main approaches^{161, 162, 164} used for determination of their complete structure can briefly be summarised as follows. Carboxy groups of PS isolated from *S. boydii* 7 and *P. aeruginosa* O10 were first reduced, and then the PS were subjected to hydrolysis. This was accompanied by cleavage of the glycosidic bonds of the reduced pseudaminic acid residues; however, the monosaccharide residues themselves that are deprived of their carboxy groups were not destroyed. The products of the hydrolysis were then treated with NaBH_4 . After methylation of the hydroxy groups, the oligosaccharide was solvolysed with liquid HF. The resulting mixture of partially methylated monosaccharides (in which the *N*-acylated amino groups were also *N*-methylated) was reduced with NaBH_4 and acetylated. Chromato-mass spectrometry of the mixture of partially methylated alditol acetates obtained after degradation of PS of *P. aeruginosa* O10 revealed the presence of the alditol **132** containing nine carbon atoms and corresponding to the residue of pseudaminic acid. Its fragmentation allowed establishment of the structure of the skeleton and localisation of deoxy units [at C(3) and C(9)] and aminoacyl substituents [at C(5) and C(7)].

These data were confirmed by NMR spectroscopy of several oligosaccharides containing residues of pseudaminic acid, which were obtained by degradation of PS. For example, the ^{13}C NMR spectrum of the oligosaccharide 133 obtained by very mild acid hydrolysis of PS from *P. aeruginosa* O5 contained signals belonging to the residue of pseudaminic acid: at 99.7 ppm [C(2)] and 34.8 ppm [a deoxy unit at C(3)]. The ^{13}C NMR spectrum of the oligosaccharide 134 obtained by solvolysis of PS from *P. aeruginosa* O10a with liquid HF contained signals at 37.1 ppm [a deoxy unit at C(3)], 49.1 ppm [C(5) carrying an aminoacyl substituent], 54.7 ppm [C(7) carrying an aminoacyl substituent] and 17.7 ppm [a CH_3 group at C(9)]. A slight difference between the chemical shifts in the ^{13}C NMR spectra of the compounds 133 and 134 is attributed to the difference in the substituents of the amino groups of pseudaminic acid in the fragments obtained from different bacteria. The ^1H NMR spectra of the oligosaccharides 133 and 134 fully corroborate the structure described above.

The configuration of pseudaminic acid was established by analysis of the ^1H NMR spectra of the fragment 135 obtained from PS of *S. boydii* 7 by three successive Smith degradations followed by its conversion into the methyl ester and acetylation. The spectrum of the compound 135 is characterised by the following coupling constant values for the ring protons: $J_{3,4} = 13$, $J_{4,5} = 3.5$, $J_{5,6} = 1.6$ Hz, that indicate the axial orientation of H(4) and the equatorial orientation of H(5). The equatorial orientation of the substituent at C(6) was confirmed by NOE measurements which indicated the proximity of H(7) and of the NH proton at C(5).

These data suggest that the C(4)–C(5)–C(6) fragment of pseudaminic acid has the *lyxo*-configuration. A large coupling constant value ($J_{6,7} = 10$ Hz) and a strong NOE on H(5) and H(6) caused by preirradiation of the NH proton at C(7) proved the *erythro*-configuration of the C(6)–C(7) fragment. Finally, the *L-erythro*-configuration of the C(7)–C(8) fragment of pseudaminic acid was established by comparison of the glycosylation effects on C(9) of pseudaminic acid and on C(1) of the glucosamine residue (linked by the glycosidic bond to C(8) of pseudaminic acid in the polysaccharide chain) as well as by analysis of the ^{13}C NMR spectra of model compounds, glycosylated derivatives of D- and L-threonine and of D- and L-*allo*-threonine. These data suggested that the C(7)–C(8)–C(9) fragment of pseudaminic acid is homomorphous with the fragment of L-*allo*-threonine, i.e., that the C(7)–C(8) fragment has the *L-erythro*-configuration. Therefore, pseudaminic acid has the *L-glycero-L-manno*-configuration 131.¹⁶¹

Later, identification of pseudaminic acid derivatives in PS was performed using ^1H and ^{13}C NMR spectroscopy (including NOE measurements) taking into account the above data.^{163,165}

Derivatives of a pseudaminic acid isomer, 5,7-diacylamino-3,5,7,9-tetra-deoxy-D-*glycero*-L-*galacto*-nonulosonic acid 136, were found in O-antigenic PS of *Salmonella arizonae* O61,¹⁶⁷ *Pseudomonas aeruginosa* O13,^{168,169} *Vibrio alginolyticus*¹⁷⁰ and *Legionella pneumophila* 1.¹⁷¹ The amino groups of this nonulosonic acid were acylated by various acids. A derivative was also found which contained an *N*-acetamidino group.¹⁷¹ The complete structure of this acid was established by the same methods as described for pseudaminic acid.^{168,169} Solvolysis of PS of *P. aeruginosa* O13 with an HF solution in methanol resulted in the disaccharide 137 containing residues of the nonulosonic acid 136 and fucosamine. After treatment with acetic anhydride in pyridine, the disaccharide 137 underwent intramolecular cyclisation to give the lactam 138.

The composition of the compounds 137 and 138 was confirmed by determination of their molecular weights using FAB mass spectrometry. The ^{13}C NMR spectra of the compounds 137 and 138 contained signals at 19.7 ppm [a CH_3 group at C(9)], at 54.4 and 53.8 ppm [C(7) and C(5) carrying acylamino groups] and 42–41 ppm [a deoxy unit at C(3)]. The data obtained by ^1H NMR spectroscopy were fully consistent with this structure of the nonulosonic acid skeleton. The presence in the ^1H NMR spectra of characteristic coupling constant values for the ring protons ($J_{3a,3e} = J_{3a,4} = 12$, $J_{3e,4} = 4.2$, $J_{4,5} = J_{5,6} = 10$ Hz) demonstrated the axial orientation of the protons in the C(4)–C(5)–C(6) fragment of the nonulosonic acid and, consequently, its *arabino*-configuration. A small coupling constant value ($J_{6,7} = 2.5$ Hz), which is close to the corresponding value for *N*-acetylneuraminic acid (1.5 Hz) but different from that for pseudaminic acid (10 Hz), indicates the *threo*-configuration of the C(6)–C(7) fragment. Finally, the C(7)–C(8) fragment was also assigned the *D-threo*-configuration which, as in the previous case, was established on the basis of glycosylation data for the nonulosonic acid 136 and model glycosides of *N*-acetylgalactosamine, D- and L-threonine, D- and L-*allo*-threonine.

Therefore, the nonulosonic acid 136 was ascribed the D-*glycero*-L-*galacto*-configuration. Later, this monosaccharide containing various *N*-substituents was detected in PS of other bacteria.^{167,170,171} Its identification was carried out mainly by non-destructive methods on the basis of NMR spectral data, some of which were partly listed above. Analysis of oligosaccharide

fragments obtained by partial cleavage of PS was performed only in a few particular cases.

Among biopolymers containing the nonulosonic acid **136**, PS of *Legionella pneumophila* (the pathogen of a severe lung disease, so-called 'Legionnaires disease') is of special interest.¹⁷¹ This PS is a homopolysaccharide built up of residues of a derivative of 5,7-diamino-3,5,7,9-tetradeoxy-D-glycero-L-galacto-nonulosonic acid with acetamido and N-acetylamino groups at C(5) and C(7), respectively, and is the first example of a polysaccharide of this type. It should be stressed that identification of this nonulosonic acid and establishment of the structure of the whole PS was carried out by a non-destructive method on the basis of NMR spectral data alone.

In conclusion, it should be noted that to finally solve the question concerning the structure and, especially, the configuration of the representatives of this novel class of monosaccharides, it is most desirable to carry out counterflow syntheses of both 5,7-diamino-3,5,7,9-tetradeoxynonulosonic acids **131** and **136**.

IV. Non-carbohydrate substituents in monosaccharide units

As indicated in the Introduction, the second factor determining the differentiation of monomeric components in O-antigenic PS and the diversity of their structures is the presence in PS of so-called 'non-carbohydrate' substituents. The presence of such substituents markedly and, sometimes, dramatically alters the spatial structure of the polysaccharide chain and the general 'topography' of the polysaccharide molecule by exposing on its surface additional polar and hydrophobic groups which eventually determine the specificity of its interaction with the protein (antibody) surface, i.e., its immunologic specificity.

It should be noted that, although the presence of some non-carbohydrate substituents in polysaccharides of various origin, e.g., in plant PS, is well known, these are microbial PS and, particularly, O-antigenic PS of Gram-negative bacteria that contain an especially great variety of such substituents. These substituents can modify hydroxy groups of monosaccharides, amino groups of amino sugars and carboxy groups of acids of the carbohydrate series.

O-Substituted monosaccharides may include ethers or esters, the latter being far more widely spread. Also known are monosaccharides carrying an acetal group linked to two hydroxy groups of a monosaccharide unit.

Exclusively N-acylated derivatives are characteristic for amino sugars, whereas N-alkylated monosaccharides are practically unknown in O-antigenic PS. The carboxy groups of uronic acids appear to be most frequently substituted to give an amide group, both unsubstituted amides and more complex derivatives, including, in particular, an amino acid residue being known. Finally, residues of phosphoric acid and some of its derivatives have also been detected in O-antigenic PS as non-carbohydrate substituents.

Establishment of the structure and localisation of a non-carbohydrate substituent in a carbohydrate unit of PS presents a separate and often complicated problem. Since in recent years the number and diversity of non-carbohydrate substituents detected in O-antigenic PS is growing fast, the search for the most effective ways to solve these problems is becoming more and more important in the chemistry of O-antigenic PS. One of these consists in selective cleavage of the non-carbohydrate substituent with subsequent determination of its structure by conventional methods; however, the problem of its localisation in the polysaccharide chain cannot be solved by this approach. Another approach is confined to isolation of the corresponding substituted monosaccharide followed by its structural analysis. Regrettably, both pathways are not always practicable, since attempts to cleave the non-carbohydrate substituent or to isolate the substituted monosaccharide often result in irreversible changes or even complete destruction of the compounds being isolated. For this

reason, the problem of elucidation of the structure is now being solved using physicochemical methods. This approach permits determination of the nature and localisation of the non-carbohydrate substituent directly by analysis of PS or oligosaccharide fragments obtained by its specific degradation.

1. O-Alkyl substituents

Substitution of hydroxy groups in monosaccharide units of O-antigenic PS with formation of the ether bond occurs rarely. Only O-methyl and 1-carboxyethyl ethers are now known.

a. O-Methyl ethers

Partially methylated monosaccharides are rather widely distributed in plant PS. Among microbial PS, they are mostly found in extracellular and capsular PS as well as in PS of photosynthetic bacteria (see review⁶); in O-antigenic PS they were detected only in a few cases. It is believed that methylation of a monosaccharide hydroxy group takes place during one of the stages of PS biosynthesis, the SMe group of methionine being the donor of the methyl group.

3-O-Methyl-L-xylose was found in PS of *Pseudomonas maltophilia* NCTC 10257,¹⁷² where it occupies the terminal position in the side chains of the branched PS. This sugar was isolated after acid hydrolysis of PS and identified by routine methods (comparison with an authentic sample).

3-O-Methyl-L-rhamnose was isolated from O-antigenic PS of *Klebsiella* O10¹⁷³ by acid hydrolysis. This monosaccharide occupies the terminal position at the non-reducing end of the polysaccharide chain. To establish its structure, the PS was first deuteromethylated with CD₃I and then hydrolysed. The resulting monosaccharide was converted into the alditol acetate **139** and analysed by mass spectrometry. Its mass spectrum contained peaks corresponding to the fragments with *m/z* 164, 134, 178 and 120 which corroborated unambiguously the structure of 3-O-methylrhamnose.

It is likely that the presence of both methylated monosaccharides at the ends of the polysaccharide chains serves as a signal for termination of further elongation of this chain during biosynthesis.

3-O-Methyl-D-glycero-D-altro-heptose and 3-O-methyl-6-deoxy-D-altro-heptose were found in some PS of *Campylobacter jejuni* where they partially substitute hydroxy groups.⁷⁶ Interestingly, the ratio of methylated to non-methylated monosaccharides in PS is determined by the cultivation conditions of these bacteria, although the actual reason for this phenomenon still remains to be elucidated. The structure of both methylated heptoses was established by mass spectrometry of partially methylated alditol acetates derived from PS after deuteromethylation, hydrolysis and reduction (see above).

b. 1-Carboxyethyl ethers (glycolactylic acids)

Glycolactylic acids present in O-antigenic PS contain a residue of lactic acid linked by the ether bond to the sugar molecule. Compounds of this type were first detected in peptidoglycan of the bacterial cell wall (muramic acid and its *manno*-isomer^{174,175}). Later, they were also found in O-antigenic and some other microbial PS (exocellular PS, capsular PS and PS of photosynthetic bacteria). Thus, glycolactylic acids are a rather large group of acidic monosaccharides.

The ether bond in these acids is rather stable; therefore, they can be isolated in the pure state after acid hydrolysis of PS using ion-exchange chromatography. Representatives of this class differ from one another by the nature of the parent monosaccharide, the absolute configuration of the lactic acid residue and its localisation. So far, the following representatives of glycolactic acids have been isolated from O-antigenic PS of Gram-negative bacteria: derivatives of D-glucose, L-rhamnose and 2-acetyl-amino-2-deoxy-D-glucose usually containing a residue of (*R*)-lactic acid, although the derivatives of the (*S*)-isomer are also known. In addition, PS of other microorganisms contain derivatives of D-mannose¹⁷⁶ and D-glucuronic acid.¹⁷⁷

Initially, the structure of glycolactic acid was established by classical chemical methods and mass spectrometry. However, more recent studies employed NMR spectroscopy for this purpose. An illustrative example of the classical approach is the establishment of the structure of glucolactic acid isolated from PS of *Shigella dysenteriae* 3.^{178,179} The substituted monosaccharide was isolated in the pure state from the acid hydrolysate of PS; its ¹H NMR spectrum contained a characteristic signal of a methyl group CH₃—CH at 1.4 ppm (d, *J* = 6.0 Hz). Its treatment with BCl₃ resulted in cleavage of the ether bond to form D-glucose. To establish the site of attachment of the lactic acid residue to the glucose residue, the polysaccharide was methylated, reduced with LiAlH₄ and hydrolysed. The resulting mixture of monosaccharides was converted into alditol acetates by reduction with NaBD₄ and subsequent acetylation. Chromato-mass spectrometry of the alditol acetate mixture revealed the tetraacetate **140** whose fragmentation provided evidence for its structure: a fragment with *m/z* 101 showed the presence of a propanediol residue (formed by reduction of the lactic acid carboxy group), and fragments with *m/z* 118, 291 and 162 indicated the site of its binding to C(4) of glucose. Based on these data, the original monosaccharide was ascribed the structure of 4-*O*-(1'-carboxyethyl)-D-glucose **141**.

The absolute configuration of the lactic acid residue was established by counterflow synthesis of glucolactic acid¹⁷⁹ using condensation of methyl 2,3,6-tri-*O*-benzyl- α -D-glycopyranoside **142** with (*S*)-2-chloropropionic acid (obtained from L-alanine) in the presence of sodium hydride (Scheme 13). Treat-

Scheme 13

ment of the condensation product **143** with diazomethane and elimination of the benzyl groups gave the methyl glycoside of the methyl ester of the glucolactic acid **144** whose physicochemical characteristics (including the specific optical rotation) were identical to those of the natural product. Thus, in the natural compound the residue of lactic acid has the (*R*)-configuration, and this glycolactic acid is 4-*O*-[(*R*)-1'-carboxyethyl]-D-glucose **141**.

The glycolactic acid **141** was also found in PS of an immunochemically related to *Shigella dysenteriae* 3 bacterium *Escherichia coli* O124 and identified in the same way. Moreover, the PS structures in both bacteria, *S. dysenteriae* 7 and *E. coli* O124, appeared to be identical. This fact provided the first experimental proof that bacteria with identical immunochemical specificity, even those belonging in biological classification to different species, contain the structurally identical PS.¹⁸⁰ Notice that another glycolactic acid, 4-*O*-[(*S*)-1'-carboxyethyl]-D-glucose, isomeric by the lactic acid residue to the glycolactic acid **141**, was isolated from an extracellular PS of the bacterium *Aerococcus viridans*.⁶

An isomeric glucolactic acid, 3-*O*-[(*R*)-1'-carboxyethyl]-D-glucose **145**, has recently been isolated in the pure state from PS of *Aeromonas haloplanktis*¹⁸¹ after acid hydrolysis of PS with trifluoroacetic acid. Its structure was established by NMR spectroscopy. The ¹H NMR spectrum contained signals characteristic of a lactic acid residue: at 1.45 (d, 7.0 Hz, a CH₃ group) and 4.41 ppm (q, a CH group) as well as signals characteristic of the glucose residue. The ¹³C NMR spectrum also contained signals characteristic of the lactic acid residue: at 19.6 (CH₃ group) and 79.5 ppm (CH group). The signal of C(3) of the glucose residue was shifted down-field to 83 ppm in comparison with the signal of unsubstituted glucose, indicating the binding of lactic acid residue to this atom. This structure was also confirmed by full coincidence of the NMR spectra for the acid **145** and the glucolactic acid isolated from a capsular polysaccharide of *Pseudomonas fragi*, for which the same structure had been established.¹⁸² The D-configuration of the glucose residue was evident from the regularities in the glycosylation effects determined from the ¹³C NMR spectrum of the original PS; the (*R*)-configuration of the lactic acid residue was suggested on the basis of the specific optical rotation of the acid **145**.

The structure of other glycolactic acids was established in a similar way (using the methods available at the time of the investigation). Thus, the 3-*O*-[(*R*)-1'-carboxyethyl]-L-rhamnose **146** (rhamnolactic acid) isolated from *Shigella dysenteriae* 5,¹⁸³ after treatment with BCl₃ gave L-rhamnose, and the mass spectrum of the partially methylated alditol **147** derived from PS revealed the presence of a lactic acid residue bound to C(3) of rhamnose. The (*R*)-configuration of the lactic acid residue was established by counterflow synthesis. More recently, this acid was isolated from PS of *Vibrio fluvialis*¹⁸⁴ and its structure was confirmed by NMR spectroscopy. The ¹H NMR spectrum contained signals at 1.42 and 4.33 ppm (a lactic acid residue) and a set of characteristic signals of the rhamnose residue. The conclusion about the (*R*)-configuration of the lactic acid residue was made on the basis of comparison of the chromatographic behaviour and optical rotation of the sample tested with synthetic samples of the (*R*)- and (*S*)-isomers of this rhamnolactic acid.¹⁷⁰

A glycolactylic acid derived from glucosamine, 2-acetyl-amino-3-*O*-[(*S*)-1'-carboxyethyl]-2-deoxy-D-glucose **148**, was found in O-antigenic PS of *Proteus penneri* 62.¹⁸⁵ Its structure was established by spectral data. The ¹H and ¹³C NMR spectra of the polysaccharide contained signals characteristic of the lactic acid residue [1.31, (d, *J* = 7 Hz) and 4.05 ppm (q) (¹H NMR) and, correspondingly, 20.3, 80.6 and 182.9 ppm (¹³C NMR)] and of the glucosamine residue. The ¹³C NMR spectrum revealed a characteristic down-field shift of the C(3) signal, indicating substitution of the corresponding hydroxy group. The monosaccharide was isolated in the pure state after solvolysis of PS with liquid HF. Its spectrum coincided with that of 2-acetyl-amino-3-*O*-[(*S*)-1'-carboxyethyl]-2-deoxy-D-glucose but differed from that of the well-known muramic acid¹⁷⁴ with the (*R*)-configuration of the lactic acid residue. On the basis of these data and using the specific optical rotation differing markedly from the corresponding value for muramic acid, the novel glycolactylic acid was ascribed the (*S*)-configuration. This compound is known as isomuramic acid.

Recently, PS of another serotype of the same species of *Proteus penneri* 35 was found to contain an isomer of isomuramic acid, 2-acetyl-amino-4-*O*-[(*S*)-1'-carboxyethyl]-2-deoxy-D-glucose, whose structure was established by similar methods.¹⁸⁶

Apart from the compounds described above, some other glycolactylic acids were identified. Thus, a capsular PS of *Klebsiella* K37 was found to contain 4-*O*-[(*S*)-1'-carboxyethyl]-D-glucuronic acid,¹⁷⁷ whereas an extracellular PS of *Mycobacterium lacticum* 121 4-*O*-[(*S*)-1'-carboxyethyl]-D-mannose;¹⁷⁶ their structures were established by the approaches described above.¹⁸⁷

2. Acetal (carboxyethylidene) groups

Monosaccharides carrying acetal groups with two hydroxy groups of the monosaccharide simultaneously substituted by a pyruvic acid residue (carboxyethylidene groups) are rather widely spread in exocellular and capsular PS. Methods have been developed for determination of the structure of their derivatives present in PS. In O-antigenic PS of Gram-negative bacteria, monosaccharides carrying carboxyethylidene groups have thus far been detected only in PS of *Shigella dysenteriae* 9¹⁸⁸ and *Escherichia coli* O149.¹⁸⁹ NMR spectroscopy in combination with chemical methods is used to identify this group. Thus, the ¹H NMR spectrum of PS of *S. dysenteriae* 9 contains a signal at 1.60 ppm that is characteristic of the methyl group of the pyruvic acid residue. This group is not affected by basic treatment of PS but gradually disappears during treatment of PS with dilute acetic acid, thus suggesting the binding of the pyruvic acid residue as an acetal. The nature of the monosaccharide unit carrying this substituent and the substitution site were established by comparing the results of PS methylation before and after its deacetalation with acetic acid: in the former case hydrolysis of methylated PS resulted in 2-*O*-methylgalactose, while in the latter case, in 2,4,6-tri-*O*-methyl-D-galactopyranose. It was thus demonstrated that

the carboxyethylidene group modified the hydroxy groups at C(4) and C(6) of galactose, and the monomeric unit of PS is 4,6-*O*-(1'-carboxyethylidene)-D-galactose **149**.

The ¹H NMR spectrum of *E. coli* PS also contains a signal at 1.50 ppm, and the ¹³C NMR spectrum has signals at 25.4 and 101.3 ppm characteristic of the pyruvic acid residue. As in the previous case, the position of this residue was established by comparison of the products of methylation of the native and deacetalised PS which revealed that the carboxyethylidene group binds to C(4) and C(6) of *N*-acetylglucosamine. Therefore, the substituted monosaccharide has the structure of 2-acetyl-amino-4,6-*O*-(1'-carboxyethylidene)-2-deoxy-D-glucose **150**.

Introduction of the carboxyethylidene group into the monosaccharide results in the formation of a new chiral centre whose configuration can be easily established by ¹³C NMR.¹⁹⁰ Depending on the conformation of the dioxane ring of the 4,6-di-*O*-substituted monosaccharide, the methyl and carboxy groups can have either axial or equatorial orientation that can be readily determined by the values of the chemical shifts of the corresponding signals. With the known conformation of the dioxane ring (defined by the structure of the parent monosaccharide), the relative position of the CH₃ and COOH groups determined from the NMR spectra provides direct evidence for the (*R*)- or (*S*)-configuration of the central carbon atom of the acetal group.¹⁹⁰ This approach was used to establish the (*S*)-configuration of the pyruvic acid residue in PS of *E. coli* O149.

The acetal group, like the lactic acid residue in glycolactylic acids, is introduced into PS in the course of PS biosynthesis in the cell by reaction of the corresponding monosaccharide with the enol form of pyruvic acid catalysed by a specific enzyme. The ester formed is probably reduced to give the (*R*)- or (*S*)-isomer of a glycolactylic acid, which, in the case of a suitable spatial arrangement of the adjacent hydroxy group, can further be converted into the corresponding acetal. An alternative pathway, namely, direct binding of the hydroxy group to the double bond of the intermediate enol (Scheme 14), is also not excluded.

Scheme 14

It was thus demonstrated that

3. O-Acyl substituents

Substitution of hydroxy groups in monosaccharide residues of PS by residues of aliphatic acids is common for plant and microbial polysaccharides. Usually, *O*-acetylation takes place but acylation with other aliphatic (including higher fatty acids) and hydroxy acids is also known. Thus, the aliphatic acids C_{12} – C_{16} and hydroxycarboxylic acids of this series are indispensable components of the lipid part of LPS (the so-called lipid A) where they acylate glucosamine residues, thereby providing the high lipophilic character of LPS needed for its fixation in the outer cellular membrane of Gram-negative bacteria.¹

O-Acetylation of particular hydroxy groups in certain monosaccharide units of the *O*-antigenic polysaccharide chain is essential for the determination of immunochemical specificity of PS. To fully characterise this epitope of the *O*-antigen, it is necessary to establish the precise localisation of the *O*-acetyl group. The assignment of the *O*-acetyl group to a certain monosaccharide unit in the PS chain is a routine task which can readily be solved using 1H and ^{13}C NMR spectroscopy.

Evidence for the presence of other *O*-acyl groups in *O*-antigenic PS is almost absent. The only experimental proof seems to be the presence of the *O*-propionyl group in PS of *Vibrio anguillarum*.⁹⁶

The paucity of variation of *O*-acyl groups seems to be remarkable, especially in comparison with the great diversity of aliphatic acids acylating amino groups of monosaccharides in *O*-antigenic PS.

4. N-Acyl substituents

The occurrence of monosaccharides with acylated amino groups in various natural compounds is a common but not compulsory phenomenon, whereas polysaccharides almost always contain residues of amino sugars with acylated amino groups. Most frequently, PS comprise *N*-acetyl derivatives, while derivatives of other organic acids are far less common. The exception is *O*-antigenic PS of Gram-negative bacteria, where the diversity of acids acylating amino groups is rather high and includes simplest aliphatic acids, hydroxy and polyhydroxy acids, and amino acids. Monosaccharides containing two amino groups can be acylated by the same or by two different acids (this is also true of the amino groups in different monosaccharide units of PS).

The great diversity of acids acylating amino groups in *O*-antigenic PS has become especially apparent recently, mainly due to the rapid progress in NMR spectroscopy. At present, the nature of *N*-acyl substituents and their position in PS is almost exclusively established by NMR spectroscopy of the PS themselves or of their fragments obtained by their specific degradation. Mass spectrometry is also used for this purpose.

a. *N*-Acylation by aliphatic acids

The most common substituents in *O*-antigenic PS are *N*-acetyl groups. Their identification is a routine task which is most often solved during interpretation of the NMR spectra of PS (by the presence of characteristic signals of the $NHCOCH_3$ group). For example, in the ^{13}C NMR spectrum the signals at 22.0–24.0 (CH_3 group) and 174–177 ppm (CO group) correspond to this group.

Localisation of the *N*-acetyl group is evident from the characteristic shift caused by this substituent in the neighbouring carbon atom and proton: in the ^{13}C NMR spectrum, it is a signal in the region 45–58 ppm; in the 1H NMR spectrum, the signal of a ring proton in the region 3.8–4.3 ppm. These data, after reliable assignment of the signal, allow both simultaneous identification of the monosaccharide unit carrying this substituent and localisation of the substituent in this unit.

Substitution of the amino group by a residue of formic acid occurs less frequently. *N*-Formyl groups were found in PS of *Escherichia coli* O119,¹²⁰ *Yersinia enterocolitica* O9,¹¹⁵ *Pseudomonas aeruginosa* O4¹²⁸ and related serotypes as well as in PS of *Vibrio anguillarum*,¹⁰⁷ *Brucella*^{110, 191} and *Francisella tularensis*¹⁰⁶ where they are localised in residues of 2,3-diamino-2,3,6-trideoxy-

D-mannose,¹²⁰ 4-amino-4,6-dideoxy-D-mannose,^{110, 115} 2-amino-2-deoxy-D-galacturonic acid^{107, 128} and 4-amino-4,6-dideoxy-D-glucose.¹⁰⁶

The presence of an *N*-formyl group can be readily established by the presence in the ^{13}C NMR spectrum of a signal in the 166–169 ppm region.

Since rotation around the CO–NH bond is restricted, and the NHCHO group may exist in stable *cis*- or *trans*-conformations, a splitting of the proton signals is characteristic of this group. By comparing the intensities of these signals, one can draw a conclusion about the ratio of both conformers.¹⁹² Localisation of the *N*-formyl group in PS is also evident from the NMR spectral data. Thus, a characteristic shift of the signal of the C atom carrying the NHCHO group (45–55 ppm) is observed in the ^{13}C NMR spectrum.

Sometimes, the presence and localisation of the *N*-formyl group is determined by mass spectroscopic analysis. Thus, the aminoalditol 151, whose mass spectrum clearly indicated the presence of an *N*-formyl group and its localisation at C(4) of 4,6-dideoxy-4-(*N*-formylamino)-D-mannose,¹¹⁰ was isolated from PS of the bacterium *Brucella melitensis* after methylation (involving the NH group of the formamide residue), solvolysis with liquid HF and subsequent conversion of the degradation products into acetates of partially methylated alditols.

The *N*-formyl group is fully cleaved by mild acid treatment of PS to give a PS with free amino groups. At the same time, this group is stable towards solvolysis with liquid HF and retained in fragments formed by degradation of PS that is employed in their structural analysis.

One of unusual *N*-acylating groups thus far found only in *O*-antigenic PS is the *N*-acetimidoyl (amidino) group, $CH_3C(=NH)-$. It was first detected in PS of several species of *Pseudomonas*,^{143, 144, 193} and, later, in PS of *Vibrio cholerae*,¹⁶⁵ *Salmonella arizonae*^{151, 167} and *Legionella pneumophila*¹⁷¹ where it acylates the amino groups of aminuronic and aminononulosonic acids to form the corresponding amidines.

The *N*-acetimidoyl group has a basic nature and it confers it on the whole PS. Its presence is readily detectable spectroscopically. Thus, the ^{13}C NMR spectrum contains signals at 19.5–21 ppm (CH_3 group) and 167–169 ppm ($N=C-N$ group), whereas the signal of the carbon atom carrying the *N*-acetimidoyl group has a chemical shift of 45–57 ppm; the 1H NMR spectrum contains a singlet at 2.2–2.4 ppm.

The amidino group is not cleaved by treatment with liquid HF; however, upon basic treatment (e.g., with triethylamine) or reduction with $LiAlH_4$, it is converted into the *N*-acetyl amino group or the *N*-ethyl amino group, respectively (Scheme 15). This property is often used in structural analyses of PS or their fragments, since these conversions of the amidino group are readily controlled by NMR spectroscopy. Thus, transformation of the amidino group to the *N*-acetyl amino group is accompanied by the appearance of a signal near 2 ppm in the 1H NMR

Scheme 15

spectrum and signals near 23 and 176 ppm in the ^{13}C NMR spectrum. When the amidino group is reduced to the *N*-ethylamino group, the changes are even more apparent: the ^1H NMR spectrum becomes a triplet at 1.35 ppm ($J = 7.5$ Hz, CH_3 group) and a quadruplet at 3.2–3.4 ppm (CH_2 group), and the ^{13}C NMR spectrum signals at 11–13 (CH_3 group) and 42–45 ppm (CH_2 group). In the process, the signal of the corresponding C atom of the pyranose ring is shifted to 62 ppm, and that of the attached proton from 3.86 to 3.62 ppm. In the spectra of a specially synthesised model compound, methyl 3-acetimido-1,3,6-dideoxy- α -L-glucopyranose, the changes were essentially the same.¹⁹⁴

As an example of identification and localisation of the acetimidoyl group, we may refer to the analysis of PS isolated from *Pseudomonas aeruginosa* O2.¹⁴³

The ^{13}C NMR spectrum of this PS contained signals at 19.9 and 167.3 ppm indicating the presence of an acetimidoyl group. Solvolysis of PS with liquid HF and subsequent reduction of degradation products with NaBH_4 gave a derivative of the trisaccharide **152** containing an acetimidoyl group. The composition of the trisaccharide **152** was corroborated by an analysis of the FAB mass spectrum. The ^{13}C NMR spectrum of the compound **152** contained signals characteristic of an acetimidoyl group localised in a residue of 2,3-diamino-2,3-dideoxy-D-mannuronic acid. The signals of the ring carbons, C(2) and C(3), at 50.9 and 55.7 ppm showed the presence of two *N*-containing substituents, one of which was an amidino group. Upon reduction of the trisaccharide **152** with LiAlH_4 , the amidino substituent was converted into the *N*-ethylamino group, corroborated by the corresponding changes in the NMR spectra (see above). Thus, the signal of the ring carbon C(3) was shifted from 57.7 to 61.4 ppm, while after treatment of **152** with triethylamine the amidino group was converted into the *N*-acetyl amino group, and the signal of C(3) shifted to 54.4 ppm. In both cases, the position of the C(2) signal did not change. These data suggest unambiguously that in the PS studied the amidino group is located at C(3) of the diaminomannuronic acid residue.

Similar methods were used to reveal the presence of the *N*-acetimidoyl substituent at the amino group of 2-amino-2,6-dideoxy-D-galactose in PS of *S. arizonae* O21,¹⁵¹ *S. arizonae* O61,¹⁶⁷ *P. aeruginosa* O12 and at the C(5) amino groups of 5,7-diamino-3,5,7,9-tetra-deoxy-L-glycero-L-manno-nonulosonic acid in PS of *Vibrio cholerae*¹⁶⁵ and its D-glycero-L-galactoisomer in PS of *Legionella pneumophila*.¹⁷¹

It is interesting to note that originally the monosaccharide forming a part of PS of several serotypes of *P. aeruginosa* and simultaneously containing an *N*-acetimidoyl and an *N*-acetyl group, was erroneously ascribed, on the basis of spectral data, the structure **153** containing a bicyclic pyrano-imidazoline system (which is quite admissible because the substituents at the C(2) and C(3) atoms were in the equatorial-axial position).^{139,140} This conclusion was revised¹⁴¹ on the grounds that the FAB-mass spectra of fragments obtained by degradation of PS lacked molecular ions corresponding to the imidazoline group but

contained ions corresponding to the acetimidoyl and acetyl amino groups which were localised by the methods indicated above.

b. *N*-Acylation by hydroxy- and polyhydroxy-acids

Apart from amino sugars *N*-acylated by unsubstituted aliphatic acids, O-antigenic PS often contain derivatives of hydroxy and polyhydroxy acids of the aliphatic series; most commonly, these are C_2 – C_6 acids having one or two hydroxy groups (3-hydroxypropionic, L-glyceric, 3- and 4-hydroxybutyric, 2,4-dihydroxybutyric and 3,5-dihydroxyhexanoic acids). The presence of hydroxy acid residues in the polysaccharide chain confers peculiar characteristics on its peripheral surface by simultaneously exposing both hydrophobic and hydrophilic regions that markedly increases the selectivity of its contacts (e.g., with the surface of an immunoglobulin during antigen-antibody interaction).

Establishment of the structure of hydroxy acids acylating amino groups of monosaccharides and determination of the site of their attachment to the monosaccharide is usually performed simultaneously with establishment of the structure of the monosaccharide itself (most often, using physicochemical methods).

Thus, PS of *Vibrio cholerae* 1875 was found to contain 3-hydroxypropionic acid¹⁹⁵ which acylates the amino group of 4-amino-4-deoxy-D-rhamnose (perosamine). The *N*-acylated monosaccharide was isolated after solvolysis of the polysaccharide with HF. Its structure, including the presence of a residue of 3-hydroxypropionic acid was established by NMR spectroscopy and confirmed by mass spectrometry. In particular, the ^1H NMR spectrum of its acetate contained signals at 4.58 (NH proton), 4.23 and 1.98 ppm (CH_2O and CH_2 groups of the hydroxyacyl residue). The presence and localisation of the 3-hydroxypropionyl residue was corroborated by mass spectrometry of alditol acetate **154**.

L-Glyceric acid was found in PS of *Citrobacter freundii* O32. This biopolymer can only conventionally be regarded as a polysaccharide, because its main chain contains alternating glycosidic and amidic bonds.¹⁹⁶ Glyceric acid acylates the amino group of 3-amino-3,6-dideoxy-D-fucose whose C(2')-hydroxy group is linked by the glycosidic bond to the adjacent residue of the same monosaccharide; as a result, a polymeric chain with alternating bond types is formed. Hydrolysis of the biopolymer with trifluoroacetic acid and subsequent reduction and acetylation of the resulting mixture of fragments gave a derivative of the corresponding alditol **155** whose mass spectrum revealed the presence of a monosaccharide *N*-acetylated by glyceric acid. The presence of the glyceric acid residue in the biopolymer was fully confirmed by characteristic signals in the ^{13}C NMR spectrum: at 173 [C(1)], 80.2 [C(2)] and 62.8 ppm [C(3)]. Glyceric acid was isolated from the acid hydrolysate of the polymer using paper electrophoresis; its specific optical rotation ($[\alpha]_D = -5.5^\circ$) proved the L-configuration.

(R)-3-Hydroxybutanoic (β -hydroxybutyric) acid was detected in a number of O-antigenic PS: *Escherichia coli* O10 (where it acylates the amino group of 4-amino-4-dideoxy-D-fucose),¹¹⁷ *Yersinia aldovae*¹⁹⁷ and *Proteus penneri* 16 (where it acylates the amino group of 3-amino-3-deoxy-D-fucose),¹⁹⁸ as well as in PS of several serotypes of *Hafnia alvei* (where it acylates the amino group of glucosamine or of 3-amino-3-deoxy-D-fucose),^{199,200} *Pseudomonas aeruginosa* O5 and O10, *Shigella boydii* O7 [where it acylates the amino group at C(5) or C(7) of 5,7-diamino-3,5,7,9-

tetradecoxy-L-glycero-L-manno-nonulosonic acid],^{162,163} and *Vibrio mimicus* 26768 (where it acylates the amino group of 3-amino-3-deoxy-D-quinovose).⁹⁵

The (S)-isomer of 3-hydroxybutanoic acid occurs less frequently: it was found in PS of *P. aeruginosa* O1 [where it acylates the amino group at C(4) of 2,4-diamino-2,4,6-trideoxy-D-glucose].¹²²

Identification of a 3-hydroxybutanoic acid residue and determination of the site of its attachment to the corresponding monosaccharide in the polysaccharide chain are usually performed by isolation of the N-substituted monosaccharide and its analysis by physicochemical methods. In some cases the PS is methylated, and an O-methyl derivative of the corresponding N-substituted monosaccharide is isolated and analysed. As a typical example, we may refer to identification of the residue of (R)-3-hydroxybutanoic acid in PS of *Escherichia coli* O10.¹¹⁷

Solvolysis of PS with liquid HF and subsequent mild acid hydrolysis gave, among other fragments, an N-acyl derivative of 4-amino-4-deoxy-D-fucose. This derivative was reduced with NaBD₄ and then acetylated. The mass spectrum of the acetate of the corresponding alditol **156** revealed unambiguously the presence and localisation of the residue of 3-hydroxybutanoic acid in the derivative of 4-amino-4,6-dideoxyhexose. Similar results were obtained in analysis of an O-methylated derivative of this alditol obtained after degradation of the methylated PS. The absolute (R)-configuration of this residue was established by its oxidation with specific D-3-hydroxybutyrate dehydrogenase in the presence of nicotinamide adenosine diphosphate.

In other cases, e.g., in studies of PS from *P. aeruginosa* and *S. boydii* 7,¹⁶² 3-hydroxybutanoic acid was isolated in the individual state and its structure was confirmed by spectroscopic data. The ¹H NMR spectrum of 3-hydroxybutanoic acid contained signals at 4.25 [H(3'), sextet; $J_{2,3} = J_{3,4} = 6$ Hz], 2.50 [H(2'), doublet] and 1.27 ppm [H(4'), doublet, $J = 6$ Hz]; the ¹³C NMR spectrum contained signals at 180.0 [C(1')], 44.8 [C(2')], 66.2 [C(3')] and 23.5 ppm [C(4')]. These characteristic signals were also detected in the NMR spectra of PS themselves containing residues of 3-hydroxybutanoic acid and are therefore employed for direct spectroscopic identification of this residue. If this acid is isolated in the pure state, its (R)- or (S)-character can be readily established from the specific optical rotation.

Usually, a repeating unit of O-antigenic PS contains not more than one residue of 3-hydroxybutanoic acid; other amino groups are acylated by other acids, most commonly, by acetic acid.¹⁶² Also, PS are known where the same amino group is partially substituted by an acetic acid residue and partially by a 3-hydroxybutanoic acid residue, as in PS of *E. coli* O10 where 60% of the amino groups in the 4-amino-4-deoxy-D-fucose residue are acylated by acetic acid and 40% by 3-hydroxybutanoic acid.¹¹⁷ This makes the polysaccharide chain irregular as could be evident from the NMR spectrum. The question still remains open as to whether such substitution has a heterogeneous character, that is, the same polysaccharide chain contains both substituents, or, in contrast, there exist two different polysaccharide chains, each of which is substituted only by the same residue. Because of the structural similarity of both chains and their rather high molecular mass, they cannot be separated by the currently available methods.

4-Hydroxybutanoic (γ-hydroxybutyric) acid has thus far been found only in O-antigenic PS of *Alteromonas macleodii* 2MM6, where it acylates the amino group of 3-amino-3-deoxy-D-fucose.¹³³ Hydrolysis of PS resulted in an N-acyl derivative of this monosaccharide. The ¹H NMR spectrum of this derivative contains, in addition to signals of the monosaccharide unit, characteristic signals of a residue of 4-hydroxybutanoic acid: at 2.37 [H(2'), triplet, $J_{2,3} = 8.0$ Hz], 1.85 [H(3'), multiplet, $J_{3,4} = 7.0$ Hz] and 3.62 ppm [H(4'), triplet]. The ¹³C NMR spectrum contained signals at 33.3 [C(2')], 28.7 [C(3')] and 61.8 ppm [C(4')]. The mass spectrum of the alditol acetate **157** derived from this monosaccharide confirmed the presence of a 4-hydroxybutanoic acid residue and its localisation at the amino group at C(3) of the monosaccharide.

(S)-2,4-Dihydroxybutanoic (3-deoxytetronic) acid was found in O-antigenic PS of *Vibrio cholerae* O1 where it acylates the amino group of 4-amino-4,6-dideoxy-D-mannose (perosamine).¹⁰⁹ This acid was isolated in the pure state after hydrolysis of PS with dilute trifluoroacetic acid and identified by NMR spectroscopy. The ¹³C NMR spectrum of this acid contained signals at 182.8 (CO group), 71.0 (CHOH group), 37.7 (CH₂ group) and 59.8 ppm (CH₂OH group). The ¹H NMR spectrum also fits this structure. The structure and localisation of the residue of (S)-2,4-dihydroxybutanoic acid was established using the mass spectrum of the acetate of the partially methylated alditol **158** obtained by solvolysis of methylated PS with liquid HF and subsequent reduction and acetylation of the corresponding N-acyl derivative of perosamine.

The (S)-configuration (L-glycero-configuration) of the acid residue was evident from the specific optical rotation ($[\alpha]_D = -8^\circ$) and confirmed by the identity of its ester with (R)-octan-2-ol to the corresponding synthetic sample.

3,5-Dihydroxyhexanoic acid was detected in PS of *Vibrio cholerae* O3 where it acylates the amino group at C(4) of 2,4-diamino-2,4,6-trideoxy-D-glucose (bacillosamine).⁵⁸ The other amino group of this monosaccharide is N-acetylated. The presence of 3,5-dihydroxyhexanoic acid in PS was corroborated by the presence in the ¹H NMR spectrum of signals characteristic of the fragment CH₃-CHOH-CH₂-CHOH-CH₂CO. The structure of the acid residue was also confirmed by the ¹³C NMR spectrum which contained signals at 45.0 [C(2')], 66.7 [C(3')], 46.1 [C(4')], 65.3 [C(5')] and 23.7 ppm [C(6')]. The mass spectrum of the methylated alditol **159** derived from PS by a conventional method also confirmed the presence and localisation of this acid residue at the corresponding amino group of bacillosamine. These conclusions are consistent with the results of mass spectrometric analysis of disaccharide fragments obtained by partial degradation of PS.

c. N-Acylation by amino acids

Among amino acids acylating an amino group of an amino sugar, mainly α -amino acids and some other more complex proline derivatives are known. Most commonly, PS contain only one amino acid residue per one repeating unit.

The finding of α -amino acids in PS of microbial origin presents substantial interest since it demonstrates the relationship between the two most important classes of carbohydrate-containing biopolymers: glycoproteins as typical representatives of the animal world and polysaccharides as classical biopolymers of microorganisms. Further expansion of our knowledge in this area may disclose interesting regularities in variations in biosynthetic pathways in the course of evolution.

An example of N-acylation of the chain of O-antigenic PS by an amino acid is acylation of the amino group of 4-amino-4,6-dideoxy-D-glucose (4-amino-4-deoxy-D-quinovose) by glycine, the amino group of the glycine itself being acetylated. This derivative was detected in PS of *Shigella dysenteriae* 7.¹⁰⁵ The residue of N-acetylglycine was first identified in PS using spectroscopic analysis: the ¹³C NMR spectrum contained a characteristic signal of C(2) of glycine at 44.1 ppm. Hydrolysis of PS with dilute HCl resulted in a derivative of 4-amino-4-dihydroxyquinovose; conventional analysis of the hydrolysate using an amino acid analyser revealed glycine. The mass spectrum of the corresponding alditol acetate **160**, derived by a routine procedure, indicated unambiguously the position of the glycine residue.

PS of *Proteus penneri* 14 was found to contain residues of D- and L-alanine. The former acylated the amino group of 3-amino-3,6-dideoxy-D-glucose (3-amino-3-deoxy-D-quinovose), while the L-isomer amidated the carboxy group of D-galacturonic acid.⁹⁴ This was the first example of a PS containing two different amino acid residues linked by different bonds to different monosaccharide residues. Solvolysis of PS with liquid HF resulted in the derivative **161** which contained a residue of N-acetyl-D-alanine linked to 3-amino-3-deoxyquinovose. The structure of this compound was confirmed by the mass spectrum of the derived alditol acetate as well as by NMR spectroscopy of the PS itself. The ¹³C NMR spectrum contained signals characteristic of D-alanine at 18.4 [C(2')], 51.8 [C(3')], and 178.3 ppm (CO), and the position of the C(3) signal of the monosaccharide residue (58.4 ppm) proved unambiguously the presence of an acylamino group at this atom.

161

A residue of N-acetyl-L-serine was found in PS of *Escherichia coli* O114^{92,98} where it acylated the amino group of 3-amino-3-deoxyquinovose. The corresponding N-acylated monosaccharide was obtained after solvolysis of PS with liquid HF, from which L-serine was isolated after acid hydrolysis and identified by conventional amino acid analysis. Its L-configuration was established by GLC using an optically active stationary phase.

A routine procedure was used to convert the monosaccharide derivative into the alditol acetate **162** whose mass spectrum revealed fragmentation indicating the presence of a serine residue and its localisation in the monosaccharide (secondary fragments were especially characteristic). The structure of this monosaccharide was also confirmed by ¹³C NMR spectral data.

162

Several O-antigenic PS were found to contain structurally more complex N-acyl substituents related to 5-oxoproline derivatives of the type **163**. They can be regarded as lactams of substituted glutamic acids. Elucidation of their structure required a great deal of effort and was performed with the help of mass spectrometric analysis and NMR spectroscopy. The first substituent of the oxoproline type was detected in PS of *Pseudomonas fluorescens*²⁰¹ where it acylates the amino group of 3-amino-3-deoxyquinovose. The derivative of the N-acylated amino sugar was isolated from the acid hydrolysate of PS and was neutral. Its IR spectrum contained bands at 1660 and 1730 cm⁻¹ which demonstrated the presence of amide and lactam groups in this compound. The molecular weight of the N-acyl substituent, as determined from the FAB mass spectrum, was 156 Da corresponding to the compound of the type **163** containing two methyl groups and one hydroxy group.

163

The ¹³C NMR spectrum of this derivative contained signals confirming the presence of two methyl groups (18.9 and 23.5 ppm), one methylene group (45.8 ppm), two tertiary carbon atoms (71.6 and 78.2 ppm) and two carbonyl groups (175.7 and 179.7 ppm). The ¹H NMR spectrum revealed signals of two isolated methyl groups (1.37 and 1.49 ppm) and a methylene group with nonequivalent protons localised near the carbonyl group [2.45 and 2.65 ppm (AB-system, J_{AB} = 15 Hz)] as well as two NH groups (7.26 and 7.57 ppm), one of which was linked to

the carbon atom carrying no protons. NOE measurements indicated the *trans*-orientation of the methyl groups. The whole body of experimental evidence suggested that the acylating amino acid can be assigned the structure of 3-hydroxy-2,3-methyl-5-oxoproline **163** ($R^1 = R^2 = H$, $R^3 = R^5 = CH_3$, $R^4 = OH$).

A structurally related substituent (also a derivative of 5-oxoproline) was identified in PS of *Vibrio cholerae* O5,¹²⁴ where it acylates the amino group of 3-amino-3-deoxyfucose. The structure of this amino acid was established exclusively on the basis of the NMR spectra of the PS itself. The ^{13}C NMR spectrum of the polysaccharide (and of the disaccharide fragment derived) contained signals of the methyl (23.4 ppm), methine (69.6 ppm), methylene (45.4 ppm) and CO groups (180.2 ppm). This corresponded to the following signals in the 1H NMR spectrum: 1.37 (methyl), 2.38 and 2.64 (methylene, $J_{H,H} = 17.4$ Hz) and 4.19 ppm (methine) as well as a singlet at 8.62 ppm (NH group). These data which were fully confirmed by several correlations and NOE measurements suggested that the amino acid has the structure of 3-hydroxy-3-methyl-5-oxoproline **163** ($R^1 = R^2 = R^5 = H$, $R^3 = CH_3$, $R^4 = OH$).

This structure of the *N*-acyl substituent was fully confirmed by FAB mass spectrometry of some oligosaccharide fragments obtained by PS degradation. The configuration of the substituent was established by NOE measurements: a strong interaction between the NH proton and H(6) in the monosaccharide residue showed the (*R*)-configuration of C(2') of the proline ring, and an interaction between the CH_3 group of the amino acid and H(4) of the adjacent monosaccharide (2,4-diamino-2,4-dideoxyquinovose), indicated the (*R*)-configuration of C(3') of the proline ring.

The third representative of *N*-acyl substituents of this type, 2,4-dihydroxy-3,3,4-trimethyl-5-oxoproline, was detected in PS of *Vibrio anguillarum*,¹⁰⁷ where it acylates the amino group of 4-amino-4-deoxyquinovose (viosamine). Selective cleavage of PS by solvolysis with liquid HF and by two successive Smith degradations gave several oligosaccharide fragments. Their 1H and ^{13}C spectra contained signals corresponding to a substituted 5-oxoproline residue which was attached to the amino group of 4-amino-4-deoxyquinovose as shown by the position of the signal for C(4) of this monosaccharide (57.4 ppm).

A special study was undertaken to establish the structure of this complex *N*-acyl substituent.²⁰² A derivative of this amino acid was isolated from a complex mixture of fragments obtained by solvolysis of PS with liquid HF and subsequent acid hydrolysis. This derivative displayed an IR spectrum with a band at 1792 cm^{-1} and gave a positive reaction with ninhydrin corresponding to the structure of a lactone carrying a free amino group. This compound was assigned the structure **164**. Its ^{13}C NMR spectrum revealed the presence of eight carbon atoms, two of which belonged to carbonyl groups (171.5 and 172.0 ppm), three other, to methyl groups (15.2, 18.0 and 19.7 ppm) and three more carbon atoms were localised in the ring. Analysis of the 1H NMR spectrum (signals at 1.62, 1.68 and 1.69 ppm) confirmed the presence of three methyl groups. Esterification and subsequent *N*-acylation of the lactone **164** gave a methyl ester whose 1H NMR spectrum contained signals of NH proton (6.14 ppm), OH proton (3.97 ppm) and a methyl group of the ester (3.82 ppm) as well as signals of three methyl groups (1.18, 1.59 and 1.75 ppm). Thus, the lactone **164** appeared to be a butyrolactone containing one amino, one hydroxy, one carboxy and three methyl groups.

164

Mild basic treatment of the butyrolactone **164** resulted in its conversion into a lactam, which, on the basis of the NMR and mass spectra of its *O*-methyl derivative, was assigned the structure

165 correlating with the structure of the lactone **164**. Thus, the *N*-acyl substituent present in the PS chain is 2,4-dihydroxy-3,3,4-trimethyl-5-oxoproline **163** ($R^2 = R^3 = R^4 = CH_3$; $R^1 = R^5 = OH$) (2,4-dihydroxy-3,3,4-trimethylpyrrolutamic acid).²⁰² The stereochemistry of this compound still remains unknown.

165

5. *N*-Substituents of hexuronic acid amides

As mentioned above, uronic acids occur occasionally in the polysaccharide chain as amides. Only one example of a glycuronic acid amide is known that is formed by an amino alcohol, 2-amino-1,3-dihydroxypropane. This compound was found in PS of *Shigella boydii* 8²⁰³ and *Vibrio cholerae*.¹⁵⁸ The amino alcohol was isolated by paper electrophoresis after strong acid hydrolysis of the PS and identified mass spectrometrically as the *N*-acetate. Its structure was confirmed by counterflow synthesis.

To determine the position of the *N*-substituent, the PS was subjected to solvolysis with liquid HF resulting in isolation of a small amount of an *N*-substituted amide of galacturonic acid. Its structure was established by mass spectrometry of the corresponding alditol acetate **166** derived by a routine procedure. A peak of the molecular ion with m/z 563 confirmed its molecular weight, and a fragment with m/z 490 the presence of a CH_2OH group.

166

α -Amino acids linked by the amide bond to hexuronic acids (*N*-glycuronoyl amino acids) are more widespread. They were found in bacteria of the genus *Proteus*.²⁰⁴

So far, the bacteria *Proteus* have been shown to contain L-alanine (PS of *P. mirabilis* O27 and *P. penneri* 14), L-serine (PS of *P. mirabilis* O28), L-threonine (PS of *P. penneri* O12)²⁰⁵ and L-lysine (PS of *P. mirabilis* O28 and *P. mirabilis* 1959) acylated by D-galacturonic acid, L-lysine being acylated at the α -amino group. In the PS of *P. mirabilis* O27, an L-lysine residue is acylated by D-glucuronic acid.

The presence of a uronic acid amide is revealed by the primary analysis of the ^{13}C NMR spectrum which showed a characteristic signal at 170–172 ppm corresponding to C(6) of uronic acid and signals of an amino acid residue. The presence of an amino acid is confirmed by its isolation using strong acid hydrolysis of PS and conventional analysis on an amino acid analyser. Its configuration was routinely established by the specific optical rotation or by esterification with (*R*)- or (*S*)-butan-2-ol.

To obtain final evidence for the amide structure, it was isolated in the pure state or within a short oligosaccharide after solvolysis with liquid HF and subjected to mass spectrometric and NMR analyses. Thus, the glycuronamide **167** whose 1H NMR spectrum contained characteristic signals of galacturonic acid and lysine residues was isolated by ion-exchange chromatography from the PS of *P. mirabilis* 1959.²⁰⁶ Notably, the signal of the C(2) proton of lysine appeared to be shifted compared to that of unsubstituted lysine (from 3.20 to 4.35 ppm) suggesting the acylation of the α -amino group of the amino acid.

A similar approach was used to solve a more complex problem, namely, to determine the structure of two different amino acids and the site of their attachment to the corresponding monosaccharide units of the chain. Thus, after solvolysis with liquid HF, the trisaccharide **168** was isolated from the PS of *P. mirabilis* O27²⁰⁷ containing L-alanine and L-lysine residues attached to residues of D-galacturonic and D-glucuronic acids; reduction with NaBH₄ and subsequent methylation of this trisaccharide gave the oligosaccharide **169**. The presence in its FAB mass spectrum of fragments with *m/z* 431, 579, 734 and 276 demonstrated unambiguously that the residue of glucuronic acid at the non-reducing end of the oligosaccharide **169** was amidated by the lysine residue, and the penultimate unit of galacturonic acid by the alanine residue.

Similarly, localisation of L-lysine and L-serine residues in the PS of *P. mirabilis* O28 was established.²⁰⁸ After mild acid hydrolysis of the PS two disaccharides, one of which contained lysine and the other a serine residue, were isolated from a complex mixture. The acetates of the glycosyl alditols **170** and **171** derived by reduction and methylation were analysed by mass spectrometry. Fragmentation of both compounds clearly demonstrated that the lysine residue was attached to the galacturonic acid bound to the galactose residue and the alanine residue to the galacturonic acid adjacent to the *N*-acetylglucosamine residue in the polysaccharide chain.

Amino acid residues in PS localised in side chains often represent immunodominant groups, i.e., they define the immunological specificity of the biopolymer. If the same PS contains residues of two different amino acids, an interesting question may arise: which particular amino acid residue plays the role of the determinant? To answer this question is essential from the viewpoint of creating diagnostic tools based on synthetic antigens. To this end, a synthesis of galacturonic acid amides with different amino acids was undertaken with their subsequent conversion to synthetic antigens by immobilisation on a polyacrylamide matrix using copolymerisation.^{209, 210} The synthesis of these amides was carried out in accordance with Scheme 16.²¹¹

Scheme 16

A uronic acid was first converted into the glycoside of 2-azidoethanol the residue of which was further converted into a synthetic antigen. 2'-Azidoethyl-2,3,4-tri-*O*-acetyl- α -galactopyranosiduronate **172** was condensed with the *tert*-butyl ester of the amino acid (in which the functional groups were protected) **173** [R = Me, R = (CH₂)₄NHCOOBu^t, R = CH₂OBu^t, R = CH(Me)OBu^t] in the presence of ethyl 2-ethoxy-1,2-dihydroxyquinoline-1-carboxylate. Deprotection of the condensation products **174** gave the corresponding derivatives of galacturonoyl-D- and -L-alanines, -L-serine, -L-threonine, -D- and -L-lysine **175** (R' = N₃).

The azides **175** (R' = N₃) were hydrogenated to give the amines **175** (R' = NH₂) which were further *N*-acylated by acryloyl chloride. The resulting derivatives of the acrylic acid **175** (R' = NHCOCH=CH₂) were copolymerised with acrylamide (R is a residue of a galacturonoyl amino acid) to give the synthetic antigens **176**.²¹¹

Comparison of the immunological specificity of the artificial antigens thus obtained with that of natural LPS isolated from bacteria allowed identification of the immunodominant group.²¹² Thus, in the PS of *P. penneri* 12 this group is the L-threonine residue, since of all synthetic antigens studied, only the antigen containing this particular amino acid appeared to be active.

6. Phosphate groups

A unique position among substituents affecting the general characteristics of the polysaccharide chain is held by groups containing residues of inorganic acids, such as sulfate and phosphate groups. These groups create fragments with localised charges along the whole length of the biopolymer chain which influence not only the general properties of the polymeric chain but also its determinant sites. There is still no compelling evidence for the presence of sulfate groups in O-antigenic PS, although these groups are widely distributed in other PS, especially in PS of marine organisms, such as algae; evidently this is related to the peculiarities of the mineral composition of their environment.

Phosphate groups were detected in many natural PS, including O-antigenic PS; the number of known phosphorylated O-antigenic PS is rapidly increasing. A distinction needs to be drawn between the two modes of incorporation of phosphorus-containing groups into PS. They can be present as substituents attached to one of the hydroxy groups of monosaccharide units in the polysaccharide chain or incorporated into the main skeleton of the polysaccharide linking together, in place of the glycosidic bond, monosaccharide or oligosaccharide fragments of the main chain of the biopolymer. The latter case may be considered as a new type of biopolymers which is not actually a polysaccharide, because its main chain consists of both glycosidic and phosphodiester bonds. Thus, this biopolymer occupies an intermediate position between PS and teichoic acids.

Biopolymers of this type, as well as lipid A, where the phosphate groups are present as components of a disaccharide,¹ are not discussed in the present review.

The presence of O-phosphate substituents in the chains of O-antigenic PS is rather well known. Usually they form phosphodiester groups esterifying a monosaccharide unit and a residue of an alcohol or an amino alcohol.

The presence of the phosphodiester group in PS was confirmed (apart from analysis of PS for phosphorus) by ³¹P NMR spectroscopic data. The nature of the second non-carbohydrate substituent in the phosphodiester group can also be found from NMR spectroscopic data and is finally established during localisation of the phosphodiester group in the PS chain using various approaches as required by the particular experimental goal.

A polysaccharide of the bacterium *Citrobacter* O16²¹³ was found to contain a glycerol phosphate group substituting a hydroxy group of an N-acetylgalactosamine residue. This polysaccharide contained 3% of phosphorus, and its ³¹P NMR spectrum revealed a signal of a phosphodiester group at 0.48 ppm. The presence of glycerol was established by GLC of the acid hydrolysate of the PS. To localise the glycerophosphate group, the PS was subjected to Smith degradation followed by mild acid hydrolysis to afford the oligosaccharide 177 containing the phosphate group.

The FAB mass spectrum of the oligosaccharide 177 contained a characteristic fragment with m/z 328 which indicated the presence of a phosphodiester group at the N-acetylgalactosamine residue. This finding was also confirmed by the presence of a fragment with m/z 141 corresponding to the residue of the phosphodiester group modified by oxidation with HIO₄ (the glycerol residue was converted into the ethyleneglycol residue). The presence of fragments with m/z 490 and 693 demonstrated localisation of the phosphorylated monosaccharide at the reducing end of the oligosaccharide 177; this determined its position in the PS chain established by the structural analysis of PS. These data were corroborated by ¹³C NMR spectroscopic data which suggested also that the glycerol phosphate group substitutes the hydroxy group at C(3) of galactosamine since the signal of C(3) is shifted down-field in comparison with the signal of the unsubstituted monosaccharide (72.4 → 76.4 ppm).

The glycerol phosphate group was also found in the PS of *E. coli* O100. This PS has previously been studied by classical methods.²¹⁴ Substitution of one of the hydroxy groups of the monosaccharide chain was demonstrated by cleavage of glycerol phosphate by alkaline hydrolysis of the PS without cleavage of the polymeric chain of PS. The binding of the substituent to one of the hydroxy groups of the rhamnose residue was evident from the stability of the residue of this monosaccharide in the native PS towards periodate oxidation, whereas in the dephosphorylated PS it was destroyed.

In some PS the phosphodiester group contained an ethanolamine residue, as in the PS of *Proteus mirabilis* O27.²⁰⁷ The ³¹P NMR spectrum of the polysaccharide containing 2.5% phosphorus includes a signal at 1.33 ppm which indicates the presence of a phosphodiester group. Ethanolamine was identified after acid hydrolysis of PS by routine methods; its presence was confirmed by the presence in the ¹³C NMR spectrum of signals at 63.2 (CH₂OH) and 41.5 ppm (CH₂NH₂). Both signals, as well as the signals of C(5) and C(6) of N-acetylglucosamine present in the PS, were split due to coupling to the neighbouring phosphorus atom, thus suggesting that the phosphodiester group is linked to C(6) of N-acetylglucosamine. Elimination of the ethanolamine residue upon dephosphorylation of the PS confirmed its attachment to the phosphate group. The phosphodiester group appeared to substitute in the PS only 80% of the monosaccharide residues as determined by analysis of the ¹³C NMR spectrum: it contained two sets of signals for C(4), C(5) and C(6) of glucosamine, of which 80% belonged to the phosphorylated monosaccharide and 20% to the unsubstituted one.

A 2-aminoethyl phosphate group was found in the PS of *P. penneri* 8 where its localisation at C(6) of N-acetylglucosamine was demonstrated using similar approaches.²⁰⁵

A more complex phosphodiester substituent containing a residue of N-(2-hydroxyethyl)-D-alanine was found in PS of *P. mirabilis* O3.²¹⁵ The polysaccharide containing 2.5% of phosphorus was dephosphorylated with concentrated aqueous HF. The resulting amino acid was isolated from the hydrolysate by chromatography and converted into the methyl ester of the N,O-diacetate 178 whose mass spectrum contained ions with m/z 200 (M - OCH₃)⁺ and m/z 172 (M - CH₃COO)⁺ characteristic of fragmentation of the molecular ion of this kind.

The presence in the ¹³C NMR spectrum of the amino acid of signals at 15.4 (CH₃), 48.8 (CH₂N), 58.2 (CHN), 56.9 (CH₂O) and 172.5 ppm (COOH) correlated with the structure ascribed to this amino acid. Its binding to the phosphate group was confirmed by the fact that signals of CH₂N and CH₂O groups are shifted from 48.3 and 54.7 ppm in the free amino acid to 47.5 and 62.3 ppm in

the PS and were split due to C—P coupling. The binding of this complex phosphodiester substituent to the hydroxy group at C(6) of a galactose unit in the PS chain is evident from the fact that in the ^{13}C NMR spectrum of the native PS the C(5) signal of this monosaccharide is split and shifted up-field as compared with the signal in the dephosphorylated PS (71.8 \rightarrow 70.6 ppm), whereas the C(6) signal is shifted down-field (62.2 \rightarrow 66.0 ppm).

Sometimes, the same PS contains two distinct phosphodiester groups linked to different monosaccharide units. An example is a PS of *P. mirabilis* D52 containing residues of 2-aminoethyl phosphate and ribitol phosphate.²¹⁶

This PS was investigated using classical methods. Apart from phosphorus, it contained 14.5% ribitol and 2.6% ethanolamine which, after strong acid hydrolysis, were isolated and identified by routine methods. Both residues could also be cleaved by alkaline hydrolysis without any cleavage of the polysaccharide chain, thus suggesting their localisation in the side chain but not in the main skeleton of the biopolymer. Reaction of the amino group of ethanolamine with 2,4-dinitrofluorobenzene showed that this group is unsubstituted and that the amino alcohol is phosphorylated at the hydroxy group. The ribitol residue was fully oxidised with HIO_4 to give formaldehyde and formic acid, thus providing a proof for ribitol phosphorylation at one of the primary hydroxy groups.

Localisation of the phosphodiester substituents in the PS chain was determined during establishment of the PS structure, for which purpose the PS was cleaved by acid hydrolysis or several repeated Smith degradations. The resulting oligosaccharides were analysed by classical methods. Thus, analysis of one of the fragments obtained by several repeated Smith degradations of the PS revealed the 2-aminoethyl phosphate group to be localised at C(6) of one of the two galactose residues. This is evident from the structure of the fragment 179 containing the 2-aminoethyl phosphate substituent at the glycerol residue, which is the end product of Smith degradation of the galactose unit.

Localisation of the ribitol phosphate group in the second galactose unit followed from the fact that in the native PS this unit is not oxidised with HIO_4 , whereas in the dephosphorylated PS it undergoes oxidation. The reason is that dephosphorylation results in formation of a vicinal glycol group, and, consequently, the ribitol phosphate group is localised at C(3) of galactose. Since localisation of these galactose units was determined in the course of structural analysis of the PS chain, the distribution of both phosphodiester groups in the chain is also established.

While considering this relatively complex example of structural analysis of a PS, it should be noted that the use of NMR spectroscopy offers a rapid, simple and reliable tool to solve similar problems.

V. Conclusions

In this review data are given on novel, scantily known monosaccharides present in O-antigenic polysaccharides of Gram-negative bacteria, many of which have thus far been detected only in this particular class of natural compounds. These data which were mainly obtained at the Laboratory of Carbohydrate Chemistry, Institute of Organic Chemistry (Russian Academy of Sciences), demonstrated that the old classical concepts of monosaccharides as a small group of structurally related organic substances are contrary to fact.

Monosaccharides represent a wide class of organic compounds integrated by one common property, namely, the ability to form cyclic oxygen-containing systems existing in a tautomeric

equilibrium with the corresponding polysubstituted hydroxy aldehydes or ketones. By appending to these data an ample body of experimental evidence on numerous monosaccharides found in antibiotics and some other natural substances, it may be well to notice that we deal with a large class of compounds whose carbon skeleton comprises very diverse functional groups and substituents, the number of individual representatives increasing largely due to their stereochemical differences determined by the presence of a large number of chiral centres. It should also be remembered that the number of novel monosaccharides carrying more than six carbon atoms (including those with a branched carbon chain) is rapidly increasing.

Such a dramatic widening of the class of monosaccharides calls for new methods and techniques for determination of their structure, conducting stereospecific syntheses and elaboration of new concepts of the spatial structure of their molecules.

The present review shows how important is the application of new methods for establishment of the structure and identification of hitherto unknown monosaccharides and their derivatives. The prominent role of physicochemical studies, without which further progress in this complex branch of organic chemistry would be impossible, becomes especially apparent.

It is quite impossible (and not necessary) to give all the details of structural analysis in a short review like this. An effort has just been made to outline the basic route and general logic which are significantly different in studies of structurally distinct monosaccharides. The syntheses of some representatives of monosaccharides described above illustrate the peculiarities of the stereospecific arrangement of rather complex compounds which may be useful in consideration of pathways of synthesis of other polychiral systems.

It should again be noted in conclusion that the data cited here are essential for development of molecular concepts in related biological sciences: biochemistry, immunochemistry, immunology and molecular biology.

A knowledge of the fine structure of monosaccharides making up the bulk of the important class of microbial polysaccharides, aside from its fundamental natural-scientific significance, is of prime importance for solution of applied tasks, firstly, in the design and synthesis of a new generation of biologically active compounds, especially of medicinal drugs used in chemotherapy and reliable diagnostics of infectious diseases.

Natural peroxides. Chemistry and biological activity

G A Tolstikov, A G Tolstikov, O V Tolstikova

Contents

I. Introduction	769
II. Naturally occurring peroxides and their biological activity	770
III. Synthesis of artemisinin, its derivatives and structural analogues	778

Abstract. This review is devoted to the chemistry of natural peroxides and their biologically active analogues. Data are presented on the natural sources of peroxy compounds and pathways of their formation. The structure, stereochemistry and chemical transformations of natural peroxides are considered; the problems of total synthesis of natural peroxy compounds and their structural analogues are also discussed. Data for the biological activity of peroxides are presented. The bibliography includes 134 references.

I. Introduction

The chemistry of peroxy compounds is a vast field which encompasses problems of organic synthesis, macromolecular chemistry, and free-radical processes. These problems have received much attention in the current literature. Lively discussions concern the involvement of peroxy intermediates in biochemical processes; much attention is given, in particular, to the role of peroxy compounds as biologically active metabolites in the synthesis of prostaglandins, thromboxanes, prostacyclins, leukotrienes, hepoxylins, and lipoxins as well as of a wide variety of unsaturated acids with oxygen-containing functions.^{1–6}

Despite the apparently convincing evidence for a relatively high stability of ascaridol, which can be isolated by steam distillation of plant material,^{7,8} further replenishment of the family of natural peroxides has long been considered problematic because of their high lability and short metabolic life.

In this regard, the history of isolation of prostaglandin endoperoxide, one of the key intermediates of prostanoid biosynthesis, commonly known as prostaglandin H₂ (PGH₂) appears to be very typical. This labile compound could be isolated only after isomerase has been blocked with mercury salts by rapid extraction of the culture medium.⁶ However, among the wide variety of natural peroxides stable compounds have been found, which do not require any special precautions connected with their isolation. The formation of stable peroxides by photosensitised oxidation of

terpenes and steroids stimulated the search for the peroxy compounds synthesised by animal and plant organisms.^{9–11}

Beginning in 1970s, the opinion was repeatedly stated that peroxy metabolites can be present in marine organisms. Later, this assumption has often received experimental support. Thus, extracts of sea sponges were found to contain, in addition to the expected 6,9-endoperoxides of sterols, relatively stable 1,2-dioxane and 1,2-dioxolane derivatives and macrocyclic peroxides.

Studies of chemical transformations of natural peroxides revealed that the suggestions of their extreme lability are in many cases unwarranted. For example, some 1,2-dioxane derivatives retain the peroxy group even in the presence of such reagents as complex aluminium hydrides and OsO₄.

Biological assays of peroxides from marine organisms revealed highly active antibacterial, fungicidal, cytostatic, and anticarcinogenic agents.

An event, which changed dramatically many current notions of the natural peroxides, was the discovery by Chinese investigators¹² of a high antimalarial activity of a sesquiterpene peroxylactone artemisinin (qinghaosu) isolated from the wild plant *Artemisia annua* L (sweet wormwood). It is of note in this connection that in traditional Chinese medicine this plant had long been considered to be a highly effective antimalarial agent. The communication by Chinese authors¹² aroused considerable interest among chemists, pharmacologists, and practitioners. The studies performed in a number of laboratories have culminated in the preparation of a drug, which has a number of salient advantages over all currently known antimalarial agents, including the possibility of its application in pregnancy.¹³ It is noteworthy that the discovery of therapeutic properties of artemisinin gave an impetus to the total synthesis of this sesquiterpene and its analogues. Data on the chemistry of artemisinin and other terpenoids isolated from *A. annua* have been reported.^{12, 14}

It is not inconceivable that medicinal drugs of peroxide nature will play a conspicuous role in the therapy of malaria, a disease which presently affects hundreds of millions of people all over the world.¹⁵ It is not therefore surprising that the interest in elaborating the methods of synthesis and bioassay of peroxides has increased considerably during the past decade. Special mention should be made of the prime importance of the general approaches to the synthesis of cyclic peroxides.^{10, 11, 16}

Nowadays, the chemistry of peroxides may be regarded as a new perspective in research in bioorganic chemistry and medicine.

II. Naturally occurring peroxides and their biological activity

The first natural peroxy compound that has been isolated in an individual state is ascaridol **1**, which is present in the so-called chenopodium essential oil obtained by steam distillation of the plant *Chenopodium ambrosioides* L. This plant was cultivated in the USA and other countries specially for the purpose of obtaining an oil known as a potent anthelmintic agent. The peak of chenopodium oil production (up to 50 tons per year) was in 1930–1940.¹⁷ The ascaridol content in this essential oil amounts to 60%. The essential oil of the plant *Chenopodium hircinum* contains 40% of ascaridol. The essential oils of the yarrow *Achillea micrantha* M.B. and *Ajania fastigiata* contain 26%–51% of ascaridol.⁸

Apart from its potent anthelmintic action, ascaridol **1** is also active with respect to the central nervous system (CNS). It has been shown, in particular, that ascaridol displays a pronounced analgesic activity in the 'acetic convulsions' test and prolongs threefold the pentobarbital-induced anaesthesia. The ability of ascaridol at a dose of 100 mg kg⁻¹ to reduce body temperature in experimental animals by 1.5 °C has been reported.

When heated above 150 °C, ascaridol explodes, which explains the cases of explosive decomposition of the chenopodium oil as a result of careless distillation. Boiling of ascaridol in a solution of *p*-cymene is accompanied by the rearrangement of the peroxy group, eventually resulting in the dioxide **2** being further hydrated into the glycol **3** (Scheme 1). At the same time, the peroxy group of ascaridol appeared to be resistant to catalytic hydrogenolysis. Thus, hydrogenation of ascaridol gives the dihydro derivative **4**.

Scheme 1

Synthesis of ascaridol by photosensitised photooxidation of α -terpinene **5** occurs practically quantitatively.¹⁸

Many plants of the *Compositae* family produce sesquiterpene peroxides. For example, the sesquiterpene analogues of ascaridol **6** and **7** were detected in extracts of the plants *Rudbeckia laciniata* and *Senecio paludatus*,¹⁹ while the sesquiterpene peroxydiol qinghaosu-A **8** was isolated from the plant *Artemisia annua* used in Chinese folk medicine as an antimalarial.²⁰ An opinion was expressed that qinghaosu is an artefact, since it had been isolated from the plant that underwent storage.

The wild plant *A. annua* widely distributed throughout the Asian continent contains, apart from the steam-distilled essential oil, terpene extractives including 12 compounds of the cadinane series.

Unquestionably, the most remarkable of these compounds is lactone **9**, artemisinin, isolated and identified by Chinese investigators.^{12, 13} The artemisinin content in *A. annua* does not exceed 0.1%, reaching a maximum two weeks before the flowering of the plant.²¹ A search for other natural sources of artemisinin led to its discovery in the extract of the wormwood *Artemisia apiacea*.²¹ The sweet wormwood growing in Middle Asian countries and Kazakhstan contains up to 0.05% artemisinin.²² The artemisinin content in *A. annua* cultivated in Central Europe does not exceed 0.001%.²³ The interest in artemisinin can be inferred from the communication describing the introduction of the sweet wormwood in the USA.²⁴

Artemisinin possesses rather high antimalarial activity; its use as a medicinal agent is due to its ability to suppress the proliferation of the plasmodium clones resistant to many modern antimalarial drugs.

It is reported that the antimalarial activity of the qinghaosu peroxydiol **8** is of the same order of magnitude as that of artemisinin.²⁵ The assay of all the sesquiterpene peroxydiones described above revealed their significantly lower antimalarial activity than that of artemisinin.²⁶

Artemisinin can regulate the plant growth. It has been shown that at a concentration of 5×10^{-6} M artemisinin inhibits the growth of the duckweed *Lemna minor*. Noteworthy, deoxyartemisinin devoid of the peroxy function does not display any inhibitory activity.²⁷

Artemisinin is a sufficiently stable compound, which not only permits its isolation in a pure state, but also makes it possible to obtain a wide range of derivatives retaining the peroxide bridge.

Thermal decomposition of artemisinin results in artemisinin D **10** and the products of more profound rearrangements of the molecule **11**, **12** (Scheme 2).²⁸ Upon treatment with a methanolic acid, artemisinin is converted into peroxy compounds **13** and **14** and the dioxo ester **15**.²⁹

It should be noted that artemisinin, like compounds **13** and **14**, possess high antimalarial activity. Treatment of artemisinin with K₂CO₃ in methanol yields products of intramolecular rearrangement **16**, **17**.³⁰ The preparation of 11-epiartemisinin **18** under alkaline conditions and a two-step conversion of artemisinin into isoartemisitene **19** have been described (Scheme 3).³¹

Scheme 2

Scheme 3

Treatment of artemisinin with alkali gives the epoxy ketone epimer 16a and oxo compounds 20, 21.³²

The peroxy lactone 22, artemisitene, has been found among the minor components of the extract of *A. annua*.^{12, 33} Its synthesis

from artemisinin based on the use of a selenium-containing intermediate has been described.³⁴

In the studies of the possibility of microbial transformations of artemisinin in the plant, it has been shown³⁵ that *Aspergillus flavipes* converts one of the components of *A. annua*, artemisinin B 23, into the dihydro derivative 24, while *Beauveria bassiana* transforms the compound 23 into the hydroxy lactones 25 and 26.

UV irradiation of artemisinin B gives the product of profound skeletal rearrangement, lumiartemisinin B 27.³⁶

The plant *Nardostachys chinensis* Batalin of the Valerianaceae family is also extensively used in Oriental medicine. To the active extracts of this plant one can refer the oxo peroxides nardosinone 28 and canchone 29.^{37, 38} Nardosinone is a cycloperoxy

derivative of the hydroxyketone **30** (canthone A) and is present in the above plant together with the peroxides **28** and **29**.³⁹

28: R = H, **29**: R = OH.

The isolation of a series of 1,4-peroxy lactones **31–41** of the guaiane type differing in not only substituents, but also in the configuration of the peroxide cycle (Tables 1, 2)^{40–45} has been described. Some of these compounds (e.g., the peroxy lactones **31–33** and **38–41**) manifest weak antimalarial activity.

It should be noted that isoachillofolidiene **42**,⁴⁶ the precursor of the peroxides **38–41**, was isolated from the leaves of the yarrow *Achillea millefolium*, while its dihydro derivative **43** was isolated, along with the esomontanine **41**, from the leaves of the yarrow *Artemisia montana* (Scheme 4).⁴⁵

Some sesquiterpenes of the guaiane type contain a peroxide bridge in a 7-membered cycle. For example, the 6 β ,10 β -peroxides,

chanalpinol **44**, chanalpinone **45**, and isochanalpinone **46** were isolated from the plant *Alpinia japonica*.^{47, 48}

One of the constituents of this plant is the peroxide alpinolide **47**. Its structure sheds more light on the biosynthetic pathways of the furoperargones A and B **48**, **49**, which are also present in this plant.

The Peruvian plant *Lialum floribundum* contains 7 β ,10 β - and 1 β ,10 β -peroxides, compounds **50** and **51**.⁴⁹

A group of peroxides structurally related to the sesquiterpene alcohol nerolidol has been described. Their precursor is davanone **52** isolated from the leaves of the tansy *Tanacetum vulgare*.⁵⁰

This plant also contains the peroxyketal **53**, whose structure was confirmed by its reduction into the diol **54**.

Peroxyketones of the davanone type **55** and **56** were isolated from the extracts of the yarrows *Artemisia maritima* and *A. abrotanum*.^{51, 52}

It is to be noted that compounds **53**–**56** possess a weak anti-malarial activity.

The dark blotches formed on the apple peel on storage contain the triene peroxide **57**.⁵³

Peroxides of the diterpene type occur less frequently. Endoperoxides formed from resin acids are the most common representatives of this group. The endoperoxides of palustic **58** and levopimaric **59** acids were isolated from the needles of the Siberian fir.⁵⁴

The peroxide **58** and its enantiomer **60** are the components of the plant *Elodea canadensis*.⁵⁵

The diterpene analogues of ascaridol differing in the configuration of the peroxide cycle (**61**, **62**) are present in the wormwood *A. absintium*.⁵⁶ The monocyclic peroxydiol **62** was found in the plant *Helichrysum acutatum*.⁵⁷ The plant *Hedichium coronarium* used in Brazilian folk medicine as an antirheumatic agent contains, along with other terpenoids, coronarin B **63**, a peroxide of the labdane type.⁵⁸

The bark of the tree *Jatropha grossidentata* is used by the Indian population of Paraguay as an antiparasitic means. The active principle of the bark extract are canioyan **64** and bisepicanioyan **65**. It has been suggested that both peroxides are formed as a result of an unusual attack of singlet oxygen at the diketone yatrogrossidione **66**, which has also been isolated from the extract of this plant.⁵⁹

The peroxide **67** is of microbial origin; it is produced by *Streptomyces phaeochomogenes*.⁶⁰

As already mentioned in the Introduction, prostaglandin endoperoxides **68** are formed from arachidonic acid under the action of prostaglandin cyclooxygenase.¹⁻⁶ The main pathways of their metabolism are as follows: synthesis of prostaglandins D₂, E₂, and F_{2α} by isomerases, synthesis of thromboxanes A₂ and B₂ by thromboxane synthetase and prostacyclin synthesis by prostacyclin synthetase; they also undergo degradation resulting in the formation of malonaldehyde and (12*R*)-hydroxyheptadeca-(5*Z*,8*Z*,10*E*)-trienoic acid.⁵

Peroxides isolated from marine organisms constitute a rather large group. Among them, the peroxides MeCH(O_nH)OOEt **69** produced by the Ascidia, *Phallusia mamillata*, *Ascidia ahodori*, *Styela plicata*, and *Halocynthia roretzi* have the most simple structure.⁶¹ Of special interest are the 1,2-dioxane derivatives formed from linear unsaturated acids. For example, chondrillin **70** and xestins A and B **71**, **72** were isolated from the sponges *Xestospongia*⁶² and *Chondriella*,⁶³ while peroxy esters **73**–**75** were isolated from the sponge *Plakortis lita*.⁶⁴ The compounds **69**–**74** possess a cytostatic activity.

R = (CH₂)_n (n = 12 (**72**), 9 (**73**), 7 (**74**)), (CH₂)₁₁CH₃ (**75**).

The sponges of the *Plakortis* genus produce a wide variety of peroxy acids, five of which [the peroxyplakoric acids A₁, A₂, A₃ (**76**–**78**), B₁ and B₃ (**79**, **80**)] have been isolated and identified.⁶⁵

76: R = CH₃, 13*E*,
77: R = CH₃, 13*Z*,
78: R = H, 13*E*.

R = CH₃ (**79**), H (**80**).

The configuration of the peroxy acids **78** and **80** has been confirmed by their hydrogenation into the diastereoisomeric hydroxy oxo esters **81** and **82**, while the stability of the peroxide cycle is corroborated by the isolation of the compound **83** upon the reduction of the methyl ester of the acid **78** with LiAlH(OBu^t)₃.

The diastereoisomeric isoprenoid peroxy acids **84** and **85** were isolated from the sponges *Latruncularia*.

84: $R^1 = \text{CH}_3$, $R^2 = \text{H}$;
85: $R^1 = \text{H}$, $R^2 = \text{CH}_3$.

The configuration of the former peroxy acid has been confirmed by hydrogenation into the dihydroxy acid **86**.⁶⁶

Branched-chain peroxides are produced by some species of marine sponges and, what is remarkable, at surprisingly high concentrations. For example, plakortin **87** was isolated from the reef sponges *Plakortis halihondrioides* with a 5.7% yield of the dry weight.⁶⁷

The transformations of this compound carried out in the course of structural analysis, testify to a high resistance of the peroxy group to reducing and oxidising reagents.

The sponges *Plakortis halihondrioides* contain a wide range of peroxides: 3-epiplakortin **88**, its dihydro derivative **89**, the unstable peroxides **90** and **91**, as well as the aryl-substituted peroxy acid **92**, its methyl ester, and lactone **93**.⁶⁸

$R = (\text{CH}_2)_2\text{CH}=\text{CHCH}_3$ (**88**), C_4H_9 (**89**)

The sponges of the *Plakortis* genus contain plakininic acids **A** and **B** **94, 95** and plakortolide **96**.^{69, 70}

The Caribbean sponge *Chondrosia colletrix* produces the epimeric acids **97** and **98** and their methyl esters, whose content amounts to 6% of the dry weight.⁷¹

97: $R^1 = \text{CO}_2\text{H}$, $R^2 = \text{H}$;
98: $R^1 = \text{H}$, $R^2 = \text{CO}_2\text{H}$.

It is worth noting that the compounds **95–98** possess antimicrobial and antifungal activities.

Mono- and bi-cyclic isoprenoid peroxy acids were first described in 1979. It was reported that the sponges *Prianos* dwelling in the Red Sea contain up to 1.5% of the peroxide **99**,⁷² which was also found in the coral reef sponges together with the peroxy acid **100**.⁷³ The sponges of the *Latrunculata* genus contain the peroxide **100** and the peroxy acid mugubilin **101**.⁶⁶

To confirm the configuration of the peroxy group in the compound **99**, the former was hydrogenated resulting in the dihydroxy acid **102**.

Sigmosceptrellin A 103, whose structure was established by the X-ray analysis, was isolated from the extract of the sponges *Sigmosceptrella laevis*.⁷⁴

Later, the isolation of sigmosceptrellins B and C 104, 105 and a series of transformations confirming their structure was reported.⁷⁵

Among metabolites of marine organisms, compounds of a cembrane series were found, which possessed high cancerostatic, antimicrobial, and fungicidal activity.⁷⁶⁻⁸³ For example, the ichthyotoxic coral *Lobophytum denticulatum* contains the cembranoid peroxide denticulatolide 106, whose structure was established by X-ray analysis, while the correct conformations were calculated by using the molecular mechanics method.⁸⁴⁻⁸⁷ The denticulatolide displays an antitumour activity.

The halogen-containing peroxide rhodophytin 107 has been isolated from the algae of the *Laurencia* genus; it isomerises on storage in solution into the compound 107a.^{64, 88}

The terpenoid peroxy ester 108 is produced by the brown algae *Taonia atomaria*.⁸⁷

Steroid endoperoxides are distributed in marine organisms fairly widely. For example, the sponge *Tethya aurantia* contains four 6,9-endoperoxides of the type 109;⁸⁷ 16 peroxides, whose structures resembled those of 109 and 110, have been isolated from the extracts of the sponges *Ascidia nigru*, *Dendrogyra cylindrus*, *Thalysias juniperiana*, and *Aplysia dactiolumea*.⁸⁹

The compounds 99–101 have a cytostatic activity, whereas the compounds 102–105 manifest an ichthiostatic action.

The formation of peroxy acids occurs, most probably, with the participation of enzymes producing singlet oxygen as well as hydrogenases and isomerases.⁶⁶

Hydroperoxides of terpene and steroid structures are produced by higher plants and marine organisms. For example, myrcene hydroperoxides 111, 112 have been isolated from the extracts of the leaves of the wormwood *A. annua*,⁹⁰ while the trans-pinocarveyl hydroperoxide 113, from the leaves of the plants *Anthemis nobilis*,⁹¹ *Chenopodium ambrosioides*,⁹² and *Achillea filipendulina*.⁹³

The plant *Anthemis nobilis* contains hydroperoxides, the derivatives of the esters of prenolic and aliphatic alcohols and the acids 114–117.⁹¹

The medicinal plant *Achillea filipendulina* was used as a source of monoterpenes of a new structural type.⁹⁴ The extraction of the aerial parts of this plant results in four hydroperoxides of the achillene series.⁸⁸ Two of them, 118 and 119, have also been found in the extract of the wormwood *A. lamcea*.⁹⁵

118: R¹ = H, R² = CH=CH₂;
119: R¹ = CH=CH₂, R² = H.

The structure of the hydroperoxides 120 and 121 was corroborated by X-ray analysis and by their reduction into the stereoisomeric diols 122 and 123.⁹⁵

The monoterpene hydroperoxide 124 structurally related to linalool has been isolated from the plant *Ferrea fruticosa*.⁹⁶

The isolation of several hydroperoxides of the guaiane type has been described. For example, the above-mentioned plant *Anthemis nobilis* contains the hydroxyperoxy lactone 125.⁹¹

The plant *Cacosmia rugosa* produces the hydroperoxides 126 and 127,⁹⁷ while the peroxy lactone hydroperoxides 130, 131⁹⁸ could be isolated from the plant *Bishopanthus solicens* together with the hydroperoxides 128 and 129.

128: R¹ = OH, R² = H;
129: R¹ = H, R² = OH.

The hydroxyperoxy lactone of the germacrane series 132 has been isolated from the leaves of the plant *Anthemis nobilis*,^{91,99} while its dihydroxy derivative 133 is present in the plant *Ferrea fruticosa*.⁹³

R = H (132), OH (133).

The tansy *Tanacetum vulgare* produces the cryspolide 134. It has been postulated that the latter is formed in the plant from the peroxyartenolide 135.¹⁰⁰

The hydroxyperoxide derivatives of davanone 50 have been isolated from the extracts of the tansy and some wormwood species. For example, flowers of the plant *Tanacetum vulgare* contain the *Z*-hydroperoxide 136, while its leaves contain the *E*-isomer 137.⁵⁰

The latter has been isolated from the southernwood *Artemisia abrotanum*⁵² as well as from the aerial parts of the wormwood *A. maritima*⁵¹ and *A. inculta*.¹⁰¹ The peroxyhydroperoxide 138 is produced by the plant *A. abrotanum*.⁵²

The hydroperoxide clavukerin C 139 has been isolated from the coral *Clavularia koellikeri*,¹⁰² and the steroid 140 is present in the plankton *Phallusia mamillata*.¹⁰³

III. Synthesis of artemisinin, its derivatives and structural analogues

In the discussion of the pathways of synthesis of artemisinin and its structural analogues, we have deliberately excluded from the synthetic schemes those stages which have no principal significance, by omitting certain experimental details. The main attention was then focussed on the methods used in the synthesis of the peroxy fragments of the molecules. They involve the oxidation by singlet (photoexcited) oxygen, ozonisation, and the use of unique reagents, such as $\text{Et}_3\text{SiO}_3\text{H}$.

One of the most promising approaches to the synthesis of artemisinin is based on the use of artemisinic acid 141 as the starting compound. Its content in *Artemisia annua* exceeds by one order of magnitude that of artemisinin, and its isolation is much easier. The synthesis of (+)-deoxyartemisinin 143 can be carried out in only three stages via the hydroxy compound 142.¹⁰⁴

(a) LiAlH_4 , $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$; (b) O_2 , $h\nu$, Methylene Blue; (c) Dowex H^+ .

An alternative synthesis of the compound 143 has been described, which requires more steps and includes the formation of dihydroxyartemisinic acid 144 at the first stage by reduction of the acid 141 with nickel boride.¹⁰⁵

(a) NaBH_4 , $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$; (b) LiAlH_4 , Et_2O ; (c) O_3 , MeOH , Me_2S , $p\text{-TsOH}$, xylene; (d) O_2 , $h\nu$, Methylene Blue, $\text{CF}_3\text{SO}_2\text{OSiMe}_3$.

The synthesis of artemisinin based on sensitised photooxidation of the dihydroxy acid **144** is initiated by the formation of the hydroperoxide **145** and further proceeds via the dioxetans **146** and **147**.¹⁰⁶

(a) O_2 , $h\nu$, Methylene Blue; (b) Dowex H^+ .

It has to be noted that the unstable epoxide **148** formed from the hydroxyperoxide **145** is converted into the deoxyartemisinin **149**.¹⁰⁷

(a) $m\text{-ClC}_6\text{H}_4\text{CO}_3\text{H}$, CHCl_3 ; (b) $p\text{-TsOH}$.

An interesting conversion of dihydroxyartemisinic acid **144** into artemisinin **9** has been described.¹⁰⁸ Its key stage is the allylic oxidation of the acid **144** by the CrO_3 -3,5-dimethylpyrazole complex into the lactone **150**, which after ozonolysis and ketalisation gives the aldehydo lactone **151**. This is followed by the synthesis of the enol ester **152** and the photooxidation sensitised with Bengal rose. This method can also be used to obtain deoxyartemisinin **143** by the reduction of the methoxycarbonyl group in the compound **152** and photooxidation of the compound **153**.

$R = \text{CO}_2\text{Me}$ (**152**), CH_2OH (**153**)

(a) CrO_3 ; (b) O_3 , $[\text{Me}_3\text{SiOCH}_2]_2$, $\text{CF}_3\text{SO}_2\text{OSiMe}_3$;

(c) Na -naphthalene, CH_3I ; (d) O_2 , $h\nu$, Bengal Rose, HClO_4 .

The synthesis of artemisinin from more simple optically active precursors are multistep. For example, the use of isopulegol **154** entails its functionalisation to form 8-benzyloxymenthone **155** and the subsequent six-step conversion of the compound **155** into the oxo acid **156**. Photooxidation of the acid **156** in the presence of Methylene Blue gives the hydroperoxide **157**, which further cyclises into artemisinin.¹⁰⁹

(a) O_2 , $h\nu$, Methylene Blue; (b) HCO_2H , CH_2Cl_2 .

The synthesis of artemisinin based on citronellal **158**, which is readily converted into isopulegol **154** and, further, into the ketone **155**, entails the annelation according to Robinson. The ketone **159** formed thereby is converted into dihydroartemisinic acid **144**, from which artemisinin is then obtained in three steps. Photooxidation of the artemisinin precursor, the compound **160**, was sensitised with Bengal Rose.¹¹⁰

(a) O_3 , Me_2S , $\text{HS}(\text{CH}_2)_2\text{SH}$, $\text{BF}_3 \cdot \text{OEt}_2$; (b) $\text{HC}(\text{OMe})_3$, $p\text{-TsOH}$, HgCl_2 ; (c) O_2 , $h\nu$, Bengal Rose, HClO_4 .

The synthesis of artemisinin based on the use of β -pinene is remarkable in that the specific rotation of the synthetic, optically active (+)-artemisinin did not practically differ from that of the natural sample.¹¹¹ The ZnCl_2 -controlled interaction of dienophile **161** with isoprene, the scission of the picean bond resulting in the ketal **162**, and hydrogenolysis of the benzoyloxy group in the compound **163** by nickel boride giving the dihydroartemisinic acid **144**, are worth noting.

(a) $\text{CH}_2=\text{CH}-\text{CMe}=\text{CH}_2$, ZnCl_2 ; (b) O_2 , $h\nu$, 5,10,15,20-tetraphenyl-21*H*,23*H*-porphyrin, Ac_2O , $\text{C}_5\text{H}_5\text{N}$, 4-dimethylaminopyridine; (c) $(\text{CH}_2\text{SH})_2$, LiI , DMF ; (d) $(\text{CH}_2\text{OH})_2$, $p\text{-TsOH}$; (e) NaBH_4 , $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$; (f) O_2 , $h\nu$, Methylene Blue, $\text{CF}_3\text{CO}_2\text{H}$, O_2 .

An approach based on the use of the optically active 3-methylcyclohexanone **164** is interesting in that the natural configuration on the C(10) atom in the artemisinin molecule is created initially.¹¹² The synthesis involves via the formation of the oxosulfoxide **165**, which is converted in several steps into the aldehyde **166**. This is followed by a remarkable transformation of the formyl group under the action of the organoaluminium reagent, $(\text{Me}_3\text{Si})_3\text{Al} \cdot \text{OEt}_2$, with subsequent acetylation, resulting in the silyl acetate **167**. The Ireland rearrangement using lithium cyclohexylisopropylamide gives the unsaturated silane **168**. If the propionate **169** is employed instead of the acetate **167**, the rearrangement results in the silane **170**. Ozonisation of the compounds **168** and **170** occurs through the formation of the 1,2-dioxetanes **171** and **172**, which are further converted in the presence of $\text{CF}_3\text{CO}_2\text{H}$ into demethylartemisinin **173** or artemisinin **9**.

(a) $(\text{Me}_3\text{Si})_3\text{Al} \cdot \text{OEt}_2$; (b) $\text{C}_6\text{H}_{11}\text{Pr}^i\text{NLi}$; (c) O_3 , MeOH ; (d) $\text{CF}_3\text{CO}_2\text{H}$, H_2O .

The total synthesis of 13,14-bisnorartemisinin **179** from non-chiral precursors begins with alkylation of the enamine **174** with (*Z*)-1,4-dichlorobutene.¹¹³ This is followed by olefination of the ketone **175** to give silane **176** and ozonolysis of **176** to form the aldehyde **177**. This elegant synthesis is completed by olefination of the compound **177** and ozonolysis of the enolsilane **178**.

(a) $Z\text{-ClCH}_2\text{CH}=\text{CHCH}_2\text{Cl}$, H_2O ; (b) $\text{LiCH}(\text{SiMe}_3)_2$; (c) O_3 , Ac_2O , CH_2N_2 ; (d) $\text{Ph}_2\text{P}(\text{O})=\text{C}(\text{OMe})\text{Me}$; (e) O_3 , $\text{CF}_3\text{CO}_2\text{H}$.

Singlet oxygen needed for the synthesis of dioxetans can be obtained from the hydrotrioxide, $\text{Et}_3\text{SiO}_3\text{H}$.¹¹⁴ Thus, the synthesis of the model compound **180** exhibiting a high antimalarial activity is realised according to the following scheme:

(a) $\text{Et}_3\text{SiO}_3\text{H}$; (b) $\text{CF}_3\text{SO}_2\text{SiMe}_3$.

A structural analogue of artemisinin was synthesised on the basis of 6-methylcyclohex-2-en-1-ol **181**. The Diels–Alder synthesis of hexa-3,5-dien-1-ol with 6-methylcyclohex-2-en-1-ol gives the hemiketal **182**, whose oxidation and subsequent hydrogenation results in the oxo acid **183**. This is followed by the conversion of the acid **183** into the ester **184** and its photooxidation into the hydroperoxy ester **185** in the presence of Bengal Rose. The resulting ester **185** is subjected to oxidation in the presence of an iron–phenanthroline complex, $\text{Fe}(\text{Phen})_3(\text{PF}_6)_3$, and copper triflate, resulting in the hydroperoxide **186** further cyclised in acid medium into the peroxy lactone **187**.¹¹⁵

(a) O_2 , $h\nu$, Bengal Rose; (b) O_2 , $\text{Fe}(\text{Phen})_3(\text{PF}_6)_3$, $(\text{CF}_3\text{SO}_2)_2\text{Cu}$; (c) p -TsOH.

The uniqueness of artemisinin as an antimalarial drug¹¹⁶ posed the question as to the synthesis of artemisinin derivatives more active and convenient in application, of which dihydro esters and aminoacetals are becoming increasingly important. For example, the hydrogen succinate **188** in the form of sodium salt

can be used for intravenous administration instead of the poorly water-soluble artemisinin.¹¹⁷

Prolonged activity was found in the glycoside **190**.¹¹⁸ The esters **191**¹¹⁹ and **192**¹²⁰ displayed a high activity against the plasmodia D-6 and W-2.

188: $\text{R} = \text{CO}(\text{CH}_2)_2\text{CO}_2\text{Na}$;
189: $\text{R} = \beta\text{-D-Glu}(1\rightarrow4)\text{-}\beta\text{-D-Glu}$;
190: $\text{R} = \text{CH}_2\text{CO}_2\text{Me}$;
191: $\text{R} = \text{CH}_2\text{C}_6\text{H}_4\text{CO}_2\text{Na}$.

Among aminoacetals, the compound **192**¹²¹ stands out as possessing a remarkably high activity.

More than 70 artemisinin derivatives and analogues of the type **193** have been described;^{122,123} 12-deoxoartemisinin ($\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{R}^3 = \text{H}$) is very promising.

$\text{R}^1 = \text{H}, \text{Me}$;
 $\text{R}^2, \text{R}^3 = \text{H}, \text{OMe}, \text{OCH}_2\text{Ph}$.

Extremely valuable artemisinin analogues have been synthesised. For example, the peroxyacetal **194** is not inferior to artemisinin as regards its activity towards *Plasmodium falciparum* (the Indo-Chinese clone W-2).¹¹⁴

The ester **195** and the carbamate **196** obtained by photooxidation of the enol ester **197** or by its treatment with $\text{Et}_3\text{SiO}_3\text{H}$ displayed, besides a high antiplasmodium activity, also a unique stability. These crystalline peroxides are now undergoing clinical trials.¹²⁴ It should be emphasised that the majority of artemisinin derivatives and analogues are active against those plasmodium clones that are resistant to potent antimalarial agents, such as plasmoquine.

195: R = COC₆H₄CO₂Me

196: R = CONEt₂.

(a) O₂, hv, Bengal Rose or Et₃SiO₃H.

The question of the activity of peroxy compounds against malarial pathogens is worth special discussion, since the search for antimalarial agents that can be obtained economically is a very urgent task. Structurally simple synthetic peroxides, which are promising as antiparasitic agents, have been described.¹²⁵⁻¹³¹

Recent publications deal with the synthesis of stable peroxides as promising drugs.¹³²⁻¹³⁴ Terpene ozonides are the components of medicinal drugs endowed with antimicrobial and antiparasitic activities.¹³³

* * *

The data presented herein attest to the fact that peroxy compounds are widely distributed in natural objects. Contrary to the earlier, common opinion about the lability of most natural peroxides, investigators encounter sufficiently stable substances more and more frequently. The literature data available on the biological activity of natural peroxides may be regarded as a pledge of future progress in the design of medicinal drugs and antiparasitic agents in agroindustrial production. The example of artemisinin, where the investigations in the area of the chemistry of natural peroxides have acquired medical orientation, is very explicit. It is probable that in the near future the list of antiparasitic agents designed for clinical application will be supplemented with not only natural derivatives of artemisinin but also with synthetic peroxy compounds.

Attention should also be paid to such important properties of natural peroxides as their cytostatic, antitumour, and antimicrobial activity as well as the recently detected CNS activity.

Thus, the comprehensive bioassay of both natural and synthetic peroxy compounds is becoming a current problem.

This review has been prepared with the financial support of the Russian Fundamental Research Fund (Grant No. 95-03-08517).

Abstract. Data on the application of the method of polycondensation cross-coupling catalysed by Pd and Ni complexes for the synthesis of carbo- and hetero-cyclic polyarylenes are systematised and generalised. The bibliography includes 126 references.

I. Introduction

Until recently, the chemistry of carbo- and hetero-cyclic polyarylenes has been among the less studied fields of science on high-molecular compounds.¹ Despite the numerous attempts of investigators to develop new approaches to the synthesis of carbocyclic^{2–11} and heterocyclic^{12,13} polyarylenes, the synthesis of high-molecular polymers having a clearly defined structure seemed to be highly problematic.

The methods of polyarylene synthesis are classified as direct and indirect ones. Direct syntheses employ the monomers already containing the aromatic units, which then become repeating units of the polymers. Characteristic examples of direct polyarylene synthesis are the synthesis of poly-*p*-phenylene according to Kovacic⁹ or using electrochemical methods.^{14,15}

In the case of indirect syntheses, a prepolymer is first prepared, which is converted into polyarylene under the action of definite factors (e.g., thermal treatment). This can be exemplified by the synthesis of insoluble poly-*p*-phenylene starting from a soluble prepolymer, a derivative of poly(5,6-dihydroxy-cyclohex-2-en-1,4-ylene); its pyrolysis gives insoluble poly-*p*-phenylene.^{8,12} The transformation of high-molecular, stereoregular poly(5,6-dicarboxycyclohex-2-en-1,4-ylene) into poly-*p*-phenylene in the presence of H₃PO₄ at 100–250 °C has been described.¹⁶

Unfortunately, both the direct and indirect methods have serious disadvantages. The conditions required for the direct polyarylene synthesis are too drastic for the regiospecific reactions. Therefore, in the case of polyphenylene not only 1,2-, 1,3- and 1,4-disubstituted phenylene fragments of the chain but also trisubstituted units can be formed. Moreover, the molecular weight of the polyarylenes obtained by direct methods are usually low due to the insolubility of polyarylenes.

The indirect method can be used to obtain polyarylenes with high molecular weight; however, the units in the polymers thus formed are not uniform¹⁷ due to the incompleteness of the prepolymer conversions.

The analysis of literature data revealed that the development of direct methods that would not require drastic conditions for their realisation is the most promising approach to progress in polyarylene chemistry. The problem of polymer solubility must be solved in parallel. The most suitable to this end are polycondensation reactions based on haloaromatic compounds catalysed by transition metal complexes.

II. Synthesis of polyarylenes by cross-coupling catalysed by palladium complexes

1. Synthesis of carbo- and hetero-cyclic polyarylenes by interaction of arene dihalides with aromatic diboronic acids or their derivatives

The first application of cross-coupling reactions catalysed by palladium complexes to the synthesis of polyarylenes was described by Suzuki¹⁸ and Muller.¹⁹ These authors demonstrated that different monobromoaromatic compounds react with benzenboronic acid or its cyclic esters to give high (up to 99%) yields of products.

The same reactions have been described in more recent works.^{20–22} The following scheme for this process has been proposed by Suzuki:²³

Later, cross-coupling reactions were used for the synthesis of polyarylenes. A great advantage of the polycondensation cross-coupling method is the possibility of introducing various side groups (aliphatic, aromatic, ester, etc.) into the monomers. On the one hand, by introducing side groups one may improve the solubility of the polymers (which is important for their processing) and, to some extent, increase their molecular weight. On the other hand, the use of these groups may confer specific (liquid crystalline, conducting, nonlinear optical) properties on the

polymer. Cross-coupling reactions have been used, in particular, in the synthesis of alkyl-substituted poly-*p*-phenylenes. The starting monomers were obtained by the treatment of 2,5-di-alkyl-1,4-dibromobenzenes with 1 equiv. of *n*-butyllithium followed by addition of trimethylborate and acid hydrolysis:²⁴

Homopolycondensation of this monomer in the presence of $\text{Pd}(\text{Ph}_3\text{P})_4$ in benzene and subsequent addition of concentrated Na_2CO_3 solution give a colourless polymer soluble in organic solvents:²⁴

The degree of polymerisation (DP) of the polymer 1 reached 30. The analysis of ^1H and ^{13}C NMR spectra revealed that this reaction is highly regiospecific. The yield of the polymer in this reaction was 100%.

It is noteworthy that in the majority of polycondensation cross-coupling reactions the yields of the polymers vary from 80% to 100% depending on the solubility of the synthetic polymer and its molecular weight.

Clearly, if bulky alkyl groups were not introduced into the original monomers, no poly-*p*-phenylenes with DP 30 could be obtained. However, the introduction of these groups plays not only a positive role. In some instances, the introduction of bulky substituents results in conformational changes in the polymer chain, e.g., in disturbance of the coplanarity of the adjacent phenyl groups.^{25–28} Minor departures from coplanarity have no appreciable influence on the electrical and optical characteristics of the polymers; however, if these deviations exceed a certain level, the properties of the polymers change drastically.²⁹

Similar approaches were used to obtain polyphenylenes,²⁴ in which the blocks of unsubstituted *p*-phenylene fragments of varying length were connected via phenylene cycles containing side alkyl groups.³⁰ The synthesis of the original monomers was carried out in accordance with the following scheme:

$y = 1-6$.

Thus, by combining various diboronic acids with dibromo compounds one can obtain polymers with the general formula:³⁰

In some cases ($y = 2$), the target products with the molecular weight M_n of 21 000 were synthesised, which corresponds to a degree of polymerisation of 37. In this case, the total number of phenylene groups may amount to 100. To date, this polymer has the highest degree of polymerisation among those obtained by Pd-catalysed polycondensation cross-coupling.

The synthesis of polymers with side alkoxy groups based on dibromides and diboronic acids has been described.¹ A significant advantage of the polycondensation cross-coupling method is the high activity of diboronic acids and their insensitivity with respect to water (e.g., in some of these reactions, an aqueous solution of Na_2CO_3 was used). In some instances, water-soluble palladium complexes, sodium tris[(trisulfonatophenyl)phosphine]palladium(0) (2) and sodium (or potassium) tris[(diphenyl-*m*-sulfonatophenyl)phosphine]palladium(0) (3), were used as catalysts.^{31,32}

The synthesis of water-soluble polymers containing sulfonatealkoxy groups has been described.^{33,34}

$\text{R} = -(\text{CH}_2)_3\text{SO}_3\text{Na}$,

The reactions were carried out in an aqueous medium, to which DMF and K_2CO_3 were added. Palladium complexes 2 or 3 were used as catalysts. The molecular weight was not determined, but, as could be judged from the low bromine content in the polymer based on sodium of 1,4-dibromo-2,5-bis(3-sulfonatopropoxy)benzene and benzene-1,4-diboronic acid (0.5%), it was of about 15 000.

Other water-soluble poly-*p*-phenylenes^{23,32} carrying carboxyl and carboxymethyl groups have also been described. Thus, the polymer 4 with a molecular weight of about 10 000 (DP ~ 25) was synthesised based on 4,4'-dibromo-2,2'-dicarboxybiphenyl and a cyclic ester of 4,4'-biphenyldiboronic acid. The polycondensation reaction was carried out in a weakly alkaline solution (H_2O –DMF, 3 : 1) in the presence of a water-soluble Pd-catalyst.³¹

It is noteworthy that cyclic diboronates are more preferable than diboric acids because of their better solubility and ease of purification.

Also, polycondensation was successfully employed in the synthesis of prepolymers of ladder systems.^{35–38} Mullen et al.^{35,38} performed the synthesis of soluble prepolymers based on dialkyl-substituted benzenediboronic acids and dibromobenzenes containing keto, aldehyde, and other groups:

$R = H, C_{10}H_{21}$; $R' = C_6H_{13}$.

Subsequent intramolecular cyclisation converted them into ladder structures devoid of non-cyclised fragments.

The ladder polymers **5** have been synthesised from the prepolymer ($\bar{M}_n = 7800$) based on substituted dibromobenzene carrying acetylene groups and cyclic benzenediboronate (Scheme 1).³⁹

Besides difunctional monomers or monomers of the AB-type, the Pd-catalysed cross-coupling reactions also involve trifunctional benzene compounds of the ABB type. The latter were used to obtain the polymeric dendrites (**6**):^{40,41}

$X = Br$.

The yield of the product was 80%–95%, $\bar{M}_n = 3820$ and $\bar{M}_w = 5750$. It was readily soluble in THF and *o*-dichlorobenzene.

Scheme 1

Its viscosity (0.031 dl g^{-1} in THF) was very low which is characteristic of highly branched oligomers. The oligomer **6** had a $T_g = 280^\circ\text{C}$ and did not melt.

Polycondensation cross-coupling is also used in the synthesis of naphthalene compounds. Using this route, a soluble poly(1,5-naphthalene) with a low degree of polymerisation has been synthesised.^{42, 43}

To obtain thermostable polymers, the *tert*-butyl groups are removed from the polymer in alkaline media or by thermal treatment. In this context, the *tert*-butyl groups have a clear advantage over linear alkyl substituents.

A great number of investigations in the area of polycondensation cross-coupling were concerned with the synthesis of polyarylenes and related aromatic polymers containing $-\text{O}-$ and $-\text{CO}-$ groups in their main chains. Thus, the interaction of the 4,4'-dibromodiphenyl ether, 4,4'-dibromobenzophenone or 4,4'-dibromobenzyl with dialkyl-*p*-phenylenediboronic acid gave the corresponding alkyl-containing aromatic polyether, polyketone, and poly- α -diketone.

The presence in the side chains of alkyl substituents renders these polymers soluble in ordinary organic solvents.

The cross-coupling reaction opens up new opportunities for the synthesis of such polymers as substituted polyimides.⁴⁴⁻⁴⁶ Recently,⁴⁴ defect-free polyimides **8** based on didodecylphenyldiboronic acid and the dibromide **7** containing imide rings have been synthesised in a heterogeneous medium (aqueous solution of $\text{Na}_2\text{CO}_3/\text{toluene}$) in the presence of the Pd^0 catalyst, $\text{Pd}(\text{Ph}_3\text{P})_4$.

The molecular weight of the polymer **8**, \bar{M}_n , equalled 20 000, which corresponded to a DP of 14. Such polymers can be obtained by conventional polycondensation of dianhydrides and diamines;⁴⁷ however, in some cases (see, for example, Ref. 46) direct synthesis of the polymers seems to be problematic.

Other imide-containing dibromides, such as the compounds cited in Ref. 46 can also be introduced into the reaction (1):

Here, the radicals R are the residues of dyes which are nonlinear, optically active chromophores. The dibromides **9b-e** enter into the polycondensation reaction with difficulty due to steric hindrances. In this case, up to 50% of the dibromide **9a** was introduced into the reaction simultaneously with the dibromides **9b-e**. The molecular weights of the copolymers so obtained were not very high, they amounted to 17 000 (50% **9a** + 50% **9b** copolymers), whereas the molecular weight of the polymer obtained from dibromide **9a** alone was 41 000 (DP = 11 and 26, respectively).⁴⁶

2. Synthesis of polyarylenes with participation of aromatic organometallic compounds

Considerable attention has been recently given to Pd-catalysed reactions between aromatic dihalides and bis(trialkylstannyl) compounds. The chemical stability and ease of purification of organotin compounds have motivated their wide-scale application in organic chemistry.⁴⁸⁻⁵¹

R, R' = aryl, alkyl, alkenyl and alkynyl.

This reaction was first described for aromatic tin derivatives and aromatic halides in Ref. 51. The interaction of bisstannyl compounds and aromatic dihalides was employed in the synthesis of polyarylenes. Thus, the interaction of 4,4'-bis(tributylstannyl)diphenyl ether with various aromatic dihalides^{52, 53} [e.g., with 4,4'-dibromodiphenyl ether (**a**), 4,4'-dibromobenzophenone (**b**), and 4,4'-dibromodiphenyl sulphone (**c**)], in the presence of

$\text{PdCl}_2(\text{Ph}_3\text{P})_2$ in dipolar aprotic solvents gives the polymers whose molecular weights [as can be judged from their residual bromine content 5.2 (a), 1.69 (b), and 0.9% (c)] are 1500, 4800, and 8000, respectively. All the synthetic polymers are poorly soluble in organic solvents; their molecular weights increase with an increase in the polymer solubility. It has been possible to measure the inherent viscosity for the latter polymer, which was equal to 0.22 dl g^{-1} .

$\text{R} = -\text{O}-(\text{a}), -\text{C}(\text{O})-(\text{b}), -\text{SO}_2-(\text{c})$.

4,4'-Bis(tributylstannyl)diphenyl ether was also used in the synthesis of soluble polyarylenes based on 4,4'-dibromobenzophenone.⁵⁴ Insoluble 4,4'-dibromobenzophenone was converted into the soluble acetal. The reaction was carried out according to the following scheme:

After polycondensation, the acetal groups can be transformed into the ketone groups. The molecular weight of the polymer 11 obtained from the acetal 10 exceeds 25 000 ($\text{DP} > 74$).

Recently, the synthesis of polymers with alternating electron-deficient quinoxaline cycles and electron-donor thiophene or furan groups, has been carried out.⁵⁵

$\text{R} = \text{C}_7\text{H}_{15}, \text{Ph}; \text{X} = \text{S} (\text{a}); \text{O} (\text{b})$.

The yield of the polymers was 96% and the reduced viscosities varied from 0.37 to 0.47 dl g^{-1} . The polymers 12a,b represent structures with charge transfer between the electron-donor and electron-acceptor groups, which eventually determines their intriguing physical properties.

Another synthetic procedure that makes use of the Pd-catalysts involves the interaction of bistrifluoromethanesulfonates (bistriflates) with bisstannin compounds (in some cases, with aromatic dihalides). Triflates are readily formed from the accessible hydroquinones by their interaction with triflic (trifluoromethanesulfonic) anhydride, $(\text{CF}_3\text{SO}_2)_2\text{O}$ (Trf_2O). This approach applied to alkyl-containing bistriflate and bis(tri-methylstannyl)benzene with catalysis by $\text{Pd}(\text{PPh}_3)_4$ and LiCl resulted in alkyl-containing polyphenylenes 13.^{56, 57}

$\text{Trf} = \text{CF}_3\text{CO}_2$;

$\text{R} = (\text{CH}_2)_{10}\text{COOC}_2\text{H}_5, (\text{CH}_2)_x\text{CH}_3 (x = 5, 7, 11)$.

The maximum molecular weight of the resulting oligomer, \bar{M}_n , was 6400.

The palladium-catalysed cross-coupling also makes use of the reactions with other organometallic compounds.⁵⁸ Thus, polycondensation of aromatic dihalides with organotin compounds as well as their interactions with Grignard (see below) and Zn-reagents have been described.⁵³ One of Zn-reagents was synthesised from the corresponding diphenyl ether by transmetalation. Its interaction with 4,4'-dibromodiphenyl ether, 4,4'-dibromop-xylene, and 4,4'-di(bromomethyl)benzene in the presence of $\text{PdCl}_2(\text{Ph}_3\text{P})_2$ in THF was used to synthesise the corresponding oligomers. Of them, the oligomer based on 4,4'-di(bromomethyl)benzene had the highest molecular weight (3100).

Polycondensation of the Zn-reagent 14 obtained from the acetal of 4,4'-dilithiobenzophenone with dibromoderivatives of some aromatic compounds has been carried out.⁵⁴

15

The maximum molecular weight of the acetal polymer 15c, $R = (\text{C}_6\text{H}_4)_2\text{SO}_2$, is not high being up to 6730 ($\text{DP} = 19$).

The crystalline polymer 16 obtained by hydrolysis of the prepolymer 15 has $T_g = 208^\circ\text{C}$ and m.p. 380°C . As regards its crystallinity and other properties, the polymer 16 is closely related to polybiphenylene ether sulfones obtained by other methods.

In general, the molecular weights of the polymers based on Zn-reagents are lower than those based on Sn-compounds, apparently due to the better solubility of the latter.

Thus, the use of the polycondensation cross-coupling method in the presence of Pd^0 and Pd^{II} complexes makes it possible to obtain polymers whose molecular weights do not exceed 20 000–25 000. These reactions can be carried out in aqueous media.

III. Synthesis of polyarylenes by cross-coupling catalysed by nickel complexes

1. Synthesis of polyphenylenes and polyarylenes using Grignard reagents

The cross-coupling reaction of dihalogenoaromatic compounds with Grignard reagents in the presence of various catalysts including predominantly bivalent Ni was first described by Yamamoto^{59, 60} in 1977–78. Thus, the interaction of 1,4-dibromobenzene with 1 equiv. of Mg and a catalytic amount of $\text{NiCl}_2(\text{bipy})$ ($\text{bipy} = 2,2'$ -bipyridyl) or other Ni^{II} compounds in boiling THF resulted in a polymer, which contained exclusively *p*-phenylene groups, with DP of up to 24.

This polycondensation reaction was based on the synthesis described by Tomao and Kumada in 1972.⁶¹

This reaction proceeds selectively and quantitatively under mild conditions.

Later, studies of cross-coupling of aromatic halides and Grignard reagents were further continued in the works,^{22, 62–65} in which not only Ni^{II} but, for the most part, Ni^0 complexes have been used as catalysts. The most probable mechanism for this reaction can be schematised as depicted in Scheme 2.⁶³

An attempt has been made⁵⁷ to obtain polymers from 4,4'-dibromodiphenyl ether and the Grignard reagent prepared from it. Polycondensation was performed in the presence of $\text{NiCl}_2(\text{dppp})$ [$\text{dppp} = 1,3$ -bis(diphenylphosphino) propane]. However, the final products appeared to be insoluble in the majority of organic solvents and had a low molecular weight (up to 600).

Two most likely reasons for the termination of growth of the poly-*p*-phenylene chain are: (i) the decrease of the product solubility in the course of polycondensation and its precipitation; (ii) chemical factors preventing the growth of the macromolecular chain, such as hydrolysis of its active end.

The fact that phenylene and, particularly, flexible side alkyl groups improve the solubility of low-molecular compounds^{66–69} and polymers^{70–72} predetermined future lines for development of investigations in the field of synthesis of polyphenylenes and polyarylenes based on Grignard reagents, viz., the use of monomers carrying side groups.

Poly(phenyl-1,4-phenylene)⁷³ was synthesised by using the Yamamoto reaction.⁵⁹ 2,5-Dibromobiphenyl was treated with an equimolar amount of Mg in THF and then 1.13 mol % of a nickel catalyst, $\text{NiCl}_2(\text{Ph}_3\text{P})_2$, was added:

The final product was soluble in chloroform; its molecular mass, \bar{M}_w , was 1100–2200 (in some cases, the proportion of an insoluble fraction constituted 13%).

The use of 1,4-dibromobenzene containing side alkyl groups [$R = \text{Alk} (\text{C}_6\text{—C}_{12})$] as monomer resulted in the polymer $[\text{—C}_6\text{H}_2\text{R}_2\text{—}]_n$.⁷⁴

The synthesis of *n*-alkyl-substituted poly-*p*-phenylenes was carried out under conditions described above. The reaction mixture was homogeneous; however, in this case, too, the degree of polymerisation did not exceed 13. The following Ni^{II} compounds were used as catalysts: $\text{Ni}(\text{bipy})\text{Cl}_2$, $\text{Ni}(\text{Ph}_3\text{P})_2\text{Cl}_2$, $\text{Ni}(\text{acac})_2$, and $\text{Ni}(\text{dppp})\text{Cl}_2$ (acac is acetylacetonate). Among those, $\text{Ni}(\text{Ph}_3\text{P})_2\text{Cl}_2$ turned out to be the best catalyst, for it gave the polymer of the highest molecular weight.

Conducting polyarylenes, polytriphenylamines⁷⁵ soluble in benzene and chloroform were synthesised based on 4,4'-dichlorotriphenylamine (a) and 4,4'-dibromo-(4''-methyl)triphenylamine (b) by Ni-catalysed polycondensation using Grignard reagents. $\text{Ni}(\text{bipy})\text{Cl}_2$ was used as the catalyst; it was added only after the formation of the Grignard reagent. This procedure made use of metallic Mg obtained *in situ* by reduction of anhydrous MgCl_2 with metallic potassium. The yield of the oligomers was 63% and 71%, respectively; the degree of polymerisation did not exceed 12.

From the above examples it can be seen that if the polycondensation is performed with the Grignard reagents, the solubility is not crucial in the preparation of high-molecular-weight polymers. The most probable reason for the termination of the chain growth in these reactions is purely chemical, i.e., hydrolysis of Mg-containing terminal fragments by trace amounts of moisture. Moreover, all the polycondensation reactions based on the use of Grignard reagents were carried out in THF, which could also restrict the growth of the polymeric chain.

Hence, the application of Grignard reagents in the cross-coupling reaction is limited due to the fact that they can give rise only to oligomeric products.

2. Synthesis of polymers using Ni⁰ complexes

a. Homocondensation of dihaloaromatic compounds

For the first time, the condensation of aryl bromides or iodides in the presence of Ni⁰ complexes in dipolar aprotic solvents has been described in Refs 76–78.

These reactions proceeded under mild conditions but had a number of limitations: (i) their realisation required large amounts of the catalyst, the catalyst to monomer ratio being 1:1; (ii) the reaction conditions must be such that traces of air and moisture must be avoided.

Using this method, Yamamoto et al.^{79,80} succeeded in obtaining poly-*p*-phenylenes and other polyarylenes. As a catalyst, Ni(COD)₂ (COD = cycloocta-1,5-diene) was used. Neutral ligands (Ph₃P or bipy) were also added to the reaction medium. Thus, oligomers with molecular weights of up to 6000 were synthesised based on *p*-dihalobenzenes.⁷⁹ The use of 9,10-dibromoanthracene as monomer gave a stable complex, L_mNiX(C₆H₄X), in high yield; in this case, the oligomer was not formed. Hence, it follows that chain growth also depends on the monomer structure.

Poly-*p*-phenylenes carrying pendant *ter*-phenyl groups have been synthesised⁸¹ from 2,5-dichloroquaterphenyl

in the presence of the same catalyst, [Ni(COD)₂ + bipy] in DMF; they possess intriguing properties (as regards their conductivity); however, the degree of polymerisation did not exceed 10.

In more recent syntheses employing this catalyst, polymers of higher molecular weights could be obtained, apparently due to perfection of the synthetic procedure, i.e., more extensive purification of monomers and better removal of traces of moisture and oxygen from the reaction medium. Thus, Mullen et al.⁸² succeeded in obtaining soluble poly-*p*-phenylene:

based on the dibromide of substituted tetrahydropyrene; its molecular weight was 35 000 (\bar{M}_w) or 17 400 (\bar{M}_n) (DP = 40).

Later, Yamamoto⁸³ synthesised polyanthraquinone and polymethylantraquinone of high molecular weights (~190 000) from dichlorides:

R = H, Me.

An alternative pathway was also proposed.^{84–86} A reactive Ni⁰ catalyst was prepared from catalytic amounts of NiCl₂(Ph₃P)₂ (or NiCl₂) in the presence of excess Ph₃P and a large excess of Zn powder (or some other reducing metal) at 60–80 °C in dipolar aprotic solvents. The reaction was completed within several minutes.

The positive factor in the use of these Ni⁰ catalysts is that aryl chlorides are most active in this process, as distinct from processes described earlier, in which aryl bromides and aryl iodides possess the highest activity.

The putative mechanism of this reaction can be illustrated by the following scheme with the synthesis of a bisarene as an example:⁸⁴

L = PPh₃.

It has been shown that the first step (oxidative attachment of ArCl to Ni⁰ to form a bivalent nickel complex) occurs at rather a high rate. The next step, i.e., the reduction of Ni^{II} to Ni^I, is slow and rate-limiting at the beginning of the reaction when the ArCl concentration is still high. At the end of the reaction, it is the third step that determines the reaction rate. It has been found that the second and third rate-limiting steps are accelerated by the introduction of electron-acceptor substituents into the benzene rings and, *vice versa*, are decelerated with the introduction of electron-donor substituents. In addition, in the presence of electron-donor substituents side reactions can take place, viz., the formation of ArH. This is due to the fact that electron-donor groups stabilise the coordinatively unsaturated Ni^I complex, and the transfer of the phenyl group from the phosphorus to the nickel atom is possible. As the reaction proceeds further, this reaction course can result in the termination of the polymer chain and, consequently, in the synthesis of a low-molecular weight polymer.

This method was used to obtain soluble poly-*p*-phenylene **17** based on 2,5-dichlorobenzophenone.^{87,88}

The polymer **17** possessed a high inherent viscosity: 1.05 dl g^{−1} when the reaction was carried out for 7 h, and 1.3 dl g^{−1} when the reaction was carried out for 50 h (\bar{M}_w = 60 000, DP = 330, T_g > 205 °C). The polymer was soluble in CHCl₃, in PhOH–CH₂Cl₂ and PhOH–C₂Cl₄ mixtures, formed films, and retained stability in air at temperatures below 500 °C (TGA).

Poly-*p*-phenylenes with side acetylene fragments **18** possessing nonlinear optical properties have been synthesised by Wright.⁸⁹

The polymer **18** had a low molecular weight ($\bar{M}_n = 8000$) and was readily soluble in ordinary organic solvents. Its glass transition temperature, T_g , is 220 °C, and its thermal stability is 300 °C (according to TGA).

The synthesis of polyether sulfones $[-C_6H_4-SO_2-C_6H_4-O-C_6H_4-C_6H_4-O-]_n$ and polyether ketones with the following formulae: $[-C_6H_4-C(O)-C_6H_4-X-C_6H_4-C(O)-C_6H_4-]_n$ where $X = O, OC_6H_4O$, has been described.⁹⁰⁻⁹² 4,4'-Bis(*p*-chlorophenoxy)diphenyl sulfone was used as the main monomer during the synthesis of polyether sulfones. Copolymers of 4,4'-bis(*p*-chlorophenoxy)diphenyl sulfone with 4,4'-dichlorodiphenyl sulfone, *p*-dichlorobenzene, etc, were also obtained. Of all polymers, the homopolymer possessed the largest reduced viscosity (0.81 dl g⁻¹); the viscosities of copolymers (in *N*-methylpyrrolidone at 25 °C) were in the range 0.4–0.69 dl g⁻¹.

The efficiency of homopolycondensation and, correspondingly, the molecular weight of the polymers obtained in the presence of Ni⁰ complexes depends on three factors. The most important is the absence of moisture, since in the presence of water aryl halide is reduced to arene,⁹³ eventually resulting in the termination of the chain. The second factor is the inert atmosphere, since even very small amounts of oxygen deactivate the catalyst (nickel oxide formed upon oxidation is not a catalyst under these conditions). The third factor is the purity of Zn (this must possess a well-developed surface and be free of oxygen).

The synthesis of polyarylenes involving Ni⁰ catalysts has also been described in many other papers. Thus, 1,2-bis(4-chlorophenyl)- and 1,2-bis(3-chlorophenyl)-1,1,2,2-tetramethyldisilane were used as monomers;⁸⁸ however, the polymers based on them had low molecular weights, 2400 and 10 000, as could be deduced from GPC data. The polyarylketone obtained from 4,4'-dichlorobenzophenone rapidly formed a precipitate (its molecular weight was as low as 1700). An alternative pathway for the synthesis of polyarylketone from polyketimine with subsequent hydrolysis of the ketimine groups has been proposed:⁸⁸

The polymer carrying ketimine groups is more readily soluble than its benzophenone analogue and has an inherent viscosity of

0.25 dl g⁻¹ (when the synthesis is performed in *N*-methylpyrrolidone, the viscosity can amount to 0.36 dl g⁻¹).

Thus, the use of Ni⁰ complexes has made it possible to obtain in some cases high-molecular-weight polymers from monomers carrying electron-acceptor substituents provided stringent conditions of the synthesis are observed.

b. Homopolycondensation of bistriflates

Ni⁰ complexes are ideal catalysts for the homopolycondensation of aromatic substituted bistriflates.^{94,95}

R = Ph, COOMe, Bu^t.

The reaction was carried out with Ni⁰ prepared *in situ* in the presence of excess Zn. It should be noted that the degree of polymerisation of polyphenylenes with phenyl, carboxymethyl, and *tert*-butyl substituents is different,⁹⁰ reaching 15, 30–47 and < 14, respectively. It may be inferred from these data that with triflates the molecular weight was the highest when monomers carrying electron-acceptor substituents were used.

One serious pitfall of this method is that the coupling of monomers can proceed in a 'head-to-tail' and 'head-to-head' manner, resulting in polymers with irregular structures. In this respect, the application of symmetrical monomers seems to be more expedient. Thus, the synthesis of the following monomer:

has been described.⁹¹

Homopolycondensation of this monomer resulted in an oligomer with DP = 7–8 (GPC) with a 33%–35% yield. The oligomer appeared to be nonconjugated due to the non-coplanarity of the benzene nuclei; however, it can be transformed into a conjugated form by intramolecular cyclisation resulting in the formation of triphenylene or perylene structural fragments.

IV. Synthesis of heterocyclic polyarylenes

There is an ample body of evidence concerning the synthesis of low-molecular organic compounds by cross-coupling of halogen derivatives of thiophenes, pyridines, *N*-substituted pyrroles, quinolines, benzotriazoles, ferrocene,⁹⁶ and even halonucleosides with the use of Ni and Pd catalysts.⁹⁷ Attempts have been made to apply this methodology to the synthesis of heteroaromatic polyarylenes (especially, of conducting systems of the polythiophene type).^{79,98-107}

Electrochemical methods or oxidation are used for obtaining heteroaromatic polymers; however, these techniques do not give, with a few exceptions,¹⁰⁸ regular structures.

By contrast, the cross-coupling reaction catalysed by transition-metal complexes allows for regio-specific interactions between the monomers, and correspondingly, the synthesis of polyheteroarylenes of a strictly defined structure. This approach was very extensively used in the synthesis of poly-2,5-thiophenes (to a lesser degree, poly-2,5-selenophene,¹⁰⁹ poly-2,5-pyrroles and related model oligomers).

Cross-coupling reactions proved to be very effective in the synthesis of polythiophenes. In addition to the reproducible method for the synthesis of high-molecular-weight poly-2,5-thiophene, other procedures were elaborated for the synthesis of substituted poly-2,5-thiophenes and individual oligomers containing up to 7 cycles. As early as 1980, Lin⁹⁸ and Yamamoto⁹⁹

described the polycondensation of 2,5-dibromothiophene and demonstrated the advantages of nickel catalysts over palladium ones in the synthesis of polythiophene.

Polycondensation cross-coupling aimed at the synthesis of heterocyclic polyarylenes developed along the three main lines: (i) the use of Grignard reagents and their further interaction with heterocyclic halides in the presence of Ni^{II} complexes; (ii) the use of stoichiometric quantities of Ni⁰ complexes; (iii) the use of Ni⁰ complexes synthesised *in situ* in the presence of reducing agents.

Poly-2,5-(thiophene) and its methyl derivatives have been obtained^{98,99,102,103} in the following way: first, Grignard reagents were synthesised from the dibromides in the presence of a stoichiometric amount of Mg. They were subjected to polycondensation in the presence of catalytic amounts of a NiCl₂(bipy) complex in THF (first approach). The resulting product was poorly soluble in organic solvents (22%). The soluble fraction had a molecular weight, $M_n = 1370$.

In more recent studies,^{106,107} the following substituted dibromothiophenes were used:

$R = C_{12}H_{25}$, Bu^p , $n-C_6H_{13}$, $(OCH_2CH_2)_nOCH_3$ ($n = 1, 2$) etc.

In both of the studies cited the monomer of the AB type was first obtained: to this end, one bromine atom was substituted by the MgBr group in the presence of the catalyst, Ni(dppp)Cl₂. The experimental conditions were such that the maximum molecular weight, M_w , reached 71 000 (DP = 160). In this case, the yield of the 'head-to-tail' polymer amounted to 99%.

Yamamoto⁷⁹ suggested to use the Ni⁰–Ni(COD)₂ complex in the presence of Ph₃P or bipy for the preparation of substituted ($R = C_6H_{13}$, C_8H_{17} , $C_{12}H_{25}$, CN) and non-substituted polythiophenes (second approach). The molecular weight of polythiophene with $R = C_6H_{13}$ was 52 000 (M_w , light scattering) and 190 000 for the samples obtained after 16 and 48 h, respectively.

Ueda et al.¹⁰⁰ described the synthesis of poly-3-phenyl-2,5-thiophene based on a chloro-substituted monomer using catalytic amounts of Ni⁰ complexes in the presence of reducing agents (third approach).

A symmetrical monomer with two thiophene groups has been recommended¹¹¹ for the synthesis of polythiophene.

This route precludes the formation of a polymer having an irregular structure. The inherent viscosity of the polymer was rather high rising to 0.23–0.25 dl g⁻¹.

Recently Bauerle^{112,113} has described the synthesis of several intriguing oligothiophenes, such as the heptamer:

which is a compound of choice for electrochemical studies. It is noteworthy that analogous oligothiophenes were earlier obtained by other methods.^{114–116}

As far as oligo- and poly-pyrroles are concerned, despite the considerable interest of investigators in these compounds (in the

context of materials technology), only a small number of them have been synthesised with the use of the polycondensation cross-coupling method.

Thus, Kovacic^{117,118} reports on the synthesis of phenyl- and benzyl-substituted poly-*N*-methyl-2,5-pyrroles from the corresponding 2,5-dibromopyrroles. After conversion into the corresponding bifunctional Grignard reagents, these pyrroles entered into the polycondensation reaction catalysed by Ni^{II}(acac) in the quantities exceeding the stoichiometric ones. The resulting oligomers were partly soluble in organic solvents but had rather low molecular weights (according to the residual bromine content).

A wide variety of oligomeric unsubstituted poly-*N*-methyl-2,5-pyrroles have been synthesised and fully characterised in the course of detailed studies carried out by Kaufman.¹¹⁹

$n = 2, 6, 8, 16$.

It is to be mentioned, however, that the presence of methyl groups at the nitrogen atoms in the pyrrole rings decreases sharply the conductivity of polypyrroles. However, in the above syntheses only *N*-substituted pyrroles could be used, since the unprotected pyrrole is unstable (its sensitivity to even trace amounts of oxidants is well known). Therefore, the progress in the synthesis of conducting polypyrroles could be achieved if the problem of the monomer stability is solved.

The best solution of this problem is the use of *N*-substituted pyrroles provided the protecting group can be removed if required.^{118,119} In this case, polycondensation of monomers results in protected oligomers and polymers, which can be converted into poly-2,5-pyrroles at the final stage of the reaction. *tert*-Butoxycarbonyl was used as the protecting group, since it decomposes completely to form CO₂ and isobutene,¹²⁰ favours an increase in the solubility of intermediate oligomers and polymers and thus facilitates their processing and analysis; it is also an electron acceptor, and, as a consequence, demonstrates a stabilising effect.

Below is given a scheme of the synthesis of the corresponding substituted oligopyrroles and of oligopyrroles prepared from them:

$n = 1, 3, 5, 7; m = n + 2$.

Bromination of *N-tert*-butoxycarbonylpyrrole ($n = 1$) has been carried out according to Gilow.¹²¹ The dibromide thus obtained¹²² reacted with two equivalents of a monotin derivative of *N-tert*-butoxycarbonylpyrrole⁵¹ to give a trimer. Bromination of the trimer at the both terminal α -positions and its repeated reaction with the organotin derivative resulted in further elongation of the chain to yield a pentamer. This pentamer was then repeatedly introduced into the chain growth cycle and so on. The resulting oligomers were fully characterised by spectroscopic methods.¹²³ The crystal structure of some of these compounds was established by X-ray analysis.¹

Heating of each of these polymers at 160–180 °C led to the elimination of the protecting COOBu^t-groups resulting in a series of unprotected oligopyrroles with $m = 3, 5, 7, 9$. According to ¹H and ¹³C NMR data, the deprotection was almost complete: the content of residual COOBu^t-groups did not exceed 4%. The longest pyrrole oligomer known thus far was terpyrrole. It is of note, however, that unprotected oligopyrroles are very unstable compounds, which form gels even at low temperatures; their treatment must be carried out in the absence of air.

The application of Pd-catalysed polycondensation to polypyrrole synthesis is coupled with certain difficulties, which are not still resolved. The attempts to synthesise polypyrroles under conditions of the Suzuki reaction (Pd-catalysed interaction of dihalides with diboronic acids) were unsuccessful, because in the case of pyrrole the electron-rich heteroatom easily loses its functional groups. For example, heating of *N*-tert-butoxycarbonylpyrrole-2-boronic acid in the biphasic toluene/Na₂CO₃ system for 24 h at 50 °C (in the absence of other components of the cross-coupling reaction and catalysts) resulted in a 50% loss of the B(OH)₂ groups, which thus determines the inapplicability of these compounds in the polycondensation reaction.^{124, 125}

Therefore, an attempt has been made to prepare oligomers based on other monomers. To this end, monomers of the AB-type containing the trimethylstannyl group instead of B(OH)₂ have been synthesised:

Studies of cross-coupling of compounds of this type have shown that monomers **19** and **20** are quite stable.⁵⁰

According to liquid chromatography data, polycondensation of the monomer **19** yields only the oligomers with $n = 3-4$. To elucidate the reason for the low DP of these products, the lowest oligomers were isolated from the mixture and their structure was elucidated. It was found that they contain Me- and SnMe₃-groups as terminal groups rather than Br- and SnMe₃-groups as could be expected for the systems obtained by the interaction of the above monomers. The attempts to prevent the undesirable termination of the chain by varying the reaction conditions have failed. In further studies, an approach well-known in polycondensation has been applied, namely, the use of monomers containing more than one repeating unit. To this end, the terpyrrole monomer **20** was used. The polycondensation again proceeded with difficulty, but since the original monomer contained three structural units, it yielded an oligomer with $n = 10$. Fractionation of a mixture gave an oligomer with 20 *N*-substituted pyrrole rings in the chain ($M_w = 3400$, $M_n = 2800$). After deprotection, this oligomer was further used in electrochemical and optical-spectroscopic studies.

Pyrrole can also be introduced into the reaction of copolymerisation with arylidiboronic acid. The copolymer

was obtained by the interaction of the substituted aromatic diboronic acid with dibrominated protected pyrrole followed by thermal deprotection.¹²⁶ The resulting product had a rather high molecular weight, $M_w = 17\,000-20\,000$.

* * *

It may be inferred from the above that the polycondensation cross-coupling employing transition-metal complexes as catalysts allows one to synthesise soluble carbo- and hetero-chain polyarylenes of a strictly defined structure.

Abstract. The main principles, characteristic features, advantages, and disadvantages, of the application of alkoxo-technology[†] for the preparation of heterogeneous oxide catalysts and carriers are examined. The bibliography includes 293 references.

I. Introduction

The traditional technologies for the preparation of inorganic oxide materials, including carriers and heterogeneous catalysts, which are based on the use of inorganic acid salts, oxides, and hydroxides as precursors, have to a large extent exhausted their possibilities. The probability that a qualitative jump in the development of this field can be achieved and that the characteristics of materials, can be appreciably improved on their basis is extremely small. One of the promising approaches to the overcoming of many disadvantages of the traditional technology and to the creation of new materials and the improvement of the quality of those already known involves the application as starting materials (precursors) of the alkoxides of various chemical elements (metal alkoxides and alkyl esters of ortho-acids). This method has been called alkoxo-technology. Abroad, alkoxo-technology, which is one of the variants of sol-gel technology, made it possible to initiate the manufacture of a series of advanced materials for microelectronic, optic fibre, aerospace, and other branches of engineering.^{1–3} The number of publications on this topic throughout the world runs into thousands, but in the Russian scientific and patent literature they are represented by few examples and are either of a purely academic character or are concerned with simple variants of alkoxo-technology associated

with the employment of only silicon alkoxides or their mixtures with inorganic salts. This situation has led to an underestimate of the possibilities of the use of alkoxo-technology in heterogeneous catalysis. Furthermore, it was evident from the very beginning that the most promising aspect of its practical application involves the preparation of catalysts and carriers for the latter.⁴

The reviews^{5–11} concerning the application of alkoxo-technology in heterogeneous catalysis are relatively inaccessible and are limited to the consideration of a narrow range of problems. The aim of the present review is to survey the most important advances in the field of alkoxo-technology (mainly during the last decade) and also to assess the potential possibilities of its use for the preparation of oxide catalysts and carriers.

II. The mechanisms of the conversion of alkoxides into oxides

Alkoxides are converted into oxides in thermal and thermooxidative degradation and hydrolytic processes and in the interaction with the surface OH groups and hydroxides.

In the synthesis of oxide powders by spray pyrolysis in an inert medium, in the chemical vapour-phase deposition of coatings, and in the preparation of coatings and bulky materials from solutions of alkoxides or the products of their partial hydrolysis, the alkoxides undergo thermal decomposition. A schematic illustration of this process, proposed by Tishchenko as early as the past century,¹² can be represented as follows:

Here the symbol E designates the fundamental element. The composition of the organic product of the thermal degradation (ethers ROR, alkenes $\text{R}_{(-\text{H})}$, alkanes RH, aldehydes $\text{R}'\text{CHO}$, and alcohols ROH) is determined mainly by the nature of the alkyl group and of the chemical element and also by the process temperature. For example, alkaline earth metal oxides are capable of dehydrating ethers and the decomposition of their alkoxides proceeds predominantly via path (2). Alkoxides with

secondary and tertiary alkyl groups decompose most readily via path (1) (since the heterolytic dissociation of the R—O bond and the abstraction of a proton from the carbonium ion are facilitated under these conditions).¹³ For catalytic purposes, it is desirable to employ the alkoxides derived from higher alcohols, since in this case the oxides formed have the most extensive porous structure. Products of the thermal decomposition of alkoxides are usually nonstoichiometric oxides E_2O_{n-x} and this factor may be used deliberately for the preparation of a series of catalysts. The thermal decomposition conditions are chosen in such a way that certain catalytically active substances are segregated not in the oxide but in the metallic form (the reduction is effected by the organic thermal degradation products). This mechanism can be achieved also in a mixture of an alkoxide (precursor of the porous carrier) and of the salt undergoing thermal decomposition (precursor of the metal catalyst).

The thermal decomposition of alkoxides for the preparation of catalysts and adsorbents is usually carried out under thermooxidative conditions in the presence of O_2 . Together with reaction (1)–(3), the alkyl groups of the alkoxide and of the organic degradation products are oxidised. The compounds formed may interact with the alkoxide: the water evolved in the thermal oxidation hydrolyses the alkoxide, as a result of which the decomposition is sharply accelerated and assumes a chain character.

Not only the final process temperature but also the rate of its increase exert a definite influence on the course of the thermooxidative degradation, which is associated with the sintering of the elementoxane skeleton at high temperatures, decrease in the oxidation surface, and hindrance to the diffusion of oxygen and volatile products. Although all this leads to a sharp fall in the rate of decomposition of alkoxides, nevertheless it is not always taken into account in practice.

Alkoxides are usually converted into oxides by hydrolysis in which the following reactions take place:^{14,15}

The hydrolysis [reaction (4)] of the majority of alkoxides proceeds at a high rate and the overall rate of hydrolysis is determined by diffusional and not kinetic factors. In order to complete the condensation with formation of ROH or H_2O [reactions (5) and (6)], an increased temperature and/or the presence of acidic or basic catalysts is usually required. The dimers formed on condensation enter into further reactions with H_2O and alkoxide hydroxides. The composition and structure of the final hydrolysis (hydropolycondensation) product depend mainly on the nature of the chemical element and the alkyl group, the pH of the reaction medium, and the ratio of the alkoxide and water.

If water has been added in an amount theoretically insufficient for the complete elimination of the RO groups via reactions (4)–(6), for example less than 2 moles of H_2O per mole of the alkoxide of a tetravalent element, then alkoxyelementoxane polymers (oligomers) of different structure are formed. The chain of such a polymer includes the following units:

By selecting the reaction conditions, it is possible to regulate the ratio of such units and the ways in which they are joined together and to synthesise polyalkoxyelementoxanes having a predominantly linear or branched structure, which makes it possible to control the porous structure of the oxides formed on their decomposition.

If the hydrolysis of the alkoxides proceeds in an excess of H_2O , then, depending on the nature of the element, the oxides E_2O_n , the hydroxides $E(OH)_n$, or the oxide hydroxides $EO_x(OH)_{n-2x}$, containing residual RO groups, are formed. This is associated with the reversibility of the reactions and the formation of three-dimensional elementoxane skeletons with sterically 'frozen' RO groups incapable of further hydrolysis or condensation with OH groups.

Complete hydrolysis is usually carried out in aqueous alcoholic media with a 10–20-fold excess of H_2O (relative to the theoretical amount). The hydrolysis products are isolated in the first stage in the form of nanometer-sized particles, so that the reaction medium remains optically transparent. Such a solution, called a sol, may be stabilised by special additives and may be used in the deposition of catalytic coatings and as a binder for carriers. Partly chelated alkoxides, for example $Ti(OR)_2(acac)_2$, are often used for the preparation of sols from the readily hydrolysable aluminium, titanium, or zirconium alkoxides, since this ensures a quieter course of hydrolysis (without the formation of powders or gels) and the stabilisation of the sol formed.

If the sol is not stabilised, the shape and size of the primary particles change during its ageing and gradually combine into various associated species. The sol loses its fluidity and is converted into a gel. The sol–gel transition may be regulated by selecting the solvent and the catalysis and by altering the temperature. An important factor is that this process is fairly controllable and that it does not entail, in contrast to the preparation of a sol from inorganic salts, the laborious washing away of extraneous ions and an increased purity of the product is attained. Although the SiO_2 carriers obtained, for example, from sodium silicates, are cheaper than those obtained from ethyl silicates, they retain 1% of Na_2O even after prolonged washing,¹⁶ which lowers their thermal stability and interferes with a series of catalytic processes.

Water and organic solvents are removed from gels by drying in air at different temperatures or by treatment in an autoclave at temperatures and pressures above the critical values for the solvent being removed (super-critical or hypercritical conditions). Xerogels and aerogels are then obtained respectively. The specific surface (S_{sp}) and the pore volume of the aerogels are somewhat greater than those of the xerogels, but the latter are cheaper and therefore have found more extensive application. Owing to the difference between the capillary tensions in pores with different diameters, large specimens crack and disintegrate during the drying of the xerogels, which, however, does not preclude their application, since the xerogels are usually employed only at starting materials for the preparation of various forms of catalysts and carriers (with the aid of comminution, moulding with a binder, and sintering). In recent years, methods have been developed for the drying of the gels under the usual conditions without cracking.¹⁷ For this purpose, chemical additives, for example formamide, which control the drying process, are introduced into the solutions being hydrolysed.

In most cases only one oxide is insufficient for the preparation of a carrier or catalyst with the optimum combination of properties. Mixed oxides are frequently used in heterogeneous catalysis. When alkoxy-technology is employed, they are obtained by the joint hydrolysis of two and more alkoxides or by the hydrolysis of an alkoxide in the presence of inorganic compounds with subsequent drying and partial sintering. The main problem in the hydrolysis of a mixture of alkoxides is that of the generation of mixed elementoxane fragments $E-O-E'$, which ensures the homogeneity of the system at the atomic (molecular) level and ultimately makes it possible to reduce sharply the crystallisation

and sintering temperatures or, conversely, to increase the temperatures of undesirable phase transitions.

The homogeneity of the distribution of the components, including small amounts of modifying additives, is the principal advantage of alkoxo-technology. Thus a microheterogeneous mixture of SiO_2 and TiO_2 is formed in the SiCl_4 – TiCl_4 system on deposition,¹⁸ whereas the joint hydrolysis of Si(OR)_4 and Ti(OR)_4 leads to the formation of a homogeneous titanosilica gel.¹⁹ When aqueous solutions of aluminium and magnesium salts are made alkaline, mixed hydroxide and oxide hydroxides with a homogeneous distribution of the metals are not formed owing to the difference between their precipitation pH values.²⁰ In contrast, on dissolution of alkoxides in organic solvents, complex formation takes place and the alkoxo-salt $\text{Mg[Al(OR)}_4\text{]}_2$ is formed, partial hydrolysis generating the Al–O–Mg fragment. Homogeneity is also retained on subsequent conversion into oxide hydroxides and oxides.²¹ Mixed E–O–E' fragments are formed mainly on condensation of the RO and OH groups attached to different elements:

It is noteworthy that the rates of hydrolysis and condensation of alkoxides differ significantly. This complicates the task of achieving atomic homogeneity (simple addition of water to a solution of a mixture of alkoxides usually results in the formation of a heterogeneous mixture of oxide and/or oxide hydroxide particles of nanometer size). A series of methods for the solution of the problem have been developed: slow hydrolysis by atmospheric moisture, selection of RO groups, the use of presynthesised mixed alkoxides, the introduction of organometallic catalysts, and preliminary partial hydrolysis of one of the alkoxides. The last method has received the greatest attention.^{22–24} Thus in the manufacture of highly porous ' SiO_2 – ZrO_2 ' carriers, Si(OEt)_4 is initially partially hydrolysed, after which Zr(OPr)_4 is added, and then the final hydrolysis is carried out:²⁵

The high chemical reactivity of the RO groups of alkoxides is manifested also when alkoxides come into contact with the OH groups of surfaces and hydroxides. This feature has been used successfully in the modification of the surfaces of catalysts and carriers. The sequence of reactions occurring under these conditions and the structure of the films (monolayer or bilayer in the initial stage of their formation), which are produced when a hydroxylated surface is treated with an alkoxide of a tetravalent element, can be represented as follows:

A similar modification of the surface may be achieved with the aid of anhydrous halides, which are virtually the only alternative to alkoxides. However, this does not afford any significant advantages, whereas the disadvantages of this procedure (among which difficulties in the storage and use of the product and the evolution of hydrogen halides during hydrolysis may be included) are fairly considerable.

The processes in which the precursors of oxide carriers and catalysts are inorganic compounds is of great interest. Alkoxides are then formed or R–O–E fragments are generated. Such processes are based on familiar reactions involving the formation of alkoxides from hydroxy-compounds, on the one hand, and oxides, hydroxides, and the salts of volatile acids (acetic, carbonic, and nitric), on the other.^{26–27} For example, the alkoxide (glycolate) was obtained directly in the reaction mixture in the synthesis of the Ni–SiO_2 catalyst:²⁸

Until recently, attention has been devoted to the specific synthesis of alkoxides from cheap inorganic compounds directly during the preparation of carriers and catalysts, i.e. to the attainment of the chain of reactions inorganic compound \rightarrow alkoxide \rightarrow oxide within the framework of alkoxo-technology.

III. Principal aspects, advantages, and disadvantages of the application of alkoxo-technology in heterogeneous catalysis

The chemical properties of alkoxide and the products of their hydrolysis described above as well as the mechanism of their conversion into oxides provide alkoxo-technology with the following important advantages:

- high purity of the final products (other elements can be fairly readily eliminated from alkoxides even at the synthesis stage or on distillation, and the preparation of powders does not require a milling stage in which the product might be contaminated);
- structural and chemical homogeneity of multicomponent mixtures;
- an appreciable decrease in the phase formation and sintering temperatures;
- simplicity of deposition of coatings with a controllable porosity and thickness on carriers of any shape;
- the possibility of synthesising new crystalline and amorphous compounds, the preparation of which by traditional methods is difficult or impossible;
- high quality of the intermediate products obtained when hydrolysed alkoxides are used as binders for large articles;
- the possibility of obtaining products in the form of fibres and microspheres;
- ecological cleanliness of the processes.

In modern chemical engineering, ecological advantages have assumed particular importance. Firstly, when alkoxides are employed, problems of the purification of waste waters do not arise. Secondly, the alcohols and organic compounds formed when alkoxides are converted into oxides may be fairly readily trapped, reused, or combusted further to CO_2 . This is significantly simpler than neutralisation of nitrogen and sulfur oxides as well as hydrogen halides, which are frequently present in the effluent gases in the synthesis of catalysts from inorganic precursors.

The main disadvantages of alkoxo-technology are as follows:

- the use of organic compounds as solvents;
- the considerable shrinkage in the preparation of dense materials;
- the higher cost of alkoxides compared with inorganic compounds.

The handling of organic compounds (solvents, alcohols, and decomposition products) requires the use of explosion-proof apparatus. However, this is not a significant obstacle to the employment of alkoxo-technology in catalysis, because the manufacture of catalysts is in general distinguished by a high degree of technological sophistication. Similar problems arise (are solved) also in the handling of ammonia, ammonium salts, and acetates.

The appreciable shrinkage during sintering is known to have a negative effect on the preparation of dense, and bulky ceramic materials.²⁹ In heterogeneous catalysis, alkoxides and their hydrolysis products are usually employed for the deposition of thin coatings or as binders in the preparation of bulky carriers and catalysts. In such cases, the problem of shrinkage is not so significant, particularly since the heat treatment is carried out at temperatures such that only partial sintering of the oxide skeleton generated from the alkoxide takes place and the optimum ratio of porosity to strength is ensured (porosity reduces sharply the strength of oxide materials).

The higher cost of alkoxides compared with inorganic compounds is undoubtedly the most important disadvantage of alkoxo-technology. Nevertheless, both in Russia and abroad silicon alkoxides are widely used in the casting of metals in accordance with smeltable models. The world prices of silicon, titanium, and aluminium alkoxides are comparable and are respectively about 3.5, and 3 U.S. dollars per kilogram.³⁰ The reasons why foreign investigators and practitioners in the field of the sol-gel process have turned to its alkoxide version are not discussed in the Russian literature,³¹ so that the hypotheses concerning the use of cheaper inorganic precursors are insufficiently convincing. It is striking that abroad it is regarded economically justified to employ for the preparation of a series of oxide materials not only alkoxides but also even acetylacetonates,^{32,33} the cost of which is higher by a factor of tens.

The application of the mixed alkoxoacetylacetonates $\text{E(OR)}_x(\text{acac})_{n-x}$, also of the acetylacetonates E(acac)_n , is considered in this review, since the latter represent a special kind of alkoxide with an intramolecular coordinate bond and a conjugation system, which are formed with participation of acetylacetone in the enolic form.

Not so much the high cost as the lack of a wide-scale industrial manufacture of aluminium and zirconium alkoxides, which together with silicon and titanium alkoxides are the principal reagents in alkoxo-technology, is a more realistic obstacle to the introduction of the latter in Russia. Their manufacture is now being initiated, but an electrochemical procedure is used for this purpose,³⁴ which differs from the industrial methods of alkoxide synthesis generally adopted in world practice.³⁵

Figure 1 presents schematically the principal aspects of alkoxide use in the technology of heterogeneous catalyst synthesis. This scheme embraces silicon, aluminium, and titanium alkoxides. Sometimes the oxide formed from one alkoxide is catalytically inactive or is insufficiently active. Such an oxide may function as a cocatalyst, a carrier, or an inorganic carrier,

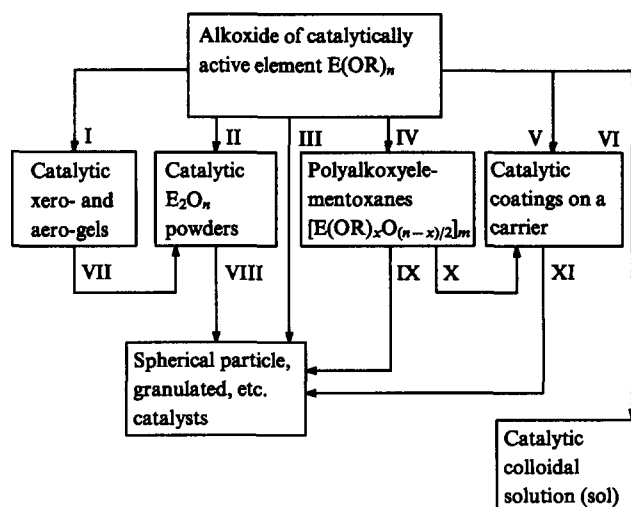

Figure 1. Principal operations in the preparation of intermediate products and catalytic materials from the alkoxides of catalytically active elements.

while the active component may be added to it, for example, in the course of, or after, joint hydrolysis.

There are several ways of synthesising heterogeneous catalysts, including the following operations (Fig. 1): I and II — total hydrolysis and drying, III — hydrolysis accompanied by the introduction of a filler and moulding, IV — partial hydrolysis; V — treatment of the carrier with a liquid or gaseous alkoxide; VI — total hydrolysis with stabilisation of the sol; VII — dispersion; VIII — introduction of inorganic binders (including their introduction via alkoxides) and moulding; IX — preparation of the solution, introduction of the filler, and moulding; X — treatment of the carrier with a polymer solution; XI — introduction of binders and moulding (preparation of fibrous and powdered carriers). The concluding operation in procedures I, III, V and VIII — XI is heat treatment. Specific ways of implementing individual variants of this general scheme will be examined below.

IV. Regulation of the chemical and phase compositions of oxide systems

The purity of the alkoxides, the uniformity of the distribution of the components in their joint hydrolysis mixtures, and the increased reactivity of the oxides formed after the removal of the organic component favour the specific regulation of the chemical and phase compositions of catalyst materials and hence exert a definite influence on their characteristics.³⁶

One of the commonest carriers and also catalysts or cocatalysts in many reactions is porous $\gamma\text{-Al}_2\text{O}_3$. In its preparation, it is necessary to solve a whole series of problems: the formation and stabilisation of a large surface area, the attainment of definite acid — base characteristics, and the retardation (shifts towards higher temperatures) of the $\gamma \rightarrow \alpha$ transition. The last problem is especially important in high-temperature catalysis, since the $\gamma \rightarrow \alpha$ transition is accompanied by an increase in grain size and in the density of the carriers and catalysts, which leads to a sharp decrease in their specific surfaces (S_{sp}) and strength up to disintegration. The use of alkoxo-technology made it possible to achieve significant advances in all these aspects. Thus $\gamma\text{-Al}_2\text{O}_3$ obtained from an alkoxide is distinguished by an increased thermal stability:^{37,38} after heat treatment at 800 °C, the specific surfaces of the alkoxide and nitrate $\gamma\text{-Al}_2\text{O}_3$ are respectively 150 and 50 $\text{m}^2 \text{g}^{-1}$.

The thermal stability of γ - Al_2O_3 increases significantly after the introduction of certain elements in the $\text{Al}(\text{OR})_3$ hydrolysis stage:³⁹ the specific surfaces of γ - Al_2O_3 without additives and following the addition of 4% of ThO_2 , ZrO_2 , and SiO_2 were 80, 99, 88, and $150 \text{ m}^2 \text{ g}^{-1}$ respectively after they had been maintained at 1000°C for 24 h, while the specimens containing 7% of SiO_2 had $S_{\text{sp}} = 116, 98.4$, and $84.9 \text{ m}^2 \text{ g}^{-1}$ after heat treatment at 1100°C for 30, 100, and 400 h respectively. The increase in thermal stability is due to the uniform distribution of the additives in the alumina matrix, which hinders the conversion of the low-temperature modifications of alumina into the thermostable α -form and shifts it into the region of higher temperatures.

Alkali and alkaline earth metal hexa-, undeca-, and dodeca-aluminates have a greater ability than γ - Al_2O_3 to retain an extensive specific surface at temperatures above 900°C . They can be most conveniently synthesised by employing alkoxides or mixtures of alkoxides with acetylacetonates and hydroxides.^{40–44} Thus barium hexaaluminate, obtained by the traditional solid-phase synthesis from BaCO_3 and Al_2O_3 , had $S_{\text{sp}} = 6.3 \text{ m}^2 \text{ g}^{-1}$ after heat treatment at 1300°C , while the specimen obtained by the alkoxide method had $S_{\text{sp}} = 20.2 \text{ m}^2 \text{ g}^{-1}$.⁴²

It is of interest to compare the alkoxide method with other procedures for the preparation of aluminates. For example, the traditional method of preparation of hexaaluminates as carriers for final-combustion catalysts includes the following principal technological operations: fusion of Al_2O_3 , B_2O_3 , and alkaline earth metal oxides at temperatures exceeding 1500°C , maintenance at 750 – 850°C , comminution, leaching with acids (for example, with acetic acid), washing, and drying.⁴⁵ This process is distinguished by high energy consumption, is laborious, and generates a series of ecological problems. When alkoxo-technology is employed, water is simply added to alkoxides and the powders are separated and heat-treated (up to 900°C). Such simplification of the technology combined with an increased heat resistance of the products justifies the view that the alkoxide method is an economically more acceptable procedure for the preparation of aluminate carriers for high-temperature catalysts.⁴³ All these advantages outweigh the disadvantages associated with the increased cost of the alkoxide precursors.

The use of alkoxo-technology makes it possible to regulate the degree of homogeneity in the distribution of the components in multicomponent systems.

Thus, depending on the conditions in the joint hydrolysis of $\text{Al}(\text{OR})_3$ and $\text{Si}(\text{OR})_4$, powders having the mullite composition ($3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$) could have a specific surface of either 6.8 or $38 \text{ m}^2 \text{ g}^{-1}$ after heating at 1500°C .⁴⁶ The degree of homogeneity of the former did not then attain the atomic level (nanocomposite) and that of the latter corresponded to the atomic or nearly atomic level of distribution of the components. In the latter case, the mullite microcrystals were formed at 900 – 1000°C and the vitreous aluminosilicate phase, through which recrystallisation accompanied by a decrease in S_{sp} in fact largely occurs, was then absent from the system.

The aluminomagnesium alkoxide spinel — a promising chemically inert carrier — also has an enhanced thermal stability.⁴⁷ Its specific surface at 1100°C is $30 \text{ m}^2 \text{ g}^{-1}$.⁴⁷

Depending on the alkoxide decomposition conditions (the effect of water or atmospheric moisture, thermal decomposition), γ - Al_2O_3 powders with different acidities, which affect their catalytic properties, are formed.⁴⁸ Thus, in the dehydration of ethanol on one of such powders, the yields of C_2H_4 and Et_2O were 73% and 8% respectively for a conversion of 82%, whereas on γ - Al_2O_3 obtained from inorganic precursors the yields were 2.6% and 10% respectively.

Modification of the chemical composition of the γ - Al_2O_3 surface by treating the latter with $\text{Si}(\text{OR})_4$ and subsequent deposition of palladium or platinum made it possible to obtain a thermostable catalyst capable of ensuring the flame-free combustion of hydrocarbons, diminishing thereby the evolution of CO and NO_x during catalytic combustion.⁴⁹

A special program for the preparation of artificial clays is being developed in Japan. Its aim is to improve the quality and to attain the stability and reproducibility of the properties of promising ceramic materials.⁵⁰ Such clays are used, for example, in the manufacture of ceramic cellular carriers for catalytic converters in internal combustion engines. The possibility of using alkoxides as oxide precursors is being investigated, which is not surprising since Japan is the leader in the introduction of alkoxo-technology. Treatment of natural clays with alkoxides makes it possible to obtain secondary clays with increased inter-layer distances and greater specific surfaces,⁵¹ which ensures the creation of a comparatively cheap heat-resistant and strong ceramics.

Studies carried out by the Nissan Motor Company and the National Chemical Laboratory of Japan have shown that, depending on the structure of the added low-molecular-mass polyether, anatase or rutile may be obtained from $\text{Ti}(\text{OPr})_4$ after hydrolysis and heat treatment.⁵² This is important, since different modifications of TiO_2 have significantly different catalytic properties. For example, anatase is preferable in the selective catalytic reduction of NO_x . The thermal decomposition of $\text{Fe}(\text{NO}_3)_3$ on surfaces modified with organic compounds, for example with ethylene glycol, has also been investigated.⁵³ As noted above, ROE fragments are generated in such systems on heating. Depending on the structure of the modifying agent, coatings having the Fe_2O_3 composition with a spinel or corundum structure are obtained.

The influence of the reaction conditions on the structure and properties of TiO_2 powders, obtained by the thermal decomposition of $\text{Ti}(\text{OPr})_4$ and $\text{TiO}(\text{acac})_2$ at 200 – 300°C , has been studied.⁵⁴ Rutile was obtained from the latter in the presence of ethylene glycol, whereas anatase with $S_{\text{sp}} = 200 \text{ m}^2 \text{ g}^{-1}$ was produced in the presence of toluene, the specific surface not diminishing on heating to 550°C .

Mixed crystalline oxides with the perovskite structure are active catalysts and promising carriers.^{55,56} The catalytic activities of a series of perovskites are comparable with those of noble metals. The inclusion of noble metals in the perovskite lattice increases the chemical and thermal stabilities of mixed catalysts and prevents the volatilisation of the noble metals in the form of oxides, for example, Ru_2O_3 or RuO_3 . The principal obstacle to the wide-scale introduction of catalysts with the perovskite structure is the high temperature of their synthesis ($\sim 900^\circ\text{C}$). This greatly hinders their preparation by the impregnation method. At the same time, the solid-phase synthesis with subsequent dispersion does not ensure the formation of a sufficiently large surface. Even on an inert carrier such as MgAl_2O_4 , only insignificant amounts of a mixed perovskite are formed from a mixture of copper, cobalt, and lanthanum nitrates. Their reaction with the support generates mainly spinels.⁵⁷ The optimum support for the synthesis of a perovskite might be ZrO_2 , but, since this carrier is expensive and has a low S_{sp} , it has not found a wide-scale application.

Low temperature methods of synthesis of perovskites at reduced temperatures (400 – 700°C) employing alkoxo-technology have been developed in recent years.^{58–59} It is to be expected that this will provide a fresh stimulus to the employment of perovskites in heterogeneous catalysis. This is of particularly great current interest for Russia, where chromium-containing catalysts or catalysts based on noble metals are mainly used for the purification of effluent gases.^{56,60} It is noteworthy that abroad the manufacture of the former has been curtailed owing to the high biological activity of chromium(VI) compounds⁶¹ and that of the latter has been reduced because of their high cost.

One of the most important advantages of alkoxo-technology is the possibility of obtaining new crystalline and amorphous phases, the synthesis of which by the traditional methods is difficult or impossible. This is caused mainly by the need to carry out the solid-phase synthesis at high temperatures,⁶² the formation of phases stable in the low-temperature region being impossible under such conditions. Furthermore, in solid-phase synthesis

it is extremely difficult to ensure the homogeneity of multicomponent systems, particularly when small amounts of additives are introduced. On the other hand, when alkoxo-technology is employed, atomic (molecular) homogeneity is already attained at the hydrolysis stage and heat treatment leads mainly to the densification of the oxide skeleton. This results in a decrease in the formation temperature of the crystalline phases and eliminates the liquation phenomenon — heterogeneous separation in glass melts (when amorphous oxides are obtained). Naturally, the transition from the theoretical consideration of the possibility of using alkoxo-technology to its practical implementation requires much effort. Nevertheless, considerable advances have already been achieved on these lines: barium titanates with the ratio $\text{BaO}:\text{TiO}_2 = 1:2$ and $1:5$,⁶³ previously regarded as metastable, the previously unknown compound $5\text{La}_2\text{O}_3 \cdot 2\text{Al}_2\text{O}_3$,⁶⁴ LiNbO_3 films,⁶⁵ and other materials have been obtained. Even though there is as yet no information about the use in heterogeneous catalysis of new crystalline compounds obtained with the aid of alkoxo-technology, data concerning the application of new amorphous materials (for example, in the manufacture of $\text{SiO}_2\text{-ZrO}_2$ porous glasses with an increased ZrO_2 content)²⁵ are already available.

V. Preparation of coatings and thin films

Catalysts obtained by deposition from solutions of catalytically active compounds onto a highly porous carrier with subsequent heat treatment are usually employed in many catalytic reactions, particularly in the external diffusion region. A carrier with a high surface area (primary carrier), treated with solution or suspensions, from which highly porous coatings (secondary carrier) are obtained on heat treatment, is also used as a support. In such cases, aqueous solutions of inorganic salts which can be decomposed by heat treatment (the cheapest and most readily available compounds) are traditionally employed for the introduction of catalytically active elements. However, the thermal decomposition of inorganic salts is usually accompanied by the evolution of corrosive and toxic gases and in addition the nitrates most frequently used are explosive. However, the main disadvantage of this technology is the crystallisation of inorganic salts on evaporation of water, which ultimately rules out the possibility of obtaining a uniform coating (a 'patchy' oxide coating is formed), reduced S_{sp} , and increases the consumption of catalytically active elements.

In multicomponent systems, the situation is aggravated by the occurrence of separate (fractional) crystallisation, since the probability of isomorphism or of the formation of complex salts is low. As a result, heat treatment gives rise to the formation of a microheterogeneous mixture of oxides, the homogenisation of which with formation of a mixed crystalline oxide having the specified structure requires an increased temperature and this leads to sintering accompanied by a decrease in S_{sp} , the formation of relatively inactive phases with participation of the carrier, and the alteration of the component ratio.

The application of alkoxo-technology makes it possible to overcome fairly readily these disadvantages of the traditional technology. The principal advantages of alkoxo-technology are ability of the products of the hydrolysis of alkoxides to form films and the establishment of homogeneity in the hydrolysis stage. The hydrolysis of alkoxides results in the formation of predominantly linear or branched polymers as well as oxide or oxide hydroxide particles of controllable size. The latter are produced either immediately in the form of a sol or (after peptisation) in the form of gels and powders.

Solutions of the hydrolysis products, deposited on supports by immersion, impregnation, or sputtering methods, give rise to uniform organic-inorganic coatings. After drying and moderate heat treatment at temperatures of 400–800 °C, ensuring the elimination of the organic component and the partial sintering of the coatings with retention of their high porosity, such coatings

Figure 2. The structure of oxide coatings formed from different hydrolysed alkoxides.

are converted into oxide ones. Their structure is illustrated conventionally in Fig. 2.

Type I coatings are characterised by a low open porosity and have no special importance in catalysis, but they can be used as an oxide binder, which sinters at a low temperature, for example in the preparation of ceramic honeycomb carriers. Type II–IV oxide coatings (films), which have a high open porosity and a large contact surface, are used as carriers and catalysts. The structure of the oxides formed from the alkoxide hydrolysis products obtained under various conditions has been examined in detail.^{66, 67}

For the deposition of coatings, one may use either liquid alkoxides directly or solutions of liquid and solid alkoxides in organic solvents with subsequent hydrolysis by atmospheric moisture and/or heat treatment. However, this method has not found extensive application, because it is fairly difficult to regulate the structure of an oxide coating having an appreciable thickness ($>0.1 \mu\text{m}$). It is more convenient to deposit monolayer and multilayer coatings from dilute solutions of alkoxides. The properties of such coatings, especially monolayer ones, differ significantly from those of bulk-phase materials owing to their anomalous structure (distortion of bond angles and changes in bond lengths and in the electronic state of their atoms), which is particularly important for catalysis. For example, Fe_2O_3 in a surface layer deposited from $\text{Fe}(\text{acac})_3$ on TiO_2 has a lower activity in the oxidation of CO than bulk-phase Fe_2O_3 .⁶⁸ This can be explained by the fact that a monolayer coating of this kind (obtained as a result of interaction with the support) is chemically closer to iron silicate rather than to Fe_2O_3 .

However, monolayer coatings exhibit much more frequently a higher catalytic activity than multilayer ones. Thus the dehydration of ethanol to C_2H_4 on the $\text{Nb}_2\text{O}_5/\text{SiO}_2$ monolayer catalyst obtained from $\text{Nb}(\text{OEt})_5$ proceeds to an extent of 99%–100%, whereas on the analogous impregnation catalyst considerable amounts of Et_2O are formed together with C_2H_4 .⁶⁹ The rate of the esterification reaction between AcOH and EtOH on a monolayer catalyst of this kind is 20 times greater than on massive Nb_2O_5 .⁷⁰ When platinum or nickel is deposited on it, the effect of the strong metal–carrier interaction is not manifested, in contrast to the deposition of the same metals on 'pure' Nb_2O_5 . The dispersity of copper in the Cu/SiO_2 monolayer catalyst obtained by deposition from $\text{Cu}(\text{acac})_2$ solution does not change even after 10 oxidation-reduction cycles, whereas in a multilayer catalyst it is lower immediately after preparation and falls to a particularly large extent after five such cycles have been performed.⁷¹

The surface monolayers obtained by depositing $\text{Nb}(\text{OR})_5$ or its mixture with $\text{Al}(\text{OR})_3$ do not crystallise with formation of Nb_2O_5 or aluminium niobates even after heating at 900 °C.⁷²

V_2O_5 coatings, for the deposition of which one may employ vanadium and vanadyl alkoxides^{73–80} or acetylacetonates,^{81–87} have acquired practical importance. They are used for the selective catalytic reduction of NO_x in effluent gases. Monolayer catalysts containing 2%–4% of V_2O_5 have activities in this reaction comparable to those of catalysts obtained by impregnating the

carrier with NH_4VO_3 solutions or deposited from $\text{V}_2(\text{SO}_4)_3$ solutions containing 20%–24% of V_2O_5 .⁸⁶ Thus the activity of the alkoxide catalyst referred to unit mass of V_2O_5 is almost ten times greater than that of a traditional catalyst obtained from inorganic precursors.

For low surface coverages of the SiO_2 , TiO_2 , Nb_2O_5 , Al_2O_3 , or ZrO_2 carriers by V_2O_5 films obtained from $\text{VO}(\text{OR})_3$, vanadate forms containing one terminal V–O bond and three VO–carrier bridge bonds are formed on the surface.⁷⁵ It has been suggested that vanadium oxide catalysts for the reduction of NO_x be obtained by impregnating cellular carriers with solutions of partly hydrolysed alkoxide-based mixtures, for example, a mixture of $\text{Ti}(\text{O}i\text{Bu})_4$, $\text{VO}(\text{O}i\text{Bu})_3$, and WCl_6 .⁸⁰

The method involving the chemical vapour-phase deposition (CVPD) of the $\text{B}(\text{O}Et)_3$, $\text{Si}(\text{O}Et)_4$, $\text{P}(\text{O}Me)_3$, and $\text{Ti}(\text{OPr}^i)_4$ alkoxides has been used to obtain the $\text{B}_2\text{O}_3/\text{SiO}_2$,^{88–90} $\text{B}_2\text{O}_3/\text{Al}_2\text{O}_3$,⁹¹ $\text{SiO}_2/\text{Al}_2\text{O}_3$,^{92–95} $\text{TiO}_2/\text{carrier}$,⁹⁶ $\text{SiO}_2/\text{aluminosilicate}$,⁹⁷ and $\text{BPO}_4/\text{SiO}_2$ ⁹⁸ catalysts. The supported catalysts obtained from alkoxides by the CVPD method have a higher activity: thus boron oxide is uniformly distributed on the carrier surface even when its content is more than 30% (in the usual impregnation deposition, large B_2O_3 crystals are formed in this case).^{89–90} This promotes a high activity and selectivity (95%–96%) of the catalyst in the rearrangement of cyclohexanone oxime to caprolactam. The $\text{SiO}_2/\text{Al}_2\text{O}_3$ alkoxide catalyst, which has a lower S_{sp} than the industrial catalyst having a similar composition (177 and 360 $\text{m}^2 \text{g}^{-1}$ respectively) has a catalytic activity in the cracking of cresol comparable to that of the latter. This is apparently associated with the fact that it contains a larger number of acid centres.⁹² The fixation of the first layer on deposition of SiO_2 formed from $\text{Si}(\text{O}Et)_4$ on Al_2O_3 takes place as a result of the interaction between the HOAl and EtOSi groups with formation of Al–O–Si fragments. In a nitrogen atmosphere, the residual EtO groups do not decompose, whilst in the presence of oxygen they are oxidised with formation of acetaldehyde and the regeneration of OH groups.⁹³

The formation of catalytic oxide coatings from alkoxides by the CVPD method has also been investigated in other studies.^{99–108} Silicon dioxide, obtained from $\text{Si}(\text{O}Et)_4$, covers only the outer surface of zeolites. This alters the dimensions of the inlet pores with retention of the inner structure of the zeolites and increases sharply the selectivity of the latter in relation to the volume of the reacting molecules, which is indicated, for example, by the results of a study of the cracking of octane isomers.¹⁰¹ Coatings in the form of SiO_2 , deposited from the vapour phase, exhibit a higher chemical reactivity even on an inert carrier such as ZrO_2 . At 550 °C, they partially coalesce with formation of clusters and partly dissolve in the carrier.¹⁰⁷

The method involving the deposition of coatings by treating the carrier with an alkoxide under thermal decomposition conditions is close to CVPD. The $\text{SiO}_2/\text{Al}_2\text{O}_3$ catalyst has been obtained by this procedure.¹⁰⁹ It is assumed that the deposition takes place via the interaction of the EtO groups in $\text{Si}(\text{O}Et)_4$ with Lewis acid centres on the Al_2O_3 surface. However, this explanation cannot be extended to the formation of the second and subsequent layers (the overall increment in the mass of SiO_2 reaches 20%).

A comparative study of several $\text{Pd}/\text{Al}_2\text{O}_3$ impregnation catalysts showed¹¹⁰ that highly disperse palladium particles are formed from PdCl_2 and $\text{Pd}(\text{acac})_2$. On reduction, they are converted into a finely disperse metallic phase, whereas the decomposition of $\text{Pd}(\text{NO}_3)_2$ leads to the formation of large particles.

Aluminium, tantalum, and titanium alkoxides have been used for the modification of the surfaces of porous carriers before deposition of catalytically active metals on the latter.^{111–113} For a comparatively slight increase in the specific surface of the specimens (for example, from 100 $\text{m}^2 \text{g}^{-1}$ for the initial $\gamma\text{-Al}_2\text{O}_3$ to 120 $\text{m}^2 \text{g}^{-1}$ for the modified oxide), this made it possible to increase sharply their activity and to obtain effective catalysts for a series of reactions. Thus the degree of conversion of carbon

monoxide into methane on a modified $\text{Ru}/\text{Al}_2\text{O}_3/\gamma\text{-Al}_2\text{O}_3$ catalyst was 99% for selectivity of 100%, whereas on the usual $\text{Ru}/\gamma\text{-Al}_2\text{O}_3$ catalyst it was 62% with a selectivity of 99%. A similar approach has been used to obtain active $\text{Pd}/\text{TiO}_2/\text{spherical glass bead hydrogenation catalysts}$ ^{114,115} and for the deposition of Al_2O_3 coatings on highly porous SiO_2 carriers.¹¹⁶ It is important to note that this procedure makes it possible to attain a significant catalytic effect for a low consumption of alkoxides.

A modified copper/zeolite catalyst, obtained by ion exchange followed by treatment in a $\text{Ti}(\text{OMe})_4$ solution, has been developed for the catalytic conversion of moist exhaust gases.¹¹⁷ Different additives have different effects on the modification of $\gamma\text{-Al}_2\text{O}_3$ ($S_{sp} = 13.7 \text{ m}^2 \text{g}^{-1}$) with $\text{Ti}(\text{OPr}^i)_4$ or $\text{Si}(\text{O}Et)_4$ solutions in hexane.¹¹⁸ Best coatings with S_{sp} up to 29.4 $\text{m}^2 \text{g}^{-1}$ are formed in the presence of EtOH, PrOH, and PrⁱOH, whereas added surfactants exhibit a negative effect.

A process involving the fixation on honeycomb ceramic carriers of secondary $\gamma\text{-Al}_2\text{O}_3$ carriers, formed from sols obtained by the hydrolysis of $\text{Al}(\text{OR})_3$ and the peptisation of the gels produced, has been patented.¹¹⁹ A disadvantage of the traditional technology for the fixation of secondary carriers from suspension is the accumulation of $\gamma\text{-Al}_2\text{O}_3$ particles in corners of the channels within the honeycomb carrier, which reduces the effectiveness of the catalyst and increases its aerodynamic resistance. The proposed method is free from this disadvantage. In addition, 14.7% of Al_2O_3 , and not 33% as in the formation of a suspension coating, is sufficient for the attainment of $S_{sp} = 25\text{--}30 \text{ m}^2 \text{g}^{-1}$.

A process has been developed for the deposition of alumina coatings on barium aluminate.¹²⁰ A catalyst obtained from platinum salts and a mixture of $\text{Ti}(\text{O}Et)_4$ and $\text{Al}(\text{OPr}^i)_3$ has been designed for use in automobile converters. The mixture of alkoxides is subjected to joint hydrolysis, deposited on a honeycomb carrier, dried, and maintained at 500 °C. The degree of conversion of CO on this catalyst reaches 94% at 250 °C and falls to 81 % after being used for 1000 h at 800 °C (for the usual catalyst, the corresponding conversions are 88% and 75%).¹²¹

VI. The use of alkoxides for the preparation of carriers and catalysts

In studies^{6,41,122–144} on the use of alkoxides for the preparation of carriers and catalysts and of their physicochemical and catalytic properties, attention was concentrated on the chemical mixing method. It has been shown for mixtures of silicon and aluminium alkoxides with aluminium, ruthenium, and copper chlorides that the process should consist of four stages:

- (1) the formation of complexes of the alkoxides and chlorides with organic polydentate ligands;
- (2) hydrolysis with formation of a sol and gel;
- (3) drying and dispersion;
- (4) sintering and reduction in a stream of hydrogen (when copper and ruthenium salts are used).

The introduction of polydentate ligands such as aliphatic diols and low-molecular-mass polyethers makes it possible to monitor the course of the hydrolysis and polycondensation (by virtue of their coordination to the RO groups of the alkoxides or their substitution, the ligands lowering the rates of these reactions), ensures the binding of the metal ions to the elementoxane chains, and regulates the shape and size of the pores as well as S_{sp} . Thus, in the hydrolysis of $\text{Al}(\text{OR})_3$ in the presence of the polyether $\text{Me}(\text{OCH}_2\text{CH}_2)_n\text{OMe}$, micropores with an average diameter of 10 nm predominated in the $\gamma\text{-Al}_2\text{O}_3$ obtained for $n = 2$, whereas for $n = 3$ or 4 a wide size distribution of the pores was observed (from 10 to more than 100 nm).¹³² In the joint hydrolysis of $\text{Si}(\text{OR})_4$ and $\text{Al}(\text{OR})_3$ in the presence of ethylene glycol, 2-methylpentane-1,2-diol, or hexane-1,6-diol, aluminosilicates (3.3% of Al_2O_3) with an average pore diameter of 0.55–0.65 nm were obtained.¹⁴⁰ The structure of the diol introduced has a decisive influence on the specific surfaces of such aluminosilicates (Table 1).

Table 1. The influence of the nature of the ligand on the specific surfaces of the 3.3% Al₂O₃-SiO₂ carriers obtained from alkoxides by the chemical mixing method.¹⁴¹

Ligand	$S_{sp}/m^2 g^{-1}$
Ethane-1,2-diol	399
Propane-1,2-diol	170
Butane-2,3-diol	179
2-Methylpropane-1,2-diol	308
Butane-1,2-diol	315
Pinacol	319
Pentane-1,2-diol	483
Propane-1,3-diol	210
Butane-1,3-diol	222
2-Methylbutane-1,3-diol	545
2-Methylpentane-2,4-diol	486
Butane-1,4-diol	5
Pentane-1,5-diol	365
Hexane-1,6-diol	595
Decane-1,10-diol	734
Dodecane-1,12-diol	637

The homogeneities in the distribution of the components were compared on TiO₂-Al₂O₃ specimens synthesised in different ways: by sintering TiO₂ and Al₂O₃ powders, by precipitating mixtures of oxide hydroxides from aqueous solutions of salts with ammonia or urea, and by chemical mixing.¹⁴⁰

In the last case, the crystallisation of TiO₂ was not noted after heating for 5 h at 550 °C. The specimen remained X-ray-amorphous, which confirmed the high degree of homogeneity attainable when the chemical mixing method is employed. In a number of instances, this is of practical importance.

The catalysts synthesised were tested in reactions involving the partial hydrogenation of benzene, the alkylation of naphthalene, and the conversion of methanol. Data on the partial hydrogenation of benzene to cyclohexene on the Ru-SiO₂ and Ru-Al₂O₃ catalyst obtained by the chemical mixing method and on impregnation catalysts employed for comparison are presented in Table 2.

Chemical mixing was used also in the study of the influence of added metal oxides (10%) on the S_{sp} of alumina.⁴¹ The introduction of SrO, BaO, La₂O₃, and ZrO₂ suppressed the sintering of Al₂O₃ in the range 1000–1200 °C. After heating the BaO-Al₂O₃ mixture for 100 h at 1000 °C, a high specific surface of alumina

Table 2. Partial hydrogenation of benzene to cyclohexene on different ruthenium catalysts.¹³⁴

Method of preparation	Ligand	Catalyst composition	Conversion of benzene (%)	Yield of cyclohexene (mol %)
Chemical mixing (TEOS-AlCl ₃)	ethylene glycol	2% Ru-SiO ₂	86.8	27.0
	ethylene glycol	(2% Ru + 0.2% Cu) SiO ₂	83.3	31.4
	pinacol	(2% Ru + 0.2% Cu) SiO ₂	42.7	14.2
	hexylene glycol	(2% Ru + 0.2% Cu) Al ₂ O ₃	53.1	24.5
		2% Ru-SiO ₂	64.3	8.6
Impregnation		2% Ru-Al ₂ O ₃	54.5	5.3

Note. Reaction temperature 453 K, H₂ pressure 7 MPa, benzene: water = 1.6:1.

(139 m² g⁻¹) was retained, whilst after heating for 3 h at 1200 °C S_{sp} diminished to 96 m² g⁻¹. The addition of CaO, MgO, and CeO₂ accelerated the sintering and reduced the S_{sp} of alumina.

The chemical mixing method was also applied in other studies.^{145–151} It was shown in relation to the selective reduction of NO_x that mixed V₂O₅-TiO₂ catalysts exhibit an enhanced catalytic activity compared with impregnation catalysts.¹⁴⁹

The average rhodium particle size in the Rh/SiO₂ catalyst synthesised using the Rh(NO₃)₃-Si(OEt)₄-HOC₂H₄OH systems increased from 1 to 5.6 nm with increase in the rhodium content from 0.34% to 6.89%. The activity of this catalyst in the PROH decomposition reaction increased sharply for particle sizes of 1–2 nm, when the fraction of metal atoms at the corners and on the edges of microcrystallites was a maximum.¹⁵¹ A similar dependence of the selectivity in the hydrogenation of propionaldehyde on the nickel particle size has been observed on the Ni/SiO₂ catalyst, in which the metal particle size increased from 4 to 12 nm with increase in the nickel content from 2% to 26%.¹⁵⁰ It was shown by IR spectroscopy that the metal particles are retained on the support as a result of the formation of the Ni-O-Si linkage. The cobalt particle size in the Co/TiO₂ catalyst increased from 10 to 40 nm with increase in the reduction temperature to 600 °C, but at ~700 °C, where the anatase-rutile transition takes place, it again decreased to 10–15 nm.¹⁴⁷ The redispersion effect, characteristic solely of catalysts obtained by chemical mixing but not of impregnation catalysts, is apparently due to a strong metal-carrier interaction.

Catalyst powders obtained as a result of the operation of the reaction chain alkoxide → xerogel → powder (Fig. 1, operations I and VII modified by the introduction of inorganic salts and ligands) were considered above. In industry, powders are rarely employed as the finished form of the catalysts, serving mainly as the starting material for the preparation of various bulk-phase catalysts.

Boehmite (AlOOH) powders synthesised via alkoxides have found the greatest practical application.¹¹⁶ Previously they were obtained as side products in the synthesis of higher alcohols by the Ziegler method, but subsequently a number of companies, for example Conoco and Vista,¹⁵² set up a special industrial process. The alkoxide obtained by the reaction of metallic aluminium with an alcohol was hydrolysed, after which boehmite was separated and dried, while the alcohol was regenerated. The process has satisfactory ecological characteristics and the powders synthesised have a high purity and dispersity. They can be readily made to undergo a transition to the sol state by adding water and small amount of acid (in certain cases the addition of acid is not required). The employment of such powders for the deposition of secondary γ -Al₂O₃ coatings on honeycomb carriers made it possible to create Pt/ γ -Al₂O₃/honeycomb carrier catalysts, which, whilst having the same activity as the industrial analogues, contain 10 times less platinum.¹⁵³

The Al₂O₃,^{154–158} SiO₂-TiO₂,^{159–161} TiO₂,^{162–166} SiO₂-Al₂O₃,^{167,168} TiO₂-ZrO₂,¹⁶⁹ SiO₂,²⁸ V₂O₅-Al₂O₃,¹⁷⁰ etc. catalytic powders have been obtained with the aid of alkoxotechnology. By selecting the method of synthesis and the reaction conditions, it is possible to regulate S_{sp} and the size and volume of the pores. For example, in the thermolysis of Al(OR)₃ solutions in secondary and tertiary alcohols, where water is generated *in situ* as a result of the thermal degradation of the alcohols, γ -Al₂O₃ powders with $S_{sp} \approx 500$ m² g⁻¹ are produced.¹⁵⁸ Gels were obtained by preliminary partial hydrolysis of Si(OR)₄ in the Si(OR)₄-Ti(OR)₄ system and were then dried, comminuted, impregnated with chromium salts, and sintered.¹⁵⁹ The uniform distribution of the components promoted an increase in the thermal stability of the resulting 1% Cr/SiO₂-TiO₂ catalytic powders; after heat treatment for 3 h at 850 °C, their specific surface was 404 m² g⁻¹ with a porosity of 2.19 cm³ g⁻¹.

By virtue of the high specific surface of alkoxide powders, they may be pelleted without a binder.¹⁷¹ A powder catalyst of the Fischer–Tropsch process has been obtained by the joint hydrolysis of $\text{Ti}(\text{OPr})_4$ and $\text{Zr}(\text{OPr})_4$ in the presence of $\text{Fe}(\text{OAc})_3$.¹⁶⁹

A spherical shape of the catalytic powder particles is preferred, since this diminishes wear due to abrasion. Porous microspheres 1–100 μm in diameter and with pore dimensions of 10–40 nm were obtained by heating the products of the hydrolysis of $\text{Si}(\text{OR})_4$ at $\text{Ti}(\text{OR})_4$ at 400–900 °C.¹⁷² Microspheres having the composition 3% Y_2O_3 – ZrO_2 with an average diameter of 40–50 μm are formed when products of the joint hydrolysis of the corresponding alkoxides are mixed with alkyl phthalates, the mixture being subsequently forced through a draw plate into high-boiling organic liquids.¹⁷³ The formation of an emulsion in the region of immiscibility of the alkoxide–ethanol–water ternary system was used to obtain SiO_2 – TiO_2 powders having spherical particles with $S_{\text{sp}} \leq 375 \text{ m}^2 \text{ g}^{-1}$ and a controllable diameter from 0.05 μm to 1 mm.¹⁶¹ Alkoxide TiO_2 and Al_2O_3 – TiO_2 microsphere powders, activated by the addition of V_2O_5 and CuO , have found a practical application in the purification of the effluent gases from various industries, while TiO_2 microsphere powders are used in the photochemical decomposition of organic compounds in waste waters.^{174, 175}

Stable TiO_2 or ZrO_2 spherical particle powders, designed for use as carriers and catalysts, with an average diameter of 1–100 μm , pore dimensions of 1–500 nm, and a porosity of 0.1–1 $\text{cm}^3 \text{ g}^{-1}$ have been obtained by the hydrolysis of alkoxides, spray drying of the resulting sols, and heat treatment at 500 °C.¹⁷⁶ The TiO_2 spherical particle powder for the promotion of photochemical reactions has been synthesised by the hydrolysis of $\text{Ti}(\text{OR})_4$ in the presence of HCl .¹⁷⁷ SiO_2 – Al_2O_3 microspheres have been obtained similarly.¹⁶⁷

Porous spherical particle powders may be obtained also without the use of alkoxides, but in most cases the alkoxide procedure is preferred. For example, a high quality SiO_2 microsphere powder with S_{sp} up to 300 $\text{m}^2 \text{ g}^{-1}$ and a porosity of 1.3 $\text{cm}^3 \text{ g}^{-1}$ is obtained by the Vycor process.¹⁷⁸ In terms of resistance to wear, this powder is superior to alkoxide powders. However, the Vycor process consumes a large amount of energy, takes a long time, and, what is most important, is designed mainly for the preparation of high-silica microspheres, whereas alkoxo-technology has virtually unlimited possibilities for the selection of components.

SiO_2 – Al_2O_3 ,^{179, 180} SiO_2 – ZrO_2 ,^{181–183} SiO_2 – TiO_2 ,¹⁸⁴ SiO_2 ,¹⁸⁵ ZrO_2 ,¹⁸⁶ and SiO_2 – B_2O_3 ¹⁸⁷ xerogels have been obtained for use in heterogeneous catalysis. Studies^{187–192} on the joint hydrolysis of $\text{Si}(\text{OR})_4$ and $\text{Zr}(\text{OR})_4$ are of great interest. These investigations have served as a basis for the establishment of the industrial manufacture of highly porous glasses with an increased thermal stability and resistance to alkalis.²⁵ Thus 30% ZrO_2 – SiO_2 glasses have specific surfaces of 392, 350, 250, and 119 $\text{m}^2 \text{ g}^{-1}$ at 300, 500, 800 and 900 °C respectively and lose their porosity completely as a result of sintering only on attainment of 950 °C. After heat treatment at 800 °C, $\text{Ti}(\text{O}i\text{Bu})_4$ xerogels contained 30% of anatase and 70% of rutile; when 5% of Cr_2O_3 was introduced with the aid of $\text{Cr}(\text{acac})_3$, the anatase content increased to 90%.¹⁹³ The addition of different amounts of $\text{R}_4\text{N}^+ \cdot \text{OH}^-$ to a mixture of silicon and aluminium alkoxides made it possible to obtain porous aluminosilicates with a molar ratio SiO_2 : Al_2O_3 from 30:1 to 500:1, $S_{\text{sp}} = 50$ –1000 $\text{m}^2 \text{ g}^{-1}$, a porosity of 0.3–0.6 $\text{cm}^3 \text{ g}^{-1}$, and a pore diameter of 1 nm. They contained no pores with diameters > 3 nm.¹⁶⁸ In order to regulate porosity, it has been suggested that a proportion of 0.03–0.4 of an organic polymer relative to the alkoxide be introduced: on formation of a gel, the latter is segregated as a separate phase, which ensures, after burning it off and sintering, the creation of a highly porous oxide structure.¹⁷⁹

The anomalously high porosities and specific surfaces of alkoxide aerogels are especially valuable in heterogeneous catalysis.^{194–207} Thus the Fe_2O_3 – SiO_2 (Al_2O_3) aerogel catalysts

obtained from $\text{Si}(\text{OMe})_4$ or $\text{Al}(\text{O}i\text{Bu})_3$ and $\text{Fe}(\text{acac})_3$ are more active in the Fischer–Tropsch reaction by 2–3 orders of magnitude than the usual iron-containing catalysts and, what is no less important, do not become saturated with coke, in contrast to the latter.¹⁹⁶ Catalysts with $S_{\text{sp}} = 20$ –700 $\text{m}^2 \text{ g}^{-1}$, a porosity of 1.5–12 $\text{cm}^3 \text{ g}^{-1}$, and an apparent density of 0.003–0.5 g cm^{-3} have been obtained by the joint hydrolysis of $\text{Al}(\text{O}i\text{Bu})_3$ and $\text{Pd}(\text{OAc})_2$ [or $\text{Ni}(\text{OAc})_2$]. They are distinguished by a uniform distribution of the components and the absence of clusters. They are designed for the reduction of nitro-compounds and hydrodesulfurisation.¹⁹⁵ The traditional catalysts based on tin and antimony or molybdenum and bismuth oxides are incapable of accelerating the synthesis of nitriles from unsaturated hydrocarbons and NO, whereas the Ni – Al_2O_3 (SiO_2) aerogel catalyst is highly active and selective in this reaction.^{201, 202}

The γ - Al_2O_3 -based porous ceramic obtained via an aerogel is used as a carrier, retaining $S_{\text{sp}} = 72 \text{ m}^2 \text{ g}^{-1}$ after heating for 5 h at 1200 °C.²⁰⁸ Alkoxo-technology is formally not used in the synthesis of aerogel from Cr_2O_3 ,²⁰⁵ but since CrO_3 and MeOH are used as the starting compounds, it follows that in this process too there is a possibility of the generation and subsequent decomposition of chromium(III) and chromium(IV) methoxides because instances of the formation of alkoxides from CrO_3 and alcohols are known.²⁰⁹ Products analogous to aerogels are formed in the glycothermal synthesis, which involves the treatment of a mixture of $\text{Al}(\text{OPr})_3$ with glycols in an autoclave at 300 °C for 2 h and subsequent heat treatment at ~ 600 °C.¹⁵⁷ The dominant pore diameters in the γ - Al_2O_3 obtained using ethylene glycol, propane-1,3-diol and butane-1,4-diol were respectively 7, 16, and 70 nm, while S_{sp} varied from 184 to 354 $\text{m}^2 \text{ g}^{-1}$. γ - Al_2O_3 modified by the addition of SiO_2 in order to increase its thermal stability has been synthesised by a similar method.²¹⁰

Catalysts with a honeycomb structure, which exhibit low aerodynamic and hydrodynamic resistances and make it possible to perform catalytic processes in liquids and gaseous media in the presence of heterogeneous admixtures, have come to be widely used abroad during recent years. A porous ceramic with a cordierite ($2\text{MgO} \cdot 2\text{Al}_2\text{O}_3 \cdot 5\text{SiO}_2$) composition, a low coefficient of thermal expansion, and a resistance to temperature gradients is most often employed as a carrier for honeycomb catalysts. The Corning Company, which has devoted a considerable amount of attention to alkoxo-technology,^{37, 39, 213–218} is the pioneer and recognised leader in the development and introduction of ceramic honeycomb carriers.^{211, 212} For example, it developed a new type of monolithic honeycomb catalysts with porous catalytic coatings, which are not on the walls (washcoat), as in the traditional catalyst, but within them (washcoat-in-the-wall), which reduces the consumption of expensive metals per unit volume of the catalyst and improves its operating characteristics.²¹⁷ It may be postulated that alkoxo-technology has found an application in the manufacture of a new honeycomb catalyst with an increased operating lifetime.²¹⁹

A cordierite ceramic has been obtained in Japan with the aid of alkoxo-technology.^{220–222} For this purpose, a mixture of ethyl silicates with magnesium and aluminium salts was spray pyrolysed, which resulted in the formation of porous cordierite microsphere powders, which were heat-treated in the temperature range 950–1450 °C. The resulting ceramic has a high porosity (48%–92%) and is promising material for honeycomb carriers. The purity of the alkoxide cordierite powders is important, since impurities significantly increase the coefficient of thermal expansion of cordierite²¹² and reduce the heat resistance of the finished product.

In Russia, the large-scale industrial manufacture of ceramic cordierite carriers has not been initiated (mainly owing to the difficulties arising during heat treatment, associated with achieving a compatible combination of the stages involving the synthesis of cordierite and sintering within a narrow process temperature range). Carriers based on glass or polycrystalline fibres (paper, cardboard, fabric, etc.) may serve as an alternative.

The deposition of porous coatings on these materials from aqueous solutions of inorganic salts is difficult because such solutions have no film-forming properties and when they are dried crystallisation takes place. The employment of alkoxides and the products of their hydrolysis makes it possible to overcome these difficulties easily. For example, the carrier and the catalyst may be obtained by impregnating various fabrics having specified mesh dimensions with suspensions based on aqueous alcoholic solutions and silicon, aluminium, and/or titanium alkoxides and oxide powders of the same elements.²²³

A convenient procedure for the creation of a heat-resistant fibrous oxide structure is the method involving the burning away of a matrix. A fibrous organic material is impregnated with a hydrolysed solution of an alkoxide (in one step or with periodic intermediate drying) and is heat-treated under conditions ensuring the burning away of the organic matrix and the sintering of the oxide coating generated.^{224–226} It has been suggested that heat-resistant highly porous carriers be obtained by the cyclic impregnation of foam-carbon articles with a chelated alkoxide and intervening heat treatment.²²⁷

Elements of alkoxo-technology and ion exchange have been used in a novel method of preparation of catalysts.^{228, 229} According to this method, soluble substitution products are obtained initially by the interaction of titanium, zirconium, or tantalum alkoxides with a methanol solution of NaOH, this being followed by hydrolysis and ion exchange with nickel, palladium, or molybdenum salts.

The catalysts synthesised have a high specific surface ($150\text{--}300\text{ m}^2\text{ g}^{-1}$) and an increased catalytic activity: for a 1% content of the catalytically active metal, they are just as effective in the liquefaction of coal as industrial catalysts with a 15% content of this metal.

Interesting procedures for the employment of alkoxo-technology in the preparation of phosphorus vanadium oxide catalysts for the synthesis of maleic anhydride by the selective oxidation of C_4 hydrocarbons have been proposed. Here the alkoxide VO(OR)_3 may be used as one of the starting compounds in the synthesis of the catalyst,²³⁰ vanadium(IV) and vanadium(III) alkoxides may be formed and segregated in one of the technological stages,²³¹ and, finally, the alkoxides may be formed *in situ* from V_2O_5 and ROH and react with H_3PO_4 .^{232–234} The use of alkoxides has a dual purpose. Firstly, they are the most convenient vanadium compounds suitable for interaction with H_3PO_4 (vanadates or vanadium chlorides are unsuitable for this purpose and the synthesis of vanadium catalysts from a mixture of V_2O_5 powders with P_2O_5 or H_3PO_4 is also impossible). Secondly, alcohols reduce vanadium(V) to vanadium(III) and vanadium(IV), which promotes the attainment of a high activity and selectivity. Another alkoxide, Si(OEt)_4 , is also used in these synthesis, its role consisting mainly in the binding of the water evolved, which facilitates the formation of a cryptocrystalline catalytic powder.

Large foreign companies, for example Union Carbide, Mobil Oil, Chevron, etc., have devoted much attention during the last decade to the use of alkoxides for the preparation of synthetic molecular sieves having the compositions $(\text{Si}_x\text{Al}_y\text{P}_z)\text{O}_2$,^{235, 236} $(\text{M}_x\text{Si}_y\text{Al}_z\text{P}_w)\text{O}_2$ ($\text{M} = \text{Mg, Fe, or Ti}$),^{237–240} $(\text{Ti}_x\text{Al}_y\text{Si}_z)\text{O}_2$,^{241–243} $\text{Al}_2\text{O}_3\text{--P}_2\text{O}_5$,²⁴⁴ etc.,^{245–248} which is associated with increased

reactivity of the oxides and oxide hydroxides formed on hydrolysis of alkoxides. The use of Ti(OR)_4 and of its modified analogues, formed when a proportion of the RO groups are replaced by chelating groups, made it possible to achieve the homogeneous insertion of TiO_2 into the aluminosilicate framework, which could not be achieved when other titanium compounds were employed.²⁴³ The molecular sieves were synthesised by the hydrothermal treatment of a mixture of compounds of the corresponding elements, at least one of which is an alkoxide or a product of its hydrolysis, in the presence of an organic structure-forming agent (alkylamine, pyridine, tetraalkylammonium hydroxide) with subsequent heat treatment in air at $200\text{--}700^\circ\text{C}$ for the complete or partial removal of the structure-forming agent. For example, SAPO-11 aluminosilicon phosphate molecular sieves have been obtained in this way and the 0.5% Pd/SAPO-11 catalyst was prepared from them. The yield of neutral distillates in hydrocracking on this catalyst reaches 75.4%, whereas in the presence of the traditional catalyst having a similar composition it is 64.7%.²³⁵ Evidently in the presence of this effect the question of the increased cost of the precursor alkoxide does not arise. An unusual method of synthesis of molecular sieves has been proposed²⁴⁹ in which Si(OR)_4 serves as the cross-linking agent for alkali metal silicates, titanates, and mixed titanates swollen in the reaction medium.

Many specialists in the field of catalysts manufacture believe (see, for example, Ref. 250) that the main problem nowadays is the creation of carriers with a definite set of characteristics ensuring their functioning under specified conditions rather than the choice of catalytically active elements and their introduction into the catalyst. For example, the widely used $\gamma\text{-Al}_2\text{O}_3$ carriers disintegrate when acted upon by the acid reagents (HCl , SO_3) present in contaminated air or formed during its purification. The replacement of $\gamma\text{-Al}_2\text{O}_3$ by SiO_2 , TiO_2 , ZrO_2 , and their mixtures is the most promising procedure. The choice of inorganic precursors for such carriers is limited and their application does not ensure the attainment of a high porosity and S_{sp} and gives rise to significant ecological problems.

These deficiencies are overcome when alkoxides are employed. Thus, among the available TiO_2 precursors, Ti(OR)_4 is most preferred. It is employed for the preparation of an aqueous TiO_2 sol (a catalyst of photochemical reactions),²⁵¹ microspheres or fibres,²⁵² powders,²⁵³ extruded materials,²⁵⁴ carriers with effective ion-exchange properties [for this purpose, Ti(OR)_4 is hydrolysed in the presence of NaOH or KOH],¹⁶⁶ and also as an organic binder with catalytic properties.²⁵⁵ In most cases, such materials possess a high catalytic activity. For example, the catalysts obtained by depositing the active component on alkoxide-derived TiO_2 powder are more effective in the reduction of NO_x than those obtained by deposition on powdered aerosil, rutile, anatase, or rutile-anatase mixtures.²⁵³

The authors of the present review initiated comprehensive studies on the chemical foundations of alkoxo-technology and its application in heterogeneous catalysis.^{256–259} A method for the joint hydrolysis of two and more alkoxides, ensuring the formation of a large number of mixed elementoxane bonds and affording significant practical advantages (the consumption of organic solvents is reduced, the effectiveness of the process is increased, and the use of inorganic acids and expensive chelating agents is eliminated) has been developed. A method of synthesis of vanadium-containing alkoxide joint hydrolysis products, envisaging the replacement of the usually employed scarce and expensive vanadium alkoxides as precursors by V_2O_5 powder, which is heated jointly with E(OR)_n ($\text{E} = \text{Si, Ti, Zr, P, Al}$) and ROH, has been proposed. The synthesis of oligomeric products by heating one or several metal acetates with high-boiling di- and tri-hydroxy organic compounds has been achieved. This procedure is free from the disadvantages associated with the use of mixtures of acetates (fractional crystallisation, low solubility in water, lack of film-forming properties). Furthermore, the application of the self-

propagating high temperature synthesis weakens significantly the interaction of the deposited catalytic coating with the carrier.

It has been suggested that the heat resistance of the aluminosilicate carrier obtained from Al(OR)_3 and Si(OH)_4 be increased by introducing 0.5% of La_2O_3 .²⁶⁰ For the ratio $\text{Al}_2\text{O}_3:\text{SiO}_2 = 99.5:0.5$, the specific surfaces after heat treatment at 550 °C (3 h) and 1100 °C (24 h) are 242 and 42 $\text{m}^2 \text{g}^{-1}$ in the absence of La_2O_3 and 245 and 72 $\text{m}^2 \text{g}^{-1}$ respectively in its presence. This process has been patented by the Conoco Company on Russian territory.

In recent years, comprehensive studies on the use of alkoxo-technology in heterogeneous catalysis have been initiated in Mexico. Carriers and catalysts with the composition $\text{Pt-Sn/Al}_2\text{O}_3$ [produced by the joint hydrolysis of Al(OBu)_3 and SnBu_4],²⁶¹ $\text{Ru-SiO}_2(\text{Al}_2\text{O}_3)$,²⁶² $\text{SiO}_2\text{-Al}_2\text{O}_3$,²⁶³ Al_2O_3 ,^{180,264} and Pt(Pd)/SiO_2 ²⁶⁵ have been obtained.

VII. Achievements of alkoxo-technology in the manufacture of materials structurally similar to carriers and catalysts

The oxide materials obtained with the aid of alkoxo-technology may be employed in a wide variety of fields. For example, $\text{SiO}_2\text{-TiO}_2$ coatings possess simultaneously catalytic, light reflecting, abrasion-resistant, and electrically insulating properties. The procedures for the preparation of alkoxide materials, developed for use in a specific field, may be employed also in other fields, naturally taking into account the specific requirements as regards some of their properties. It is therefore of interest to examine also the advances of alkoxo-technology in the manufacture of oxide materials structurally similar to carriers and catalysts but having a different functional purpose.

High-temperature superconducting ceramics occupy a special place among such 'related' materials. The main task of alkoxo-technology in this field is the low-temperature synthesis of thin layer multicomponent oxide coatings with a perovskite structure on different supports. The same problem is also faced by heterogeneous catalysis. The fact that many perovskites used nowadays as high-temperature superconductors possess also catalytic properties brings these two aspects even closer together. For example, the high temperature superconducting $\text{YBa}_2\text{Cu}_3\text{O}_7$ perovskite actively catalyses the oxidation of CO and hydrocarbons.²⁶⁶

The low-temperature synthesis of perovskites with the aim of obtaining coatings makes it possible to diminish their chemical interaction with the support and helps to overcome the negative phenomena associated with this factor. During several years of studies (the high-temperature superconductivity of oxide ceramics was not discovered until 1986),²⁶⁷ it has been possible to develop with the aid of alkoxo-technology procedures for the synthesis of superconducting perovskites at temperatures of about 400 °C²⁶⁸ or 650–700 °C,²⁶⁹ whereas the traditional synthesis requires heating above 950 °C. Evidently further advances of alkoxo-technology in the preparation of high-temperature superconducting ceramics still remain in the future. The task of specialists in catalysis is a critical analysis and purposeful employment of these developments.

The principal difference in the requirements which must be met by the oxide materials used as superconductors and catalysts (carriers) concerns the size and distribution of pores. Superconductors and catalysts must have respectively minimum and maximum porosities. In this respect, specialists in catalysis are in the best position, since, owing to the high content of the organic component in the initial mixture and the sharp increase in density on passing from organometallic to inorganic oxide materials, it is much simpler to obtain porous coatings from alkoxides than dense nonporous ones.

Another field close to heterogeneous catalysis is the electronics industry, where the employment of alkoxo-technology for the synthesis of powders with the aim of depositing coatings has been vigorously investigated and introduced.²⁷⁰ For example, NiFe_2O_4 powders with $S_{\text{sp}} = 221 \text{ m}^2 \text{g}^{-1}$ have been obtained from alkoxides.²⁷¹ Evidently these and similar powders can be used also as catalysts for a series of reactions. A review on the preparation of powders for electronics, including their preparation with the aid of alkoxo-technology, has been published.²⁷²

There are no fundamental differences in the structures of the porous oxide coatings used in ultrafiltration or membrane separation and in catalysis. The principal difference concerns the form of the primary carrier and the operating conditions. The employment of alkoxides in the technology for the manufacture of inorganic (ceramic) membranes is the most promising method, since it ensures the possibility of a fine regulation of the pore dimensions within wide limits.^{273,274} Like high-temperature catalysis, the filtration of hot gases or the purification of liquids with subsequent burning away of organic impurities gives rise to the problem of increasing the heat resistance, which is solved, for example, by synthesising aluminate-based membranes by means of alkoxo-technology.⁴⁴ Filtering coatings based on $\gamma\text{-Al}_2\text{O}_3$ and the products of its hydrolysis are most often employed.^{275–278} $\text{TiO}_2\text{-SiO}_2$ membranes with an average pore size of 4 nm and $S_{\text{sp}} = 324 \text{ m}^2 \text{g}^{-1}$ have been obtained from the products of the joint hydrolysis of alkoxides.²⁷⁹ Aluminosilicate membranes, the specific surfaces of which were 217, 384, 456, and 472 $\text{m}^2 \text{g}^{-1}$ with pore radii of 2.21, 2.15, 2.15, and 1.72 nm for the ratios $\text{Al}_2\text{O}_3:\text{SiO}_2 = 5.6:1, 4.4:1, 4.2:1, \text{ and } 1.5:1$ respectively have been obtained by the separate hydrolysis of Si(OMe)_4 and Al(OBu)_3 with formation of sols and subsequent mixing and heat treatment.²⁸⁰ It has been recommended that these membranes be used also in heterogeneous catalysis.

Separating ZrO_2 layers are used in catalysts with metallic carriers, which are employed in the high-temperature purification of gases, for improving the resistance of the metal to oxidation and for increasing the adhesion of the metal to the porous $\gamma\text{-Al}_2\text{O}_3$ carrier.²⁸¹ Such layers, 0.1 μm thick and obtained from Zr(acac)_4 , retained their continuity and did not peel off on heating to 1000 °C.²⁸²

Oxide coatings synthesised from various alkoxides and their mixtures prevent the high-temperature oxidation of metals.^{283–286} They also prevent chemical corrosion and increase the resistance of materials to abrasion. The chemical compositions of the coatings (SiO_2 , TiO_2 , Al_2O_3 , ZrO_2) suggest their possible use in catalysis not only for the creation of separating layers but also directly as acid–base catalysts or carriers. Here one must take into account the difference between the requirements as regards the porosities of protective and catalytic coatings. Special procedures and methods are used to increase the porosity, for example, additives which are burnt off with formation of pores are introduced.

In systems for the catalytic purification of exhaust gases in automobile transport, oxygen sensors prepared from Zr(OR)_4 and ZrO_2 powder are employed.²⁸⁷ After their deposition on a suitable support and the introduction of catalytically active metals, such materials may also function as high-temperature catalysts, for example, in the same systems for the purification of exhaust gases.

It is believed²⁸⁸ that alkoxo-technology will play an important role in the creation of sensors in the future.

One of the most significant advances in modern ceramic technology is the use of the products of the hydrolysis of alkoxides as binders in the preparation of bulky ceramic materials.²⁸⁹ Such binders make it possible to reduce or to eliminate completely the cracking occurring during moulding, drying, and heat treatment (sintering) of the ceramic, improving its strength. This approach has a great future in the manufacture of porous ceramic glass and composite materials,^{290,291} which may be employed also as carriers for heterogeneous catalysts.

VIII. Conclusion

The alkoxides of various chemical elements (as precursors of oxides) have come to be widely used nowadays for the preparation of heterogeneous catalysts and carriers. Large chemical companies of the USA and Japan have shown special interest in alkoxo-technology. Although a considerable proportion of the publications in this field are in the nature of advertisements and many details of the process are not specified, nevertheless there have evidently been significant advances associated principally with the creation of catalytic materials having a high specific surface and porosity and a controllable pore size. The use of alkoxo-technology also makes it possible to obtain heat-resistant carriers and catalysts with a high activity and selectivity combined with a reduced (by an order of magnitude and more) consumption of catalytically active elements. A series of alkoxide catalysts possess unique properties which traditional catalysts lack. The ecological cleanliness of the process involving the preparation of catalysts and carriers by the alkoxo-technological method is very important.

At the same time, the use of alkoxo-technology in heterogeneous catalysis is still at the development stage. Among the numerous possibilities provided by alkoxo-technology, only a small proportion have been realised. For example, possibilities for the low-temperature synthesis of known and especially new crystalline and amorphous compounds are only beginning to be realised. Alkoxo-technology is also used in the preparation of a series of oxide materials structurally similar to catalytic substances but having a different functional purpose. The approaches to the appropriate modifications developed in this connection may be used also in the technology for the manufacture of heterogeneous catalysts and carriers.

In Russia and the Commonwealth of Independent States, adequate attention has not so far been devoted to the application of alkoxo-technology in heterogeneous catalysis. At the same time, some investigations have led to the development of a series of approaches (for example, the synthesis of catalysts via metal resins),^{292,293} which, although they have no direct bearing on alkoxo-technology, can nevertheless find partial applications in the preparation of heterogeneous catalysts by this method.

Studies on alkoxo-technology have been initiated in recent years at the Faculty of Chemistry of the Moscow State University, at the State Institute of the Chemistry and Technology of Organoelement Compounds, at the Institute of Petrochemical Synthesis of the Russian Academy of Sciences, and in certain other scientific establishments. The practical introduction of alkoxo-technology has also begun. Thus the synthesis of boehmite has been implemented in the undertakings of Yaroslavl' and Ufa (the Condea chemie Company).

Abstract. The phenomena involving a decrease in the mechanical strength and durability of catalysts during their use, which can be explained in the light of ideas concerning the mutual influence of the solid phase and the medium during catalysis, are examined. Analysis of the mechanism and the set of conditions inducing these phenomena makes it possible to develop methods for a significant improvement of the quality of a catalyst. It is shown that the appearance on the catalyst surface of a multiplicity of mobile adsorbed atoms on dissociation of chemical bonds during the catalytic reaction can give rise to the acceleration of the surface self-diffusion by a large factor, which promotes a significant decrease in the temperature of the sintering of powdered materials. The bibliography includes 105 references.

I. Introduction

In the study of the mechanisms of catalytic reactions, allowance for the interaction of catalysts with the reaction medium and also for the nature of the surface and the bulk phase of the solid catalyst is extremely important.

In order to ensure a prolonged operation of the catalyst, it is essential to create conditions preventing its disintegration and to increase its mechanical strength. The porous solids of different chemical nature employed in catalysis usually disintegrate under the influence of the reaction medium, the chemical processes occurring on their surfaces, and thermal and internal stresses.^{1–5}

Many examples of the effect of the catalytic process on the mechanical and structural characteristics of catalysts are known: the disruption of contacts between corundum grains,⁶ the detachment and removal of quartz glass macroparticles in the pyrolysis of benzene,⁷ the sputtering of an aluminosilicate catalyst,⁷ and the

disintegration of the nickel catalyst in the decomposition of n-hexyl alcohol.⁸ The disintegration of catalysts (the detachment of solid macroparticles and other types of dispersion of the porous structure) may be associated with the adsorption-induced decrease in mechanical strength (ADS). This question was first formulated as early as the 1960s.^{9,10} It was postulated that there is an analogy between the ADS of catalyst under the real conditions of their operation and the phenomenon which is observed when metals and other solids (ionic and covalent compounds, molecular crystals, amorphous materials, etc.) come into contact with surfactants.¹¹ This phenomenon is due to the decrease in the free surface energy of the grains of the solid material under the influence of the surrounding medium, which must contain adsorption-active components (such are the catalytic conditions).

Such phenomena may (or may not) be accompanied by corrosion, dissolution, the condensation of a new phase, and the formation of films or other phase and chemical transformations (including the reconstruction of the surface, the rearrangement of the lattice, and the formation of a wide variety of structural defects), which influence the mechanical strength of the catalyst. Thus there is the phenomenon of 'catalytic corrosion'¹² expressed by a change in the topography of the surface of platinum, palladium, or nickel under the influence of catalytic hydrogen and ammonia oxidation reactions at comparatively low temperatures. The dynamics of catalytic corrosion and the intensity and mechanism of the rearrangement of the surface of the platinum catalyst have been investigated.¹³ Various aspects of the mutual influence of the reaction medium and the chemical (phase) composition, the structure of the surface, and the activity and selectivity of catalysts have been examined.^{14–16} Numerous data concerning the migration atoms and ions on the surfaces of heterogeneous catalysts during catalysis and the formation and growth of interacting clusters which represent the nuclei of phase formations and structural reconstruction, have been published.^{17–32}

Catalysis and the decrease in the mechanical strength of a solid represent different aspects of the same phenomenon, namely the interaction of the solid with the reaction medium, which induces a change in the bonds within both the solid and the reactant. The catalytic reactions of the initial materials and the changes in the structure of the catalyst, occurring simultaneously, may lead to disintegration of the latter.

Shchukin and coworkers^{9,10} showed for the first time that the mechanical strength and durability of catalysts[†] depend to a large extent on the number, distribution, and strength of individual contacts between the catalyst particles and on the magnitude of the residual internal stresses arising under the conditions in the formation of structures. The kinetics of the ADS in disperse porous structures with an open porosity have their specific features: the pores are readily accessible to the reactive medium and the rate of permeation of the latter into the bond rupture zone is not the limiting factor, as in the propagation of a macrocrack in a continuous material. Therefore the influence of the medium on the parameters of a porous catalyst should be manifested relatively rapidly and should be determined by thermodynamic factors.

The studies of Shchukin and coworkers^{9,10} and subsequent systematic theoretical and experimental investigations³³⁻⁸⁸ served as a basis for the creation of a physicochemical theory of the mechanical strength of disperse porous structures. The thermodynamic nature of the ADS (partial compensation of the energy of the ruptured bonds by the interaction with the corresponding 'related' medium) at a macroscopic level is manifested by a decrease in the work of formation of new surfaces, i.e. the work of fracture, and hence by a decrease in mechanical strength. Under conditions close to equilibrium, the effect of the ADS may be expressed quantitatively by the decrease in the free surface energy. It has been observed experimentally that the relation between the decrease in surface energy (σ) and in the mechanical strength (P) of any solids in the corresponding medium is described by the well known Griffith relation

$$\frac{P_0}{P_c} = \sqrt{\frac{\sigma_0}{\sigma}},$$

where the quantities P_0 and σ_0 refer to an inert medium, whilst P_c and σ refer to an adsorption-active medium.

At the same time a definite micromechanism of the facilitation of the rearrangement and rupture of the bonds in the solid corresponds to each specific case of a real decrease in mechanical strength. Either the van der Waals pair potential for spherically symmetrical molecules (noble gas atoms) or the ideas concerning donor-acceptor interactions and the changes in the structure of near-surface zones are used for its description.⁷⁸⁻⁸⁰ The outcome of all these investigations has been the establishment of the characteristics and the mechanism of the disintegration of catalysts' structures in adsorption and catalytic processes and the creation of the scientific foundations for the regulation of the mechanical strength of disperse porous bodies and for the control of cohesion and structure-formation processes.^{1-5,64,66} A set of methods and several series of instruments for a comprehensive estimation of the mechanical properties of materials in different stressed states (under static and dynamic conditions) and also in the processes associated with wear (in various media) have been developed.^{34,35} There have also been other approaches. For example, it has been suggested that the deformation and level of disintegrating stresses can be estimated with the aid of acoustic emission.[‡] The choice of the method for estimating the mechanical strength under the conditions of a catalytic reaction is determined by the type of reactor in which the process takes place (reactors with stationary, fluidised or moving catalyst beds).³⁶ Novel methods for the determination of the mechanical strength of the

catalyst directly under the conditions of catalysis³⁷ and also for the determination of the internal microstresses in porous structures before and after catalysis have been devised.^{38,39} A series of publications have been devoted to the mechanical strength and durability of catalysts. For example, Fenelonov⁸¹ proposed a texture-geometrical model of the mechanical strength of porous bodies, which differs from the model of Rebinder, Shchukin, and Margolis⁹ (RSM) by the allowance for the real statistical packing of the particles. He also obtained an equation for the calculation of the specific strength of a single contact when different methods are employed in tests of mechanical strength, which was checked by employing the results of different investigations.⁸²

The applicability of the postulates of the statistical theory to data on the mechanical strength of catalysts and sorbents [the 'weak link' and 'fibre bunch' (rope) models] has been examined.⁸⁷ The results of tests on porous materials in different stressed states are presented in the same communication and the validity of the equation $PV = \text{const}$ (P = stress, V = deformation) was checked and confirmed.

The influence of the porosity (including the porosity in the 'critical' cross-section) of the catalyst grains and of the conditions in their preparation (temperature and duration of heat treatment) on their mechanical strength have been studied.^{88,89} The dependence of the mechanical properties of catalysts (and the possibility of using these properties for a form of monitoring of the mechanical strength testing methods arising from it) on a series of technological factors (for example on the duration of drying, hydrothermal synthesis in hot water, and drying) has been investigated.⁹⁰ The change in phase composition (during heat treatment) and the rearrangement of the structures of catalysts under the influence of the reaction medium increase the mechanical strength of the grains of cement-containing systems used in organochlorine synthesis,⁹¹ which indicates the occurrence of crystallisation contacts at the interface. The reason for fracture during the employment of copper-containing catalytic systems designed for the oxidation of hydrocarbons and CO to CO₂ is believed to be the extensive reduction of CuO to zerovalent copper accompanied by the formation of highly crystalline phases which leads to the breakdown of interparticle contacts (point and phase contacts).⁹²

The need for the creation of a theoretical basis for the development of a technology for the preparation of industrial catalysts and its implementation has now appeared.^{93,94} The problem of the mechanical strength of the catalyst again arises in this connection. The strength properties of specific catalysts may be determined by extremely diverse factors.

The mechanical properties of solids and materials have been the subject of numerous fundamental and applied sciences. The concept of the thermofluctuation nature of fracture has arisen from solid state physics. In this case, the dependence of durability under load (t) on the applied stress and temperature is described by the familiar Zhurkov equation

$$t = t_0 \exp \frac{U_0 - \gamma P}{kT},$$

where γ is a constant of the material, t_0 the period of the vibrations, and U_0 the dissociation energy of the interatomic bonds.

In the mechanics of granular media, elastic behaviour is considered from the standpoint of the packing of the particles in monodisperse and polydisperse systems and the nature of the contacts. In the statistical theory of mechanical strength, schematised ideas concerning the parameters of the statistical distribution of defects in the bulk of the material are employed for the description of the macroscopic behaviour of bodies under load. Rheology which studies the viscoelastic, viscoplastic, etc. mechanical behaviour of bodies (usually without taking into account their internal structure) describes the changes occurring during their deformations.

[†] Mechanical strength is a characteristic of the resistance of solids to disintegration at a constant rate of deformation. It depends on the type and method of application of an external mechanical load. Durability or long-term mechanical strength is characterised by the time required for the disintegration of the material subjected to a constant load.

[‡] B I Malyshev, O V Dmitrik, R V Fishkin, in *Nauchnye Osnovy Prigotovleniya Katalizatorov* (Scientific Foundations of the Preparation of Catalysts) (Novosibirsk: Nauka, 1984) p. 249.

In the physicochemical mechanics of solids and disperse materials,^{5,11} the strength and mechanical fracture of the material are considered from the standpoint of surface physicochemical interactions, because the rupture of interatomic (chemical) bonds actually leads to the formation of new surfaces and at the instant of their appearance (*in statu nascendi*) they are accessible to the physicochemical influence of the medium, which affects the nature of the deformation and rupture. The rupture of interatomic bonds can be achieved in three ways (in various proportions):

(1) as a result of the work performed by mechanical forces (external and internal stresses) given by

$$Pb^2b\sqrt{\frac{L}{b}} = P\gamma,$$

where b is the lattice period (b is the path traversed and b^2 the area of application of the force), L the characteristic linear parameter describing the defective structure of the body, and $\sqrt{L/b}$ the stress concentration factor;

(2) as a result of the thermal fluctuations

$$kT \ln \frac{t}{t_0},$$

where t is the residence time under load and t_0 the period of the vibrations, whilst the quantity $\ln(t/t_0)$ characterises the increase in the probability of the manifestation of fairly large fluctuations in the course of time;

(3) as a result of the work of adsorption ΔU (which includes the work of reversible physical adsorption, chemisorption, and the chemical reaction),¹¹ which reduces U_0 to $U = U_0 - \Delta U$ and increases the activation volume (i.e. the path leading to the overcoming of the bonding force) to $\gamma' = \gamma + \Delta\gamma$; in this case

$$P\gamma' + kT \ln \frac{t}{t_0} = U.$$

The universal Zhurkov equation, mentioned above, follows from the last equation.

Studies by the method of molecular dynamics, i.e. numerical experiment of a dynamic type (NEDT) of the long-term strength of an individual bond subjected to a constant load have shown⁶⁷ that the logarithm of the average lifetime of an atomic (molecular) bond diminishes linearly with increase in the applied load strictly in accordance with the Zhurkov equation.

The deformation and fracture of a two-dimensional crystal with a concentrator-cavity, the adsorption of a surface-active component on the walls of this cavity, the initiation and growth of a crack when a crystal is subjected to a load in the presence of a second component, and the permeation into the growing crack of foreign atoms which promote its development have been investigated by the NEDT method.⁶⁸ The results agree with the ideas concerning the molecular nature of the Rebinder effect.

II. The influence of adsorption on the mechanical strength of catalysts

One of the first pieces of direct evidence concerning the influence of adsorption on the mechanical strength of porous structures has been the results of a study of porous magnesium hydroxide specimens in the presence of the vapours of various liquids: water, sulfuric acid solutions at different concentrations (the presence of H_2SO_4 ensured a change in the partial pressure of water vapour), ethyl alcohol, benzene, cyclohexane, etc.^{40,41} It was established that the coverage of the surface by 1–4 adsorbate monolayers induces an appreciable decrease in the strength of the magnesium hydroxide specimens (Fig. 1). The principal contribution to the decrease in mechanical strength (by a factor of 1.5–2) corresponds to the range with increasing moisture content up to 1%–1.5%, which corresponds to the formation of a saturated monolayer of the molecules of the medium on the external and internal surfaces of the porous specimen. The decrease in the

Figure 1. Variation of the compressive strength of magnesium hydroxide specimens during the adsorption of water (a) and ethyl alcohol (b).^{40,41}

mechanical strength of the specimens is not a consequence of the condensation of the adsorbent molecules in contacts between the particles of the solid. The absence of water as an individual phase in magnesium hydroxide (within the limits of monolayer adsorption) has been demonstrated by the NMR method. The true cause is the decrease in the surface energy of the solid on adsorption, i.e. the weakening of the bonds between the atoms (ions) at the surface. The maximum decrease in mechanical strength, attained for a 3%–4% moisture content, is associated with a further decrease in the free surface energy on multilayer adsorption. The subsequent increase in mechanical strength and then its resumed decrease in the presence of high contents of the adsorbate has been explained by the fact that in contrast to continuous media, in disperse porous media the decrease in mechanical strength may be reduced by capillary contracting forces which arise on condensation of the vapour of a liquid in pores.

In the presence of ethyl alcohol, the rise in the curve is not quite so pronounced as in the presence of water owing to the weakening of the capillary contraction forces as a consequence of the smaller surface tension of the boundary with air than for water. The adsorption nature of the decrease in the mechanical strength of magnesium hydroxide specimens in the presence of water is also indicated by the correlation between the relative decrease in the strength of the porous structure and the decrease in the free surface energy of this material ($\Delta\sigma$), which were measured in the presence of water by independent methods (Fig. 2).^{42,43} The quantity $\Delta\sigma$ by which the surface energy decreases, i.e.

$$\Delta\sigma = \sigma_0 - \sigma = RT \int_0^p \Gamma \ln p,$$

(p is the water vapour pressure at which the specimens were moistened) was found from the adsorption (Γ) isotherm for water vapour.

Figure 2. Relation between the decrease in mechanical strength and the decrease in the surface energy of highly disperse porous magnesium hydroxide specimens⁴² in terms of the variables of the Griffith equation.

The relation obtained confirms the validity of the Griffith relation, i.e. a proportionality between the relative decrease in mechanical strength ($(P_0^2 - P_a^2)/P_0^2$ (P_0 and P_a are the mechanical strengths of the dry specimen and the specimen moistened under equilibrium conditions respectively)) and the decrease in surface energy holds for these structures. Hence it follows that $P \sim \sigma^{1/2}$. The quantity $\sigma_0 = 300 \text{ mJ m}^{-2}$, found from the slope of the straight line, has an acceptable value. The same correlation has been observed in the adsorption of water vapour on silica gel.⁹⁵ A relation between the decrease in surface energy and the decrease in the mechanical strength of porous bodies has been indicated.⁴⁴ The values of σ for cement were found from the Griffith equation; for a water : solid (WS) ratio of 0.45, we have $\sigma = 1370 \text{ erg cm}^{-2}$, whilst for WS = 0.60 we have $\sigma = 657 \text{ erg cm}^{-2}$.

The ADS effect for the monomolecular surface coverage by the adsorbate has been observed in experiments with ionic polycrystalline KCl and NaCl immersed in water–dioxane mixtures of different composition.⁴⁵ The decrease in mechanical strength under these conditions was not associated with the impregnation of the grains between the crystals by the liquid.

In the study of the influence of the polarity of the adsorbate on the mechanical strength of porous structures in relation to magnesium hydroxide as an example, it was shown that, in contrast to the polar water and ethanol molecules, the nonpolar benzene and cyclohexane molecules hardly influence the mechanical strength of the hydroxide.⁴¹ Similar features were observed in the study of the decrease in the mechanical strength of pressed calcium carbonate, zinc oxide, sodium chloride, charcoal and silica gel specimens in the presence of water, benzene, and carbon tetrachloride vapours, carbon dioxide, and nitrogen.^{95–97} The specimens on the surfaces of which a saturated monolayer of the molecules of the medium had been adsorbed were found to be the least strong. The effect involving a decrease in mechanical strength was greater the closer were the polarities of the adsorbent and the medium (water on silica gel, benzene on charcoal). This indicates a decrease in mechanical strength with decrease in the free surface energy on adsorption. In all the systems indicated, the decrease in mechanical strength was not accompanied by the occurrence of dissolution and chemical interaction processes. The mechanical strength of ionic polycrystalline sodium and potassium halides in heptane, water, and dioxane decreased to a greater extent the greater was the polarity of the medium.⁴⁵ Thus in water it amounted to 0.2 of the initial value.

The dispersity of the structure-forming particles, the degree of porosity of the medium, and the nature of the individual contacts did not affect the decrease in mechanical strength in adsorption on magnesium hydroxide specimens.⁴¹ It was observed by X-ray diffraction that, in physical and chemical adsorption (for example, of isopropyl alcohol on magnesium oxide⁴⁶ and of water and ethyl alcohol on magnesium hydroxide,⁴⁷) the microdeformations (internal stresses) increase with the consequent adsorption-induced decrease in the strength of the structure. The appearance of internal stresses has been explained by the change in the relation between the resistance of the rigid framework comprising interlinked particles and the Laplace pressure compressing the particles (as a consequence of the decrease in free surface energy on adsorption).

The transition of silica gel to a complex stressed state occurred when it was moistened and dried.⁹⁸ When silica gel was fully immersed in water, air was trapped in the structure and was compressed by the capillary pressure due to the gradually permeating water. As a result, high counterpressures arose in the structure, reaching limiting disruptive values.

The ADS phenomenon was observed also on chemically more complex porous structures: specimens of clays of different mineralogical composition (kaolinite, bentonite), NaA and NaX zeolites,^{48,49} and an aluminosilicate zeolite-containing cracking catalyst.⁵⁰ The mechanical strength of these materials diminished sharply following the adsorption of various substances. The adsorption and especially chemisorption of isopropyl alcohol

induces an appreciable comminution of the block structure of magnesium oxide crystals (an increase in the density of dislocations).⁴⁶ The possible cause of this is the nonuniformity of the adsorption combined with the mechanical anisotropy of the crystals. The relaxation processes occurring after the catalytic reaction again lead to an increase in the size of the blocks and a decrease in the density of dislocations.

Among the multiplicity of the elementary mechanisms for the formation of the texture of catalysts under various conditions, two most common mechanisms of the increase in surface are distinguished. The characteristics of the thermodynamics of highly disperse systems, which determine the direction and driving force of the process, are manifested in these mechanisms.⁹¹ One of the mechanisms involves the growth of the surface in phase transformations, where the decrease in the phase potential compensates for the increase in the surface potential, which is appropriately reflected in the radius of the critical nucleus of the new phase.^{3,91} The second mechanism is associated with the change in entropy. If the interfacial energy is small, the increase in entropy may compensate for the increase in surface energy.³ On the basis of these mechanisms, it is possible to estimate the minimum size of the nucleus or the 'maximum area which can then only decrease in the absence of phase transformations or a sharp decrease in the interfacial energy'.⁸¹

The driving forces and the principal mechanisms of the decrease in the surface (for example, as a result of coagulation) can also be related to the local (in the contact zones) decrease in the interfacial energy.⁴ On the other hand, the specific mechanisms of the processes, including the mechanisms of the change in porosity, may be extremely varied.⁸¹

Examination of the ADS phenomena helps us to understand the mechanisms of certain intermediate stages in the new processes involving the formation of a wide variety of aluminium oxide carriers and catalysts using thermochemical (TCA) and mechanochemical (MCA) methods for the activation of solids (see, for example, Refs 84 and 99–101). Thus it has been shown that, in the transformation of the products of the MCA and TCA of technical hydrated alumina, as a result of hydration, from the amorphous to the pseudoboehmite state (which can be readily converted into various aluminium oxide carriers or binders for catalysts), bonds between the elements of the layered structure (plates) are disturbed by the ADS and by the presence of the disjoining pressure of the liquid phase on the surfaces bounding it.⁸⁴ This results in the cleavage of the highly disperse particles of the products of the TCA into finely disperse (2–5 nm thick) plates and their subsequent hydration. This phenomenon as well as others have been used in creating a low-waste technology for the manufacture of aluminium oxides used as carriers, adsorbents and catalysts.⁸⁴ The formation of surface compounds, which occurs, for example, in the interaction of methanol with magnesium oxide,⁸⁵ is accompanied by the dissociation of the bonds in the alcohol molecule and the liberation of energy. In the chemisorption of ethanol on Al_2O_3 ,⁸⁶ the bonds between the aluminium and oxygen ions are 75%–90% weakened according to quantum-chemical calculations and IR spectroscopic data. The clusters formed and their varieties, participating in the formation of surface compounds, also play a definite role in this process.

Comparison of the behaviour of adsorbates having molecules of different size (water, benzene) made it possible to observe that the filling of the inner cavities of the zeolite crystals (within the limits of sorption capacity) with adsorbate molecules prevents a decrease in mechanical strength of granules.^{48,49} If there is steric hindrance to the permeation of the adsorbate molecules into the cavities, the mechanical strength of the zeolite grains diminishes already for low degrees of adsorption (of the order of monolayer coverage of the surface of the clay binder). A similar 'protective' effect has been observed in the dispersion of brown coal in the presence of water and heptane.⁵¹

The data presented referred to physical adsorption, but in catalytic processes the chemical adsorption of the reactants and reaction products plays the main role.

The influence of chemisorption on the short-term and long-term mechanical strength of disperse porous structures has been investigated in detail in relation to the behaviour of the cobalt-molybdenum catalyst under conditions involving a change in the temperature and pressure of the vapours of the products of the incomplete oxidation of propene (carbon dioxide, acetaldehyde, and especially acrolein).^{52-54, 102, 103} It was established that the degree of disintegration of the catalyst depends on the degree of surface coverage by chemisorbed molecules and on the strength of the chemisorption bond, i.e. on the decrease in free surface energy on chemisorption (Fig. 3).

Figure 3. Dependence of the time to fracture of a cobalt-molybdenum catalyst on the applied load in various media at 483 K: (1) nitrogen; (2) carbon dioxide (partial pressure 350 mm Hg); (3) acetaldehyde (60 mm Hg); (4) acrolein (60 mm Hg).⁴⁹

The disintegration of a catalyst as a consequence of chemisorption has been observed also under the conditions where the grains of an alumina-chromium oxide-potassium oxide catalyst were ground up in a stream of n-butane and butenes at elevated temperatures.⁵⁵

III. The effect of the catalytic reaction on the mechanical strength of catalysts

The phenomenon of the accelerated disintegration of the structures of catalysts under the reaction conditions has long been known. Shchukin and coworkers^{9, 10} showed for the first time that the surface phenomena at the interfaces in the porous structures should be regarded as the main causes of the decrease in the mechanical strength and durability of catalysts. A similar view has been expressed in a study of the surface phenomena accompanying a heterogeneous chemical reaction using methods based on the thermodynamics of irreversible processes.¹⁰⁴ If intermediate compounds or a series of states which possess a higher surface activity than the initial and final compounds are formed in a chemical reaction,[§] then their adsorption at the interface reduces the interfacial energy and increases the area of the interface. Consequently, the surface energy of the catalyst should diminish during the catalytic process. A decrease in the hardness of

amalgamated zinc and brass catalysts in the decomposition of aqueous solutions of hydrogen peroxide has been observed experimentally and explained by a decrease in the surface tension of mercury during catalysis.¹⁰⁵ According to the data of Shchukin and Margolis,⁶⁴ the active intermediate complex interacts more strongly with the catalyst surface than the initial reactants and chemisorption appreciably weakens the metal-metal bond. As a result, surface metal atoms are frequently detached on formation of a bond with active adsorbates.

The mechanical strength of sulfur dioxide oxidation catalysts under the reaction conditions differs appreciably from their strength outside the reactor.⁷⁷

The influence of catalysis on the mechanical strength and durability of porous magnesium oxide catalysts in the endothermic isopropyl alcohol dehydrogenation reaction has been studied systematically.^{37, 40, 46, 52, 56, 66, 67} Already 20-30 s after the start of the reactions, even before the establishment of stationary conditions, the compressive strength of the catalyst diminished by a factor of 1.5-2 (the tests were carried out after the cessation of the catalytic reaction and the drying of the grains).^{46, 56} A further increase in the duration of the use of the catalyst induced only a slight decrease in its mechanical strength. It was demonstrated by X-ray diffraction that the internal stresses in the catalyst diminish during the reaction owing to the irreversible rupture of the bonds (contacts between the particles).

Numerous experiments have shown that the mechanical strength of the catalyst decreases with increase in the internal stresses associated both with the genesis of the structure (for example, on pressing a magnesium oxide powder or on dehydration of magnesium hydroxide) and with the catalytic reaction conditions (thermoelastic stresses due to the cyclic changes in temperature during catalysis). The mechanical strength of the catalyst, measured directly during catalysis with the aid of a dynamometric device mounted in a specially constructed reactor,⁵⁷ proved to be lower than after the cessation of the reaction for the same exposure time. It may be that the decrease in the interfacial energy is influenced by the nonequilibrium adsorption of intermediate compounds during catalysis. If the conditions of the catalysis promote the appearance of internal stresses (for example, as a consequence of cyclic changes in temperature), then the mechanical strength decreases significantly not only at the beginning of the process but also throughout it. The decrease in mechanical strength may be accompanied by a change in the specific surfaces of the specimens, but a direct relation between the decrease in mechanical strength and dispersity was not observed.

The decrease in mechanical strength was independent of the change in the specific surface of the porous structure as was confirmed in experiments on the dehydrogenation of isopropyl alcohol on aluminium oxide specimens.⁵⁸

During the catalytic reaction, not only the mechanical strength but also the durability of the catalyst under load decrease. Thus the disintegration time of a magnesium oxide catalyst subjected to a 0.8 MPa load decreases dramatically in the reaction medium (the disintegration time was determined from the projections of the corresponding points on the relations illustrated in Fig. 4 onto the ordinate axis). A decrease in durability under the conditions of catalysis has been observed also for the cobalt-molybdenum catalyst of the incomplete oxidation of propene.⁵²

There are data on the disintegration of sulfate catalysts in stationary and fluidised beds used in the synthesis of sulfuric acid.^{59, 60}

In order to test the hypothesis that the bonds are weakened in the solid under the reaction conditions, CO was oxidised on disperse porous iron and nickel specimens.⁶¹ An increase in the area of contact between the metal particles was observed with an electron microscope.

The migration of crystallites as well as the disappearance of small particles and the appearance of large ones with formation of irregular shapes have been observed also in a study of the

§ The possibility of the appearance of intermediate forms of the interaction in catalytic processes was already noted by D I Mendeleev [see D I Mendeleev *Osnovy Khimii* (Fundamentals of Chemistry) Vol. I (Moscow, Leningrad: Goskhimizdat, 1947) pp. 523, 524].

Figure 4. Dependence of the time to fracture of a magnesium oxide catalyst on the applied load at 668 K in nitrogen (line 1) and in the reaction medium during the dehydrogenation of isopropyl alcohol (line 2).

behaviour of the $\text{Ag}/\text{Al}_2\text{O}_3$ catalyst in the ethene oxidation reaction.¹⁰³

These results as well as the data mentioned above concerning the decrease in the durability of the cobalt–molybdenum catalyst in the chemisorption of the reaction products^{52,53} confirm the hypothesis of Shchukin and coworkers,^{9,10} according to which the decrease in the mechanical strength of the specimens under the conditions of catalysis is caused by the simultaneous effect of the internal stresses in the catalyst and of the weakening of the bonds between the atoms (ions) on the surface of the solid as a result of the adsorption of the reacting components, including the effect resulting from the nonequilibrium adsorption of intermediate compounds.

The rate of the surface diffusion (self-diffusion) in iron under the conditions of catalysis and in the absence of the reaction medium has been investigated.⁶² The method involving the 'healing' of a scratched groove was employed: for a specified observation time, the decrease in the depth of the groove δ is proportional to the surface diffusion coefficient D raised to the power $1/4$. It was established that, under the conditions of the synthesis of ammonia at 800 K, the diffusion coefficient of iron atoms on the surface of the catalyst increases by a factor of 10^5 compared with the value of D at the same temperature in the absence of catalysis. This effect is due to the sharp increase in the number of mobile adsorbed atoms as a result of the implementation of the reaction steps (in this case, an exothermic reaction). Similar phenomena have been observed in the hydrogenation of benzene on nickel.⁵⁴ The similarity in the behaviour of these metals in the reaction described above is due to the fact that molecular hydrogen dissociates on these catalysts and atomic hydrogen induces their embrittlement.

It is noteworthy that, under the conditions of experiments⁵⁴ involving the 'healing' of a scratch, the migration mechanism is known to be determined by the surface mass transfer on nickel, since the mechanism involving transfer through the gas phase is impossible owing to the low vapour pressure of nickel, while the bulk diffusion mechanism cannot be achieved because of the considerable predominance of surface self-diffusion over the bulk-phase diffusion at the experimental temperature. The exothermic reaction in which benzene is hydrogenated to cyclohexane at 100 °C and the endothermic cyclohexane dehydrogenation reaction at 350 °C have been investigated.⁵⁴ In control experiments, nickel specimens with scratches were annealed in a stream of hydrogen at 100 °C and in a stream of helium at 350 °C. The smoothing of the scratch was estimated from the decrease in its initial depth. This occurred only under the conditions of the exothermic reaction involving the hydrogenation of benzene to cyclohexane. As in the synthesis of ammonia on iron, the nickel

diffusion coefficient was greater by a factor of 10^4 – 10^5 than the value of D in the absence of catalysis. Since the coefficient D increased only in the presence of an exothermic reaction, it is evident that the energy of the chemical reaction is necessary for the acceleration of the mass transfer.

It has been suggested that this effect is possible also in an endothermic reaction, provided that an intermediate stage proceeds with evolution of energy. The role of catalysis in the rearrangement of the surface consists precisely in facilitating a single nickel adatom formation due to an elementary catalytic step and not in facilitating the subsequent migration of the adsorbed atom over thousands of interatomic distances. In other words, since the scratch is not 'healed' in an endothermic reaction, the increase in D during catalysis may be attributed to the heat of reaction: the energy evolved in each catalytic step is consumed predominantly (or completely) not on heating the catalyst but on the local rupture of the bonds of individual atoms (ions) in the surface layer of the solid (on which or in the vicinity of which the catalytic step occurs), on the 'abstraction' of atoms from the defective region of the crystal lattice (for example, from kinks in the steps on the surface), and on their transition to the state of adsorbed atoms. Since the absolute heat of the reactions investigated calculated per mole exceeds by a factor of 2–3 the energy required for the formation of 1 mole of adsorbed atoms, it was postulated⁵⁴ that 2–3 additional adsorbed atoms, which participate in the diffusional surface mass transfer, arise in each step.

IV. Contacts between the particles and internal stresses

According to the ideas of physicochemical mechanics, the mechanical strength of a solid depends on the nature of the contacts between the particles. The strength of the crystallisation contacts is relatively high, amounting to 10^{-6} N and more. Depending on the conditions in the preparation of the catalysts and on their chemical properties, the number and strength of the individual contacts may vary and hence the mechanical strength also varies. The characteristics of the structure of the solid (defects, dislocations, etc.) are superimposed on the properties of the porous structures of the catalyst.

It has been shown^{37,63} that, in contrast to the decrease in mechanical strength during adsorption, in many cases the adsorption-induced decrease in mechanical strength during catalysis may be sharply weakened with increase in the strength of the contacts in the porous structure. These results have been obtained on specimens of a magnesium oxide catalyst with the same fine and overall porosities, on which the catalytic reaction proceeds at the same rate. Specimens with 'low strength' contacts were formed from a magnesium oxide powder obtained by heating magnesium hydroxide at 1173 K. After moulding, they were annealed at 723 K. Specimens with 'strong' contacts were obtained from hydrated magnesium oxide, by dehydration of magnesium hydroxide specimens at 723 K and following calcination at 1173 K. In both cases the heat treatment conditions were the same and only the sequence of the operations was altered.

Figure 5 presents data on the relative decrease in the compressive strength (along the axis of a cylinder) of magnesium oxide specimens, obtained under the conditions of the dehydrogenation of isopropyl alcohol at 653 K, as function of their porosity (Π). These relations have been attributed^{37,63} to the lower mobility of the chemisorbed molecules ('kinetic difficulties') compared with the mobility of the molecules in the state of physical adsorption. In the latter case, the molecules have sufficient time to migrate, following the tip of the crack opening as a result of the applied stress.

The increase in the durability of the magnesium oxide catalyst containing 15 mass % of added silica, known as white soot, has also been explained by the kinetic difficulties arising following an increase in the strength (area) of the contacts.^{56,62} In the presence of white soot, the longterm strength of this catalyst falls to an

Figure 5. Dependence of the relative decrease in the strength of the samples with 'weak' (line 1) and 'strong' (line 2) contacts on the porosity of a magnesium oxide catalyst under the conditions of the dehydrogenation of isopropyl alcohol at 653 K. P = mechanical strength of the specimen 1 h after the start of the reaction; P_0 = mechanical strength of the initial specimen kept in the reactor at the temperature of the catalytic reaction in a stream of dry nitrogen.

appreciably lesser extent 50 min after the start of the catalytic reaction than in its absence. The specimen with the additive possesses the same and in certain cases a higher catalytic activity. The strengthening of the contacts has been attributed to the improvement in the sintering of the magnesium oxide particles as a result of the chemical interaction with silicon oxide.

The possibility of the reconstruction of the catalyst surface under the conditions of adsorption and the catalytic reaction has been demonstrated.^{7,8} The driving force for the reconstruction of the lattice of the solid is the decrease in the free surface energy. The kinetics of the mass transfer accompanying this phenomenon indicate^{54,62} that, in the course of exothermic catalytic reactions, there is a sharp (by 4–5 orders of magnitude) increase in the coefficient of the surface self-diffusion of the metal atoms on the catalyst surface (the heat of chemisorption, which is always positive, is insufficient for an appreciable acceleration of the surface diffusion). Experiments with porous nickel and iron catalysts have shown that this increases by a factor of 4–6 the strength of the porous structures under the conditions of catalysis by virtue of the increase in the number of adsorbed atoms and their directed diffusion to sites with a changed chemical potential, including contact regions. The same mechanical strength under an inert gas atmosphere as in catalysis may be attained only at an appreciably higher (by 300 °C) temperature. Under the conditions of catalysis, where the self-diffusion coefficient increases by a factor of 10^5 , the calculated sintering temperatures of a series of substances (iron, nickel, magnesium oxide, iron oxide) decrease by several hundreds of degrees; a decrease in the sintering temperature is promoted by a decrease in the activation energy for self-diffusion.⁶²

The relation between the elementary catalytic events and the adsorption mechanisms of the decrease in mechanical strength was established by comparing the processes involving the synthesis of ammonia on an iron catalyst, one of the stages of which is the dissociative chemisorption of hydrogen, and the hydrogen-induced embrittlement of iron.^{64–66} The weakening of the interatomic bonds in molecular hydrogen and in iron are two aspects of a single process: the iron catalyst promotes the dissociation of the bond in the H_2 molecule, while atomic hydrogen facilitates in its turn the rupture of the Fe–Fe bonds in the iron lattice. Nickel, which is a catalyst for exothermic hydrogenation reactions and is also susceptible to hydrogen-induced embrittlement, behaves similarly.

In other words, together with the 'direct' effect of the surface of the solid phase on the reaction kinetics, there is a 'reverse' effect of the medium on the structure of the solid — the catalyst.

The appearance and decomposition of contacts as a result of fluctuating oscillations, the mechanisms of the elementary steps in the deformation and disintegration, and the influence of the medium on these processes have been examined at the atomic-molecular level with the aid of the method of molecular dynamics (numerical experiment of a dynamic type).^{67,68} Analysis of the long-term strength of an individual bond subjected to a constant load showed that the logarithm of the average lifetime of the bond decreases linearly with increase in the applied load, which is strictly consistent with the universal Zhurkov equation.

This approach made it possible to confirm also the idea of the molecular nature of the Rebinder effect. The deformation and fracture of a two-dimensional crystal having a concentrator-cavity during the adsorption of a surface-active component on the walls of the cavity have been explained by the fact that when a crystal is subjected to a load, a crack is initiated, which is followed by its growth and the permeation into the growing crack of surface-active atoms, which promote its propagation.

The principle of the interrelation between the elementary catalytic steps and the adsorption-induced decrease in mechanical strength,^{64–66} i.e. the analogy between the rupture of the interatomic bonds induced by mechanical disintegration and the chemical reaction, has been confirmed in a theoretical analysis of the catalytic cracking of hydrocarbons.⁶⁹ Acid catalysts are used in cracking processes and the reaction proceeds via a stage involving the formation of a carbonium ion. In this connection, it was postulated that the acid agents must facilitate also the mechanical disintegration of the hydrocarbon chain. In order to establish the mechanism of the Rebinder effect and to determine the quantitative characteristics of the adsorption-dependent influence of the medium, a direct quantum-mechanical calculation of the force and energy parameters of single and double C–C bonds during their mechanical rupture was carried out and the influence of the hydrogen cation — the active principle in acid catalysts of the cracking of hydrocarbons — on this process was estimated. The calculation showed that the addition of a proton diminishes the strength of the C–C bond and that the magnitude of the effect depends significantly on the nature of the carbonium ion formed. The interrelation principle has been confirmed also in numerous experimental observations of the rearrangement of the surfaces of catalysts under the conditions of a catalytic reaction.

It was established that the stresses in solids arising during the formation of the structure can both decrease and increase their mechanical strength.² The increase in the mechanical strength of solids has been observed on pressing powders, whereupon phase contacts were produced as a result of the plastic deformation in the contact zone. On the other hand, the presence of residual internal stresses in the solid always induces a decrease in mechanical strength, especially in the study of catalytically active media which accelerate the relaxation of stresses due to the weakening, as a result, of chemisorption of the bonds between the atoms (ions) of the surface.^{2,3} One of the most important conditions governing the increase in the durability of heterogeneous catalysts, sorbents, and carriers is therefore a decrease in the residual internal stresses by the optimisation of structure formation.

Among the procedures for decreasing the residual internal stresses one may name, for example, the regulation of the dispersity of the initial binding substance in the structures arising as a result of the hydration-induced hardening of calcium and magnesium oxides, the introduction of seeds in crystallisation processes, and the addition of some electrolytes (i.e. the creation of conditions promoting a decrease in the supersaturation of suspensions in the aqueous phase during the preparation of the catalyst).^{2,70} An increase in porosity and a decrease in the rigidity of the crystallisation structures are also used to eliminate internal stresses, for example by introducing small amounts of a highly

disperse inert filler, which hinders the formation of phase contacts in the bulk of the material in the initial stages.

Catalysts based on silica and alumina gels having an amorphous matrix constitute a separate group. They acquire special functional (catalytic, adsorption, etc.) properties following the introduction of a crystalline filler, for example, a zeolite. As in crystallisation structures, in these composite structures the internal stresses reach magnitudes close to the mechanical strength of the material itself ($\sim 10^7$ N m⁻²).^{4,71} An increase in the dispersity of the filler crystals and the introduction of anisometric particles are procedures for reducing the residual stresses in such materials.² Thus the introduction into an amorphous aluminosilicate xerogel (a cracking catalyst) of fluorite crystals with a lower dispersity as a filler reduces the internal stresses by a factor greater than two, while small amounts of added ($\sim 2\%$) asbestos fibres diminish microdistortions by a factor of two.²

The internal stresses in catalysts and sorbents become smaller when vibration-induced compaction is used instead of static pressing.^{72,73} In this case, the decrease in the internal stress is accompanied by the simultaneous increase in the density of the structure, increasing its strength,^{1,10} which depends on the number of particles per unit cross-section (the granulometric composition is the same under the conditions of static and vibration-induced compaction). A decrease in the fraction of large pores, which under the conditions of catalysis in the presence of residual stress may play the role of the nuclei of cracks, has an extremely positive effect on the increase in density. It has been shown for the bismuth-molybdenum catalyst of the oxidative ammonolysis of propene that a denser structure with smaller internal stresses obtained by vibrocompaction is also more durable.⁷³ Its catalytic properties remain unchanged under these conditions.

V. The sintering and strengthening of catalysts

Since the coefficient D increases during the catalytic reaction,⁶² a decrease in the sintering (presintering) temperature and hence an increase in the strength of the porous structure of the powdered pressed catalysts compared with similar specimens heat-treated at the temperature of the catalytic reaction but in an inert medium might have been expected. A heterogeneous catalytic reaction proceeds only on the outer or inner surface of the solid catalyst and therefore one should expect that the cause of such strengthening is an increase in the area of the true contact between the particles for an unchanged porosity of the specimens.

Naturally the postulated effect involving the strengthening of catalysts in exothermic reactions may be observed only if it surpasses the effect involving the adsorption-induced decrease in the strength of the porous structure.

The oxidation of CO has been investigated in through-put apparatus at atmospheric pressure under isothermal conditions, where the temperature of the catalyst (carbonyl iron) increase during the reaction by not more than 0.2 °C.^{61,75,76} The reacting gases — oxygen and carbon monoxide in stoichiometric proportions — were supplied to the reactor in a mixture with helium. The influence of the reaction mixture and of its individual components — CO (in a mixture with helium) and O₂ (in a stream of air) as well as H₂ — on the mechanical strength of the catalyst was elucidated. 'Mild' conditions in the preparation of the specimens promoted a decrease in the residual internal stresses and the adsorption-induced decrease in mechanical strength.

Table 1 presents the results of the measurement of the mechanical strengths of carbonyl iron specimens after their annealing in various media. During the reaction at 573 and 623 K, there is a sharp (by a factor of 4–5) increase in the mechanical strength of the catalyst compared with the initial specimen and the specimens annealed in the presence of one of the reaction components. It was demonstrated by means of an electron microscope that the catalyst particles form contact chords, produced during the annealing of the specimen under the reaction

Table 1. The influence of the carbon monoxide oxidation reaction and of the components of the reaction medium on the mechanical strength of the porous structure of the catalyst — carbonyl iron.⁵⁴

Composition of medium (vol. %)	Strength (in MPa) at	
	573 K	623 K
8% CO + 4% O ₂ + 88% He	6.4	7.46
21% O ₂ + 78% N ₂ (air)	2.40	2.88
100% Ar	1.37	1.46
8% CO + 92% He	0.31	0.36

Note. The porosity of the specimens was $57.5 \pm 0.2\%$ before and after catalysis and the mechanical strength was 1.27 MPa.⁵⁴

conditions. In the absence of the reaction medium at the same temperature, the effect is much weaker.

The increase in mechanical strength is due to the increase in the area of contact between the particles as a result of the surface self-diffusion. A sharp increase in the strength of the catalyst for a constant porosity was achieved in this reaction also on specimens of electrolytic nickel.

A decrease in the sintering temperatures of iron and nickel during the catalytic reaction was established experimentally. The strength of the porous structures of iron and nickel in an inert medium increased only at higher temperatures (by 300–350 °C).

Thus the sintering temperatures of metallic powders decrease appreciably under the conditions of an exothermic catalytic reaction. A significant strengthening of the porous structures is then attained as a result of the development of contacts between the particles with retention of the initial porosity, which is important for both catalysts and adsorbents and for membranes. Qualitatively similar results have been obtained on the MgO and V₂O₅ oxide catalysts in exothermic oxidation reactions,^{74,75} but the strengthening effect proved to be smaller in this case than on porous metallic catalysts. This is apparently due to the greater defectiveness (metastability) of the oxides obtained by the decomposition of hydroxides and salts at relatively low temperatures, appreciably those lower than the melting points of the corresponding oxides.

VI. Conclusion

The interaction between the catalyst surface and the molecules of the medium induces certain changes both in the adsorbed molecules and in the catalyst itself. For example, the mechanical strength and durability of the MgO, Co-Mo, Al-Cr-K, etc. catalysts may decrease significantly in the course of the catalytic reaction. Iron may serve as yet another striking example: as a catalyst of the synthesis of ammonia, iron participates in the cleavage (dissociative adsorption) of the hydrogen molecule and is in its turn subjected to hydrogen-induced embrittlement.

The influence of the catalytic reaction on the mechanical properties of the catalyst must be regarded as one of the manifestations of the Rebinder effect — a decrease in the mechanical strength of a solid under the influence of the adsorption active components of the medium, which reduce the surface energy (and the work of disintegration), and of the mechanical stresses induced by the weight of the catalyst layer, collisions, and thermal gradients. The residual internal stresses, arising at different stages in the preparation of the grains, also make their own contribution. The catalyst is therefore, as it were, doomed to accelerated wear precisely by virtue of its purpose.

However, comprehensive analysis made it possible to also discover ways whereby these undesirable effects can be significantly weakened. The strengthening and increase in the stability of granules in an active medium are achieved by the optimisation of the entire technological chain in the preparation of the catalyst by selecting pressing and hydration conditions, by the use of inert carriers, by employing modifying agents during sintering, by

introducing mineral binders, by modifying the contacts themselves, which promotes a decrease in their sensitivity to the medium, by combining finely disperse and coarsely disperse fractions, by adding anisometric (fibrous), including inert, fillers, etc. All this makes it possible to increase drastically the useful life of the catalyst.

At the same time, the weakening of the bonds between the atoms on the surface of the catalyst leads to a sharp increase in the number of mobile atoms and intensification of the surface self-diffusion. Direct observations by the method involving the 'healing' of a scratch indicate an enormous (by 4–5 orders of magnitude) increase in the coefficient of surface self-diffusion. This effect has been observed on iron during the synthesis of ammonia and on nickel during the hydrogenation of benzene.

The intensification of self-diffusion may in its turn intensify the sintering process, making it possible to carry it out at reduced temperatures. The sintering temperatures of iron and nickel powders under the conditions of the oxidation of CO may be reduced by 300 °C without affecting the mechanical strength of the specimens, i.e. it ensures the development of strong contacts between the particles. Similar effects have been observed on the MgO, V₂O₅, and Al₂O₃ catalysts under the conditions of the corresponding reactions.

The approach described leads to new possibilities for the selection of catalysts and the optimisation of the technology of their preparation, the improvement of the processes involving the sintering of high-temperature components, and in general the development of new principles of the treatment of materials.

Abstract. X-Ray photoelectron spectroscopy (XPS) and theoretical calculations show that under certain conditions inner valence molecular orbitals (IVMOs) can form within a rather broad binding energy range (15 eV to 50 eV) in compounds of many elements of the Periodic Table. This results in the appearance of a fine structure in their X-ray photoelectron spectra. The structure of X-ray photoelectron spectra associated with electrons of IVMOs correlates with contributions of the filled atomic orbitals (AOs) to the IVMO formation and the structure of compounds. In certain cases, the total contribution of electrons of the inner valence molecular orbitals to the bond energy in molecules and compounds is comparable to that of electrons of the outer valence molecular orbitals. This phenomenon is extremely important and new in principle for chemistry. The bibliography includes 128 references.

I. Introduction

X-Ray photoelectron spectra of compounds of various elements of the Periodic Table often exhibit, instead of the expected atomic singlets and doublets associated with spin-orbital interaction, a more complicated structure. This spectral fine structure can appear due to the formation of molecular orbitals (MOs),^{1–8} multiplet splitting, dynamic effect, multielectron excitation, etc.^{7–10} Recently, much attention has been paid to the analysis of the reasons for the appearance of fine structure in X-ray photoelectron spectra of various compounds since it gives information on the physical and chemical properties and the structure of compounds, the nature of chemical bonds in them, oxidation states of constituent atoms, etc.^{10–20} Although this problem is far from being completely solved, it becomes possible in certain cases to obtain unique information on compounds using the characteristics of the fine structure of X-ray photoelectron spectra.

Basically, the electrons of non-filled low-energy shells of neighbouring atoms (with energies ranging from 0 eV to ~15 eV) have been traditionally taken into account in spectral studies of the nature of chemical bonds. To some extent, it was facilitated by the widespread use of excitation sources of visible and UV-radiation in atomic and molecular spectroscopy. In most cases, X-ray emission spectroscopy studies of a wide range of compounds utilised the same interval of energies. Although, from the standpoint of quantum chemistry, the contribution of deep-lying filled atomic shells to the formation of MOs is well established,^{21,22} it has been believed that the effect of these electrons on chemical bonding could be neglected compared to that of weakly-bound (from 0 eV to ~15 eV) electrons.

Progress in precision XPS, with soft X-ray radiation ($h\nu < 1.5$ keV) as a source of excitation, allowed the study of fine structure in the spectra of both weakly-bound and inner electrons. In X-ray photoelectron spectra of compounds taken in the interval from ~15 eV to ~50 eV, instead of separate lines associated with electrons of filled atomic subshells, a more complex structure attributed to electrons of MOs is observed.

Studies of the fine structure in X-ray photoelectron spectra of compounds of various elements of the Periodic Table have shown that, in many cases, rather strong interaction between the electrons of low-energy AOs, closed in the ground state, results in the formation of MOs lying in the energy range from 0 eV to ~50 eV.^{1–8, 11–16, 23–28} This fact agrees with predictions of theoretical calculations.^{29–33} Thus, clear experimental evidence of arrangement of filled AOs into MOs has been attained. However, the significant binding energy difference between certain pairs (bonding and antibonding) of low-lying MOs (from ~15 eV to ~50 eV) in some compounds allowed one to suggest that the perturbation induced by electrons of these MOs substantially affect bond strengths in these compounds.^{1–6}

To this end, from the practical viewpoint, it is expedient to divide the X-ray photoelectron spectra into three regions depending on the electron binding energy. The first region (from 0 eV to ~15 eV) typically involves a poorly-resolved structure corresponding to the outer valence molecular orbitals (OVMOs), which are mainly built up of partially filled valence atomic orbitals. The second region (~15 eV ... 50 eV) exhibits a well-resolved structure associated with electrons of the inner valence molecular orbitals (IVMOs) which are mainly composed of closed atomic shells. Peaks that belong to the third region (more than 50 eV) reflect inner(core) MOs (CMOs) primarily consisting of deep-lying inner (core) AOs. However, due to the limited resolution of X-ray photoelectron spectrometers, separate peaks of electrons of

these CMOs cannot be observed even in the spectra of homonuclear gaseous molecules.¹ When we proceed to correlation of the structure of a compound with the structure of its IVMOs, the expedience of this division is most evident.

It should be noted that one cannot strictly divide MOs into categories of CMOs, IVMOs, and OVMOs, when considering the IVMO problem in general terms of the formation of MOs in various compounds. The character of the IVMOs in light-element compounds discussed in this review is closer to that of conventional OVMOs. Some of IVMOs of compounds containing heavy atoms are like CMOs. In other words, we should carefully consider this question for each particular compound. Moreover, although *de facto* the term 'IVMO' for light-element compounds has been used earlier, scientists started using this term for heavy-atom compounds only recently, since the existence of fine structure that could be interpreted in terms of the formation of IVMOs had been discovered in X-ray photoelectron spectra in the energy range of ~ 15 eV... ~ 50 eV.²⁻⁶

As has been mentioned in previous studies,^{17,20} one of the reasons that a group of MOs referred to as IVMOs should be considered separately from the rest of MOs is that the peaks corresponding to IVMOs are well resolved, unlike those corresponding to OVMOs, and the fine structure associated with them depends on the nearest environment of the absorbing atom in the molecule or cluster. We should mention that, simultaneously with the appearance of a fine structure, multielectron effects can manifest themselves in the low-energy region of X-ray photoelectron spectra. It has been shown^{1,17-20} that multielectron effects give rise to additional bands, as a rule, of much lower intensity than that of the major peaks, and a certain smearing of the spectrum. However, the spectral structure determined by the ground and final electronic states of the system with a vacancy after photoemission almost always remains firmly pronounced.

Fine structure observed in X-ray photoelectron spectra of shells of various compounds are evidence that multielectron effects play a noticeable role in their formation. However, one should keep in mind that XPS is of greatest practical use for a wide range of researchers when the spectra can be interpreted in terms of the one-electron approximation.

In the present review we discuss the IVMO problem from the general viewpoint. An attempt has been made to answer the following questions:

1. How common is IVMO formation for compounds of various elements of the Periodic Table?
2. What qualitative and quantitative information on physico-chemical properties can be obtained from the spectral parameters of the IVMO-assigned fine structure?
3. How significant is the role of IVMOs in chemical bonding and what is the overall contribution of electrons of these orbitals to the covalent component of the bond energy?

For the sake of simplicity, we interpret the spectra containing fine structure using atomic notation as well as molecular ones.

II. General notions

In terms of the MO LCAO model, chemical bonding in diatomic molecules occurs by filling MOs with the common electrons. The positive, negative, or zero contribution of an electron to the bond energy depends upon the character of the corresponding MO (bonding, antibonding, or non-bonding). This concept was developed to the largest extent in the consideration of the nature of the chemical bond in diatomics, viz., homonuclear molecules of $D_{\infty h}$ symmetry and heteronuclear ones of $C_{\infty v}$ symmetry. The main qualitative postulate, which defines the relative bond energy in a diatomic molecule, is that the bond energy contributions of the electrons to the bonding and the corresponding antibonding MOs are approximately equal. The bond order, determining the bond strength, equals half the difference in populations of the bonding and antibonding MOs.^{21,22,34-37} Therefore, the number of excessive 'bonding' electrons is considered to be the measure of

the bond strength.^{35,38-41} However, this rule is approximate,^{21,35} since a molecule is destabilised by the electrons of antibonding MOs to a somewhat greater extent than stabilised by electrons of the corresponding bonding MOs.

The bonding or antibonding character of individual MOs can be established experimentally from the deviation, ΔR_e , of the internuclear distance from its equilibrium value in the ground state,^{41,42} variations in dissociation energy ΔD_e ,^{37,41,43} and vibrational frequencies occurring due to the ionisation.⁴⁴ The MO character can be estimated roughly by consideration of the specific distribution of electron density in internuclear space²¹ and on the basis of difference electron density maps $\Delta\rho$,³⁹ i.e. a difference between the molecular electron density and initial atomic electron densities.

As mentioned earlier,^{21,22,34-41} the contributions of the electrons of the bonding and antibonding IVMOs to the covalent component of the bond energy compensate each other. Thus, the overall chemical bonding in a molecule is solely attributed to the electrons of OVMOs. Thus, it is believed that in a diatomic molecule AB of $C_{\infty v}$ symmetry, where A and B are second Period elements, as a first approximation, the bonding (3σ) and antibonding (4σ) IVMOs, which are composed of the $2s$ AOs of neighbouring atoms, in the first approximation do not affect the A-B bonding. Populations of the 1π , 5σ , and $2\pi^*$ OVMOs formed by the $2p$ AOs determine the total bond order. In homonuclear molecules A_2 , such orbitals are classified as $2\sigma_g$ and $2\sigma_u^*$ IVMOs. The corresponding OVMOs within the framework of the D_{2h} symmetry point group are classified as the $1\pi_u$, $3\sigma_g$, and $1\pi_g$ outer valence molecular orbitals. This concept of the negligibly small influence of the electrons of MOs formed by doubly-occupied AOs on chemical bonding had been so widely used that it almost became an axiom. It is represented in a number of monographs^{21,34,38,39,43,44} and textbooks for college students^{35,37,40,41} and school teachers.^{45,46} Until recently, attempts to revise this established model have hardly been undertaken.

However, the first *ab initio* calculations on the CO molecule (e.g., see review⁴⁷) indicate either a weakly-bonding or antibonding character of the 5σ OVMO. The latter is usually used to explain the increased vibrational frequency of the CO^+ as well as $CO\delta^+$ ions, where δ^+ is a small charge induced upon the adsorption of the CO molecule on electron-deficient centres of a solid surface, compared to that of the neutral molecule. In an attempt to tailor this fact to a simple scheme of MO formation, the authors⁴⁴ assigned the bond order of the carbon-oxygen bond as 2 instead of 3, that is determined by four electrons in the 1π OVMO. It was considered that the electrons of the 3σ and 4σ IVMOs do not contribute to the chemical bonding owing to the mutual compensation of bonding and antibonding effects.

Another approach (see Refs 41, 44) implies a non-bonding character of the 3σ IVMO of the CO molecule (it is occupied by a lone electron pair of the O atom). The triple bond in the molecule is attributed to two electrons of the 4σ IVMO and four electrons of the 1π OVMO. In contrast, the authors of another study²¹ assumed that the 4σ IVMO and 5σ OVMO are non-bonding, while the electrons in the 3σ IVMO and 1π OVMO account for the bond order 3.

Traditionally, triple bond formation in the CO molecule is attributed to the electrons of the $5\sigma^2$ and $1\pi^4$ OVMOs.^{34,43} We should note that, according to the valence bond approach,⁴⁸ the bond order in the CO molecule is intermediate between 2 and 3 due to the contribution of resonance structures, namely, $:C \equiv O:$ and $:C \equiv \dot{O}$.

Recently, attempts to quantify the bonding character of MOs in the CO molecule have been undertaken based on division of the total Hartree-Fock energy⁴⁹ and the values of Mulliken MO populations.⁵⁰ In these studies, the 3σ electrons were found to contribute significantly to the binding of C and O atoms in the CO molecule. Qualitative arguments in favour of the participation of the inner valence electrons in chemical bonding can be obtained by linear transformation of the 4σ IVMO and 5σ OVMO.⁴² It has

been found that electrons occupying these MOs are essentially the lone pairs, and the $3\sigma(2\sigma_g)$ IVMO and $1\pi(1\pi_u)$ OVMO are involved in the triple bond formation in CO (or N_2).

Studies of the electronic structure of compounds by XPS^{1-9, 17-20, 26-28} and theoretical calculations conducted at different levels of theory^{3, 4, 29-32, 49-57} have demonstrated that the conventional concept of the dominant participation of electrons of the OVMOs in chemical bonding is too rough an approximation.

III. Theoretical consideration

At present, there is no unified qualitative measure that allows the contribution of electrons of individual MOs to the bond strength, even for diatomic molecules, to be estimated. This quantity must be additive, i.e. the total bond energy must be equal to the sum of the individual MO contributions with respect to their populations. This condition is satisfied in the Mulliken bond population theory and in various quantum-chemical bond strength characteristics based on division of the total molecular energy into orbital and other components. Criteria concerned with an internuclear force, which arise due to changes in MO populations, are also of interest. This section discusses possible approaches to the solution of this problem.

1. Contribution of electrons to bond populations

In this approach, the contributions of electrons to the bond strength are estimated from Mulliken populations of MOs and AOs.⁴⁷ Within the MO LCAO approximation for a heteronuclear molecule AB, every pair of interacting orbitals satisfies the following equation:

$$\psi^\pm = \frac{1}{(2 \pm 2S)^{1/2}} (\chi^A \pm \chi^B), \quad (1)$$

where ψ^+ and ψ^- are the bonding and antibonding MOs respectively, χ^A (χ^B) an atomic orbital or, more generally, a linear combination of atomic orbitals of the atom A (B), and S is an absolute value of the overlap integral between χ^A and χ^B . The one-electron density in these MOs is defined as follows:

$$|\psi^\pm|^2 = \frac{1}{2(1 \pm S)} [|\chi^A|^2 + |\chi^B|^2] \pm \frac{1}{1 \pm S} \chi^A \chi^B. \quad (2)$$

The bonding space is an area between two planes passing through nuclei A and B perpendicularly to the bond axis. If χ is a non-hybrid AO, then the electron densities $|\chi^A|^2$ and $|\chi^B|^2$ contribute equally to the total electron density, not only in the bonding space, but also in the rest of space. The second term in Eqn (2) is the charge density localised essentially in the internuclear area. Therefore, one may consider this term as a qualitative measure of the bonding (antibonding) character of the MO. If ψ is the sp hybrid AO, then the first term in Eqn (2) also contributes to the bond order. The second term integrates to the following expression:

$$n(j_\pm, AB) = \pm \int \frac{1}{1 \pm S} \chi^A \chi^B d\tau = \pm \frac{S}{1 \pm S}, \quad (3)$$

which is the contribution of an electron in the j th MO to Mulliken's bond population. It follows from Eqn (3) that the contribution of an electron in the bonding MO ψ_i^+ is positive while the contribution of an electron in the antibonding MO ψ_i^- is negative and is larger in magnitude.

For diatomic heteronuclear molecules, the j th MO is expressed as:

$$\psi_j = c_j^A \chi^A + c_j^B \chi^B, \quad (4)$$

and the contribution of the electron in this MO to the bond population is:

$$n(j, AB) = 2c_j^A c_j^B \int \chi^A \chi^B d\tau. \quad (5)$$

Since the contributions are additive, the total population of the A–B bond is:

$$n(AB) = \sum_j N_j n(j, AB), \quad (6)$$

where N_j is the population of the j th MO.

In multiatomic molecules, $n(j, AB)$ refers to pairs of adjacent atoms. The partial contribution of an electron on the j th MO is defined as follows:

$$n(j) = \sum n(j, AB), \quad (7)$$

where the sum is taken over all the bonds.

2. Estimation of orbital character by separation of the total energy

Different kinds of interactions within the quantum-chemical approach are widely treated by separation of the total energy of a multiatomic molecule into one-, two-, three-, and four-centre components. The method of the complete neglect of differential overlap (CNDO/2)⁵⁵ serves as an example. The total energy E_{tot} within this method assumes the form:

$$E_{tot} = \sum_A E_A + \sum_{B,A} E_{AB}, \quad (8)$$

where E_A and E_{AB} are corresponding one- and two-centre components. The latter has the form:

$$E_{AB} = 2 \sum_\mu^A \sum_\nu^B p_{\mu\nu} H_{\mu\nu} - \frac{1}{2} \sum_\mu^A \sum_\nu^B p_{\mu\nu}^2 \gamma_{AB} + Z_A Z_B R_{AB}^{-1} - p_{AA} Z_B \gamma_{AB} - p_{BB} Z_A \gamma_{AB} + p_{AA} p_{BB} \gamma_{AB}, \quad (9)$$

where $p_{\mu\nu}$ is referred to as the bond order, the result of interaction of the μ -AO of atom A with the ν -AO of atom B; $H_{\mu\nu}$ are elements of the core Hamiltonian, γ_{AB} are repulsion integrals of the electrons of the s -type functions, Z_A (Z_B) is the charge of the nucleus (the effective value is used for the valence shell), p_{AA} (p_{BB}) is the electron density of the atoms.

The first term in Eqn (9) is referred to as the resonance energy.⁵⁶ Its magnitude characterises the covalent component of the A–B bond. The other terms denote the exchange component of the energy, core–core repulsion energy, potential energy of electrons of the atom A in the field of the core B, potential energy of electrons of the atom B in the field of the core A, and energy of electron–electron repulsion for atoms A and B respectively.

Despite the variational nature of the CNDO/2 approach, its semiempirical character does not yield total energy values that correspond to the results obtained with more rigorous approaches or from experiment. However, atomisation energies and bond energies of molecules can be estimated from components of the total energy in Eqn. (8).⁵⁷ It will be shown (see Section V.1) that the results of CNDO/2 calculations can provide an estimate of the bonding character of MOs. To this end, the resonance energy E_{AB}^R is separated into contributions E_α^R of individual MOs:

$$E_{AB}^R = \sum_\alpha E_\alpha^R, \quad (10)$$

$$E_\alpha^R = 2n_\alpha \sum_i^A \sum_j^B c_{i\alpha} c_{j\alpha} H_{ij},$$

where n_α is the population of the α MO, H_{ij} the core Hamiltonian, $c_{i\alpha}$ and $c_{j\alpha}$ are the coefficients of the i th and j th AOs in an expansion of the α MO by atomic orbitals found from self-consistent field (SCF) calculation, CNDO/2. The positive (negative) sign of the contribution E_α^R to the resonance energy corresponds to the antibonding (bonding) character of the α MO.

3. Estimation of the orbital character within the orbital force approach

According to the Hellmann–Feynman theorem, the internuclear force is equal to the expectation value of $\partial\hat{H}/\partial R$, where \hat{H} is the Hamiltonian and R is the internuclear distance.

Forces acting on nuclei in a molecule are determined as derivatives of the potential energy with respect to internal bond lengths and bond angles or cartesian coordinates. These forces can also be calculated from the known wave functions. Regarding a diatomic molecule AB, the total force acting on the nucleus A is:

$$F_A(R) = \frac{Z_A}{R^2} \left(Z_B - n_e R^2 \int \psi_{AB}^* \frac{\cos\theta_{\mu A}}{r_{\mu A}^2} \psi_{AB} d\tau \right), \quad (11)$$

where n_e is the total number of electrons, R is the internuclear distance, μ is the electron index, A is the atom index, $r_{\mu A}$ is the distance from the μ th electron to the nucleus A, $\theta_{\mu A}$ is the angle between the bond direction and radius-vector of the μ th electron of the atom A, $d\tau$ is the space unit. At $R = R_e$, $F_A = -F_B = 0$, therefore the second term in Eqn (11) must be equal to Z_B , i.e.

$$n_e R_e^2 \int \psi_{AB}^* \frac{\cos\theta_{\mu A}}{r_{\mu A}^2} \psi_{AB} d\tau = Z_B. \quad (12)$$

This term reflects the contribution of electrons to the total force acting on the nucleus. Within the MO LCAO approach, the following expression is valid for each MO:

$$\eta_i = R^2 N_i \int \phi_i^* \frac{\cos\theta_{\mu A}}{r_{\mu A}^2} \phi_i d\tau, \quad (13)$$

where ϕ_i is the MO, N_i is the number of electrons in the i th MO. Subject to Eqns (12) and (13), it follows that:

$$\sum_i \eta_i = Z_B, \quad (14)$$

where the integration is performed over the occupied MOs.

A modified orbital force f_i , which determines a one-electron contribution to the total force,¹⁷ can be introduced

$$f_i = \frac{Z_B}{N_i R^2} \eta_i, \quad (15)$$

This force is also additive, i.e.

$$\sum_i N_i f_i = \frac{Z_B^2}{R^2}. \quad (16)$$

The force f_i can be calculated from the derivative of the orbital energy vs. the internuclear distance. Indeed, according to the Fock equation for the MO

$$\hat{F}\phi_i = E_i\phi_i, \quad (17)$$

it follows that:

$$E_i' = \frac{dE_i}{dR} = \int \phi_i^* \left| \frac{d\hat{F}}{dR} \right| \phi_i d\tau. \quad (18)$$

Since

$$\hat{F} = \hat{h} + \hat{G},$$

where \hat{h} is the one-electron Hamiltonian, \hat{G} is the operator of the electron–electron electrostatic interaction, then

$$E_i' = f_i + \int \phi_i^* \left| \frac{d\hat{G}}{dR} \right| \phi_i d\tau. \quad (19)$$

According to Eqn (19), f_i differs from E_i' only by electron–electron repulsion terms. These terms can be estimated using the values of E_i' and f_i listed in Table 1.

Presumably, the second term in Eqn (19) equals f_i times a constant factor. Then Eqn (19) takes the form:

$$E_i' \simeq f_i + cf_i = (1+c)f_i. \quad (20)$$

A correlation plot of E_i' versus f_i using the data in Table 1 proves this assumption (Fig. 1). According to this plot, the coefficient c equals approximately 0.23. Therefore, Eqn (20) may be rewritten:¹⁷

$$E_i' \simeq 1.23f_i. \quad (21)$$

Figure 1. Dependence of the derivatives of the orbital energies E_i' on the orbital forces f_i for: (1) O_2 ; (2) B_2 ; (3) C_2 ; (4) N_2 (1 at. unit = 8.24×10^{-8} N).¹⁷

The orbital forces can be substituted by E_i' values in a semiquantitative estimation of the relative contributions of electrons of individual MOs to the covalent bonding, since the total covalent component of the bond energy of the molecule can be represented as the sum of the orbital energies with respect to their populations.⁵⁹ Ruedenberg⁶⁰ has suggested an empirical correlation between the total covalent component of the Hartree–Fock energy E of a molecule and the sum of the orbital energies of the occupied MOs:

$$E \simeq k \sum_i N_i E_i, \quad (22)$$

where k is a constant.

Table 1. The orbital forces f_i and derivatives of the MO energies ($E_i'/10^{-8}$ N).¹⁷

Molecule	$2\sigma_g$ IVMO		$2\sigma_u$ IVMO		$1\pi_u$ OVMO		$3\pi_g$ OVMO		$1\pi_u$ OVMO	
	E_i'	f_i	E_i'	f_i	E_i'	f_i	E_i'	f_i	E_i'	f_i
B_2	0.824	5.257	-0.585	-1.121	0.634	2.711	—	—	—	—
C_2	1.524	10.086	-1.162	-1.953	1.038	5.043	—	—	—	—
N_2	3.486	18.087	-1.195	-3.123	2.175	8.199	0.709	1.014	—	—
O_2	4.227	18.573	-1.640	-3.280	1.838	8.240	1.129	1.104	-1.607	2.694

From Eqn (22),

$$F = -\frac{\partial E}{\partial R} \cong -k \sum_i N_i E_i' \quad (23)$$

Roedenberg's value $^{60} 3/2$ for k in Eqn (22) differs somewhat from 1.23 in Eqn (21). Apparently, the coefficient in Eqn (21) varies for series of diatomic molecules made up of elements of different Periods. The same is valid for the constant k in Eqn (22). Goscinsky⁶¹ also noted the approximate character of the estimation of the orbital forces from E_i' . He suggested a technique for calculation of the derivatives, which takes into consideration the MO relaxation occurring during the ionisation of a molecule. According to this approach, a force arising on nuclei due to the removal of an electron from the i th MO equals the derivative of the energy of the ion (i) with respect to the internuclear distance at the equilibrium point of the initial molecule:

$$\tilde{f}_i = -\left. \frac{dE_i^i(R)}{dR} \right|_{R_e} \quad (24)$$

Koopmans's theorem states that

$$E_i^i(R) = E(R) - E_i(R), \quad (25)$$

where $E(R)$ is the total energy of the ground state of the molecule. Then within this approach,

$$\tilde{f}_i = E_i' \quad (26)$$

Taking into account MO reorganisation caused by a change in the populations, we obtain:

$$\tilde{f}_i = E_i' + \left. \frac{dE_i^{\text{rel}}(R)}{dR} \right|_{R_e} \quad (27)$$

where $E_i^{\text{rel}}(R)$ is the relaxation energy of the system upon removal of an electron from the i th MO. A method for the determination of the contribution of MO relaxation within the transition operator approach has been suggested.⁶¹

The effect of relaxation is automatically taken into account if orbital forces are determined from experimental rather than the calculated spectral data.⁶² In this case, the orbital forces are referred to as the orbital vibronic constants.^{63,64,65} A deformation force, which arises on nuclei upon vertical electron excitation or ionisation of a diatomic molecule, is determined as a derivative of the potential energy of the final state versus the interatomic distance at the transition point. For a Morse potential we may write²¹

$$U(x) = D_e[\exp(-2\beta x) - 2\exp(-\beta x)], \quad (28)$$

where D_e is the depth of the well, β is a variable parameter, and x is the deviation of the interatomic distance R from its equilibrium value R_e . Then the classical force \tilde{f} is determined as follows:

$$\tilde{f} = -\left. \frac{dU(x)}{dx} \right|_{x^*} = -2D_e\beta[\exp(-\beta x^*) - 2\exp(-2\beta x^*)], \quad (29)$$

where x^* is the difference between the equilibrium distances in the initial and final states.

4. Relationship between various characteristics of the orbital contributions

Most simply, the estimation of the MO contribution to the bonding is determined as a part of the Mulliken bond population associated with this MO. The values of the bond populations for a series of diatomic molecules and the values of the orbital forces for some of them⁴⁷ are listed in Table 1. Correlation plots of the bond population vs. the orbital force f_i for the valence MOs of C_2 , N_2 , and O_2 shown in Fig. 2 yield straight lines. This reflects the approximate character of the bond order as an index of the bond

Figure 2. Dependence of the bond populations $n(j, AB)$ on the orbital forces f_i for valence MOs of (1) O_2 , (2) N_2 , and (3) C_2 .⁶⁵

strength. We have to note that only the MO contributions to the bond order $n(j, AB)$ calculated within the extended Hückel approach correlate satisfactorily with other characteristics, such as the orbital forces f_i , and the orbital vibronic constants for MOs of the same molecule.¹⁷ The CNDO/2 calculations for N_2 , CO, NO, O_2 , C_2 , and CN have been carried out in order to test whether the bonding character of MOs can be estimated from values of the orbital resonance energy.⁶⁵ For the first four molecules, the orbital vibronic constants, which had been calculated earlier from spectral data,⁶² were used as the bonding indices. The values of the orbital vibronic constants for the last two molecules were calculated from the corresponding wave functions of OVMOs.⁶² The total number of data points reached 20. The correlation between the CNDO/2 resonance orbital energies and the orbital vibronic constants has been established (Fig. 3). Characteristically, the plot yields a straight line through the origin of coordinates, and the correlation has the form:

$$a_\alpha = -7.1 E_\alpha^R, \quad (30)$$

where a_α is the orbital vibronic constant (in 10^{-8} N) and E_α^R is the resonance orbital energy in atomic units. The orbital vibronic constants of arbitrary MOs can be calculated from the orbital contribution to the resonance energy using this dependence. In particular, it makes possible the determination of the orbital vibronic constants of IVMOs for which spectral data are currently unavailable.

Ab initio calculations of the electronic structure of molecules N_2 ,^{66,67} CO,^{67,68} and a radical CH⁶⁹ have provided the values of derivatives (E_α') at the equilibrium interatomic distances. Graphical analysis reveals a correlation between E_α' and a_α of the form:

Figure 3. Dependence of the orbital vibronic constants a_α on the orbital resonance energies E_α^R for: (1) N_2 ; (2) CO; (3) O_2 ; (4) NO; (5) CN; (6) C_2 .⁶⁵

Figure 4. Correlation of the orbital vibronic constants a_α with the derivatives of the MO energies E'_α for: (1) CO; (2) N₂; (3) CH.⁶⁵

$$a_\alpha = 0.71E'_\alpha, \quad (31)$$

where both E'_α and a_α are expressed in nN (Fig. 4). Obviously, Eqn (31) can also be applied to calculations of the missing orbital vibronic constants. We should keep in mind that formula (31) was derived with a limited number of data points due to incomplete sets of experimental a_α values rather than due to the absence of *ab initio* studies with varied R .⁶² Consequently, an examination of the correlation between E'_α and E_α^R would be helpful for verification of Eqn (31). This challenge is feasible since non-empirical $E_\alpha(R)$ dependences have been published for a number of diatomic molecules and the corresponding CNDO/2 values of E_α^R can be readily calculated. With this in mind, we appended the values of the orbital energy derivatives from *ab initio* calculations for molecular hydrides LiH, BeH, BH, NH, and HF^{69,70} to the list of those for N₂, CO₂, and CH, so that the total number of data points reached 32. From least-squares analysis of the data collected

$$E'_\alpha = b_0 + b_1E_\alpha^R$$

the coefficients b_0 and b_1 were found to be equal to 0 and -10 respectively. Thus the correlation between the non-empirical derivatives of the orbital energies and the semiempirical values of the orbital resonance energies has the form:

$$E'_\alpha = -10E_\alpha^R. \quad (32)$$

Composition of Eqns (32) and (30) corroborates Eqn (31). Also, it can be demonstrated that the CNDO/2 derivatives of the orbital energies are of certain interest for the estimation of orbital vibronic constants. Indeed, reasoning by analogy with Eqn (32), we have

$$E'_\alpha(\text{CNDO/2}) = -10.9E_\alpha^R. \quad (33)$$

On other hand,

$$a_\alpha = 0.65E'_\alpha(\text{CNDO/2}). \quad (34)$$

The last two dependencies corroborate additionally the validity of Eqn (30). It can be deduced from Eqns (33) and (34) that the non-empirical and CNDO/2 values of E'_α correlate. The dependence presented in Fig. 5 confirms this expectation.

According to the data mentioned above, derivatives of the orbital energy versus the internuclear distance can serve as an estimate of orbital vibronic constants in diatomic molecules.¹⁷ It is not surprising that CNDO/2 values are successfully used on even terms with non-empirical data since the initial parametrisation of the semiempirical method employed *ab initio* data for small molecules. At the same time, the derivatives E'_α obtained in terms of the extended Hückel method correlate with the orbital vibronic

Figure 5. Correlation of the derivatives of the orbital energies E'_1 obtained from *ab initio* calculations with those, E'_2 , obtained from SCF CNDO/2 calculations for N₂, CO, CH, LiH, BeH, BH, NH, and HF.⁷⁰

constant to a lesser extent although satisfactory results can still be obtained in certain cases. The same holds for the correlation between the orbital vibronic constants and the Mulliken orbital populations (Fig. 6).

IV. The structure of X-ray photoelectron spectra

X-Ray photoelectron spectroscopy is based on the photoeffect.¹ Under exposure to exciting X-ray radiation, e.g., $\text{MgK}_{\alpha 1,2}$, photoelectrons with kinetic energy of up to ~ 1.2 keV are emitted. The electron energy is measured to an accuracy of 0.1 eV. As a result, the binding energies (electronic work functions) of inner and outer levels of the compound under examination can be determined up to a constant factor from the Einstein equation.

An X-ray photoelectron spectrum represents the number of photoelectrons (peak intensity I expressed in relative units) plotted against the binding energy E_b (in eV). To enable compar-

ison of X-ray photoelectron spectra, they are calibrated against a known value of the binding energy E_b of electrons of a certain shell of a standard substance, e.g., gold (Au 4f_{7/2}).

The X-ray photoelectron spectra of the compounds to be discussed in this review were obtained in the gas phase¹ and solid state.^{17–20} High-resolution spectra of solid compounds are usually obtained with the monochromatic AlK_{α1,2} (1486.6 eV) characteristic X-ray radiation and a low-energy electron gun. Samples are usually prepared as dense layers precipitated from inert solvents or depressed on an indium support. Experiments are carried out either at ambient or liquid-nitrogen temperatures. All the spectra discussed are reduced to the same scale in which the binding energy E_b of the C 1s electrons in hydrocarbons was set equal to 285.0 eV (except for gas-phase spectra).

Fine structures in X-ray photoelectron spectra are often interpreted using calculations of the electronic structure of molecules and clusters performed mainly by non-relativistic SCF methods, namely, the SCF CNDO/2, SCF X α -SW,^{29, 55, 71–75} and SCF X α -DV.^{31, 32, 76–80}

The formation of IVMOs between neighbouring atoms requires that:

(a) the energies of the corresponding filled AOs are comparable;

(b) these AOs possess the same symmetry type with respect to the interatomic axis;

(c) the interatomic distance is sufficient for effective overlap of these AOs.^{17, 21, 81–85}

According to (a) and (b), it is anticipated that IVMOs effectively form in homonuclear molecules, and, with (c) satisfied, IVMOs can form in heteronuclear compounds too.

Such difficulties as fast oxidation and decomposition of highly-reactive compounds as well as the influence of aggressive species, e.g. F₂, Cl₂, etc., on units of the spectrometer often arise in XPS studies of these compounds, for which the formation of IVMO is expected. Generally, these difficulties are not fundamental since the current level of the experimental technique is sufficient to overcome such problems. However, XPS studies are preferably performed with stable inert compounds to obtain the most reliable results. It is the main factor that defines up to now the set of available spectra of homo- and heteronuclear compounds.

We should also mention that solid compounds form a lattice where electronic states are described in terms of the band structure. In a certain approximation, the bands represent MOs, thus they reflect the electronic structure of clusters typical of a given compound in the solid phase. This seems to be quite admissible for the less-delocalised core electrons, and the corresponding peaks in X-ray photoelectron spectra are broadened. Such broadening due to effects of the solid lattice gives maxima, attributable to the band structure, which are referred to as peaks for the sake of simplicity and attributed to electrons of individual clusters.

In this review we discussed X-ray photoelectron spectra of compounds of group IVA–VIIA elements, lanthanide oxides and fluorides (except for Pm compounds), and a wide range of actinide series compounds.

1. Manifestation of inner valence molecular orbitals in X-ray photoelectron spectra

a. Homonuclear molecules and clusters of group IVA–VIIA elements

X-Ray photoelectron spectra of solid compounds under consideration reveal a fine structure occurring in the low-energy region. Since the electronic configuration of these elements is ns^2np^m , where $2 \leq m \leq 5$, this fine structure can be concerned considerably with the interaction of ns electrons. A simpler fine structure appears in the spectra of gaseous diatomic molecules of these elements (Fig. 7). In this case, on the one hand, homonuclear molecules provide the most favourable conditions for IVMO

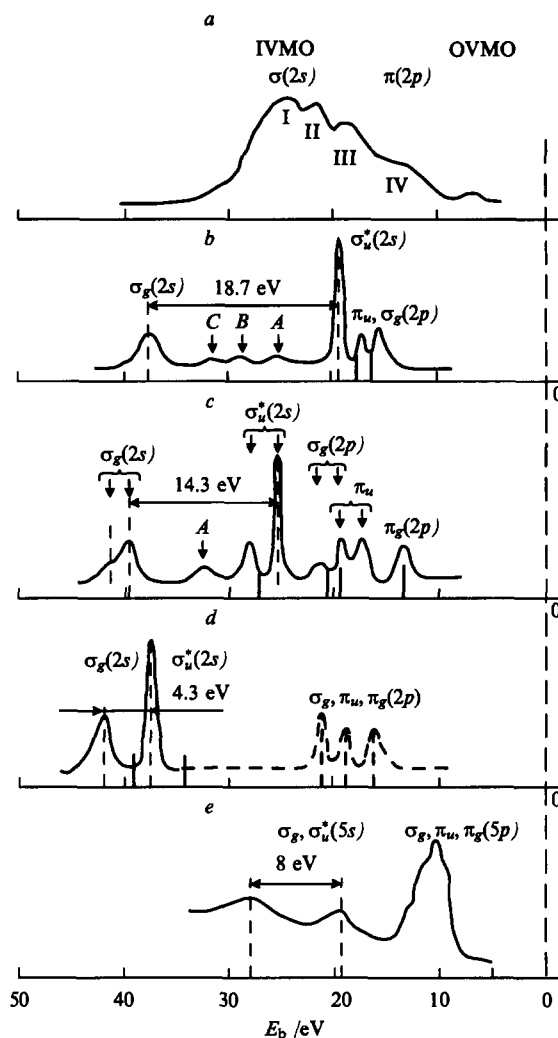

Figure 7. The X-ray photoelectron spectra of pyrographite ($E_b(\text{C}1s) = 290$ eV) (a)²⁵ and gaseous N₂ (b),¹ O₂ (c),¹ F₂ (d),²³ and I₂ (e).²⁴ The bond lengths (in Å) are 1.42 (C–C), 1.098 (N≡N), 1.207 (O=O), 1.417 (F–F) and 2.666 (I–I).

formation; on the other hand, rigorous theoretical studies of the electronic structure of these compounds can be performed and interpreted relatively easily.

The results of the CNDO/2 and X α -DV theoretical calculations^{1, 32, 51, 56, 86, 87} for the N₂ molecule, establish that the two most intense low-energy peaks in the X-ray photoelectron spectra of this molecule, separated by 18.7 eV, are associated essentially with the electrons of the antibonding $2\sigma_u^*$ and bonding $2\sigma_g$ IVMOs. The calculated gap (ΔE_{theor}) between the binding energies of electrons of the $2\sigma_g$ and $2\sigma_u^*$ IVMOs in the N₂ molecule equals 16.9 eV (X α -DVM) and 18.1 eV (CNDO/2) at the equilibrium distance $R_e = 0.109$ nm.^{51, 56} The fine structure of the X-ray photoelectron spectrum of N₂ theoretically modelled at the SCF X α -DVM level (bond length $R = 0.106$ nm, $\Delta E_{\text{theor}} = 18.59$ nm) is shown in vertical lines below the experimental spectrum (Fig. 7 b). The scales of the experimental and theoretical spectra do not match; the binding energy differences of the N 1s electrons are not equal ($|E_{\text{exp}}(\text{N } 1s) - E_{\text{theor}}(\text{N } 1s)| = 7.5$ eV). Additional peaks (A, B, and C) attributable to multielectron effects, characteristic losses, and MgK $\alpha_{3,4}$ excitation appear in the X-ray photoelectron spectrum of N₂.¹ The spectrum of the weakly-bound electrons of the nitrogen molecule is an exemplary demonstration of IVMO formation in molecules.

The spectrum of the O_2 molecule provides yet another example.¹ In the low-energy region of its spectrum, as in the spectrum of N_2 , two peaks associated with electrons of the $2\sigma_g$ and $2\sigma_u^*$ IVMOs appear; the binding energy gap ΔE_{exp} between them equals 14.3 eV (Fig. 7 c). These IVMOs to a great extent consist of the $O\ 2s$ AOs. Since O_2 is paramagnetic, multiplet splitting of the electronic states appears in the spectrum. Thus, every peak except for one of the π_g^* electrons is split into two components corresponding to the $^2\Sigma^-(^2\Pi)$ and $^4\Sigma^-(^4\Pi)$ possible electronic states of the system after electron photoemission. Additional peaks (A, B,...) associated with multielectron effects, characteristic losses, and the $MgK_{\alpha,3,4}$ excitation are present in the O_2 spectrum as well as in the spectrum of N_2 .¹ The theoretically predicted spectrum obtained within the framework of the SCF X α -DVM approach³² is represented by vertical lines in Fig. 7 under the experimental one.

Theoretical predictions of X-ray photoelectron spectra of diatomic molecules, namely N_2 , CO, O_2 , NO, etc., taking into account multielectron effects demonstrate that configuration interaction somewhat complicates the spectra calculated within the one-electron approximation.¹ However, one-electron spectra can be used in considering the IVMO formation since they are much like the experimental spectra.

The binding energy difference between electrons of the $2\sigma_g$ and $2\sigma_u^*$ IVMOs in the F_2 molecule is essentially smaller than those in N_2 and O_2 and equals $\Delta E_{exp} = 4.28$ eV.²³ The results of the SCF X α -DV calculation³² of the electronic structure for the F_2 molecule ($\Delta E_{theor} = 5.6$ eV) are shown in Fig. 7 d and compared with the experimental spectrum. Another detailed study on the IVMO formation in the F_2 molecule, in which the contribution of the IVMO electrons to the bond energy was estimated, was accomplished at the SCF X α -SW level of theory.⁷³

There is a slight difference between the low-energy part of the spectrum of molecular iodine in gaseous and condensed states.²⁴ In the region of the $I\ 5s$ electrons (~ 15 eV–35 eV), two broadened peaks are present in both spectra.²⁴ These peaks are attributed to the σ_g and σ_u^* IVMOs that refer to the $I\ 5s-5s$ interaction. The energy difference between these IVMOs is of about 8 eV (see Fig. 7), although the bond in the I_2 molecule is relatively long ($R_e = 0.2666$ nm) to result in such a considerable difference in energy. Therefore, it was hypothesised¹⁷ that the energies of these IVMOs differ much less and the peaks associated with them appear at around $E_b = 19$ eV. However, this assumption still has to be confirmed by theoretical calculations.

The calculated electronic structure of the C_2 molecule⁸⁸ implies also an essential feature of the $C\ 2s-C\ 2s$ overlap resulting in the formation of the $2\sigma_g$ and $2\sigma_u^*$ IVMOs. At the interatomic distance $R_e = 0.1242$ nm, the binding energy difference between electrons of the $2\sigma_g$ and $2\sigma_u^*$ IVMOs is 18.2 eV, which substantially extends the energy range of the X-ray photoelectron spectrum of C_2 compared to the atomic spectrum of carbon. This accounts for a larger width (~ 25 eV)^{17,25} of the low-energy band in highly-oriented pyrolytic graphite (Fig. 7 a) and diamond compared to the width of the valence band in solid Si and Ge, which possess the diamond-type structure.¹⁷ Since the X-ray photoelectron spectra of graphite and diamond recorded in this region are essentially associated with the $C\ 2s$ electrons,^{17,25} it was postulated⁸⁸ that the base of the valence band is strongly lowered due to the IVMO formation by the $C\ 2s$ AOs.

Peaks attributed to electrons of the IVMOs arising mainly from the $ns-ns$ interaction are also present in X-ray photoelectron spectra of other homonuclear compounds of Group IVA–VIIA elements (see Refs 17, 52, 72 and Figs 8 and 9). The binding energy difference between the electrons of the IVMOs decreases as the atomic number Z increases.^{17,20} In other words, the character of the IVMOs is getting closer to that of the inner (core) MOs, i.e. the overlap between occupied and vacant valence AOs decreases. A similar tendency in the formation of IVMOs is observed when the atomic number increases in a Period.

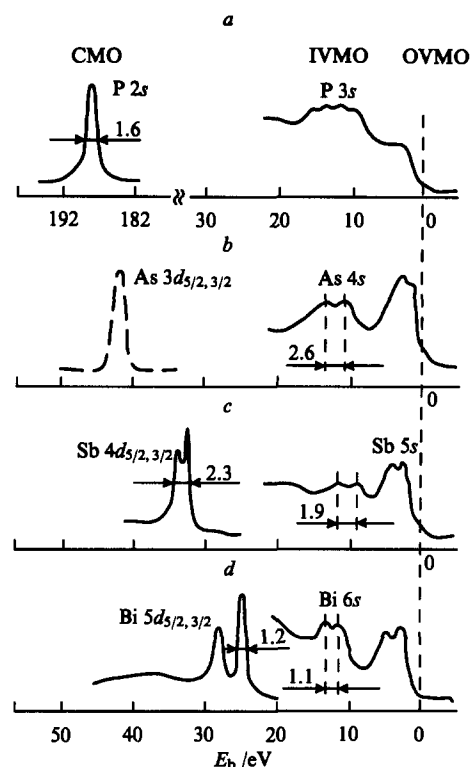

Figure 8. The X-ray photoelectron spectra of red phosphorus (a), As (b),¹¹ Sb (c), and Bi (d) in the solid state.⁷² Here and elsewhere the CMO and IVMO spectra are not calibrated in terms of intensity. In this case, for phosphorus, the intensity of the CMO spectrum is 15 times that of the IVMO one; the intensity of the CMO spectra of As, Sb and Bi is 20 times that of the IVMO one.

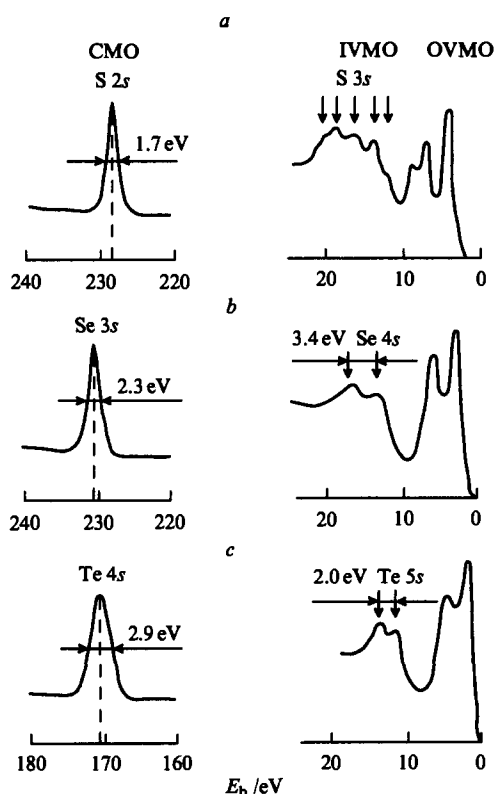

Figure 9. The X-ray photoelectron spectra of solid S (a), Se (b), and Te (c).⁵²

b. Heteronuclear compounds of group IVA – VIIA elements

In some cases, the very fact of the formation of IVMOs in heteronuclear compounds as well as in homonuclear ones can be established definitely on the basis of characteristics of the fine structure in their X-ray photoelectron spectra. It becomes feasible since IVMO formation does not lead to an appearance of separate peaks, but to a complex fine structure in the energy range of ~ 15 eV to ~ 50 eV of the X-ray photoelectron spectra of a heteronuclear compound. Separate peaks can often be classified as being associated with the electrons of IVMOs based on the cooperative analysis of characteristics of the fine structure in spectra of inner and outer electrons. The X-ray photoelectron spectra can then be interpreted qualitatively in terms of group theory. However, in certain cases, especially if electrons of AOs contributing to the IVMOs have significantly different photoionisation cross-sections, a rigorous assignment of the peaks attributed to these MOs can be performed with the aid of theoretical calculation. Thus, the O 2s peak in the X-ray photoelectron spectrum of SiO₂ has a shoulder on its high-energy slope and it is significantly broadened (Fig. 10). This structure of the spectrum of O 2s cannot be attributed to the participation of the oxygen atoms in different types of chemical bonding since the spectrum of O 1s electrons consist of one, relatively narrow peak. The electronic structure of the Si₂O₇⁴⁻ cluster calculated at the SCF X α -DV level¹⁷ points to a noticeable interaction between the electrons of the Si 3s and O 2s AOs resulting in IVMO formation (Fig. 10). This result agrees with published data.³³

A complex structure is observed in the F 2s region of the X-ray photoelectron spectra of compounds [CpMn(CO)₂NO]⁺PF₆⁻, [CpMn(CO)(NO)PPh₃]⁺PF₆⁻, and [CpMn(NO)(PPh₃)₂]⁺PF₆⁻, where Cp is cyclopentadienyl (Fig. 10).¹⁷ This structure cannot be attributed to the fluorine atoms with different effective charges since the F 1s electrons are represented with one symmetrical, relatively narrow peak. Thus, it was suggested¹⁷ that the structure of the F 2s peak of the PF₆⁻ cluster can be partially assigned to the interaction between the F 2s and P 3s AOs resulting in IVMO formation.

An analogous peak profile is observed in the F 2s region of the X-ray photoelectron spectrum of SF₆. Its three components are identified as the 1a_{1g}, 1t_{1u}, and 1e_g MOs (in descending order of the absolute energy values).¹ These orbitals comprise the F 2s and S 3s, F 2s and S 3p, and F 2s and F 2p AOs to an extent of 64 and 33, 77 and 20, and 98 and 2 percent respectively. Since the electron configurations of sulfur {3s²3p⁴} and phosphorus {3s²3p³} atoms are similar, the X-ray photoelectron spectrum of the PF₆⁻ cluster has been interpreted by analogy with the SF₆ spectrum.

Instead of an expected single peak, two peaks of electrons of the 1a₁ and 1t₂ IVMOs are observed in the X-ray photoelectron spectrum of gaseous CF₄. These MOs consist of the F 2s and C 2s AOs to an extent of 69 and 27, and 82 and 15 percent respectively. A fine structure associated with electrons of the filled AOs, which take part in the IVMO formation, also appear in the X-ray photoelectron spectra of NO, CO, CH₃OH, H₂O, and H₂S.¹ It has been noted^{74,89} that the structure of the O 2s region of the X-ray photoelectron spectra of the MO oxides, where M denotes Ca, Sr, and Ba, is associated with the IVMOs made up partially of the M *np* and O 2s AOs of neighbouring atoms. This is consistent with the results of an electronic structure calculation for the CaO₆¹⁰⁻ of O_h symmetry (the SCF X α -SW method was used).⁷⁴

The interpretation of fine structure in the low-energy region of the X-ray photoelectron spectra of La-, Y-, Bi-, and Tl-based high-temperature superconductors^{90–92} has revealed that IVMOs form in these due to interaction between the O 2s AOs and the closest-in-energy-shell of metal atoms in these compounds. Previously,^{93,94} the fine structure in the X-ray photoelectron spectra of these compounds led to the hypothesis that all the elements in high-temperature superconductors possess shells with energies close to that of the O 2s AO. Then, by correlation of the oxidation state of metal ions with their radii, the range of elements that can form HTSC has been defined.⁹³

c. Lanthanide compounds

With all other conditions satisfied IVMO formation also requires that the energies of the corresponding occupied AOs of neighbouring atoms are comparable.²¹ In this connection, lanthanide compounds are of great interest since the energies of Ln 5p (where Ln designates a lanthanide element) and O (F) 2s orbitals are close in magnitude. As the atomic number increases from 57 (La) to 71 (Lu), the binding energy of the Ln 5p_{3/2} electrons in lanthanide oxides ranges within the limits from 17.7 to 27.5 eV.¹⁹ The binding energies of the O 2s electrons (~ 21 eV) fall approximately in the middle of this interval. All lanthanide oxides from La to Lu (except for Pm) have been studied by XPS.^{19, 78–80}

The structures of the oxides vary in a series, and, in certain cases, the oxidation states of metal atoms vary too. Therefore, two sets of isostructural lanthanide compounds, viz. *o*-methoxybenzoates and diphenylacetates, have been studied (for all but promethium compounds) to solve the problem of IVMO formation (Fig. 11).¹⁹ These compounds are non-hygroscopic, stable in high vacuum, and insensitive to exciting X-ray radiation. Therefore one could expect that the compounds considered do not undergo structural changes and decomposition during the spectra collection.

Together with the expected separate peaks of Ln 5p_{3/2,1/2} and O 2s electrons, a fine structure is observed in the region of the binding energies of Ln 5p and O 2s electrons in the X-ray photoelectron spectra of all the compounds studied (Fig. 11). The most complex fine structures are observed in the mid-row lanthanide oxides since in this case the Ln 5p and O 2s AOs are closest in energy.^{4,5} Theoretical calculations for various Ln–O bond lengths have been performed for clusters LnO₇¹¹⁻ and LnO₆²⁻ of C_{3v} and D_{3d} symmetry types respectively at the SCF X α -DV level and for a cluster LnO₃³⁻ of D_{3h} symmetry type at the SCF X α -SW level of theory. The results obtained support the assumption that the fine structure in the spectra of lanthanide compounds is partly associated with interaction of the Ln 5p and O 2s shells resulting in

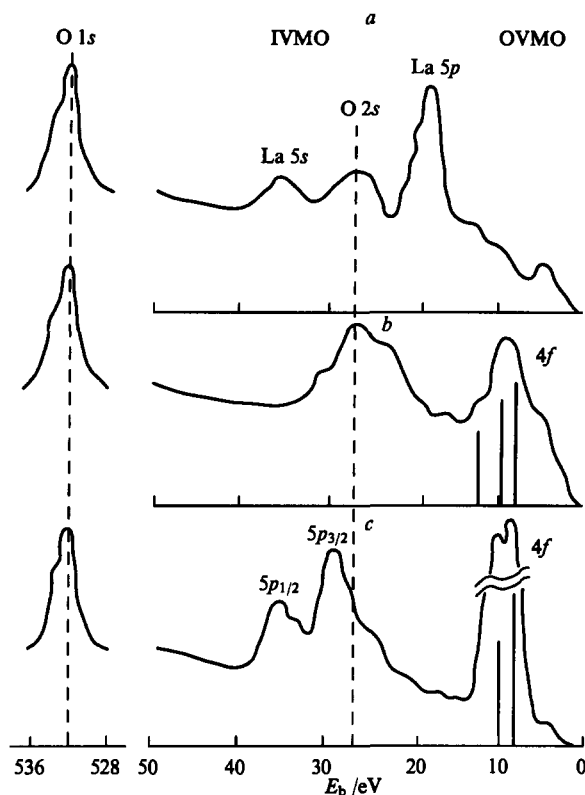

Figure 11. The X-ray photoelectron spectra of La (a), Eu (b), and Lu (c) (LnL_3 *o*-methylbenzoates). Vertical lines represent the theoretical metal 4f spectra.⁴

Figure 12. The IVMO diagram (a), dependence of the energies of the IVMOs, which consist of the Ln 5p and O 2s AOs, on the atomic number of the lanthanide element (b) for the cluster LnO_3^{3-} (symmetry group D_{3h}).⁴ (1) $1e'$, (2) $1a_2'$, (3) $1a_1'$, (4) $2e'$.

IVMO formation (Fig. 12). However, the calculations⁴ performed do not take into account the relativistic effects, and the cluster LnO_3^{3-} does not exactly represent the structure of the oxygen-containing compounds under consideration. Therefore, a direct, quantitative comparison of the theoretical and experimental results is not possible. However, the very fact of IVMO formation can be proved by the calculation results.

Spectra of lanthanide fluorides also exhibit fine structure in the region of F 2s electrons.^{19,82} These structures cannot be attributed to the presence of fluorine atoms in different oxidation states since only one relatively narrow peak corresponds to the F 1s electrons in the X-ray photoelectron spectrum. It was therefore assumed that the structure observed is concerned with the IVMO electrons.^{19,82} The results of the SCF X α -DV calculation⁹⁵ of the electronic structure for cluster LaF_{11}^{8-} of D_{3h} symmetry group agree qualitatively with these experimental data.

d. Actinide compounds

In XPS studies of actinide compounds, much attention has been paid to uranium compounds. It is on the basis of their X-ray photoelectron spectra that the most interesting conclusions on the role of the An 5f electrons (where An is an actinide element) in chemical bonding in actinide compounds⁹⁶ and on the contribution of the low-energy filled subshells to the bonding have been derived.^{2, 3, 6, 18, 78}

It is most convenient to consider the participation of the U 5f electrons in chemical bonding with stable uranium oxides as an example. Uranium dioxide UO_2 has a fluorite-type (CaF_2) structure, while the trioxide UO_3 is built up of planar networks of tetragons centered with nearly linear uranyl UO_2^{2+} fragments.¹⁸ This fragment serves as a basis for many oxygen-containing uranium compounds with various ligands in its equatorial plane. Special attention is drawn to the low-energy part of the X-ray photoelectron spectra of these compounds.

A high extent of localisation of the non-bonding U 5f electrons on the uranium atoms in UO_2 has been suggested from a neutron diffraction study.⁹⁷ The electronic configuration of the U atom in UO_2 is $\{\text{Rn}\} 5f^2$, where $\{\text{Rn}\}$ is that of the Rn atom in the ground state. This conclusion has been corroborated with XPS^{18,96} and theoretical studies.^{3,31,54}

A rather narrow peak corresponding to the U 5f electrons is found near the Fermi level in the X-ray photoelectron spectrum of UO_2 (Fig. 13 a). This peak is absent in the spectrum of $\gamma\text{-UO}_3$, but, instead of separate peaks of the U $6p_{3/2,1/2}$ and O 2s electrons, a fine structure is observed in the region of the U 6p and O 2s electrons. Binding energies of the electrons that account for different components of the spectrum change with variation in the U–O bond length in the UO_2^{2+} fragment of various compounds. In particular, the difference in energies between the components in the U $6p_{3/2}$ region of the spectra is the most convenient for measurements. This difference may serve as a measure of the bond length $R_{\text{U}-\text{O}}$ in the UO_2^{2+} fragment of various compounds.^{2, 3, 6, 14, 18, 76, 85}

The X-ray photoelectron spectra of UO_2 , UF_4 , and other non-uranyl compounds do not exhibit such a complex structure in the region of the U $6p_{3/2}$ electrons. Therefore, the fine structure observed in this spectral interval cannot be attributed to the dynamic effect.¹⁸ Also, the most intense peak of this structure cannot be explained by multielectron excitation. The latter give rise to so-called 'shake-up' satellites of relative intensity of $\sim 20\%$ with respect to that of the major peaks in the spectra of inner electrons. The structures of the low-energy part of X-ray photoelectron spectra of uranyl-containing compounds differ essentially in relative intensities of the constituent peaks, their energy distribution, and relative distances from the structure associated with multielectron excitation and observed in the inner electron spectra of these compounds.⁷⁸ The presence of two components in the U $6p_{1/2}$ and O 2s region of the spectrum of $\gamma\text{-UO}_3$ (see Fig. 13) is not consistent with the splitting of the U $6p_{3/2}$ component in the crystal field.¹⁴

Figure 13. The X-ray photoelectron spectra of uranium oxides UO_2 (a) and $\gamma\text{-UO}_3$ (b) and the corresponding energy levels calculated at the SCF $\text{X}\alpha\text{-SW}$ level of theory.³

Experimental data^{2, 3, 6, 78, 83} and the results of theoretical studies performed within the framework of the SCF $\text{X}\alpha\text{-SW}$ ^{3, 29} and SCF $\text{X}\alpha\text{-DV}$ ³⁰ approaches demonstrate that the complex structure in the U 6p and O 2s region of the spectra is concerned with the IVMOs that comprise U 6s, U 6p, and O 2s AOs.

The spin-orbit splitting energies of the U 6p and Th 6p levels differ for the corresponding fluorides, oxides and pure metals (Table 2).^{98–101} The variation in the splitting of the level under discussion for Th and its compounds is not attributed to a

multiplet splitting effect also does not account for this splitting as long as these compounds are diamagnetic. Extensive experimental data¹⁻⁸ show that spin-orbit splitting of inner levels of metal ions depends slightly on the properties of their ligand environment. With this in mind, it was suggested that electrons of the low-energy subshells of Th and U are affected by the chemical bonding in these compounds and take part in IVMO formation.

It is evident from general considerations that, for example, IVMO formation by the Th(U) 6p and O 2s AOs lowers the binding energy of the Th(U) 6p_{3/2} state, etc. It has been mentioned¹⁸ that other effects that shift the energy of low-energy AOs can affect MO formation. Such shifts can be most rigorously detected if the difference in binding energy between the inner valence electrons and deep-lying electrons of core atomic shells in Th and U and their compounds is considered (Table 2). These data accord with the participation of at least Th(U) 6p_{3/2} electrons in chemical bonding in the compounds under discussion.

The binding energy difference between the Th 5d_{5/2} and 4f_{7/2} inner atomic levels is the same for thorium and its compounds within the standard error of measurement. Thus, the essentially increased energy difference between the Th(U) 6p_{3/2} and Th(U) 4f_{7/2} electrons in Th compounds compared to that in Th metal is a fairly reliable criterion of the contribution of the Th(U) 6p_{3/2} and F(O) 2s electrons to the chemical bonding in thorium (uranium) oxides and fluorides.^{81, 101} It has been noted¹⁸ that this difference can be measured most accurately since the corresponding peaks are relatively narrow and hardly overlap with other peaks. Calculations have confirmed a significant participation of the fully occupied Th(U) 6p and O 2s AOs in the formation of IVMOs in uranium and thorium dioxides.^{31, 54}

To establish experimentally the formation of IVMOs by An 6p and O 2s AOs in compounds containing AnO_2^{2+} groups, a series of isostructural single crystals of U, Np, and Pu compounds ($\text{Cs}_2\text{UO}_2\text{Cl}_4$, $\text{Cs}_3\text{NpO}_2\text{Cl}_4$, $\text{Cs}_2\text{NpO}_2\text{Cl}_4$, $\text{Cs}_2\text{PuO}_2\text{Cl}_4$) and polycrystalline samples of Np compounds ($\text{Cs}_2\text{NpO}_2(\text{CH}_3\text{COO})_3$, $\text{RbNpO}_2(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$, $\text{NaNpO}_2(\text{CH}_3\text{COO})_3$)¹⁰²⁻¹⁰⁴ have been studied by XPS. From analysis of the spectra of the low-energy and inner electrons of these compounds in the X-ray photoelectron spectra of the corresponding oxides and cesium chloride as well as the photoionisation cross-section,¹⁰⁵ it has been concluded¹⁰²⁻¹⁰⁴ that IVMOs form in the compounds of Np and Pu considered as well as in uranyl compounds. The inner valence electrons account for the fine structure in the low-energy region of the X-ray photoelectron spectra of these species (Figs 15 and 16). These results are in satisfactory agreement with the results of electronic structure calculations for clusters AnO_2^{2+} (An = U, Np, Pu) of $D_{\infty h}$ symmetry within the framework of non-relativistic SCF $X\alpha$ -SW^{104, 106} and relativistic^{107, 108} approaches as well as clusters $\text{AnO}_2\text{Cl}_4^{2-}$ (An = U, Np, Pu) at the relativistic $X\alpha$ -DV level of theory.¹¹¹ The structure of the X-ray photoelectron spectra of the 'new product' from the Chernobyl nuclear plant¹⁰⁹ and americium nitrate¹¹⁰ are also consistent with these results.

It follows from the examples considered in this Section that IVMOs form effectively in compounds of any elements of the Periodic Table if certain conditions are satisfied.

2. Relationship between the structures of compounds and the structures of their X-ray photoelectron spectra

The interpretation of fine structure in an X-ray photoelectron spectrum concerned with IVMOs often utilises not only experimental data, but also results of rather tedious and complicated calculations of the electronic structure of the compound within the framework of the $X\alpha$ - and other methods that require powerful hardware.^{32, 106-108} However, the correct model cluster cannot be always chosen at once. In some cases, only approximate data on the structure of the compound are available (especially for amorphous ones). All these factors increase the CPU time required to execute the calculations of the electronic structure. Therefore, qualitative information on the structure of the com-

pound under study obtained from its spectrum is rather helpful, e.g. see Ref. 109.

Several reasons account for the importance of this information. First, reliable information defines a range of species where the formation of IVMOs is expected, thus more precise laborious calculations can be accomplished for them in order to examine the contribution of the IVMO electrons to the chemical bonding. Second, this is useful when relativistic effects are to be taken into account in the interpretation of the spectrum. Third, a possible qualitative interpretation of fine structure in X-ray photoelectron spectra extends the scope of X-ray photoelectron spectroscopy for applied studies of the physicochemical properties of matter.^{6, 78, 109}

From the standpoint of group theory, it is expected that fine structure in an X-ray photoelectron spectrum attributed to the IVMO electrons reflects the local environment of the specified atom. The structure of the X-ray photoelectron spectrum is determined by the symmetry point group of the cluster comprising the central atom and the ligands from the closest coordination shells. It is also obvious that the distance between the peaks corresponding to the electrons of different IVMOs must depend on the bond lengths in the cluster. If the IVMO-associated structure in the spectrum is pronounced, then the relative positions of the ligands with respect to the central atom can be easily determined.^{17, 20, 78} Estimation of the contribution of the electrons of the inner closed shells to chemical bonding can also be performed. With an experimental or theoretically predicted correlation of the binding energy of the IVMO electrons with the bond lengths in the specified cluster, e.g., UO_2^{2+} , available, the bond lengths in the UO_2^{2+} fragment in any compound or on a solid surface can be determined.¹⁸ It has been mentioned^{20, 85} that information of this kind for amorphous compounds cannot be obtained with the same ease since X-ray diffraction cannot be applied for bond length determination in them. Thus, if bond lengths in a cluster have not been determined, then the calculation should be carried out for a certain range of expected distances. We shall consider these points with examples.^{1, 17–20, 78}

As has been mentioned above (see Section IV.1), the simplest fine structure is observed in the spectra of diatomic molecules N_2 , O_2 , F_2 , and I_2 (Fig. 7). Two filled ns AOs form two IVMOs, one of them, in accordance with conventional quantum-chemical notation for the two-level system, is formally referred to as the bonding $\pi\sigma_g$ MO, and the other as the antibonding $\pi\sigma_u^*$ MO.²¹ A considerable energy difference between these two IVMOs (18.7 eV in N_2) points to a significant interaction of electrons of doubly-occupied levels. We should note that, up to the present, the maximum reported to date energy difference is that between $\pi\sigma_u^*$ and $\pi\sigma_g$ IVMOs observed in the X-ray photoelectron spectrum of N_2 .^{1, 51, 56} Despite configuration interaction complicating the fine structure in this region of the spectrum,^{86, 87} the peaks corresponding to the electrons of these orbitals are easily distinguished from others (Fig. 7).

The interaction between the electrons of subshells of carbon atoms in the planar layers of pyrographite is of more complex character, therefore, the spectrum of C 2s electrons does not exhibit a sharp fine structure associated with a system of IVMOs (Fig. 7a).²⁵ Nevertheless, the spectrum shows interaction between the C 2s electrons of neighbouring atoms. This interaction manifests itself in the appreciable broadening of the valence band⁸⁸ compared with that in the spectra of weakly-bound electrons in solid Si, Ge, and Sn possessing analogous structures.¹⁷

Fine structures are observed in the ns region of the spectra of solid P, As, Sb, and Bi (the electronic configuration of atoms is $\{\text{ns}^2\text{np}^3\}$)⁷² as well as in solid S, Se, and Te (the atomic electronic configuration is $\{\text{ns}^2\text{np}^4\}$) (Figs 8 and 9).⁵² It is known that, in solid sulfur, atoms are arranged in 8-membered twisted rings, and, in solid Se and Te, atoms form linear zigzag chains.^{52, 72} A diagram of the energies of IVMOs consisting of the occupied ns AOs versus the number of atoms in a planar closed ring or linear chain has been constructed (Fig. 17).⁵² These models are closely related to

Figure 17. Dependence of the IVMO diagram on the number of atoms in a molecular system (E_c denotes the energy of the ring system, E_l the energy of the linear system, V a relative (Hückel) energy unit).⁵²

the real picture. The number of fully-occupied IVMOs increases with the number of atoms k in the ring. The closest agreement between the theoretical and experimental spectra of S 3s electrons is reached at $k = 8$. The spectrum considered comprises five peaks in a 1:2:2:2:1 ratio which agrees satisfactorily with the experimental data (see Fig. 9). The linear-chain model does not explain the structure of the spectrum of S 3s electrons in solid sulfur. At the same time the predicted and experimental spectra of Se 4s and Te 5s electrons best fit a linear model with small even k (see Figs. 9 and 17).⁵² The Se 4s and Te 5s spectra of ion-bombarded surfaces of solid Se and Te reveal a single relatively narrow peak^{17, 52} with the concurrent disappearance of two peaks, which indicates atomisation of Se and Te on the samples' surface, i.e. the weakening of chemical bonding between neighbouring atoms. This phenomenon may be useful for practical study of radiation-induced damage and defects.

A dependence between the difference ΔE_b in binding energies of the IVMO electrons and the bond length R_{X-X} in solid Se, Te, As, Bi, etc. has been revealed (Fig. 18). A linear correlation of ΔE_b with R_{X-X} suggested previously¹¹ has a purely illustrative significance.

In transition 3d metal disulfides and diselenides, the sulfur and selenium atoms form clusters X_2^{2-} with a marked interaction between the X ns electrons of neighbouring atoms.¹⁶ Two peaks associated with electrons of IVMOs are therefore present in the S 3s and Se 4s X-ray photoelectron spectra.¹⁶ An analogous phenomenon is observed in the X-ray photoelectron spectrum of CuP_2 , where, instead of a single peak, two peaks separated by ~4.5 eV are present in the P 3s region of the spectrum. It has been noted¹⁶ that these two peaks are concerned with the interaction of P 3s orbitals. For the S_2^{2-} cluster, a qualitative agreement between the theoretical and experimental dependences between the binding energy difference ΔE_b of inner valence electrons and the bond length R_{S-S} has been found (Fig. 19). The theoretical dependence obtained within the framework of the CNDO/2 method¹⁷ differs by about 3 eV from the experimental one.

Cluster models can be used to illustrate the correlation of the energy and structure of IVMOs in lanthanide compounds with the structure of the local environment of the metal atom and the distances R_{Ln-X} to the nearest atoms. Within the non-relativistic approximation for the cluster LnO_3^{3-} of D_{3h} symmetry, the IVMO spectrum associated with the Ln 5p and O 2s AOs corresponds to four energy levels. The highest and lowest ones are the two-fold degenerate $1e'$ and $2e'$ IVMOs, and the two others are the quasi-atomic $1a_1'$ and $1a_2'$ IVMOs (Fig. 12a).⁴ The energies of the $1e'$ and $2e'$ MOs must depend on the bond length R_{Ln-O} to a greater extent than those of the $1a_1'$ and $1a_2'$ MOs. The dependence of the

Figure 18. Dependence of the energy gap ΔE_b between the IVMOs, which consist of the ns AOs, in solids on the bond lengths R . An equation $\Delta E_b = 8.0 - 2.2R$ is in qualitative agreement with results of studies described in Refs 52, 72 (1) and Ref. 11 (2).

Figure 19. Dependence of the binding energy difference between the $3\sigma_u^*$ and $3\sigma_g$ IVMOs associated with the $S\ 3s$ AOs on the bond length R_{S-S} in the S_2^{2-} cluster of the $3d$ transition metal disulfides: (1) experiment; (2) theoretical results.⁵²

energies of these MOs on the atomic number Z of the central $4f$ element has been calculated for various R_{Ln-O} values at the SCF $X\alpha$ -SW level of theory (Fig. 12 b).⁴ The energy was calibrated with respect to the energy of the quasiatomic $1a_1'$ IVMO associated mainly with the $O\ 2s$ AO.

The structure of IVMOs for cluster LnO_3^{3-} obtained in terms of group theory is in qualitative agreement with computational results.⁴ The IVMO structure for clusters LnO_7^{11-} (symmetry group C_{3v}) and LnO_6^{9-} (symmetry group D_{3d}) is different.⁷⁸⁻⁸⁰ Electronic structure calculations for lanthanide compounds within the relativistic approach would enable more precise quantitative comparison of theoretical and experimental data.

Oxygen-containing actinide series compounds are the species structural information on which, namely the structure of the local environment of the metal atom and its oxidation state, can be determined from the fine structure corresponding to electrons of IVMOs in their X-ray photoelectron spectra.^{3, 6, 17, 18, 85, 106, 107, 111} Most clearly this can be illustrated with the spectra of uranium compounds. The results of calculations demonstrate that taking into account the relativistic effects leads essentially to the strong splitting of the $U\ 6p_{1/2}$ component of the doublet and hardly affects the energy of the $U\ 6p_{3/2}$ electrons.³¹ Thus, the interpretation of the spectrum in the region of the $U\ 6p_{3/2}$ and $O\ 2s$ electrons can be carried out within the non-relativistic approach.³

Substantially different structures of uranium dioxide and trioxide give rise to a fundamental distinction in the spectra of weakly-bound electrons (Fig. 13). Since the $U-O$ bond in the UO_2^{2+} fragment of UO_3 is much shorter than the equatorial $U-O$ bonds, in the first approximation, the structure of the valence region of the spectra is determined by this fragment. It has been mentioned^{6, 85} that, within the non-relativistic approximation, the correlation diagram of IVMOs consisting of the $U\ 6s$, $U\ 6p$, and $O\ 2s$ AOs makes it possible not only to rationalise the structure of the spectra of the uranium oxides under discussion, it can also be helpful in the investigation of the structures of these compounds (Fig. 20).^{6, 85} According to this scheme, variations in the $U-O$ bond lengths in clusters UO_8^{12-} and UO_2^{2+} slightly influence the energies of the quasi-atomic t_{2g} , t_{2e} (in UO_8^{12-}), and π_u (in UO_2^{2+}) MOs, but can have a substantial effect on the t_{1u} , t_{1u}^* (in UO_8^{12-}), σ_u , σ_u^* , σ_g , and σ_g^* (in UO_2^{2+}) IVMOs. In practice, this phenomenon permits the determination of the structures of oxides and the bond lengths in them.

However, this diagram does not describe completely the structure observed in the spectrum of γ - UO_3 .^{2, 3, 6} It is concerned with the fact that it does not take into account the influence of the ligands in the equatorial plane of the UO_2^{2+} fragment on the spectra of the valence electrons of oxygen. Apparently, this

Figure 20. The diagram of IVMOs attributed to the interaction of the $U\ 6p$ and $O\ 2s$ AOs for clusters UO_8^{12-} (a) (O_h symmetry group) and UO_2^{2+} (b) (D_{oh} symmetry group).^{6, 85}

Figure 21. The principal scheme for MO formation in clusters UO_2^{2+} ($D_{\infty h}$ symmetry group) and $UO_2O_4^{6-}$ (D_{4h} symmetry group) (a) and the X-ray photoelectron spectrum of γ - UO_3 (b).¹⁰⁶

influence gives rise to additional IVMOs consisting of the U 6p and O 2s AOs. In the scheme, which accounts for the effect of the equatorial ligands on the structure of IVMOs of the UO_2^{2+} ion, these MOs correspond to the e_u and e_u^* orbitals (Fig. 21).¹⁰⁶ The latter scheme almost completely describes qualitatively the structure of the valence electron region of uranyl compounds. The results of theoretical calculations for clusters of uranyl compounds,^{3, 106} which take into account the effect of the equatorial ligands are consistent with the results obtained from this scheme.

Thus, the experimental correlation of the energy gap between the two components in the U 6p_{3/2} region of the spectrum (in Fig. 20, they are related to the a_{2u}^* and e_u^* IVMOs) with the U—O bond length in the UO_2^{2+} fragment in a series of uranyl compounds becomes comprehensible.^{17, 85} The results of semiempirical calculations¹⁰⁶ of structural characteristics of clusters $UO_2L_n^{m-}$ are consistent with this dependence. In certain cases, the phase content of natural uranium oxides and some bond lengths in them have been determined from these data.^{2, 6, 17, 85} The correlation of the structure of a compound with the fine structure in the X-ray photoelectron spectra of the valence region has also been studied in a series of Np, Pu (Figs 15 and 16),^{102–104} and Am¹¹⁰ compounds.

Since ThO_2 and UO_2 have similar structures,¹⁷ their spectra (Figs 13 and 14) have much in common (see Fig. 20). Thus, in the O 2s region, the structure associated with the t_{1u} IVMO is observed. In the Th 6p_{1/2} region of the X-ray photoelectron spectrum of $Th(NO_3)_4 \cdot 4H_2O$, peaks corresponding to the $1a'_1$ and $1e'_1$ IVMOs of the NO_3^- cluster are present.⁸¹

In many cases, the fact of the formation of IVMOs in various compounds can be authenticated by the presence of fine structure in the region of weakly-bound electrons in their X-ray photoelectron spectra. This structure can often be interpreted without recourse to rigorous theoretical calculations by a simple approach based on group theory.^{17, 20, 78} A correlation of the structure of a compound, i.e., bond lengths, with the structure of their spectra associated with the inner valence electrons has been established. It allows in some cases the retrieval of qualitative and quantitative information on the structure of compounds, which is exceptionally important for amorphous materials.

V. Contribution of inner valence molecular orbitals to chemical bonding

From the viewpoint of quantum-chemical theory, provided certain conditions are satisfied, MOs can be formed from arbitrary low-lying filled AOs.^{21, 22} The contribution of electrons to the chemical bonding is defined with a specific model describing the bond formation. The chemical bonding in homonuclear molecules is assumed to occur essentially due to the electrons of valence atomic shells,^{21, 22} and the electrons of inner closed shells contribute to the chemical bonding to a lesser extent and destabilise the bonds. Thus, in a molecule A_2 , two occupied 1s AOs can form a bonding $1\sigma_g$ and antibonding $1\sigma_u^*$ MOs. The bonding MO stabilises the bond to a lesser degree than the antibonding one destabilises it.²¹ Therefore, the total contribution of the CMO electrons to the covalent component of the bond energy is negative. In particular, this explains the instability of the helium molecule He_2 .²¹

However, as follows from experimental data on light-element compounds, both filled and valence shells with the same principal quantum number contribute to the chemical bonding.¹ Calculations of the electronic structure of light-element diatomic molecules within the MO LCAO approach have indicated that the occupied low-energy AOs do not form 'pure' CMOs but mix with valence AOs.^{1, 51, 52, 56, 73, 88} These CMOs lose their 'inner' character and have to be considered collectively with the OVMOs. They are referred to as IVMOs since they have not fully become the valence ones.^{51, 56}

The question of the participation of the electrons of filled low-energy shells in chemical bonding for light-element compounds has been considered to some extent. However, it had barely been raised for heavy-element compounds until recently.^{17, 85} Consider, for example, an established fact of the formation of IVMOs in uranyl compounds by the U 6p and O 2s AOs.^{2, 3, 6} If these MOs consisted solely of the U 6p and O 2s AOs, they would not be referred to as valence MOs. However, they were given the name 'IVMO' since they also consist of the valence U 7s, 6d, 4f, and O 2p AOs.

The question of the role of the low-energy closed shells of heavy elements (lanthanide compounds, actinide compounds, etc.) in chemical bonding raised on the basis of XPS studies^{2–6, 26, 27, 78} is very important. Its examination will help in understanding the nature of chemical bonding in these compounds, furnish an explanation of the existence of unique nearly linear stable fragments, AnO_2^{2+} , in certain actinide compounds, etc. However, difficulty in rigorous theoretical calculations for actinide series compounds is now evident. Therefore, as has been mentioned,^{17, 20} the first step is to consider the participation of inner electrons in chemical bonding for the most simple molecules,^{51–53, 56, 71, 73–75, 88} and then to proceed to heavy-element compounds.

1. Simple models

Examination of correlations of MO energies with interatomic distances can help understanding of the formation of these MOs.^{3, 4, 51–53, 56, 72, 73, 85, 112} The N_2 molecule is the most convenient subject for examination of this kind. Calculations of the MO energies for N_2 at different interatomic distances were carried out at the SCF CNDO/2 and SCF X α -DV levels (Fig. 22).^{51, 56} The results obtained by these two approaches are in good conformity with each other. They display the same trend of changes in the orbital energies with decrease in the bond length and the same order of MO energies at the equilibrium interatomic distance $R_e = 0.109$ nm. They also give comparable values of the binding energy gap between electrons of the bonding $2\sigma_g$ and antibonding $2\sigma_u^*$ IVMOs.

Figure 22. The SCF X α -DV orbital energies of N₂ as functions of the bond length R_{N-N} (R_e is the equilibrium distance).^{51, 56}

As nitrogen atoms are brought together to the equilibrium distance, not only the orbital energies, but also the order of MO as regards their energies change. This results in the formation of the $1\sigma_g$ and $1\sigma_u^*$ CMOs and $2\sigma_g$ and $2\sigma_u^*$ IVMOs, which, to a substantial degree, are contributed by the N 1s and N 2s AOs respectively. An increase in the energy of the doubly-degenerate $1\pi_u$ VMO made up of the $2p_x$ and $2p_y$ AOs is greater in magnitude than that of the $3\pi_g$ VMO that is primarily composed of the $2p_z$ AO. It points to a greater contribution of the $1\pi_u$ VMO to the covalent component of the N–N bond compared with that of the $3\sigma_g$ VMO. Weak dependence of the energies of the $2\sigma_u^*$ and $3\sigma_g$ MOs on the interatomic distance ranging from R_e to $R = 0.35$ nm indicates insignificant values of the corresponding orbital force f_i and thus essentially non-bonding character of the N 1s AOs.

In a certain approximation, the contribution of the N 1s electrons to the chemical bonding in N₂ can be neglected since the energies of the $1\sigma_g$ and $1\sigma_u^*$ CMOs hardly depend on the interatomic distance within the same interval. As the atoms continue to close with each other, the energy of the $1\pi_u$ VMO increases and that of the $3\sigma_g$ VMO decreases. Such behaviour could be attributed to an increase in the overlap integral of $2p_x$ and $2p_y$ AOs and a decrease in that of $2p_z$ AOs of neighbouring atoms at small R . At $R \leq R_e$, the energies of the $1\sigma_g$ and $1\sigma_u^*$ CMOs behave like those of the $2\sigma_g$ and $2\sigma_u^*$ IVMOs at $R > R_e$. The energies of the antibonding $1\sigma_u^*$ and $2\sigma_u^*$ MOs depend on the interatomic distance to a lesser extent than the energies of the corresponding bonding $1\sigma_g$ and $2\sigma_g$ MOs.

Changes in orbital energies of N₂ with decreasing bond length can be easily followed in a simple scheme (Fig. 23).^{51, 56} This scheme may be used for consideration of any homonuclear diatomic molecule formed from p -block elements $\{ns^2np^m\}$. An example of a molecule where MOs are formed by individual AOs (the $1\sigma_g$ and $1\sigma_u^*$ CMOs, $2\sigma_g$ and $2\sigma_u^*$ IVMOs, and $3\sigma_g$, $1\pi_u$, $1\pi_g^*$ and $3\sigma_u^*$ VMOs are represented) is shown in Fig. 23 a. The value of the splitting $\Delta'_i > \Delta_i$ ($i = 1, 2, 3$), and $\Delta_+ = \Delta_i + \Delta'_i$ depends on the bond length. Totally occupied CMOs destabilize the bond. Since the difference $\Delta_- = |\Delta'_i - \Delta_i|$ is not too great, decrease of the bond

Figure 23. Scheme of formation of OVMOs, IVMOs, and CMOs in a nitrogen molecule: (a) — overlap of 2s and $2p_z$ AOs is neglected; (b) — the 's-p' interaction; (c) — with 2s-2p overlap taken into account.^{51, 56}

length causes comparable changes in energies of the bonding and antibonding MOs. It is observed for $1\pi_u$ and $1\pi_g^*$ VMOs (Fig. 22). Unlike the π -type MOs, the σ -type MOs are formed by the 2s AOs as well as the $2p_z$ AOs. At $R_e = 0.109$ nm, the 2σ and $2\sigma_u^*$ IVMOs and $3\sigma_g$ VMO consist of the 2s and $2p_z$ AOs in 84 : 16, 69 : 31, and 84 : 16 ratios respectively. In Fig. 23 b, the formation of the σ -type MO by the $2p_z$ and 2s AOs is schematically shown. The magnitude of this 's-p' interaction also depends on the bond length. Bonding and antibonding MOs shift in opposite directions to the same extent if the 's-p' interaction affects them equally (Fig. 23 b). In reality, this interaction does not affect each type of MO equally, thus it gives rise to an even more asymmetrical shift of the MO energies from their initial values. With regard to this, with decrease in the bond length in the N₂ molecule, the 'centre of mass' of the σ -type VMOs shifts to a greater extent than that of the IVMOs, i.e., formally, $\delta_3 > \delta_2$ (see Figs 22 and 23). Thus the order of MOs may change, as is observed in the $1\pi_u$ – $3\sigma_g$ pair of VMOs. Also, the overlap between the $2p_z$ AOs decreases at shorter R compared with that of the $2p_x$ and $2p_y$ AOs, and it affects the energies of the $1\pi_u$ and $3\sigma_g$ VMOs.

Despite the formalism of the separation of the total interaction between the electrons of neighbouring atoms, this simple approach, not taking into account atomic s-p hybridisation, furnishes an explanation of the observed changes in the orbital energies with decrease of the N–N bond length and inversion of the $3\sigma_g$ and $1\pi_u$ MOs. Also, it explains the non-bonding character of the $2\sigma_u^*$ and $3\sigma_g$ MOs and the positive contribution of the $2\sigma_g$ and $2\sigma_u^*$ IVMOs to the bond energy in N₂. Estimation of contributions of individual MOs to the chemical bonding in N₂ within the CNDO/2 approach has been based on analysis of the resonance energy E_{AB}^R (see Eqn 10) that represents the degree of covalence of the bond A–B (Fig. 24).^{51, 52, 56} The contributions of electrons of the $1\sigma_g$ and $1\sigma_u^*$ CMOs to the bond energy were not estimated.

We should mention that the results obtained do not conform to the conventional viewpoint on the character of the chemical bond in N₂.^{21, 22} To a certain approximation, as before, this bond may be treated as a triple bond, which is not attributed to electrons of the $3\sigma_g$ and $1\pi_u$ OVMOs,^{21, 22} but to electrons of the $1\pi_u$ OVMO and $2\pi_g$ IVMO. The contribution to the N≡N bonding of electrons of the $2\sigma_g$ IVMO, which primarily consists of N 2s AOs, is comparable with that of electrons of the twofold-degenerate $1\pi_u$ OVMO.^{51, 56}

The F₂ molecule, in which both the antibonding $1\pi_g^*$ and bonding $1\pi_u$ OVMOs are totally-occupied is yet another example of the contribution of the inner valence electrons to the chemical bonding. According to the traditional model of the formation of a

chemical bond,^{21,22} the contributions of electrons of these OVMOs and of electrons of the bonding $2\pi_g$ and antibonding $2\pi_u^*$ IVMOs are assumed to mutually neutralise. However, this assumption is not valid since the dependence of the MO energies in F_2 on the bond length R_{F-F} (see Ref. 73) points to different orbital forces f_i for the $2\sigma_g$ and $2\sigma_u^*$ IVMOs.

The estimation of the contributions of the electrons of various MOs to the chemical bonding in F_2 within the approach of separation of total energy demonstrates that, at an equilibrium distance R_e , the influence of electrons of the $1\pi_u$ and $1\pi_g^*$ OVMOs compensate each other, and the contribution of electrons of the $2\sigma_g$ IVMO is somewhat greater than that of electrons of the $2\sigma_u^*$ IVMO.⁷³ As a result, the covalent component of the $F-F$ bond is mainly associated with the electrons of the $3\sigma_g$ OVMO and, partly, $2\sigma_g$ IVMO. The latter accounts for 44% of the total covalent component of the bond energy. Thus, the substantial contribution of the IVMOs to the chemical bonding in F_2 is attributed to mixing of fully-occupied and valence AOs (Table 3).

The quantum-chemical estimation of bonding (antibonding) character of MOs for F_2 was also accomplished with the aid of the orbital force f_α approach. The calculation utilised the SCF X α -SW method with respect to the orbital relaxation within the framework of the transition state principle.⁷³ The X-ray photoelectron spectrum of the weakly-bound electrons of F_2 has been used for the data interpretation (see Fig. 7).²³ Unlike the X α -calculation, *ab initio*¹¹³ and semiempirical CNDO/2⁷³ calculations give the wrong order of the MO energies within the Koopmans's approximation (Table 4): the $3\sigma_g$ OVMO is between two π -type MOs, which does not agree with the order determined experimentally (see Fig. 7). The results obtained at these levels of theory are less precise than those obtained by X α -methods of calculation. The

X α -SW modification is preferable for the interpretation of the binding energies of electrons of IVMOs.

The values of the derivatives E'_b (of the orbital forces f_i) at the equilibrium interatomic distance $R_e = 0.1417$ nm in the F_2 molecule show that the electrons of the $2\sigma_g$ IVMO make the largest contribution to the bonding in the system. The $2\sigma_u^*$ IVMO destabilises the $F-F$ bond, but does not entirely compensate the stabilisation from the $2\sigma_g$ IVMO (Table 5).

Table 5. Orbital forces E'_b for valence orbitals of F_2 at the equilibrium distance $R_e = 0.1417$ nm.¹⁷

^a Calculated from cited in Ref. 113 MO energies at two distances R_{F-F} equal to 0.1336 and 0.1417 nm.

In the X-ray photoelectron spectrum of F_2 , the peak corresponding to the $2\sigma_g$ electrons is broader than that corresponding to the $2\sigma_u^*$ electrons (their half-widths are 2.7 and 1.6 eV respectively).²³ Several final states of the system after photoemission could account for this distinction. Theoretical calculation in terms of the configuration interaction can corroborate this assumption. A dependence of the gradient of the ionisation potential of these orbitals on the bond length R_{F-F} could be another reason; this is in full agreement with results of the X α -SW calculation. Actually, the ratio of $2\sigma_u^*$ and $2\sigma_g$ peaks' half-widths is 0.59, while the ratio of the absolute values of the orbital forces f_α is 0.62 (Table 5).

Despite the different profiles assigned to the different contributions of electrons of the $2\sigma_u^*$ and $2\sigma_g$ IVMOs to the chemical bonding in F_2 , the integral intensities of these peaks are almost equal,²³ which points to their essentially identical photoionisation cross-sections, and thus to equal 2s character of these IVMOs. The results of the X α -SW calculation⁷³ are also consistent with this

Table 6. Energies E_b and distribution of electronic charge Q (%) for valence orbitals of F_2 at the equilibrium distance $R_e = 0.1417$ nm for ground and transition states.⁷³

premise (Table 6). Different contributions of the $2\sigma_u^*$ and $2\sigma_g$ IVMOs would imply a significant dependence of the photoionisation cross-sections on the energy of the levels in question, a dependence that is unlikely due to the close binding energies of electrons of the $2\sigma_u^*$ and $2\sigma_g$ IVMOs (see Table 5). It follows from Table 6 that the IVMOs are built up mainly of the F 2s AOs, the contributions of which are nearly the same and change little during the relaxation of the ionised system. An essential contribution of the F 2s AO to the $2\sigma_u^*$ IVMO accounts for the significant stabilisation of this MO, unlike that in N_2 molecule, which is characterised by a greater percentage of the N_2 2p AO.^{51,56} The energy gap between the IVMOs in F_2 (4.3 eV, Table 4) is much smaller than the corresponding value (18.7 eV) in N_2 .^{51,56} Specific characteristics of the IVMO in F_2 also account for a clearly bonding character of the $3\sigma_g$ OVMO (Table 5), as soon as this OVMO consists mainly of the F 2p_σ AOs (see Table 6).

Analogous results have also been obtained for other diatomic Group IV–VIIA second and third Period molecules and clusters.^{17, 52, 71, 72, 88}

The same reasoning can be applied to the dependence of the orbital energies of the uranyl fragment UO_2^{2+} on the bond length R_{U-O} obtained within the framework of the SCF X α -SW approach (Fig. 25).^{3, 106} The dependence obtained is in a good qualitative agreement with the corresponding data for N_2 . As atoms are brought together, the energies of the antibonding $8\sigma_u^*$ (UO_2^{2+}) and $2\sigma_u^*$ (N_2) IVMOs change to a lesser extent than the energies of the corresponding bonding $7\sigma_u$ and $2\sigma_g$ IVMOs, thus a considerable contribution of the $8\sigma_u^*$ and $7\sigma_g$ electrons to the bonding in UO_2^{2+} is suggested. As has already been mentioned for N_2 , this effect arises due to the mixing of the valence and doubly-occupied low-energy AOs of adjacent atoms leading to the formation of IVMOs. Apparently, this mixing also accounts for the inversion of the $7\pi_u$, $9\sigma_u$, $4\sigma_g$, and $12\sigma_g$ OVMOs of the uranyl fragment caused by a change in the U–O bond length (Fig. 25). The MO contributions to the chemical bonding were estimated from the values of orbital forces f_i calculated from the E_i vs. R_{U-O} dependences.¹¹³ It has been found that, at $R_{U-O} = 0.173$ nm, electrons on IVMOs account for 29% of the total electron contribution in the uranyl cluster.

The calculation of the electronic structure of the uranyl cluster by the SCF X α -DV method yields similar results (Figs 26 and 27).⁷⁷ In Fig. 27, vacant MOs are shown as dashed lines, and occupied MOs as solid lines. Presented in the Figure are the atom content, energies (to the left), and the E_α^R values (to the right), which characterise the contribution of IVMOs to the

Figure 25. Dependence of the MO energies for the cluster UO_2^{2+} (symmetry group $D_{\infty h}$) on the bond length R_{U-O} calculated in the SCF X α -SW approach.¹⁰⁶

Figure 26. Dependence of the energy contribution of electrons of the IVMOs (1), OVMOs (2), and of the total electron contribution (3) to the covalent bonding E_α^R on the bond length R_{U-O} for UO_2^{2+} .⁷⁷

covalent bonding of the cluster UO_2^{2+} . At $R_{U-O} = 0.173$ nm, the electrons of IVMOs account for 37% of the total electronic contribution in UO_2^{2+} . Similar calculations have also been performed for the cluster $UO_2Cl_2^{2-}$ of D_{4h} symmetry.¹⁷ The contributions of the electrons of OVMOs and IVMOs to the chemical bonding in UO_2^{2+} somewhat depend on the bond lengths R_{U-O} (Fig. 26).

Figure 27. The MO diagram for UO_2^{2+} (symmetry group $D_{\infty h}$) at $R_{\text{U-O}} = 0.173$ nm (the SCF X α -DV method). Energies of MOs (in eV), their content (%), and the values of E_{α}^R (in eV) characterising the MO contribution to the covalent bonding are displayed in parentheses.⁷⁷

2. Crystal framework

From the data presented above we may assume that the inner valence electrons contribute to the chemical bonding not only in molecules, but also in crystals. In essence, this applies to covalent crystals. To this end, quantum-chemical calculations of the band structure of black phosphorus have been made.⁷⁵ The choice of the subject of study is concerned with the monoatomic character of the crystal lattice, which excludes the ionic component of the bonding, the availability of reliable crystallographic data¹¹⁴ and of X-ray photoelectron spectra obtained with a synchrotron radiation source.¹¹⁵ The calculations of the band structure of black phosphorus have been carried out by the crystal orbital

method within the framework of the extended Hückel method (EHM) by a program described in a previous study.¹¹⁶

The crystal lattice of black phosphorus is built up of crimped layers.¹¹⁴ The unit-cell dimensions a , b , and c are 0.33136, 1.0478, and 0.43763 nm respectively. Each phosphorus atom has three closest neighbours within the layer at a distance of 0.2244, 0.2224, and 0.2224 nm. The layers are separated from each other so that the minimum distance between two phosphorus atoms belonging to adjacent layers is 0.3592 nm. At this distance, the overlap integral between the two atomic Slater 3s and 3p orbitals, the exponential factors of which have been defined according to Clementi¹¹⁷ is close to zero. Therefore, the basic aspects of the band structure of black phosphorus can be described satisfactorily within a two-dimensional representation with four atoms per unit cell.

The unit cell of the layer consists of two pairs of phosphorus atoms. The bond axes make an angle of 44.17° with the crystallographic a axis.¹¹⁴ The distance $R_{\text{P-P}}$ within pairs is 0.2224 nm, the distance between the axes of pairs along the c axis is 0.2130 nm. Translational constants along two perpendicular directions are equal to the values of constants a and c , respectively.

The two-dimensional Brillouin zone for the layer under consideration is rectangular, its centre is designated as Γ ; points J and K refer to the middle of the longest side and the vertex of the Brillouin zone, respectively. Direction $\Gamma \rightarrow J$ is denoted as Σ_1 , $J \rightarrow K$ as Σ_2 , and $K \rightarrow \Gamma$ as Σ_3 .

The energies of the crystal valence orbitals $E_i(k)$ are determined along these directions and in points Γ , J , and K from the secular equation:

$$\sum_{\nu} [F_{\mu\nu}(k) - S_{\mu\nu}(k)E_i(k)]c_{i\nu}(k) = 0, \quad (35)$$

where $F_{\mu\nu}(k)$ and $S_{\mu\nu}(k)$ are matrix elements of the one-electron operator and the overlap integral between the Bloch basis functions, respectively.

For the P 3s and 3p AOs, the orbital ionisation potentials have been taken as recommended by Charkin.¹¹⁸ Eqn (35) as applied to the band structure calculations was examined first by Messmer¹¹⁹ and then was successfully employed by Nishida¹²⁰ and Hoffmann et al.¹²¹ The crucial point of this approach is a proper choice of parameters.¹²² As shown below, data on the orbital exponent factors¹¹⁷ and ionisation potentials¹¹⁸ lead to a satisfactory description of the valence band structure of black phosphorus.

With a basis set incorporating the P s and p orbitals for four atoms in a unit cell (each atom has five valence electrons), the LCAO equation (35) yields 16 crystal orbitals; the lowest 10 of them are doubly occupied. Dispersion curves calculated for 10 occupied and two vacant crystal orbitals are shown in Fig. 28. The energy zero corresponds to the top of the valence band reached

Figure 28. The dispersion curves of the energy bands in black phosphorus calculated by the extended Hückel method,⁷⁵ and from its photoelectron spectrum.¹¹⁵ Horizontal lines represent levels of a cluster P_2 .

near the point J along the direction Σ_1 . According to the calculation, black phosphorus possesses the semiconducting properties.

The two lowest valence crystal orbitals are genetically linked with the $2\sigma_g$ IVMO of the diatomic cluster P_2 , the next two, with the $2\sigma_u$ IVMO. Three pairs of the upper filled crystal orbitals originate from the $1\pi_u$ and $3\sigma_g$ OVMOs. The corresponding crystal orbitals are degenerate along the direction Σ_2 . The photoelectron spectrum of a single crystal of black phosphorus obtained at a photon energy of 110 eV¹¹⁵ is shown on the right side of Fig. 28.¹¹⁵ Five distinct peaks sequentially spaced by 2.0, 1.9, 4.2, and 4.6 eV appear in the spectrum. All features of the photoelectron spectrum including the energies and relative heights of the peaks are represented satisfactorily by the calculated dispersion curves. The positions of MOs of the P_2 cluster at $R_{P-P} = 0.2224$ nm are displayed also in Fig. 28. As is seen, the splitting of the $2\sigma_g$ and $2\sigma_u$ IVMOs composed of the P $3s$ AOs with addition of P $3p_z$ AOs describes well the relative positions of peaks 2 and 1, while the $1\pi_u$ and $3\sigma_g$ MOs fall near the centroid of peaks 3–5. Thus, the qualitative features of the chemical bonding in black phosphorus crystals can be understood even in terms of diatomic interactions, i.e. in a close-order approximation, while the details of the electronic structure are determined by the band character of the wave functions.

In diatomic molecules, the orbital vibronic constants determined from spectral data can serve as a quantitative measure of the contributions of electrons to the chemical bonding. It has been shown that orbital vibronic constants correlate intimately with the orbital forces f_i [see Eqn (24)] defined as derivatives of the orbital energies $E_i(R)$ versus the interatomic distance R at the equilibrium point R_e , where i is an orbital index. Provided the orbital energies are obtained from *ab initio* calculations, the plot of orbital vibronic constant versus f_i yields a line through the coordinate origin.⁵³ To verify the legitimacy of this approach within the adopted semi-empirical Hoffmann method, the dependences $E_i(R)$ have been calculated⁷⁵ and the orbital forces f_i determined for N_2 (an analogue of P_2),⁷⁵ so far as the orbital vibronic constants for N_2 are available.^{53, 65}

The correlation plot of the orbital vibronic constants of N_2 versus the orbital forces f_i calculated according to Eqn (24) at the experimental equilibrium distance R_e (see Refs 17, 75) is presented in Fig. 29. It may be concluded that the extended Hückel method is quite suitable for estimating the orbital vibronic constants. It has also been found that orbital vibronic constants correlate with the contributions $n(j, NN)$ of individual MOs to the total bond order.⁵³ Therefore, Mulliken orbital bond populations are also applicable to the calculation of the orbital vibronic constants. The

Figure 29. Dependence of the orbital vibronic constants a_α on the orbital forces f_i for N_2 (the extended Hückel calculation): (1) $2\sigma_g$; (2) $2\sigma_u$; (3) $2\sigma_g$; (4) $1\pi_u$; (5) $1\pi_g$.⁷⁵

$n(j, NN) - f_i$ correlation for N_2 , a correlation which is also confirmed by calculation for P_2 ,⁷⁵ is evident from comparison of Fig. 29 and data from Ref. 53.

We should mention that the $2\sigma_g$ IVMO plays a particular role in the chemical bonding in P_2 as well as in N_2 . Thus, orbital forces according to the EHM can be regarded as quantum-chemical indexes in the qualitative analysis of electronic contributions to chemical bonding.

As has been mentioned,^{17, 75} it seems natural to extend this approach to band structure calculations for solids. To this end, a solution of the secular equation (35) is differentiated with respect to R . For the sake of convenience, two additional calculations should be carried out at $R = R_e - \Delta R$ and $R = R_e + \Delta R$, where ΔR is a small variation of the interatomic distance. The value of 0.001 nm for variations of all distances in a unit cell has been adopted in calculations of the band structure of black phosphorus. The dispersion curves obtained have been numerically differentiated with respect to R , and the orbital forces have been determined at various points of the two-dimensional Brillouin zone for the dispersion curves presented in Fig. 28. The results obtained are listed in Table 7; the average directions of Σ_1 , Σ_2 , and Σ_3 in the Brillouin zone are referred to these points. As follows from Table 7, the inner valence crystal orbitals 1 and 2 display slightly bonding character (the positive sign of the corresponding orbital forces). The higher crystal orbitals exhibit either a weakly-bonding (non-bonding) or antibonding (the negative sign of the orbital forces) character. The lower vacant crystal orbitals 11 and 12 possess highly antibonding character, as expected. However, the values of the orbital forces f_i depend on the coordinates of the point in the Brillouin zone. For example, at the point K , all crystal orbitals are less bonding, the inner valence crystal orbitals included. The angular dependence of the indexes of interatomic bonding f_i of crystal orbitals, e.g. 1 and 2, can be used in studies of the anisotropy of properties of black phosphorus and other compounds.

Table 7. Orbital forces ($f_i / 10^{-8}$ N) for the energy bands of the black phosphorus.⁷⁵

Dispersion curve number	Points of the two-dimensional Brillouin zone					
	Γ	Σ_1	J	Σ_2	K	Σ_3
12	-2.9	-3.9	-8.4	-8.3	-8.0	-7.2
11	-4.5	-6.0	-6.4	-7.3	-6.4	-4.5

2	2.2	1.8	1.8	1.1	-0.3	1.1
1	2.5	2.3	1.8	1.1	-0.2	1.7

The results of the study imply a prevailing contribution of the electrons of inner valence bands of atomic crystal to the covalent bonding. When considering the electronic structure of solids within the framework of the band theory, the IVMOs of the diatomic cluster, which is a building block of the crystal lattice, possess a bonding character as well.

Thus the contribution of the electrons of the inner valence MOs to the chemical bonding cannot be neglected. In certain cases, it is comparable with that of the electrons of the valence MOs.

VI. Conclusion

Widespread use of XPS in the studies of the electronic structure of molecules and solids consisting of diverse elements of the Periodic Table have provided unique results on the interaction between the electrons of the closed low-energy subshells of neighbouring atoms. In many cases, this interaction is strong enough so that one cannot neglect it in the analysis of the electronic structure of compounds. The X-ray photoelectron spectra of such compounds usually reveal a fine structure in the region of weakly-bound electrons (~ 15 – 50 eV). The parameters of this fine structure, attributed to the inner valence electrons, reflect structural characteristics of the compounds. Experimental XPS data on the formation of IVMOs, the interrelation of the fine structure of X-ray photoelectron spectra with the structure of compounds, and the data on the participation of the inner valence electrons in chemical bonding are in good agreement with results of theoretical calculations. Qualitative interpretation of the structure of X-ray photoelectron spectra in the region of the inner valence electrons by means of group theory allows a wide range of researchers to apply XPS in various structural studies, for instance on radiation-induced damage and defects in solids.

We should note that the role of IVMOs in the formation of compounds and in the determination of their physico-chemical and structural features, has not been firmly established yet. In particular, this topic has been little covered for lanthanide and actinide series compounds. However, currently, there are several examples of the practical application of the concept of effective (experimentally observed) formation of IVMO in the explanation of experimental data. These are an inversion of the $3\sigma_g$ and $1\pi_u$ IVMOs and the exceptionally high bond strength of N_2 ;^{51, 56} the relatively broad valence band (25.2 eV) in graphite and diamond, and energies of the C—C bonds within graphite layers;^{25, 88} the appearance of a fine structure in the ~ 15 – 50 eV range of the X-ray photoelectron spectra of lanthanide^{4, 5} and actinide series^{2, 3, 102, 103} compounds; the relation of the characteristics of fine structure in X-ray photoelectron spectra of compounds containing actinide series^{18, 109, 123} and other¹⁷ elements with the structure of the local environment and the bond lengths to the closest ligand atoms; the appearance of a fine structure in the emission spectra of lanthanide¹⁹ and uranium¹²⁴ compounds and in the electron conversion spectra of uranium compounds^{125, 126} if electrons with bonding energy within the ~ 15 – 50 eV range contribute to these spectra.

One cannot rule out [the possibility] that the formation of IVMOs in actinide series compounds explains the formation of stable groups AnO_2^{2+} . We should also note that a new method has been proposed to determine U—O distances, which can help in the identification of the products of reactions of uranium compounds with solid surfaces.^{109, 123, 127, 128}

Thus, taking into account the results considered hitherto, the following conclusions, which answer the questions listed in the 'Introduction', can be derived:

1. Under certain necessary conditions, IVMOs can form in compounds containing virtually any element of the Periodic Table.
2. The fine structure in X-ray photoelectron spectra associated with the inner valence electrons allows one to assess the contribution of electrons of the occupied AOs to the chemical bonding, the local environment of atoms under consideration, and the bond lengths in compounds.
3. In certain instances, the overall contribution of the inner valence electrons to the bond energy is comparable to that of the valence electrons. This phenomenon is novel and important for chemistry.

Abstract. The results of studies on direct functionalisation of activated alkanes and cycloalkanes under the action of 'classical' Friedel–Crafts complexes (*viz.* equimolar complexes of acyl halides with aluminium halides) and related systems containing smaller or somewhat larger amounts of aluminium halide are surveyed. The studies carried out during the last decade on functionalisation of saturated hydrocarbons devoid of tertiary carbon atoms, by aprotic organic superacids $\text{RCOX} \cdot 2\text{AlCl}_3$ are summarised. Reactions of alkanes with acylium cations in superacidic media are considered. The published data on the structure of complexes $\text{RCOX} \cdot \text{AlCl}_3$ and $\text{RCOX} \cdot 2\text{AlCl}_3$ and on the nature of the active complexes in the reactions of arenes with acylium cations and with complexes $\text{RCOX} \cdot \text{AlCl}_3$ in both acidic and organic media as well as in the reactions of alkanes with acylium salts in protic superacids and with superacidic complexes $\text{RCOX} \cdot 2\text{AlCl}_3$ in aprotic solvents are analysed. The prospects for the synthesis of organic compounds from alkanes and cycloalkanes under the action of complexes of acyl halides with aluminium halides are outlined. The bibliography includes 128 references.

I. Introduction

Alkanes and cycloalkanes, which are the major components of oil and natural gas, still remain the most promising raw material for the synthesis of organic compounds. Although there is a possibility, in principle, to carry out direct functionalisation of alkanes and cycloalkanes and although some selective reactions of this type have been reported, only few saturated hydrocarbons are used currently in organic synthesis. Therefore, Mendeleev's words that to use petroleum as a fuel is like firing a furnace with banknotes are still timely.

The main difficulties that hamper selective one-stage functionalisation of alkanes (or cycloalkanes) arise because compounds

of this class are inert and, hence, the products of their transformations are more reactive than the initial hydrocarbons.

In the early 1970s, a new stage in the chemistry of alkanes began. Since then, two non-traditional approaches are being developed successfully, which have given an impetus to the new 'low-temperature' chemistry of alkanes. (Low-temperature catalysts for transformations of alkanes have indubitable advantages over catalysts that are active at elevated temperatures, since the former make it possible to perform more selective processes and to work under thermodynamically more favourable conditions.¹). The activation of the C–H bonds in alkanes, including methane, by transition metal complexes in solution has been discovered.^{2–4} Over the past two and half decades, a wide range of transition metal complexes and lanthanide and actinide derivatives that are capable of activating alkanes have been described, the scientific fundamentals for the metallocomplex activation of C–H σ -bonds have been created, and processes for the transformation of alkanes and cycloalkanes into their derivatives (alkenes, oxidation products, carbonyl compounds, *etc.*) have been developed. The 'biomimetic' approach based on the development of activating systems, similar to metalloenzymes acting in living nature, proved quite promising.

At about the same time as the first transition metal complexes activating alkanes were described, the activation of saturated hydrocarbons by protic superacids was discovered.^{5–7} The use of these systems made it possible to accomplish for the first time cracking, isomerisation, alkylation, and some other reactions of alkanes under mild conditions, at high rates, and with good yields of products. It has been shown that direct functionalisation of nonactivated cycloalkanes and alkanes including methane in protic acid media is, in principle, possible, and some examples of selective reactions of this type have been reported.

A great achievement in the chemistry of alkanes has been the elucidation of the mechanism of σ -bond activation by protic superacids and evidence for the existence of hypervalent carbon and for the formation of a two-electron three-centre ($2e-3c$) transition state. The intermediates in these reactions, namely, derivatives of pentacoordinated and hexacoordinated carbon, carbonium ions, and carbenium ions, the existence of which had been postulated previously, were generated and studied experimentally.⁵ As a result of these studies, the views on the mechanism of the electrophilic activation of alkanes, which had previously been speculative, became substantially more profound and acquired a reliable theoretical base. The Nobel prize in chemistry awarded to Olah in 1994 for his pioneering studies on the activation of alkanes by protic superacids reflected the recogni-

tion of his fundamental contribution to the chemistry of alkanes⁷ and, simultaneously, the recognition of the current interest in this subject.

Among the new approaches to the chemistry of alkanes, which have been successfully developed during the past two decades, gas-phase reactions of alkanes with metal ions⁸⁻¹⁷ and with metal atoms or small clusters¹⁷⁻²⁸ are noteworthy. The former have provided valuable information concerning the mechanisms of the activation of C-H and C-C bonds and on the energies of M-H and M-C bonds. The studies on the reactions of alkanes with metal atoms and small clusters have led to the development of new active heterogeneous catalysts^{17,18} and to the direct synthesis of organometallic compounds from alkanes.^{26,27}

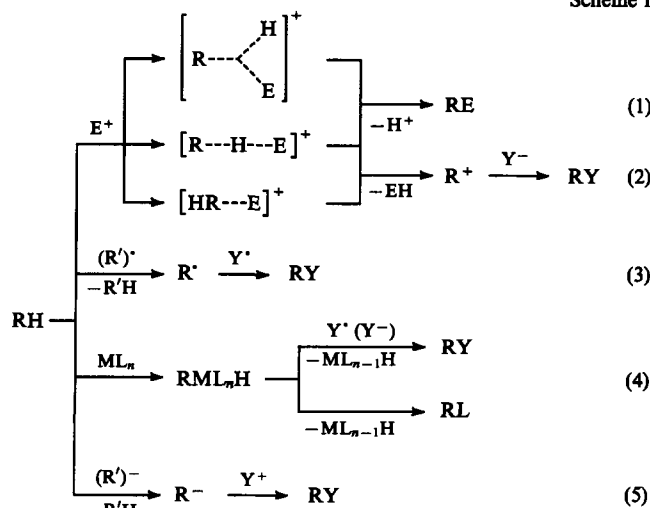

The traditional field involving gas-phase reactions of alkanes in the presence of heterogeneous catalysts, which still occupy a prominent position among industrial processes, has also been substantially revolutionised. Great progress has been achieved in studies on the structures of heterogeneous catalysts and mechanisms of reactions involving them (including industrial processes) as well as in the development of a new generation of catalysts.²⁰⁻³⁴ The elaboration of novel catalysts for the oxidation of alkanes based on polyoxometallates ('inorganic porphyrin'), which combine the advantages of homogeneous systems (selectivity and controllability of processes; see Chapter VIII in the published book²) with stability, which is the basic advantage of heterogeneous catalysts, especially significant for industry, demonstrates the fruitfulness of using different approaches for solving a common problem.

In recent years, some selective radical processes of functionalisation of alkanes have been reported. The photoinduced single electron transfer (SET), which has been achieved using photochemical oxidising agents (for example, tetracyanobenzene) generating radical cations from saturated hydrocarbons, can serve as an example. The subsequent exothermal transformation of the alkyl radical cation into the alkyl cation, which then adds to the radical derived from the oxidising agent, affords a functional derivative of the alkane.³⁵ Somewhat earlier, Crabtree (see for example, Chapter III in the published book²) has proposed another method for the generation of alkyl radicals from alkanes; this involved the use of photoexcited mercury atoms. The alkyl radicals thus formed can undergo cross-coupling with other radicals generated in the system. For example, the interaction of cyclohexane and methanol yields the cross-coupling product, cyclo-C₆H₁₁CH₂OH, in addition to the products of dimerisation of the radicals — (cyclo-C₆H₁₁)₂ and (CH₂OH)₂. Crabtree believes that this approach is quite promising for practical purposes, because it permits a large number of catalytic cycles. In this respect, the 'mercury' method compares favourably with the dehydrogenation of alkanes under the action of phosphine complexes of transition metals, which are readily deactivated during the reactions. Unfortunately, the Hg/hv and Hg/hv/H₂ systems are relatively ineffective for the transformation of methane or other alkanes with strong C-H bonds.

The simplest pathways to the functionalisation of alkanes are shown in Scheme 1. Obviously, compounds of the same type can react by different mechanisms. For example, metal complexes can act either as electrophiles or as radicals or react by the oxidative addition mechanism.

The electrophilic functionalisation (1), electrophile-promoted nucleophilic functionalisation (2),^{5,6} the radical mechanism (3), and the metalcomplex mechanism (4) of hydrogen substitution in a saturated hydrocarbon²⁻⁴ shown in the Scheme have been proved, while reaction (5) has not been performed so far. However, since the H/D isotope exchange in saturated hydrocarbons including methane under the action of strong nucleophiles is well known,³⁶⁻³⁹ this functionalisation pathway seems possible, although it is unlikely to play a noticeable role in the chemistry of alkanes, because the reagents needed for the irreversible functionalisation are difficult to select.

Scheme 1

It can be concluded from the foregoing that the chemistry of alkanes has developed vigorously over the last 20–25 years. It has been reported² that the number of publications devoted to the activation of alkanes and their catalytic reactions increases exponentially and doubles every 3–4 years. The advances made in this field bring closer the solution of the problem of the direct synthesis of organic compounds from alkanes and cycloalkanes.

The present review is devoted to the functionalisation of alkanes and cycloalkanes by complexes of acyl halides with aluminium halides.

Studies on the transformations of saturated hydrocarbons under the action of equimolar Friedel–Crafts complexes have been carried out desultorily for 65 years. The reported examples of functionalisation of activated saturated hydrocarbons seemed to be of purely abstract interest. However, recently it has been shown that, in some cases, the acylation of activated cycloalkanes with these systems can be applied to organic synthesis.

The discovery of the 'superacidic' properties of the RCOX·2AlX₃ complexes has opened new prospects in the chemistry of alkanes.⁴⁰ The RCOX·2AlX₃ complexes, which were called by us aprotic organic superacids (AOS) proved extremely reactive toward *n*-alkanes and non-activated cycloalkanes under mild conditions,⁴¹ which markedly distinguishes them from the equimolar complexes RCOX·AlX₃, which are inert with respect to these substrates. Regarding their activity in the initiation of transformations of alkanes, AOS surpass not only the known systems based on aluminium halides but also the strongest protic superacids. In the presence of AOS, functionalisation of linear alkanes and nonactivated cycloalkanes has been accomplished; among these processes, novel reactions of alkanes were found. It is also essential that, although AOS readily initiate transformations of alkanes and cycloalkanes accompanied by the rupture of C–C bonds, the fragmentation processes can be suppressed under certain conditions and a one-stage selective functionalisation of saturated hydrocarbons can be performed.

II. Functionalisation of isoalkanes and activated cycloalkanes by equimolar complexes RCOX·AlCl₃ and related systems

The discovery of the activating influence of aluminium chloride on acyl halides made by Friedel and Crafts in the late XIX century marked the beginning of the fruitful use of the complexes RCOX·AlX₃ in organic chemistry and, actually, the beginning of the use of catalysis in organic synthesis. However, the use of RCOX·AlX₃ complexes has long been confined only to reactions of unsaturated or aromatic compounds.⁴²⁻⁴⁵ The use of these

complexes for transformations of alkanes and cycloalkanes was far from being equally successful. The first studies in this field were carried out by Nenitzescu, Zelinsky, Hopff, and other researchers^{46–53} as early as the 1930s. The results of these studies have been discussed in monographs^{42,43} and in a review.⁵⁴

In early papers, only qualitative experiments were carried out. For example, it was found that stirring cyclopentane, acetyl chloride, and aluminium chloride in a molar ratio of 3 : 1 : 1.1 for two days affords acetylcyclopentane.⁴⁷ If methylcyclopentane is used instead of cyclopentane and the ratio of the reagents is 5 : 1 : 1.2, 2-acetyl-1-methylcyclopentane is formed in three days.⁴⁶ Later, reactions of cyclohexane, methylcyclopentane, methylcyclohexane, and decalin in the presence of $\text{AcCl} \cdot n\text{AlCl}_3$ ($n = 0.8–1.5$) were studied in detail by various researchers. It was found that the transformations of cyclohexane and methylcyclopentane carried out in the medium of the hydrocarbon itself lead to the corresponding saturated ketones, while in a solvent (CH_2Cl_2 or CHCl_3), α,β -unsaturated ketones or diketones of the cyclopentane series are formed.^{55–64}

Acetylation of methylcyclopentane, cyclohexane, methylcyclohexane, and decalin with the reaction conditions are shown in Scheme 2.^{55–58}

Thorough investigation of the acetylation of methylcyclopentane carried out recently has made it possible to increase the overall yield of the monoacetylated product 1 and diacetylated product 2 to 65%–70%.⁶⁴

The ratio of 1 and 2 depends on the $[\text{AcCl}]:[\text{AlCl}_3]$ ratio. When this is 2 : 1.5, the yield of the compound 2 is 50%.

Although the exact mechanism of the formation of the diketone 2 is unknown, the researchers cited presented some facts indicating that it is formed *via* enol derivative 3 rather than by the direct acylation of the unsaturated ketone 1 (Scheme 3).

In keeping with this scheme is the fact that treatment of the enol derivative 3 with AlCl_3 or TiCl_4 gives the diketone 2 in a quantitative yield. Conversely, acylation of 1 leads mostly to

- (a) $\text{AcCl} \cdot \text{AlCl}_3$, 20 °C, 5 h (yield 27%);⁵⁵
 (b) $\text{AcCl} \cdot \text{AlCl}_3$, 40 °C, 2 h (yield 50%);⁵⁶
 (c) $\text{AcCl} \cdot \text{AlCl}_3$, 60 °C, 5 h, 20 °C, 12 h (yield 36%);⁵⁷
 (d) $\text{AcCl} \cdot \text{AlCl}_3$, 40 °C, 24 h + 20 °C, 18 h (yield 58%);⁵⁶
 (e) $\text{AcCl} \cdot \text{AlCl}_3$, 20 °C, 17 h (yield 30%);⁵⁸
 (f) $\text{AcCl} \cdot 0.8\text{AlCl}_3$, 60 °C, 70 h (total yield 13%);⁵⁸
 (g) $\text{AcCl} \cdot 1.5\text{AlCl}_3$, 20 °C, 48 h (total yield 71%).⁵⁹

heavy products in which the proportion of the diketone 2 is very low.⁶⁴

The acetylation of methylcyclohexane and decalin occurs with the retention of the structures of the initial cycloalkanes.

Unlike reactions (6)–(9) (Scheme 2), acetylation of decalin [reaction (10)] is conducted with a substantial excess of aluminium

$[\text{RH}]:[\text{AcCl}]:[\text{AlCl}_3] = 1:2.4:1.5$; CH_2Cl_2 , 10 °C, 10 h (yield 46%).

Scheme 3

chloride. Although this reaction is not selective, the overall yield of acylated products is quite high. A decrease in the amount of aluminium chloride in the $\text{AcCl} \cdot n\text{AlCl}_3$ system to $n < 1$ and a decrease in the temperature change sharply the direction of the reaction. Instead of the decalin acylation products, vinyl ether 4 is formed.⁶³ It was shown that only *cis*-decalin enters into this process, while *trans*-decalin is inactive. The scheme proposed for the transformation of *cis*-decalin into the vinyl ether 4 involves the formation of 9,10-decalene, which is then acylated giving a tertiary carbocation. The latter undergoes an axial shift and cyclisation and, after elimination of HCl , it is finally converted into the vinyl ether 4.^{63, 64}

When cyclic hydrocarbons that are not prone to form alkenes are made to react with $\text{RCOCl} \cdot \text{AlCl}_3$ systems, halogenation products rather than acylation products are formed.⁶⁵ For example, treatment of adamantane with $\text{RCOCl} \cdot \text{AlCl}_3$ leads to 1-chloroadamantane.

$[\text{AdH}]:[\text{RCOCl} \cdot \text{AlCl}_3] = 1:1$; $\text{R} = \text{Me}, \text{Pr}^n, \text{Pr}^i, \text{cyclo-C}_6\text{H}_{11}$ ($\text{R} \neq \text{Ph}$).

At 50°C and at the molar ratio $[\text{RCOCl} \cdot \text{AlCl}_3]:[\text{AdH}] = 6:1$, dichloroadamantane is formed in a good yield, instead of 1-chloroadamantane.⁶⁵

The only transformation observed for linear and branched alkanes in earlier studies, was their acylation, which led predominantly to the formation of saturated ketones and, to a lesser degree, of unsaturated ketones.^{47, 55, 66–69} The yields of the acylation products were extremely low even after prolonged heating of the reactants.

$n = 4–6$.

n-Butane does not react with $\text{AcCl} \cdot \text{AlCl}_3$ at room temperature. However, if a mixture of *n*-butane with $\text{AcCl} \cdot \text{AlCl}_3$ (molar ratio 3:1) is stirred for 15 h at 60°C without a solvent, $\text{Me}_2\text{CHCH}_2\text{Ac}$, formed in a very low yield can be detected. The same product is also obtained from isobutane.⁶⁶

Pentane and hexane can be acylated by prolonged stirring with $\text{AcCl} \cdot \text{AlCl}_3$ at room temperature without a solvent. For example, when *n*-pentane reacted with $\text{AcCl} \cdot \text{AlCl}_3$ for 8 h, the formation of a mixture of $\text{Me}_2\text{CHCH}(\text{Me})\text{Ac}$ and $\text{Me}_2\text{C}=\text{C}(\text{Me})\text{Ac}$ was qualitatively detected.⁶⁷ Under similar conditions, *n*-hexane is converted into $\text{Me}_2\text{CHCH}(\text{Et})\text{Ac}$ and $\text{Me}_2\text{C}=\text{C}(\text{Et})\text{Ac}$. The indirect data reported by Nenitzescu et al.⁴⁷ suggest that the yield of $\text{Me}_2\text{CHCH}(\text{Et})\text{Ac}$ relative to AcCl does not exceed 5%. Japanese workers⁵⁵ have studied the interaction of isopentane with $\text{AcCl} \cdot \text{AlCl}_3$ by heating the reactants ($[\text{RH}]:[\text{AcCl} \cdot \text{AlCl}_3] = 1:1$) in a solvent. Under these conditions, only the unsaturated ketone 5 was obtained in a yield of no more than 6%.⁵⁵

Prolonged heating of isooctane, which readily undergoes cracking, with the $\text{AcCl} \cdot \text{AlCl}_3$ complex gives rise to the unsaturated ketone 6 and compound 7, resulting from its further chlorination, the degree of conversion of the initial hydrocarbon not exceeding 37%.

Yet another interesting route for the transformation of alkanes containing a tertiary carbon atom in the presence of $\text{AcCl} \cdot \text{AlCl}_3$ systems (excess AcCl is normally used) has been reported by French researchers.^{70, 71} They found that, apart from the products resulting from monoacylation of isoalkanes (2-methylbutane, 2-methylpentane, 3-methylpentane, and 2,3-dimethylbutane), diacylated and triacylated compounds are formed intermediately; under the reaction conditions, they are converted into a mixture of pyrylium salts and, after treatment of the reaction mixture with NH_4OH , they are transformed into a mixture of pyridinium salts. The transformation of isopentane into a mixture of four pyrylium salts is illustrated in Scheme 4.⁷⁰

Pyrylium salts are synthesised at $25–53^\circ\text{C}$ over a period of 5–23 h without a solvent or in CHCl_3 . The yields of the products depend strongly on the reaction conditions and do not exceed 20%–25%.⁷⁰ The reactions of 2,2,4-trimethylpentane, which readily undergoes cracking, with $\text{RCOCl} \cdot \text{AlCl}_3$ systems ($\text{R} = \text{Me}, \text{Et}, \text{Pr}^i$) afford isobutane, saturated and unsaturated

	AcBr·AlCl ₃	2.0	10 : 4 : 1	0	—

^a At 10 °C. ^b At 20 °C.

Another possibility is that a carbocation (R⁺) is generated from RH by the action of the superacid RCO⁺Al₂Br₇[−]; this carbocation withdraws Br[−] from Br₂ thus forming a bromide.

Both schemes include stages in which the catalyst is regenerated. The Ac⁺Al₂Br₇[−] complex is the catalyst of the bromination shown in Scheme 8b, whereas in the process shown in Scheme 8a, this complex initiates the reaction catalysed by the Br₃⁺Al₂Br₇[−] complex. By increasing the amount of Br₂ in the initial mixture and the reaction period, one can accomplish polybromination of alkanes, for example, of propane.

The overall yield of polybromopropanes is quantitative relative to Br₂.

b. Carbonylation of cyclopentane

Acetyl bromide initiates carbonylation of cyclopentane with CO in the presence of excess AlBr₃ (AlBr₃ : MeCOBr > 1.8).⁷⁹ This reaction occurs at room temperature and under atmospheric pressure and, after treatment of the reaction mixture with ethanol, it leads to the corresponding ester.

The selectivity of this reaction is 90%–99% and the yield of the ester varies from 53% to 93% depending on the proportion of AlBr₃. Dicyclopentyl ketone and acetylcyclopentane are formed as side products. The equimolar AcBr·AlBr₃ complex is inert under these conditions.

The mechanism suggested for this reaction is similar to that of the known Haaf–Koch reaction,⁸⁰ which includes generation of a carbocation from a cycloalkane through the action of an electrophile and subsequent addition of a CO molecule leading to the formation of an acylium-cation.

Side reactions:

It is significant that in the presence of AOS, alkanes and cycloalkanes have been introduced into reactions of new types (see Sections c and d).

c. The synthesis of RSCOR'

Compounds RSCOR' have been synthesised from alkanes (or cycloalkanes) RH, elementary sulfur, and the R'COX·2AlX₃ complexes in 25%–60% yields relative to the initial sulfur (Table 3).⁸¹

RH = C₃H₈, n-C₄H₁₀, n-C₅H₁₂, cyclo-C₅H₁₀, cyclo-C₆H₁₂;
R'CO⁺ = MeCO⁺, PrCO⁺, PhCO⁺.

With cycloalkanes, the corresponding dicycloalkyl sulfides R₂S (R = cyclo-C₅H₉, cyclo-C₆H₁₁) are formed in small yields. The mechanisms possible for this reaction are shown in Scheme 9.

In the case of hydrocarbons containing tertiary carbon atoms (isobutane, methylcyclohexane, adamantane), which are usually more reactive than *n*-alkanes and than unsubstituted cycloalkanes, organosulfur compounds either are not formed at all under the conditions studied or are formed in low yields.

In the presence of Al₂Br₆ or the equimolar MeCOBr·AlBr₃ complex, no organosulfur compounds are formed from alkanes and sulfur, which is in agreement with published data indicating that alkanes are inert with respect to sulfur at low temperatures.

Table 3. One-stage synthesis of organosulfur compounds RSCOR' from alkanes (cycloalkanes), elemental sulfur, and R'COCl·2AlBr₃ complexes (according to a published study⁸¹).

RH	R'	T/°C	t/h	RSCOR'	Yield relative to S (%)
C ₃ H ₈	Me	20	2	Pr ⁱ SCOMe	47
n-C ₄ H ₁₀	Me	0	2.5	Bu ⁱ SCOMe	29
cyclo-C ₅ H ₁₀	Me	0	2	cyclo-C ₅ H ₉ SCOMe	45
cyclo-C ₆ H ₁₂	Me	0	4	cyclo-C ₆ H ₁₁ SCOMe	60
	Pr	0	4	cyclo-C ₆ H ₁₁ SCOPr	52
	Ph	0	4	cyclo-C ₆ H ₁₁ SCOPh	34

At elevated temperatures, the reactions of alkanes with sulfur are non-selective and ineffective.^{82, 83}

Note for comparison that sulfurisation of alkanes (or cycloalkanes) with elementary sulfur in CF₃SO₃H giving rise to the corresponding (or isomeric) disulfides proceeds only upon prolonged reaction at a high temperature.⁸⁴

RH	T/°C	t/h	Reaction product	Yield relative to the reacted sulfur (%)

iso-C ₄ H ₁₀	125	10	Bu ₂ S	33

d. Alkylacylation of aromatic hydrocarbons with alkanes (or cycloalkanes) in the presence of RCO⁺Al₂X₇⁻ complexes

The ability of superacidic RCO⁺Al₂X₇⁻ complexes to acylate under mild conditions not only unsaturated compounds⁸⁵ but also alkanes^{40, 41, 72} seemingly precludes the possibility of alkylation of aromatic compounds in the presence of these complexes. However, it has been found that the acylating ability of these complexes is suppressed in the presence of alkyl halides, and they act as catalysts for alkylation, for instance, of benzene.⁸⁶

$$[\text{C}_6\text{H}_6]:[\text{tert-C}_5\text{H}_{11}\text{Cl}]:[\text{Ac}^+ \text{Al}_2\text{Cl}_7^-] = 180:36:1.$$

Alkylated aromatic ketones *tert*-C₅H₁₁C₆H₄COMe are formed as side products in these reactions. The yield of the alkylated aromatic ketones can be increased to 57% (relative to

Ac⁺Al₂Cl₇⁻) when the molar ratio of the reactants is 5:15:1. The reaction is completed over a period of 5 min at 20 °C.

Apparently, the alkylacylation of benzene with alkyl halides involves generation of a carbenium ion, which alkylates benzene. Subsequently acylation of the alkylated benzene occurs (Scheme 10).

Since alkanes can give rise to carbenium ions in the presence of RCO⁺Al₂X₇⁻ complexes, they can be successfully used, instead of alkyl halides, as alkylating agents for aromatic hydrocarbons.^{86, 87} These reactions result in the formation of alkylated aromatic ketones (Scheme 10). The one-stage alkylacylation of benzene with isoalkanes or *n*-alkanes in the presence of the RCO⁺Al₂X₇⁻ complexes occurs at 0–20 °C. The yields of alkylacylation products reach 65%–87% (Table 4). The yields of non-alkylated aromatic ketones, the products of a competing reaction, are relatively low (3%–20%). Isobutane and *n*-butane can be used as alkylating agents. Butylated ketones are normally obtained in somewhat lower yields (up to 68%) but they are also the major reaction products.

R' = Buⁱ, Buⁿ, *n*-C₅H₁₁, 2,3-Me₂C₄H₇, cyclo-C₅H₈Me;

R = Me, Pr, Ph; X = Cl, Br.

Alkylacylation reactions result in good yields of products only when an excess of the 'alkylating system' (R'H + RCO⁺Al₂X₇⁻) is used, the molar ratio [R'H]:[RCO⁺Al₂X₇⁻]:[C₆H₆] is (10 to 15):(3 to 12):1, and the experimental procedure is thoroughly followed.^{86, 87}

Alkylacylation of benzene with isobutane occurs regioselectively and leads to the *para*-isomers of the corresponding ketones.

The reaction of benzene with isopentane gives equal amounts of *para*-substituted ketones differing in the structure of the pentyl group.

Alkylacylation of bromobenzene is more selective than that of benzene, the yield of the corresponding ketone reaching 74%–82% (see Table 4). The reaction with isobutane affords only one isomer, 2-bromo-4-*tert*-butylacetophenone.⁸⁶

Table 4. One-stage alkylation of benzene and bromobenzene with alkanes (cycloalkanes) and $\text{RCO}^+ \text{Al}_2\text{X}_7^-$ complexes.

^a Before the reaction, the initial alkane was held for 3 h with a catalytic amount of $\text{RCO}^+ \text{Al}_2\text{X}_7^-$.

Apparently, the *para*-bromo-*tert*-butylbenzene formed initially isomerises into the more stable *meta*-isomer in the presence of a strong aprotic superacid. The acylation of the *meta*-isomer into the *para*-position with respect to the *tert*-butyl group gives rise to the reaction product observed. Activated arenes (toluene, naphthalene, and *meta*-xylene) also form alkylation products, but their yields do not exceed 10% of the yields of products obtained by the direct acylation of arenes. At the same time, arenes that contain strong electron-withdrawing groups (nitrobenzene and acetophenone) remain unchanged under the reaction conditions. This fact suggests that the reactions under consideration occur as the initial alkylation of arenes followed by acylation of the alkylated arenes. Apparently, in the case where the aromatic compound is activated toward an electrophilic attack, the acylation and alkylation reactions proceed at comparable rates. Therefore, in the presence of excess acylating agent, the acylation occurs as the prevailing process. The difference between the acylation and alkylation rates increases on passing from activated aromatic compounds to benzene and, especially, to bromobenzene, which is inert toward electrophiles. Therefore, in these cases, the initial alkylation is the predominant or even the only reaction pathway.

Apparently, the scheme of the alkylation with alkanes (or cycloalkanes) is similar to Scheme 10 and differs from it only by the absence of the stage for the regeneration of the acylium cation.⁸⁶

We have also detected the 'alkane-type' reactivity of Bu^t-COMe in its interaction with benzene, which resulted in the formation of the corresponding product of the alkylation of benzene in 40% yield.⁸⁶

IV. Reactions of acylium salts with saturated hydrocarbons in protic superacids

Reactions of saturated hydrocarbons with acylium salts in a medium of a protic superacid were described for the first time by Brouwer and Kiffen.⁸⁸ They showed that in the HF–BF₃ and HF–SbF₅ systems at 25 °C, acylium ion detaches a hydride ion from the tertiary carbon atom in isobutane, isopentane, or methylcyclopentane. In the case of isobutane, the degree of conversion of an acylium salt amounts to 90% over a period of 12 h. The acylium salt is transformed into protonated ethyl acetate, which arises, in the authors' opinion,⁸⁸ via the interaction of MeCO⁺ with the ethanol resulting from the reduction of MeCO⁺ by the isoalkane. The conversion of isobutane leads initially to protonated mesityl oxide (Scheme 11). The second-order rate constant for this reaction is $3 \times 10^{-5} \text{ l mol}^{-1} \text{ s}^{-1}$.

Scheme 11

Scheme 12

When the duration of the process is more than 12 h, the mesityl oxide formed is reduced by isobutane to give protonated isobutyl methyl ketone.

Methylcyclopentane reacts with MeCO^+ in a protic acid in a similar way and gives rise to protonated 1-acetyl-2-methylcyclopentene and ethyl acetate.

The reaction involving isopentane yields a more complex mixture of products.

When cyclohexane is treated with MeCO^+ in excess $\text{HSO}_3\text{F}-\text{SbF}_5$, an α,β -unsaturated ketone — 1-acetyl-2-methylcyclopentene — is formed in 44% yield.⁸⁹ It was suggested that the dehydrogenation of cyclohexane is due to the generation of a carbocation upon the action of the superacid $\text{HSO}_3\text{F}-\text{SbF}_5$ on the cycloalkane rather than to the hydride transfer to the MeCO^+ cation.^{90,91} Thus, the role of MeCO^+ reduces only to acylation of the alkene existing in an equilibrium with the carbenium ion (Scheme 12).

It should be noted that with *n*-alkanes, hydride transfer barely takes place under the same conditions. For example, when butane has been in contact with a solution of $\text{MeCO}^+\text{BF}_4^-$ in $\text{HF}-\text{BF}_3$ for 72 h, the transformation occurred by no more than 1%, and the rate constant for this reaction, as estimated by Brouwer and Kiffen,⁸⁸ did not exceed $2 \cdot 10^{-8} \text{ l mol}^{-1} \text{ s}^{-1}$. No transformations of *n*-alkanes have been observed when they were treated with MeCO^+ in excess $\text{HSO}_3\text{F}-\text{SbF}_5$.⁸⁹

V. The nature of the active complexes in acyl halide – aluminium halide systems

Evidently, the abstraction of a hydride ion from a saturated hydrocarbon by a superelectrophile leading to a carbocation is the key stage of the functionalisation of alkanes and cycloalkanes. This process includes one or several stages and occurs either by the classical Olah scheme [Eqns (1) and (2) in Scheme 1]⁹² or by a different mechanism.

From studies of equimolar $\text{RCOX}-\text{MX}_n$ systems, which were started as early as the beginning of this century and developed most significantly in the 1960–1970s, the structures of these

systems in the solid state and in solution are well known (see, for example, reviews^{44,93,94} and monographs^{43–45,93–96}).

The solid $\text{RCOX} \cdot \text{AlX}_3$ complexes ($\text{R} = \text{Alk}$, $\text{X} = \text{Cl}, \text{Br}$) exist as ionic acylium salts or donor-acceptor complexes.⁹⁴ The structures of $\text{MeCO}^+\text{AlCl}_4^-$,⁹⁷ and $\text{RC}(\text{Cl})=\text{O} \rightarrow \text{AlCl}_3$ [$\text{R} = \text{Et}$,⁹⁸ C_6H_5 ,⁹⁹ and *o*- and *p*- MeC_6H_4]¹⁰⁰] were determined by X-ray diffraction analysis. The cationic fragment MeCO^+ in the ionic complex $\text{MeCO}^+\text{AlCl}_4^-$ is linear, which corresponds to *sp*-hybridisation of the carbonyl carbon atom. The C–C–O angle is close to 180° , and the C–O bond is markedly shorter than the $\text{C}_{\text{sp}^2}=\text{O}$ bonds in ketones and acyl halides and even than that in CO. The structure of the AlCl_4^- moiety is close to tetrahedral.

X-Ray diffraction data provide valuable information also on the electron density distribution in acylium cations. The positive charge in the acylium cation $\text{C}(2)\text{H}_3\text{C}(1)\text{O}^+$ has been shown to be mostly localised on the C(1) atom and on the hydrogen atoms attached to C(2) but not on the oxygen atom. In fact, the $\text{C}(1) \cdots \text{Cl}$ and $\text{C}(2)\text{H}_3 \cdots \text{Cl}$ intramolecular distances between the nonbonded atoms are almost always smaller than the sums of the van der Waals radii of the corresponding atoms, whereas the $\text{Cl} \cdots \text{O}$ distances are greater than the sum of the covalent radii of Cl and O. This conclusion was totally confirmed by the data of an *ab initio* LCAO MO SCF calculation.¹⁰¹ The results of this quantum-chemical calculation are in good agreement with the experimental values of bond lengths and bond angles shown in Scheme 13.

Scheme 13

The electron density distribution in the MeCO^+ ion inferred from an X-ray diffraction structural study of $\text{MeCO}^+\text{SbF}_6^-$ (see Ref. 102) is, in our opinion, less probable,⁹⁴ because, according to these data, the charge on the hydrogen atom (+0.07) in CH_3CO^+ is close to that in ethane, which is at variance with a number of other studies indicating that the hydrogen atoms in the acylium cation carry a substantial positive charge.

According to X-ray diffraction studies, the Lewis acid in nonionic $\text{RCOX} \cdot \text{AlX}_3$ complexes is coordinated to the electron pair of the oxygen atom of the acyl halide. This follows from the presence of Al–O bonds in these compounds. The Al–O bond lengths vary in the range 1.820–1.847 Å, and they are only slightly larger than the Al–O bond lengths in such stable compounds as aluminosilicates (1.79 Å). The complex formation involving oxygen results in the elongation of the C–O bond (1.21–1.24 Å) compared to this bond in noncoordinated RCOX (1.17 Å).¹⁰³ It is significant that the C–O and C–Cl bond lengths are much the same in various donor-acceptor complexes, which apparently indicates that their strengths are similar. Conversely, the C–C bond lengths in donor-acceptor complexes of the aliphatic and aromatic series are markedly different. For example, the C(1)–C(2) bond length in the complex $\text{EtC}(\text{Cl})=\text{O} \rightarrow \text{AlCl}_3$ is close to the length of the classical $\text{C}_{\text{sp}^3}-\text{C}_{\text{sp}^2}$ bond, while the Ar–C bond

in complexes like $\text{ArC(X)=O} \rightarrow \text{AlX}_3$ is shorter than the Ar-C bond in a non-coordinated ArC(X)=O molecule.⁹⁴ A specific feature of the geometry of the donor-acceptor complexes $\text{ArC(X)=O} \rightarrow \text{AlX}_3$ is a substantial increase in the bond angles with respect to 120° typical of an sp^2 -hybridised carbon atom. This distortion of the angles has been attributed¹⁰⁴ to steric effects occurring upon packing of the molecules in a crystal. The geometry of the O-AlCl_3 fragment is that of a somewhat distorted tetrahedron.⁹⁴

According to ^{81}Br NQR data,¹⁰⁵ the $\text{AcBr} \cdot \text{AlBr}_3$ complex at 77 K is an ionic acetylum salt. The same complex obtained in a solution in CH_2Br_2 at 77 K exists as the ionic salt $\text{MeCO}^+[\text{AlBr}_4 \rightarrow \text{CH}_2\text{Br}_2]^-$.

The $\text{RCOX} \cdot \text{AlX}_3$ systems have been studied in a broad range of solvents (CH_2Cl_2 , CH_2Br_2 , CHCl_3 , $\text{C}_2\text{H}_4\text{Cl}_2$, $\text{C}_6\text{H}_5\text{NO}_2$, MeNO_2 , SO_2 , HF , $\text{CF}_3\text{SO}_3\text{H}$, etc.) by IR, Raman, and ^1H , ^{13}C , and ^{27}Al NMR spectroscopy.^{41, 94, 106–109} The whole set of the results obtained indicate that in the solvents listed above, except for strong protic acids, the systems under study exist exclusively as donor-acceptor complexes (the state of these systems in SO_2 is less definite⁹⁴).

1. Acylation of arenes

Since 1877, when the AlCl_3 -catalysed acylation of aromatic hydrocarbons was discovered by Friedel and Crafts,¹¹⁰ the mechanism of this reaction has been intensely studied both by the same researchers and by many others. The current views on the nature of the active species involved in this process and the arguments in favour of the concept outlined are the following.¹¹¹

The acetylum cation is a relatively weak electrophile due to the resonance stabilisation of the carbocation centre by the electron pairs of the oxygen atom.

Therefore, it seems unlikely that benzene or other non-activated arenes would react with the acetylum cation or with the donor-acceptor complex, which is even less reactive. In fact, a study of the influence of the acidity of the medium on the rate of acetylation and benzoylation of benzene, toluene, and chlorobenzene with $\text{MeCO}^+ \text{SbF}_6^-$ and $\text{PhCO}^+ \text{SbF}_6^-$ has led to the conclusion that in an acidic medium, the protonated acetylum $\text{MeC}^+ = \text{O}^+ \text{H}$ or $\text{PhC}^+ = \text{O}^+ \text{H}$ is the main reacting species.¹¹¹ For example, the reaction of benzene with $\text{MeCO}^+ \text{SbF}_6^-$ carried out in CF_3COOH ($H_0 = -2.7$) at 5°C for 12 h, yields less than 10% of acetophenone, while chlorobenzene remains unchanged over a period of 24 h under the same conditions. The rate of acetylation increases by a factor of 10 and more on passing from a solvent with $H_0 = -12$ (a mixture of CF_3COOH with $\text{CF}_3\text{SO}_3\text{H}$) to a solvent with $H_0 = -14$ ($\text{CF}_3\text{SO}_3\text{H}$).¹¹¹ The NMR data indicate that for $H_0 = -12$, the proportion of the MeCO^+ ion in the complex is 60%, whereas for $H_0 = -14$, it reaches 75%. Calculations show that if it were the acetylum cation that acted as the reactive species, the acylation rate would increase by a factor of less than 2 following the change in the acidity from $H_0 = -12$ to $H_0 = -14$.

Unlike benzene and chlorobenzene, toluene, which is more reactive, gives acetylation products in 55% yield over a period of 12 h at 0°C in CF_3COOH . However, the ratios of the isomers resulting from the acetylation of toluene in CF_3COOH and $\text{CF}_3\text{SO}_3\text{H}$ are markedly dissimilar, which indicates that the process occurs by different mechanisms in the media with different acidities. Conversely, the isomeric compositions of the acylation products obtained in media with $H_0 = -10$ and -18 are identical. It has been assumed that toluene, which is an activated arene, is capable of being acetylated with the MeCO^+ ion in low-acidity media. The strong acid HSbF_5X formed in this reaction also can catalyse subsequent reactions. In a medium with higher acidity, the reaction involving the protonated acetylum cation is the main route for the acylation of toluene.

The benzoylation of arenes with $\text{PhCO}^+ \text{SbF}_6^-$ follows the same regularities. It is noteworthy that an increase in the benzoylation rate is observed at a higher acidity than $H_0 = -14$, although spectral studies indicate that at $H_0 = -14$, the system exists exclusively as the ionic salt $\text{PhCO}^+ \text{SbF}_6^-$.¹¹¹ The fact that benzoylation requires more acidic media than acetylation has been explained¹¹¹ by the lower reactivity of aryl cations ArCO^+ compared to that of the acylium cations AlkCO^+ , which is due to the contribution of ketene-like structures.

It has also been suggested that the species formed from two acceptor molecules play an important role in the acylation of arenes in organic media. This hypothesis was stated for the first time by Gillet to account for the activating influence of AlCl_3 on the synthesis of ketones from arenes and $\text{RCOX} \cdot \text{AlCl}_3$ complexes.¹¹² The hypothesis of Gillet was soon confirmed experimentally.

A kinetic study of the AlCl_3 -catalysed benzoylation of aromatic hydrocarbons¹¹³ has led to a complex equation for the rate constant, most closely consistent with the concept of participation of complexes of two types

Based on a kinetic study of the acylation of arenes with acetyl chloride in the presence of AlCl_3 in dichloroethane, *ortho*-dichlorobenzene, or in excess acetyl chloride, the workers cited¹¹³ concluded that complexes of three types participate in the reaction, namely, $\text{MeCO}^+ \text{AlCl}_4^-$, $\text{MeC(Cl)=O} \rightarrow \text{AlCl}_3$, and $\text{Cl}_3\text{Al} \leftarrow \text{ClC(Me)=O} \rightarrow \text{AlCl}_3$.

Other investigators,¹¹⁴ who have also studied the acylation of benzene with $\text{RCOCl} \cdot \text{AlCl}_3$ complexes in dichloroethane, have shown that this reaction can be described by a simpler equation

$$v = k[\text{ArH}][\text{RCOCl} \cdot \text{AlCl}_3]$$

The benzoylation of arenes with acyl halides in the presence of AlBr_3 , at $[\text{AlBr}_3]:[\text{PhCOBr}]$ molar ratios of 1 and 1.5 has been shown¹¹⁵ to obey second-order kinetics. Further increase in the amount of AlBr_3 results in a change in the reaction mechanism. In this case, the reaction rate is described by a third-order equation. The rate constants (k) for the benzoylation in a trichlorobenzene solution are given below.

$[\text{AlBr}_3]:[\text{PhCOBr}]$	1	1.5	2	2.5	3
k	0.4	6.0	128	225	327

It is seen from the above data that on passing from the $\text{PhCOBr} \cdot \text{AlBr}_3$ system to the $\text{PhCOBr} \cdot 2\text{AlBr}_3$ system, the rate constant for benzoylation increases by a factor of 320. When the quantity of AlBr_3 is further increased, the rate constant smoothly and slightly increases. The researchers¹¹⁵ could not explain this phenomenon, and they stated only that the electrophilicity of $\text{PhCOBr} \cdot n\text{AlBr}_3$ systems at $n = 2$ is markedly higher than that at $n = 1$.

2. The nature of active species in reactions of activated alkanes with acylium salts in media of protic superacids

The results obtained for reactions of isobutane with the acetylum cation are in full agreement with the above data on the protonated acylium cations as the species responsible for the acylation of arenes in acidic media. Brouwer and Kiffen⁸⁸ have reported on the hydride transfer from isobutane to the acetylum cation generated from acetic acid in an $\text{HF}-\text{BF}_3$ medium.

At the same time, Olah and coworkers¹¹⁶ have shown that in aprotic solvents such as SO_2 , SO_2ClF , AsF_3 , and CH_2Cl_2 this reaction with the acetylium cation does not occur.

The views about a crucial role for protonated acetylium are in agreement with the results of calculations, which indicate that the abstraction of a hydride ion from isobutane by the acetylium cation in the gas phase requires $8.5 \text{ kcal mol}^{-1}$. The protonated acylium dication has not been detected by ^1H NMR; however, in the IR spectrum of the acetylium cation in a protic superacid, a shift of the frequency corresponding to the carbonyl group has been observed. Calculations have shown that a global minimum on the potential energy surface corresponds to the $[\text{MeC}-\text{OH}]^{2+}$ structure.¹¹⁷ It should be noted that the $\text{C}_2\text{H}_4\text{O}^{2+}$ dication has also been observed in the gas phase by mass spectrometry.¹¹⁸

3. The nature of active species generated in aprotic superacids $\text{RCOX} \cdot 2\text{AlX}_3$ and responsible for their reactivity toward alkanes

In order to understand the reason for the high reactivity of the $\text{RCOX} \cdot 2\text{AlX}_3$ complexes, which differs so markedly from the reactivity of the corresponding equimolar $\text{RCOX} \cdot \text{AlX}_3$ complexes, we have studied the structures of both types of complexes in the solid state and in solutions in CH_2X_2 using ^{81}Br NQR, ^1H , ^{13}C , ^{27}Al , and ^{17}O NMR (in the solid state and in solutions), IR, and Raman spectroscopy.^{41, 105, 109} It was found that in the solid state complexes of both types are ionic acylium salts differing only in the structure of the anions: $\text{MeCO}^+ \text{Al}_2\text{X}_7^-$ for $\text{MeCOX} \cdot 2\text{AlX}_3$ or $\text{MeCO}^+ \text{AlX}_4^-$ for $\text{MeCOX} \cdot \text{AlX}_3$. This conclusion is at variance with the suggestion of Bertoluzza, who has attributed the structure $(\text{Ac}^+ \cdot \text{AlCl}_3)^+ \text{AlCl}_4^-$ to the isolated complex $\text{AcCl} \cdot 2\text{AlCl}_3$.¹¹⁹

In CH_2X_2 solutions, the former complexes exist as equilibrium mixtures of acylium salts $\text{MeCO}^+ \text{Al}_2\text{X}_7^-$ and donor-acceptor complexes $\text{MeC}(\text{X})=\text{O} \rightarrow \text{Al}_2\text{X}_6$, whereas the latter exist exclusively as coordination complexes $\text{MeCO}(\text{X})=\text{O} \rightarrow \text{AlX}_3$.

Thus, only $\text{RCOX} \cdot 2\text{AlX}_3$ ($\text{R} = \text{Alk}$), which are active in the reactions with alkanes, are able to generate effectively acylium cations in low-polarity solutions, and this is their basic difference from the corresponding equimolar complexes. A comparison of two pairs of complexes: $\text{MesCO}^+ \text{Al}_2\text{Br}_7^-$ and $\text{MesCO}^+ \text{AlBr}_4^-$ ($\text{Mes} = 2,4,6\text{-Me}_3\text{C}_6\text{H}_2$), on the one hand, and $\text{Ac}^+ \text{Sb}_2\text{F}_{11}^-$ and $\text{Ac}^+ \text{SbF}_6^-$ in SO_2 , on the other hand, has shown that only acylium salts with dimeric anions are active in the reactions with alkanes under mild conditions (Table 5).¹²⁰

The very close similarity of the ^1H and ^{13}C NMR spectra of active and inactive complexes of the composition $\text{RCOX} \cdot n\text{AlX}_3$ ($n = 1, 2$) differing only in the structure of the anion (Table 6) gave grounds to suggest that it is not the acylium salts themselves that

Table 6. ^{13}C NMR spectra of $\text{MesCO}^+ \text{X}^-$ salts with anions $\text{X}^- = \text{AlBr}_4^-$ and $\text{X}^- = \text{Al}_2\text{Br}_7^-$ (δ , ppm).¹²⁰

δ , ppm		Assignment
$\text{X}^- = \text{AlBr}_4^-$	$\text{X}^- = \text{Al}_2\text{Br}_7^-$	
21.4	21.7	C(2)-CH ₃
23.7	24.2	C(4)-CH ₃
85.3	84.6	C(1)
153.7	153.9	C(2)
130.9	131.5	C(3)
162.1	163.1	C(4)
159.2	159.7	CO

Note. In the ^{27}Al NMR spectra of the $\text{MesCO}^+ \text{AlBr}_4^-$ and $\text{MesCO}^+ \text{Al}_2\text{Br}_7^-$ complexes, the corresponding shifts of the ^{27}Al nuclei are 79.4 ($\Delta = 12 \text{ Hz}$) and 93.0 ppm ($\Delta = 930 \text{ Hz}$).

are responsible for the superacidic properties of the $\text{RCOX} \cdot 2\text{AlX}_3$ systems. It was suggested that in solutions, the acylium salts with the dimeric anions Al_2X_7^- occur in an equilibrium with more electrophilic ionic complexes, namely, cationic acylium complexes of the type **10a** or **10b** in which the cation is additionally coordinated to the Lewis acid.^{41, 94, 120}

Table 5. Comparison of the activities of acylium salts with monomeric and dimeric anions in the cracking of *n*-alkanes and in the isomerisation of trimethylenenorbornane **9** (according to a published study¹²⁰).

^a In SO_2 . ^b Not determined. ^c In CH_2Br_2 .

It is clear that the additional coordination should lead to a more electrophilic cation, which in its extreme form, can be represented as the acylium dication. The fact that these species are difficult to detect experimentally must be due to their very low concentration.

Data about the complexes that can be generated in the $\text{MeCOCl} \cdot n\text{AlCl}_3$ systems ($n = 1-3$) have also been obtained by semiempirical CNDO quantum-chemical calculations. The most significant conclusion which can be drawn from these calculations is that in the systems containing an excess of aluminium chloride ($n = 2$ and 3), the formation of complexes **12** and **13**, in which the carbonyl carbon atoms carry larger positive charges than this carbon atom in the acetylium cation **11**, is in principle possible.¹²¹

$$H_0 = -185 \text{ kcal mol}^{-1}$$

$$H_0 = -322 \text{ kcal mol}^{-1}$$

$$H_0 = -423 \text{ kcal mol}^{-1}$$

In the complex **12**, which can be regarded as the acetylium cation with a donor–acceptor bond $=\text{O} \rightarrow \text{AlCl}_3$ (**10b**) postulated previously as a key intermediate, the electron density on all the atoms in the $\text{MeC}=\text{O}$ fragment is substantially lower than that in the non-coordinated cation **11**: the positive charge on the carbonyl carbon atom is $+0.56$. The structure of **13**, which also corre-

sponds to a local minimum on the potential energy surface, is of special interest. The complex **13** can be regarded as a system incorporating a $\text{Cl}_2\text{Al}-\text{OC}^2+\text{Me}$ dication and two AlCl_4^- anions. The charge on the carbon atom in this complex reaches a record value of $+0.79$.

Table 7 presents the enthalpies of the reactions, which characterise the relative stabilities of the $\text{MeCOCl} \cdot n\text{AlCl}_3$ complexes. From the data given in the Table, it follows that the reactions (1) and (2) leading to charged species are strongly endothermic. The formation of the polar complex **11** requires less energy than the formation of separated ions. It should be taken into account that these data refer to the gas phase, whereas the energies of formation of the ions in solution can be much lower due to solvation and agglomeration. In fact, the existence of acetylium salts in solution has been proved, although calculations for the reactions (1) and (2) indicate that their formation requires a lot of energy ($110.5 \text{ kcal mol}^{-1}$). The formation of donor–acceptor complexes of the composition 1 : 1 and 1 : 2 involves either release of energy or absorption of a small quantity of energy. It is significant that the formation of the complex **12** and even of the dicationic complex **13** in the reaction of acetyl chloride with AlCl_3 (but not with Al_2Cl_6) is energetically favourable, unlike the formation of the acetylium complex **11**.

Thus, the complexes **12** and **13** can be regarded as the most likely key superelectrophiles, which are responsible for the high activity of acyl halides (in the presence of excess aluminium halides) with respect to alkanes. Apparently, the role of the complex **13** is manifested only when the reaction mixture contains a substantial excess of aluminium halide. The generation of the carbenium ions from alkanes under the action of $\text{RCOX} \cdot 2\text{AlX}_3$ can be represented as follows:

At present, the idea concerning the participation of dications or even of multicharged positive ions in organic reactions is becoming more and more popular.^{117, 121}

Table 7. Enthalpies (ΔH) of reactions, characterising the stability of the $\text{MeCOCl} \cdot n\text{AlCl}_3$ complexes (according to a published study¹²¹).

Number of the reaction	Reaction	$\Delta H/\text{kcal mol}^{-1}$

(9)	$\text{MeCOCl} + \frac{3}{2} \text{Al}_2\text{Cl}_6 \longrightarrow [\text{MeC}^{2+} \text{OAlCl}_2] 2\text{AlCl}_4^-$ 13	75.4
(10)	$\text{MeCOCl} + 3\text{AlCl}_3 \longrightarrow [\text{MeC}^{2+} \text{OAlCl}_2] 2\text{AlCl}_4^-$ 13	-2.3

VI. Conclusion

The high selectivity and the ease of one-stage functionalisation reactions, the high yields of products, and the accessibility of both initial compounds and $\text{RCOX} \cdot n\text{AlX}_3$ complexes (which are obtained by mere mixing of acyl halides with aluminium halides) suggest that the reactions considered above can be of interest as methods for the laboratory syntheses of organic compounds from alkanes and cycloalkanes.

The 'classical' Friedel–Crafts complexes can find application in the functionalisation of activated saturated hydrocarbons. The superacidic $\text{RCOX} \cdot 2\text{AlX}_3$ complexes substantially extend the possibilities for the direct functionalisation of alkanes and make it possible to perform selective and effective transformations of linear alkanes and simple cycloalkanes into functional derivatives.

The conclusion that dication-type species play a key role in the reactions of alkanes with $\text{RCOX} \cdot 2\text{AlX}_3$ complexes has stimulated the search for new superelectrophilic complexes, which would be more accessible and more convenient to work with than the complexes based on acyl halides and would open the way to new types of functionalisation. Testing of a number of systems in which the generation of dications is, in principle, possible has led in recent years to new aprotic superacids, which are quite promising regarding the functionalisation of alkanes.^{123–128} The direct one-stage synthesis of organic compounds from saturated hydrocarbons may be accomplished in the near future, at least, for lower alkanes and cycloalkanes, which are relatively resistant to cracking. The subsequent important and complicated task is to develop new superacids containing no aluminium halides. The advantages of such systems are obvious. In this case, the problem of catalyst regeneration as well as ecological problems would be solved more easily.

Advances in the development of homogeneous aprotic superacids also seem very important for the elaboration of solid superacids of a new generation, which play a crucial role in the chemistry of alkanes.

This work was partially supported by the Russian Foundation for Basic Research (Grant 96-03-33255) and by the International Science Foundation (Grant MRA 000). During the preparation of this review, we were encouraged and given practical support by Professor Yu. T. Struchkov. To our great sorrow, we could not express our gratitude to him fully — it remains in our hearts.

Abstract. The influence of external factors on the formation of various polymorphic modifications of poly(vinylidene fluoride) (PVDF) and the copolymers and blends based on it is examined. It is shown that the formation of a particular conformational structure of the PVDF chains may be controlled by regulating, for example, the fraction of irregular 'head to head' ('tail to tail') attachments and by selecting a suitable comonomer or component of the blend. It is shown that polar modifications of PVDF may be obtained by its crystallisation from solutions in specific solvents. The important role of high pressures was noted in block crystallisation. Solid-phase transformations may be initiated with the aid of tensile and compressive deformations (within certain temperature ranges), high electric fields, and exposure to radiation. It is shown that both the type of the lattice and the variety of the morphology of the PVDF change on crystallisation in a blend with amorphous poly(methyl methacrylate). The characteristics of the dynamics of the block PVDF chains, obtained predominantly with the aid of dielectric spectroscopy, have proved sensitive to the polymorphism and the kind of morphology and may yield additional information about the structure of the noncrystallising regions of the polymer under consideration. The bibliography includes 383 references.

I. Introduction

A systematic treatment of the structure and properties of poly(vinylidene fluoride) (PVDF) is of interest because it has effective piezoelectric and pyroelectric properties.^{1,2} It is one of the most promising polymeric ferroelectrics. It is used for practical purposes in the polarised state (for example, in various kinds of

transducers³), so that knowledge of the mechanism of the structural changes in strong electric fields is obligatory. Analysis of published studies has shown that polarisation processes depend on the characteristics of the structure and the nature of the molecular mobility in crystalline and amorphous regions.

One of the most informative methods for the study of the microstructure of PVDF chains is high-resolution nuclear magnetic resonance, NMR spectra of polymer solutions being recorded. A series of peaks, associated with defects in the 'head to head' or 'tail to tail' attachment, may be distinguished for ¹⁹F nuclei.⁴ As the apparatus improved, it became possible to obtain spectra at higher frequencies,^{5–8} which yield detailed information about the microstructure of the PVDF chain. In particular, the influence of the suspension (or emulsion) polymerisation method on the microstructure of the PVDF chain has been discussed.⁷ In order to obtain additional information, data on the ¹³C resonance^{9–10} or the resonances involving all three nuclei entering into the composition of the chain (¹H, ¹³C, and ¹⁹F) at once¹¹ are resorted to. The application of two-dimensional NMR spectroscopy^{12,13} has also expanded the existing ideas about the microstructure of the PVDF chain. This method is used in the study of the microstructure of the chains in vinylidene fluoride (VDF) copolymers with perfluoroalkyl trifluorovinyl ethers,¹⁴ trifluoroethene (TrFE),¹⁵ tetrafluoroethene (TFE), or hexafluoropropene.^{16,17} Having estimated the spin-spin coupling constants for neighbouring sections of PVDF in the *trans*-(*T*) or *gauche*-conformations (*G*), it is possible to estimate their proportions. For example, the fraction of the *TT* conformations for the monochlorobenzene–dimethyl sulfoxide solvent mixture increases significantly when the fraction of monochlorobenzene is reduced.¹⁸ It is assumed that there must exist a correlation between the conformations of the VPVF chains in solution and in the block state.

The crystalline phases of PVDF and of its copolymers are characterised by the presence of at least four polymorphic modifications [α (II), β (I), γ (III), and α (IV)]. These modifications are distinguished by the conformational structure of the chain and by the nature of the packing of the macromolecules in the unit cell of the crystallites. The characteristic conformational

chain structures for three of the modifications listed above are presented in Figs 1–3. Evidently conformations of the $TGT\bar{G}$, $T_3GT_3\bar{G}$, and ‘planar zigzag’ types are characteristic of the α phases, γ phases, and β phases respectively.¹⁹ One may note that, owing to the phenomenon of rotational isomerism involving the hydrocarbon skeleton of the chain, the transition from the ‘planar

zigzag’ conformation to the $TGT\bar{G}$ conformation is accompanied by an almost twofold increase in the identity period along the chain (c axis of the cell).

The Raman and IR spectroscopic methods are known to be ‘sensitive’ to the short-range order, i.e. they should be more informative as regards the chain conformation. Numerous literature data on the vibrational spectra of PVDF have confirmed this.^{19–35} Table 1 presents the results of the study of PVDF crystallised in three different modifications — their symmetries and characteristic vibrational frequencies. It follows from the tabulated data that there exist a series of characteristic absorption bands for each conformation and that this can be used to identify a particular PVDF conformation.

Since Table 1 presents mainly the characteristics of localised vibrations, it should be supplemented by data on the low-frequency vibrations characterising as a rule the lattice modes of motion. Thus, according to Latour et al.,²⁰ these modes for PVDF crystallised as the α , β , and γ phases are characterised by absorption bands at 100, 70, and 90 cm^{-1} respectively.

The need to characterise PVDF and its copolymers by the degree of crystallinity α frequently arises. The so called ‘crystalline’ or ‘amorphous’ bands are usually found for this purpose in spectroscopic practice for crystallisable polymers. Such bands have been found also for PVDF. The bands at 600, 740, and 905 cm^{-1} have been classified as amorphous and those at 1180 and 1235 cm^{-1} have been classified as crystalline.^{34, 35} According to Kobayashi et al.,²⁵ the 489 cm^{-1} band for PVDF crystallised in the β and γ modification should also characterise the nonordered phase. The 442 cm^{-1} band characterises the chain vibrations in the ‘planar zigzag’ conformation present in the crystal whereas the 510 cm^{-1} band is characteristic of such conformers in the crystalline and amorphous phases.¹⁵ The conclusion that bands sensitive to the presence of fragments with long *trans*-sequences is useful for practical purposes: these are vibrations with frequencies of 840 and 1275 cm^{-1} .²⁷ Regions which may yield information

about the defects of 'head to head' attachment have been differentiated by calculating the densities of vibrational states in PVDF chains.³¹

We shall consider certain crystallographic aspects of the packing of the chains in the unit cell. Fig. 1 presents the unit cell parameters for β -phase crystals. According to Servet et al.¹⁹ and Lando and Doll³⁶, this is an orthorhombic cell belonging to the $Cm2m$ space group and the density of the crystal is 1.97 g cm^{-3} . Fig. 2 presents a schematic illustration of the unit cell of the α

phase with a parallel arrangement of the chains in the lattice. In this case, the cell is monoclinic with the Cc space group, whereas for antiparallel chains it is orthorhombic with the space group $P2_1cn$. In both cases, the cell is found to be nonpolar, since the two chains in the repeat unit have opposite dipole moments. The α_p phase[†] differs from the α phase only by the fact that the overall dipole moment per cell is not zero. The appearance of additional extinctions of the reflections in the case of the α_p phase indicates its greater symmetry compared with the α phase.

The nature of the packing of the chains in the PVDF γ phase is illustrated in Fig. 3. The workers who have studied systematically

† The mechanisms of the formation of this form will be discussed below.

the PVDF structure hold different views concerning the crystallographic identification of the γ phase. One of the reasons for this is the difficulty of obtaining the γ phase in the oriented state. Another one is the possibility of the formation of two modifications of the γ phase. According to Weinhold et al.³⁷ this may be the cause of the assignment of the γ phase to the orthorhombic system with the $C2cm$ space group, on the one hand, and to the

monoclinic system with the Cc space group, on the other. Tables 2–4 present the angular positions of the principal reflections with their identifications and their structure factors (F_{hkl}) for all four polymorphic modifications of PVDF considered.

II. The specific effect of solvents on the conformational characteristics of the chains of poly(vinylidene fluoride) obtained by polymerisation or crystallisation from solution

An attempt has been made³⁹ to obtain PVDF single crystals by crystallisation from solution. A 90:10 mixture of monochlorobenzene and dimethylformamide was used as the solvent. At a solution concentration of 0.01%–0.1% and with the solutions cooled slowly, crystals of the α phase were obtained with a thickness of the lamellae of 90 \AA , the chain axis being arranged at right angles to the surface of the crystal. According to the assignment, crystals with a monoclinic lattice in the β modification were obtained as a result of precipitation from dimethyl sulfoxide. This can hardly be regarded as reliable, since later this conclusion was not confirmed by any investigator using the same solvent. Crystallisation from a good solvent such as dimethyl sulfoxide is most likely to result in the γ phase. For example, Makarevich and Sushko³⁵ and Gal'perin et al.⁴⁰ arrived independently at this conclusion. The crystallisation conditions apparently play a by no means secondary role. Thus, according to the results of Gal'perin et al.,⁴⁰ crystallisation from solution in a good solvent (dimethyl sulfoxide or dimethyl formamide) affords the γ modification of PVDF only at a temperature of the support below 140–150 $^{\circ}\text{C}$. Analysis of the formation of films from solutions in variable solvents showed that the crystals of the γ phase are obtained from solutions in acetone, dimethyl sulfoxide, and ethyl methyl ketone, whilst those of the α phase are obtained from solutions in methyl propyl ketone, dipropyl ketone, butyl methyl ketone, acetophenone, cyclohexanone, or their mixtures.³⁵ The presence of the α phase on crystallisation from solution in cyclohexanone (on the surface of water) has been confirmed indirectly by the presence of spherulites in the crystallised films⁴¹ which are usually produced by crystals of this modification.

The conclusion that the γ phase is formed on crystallisation from a mixture of good and poor solvents for PVDF³⁹ has been confirmed by the results of a study⁴² where monochlorobenzene was again used as the poor solvent, whilst the good solvent was dimethylacetamide. According to this study,³⁹ the γ phase crystallises at a concentration of 0.1%, whereas at a concentration of $\sim 0.5\%$ the α modification is actually produced. It has been noted that the crystals of the γ phase are very resistant to an electron beam, i.e. they are not converted into an amorphous form in the course of 10 min and longer (for comparison, we may note that the crystals of the α phase are preserved for 0.5 min and those of polyethylene for 1.5 min).

The influence of ionogenic impurities (in the polymer and in the solvent) on the characteristic features of the crystallisation process may be traced in relation to solutions of PVDF in cyclohexanone. Thus crystallisation from a 0.02% solution of PVDF in cyclohexanone is accompanied by the formation of a pseudohexagonal structure.⁴³ This was inferred from the ratio of the unit cell parameters: $a/b = 1.73$ (for the pseudohexagonal structure, $a/b = \sqrt{3}$). Taking into account literature data, Miller and Raison⁴³ concluded (in contrast to Makarevich and Sushko³⁵) that PVDF crystallises as a mixture of β and γ phases. However, it was established with the aid of a series of methods for monitoring the crystal structure that crystallisation from this solvent is accompanied by the formation of the α phase or its mixture with the γ phase.⁴⁴ In the latter case, the X-ray method did not permit the estimation of the contributions of each phase and their fractions were therefore calculated from IR spectroscopic data: the γ phase was assumed to be associated

with the presence of absorption bands at 430 and 776 cm^{-1} in addition to others.

Comparison of the published data permits the conclusion that the polymorphic modifications deduced by different investigators for solutions of PVDF in the same solvents are poorly reproducible. This forced Grubb and Choi⁴⁴ to postulate the important role of ionogenic impurities in crystallisation processes. The same workers confirmed this hypothesis later⁴⁵ in relation to dilute (0.01%) and concentrated (5%–9%) solutions of PVDF in dimethylacetamide (or in its mixture with monochlorobenzene). It was observed that an increase in the concentration of ionogenic impurities leads to an increase in the fraction of the γ phase if the polymer crystallises as a mixture of the α and γ phases. This is explained by the fact that, under the conditions governing the formation of crystals with intrinsic polarisation, the latter possess an appreciable electrostatic energy. For example, on the assumption that the perpendicular and parallel components of the dipole moment for the orthorhombic lattice of the γ phase crystal are 4×10^{-30} and 3.4×10^{-30} C m respectively, the surface charge densities on the 100 and 001 planes were found to be $P_a = 0.073$ and $P_c = 0.062$ C m⁻². As a result of an increase in the concentration of ionogenic impurities, the latter are deposited on a plane having the opposite charge and give rise to a depolarising field. An appreciable decrease in electrostatic energy thus has a favourable effect on the crystallisation of the polymer in a polar phase.

The high energy of the electrostatic interaction between the PVDF chains is apparently one of the causes of an unusual phenomenon — the displacement of the solvent from the bulk phase in experiments on the swelling of PVDF in various solvents, including those having a high affinity for the polymer (for example, in dimethylformamide).⁴⁶ Experiments on the swelling of biaxially oriented PVDF film in various solvents (or their mixtures) have shown that the equilibrium swelling tends to decrease with increase in the amount of precipitant in dimethylformamide — water and acetonitrile–water mixtures. It was noted that even the best solvents have a low affinity for the polymer, which is approximately the same for the α and β modifications. The remark by Chapiro et al.⁴⁶ that all solvents are spontaneously desorbed from the film after its removal from the medium (liquid or gaseous) owing to the higher energy of the polymer–polymer interaction is significant.

Yet another contradiction, noted when data on the crystallisation of PVDF from acetone were compared, can probably also be accounted for by the influence of ionogenic impurities on the nature of the polymorphic modification formed when PVDF crystallises from solutions. According to the data of Makarevich and Sushko,³⁵ this process results in the formation of the γ phase, whilst according to those of Kochervinskii et al.⁴⁷ this should be the α phase, since bands typical of the $TGT\bar{G}$ conformers were observed in the IR spectrum: 100, 214, 287, 411, and 530 cm^{-1} , etc. It is noteworthy that the crystallisation from acetone in the latter study⁴⁷ was accompanied also by a significant change in the nature of the morphology. If the polymer crystallises from the melt, spherulites with a high birefringence coefficient are formed. In contrast to this, spherulites were hardly noted in the film crystallised from acetone.

Yet another cause of the contradictions noted in different investigations may be failure to take into account other factors, for example, the molecular mass, the characteristics of the molecular mass distribution (MMD), the number of 'head to head' defects, the form of the end groups, etc., data on which are not always reported. One should apparently consider separately the characteristics of crystallisation from solutions not of the homopolymer but of the VDF–TFE 94/6 copolymer, which, in contrast to the homopolymer, crystallises from the melt at once mainly as the β phase.^{32,48} It has been observed that the crystallisation of this copolymer from an 8% solution in pure dimethylformamide leads to the formation of the β phase with a morphology comprising spherulites with an average size of 2–3 μm .⁴⁸ The crystallisation of the same copolymer from

solution in a 76:24 dimethylformamide–ethyl acetate mixture leads to an appreciable alteration of the morphology of the β phase formed. In this case, the spherulites are no longer formed and the film (in contrast to the film obtained from pure dimethylformamide) is characterised by an optical transparency which is several times greater. Analysis of the results of X-ray analysis has shown³² that the size of the crystallites for the coexisting ferroelectric and paraelectric phases is smaller in the case of crystallisation from the solvent mixture and the fraction of the paraelectric phase is also reduced.

It appears attractive to use the phenomenon of epitaxy for the formation of the required polymorphic PVDF modification. In this case, one should consider the results of several studies in which the crystallisation of PVDF from solution onto a support of a particular crystal was investigated. Thus the crystallisation of the homopolymer of the Kynar 460 type ($M_w = 451\,000$, $M_n = 160\,000$) from 6.3 vol.% solution in dimethylacetamide on the surface of a KBr crystal at 60 °C leads to the formation of a nonoriented γ phase,²⁶ while crystallisation of the same crystal (on the 001 plane) from a dilute solution (0.1%) of PVDF in dimethylformamide at a temperature of the support of 165 °C leads to the formation of lamellar crystals of the β phase oriented along two directions in the 110 plane of the support.⁴⁹ An exact correspondence of the lattices in epitaxial crystallisation is not obligatory, since the difference between the identity periods of the substrate and support ranges from 4.3% to 5.6%. Analysis of electron diffraction patterns has shown that the bc plane of the unit cell of the PVDF β phase grows parallel to the plane of the support, the growth being directed predominantly along the b axis. Crystallisation from a dilute solution of PVDF in dimethylformamide onto the 001 plane on the surface of muscovite or NaCl at 180 °C has been investigated.⁵⁰ The γ phase formed is characterised by a monoclinic cell with a 93 °C angle and the $T_3GT_3\bar{G}$ conformation of the chain. The possibility of the formation on NaCl of two lattices with mirror symmetry relative to the 001 plane of the substrate has been demonstrated. According to the ideas developed, the possibility of the formation of a modification of the γ phase with antiparallel packing of the dipoles in the cell is not ruled out. Epitaxial crystallisation of a copolymer of vinylidene fluoride and vinyl fluoride (molar ratio 95/5) has been investigated.⁵¹ The crystallisation was carried out from a 0.1% solution in nitrobenzene at 90–105 °C onto the 001 planes of NaCl and KCl crystals. Lamellar crystals with a rod-like morphology are formed in both cases (according to electron microscope data). Electron diffraction patterns have shown that more perfect crystals are formed on the KCl support than on the NaCl support, although their size is greater in the latter case.

The differences are explained by the unequal concentrations of specific defects on the surface of the support, which are the nucleation sites. The above copolymer crystallises as the orthorhombic β phase, which has been confirmed by electron diffraction data. The reflections have been indexed as $0kl$, which implies that the bc plane of the cell grows parallel to the plane of the support.

The studies of the influence of the conditions of the synthesis of PVDF on its crystallographic and conformational characteristics must be analysed in the light of the data considered. In one of the early studies,⁵² the characteristics of the polymer obtained for different methods of initiating the polymerisation of VDF were compared. It was shown that the change from chemical to radiation-induced initiation is accompanied by a transition from the β phase crystals to those of the weakly ordered α phase. It was observed later that the decisive factor in the formation of a particular polymorphic modification is nevertheless the medium and not the initiation method.⁵³ Indeed, whereas the radiation-induced initiation in the gas phase is characterised by the formation of the relatively imperfect α phase, the transition in an aqueous medium is accompanied by the appearance of β crystals, i.e. the 'planar zigzag' conformation of the chain proves to be more favourable for the chain in a polar condensed medium in which the polymerisation takes place.

The study of the influence of the initiation method on the nature of the morphology of the films obtained on crystallisation from solution of the polymerisation products has shown that, regardless of the molecular mass of the polymer, chemical initiation always results in the formation of spherulites with an average size of 1–12 μm .⁵³ On radiation-induced initiation, the spherulites are formed in the film only for molecular masses below 2×10^5 . With increase in molecular mass, dendritic crystals appear initially and then structures of the 'shish-kebab' type. PVDF obtained by the radiation-induced cross-linking has been characterised in greater detail by Doll and Lando.⁵⁴ Analysis showed that the polymerisation conditions do not affect significantly the number of 'head to head' defects, which varied in the range from 6.8% to 9.7%, but may be reflected appreciably in the molecular mass of the chain formed. For example, the radiation polymerisation of VDF in acetone is accompanied by an appreciable decrease in the intrinsic viscosity of the product compared with that of the commercial polymer obtained by suspension polymerisation. At the same time, this leads to an increase in the melting point of the former by 15–17°.

Polymerisation in dimethylacetamide, dimethylformamide, and dimethyl sulfoxide is accompanied by the crystallisation of the polymer with the 'planar zigzag' conformation (β phase), but the polymers are distinguished by instability and are degraded on heat treatment. Polymerisation in fluorine-containing solvents (trifluoroacetic acid, etc.) leads to a high-molecular-mass product, which may ensure the formation of a well oriented state under the conditions of uniaxial stretching. Fairly unusual properties have been reported for PVDF obtained by a special type of polymerisation ensuring single additions of the repeat units to the chain.⁵⁵ The polymer obtained exhibits a weak absorption of water and has enhanced electrical parameters (specific volume resistance, breakdown potential, etc.) The effective electret characteristics of the films obtained from the above polymer are also included among its quite unusual properties (admittedly these were not subsequently confirmed by any investigator). Thus it has been noted that the electret charge (with a surface density of 10–20 CGSE charge units per cm^2) may be retained for ten years and does not require preliminary protection by 'short circuiting' the charged surfaces. The electret charge is also more resistant to the effect of temperature and various media (air, oil, solvents).

Certain properties of polymer with a reduced number of 'head to head' defects in the chains (2.7%–3.2%) have been reported.⁵⁶ New types of initiators and catalysts (for example, Ziegler–Natta catalysts) were employed in this investigation. Comparison of the characteristics of this polymer and those of commercial PVDF (having 6% of irregular attachments) showed that the extinction of the absorption bands characteristic of the different polymorphic modifications of the polymer varies in the sequence $\alpha > \beta > \gamma$, whereas for the commercial product it varies in the sequence $\alpha < \beta < \gamma$. According to the results of Liepins et al.,⁵⁶ the crystallisation of the new polymer from hot dimethylformamide results in the formation of crystals of the α phase[†] whilst the crystallisation of the commercial PVDF affords crystals of the β phase. Thus, when the concentration of the chemical irregularities along the PVDF chain is reduced, the $TGT\bar{G}$ conformation becomes energetically more favourable than the $T_3GT_3\bar{G}$ or 'planar zigzag' conformation.

In a number of studies,^{57–61} attention was concentrated on the investigation of the influence of the end groups in the PVDF chains on the properties of the polymer, including its properties in the block state. It was noted that the radical polymerisation of VDF in an aqueous medium under the influence of two different initiators — potassium persulfate (PPS) and β -hydroxyethyl *tert*-

butyl peroxide (HETBP) — is accompanied by a significant change in the properties of the polymer obtained. When PPS was used, the number of volatile substances in the latter proved to be higher by an order of magnitude,⁵⁸ which was manifested by a reduced thermal stability of the polymer.⁵⁹ The results obtained by analytical methods, including isotope analysis,⁶¹ showed that CH_3 end groups predominate in polymerisation with participation of HETBP, whereas in polymerisation involving PPS there is a possibility of the formation of hydroxy-groups at the ends. In the version involving the addition of $\sim\text{CH}_2\text{--CF}_2\text{--OH}$ groups, the latter prove to be unstable and there is a possibility of dehydrofluorination reactions with elimination of HF in accordance with the mechanism $\sim\text{CF}_2\text{--OH} \rightarrow \text{HF} + \sim\text{CF}=\text{O}$.⁵⁹ The thermal stability and the electrophysical characteristics of the polymer are impaired under these conditions. According to the ideas developed,⁵⁹ this difference in the macroproperties can be explained precisely by the type of end groups, since other characteristics of the microstructure hardly differed in the two polymers (the number of irregular attachments, the molecular mass of the chain).

The difference between the end groups in PVDF noted above can be manifested also in finer details on the formation of the polymer by crystallisation from the melt. It has been shown⁶² that, in the isothermal crystallisation of polymers under identical conditions, the spherulites formed for PVDF with PPS proved more perfect and were larger than for PVDF with HETBP. Under the conditions of nonisothermal crystallisation in PVDF with PPS, only 'normal' spherulites were formed, whereas for the other initiator it was possible to find also 'anomalous' spherulites, differing from the former in the way in which the lamellae were packed along the spherulite radius. Films based on PVDE with HETBP, obtained on rapid nonisothermal crystallisation, may involve the formation of spherulites with a bimodal size distribution, in contrast to the films based on PVDE with PPS. The difference between the end groups and hence between the morphologies of the films affected indirectly also the characteristics of the molecular mobility in the nonordered phase in the vitrification region.⁶² Whereas the average relaxation times differed only slightly in the two polymers, this could not be said of either the form of the relaxation time distribution curve or of the magnitude of the total dielectric absorption.

Several investigations touched upon the question of the influence of the polymerisation temperature on the properties of the polymer obtained. Thus, according to the data of Madorskaya et al.,⁶³ for the copolymerisation of VDF with TEF, an increase in the synthesis temperature from 303 to 373 K gives rise to a tendency towards an increase in the number of 'head to head' defects (from 3.5% to 4.7%)[§] for an approximately similar molecular mass of the chain. This leads to a small decrease in the equilibrium melting point and the enthalpy of fusion and to an almost two fold increase in the half-crystallisation time. An increase in polymerisation temperature leads to an increase not only in the number of chemical irregularities in the chain but also in the number of branches in them. For another VDF copolymer (with fluorovinyl ether), an increase in emulsion polymerisation temperature leads to even more striking changes: whereas at low synthesis temperatures the copolymer is characterised by a unimodal molecular mass distribution, at high temperatures it has a bimodal distribution. It is concluded that an increase in the synthesis temperature increases the low-molecular-mass fraction. The study of various factors influencing the microstructure of the VDF homopolymer with the aid of gel-permeation chromatography, electron microscopy, and sedimentation analysis showed that the kinetic parameters of the polymerisation process, the molecular mass distribution, and the dimensions of the latex particles depend primarily on the presence of the emulsifying

† In this and all other casts where one is dealing with crystallisation from a solution in hot dimethylformamide of a VDF/TFE copolymer, one should note that the process is accompanied by dehydrofluorination reactions with formation in the chain of new functional group of the type $-\text{CH}=\text{CF}-$, $\text{CH}=\text{CF}_2$, $\text{C}=\text{O}$.

§ Cais and Soane⁶⁴ also arrived at the same conclusion in the analysis of the NMR spectra of two types of PVDF with different numbers of chemical irregularities in the chain.

agent in the reaction medium. The polymer synthesised in the presence of the latter is linear, in contrast to the randomly branched polymer formed in a system without an emulsifying agent.⁶⁵

III. The influence of various factors on the polymorphism of poly(vinylidene fluoride) in the isotropic state

For the practical use of PVDF, for example in sensors of different kinds,³ the choice of crystallisation conditions which would ensure the formation of the required polymorphic modification is important. It was shown above that this can be achieved by selecting a suitable solvent in crystallisation from solution. In the present section, attention is concentrated on the analysis of the characteristics of crystallisation from the melt (at not very high pressures) with emphasis on the discovery of the role of defects in the chemical attachment of units to the chain and on the previous thermal history of the specimen being crystallised.

Doll and Lando devoted several of their studies of the polymorphism in PVDF^{36, 37, 66–70} to the discovery of the influence of 'head to head' type defects (HHTT) on the characteristic features of its crystallisation. The fraction of the above defects was varied by copolymerisation with TFE or TrFE. It was shown that the VDF/TFE 93/7 copolymer is in the polymorphic β modification even in the isotropic state on crystallisation from the melt, whereas the homopolymer always constitutes the α phase under the same crystallisation conditions. Here it is evidently necessary to emphasise the special role of the TFE comonomer, since the VDF/TrFE 91/9 copolymer still crystallises, like the homopolymer, in the form of the α phase. Different workers attribute this to the easier cocrystallisation of the CF_2CF_2 groups with similar groups in PVDF, where the latter also enter into the composition of the usual chemical irregularities of the homopolymer chains. Tables 5 and 6 present the interplanar spacings d and the indexing of the reflections for the β phases of the homopolymer and the VDF/TFE 93/7 copolymer. The tables show that the spacings d , in particular for the intermolecular reflection 200, differ appreciably in these phases.

Table 7 presents the unit cell parameters for PVDF and three of its copolymers. Evidently the introduction of the TFE comonomer into the chain leads to an appreciable loosening of the lattice in the basal plane precisely for the β phase.

The equilibrium packing density in the crystal depends on the number of the defects noted above, so that one may expect also their influence on the kinetic parameters of the crystallisation. This influence has been studied in detail in the crystallisation of the α phase.^{71–73} The kinetics of the crystallisation of a large

number of PVDF specimens differing both in the number of 'head to head' defects and in the molecular mass have been investigated.⁷⁴ The fraction of the former was varied in the range 3.3%–6.1%, while the molecular mass was varied by more than an order of magnitude from 52 000 to 703 000. Differential scanning calorimetric (DSC) data were interpreted in terms of the Hoffman–Weeks relation in the model with nucleation on folded chains. The following relation is valid for this model:

$$T = T_0 \left(1 - \frac{2\sigma_e}{\Delta H_f l} \right), \quad (1)$$

where T is the experimentally measured melting point, T_0 the equilibrium melting point for a perfect crystal with an infinite thickness, σ_e the free energy of the 'fold surface' of the nucleus, ΔH_f the heat of fusion per unit volume of the crystal, and l the thickness of the lamella.

One of the tasks in the study by Chen and Frank⁷⁴ was to elucidate the question of the location of the 'head to head' defects, namely whether they enter into the composition of the lamella or are displaced on crystallisation into the interlamellar region. Evidently, the former is valid, since the thermodynamic stability of the crystallites decreases with increase in the fraction of the above defects. For a hypothetical defect-free specimen, $T_0 = 481.3$ K is obtained. It has been noted that the linearity of the T –fraction of HHTT relation agrees with the prediction based on Flory's theory⁷⁵ and on the Sanchez model⁷⁶ if it is assumed that the 'head to head' defect can be regarded as a comonomer unit. The degrees of crystallinity calculated from the heats of fusion on the assumption that $\Delta H_f = 1570$ cal mol^{−1} also decrease linearly with increase in the fraction of the defects. The degrees of crystallinity based on DSC data, corrected by the linear dependence of ΔH_f on the fraction of defects, agree very well with the degrees of crystallinity obtained from density data. The degree of crystallinity of a specimen free of the above defects, found by extrapolation, is 82.5%. The study of PVDF specimens with approximately the same number of irregular junctions but differing in molecular mass has led to the conclusion that the degree of crystallinity may depend also on the molecular mass, other conditions being equal.

The above experimental facts, indicating the influence of the HHTT type defects on the nature of the packing of the chains in

the lattice, initiated the development of studies on the theoretical justification of the above phenomenon. For this purpose, the nature of the variation of the potential energy of both isolated PVDF chains and of block PVDF as the number of defects in the HHTT form or in the form of the TFE comonomer is varied was analysed in detail.⁷⁷ For an isolated chain having the *TGTG* conformation, an increase in the number of defects of both types leads to a linear increase in the potential energy. For an isolated chain in the 'planar zigzag' conformation, the potential energy also increases linearly with increase in the number of defects in the form of the TFE comonomer, whereas for the HHTT defects it diminishes. Therefore the potential energy of an isolated PVDF chain with the 'planar zigzag' conformation and a content of HHTT defects in excess of 10% also proves to be lower than for a chain with the *TGTG* conformation (in contrast to defect-free chains). However, the use only of data on intramolecular interactions (isolated chain) can give rise to serious errors in the conclusions concerning the influence of the number of defects on the properties of a real block polymer, since it is obligatory to take into account also the change in the nature of the packing (intermolecular interactions). For PVDF with 5% of type HHTT defects, it has been shown that some increase in the potential energy minimum is observed for both forms of the polymer. More complete data are presented in Table 8.

Evidently the introduction of 5% of HHTT defects into the chain has a more significant influence on the intermolecular component of the energy. Comparison of the nature of the change in the total energy for the β and α phases in the monoclinic system (usually adopted by the majority of investigators) has shown that the changes are greater in the former case. This agrees qualitatively with the conclusion that the loosening of the α phase lattice is less marked compared with the β phase when comonomers are introduced into the PVDF chain (Table 7).

In order to develop their concept, Chen and Frank⁷⁴ investigated the influence of the concentration of the HHTT defects on the characteristics of the solid-phase $\alpha \rightarrow \gamma$ transformation. We shall consider the principal features (based on the data of different investigators) of this transformation. Ishida and coworkers and Prest and Luca⁷⁸⁻⁸⁰ should apparently be regarded as the first to report the possibility of this process, their papers being published at approximately the same time. In the study of the annealing defects in PVDF, it was shown⁷⁸ that the γ phase, or more precisely its further two modifications, appear during high-temperature annealing in the α phase of PVDF specimens crystallised from the melt.⁷⁹ The above phases were identified from specific absorption bands: these are the 530, 767, 796, and 855 cm^{-1} bands for the α phase and the 510, 779, 809, and 833 cm^{-1} bands for the γ phase (Table 1). In the general case, three melting endotherms were observed on the DSC curves, one of which is presented in Fig. 4. It was shown by spectroscopic methods that the lowest-temperature fusion peak (P_3) is associated with the α phase, and that the two peaks at higher temperatures (P_2 and P_1) are associated with the γ phase. It has been suggested that the fraction of the latter be estimated from the ratio of the optical densities of the 510 and 530 cm^{-1} absorption bands:

$$F(\gamma) = \frac{D_{510}}{0.81D_{530} + D_{510}} \quad (2)$$

Figure 4. The melting endotherm for PVDF crystallised as the α phase after high-temperature annealing (a) and the variation of the ratio of the peaks on the melting endotherm as a function of the annealing temperature (b).⁷⁹

Eqn (2) was obtained by interpreting the results of experiments with different film thicknesses. Such experiments made it possible to determine the molar absorption coefficients of the above bands: $K_\alpha = 10 \times 10^3$ and $K_\gamma = 8.1 \times 10^3 \text{ cm}^2 \text{ mol}^{-1}$. The variation of the fractions of the α and γ phases as a function of the annealing temperature T_a is illustrated in Fig. 4b. Evidently in the range $T_a = 160-170^\circ\text{C}$ the fraction of the former phase decreases sharply, whilst that of the second increases appreciably. This has been attributed to the occurrence of the high-temperature solid-state transformation $\alpha \rightarrow \gamma$. The equilibrium melting points of the α and γ phases, found with the aid of the Hoffman-Weeks relations, are 188 and 218°C respectively. Prest and Luca⁸⁰ investigated the high-temperature crystallisation of PVDF, the morphology of the PVDF being studied together with the phase analysis. According to their data,⁸⁰ the melting endotherm is also characterised by three fusion peaks, but (in contrast to the paper by Osaki and Ishida⁷⁹) the peak with the intermediate temperature is assigned to the fusion of the β phase. The morphology of the specimen is characterised by the presence of spherulites with negative birefringence (Δn) and a bimodal size distribution. The largest spherulites (with a high Δn) are attributed to the α phase, whilst the small ones (with a low Δn) are attributed to the β phase. The γ phase crystals produce structures which give rise to a specific pattern in crossed polarisers, called by Prest and Luca⁸⁰ a 'wagon wheel', and not a Maltese cross.

Table 8. The energies of two polymorphic modifications of PVDF with and without allowance for type HHTT defects.⁷⁷

Modification of PVDF	β Phase			Monoclinic α phase			Triclinic α phase		
	I	II	III	I	II	III	I	II	III
Without HHTT	-16.4	-64.5	-80.9	-21.6	-57.7	-79.3	-21.6	-63.9	-85.5
With 5% of HHTT	-16.6	-58.6	-75.2	-19.5	-56.5	-76	-19.5	-56.3	-76.4

Note. The following designations have been adopted for the energy (kcal mol^{-1}): I — intramolecular; II — intermolecular; III — total.

Somewhat later, the same investigators concluded⁸¹ that the acceleration of the crystallisation process in the $\alpha \rightarrow \gamma$ transformation may be ensured by introducing surface-active additives. The tentative mechanism of their action is believed to be associated with the fact that, on fusion of the α phase, the molecules of the additives retard the diffusion of the chains in the melt and hence increase the probability of the stabilisation of the fluctuation nuclei of the γ phase. These questions were investigated in greatest detail in a series of studies.^{82–85} Their authors observed three types of spherulites depending on the crystallisation temperature T_c . For low T_c ($< 150^\circ\text{C}$), spherulites with the α phase are produced, whilst at higher T_c the so called mixed spherulites are formed where large spherulites of the α phase and small spherulites of the γ phase coexist. The latter have a low Δn owing to the poor regularity of the arrangement of the lamella along the spherulite radius. For still higher T_c , spherulites of the pure phase are formed. As in the study of Prest and Luca,⁸⁰ they are characterised by the 'wagon wheel' scattering figure. A general feature has been noted for the two types of PVDF: for low T_c , the α spherulites grow faster than the mixed ones, whereas for higher T_c the mixed spherulites actually increase faster than the α spherulites. It is concluded that the solid-state transformation $\alpha \rightarrow \gamma$ begins in mixed spherulites at the boundaries of coexistence of the α and γ phases. The latter grows in the direction opposite to that of the growth of the α phase spherulite. It was shown that the rate of the transition $\alpha \rightarrow \gamma$ along the spherulite radius is much higher than in the tangential direction.

The questions concerning the possible degradation of the polymer and the high crystallisation temperatures necessary for the $\alpha \rightarrow \gamma$ transition have been examined.⁸⁵ Attention was drawn to the fact that the specimens crystallised under the conditions mentioned above (high temperatures and long times) have a yellowish colour. It is believed that thermal degradation reactions may occur under these conditions together with the transformations $\alpha \rightarrow \gamma$. The colouring of the specimens is heterogeneous in character, since the colour centres are mainly located in the regions of the γ phase formed. It has been suggested that the chains in this phase have an increased intramolecular energy. In stressed chains of this kind, the occurrence of dehydrofluorination reactions with formation of $\text{CH}=\text{C}-\text{CH}=\text{CF}$ groups, responsible for the appearance of the colour, is more likely at high temperatures.⁸⁵ The mechanism of the parallel occurrence of the thermal degradation reactions can apparently be also more complex if account is taken of data on the characteristics of the dynamics in PVDF.

As in the above studies,^{80–85} Kochervinskii et al.⁶² observed two types of spherulites, which differed in the magnitude of the Δn and in the average size, on high-temperature nonisothermal crystallisation of two types of the homopolymer (with different end groups). On the basis of the results of the analysis of the form of the absorption bands for the symmetrical and antisymmetrical stretching vibrations of the methylene groups, the small spherulites were attributed to the γ phase.⁶² Attention was drawn to the fact that the PVDF obtained by suspension polymerisation (PVDF-S) exhibits, under identical crystallisation conditions, a higher degree of the $\alpha \rightarrow \gamma$ transformation and a more intense colour than the PVDF obtained by emulsion polymerisation (PVDF-E). This means that the thermal degradation reactions should occur more vigorously for PVDF-S. The relaxation times of the cooperative forms of motion in the noncrystalline regions, extrapolated to the region of the crystallisation temperatures for PVDF-S, proved to be several orders of magnitude shorter than in PVDF-E. Since the amorphous sections in the crystallising polymers may be 'weak' sites in the thermal degradation reactions, the probability of such processes should be higher precisely in PVDF-S, where the average relaxation time is shorter (the frequency of the reorientations of the segments of the amorphous phase is higher). One may postulate that the higher degree of the $\alpha \rightarrow \gamma$ transformation noted in PVDF-S can be explained precisely by the characteristic features of its dynamics in the nonordered

regions of the polymer. Indeed, the packing density of the γ phase lattice is higher than that of the α phase lattice. The polymorphic transformations $\alpha \rightarrow \gamma$ should therefore be accompanied by an increase in the free volume, which is naturally located in the interlamellar regions. Since the relaxation times of the chains of the amorphous phase are inversely proportional to the fraction of the free volume, there should in fact be shorter relaxation times in PVDF-S, which has been confirmed experimentally.⁶²

Conclusions similar to those examined above have been obtained also in a study⁸⁶ where the crystallisation in the temperature range $151\text{--}161^\circ\text{C}$ was also accompanied by the formation of spherulites of two types. The DSC curves reached in this study are qualitatively similar to those presented by Osaki and Ishida⁷⁹ (Fig. 4). Morra and Stein⁸⁶ also observed three fusion peaks but only the P_2 and P_1 peaks were attributed to the fusion of the γ and γ' phases respectively. It was postulated that the first phase is formed on crystallisation, whilst the second is produced as a result of the transformation $\alpha \rightarrow \gamma$. It is assumed that the formation of the α phase is kinetically favourable, whilst that of the γ phase is favoured by thermodynamic factors. On the one hand, it is concluded that the γ and γ' modifications are crystallographically identical but differ markedly morphologically. On the other hand, the α and γ' modifications have identical morphologies but are crystallographically completely different.

In experiments with wide variation of the molecular masses of PVDF and the type HHTT defects, an attempt was made⁸⁷ to discover the characteristic features of the influence of the latter on the polymorphic transformations $\alpha \rightarrow \gamma$. The dependence of the degree of transformations $\alpha \rightarrow \gamma$ on the content γ of phase spherulites was found from DSC data. According to the authors,⁸⁷ the observed linear relation confirms the conclusion that the polymorphic transition $\alpha \rightarrow \gamma$ occurs mainly along the boundaries of the coexisting phases. The influence of the concentration of the HHTT defects both on the fraction of the interlamellar amorphous phase and on the content of γ spherulites was considered for PVDF specimens crystallised at 433 K in the course of 24 h. In the first case, the increase in irregularities increases sharply the fraction of amorphous regions. In the second case, it was concluded that an increase in the fraction of chemical irregularities in the PVDF chain should be reflected in a complex manner in the degree of polymorphic transformations $\alpha \rightarrow \gamma$. This conclusion is due to the fact that the fractions of the amorphous interlamellar phase and of γ spherulites have opposite effects on the degree of the $\alpha \rightarrow \gamma$ transformation.

Thus the experimental data indicate the possibility of the high-temperature polymorphic transformation $\alpha \rightarrow \gamma$. In a series of studies,^{88–90} this transition was predicted theoretically — by calculating the free energy of the PVDF chain in various conformations.

A number of studies^{91–97} have dealt with questions concerning the detailed specification of the conformational rearrangements in PVDF chains in the transition mentioned above. The authors began with the concept that regions of conformational disorder arise (the presence of kink bonds), a confirmation of which was found in the consistent blurring of the 02 ξ reflections.⁹² Fig. 5 presents the detailed pattern of the changes in the chain conformation for α phase crystals in the region of the formation of 'kink' defects, where sections of the chain in the $TGT\bar{G}$ conformation alternate with bonds in the 'planar zigzag' conformation, the number of which may be even or odd. Model studies on different versions of the formation of kink bonds led to the conclusion that the formation of kinks with an odd number of monomer units is more probable. The best agreement with experiment occurs if it is assumed that the kink contains one monomer unit (two neighbouring bonds in the TT position). For its formation, it is necessary to postulate the transition $TGT\bar{G} \rightarrow T\bar{G}TG$, which takes place as a result of a 'flip-flop' type of movement with subsequent transition from G or \bar{G} to T . It is emphasised that the first stage of this transition is decisive.

Figure 5. Schematic illustration of the formation of kink bonds in the α modification of PVDF.⁹⁷

Overall, the nature of the transition should be distinguished by its cooperativeness.

According to Lovinger's conclusions,⁹⁸ 'flip-flop' movements with participation of three bonds are more favourable than movements involving five–seven bonds. This means that the conformational rearrangement in the transition must proceed via a two-stage mechanism. An intermediate state (with a low potential energy) is formed in the first stage in accordance with the scheme

The second stage involves the formation of the polar lattice of the γ phase, which should be accompanied by the reorientation of each second chain of the cell, which may occur as a result of the inverse movements of the chain with the altered conformation (Fig. 6b).⁹⁷

We shall now deal with the analysis of a series of results obtained in the study of the formation of the isotropic ferroelectric β phase of the pure VDF homopolymer on crystallisation from the melt in accordance with a definite regime.

The appearance of β crystals on quenching thin (~ 100 nm) films of the PVDF melt in a medium with liquid nitrogen, melting ice, or even in water at room temperature was reported by Hsu and Geil.⁹⁹ It is emphasised that a significant factor in this process is the film thickness. For example, for a film μm thick, β crystals are formed only in the surface, whereas α crystallites are produced in the bulk phase. Later the same workers investigated this phenomenon in greater detail.¹⁰⁰ They varied the temperature of the quenching agent more widely and the results of electron diffraction were supplemented by the results of the study of the

Figure 6. Two modes of molecular motion associated with the solid-state transformation $\alpha \rightarrow \gamma$. (a) Segmental 'flip-flop' motion; (b) inverse motion.⁹⁷

morphology of the films formed on quenching. According to data obtained by transmission electron microscopy, the most homogeneous structure is obtained in films quenched in liquid isopentane. At quenching temperatures of 136 and 273 K, inhomogeneous 20–30 nm sections are seen. At a quenching temperature of 288 K, it is possible to see the appearance of individual fibrils with a transverse dimension of 25 nm and a length up to several hundreds of nanometers. An increase in the quenching temperature to 313 K complicated the morphology somewhat, but crystals of the β phase are formed in all cases. The possibility of obtaining the latter at fairly high quenching temperatures has been confirmed also by other workers.^{101, 102} In these studies the 'planar zigzag' conformations, detected from the 470, 510, 840, and 1280 cm^{-1} absorption bands, were noted for films at a quenching temperature of 303 K. An increase in temperature to 358 K leads to the formation of the α and γ phases together with the β crystals, the size and perfection of the α and γ crystals increasing with increase in the quenching temperature.¹⁰⁰ The morphology of the films becomes more complicated: together with fibrils, structures of incomplete spherulites appear.

Similar results were obtained also in another study, where type KF200 PVDF films 10–15 μm thick were quenched from the melt in melting ice. The appearance of absorption bands at 442, 470, and 510 cm^{-1} , characteristic of the 'planar zigzag', was also noted in the IR spectra of the quenched films. However, it is significant that the conformers obtained apparently serve as nuclei in the subsequent annealing, since the intensity of the above band increases. The results of X-ray studies have shown that the annealing is accompanied by the improvement of the β phase crystals, since the narrowing of the main intermolecular 100, 200 reflection is observed.

Figures 7 and 8 illustrate the scheme which explains the appearance of β crystals on crystallisation under the conditions of rapid quenching. It is postulated that the rate of nucleation is characterised by a distribution curve, the rate maximum for the α phase being displaced towards higher temperatures compared with that for the β phase (Fig. 7). The time taken to traverse the $T_3 - T_4$ (t_α) temperature range depends on the rate of cooling of the melt (Fig. 8). Then the rate of cooling is high, t_α proves to be low and there is insufficient time for the formation of the nuclei of the α phase. Since the maximum in the rate of nucleation for the β phase is displaced towards lower temperatures, the time taken to traverse the temperature range $T_1 - T_2$ is longer and may be sufficient for the formation of β crystals. Estimates¹⁰³ have shown that such crystals may be formed at rates $> 800 \text{ K s}^{-1}$. The above hypothesis has been confirmed also by the results of thermal analysis.^{104, 105} An increase in the rate of cooling of the melt of the VDF homopolymer creates a tendency towards a displacement of the main crystallisation peak towards lower temperatures, whilst quenching in liquid nitrogen leads to its shift into the region of temperatures actually below 300 K.

Figure 7. Temperature variation of the rate of nucleation for the α and β phases.¹⁰³

Figure 8. Diagram illustrating the formation of α and β crystallites on rapid (1) and slow (2) quenching.¹⁰³

Under real experimental conditions (fairly thick specimens and not unduly high rates of cooling), nuclei of both phases are apparently formed, although their fraction in the α modification may in fact be low. This is confirmed by the fact that, together with the bands due to the β phase, there are a further two bands (612 and 765 cm^{-1}) characteristic of the $TGT\bar{G}$ conformations.¹⁰³ Analysis of the X-ray diffraction profile indicates that there are few nuclei of the α phase and they do not attain large sizes, since reflections characteristic of the α phase have not been noted. Annealing of the quenched specimens leads to an increase in the number of $TGT\bar{G}$ conformers, since the intensity of the above bands increases. The possible structure of such defective regions of the α phase has been examined on the basis of the results of thermal analysis.^{104, 105} It was noted that, on rapid cooling of the melt ($\geq 10 \text{ K min}^{-1}$) of the VDF homopolymer, an additional endotherm appears on the DSC curves in the range 320–350 K of the kind not observed for specimens obtained at low rates of cooling.¹⁰⁵ The appearance of this endotherm had been attributed to the existence of conformational disorder in the imperfect crystals of the α phase (condis-crystal). In terms of Takahashi's concept,¹⁰⁶ when the PVDF chains have the same $TGT\bar{G}$ conformation, they may assume four possible orientations under the conditions of nonequilibrium crystallisation temperatures (Fig. 9) — AC , $\bar{A}C$, $A\bar{C}$, and $\bar{A}\bar{C}$. Evidently the fluorine atoms may be located above (\bar{C}) or below (C) and to the left (\bar{A}) or to the right (A) relative to the molecular axis. Since the CF bonds have a high dipole moment, such orientations are characterised by different directions (upwards or downwards) of the axial component of the dipole moment. The transition from the A to the \bar{A} orientation is possible as a result of rotation about the c axis, while the C and \bar{C} states are obtained by the mirror reflection relative to this axis. The transitions between the above orientations, occurring as a result of the movement of the entire chain are impossible because of the very high activation barrier, but they can be achieved as a result of local conformational rearrangements.

The studies, mentioned above, of the influence of the copolymerisation of VDF with TFE and TrFE⁶⁷ on the change in the equilibrium polymorphic modification of the homopolymer have greatly developed recently. This was caused by two facts. On the one hand, it was the discovery of ferroelectric properties in PVDF: it was found, in the presence of fairly high contents of the second component, that the ferroelectric–paraelectric transitions in the

Figure 9. The possible orientations of the chains of the PVDF α phase in the $TGT\bar{G}$ conformation.¹⁰⁵

VDF/TrFE copolymers and fusion proper differ appreciably as regards temperature, which makes it possible to employ this copolymer as a model compound for the study of the mechanism of the appearance of ferroelectric properties in organic polymers. On the other hand, modifications of the materials employed, particularly those with increased piezoelectric constants, were needed for practical purposes. Therefore, when it was shown for a series of VDF/TrFE copolymers¹⁰⁷ that an approximately equimolar component ratio in the copolymer leads to a significant increase in both the electromechanical coupling factor and in the piezoelectric constant d , the interest in the study of the structures of the above copolymers increased.

Initially Lovinger et al.¹⁰⁸ demonstrated in relation to the VDF/TrFE 52/48 copolymer that the specimen crystallised from the melt consists of a mixture of two disordered crystalline phases, one of which is characterised by the 'planar zigzag' conformation, whereas the other has the 3/1 helical conformation. The wide variation of the composition of the copolymer made it possible to obtain later more detailed information about its crystal structure.¹⁰⁹ On the basis of the analysis of the results of detailed X-ray diffraction patterns and spectra over a range of temperatures, the authors concluded that the low-temperature phase (LTP), a cooled phase (CP), and a high-temperature phase (HTP) exist in the isotropic state. Comparison of model calculations with experiment showed that the 'planar zigzag' conformation in the LTP should be characterised by a deviation from the plane by an angle 2σ . As for the β phase of the VDF homopolymer,^{110, 111} this conclusion follows from the passage of the relative difference between the calculated and observed structure factors (the R factor) through a minimum as the angle σ is varied. When such chains are packed in the cell, the following parameters of the low-temperature phase are obtained: monoclinic system, $a = 9.12 \text{ \AA}$, $b = 5.25 \text{ \AA}$, c (chain axis) $= 2.55 \text{ \AA}$, $\beta = 93^\circ$, tilt angle (in the 130 plane) $= 3^\circ$. The scheme of the transitions in the above copolymers¹⁰⁹ shows that the transition from the ordered LTP to the fully disordered HTP proceeds via the formation of the intermediate (cooled) phase CP. The model of the conformational rearrangements in an isolated chain in this transition is illustrated in Fig. 10. An increase in temperature is accompanied by the appearance of 'skew' bonds (S and \bar{S} in Fig. 10) for the chain in the 'planar (distorted) zigzag' conformation. A further increase in temperature leads to the appearance of single bonds in the G or \bar{G} conformation, which corresponds to the chain conformation in the cooled phase.

The transition from LTP to CP is accompanied by a change in the unit cell parameters ($a = 9.16 \text{ \AA}$, $b = 5.43 \text{ \AA}$, $c = 2.53 \text{ \AA}$, and

Figure 10. A model of the conformational changes in the single chain of the VDF/TrFE 55/45 copolymer during heating-cooling cycles.¹⁰⁹

$\beta = 93^\circ$) and an appreciable increase in the tilt angle (in the 130 plane) to 18° . The packing of such chains in the cell of the cooled phase is presented in Fig. 11. This lattice may be considered also in the light of the concept of a crystal with kink bonds. The transition from the cooled phase to the high-temperature phase on further increase in temperature is accompanied by the accumulation of conformational irregularities, which, according to IR spectroscopic data, represent a set of sequences of the type $TGT\bar{G}$ and $T_3GT_3\bar{G}$. To a first approximation, the lattice is characterised by hexagonal packing with the parameters $d' = 9.75 \text{ \AA}$ and $b' = 5.63 \text{ \AA}$ ($d'/b' = \sqrt{3}$). Taking into account these values, the calculated and experimentally observed interplanar spacings d and the structure factors \sqrt{I} for a series of reflections are presented in Table 9.

Figure 11. A model of the structure of the crystal of the cooled phase for the VDF/TrFE 55/45 copolymer.¹⁰⁹

Evidently, there is a satisfactory agreement between the measured and calculated parameters, which confirms the correctness of the chosen lattice. Overall, the lattice is found to be nonpolar and the chains may execute rotational motions with large amplitudes. According to Tashiro et al.,¹⁰⁹ the crystal in this state may resemble one of the varieties of a rotator phase. When the HTP is cooled, the reverse transition of the type HTP \rightarrow CP takes place and is accompanied by the conformational rearrangements noted above (Fig. 10). The cooling of the CP is not accompanied by the reverse transition to the LTP. In this case, chains with conformations of the type

...TTTTTTTTTSTTTTTTTTTT \bar{S} TTTTTTTTTT...

are found to be frozen.

For the occurrence of the transition from the CP to the LTP, one may deform the specimen or subject it to a strong field.

The attempt to find definite analogies between the formation of the structure on quenching of the above 65/35 copolymer and of the homopolymer yielded a somewhat unusual result.¹¹² It was found that the ferroelectric-paraelectric transition (according to DSC data) in the quenched copolymer is observed at a higher temperature than in the specimen with slow rate crystallisation. Annealing of the quenched specimen (at 120 and 140 $^\circ\text{C}$) leads to a decrease in the temperature of this transition, although the fraction of the long sequences with the 'planar zigzag' conformation, entering into the composition of the ferroelectric phase, increases under these conditions.

In order to investigate the influence of the polarity of the comonomer in the VDF copolymers on the nature of the crystal structure formed, a study was made of a wide range of VDF copolymers with nonpolar tetrafluoroethene, the fraction of the latter being varied within wide limits (19%–100%).¹¹³ Comparison of the structural data with those for the copolymer of VDF with the polar TrFE comonomer shows that the nature of the phases formed and their interconversions are similar. Admittedly certain nuances were also observed for the 81% VDF content in the VDF/TFE copolymers. Thus the temperature of the LTP \rightarrow HTP transition (with a conformational change from *trans*- to *gauche*-) proved to be close to the melting point. In the case of high VDF contents, such transitions become more diffuse and the hysteresis phenomena are weaker than in the VDF/TrFE copolymers.

The crystallisation of the VDF/TFE 94/6 copolymers from the melt (or from solution) always leads to the coexistence of the ferroelectric and paraelectric phases at room temperature. The presence of the former was inferred from the 100, 200 reflection, whilst the presence of the latter was associated with the broadened reflection in the range $2\theta \approx 18^\circ$ ($\text{CuK}\alpha$ radiation).³² The morphology of the films obtained is characterised by the presence of

spherulites which become small and defective on quenching from the melt¹¹⁴ or a morphology in the form of aggregates of optically anisotropic rods is established.⁴⁸ For crystallisation conditions involving quenching, an unusual phenomenon has been observed — the formation of sections of the α phase, the presence of which was inferred from the appearance of either the weak 021 reflection¹¹⁴ or of strong intermolecular 020, 110 reflections.^{115,116} The latter phase proved to be metastable, since even on heating to 70 °C the above reflections are markedly weakened.^{117,118} The crystallisation of the copolymers (predominantly as the polar β phase) is accompanied, according to spectroscopic data,^{48,114} by the formation of irregular sequences in the $TGT\bar{G}$ and $T_3GT_3\bar{G}$ conformations, the ratio of which depends on the previous thermal history of the specimen.

The study of Roussel et al.¹¹⁹ was devoted to the influence of the molecular mass on the kinetics of the crystallisation of PVDF. When the DSC method was employed, the crystallisation kinetics were described in terms of the constants of the Avrami equation. It was noted that the rate of crystallisation was lowest in the case of the PVDF with an intermediate molecular mass. According to the authors, this unusual phenomenon could not be associated with different crystallographic forms, since the specimens were selected taking into account IR spectroscopic data. However, the exponent in the Avrami equation could reach 11. The reason for this is believed to be the fact that the additional type HHTT irregularities in certain specimens may serve as additional nucleation centres. It is believed that the above crystallisation anomalies are bounded on the side of high degrees of supercooling.

The influence of the crystallisation temperature on the possibility of polymorphic transformations in PVDF has been investigated¹²⁰ mainly with the aid of a spectroscopic technique. The PVDF produced by the Atochem Company (France) in the form of thin (6 μm) films was crystallised from a concentrated solution in dimethylacetamide. On varying the crystallisation temperature, appreciable changes were observed in the IR spectra, which is explained by crystallisation in the form of different modifications. The presence of the α , β , and γ phases was inferred from the presence in the IR spectrum of the 766, 840, and 510 cm^{-1} bands respectively. The fraction of a particular modification was estimated from their intensities. In particular, it was shown that, on prolonged high-temperature (160–185 °C) crystallisation, predominantly the γ phase is formed. This result agrees qualitatively with earlier data.^{78–85} A new feature in the above study¹²⁰ is the observation of the influence of the crystallisation temperature on the ratio of the α and β phases in isotropic films. It was shown that a decrease in temperature (from 160 to 50 °C) leads to a significant increase in the fraction of the β phase in its mixture with the α phase for the same (20 min) crystallisation time. This feature is not fortuitous, since a similar relation has been observed also for a solution of PVDF in dimethylformamide. At a fundamental level the observed phenomenon may have a common basis with the $\alpha \rightarrow \beta$ transformation in the low-temperature deformation of PVDF.

IV. Characteristics of the solid-state transformations under the conditions of tensile deformations

More than twenty years ago, the ferroelectric properties of PVDF and of its copolymers were unknown, but in the studies of Lando¹²¹ and Gal'perin¹²² attention was already drawn to the possibility of the polymorphic transformations $\alpha \rightarrow \beta$ on uniaxial stretching of PVDF films. It was shown that a decrease in the temperature of the uniaxial stretching and an increase in the draw ratio promote an increase in the latter. It was noted, in particular, that orientation at low temperatures (< 60 °C) leads to an abrupt $\alpha \rightarrow \beta$ transition, which is also accompanied by the formation of microcracks in the matrix. At higher temperatures the transition becomes smoother, i.e. the crystals of the α phase are initially

oriented along the draw direction, after which the polymorphic transformation takes place in them. Small angle diffraction has shown that an increase in the draw temperature (T_d) is accompanied, on the one hand, by an increase in the long period, and, on the other, by an increase in the intensity of the small angle reflection. Furthermore, a change has also been noted in the nature of the diffraction patterns: whereas at low T_d the reflection has the form of a vertical line or four points, at high T_d it has the form of two points. Annealing of the oriented PVDF films in the isometric or free state has shown¹²³ that in the latter case a transition from the fibrillar structure to the lamellar structure, accompanied by a change from the c -texture to the a -texture, is observed.

For PVDF films with an oriented β phase, the nature of the structural transformations on annealing may depend significantly on the previous history of the specimens. Thus, when an unannealed specimen is heated, shrinkage stresses σ arise in it already at 40 °C, reaching a maximum ($\sim 1.5 \text{ kg mm}^{-2}$) at 120 °C.¹²⁴

In the specimen (with fixed ends) annealed up to 140 °C, these stresses are insignificant, after which they also increase, although their maximum values are appreciably lower ($\sim 0.5 \text{ kg mm}^{-2}$), while the maximum is displaced towards higher temperatures — to ~ 180 °C. In both cases, the decrease in σ is attributed to the fusion of the β phase crystals, since the intensity of the principal 110, 200 reflections due to the β phase decreases under these conditions (to zero at 189 °C). However, when a specimen with free ends was heated, a sharp fall in the intensity of the above reflection occurred at 166 °C, i.e. for the free state the melting point of the β crystallites is lower by more than 20 °.

An analytical description of the $\alpha \rightarrow \beta$ interconversion in PVDF on uniaxial stretching has been formulated in a study¹²⁵ the authors of which used the method developed¹²⁶ for the estimation of the fraction of the α phase N_2 under the conditions of its coexistence with the β phase. The experimental dependences of N_2 on the draw ratio λ , expressed in semilogarithmic coordinates, are linear, i.e. the following relation holds:

$$N_2 = 1 - \frac{\ln \lambda}{10.8 - 29/RT}, \quad (3)$$

where 29 kJ mol^{-1} is the potential barrier to the $\alpha \rightarrow \beta$ transformation.

Temperature has a significant influence on the effective tensile stress, so that the $N_2 - \sigma$ relation is linear (Fig. 12). Extrapolation of this relation showed that the complete disappearance of the α

Figure 12. Dependence of the fraction of the α phase (N_2) on the tensile stress in the uniaxial drawing of PVDF before (1) and after (2) the formation of a neck.¹²⁵

phase requires a stress of 180 N mm^{-1} . Evidently, other conditions being equal, the $\alpha \rightarrow \beta$ transformation takes place more effectively in the region where the material assumes the form of a neck. This conclusion has been confirmed by the data of Matsushige and Takemura,¹²⁷ which also showed that the main $\alpha \rightarrow \beta$ transformation on uniaxial stretching begins in the region of deformations where the material assumes the form of a neck. Under the conditions of uniaxial stretching of PVDF, the existence of a critical deformation where intense rotation of the crystals of both modifications begins has been established. For example, the effective rotation in the direction of stretching, for both the newly formed β crystals and for the remaining α crystals, takes place in the range $\lambda = 2-2.5$.¹²⁵

The importance of the role of the tensile stresses in the polymorphic $\alpha \rightarrow \beta$ transformation has been emphasised also in another study.¹²⁸ Taking into account the role of temperature as regards the values of σ , the author also showed that the values of σ may be raised by increasing the rate of deformation. For large draw ratios ($\lambda = 7$), the final values of Young's modulus (E) in the PVDF specimens may depend significantly on the previous thermal history of the isotropic specimens crystallised from the melt. Thus it was found that Young's modulus for films with the same value of λ is higher in the case of slow crystallisation of the initial films obtained by quenching. The maximum values of E in the direction of the draw axis are $\sim 4 \text{ GPa}$, whereas along the c axis they are 177 GPa (according to X-ray diffraction data), which is comparable to the theoretical value of 237 GPa for β phase crystals.

It was found with the aid of the dependence of E on λ for films of one kind, obtained at different draw temperatures, that, other conditions being equal, the decrease in T_d leads to an increase in E . This can be explained [in conformity with Eqn (3)] by an increase in the fraction of the β phase, for which E in the direction of the c axis is found to be greater than E for the α phase. However it appears that this is not the only reason. Such doubts arise from the results of studies^{129,130} in which uniaxial stretching processes were investigated in specimens of the VDF/TFE 94/6 copolymer. Here it was also found that a decrease in T_d leads to an increase in E (according to the results of acoustic measurements). However, since this copolymer crystallised in isotropic films in the form of the β modification, the polymorphic $\alpha \rightarrow \beta$ transition noted above was absent, as in the homopolymer. For this reason, the increase in E for films with different T_d was attributed to the different microstructures of the noncrystallising regions. In particular, it was shown that in films with a lower T_d the latter are characterised by an increased concentration of chain sections in the 'planar zigzag' conformation, while the packing density in them should be greater, since there is a steady decrease in the intensity of the maximum of the small angle meridional X-ray scattering.

The results of the analysis of the acoustic characteristics indicate that one may expect a high content of stressed chains passing through films with a lower T_d . NMR data for PVDF specimens with different draw ratios agree qualitatively with this conclusion. This can also be inferred from the decrease in the mobility of the 'fast' protons associated with the noncrystallisable chain sections in specimens with larger draw ratios.¹³¹

The nature of the polymorphic transformation $\alpha \rightarrow \beta$ occurring on uniaxial stretching affects also the morphology being established. Thus the diffraction pattern produced by a laser beam which has passed through a deformed PVDF film, crystallised in the isotropic state with formation of α phase spherulites, has been investigated.^{132,133} It was observed that at high T_d there is intense equatorial scattering, which indicates the existence of spherulites deformed in the direction of the draw axis. At low T_d , there exist, together with the latter spherulites also undeformed spherulites with the initial phase, which was inferred from the 'anomalous' eight-lobe dispersion pattern. It is assumed that the mechanism involving the 'retwisting' of the lamellae on deformation plays an important role in spherulites disposed favourably in relation to the direction of action of the external force and that the transition

from the α to the β modification may proceed as a result of local fusion and subsequent recrystallisation.¹³² As the draw temperature is reduced due to the higher viscosity of the noncrystallising sections, the external stress may be effectively transmitted to the crystallites of the α phase, reaching critical values for the $\alpha \rightarrow \beta$ transition noted above.¹³³

For intermediate draw ratios, the 'anomalous' eight-lobe H , scattering pattern (in crossed polarisers) has been observed also in the polymorphic $\gamma \rightarrow \beta$ transition.¹³⁴ An analogy between the $\alpha \rightarrow \beta$ and $\gamma \rightarrow \beta$ transitions was noted, although the required deformation energy for the former is found to be greater than for the latter. Indeed, the complete transformation can be achieved at $T_d = 80^\circ \text{C}$ and $\lambda = 4$. On the other hand, in the case of the $\gamma \rightarrow \beta$ polymorphic transition with the same λ , it takes place fully at a draw temperature as high as $T_d = 150^\circ \text{C}$. An unusual feature of the latter transformation is the fact that the appearance of the β phase is noted not immediately after the start of the orientation of the initial crystallite but in the deformation process, where the orientation function reaches 0.25.

In the light of the foregoing, one may conclude that the preparation of PVDF with highly oriented γ phase crystals is by no means a simple task. Indeed, the procedure usually employed, involving the uniaxial stretching of an isotropic film with γ phase crystallites, fails because of the $\gamma \rightarrow \beta$ transformation noted above. In this connection, the results of a study¹³⁵ in which a novel method of preparation of such PVDF was proposed are of interest. The scheme reduces to the following features. In the first stage, an isotropic film with α phase crystallites was oriented at 150°C up to $\lambda = 4-5$ without the polymorphic $\alpha \rightarrow \beta$ transition. In the second stage, the film obtained was polarised in a field with $E = 1 \text{ MV cm}^{-1}$, after which the crystals of the α phase were converted into the polar α_p form. In the third stage, the film obtained was annealed isometrically at temperatures above 120°C (it is even better when $T > 170^\circ \text{C}$), after which the formation of the γ phase was observed. The presence of the latter was inferred from the presence of specific absorption bands in the vibrational spectra — at $300, 430, 656, 776$, and 813 cm^{-1} .

A method was proposed in the same study for the quantitative estimation of the fraction of the γ phase $\rho(\gamma)$ from the optical densities D of the 410 and 430 cm^{-1} bands. It was found that

$$\rho(\gamma) = \frac{D_{430}}{rD_{410} + D_{430}}, \quad (4)$$

where $r = K_{430}/K_{410}$, while K_{430} and K_{410} are the molar absorption coefficients for the 430 and 410 cm^{-1} bands respectively, the values of which proved to be similar. The kinetics of the increase in the fraction of the γ phase, calculated by Eqn (4) for different annealing temperatures in the $\alpha_p \rightarrow \gamma$ transition stage, have shown that an increase in the annealing temperature leads not only to an increase in the rate of transformation on the initial section but also increases the equilibrium value of $\rho(\gamma)$.

According to Brillouin scattering data, under the conditions of the uniaxial stretching of PVDF it is possible to estimate the changes in its nonordered regions.¹³⁶ Thus a significant increase in the velocity of ultrasound V_s in the direction of the draw axis with increase in λ has been observed. The ultrasonic wavelength is $\sim 10^3 \text{ \AA}$, while the side of the crystallite is $\sim 10 \text{ \AA}$, so that the orientation function determined should characterise the rotations of the chains both in the crystal and the amorphous phase. The velocity of ultrasound can be estimated from the following relation:

$$V_s \approx \left(\frac{E}{\rho} \right)^{1/2},$$

where ρ is the density. The increase in V_s with increase in ρ during the drawing process was attributed by the authors to a more significant increase in Young's modulus. Comparison of the values of E for the crystals of the α and β phases shows that an increase in Young's modulus during drawing cannot be attributed

solely to the polymorphic transition $\alpha \rightarrow \beta$ and account must be taken of the possibility of the partial additional crystallisation of the chains in the amorphous phase.

In order to investigate in greater detail the mechanism of the polymorphic transformation $\alpha \rightarrow \beta$ on uniaxial stretching, the changes in a series of physical characteristics were followed in oriented PVDF films where the initial polymers differed both in the number-average molecular mass M_n and by in polydispersity factor M_w/M_n . In particular, it was shown that higher values of Young's modulus (~ 6 GPa) are more likely to be obtained on uniaxial stretching on a polymer the M_n value for which is lower and that the isotropic specimen should be prepared by slow crystallisation.¹³⁷

The PVDF films used for practical purposes were treated in a high electric field, so that the orientation of the 'polar' b axis of the lattice in relation to the plane of the film is very important. The data of Mizuno et al.¹³⁸, who carried out structural studies on PVDF films obtained by the double orientation method, merit attention in this connection. It was shown that, for a film subjected to repeated uniaxial restretching in a direction perpendicular to that of the initial stretching ($T_d \leq 100^\circ\text{C}$, the initial specimen was quenched), the b axis of the cell is in the plane of the film. It was noted that the rolling of a PVDF film subjected to uniaxial stretching and different heat treatment conditions make it possible to obtain textures in which the b axis may form angles of 0° , 30° , and 60° with the plane of the film.

Detailed studies of the morphology in thin and thick PVDF films by electron microscopy, electron diffraction, and X-ray diffraction (large or small angle diffraction) indicate significant differences between the structures of thick films oriented at low ($80\text{--}90^\circ\text{C}$) and high ($130\text{--}140^\circ\text{C}$) temperatures.¹³⁹ Approximately 85% of well oriented but highly defective β phase crystals and $\sim 15\%$ of residual virtually unoriented α crystals were observed for the former films in the region of the macroscopic neck (with 280% deformation). The residues of the unoriented α phase are visible even for deformations of $\sim 350\%$, whereupon the growing neck can reach the ends of the specimen. The long period (in the direction of stretching) is ~ 10.5 nm, which is less than for the initial specimen (13.0 nm). The ellipsoidal microcracks arising under these conditions are located between the microfibrils. In hot drawing, the $\alpha \rightarrow \beta$ transition proceeds somewhat differently: initially the α phase is transformed into microfibrils and then, after the attainment of critical stresses, the polymorphic transition begins. At both high and low temperatures, the deformation occurred heterogeneously, since the regions of the initial α phase remain even for an elongation of 500%.

For polar polymers with fairly high dielectric losses, it is of interest to employ nontraditional heating sources for the specimen during the drawing process. For example, microwave heating may be employed for this purpose. Drawing with this method of heating in polyoxymethylene specimens leads to appreciable improvements in the elastic characteristics.^{140–142} or PVDF, this heating method is of interest for a number of reasons. On the one hand, the increased dielectric losses at high frequencies (at room temperature) provide a basis for effective uniform heating throughout the bulk of the specimen by the energy of the UHF field. On the other hand, the similarity of the frequencies of the electromagnetic field to the average reorientation frequencies of the polar segments in the nonordered phase makes it possible to 'pump' the internal energy precisely into the amorphous regions of the PVDF, which play an important role in the processes involving the deformation of a partly crystalline polymer. The data of a study¹⁴³ where a magnetron with a power of 1.2 kW and a working frequency of 2.45 GHz was used for heating of the kind described above merit attention in this connection.

Comparison of the limiting PVDF draw ratios and of the acoustic modulus for traditional and UHF heating of the specimen showed that the use of the latter method does not afford a significant increase in the elastic characteristics compared with the

Figure 13. Dependence of the maximum draw ratio (a) and the acoustic modulus (b) in PVDF specimens on the drawing temperature for HF (1) and traditional (2) heating.¹⁴³

traditional heating of the specimen from an external source. According to the authors, the reason for this is that, in contrast to polyoxymethylene, in PVDF the range of temperatures most favourable for maximum stretching is close to the melting point (Fig. 13). In the range of stretch temperatures $150\text{--}160^\circ\text{C}$ (appreciably below the melting point), UHF heating yields a higher maximum draw ratio and hence the highest acoustic modulus. This feature may be a consequence of the local heating of the amorphous regions of PVDF noted above. We may note that Nakagawa and Amano¹⁴³ obtained PVDF specimens with the highest draw ratio (8.6) and acoustic modulus (7.5 GPa).

The influence of the state of the melt on the characteristics of the orientation crystallisation of PVDF has been studied.¹⁴⁴ The initial specimen was subjected to preliminary radiation-induced cross-linking, after which it was melted. Next the specimen was stretched to different values of λ and recrystallised isothermally. The task formulated was to trace the influence of the initial function of the orientation of the chains in the melt and of the density of the cross links in it on the values of the orientation function for the crystallites and the amorphous phase after recrystallisation. On the basis of data obtained by X-ray diffraction and birefringence, it was concluded that in this type of process the c axis in the crystal of the α phase formed is disposed along the direction of stretching of the melt, while the chains of the amorphous phase are perpendicular to this direction. It was found that the orientation state of both phases after recrystallisation depends both on the density of the cross links and on the chain orientation function in the amorphous melt, the role of the latter factor being decisive. Here it is also useful to quote the values of the intrinsic birefringence obtained from optical measurements. Thus the intrinsic birefringence is $\Delta_{c,\alpha}^0 = 0.145 \pm 0.002$ for the crystal of the α modification, whereas for the amorphous phase we have $\Delta_a^0 = 0.098 \pm 0.017$.

The method involving the solid-phase extrusion of polymers, which in many instances yields high orientation characteristics, occupies a definite place in film technology. In this connection, one should mention a series of studies^{145–147} in which this technique was used to obtain oriented PVDF films. The extrusion conditions selected by Mead et al.¹⁴⁶ corresponded to a pressure of 0.23 GPa in the extruder and a temperature of 160°C . The change in melting point corresponding to a pressure change of 1 Pa is 3.3 degree. The pressures employed yield an increase in melting point by 76°C . For this reason, deformations under conditions such that the temperature was much lower than the melting point of PVDF at the normal pressure corresponded to the chosen deformation regimes. It was shown that an increase in draw ratio is accompanied by an increase in the degree of crystallinity and in the magnitude of the birefringence. The phase composition in the film is characterised by a mixture of the α and β crystals, while the morphology is represented predominantly by the folded-chain form of the crystals with a large period of 20 nm. Contradictory results were obtained, according to X-ray data, the fraction of the

crystals of the α phase is greater than that of the β phase, while IR spectroscopy shows that the crystals of the β phase predominate. The discrepancies may be avoided by postulating that the chosen extrusion regime ensures more intense conformational transformations of the type $TGT\bar{G} \rightarrow (TT)_n$ in the nonordered regions than in the crystal. By selecting the extrusion regimes it is possible to achieve the optimum conditions for the $\alpha \rightarrow \beta$ transformation. Indeed, it has been reported¹⁴⁷ that extruded films predominantly in the β modification have been obtained by this method; at the same time, one should expect a high correlation with the arrangement of the chains of the amorphous phase, since the measured birefringence indicated for the extruded films is $\Delta n = 67 \times 10^{-3}$, which had never been noted previously in the literature.

The mechanical characteristics of the PVDF films are improved also when nontraditional orientation methods are used for polymers, for example, rolltruding.¹⁴⁸ At rolling temperatures of 140–160 °C, there is a twofold increase (for the main rolling direction) in Young's modulus and a 12-fold increase in the ultimate strength.

In uniaxial or biaxial mechanical stretching of PVDF films, there is a possibility of the appearance of all kinds of long defects (of the type of voids). It therefore seems promising to develop methods effecting orientation crystallisation without mechanical influences. Lovinger and Wang¹⁴⁹ carried out the zone crystallisation of PVDF at zone migration velocities of 0.6–20 $\mu\text{m min}^{-1}$ and a zone temperature of 153 °C. Analysis of the results obtained by polarisation microscopy, X-ray diffraction, and IR spectroscopy demonstrated that crystallisation in the form of the α phase predominates. Weakly developed β phase spherulites serve mainly as nuclei of α spherulites deformed in the direction of migration of the zone. Analysis of the nature of the diffractometer traces and of the dichroism of a series of IR absorption bands with a known value of the transition moment vector permitted the conclusion that the b axis of the lattice is oriented along the direction of migration of the zone. We may note that, in the textured specimens obtained by mechanical stretching, the cell c axis is aligned along this direction. A version of the zone stretching of PVDF films at high rates or zone migration has been described.¹⁵⁰ Having selected the stretching conditions, specimens with well oriented crystals and preferential crystallisation in the form of both α and β phases were obtained.

The problem of the formation of voids in PVDF films on uniaxial stretching may be of applied importance since, the formation of microcracks in the bulk of the film is accompanied by a decrease in its relative permittivity. Under certain conditions, this may lead to an increase in the piezoelectric constant g for the polarised films, which affects the output characteristics of the energy converters based on these materials. Specialists of the Thorn-EMI Company (England) and of Leeds University have been most actively concerned with this problem. In particular, they developed a method for the preparation of PVDF films with voids resulting from cold drawing ($T_d = 80$ °C) at high rates.¹⁵¹ The nature of the morphology arising under these conditions has been studied in detail by electron microscopy.^{152, 153} It was shown that the voids have the form of an ellipsoid with transverse spans, i.e. they may be regarded as a form of crazing. The voids were disposed between fibrils and were characterised by a fairly wide size distribution. In one case, the average size of the voids in the longitudinal direction was 1.5 μm ,¹⁵² whilst in another it was ~ 5 μm ,¹⁵³ although in both cases their volume fraction was estimated as 17%.

In a study of the mechanical shear anisotropy in oriented PVDF films, it was shown that the presence of voids in the bulk phase promotes an increase in virtually all the components of the elastic pliability tensor.¹⁵⁴

Certain details of the formation of the voids in the cold drawing ($T_d = 80$ °C) of PVDF have been investigated by Kochervinskii et al.⁴⁷ Attention was drawn to the fact that the probability of the formation of voids under identical cold drawing conditions may depend significantly on the nature of the initial

supermolecular structure. Two PVDF films, obtained by quenching from the melt and by slow crystallisation, were investigated. Spherulites differing significantly in size and degree of defectiveness were detected in them by the method involving small angle scattering of polarised light. The spherulites in the quenched films were an order of magnitude smaller, while the internal arrangement of some of them was characterised by the disposition of the lamella at an angle of 45° relative to the radius of the spherulite (the so called 'anomalous' spherulites). The morphology of the two films was different after cold drawing. For the quenched film, the H_v -diffractometer trace had the form of an eight-lobe figure, arising, as noted above,^{132, 133} from the presence of deformed and undeformed spherulites. A stronger equatorial scattering in crossed polarisers and a decrease in density and transparency caused by the formation of ellipsoidal voids are characteristic of the stretched film with large spherulites.

A similar result was also obtained on cold drawing ($T_d = 20$ °C) of films of the VDF/TFE 94/6 copolymer.⁴⁸ The formation of voids in the bulk phase (according to small-angle X-ray scattering data) is also observed in the film where the presence of β phase spherulites was noted in the initial state. The formation of voids is apparently accompanied by local releases of the stress, which should affect the conformational characteristics of the crazed films. In the case of the homopolymer, this is accompanied by a decrease in the fraction of the β phase in the oriented state,³³ while for the VDF/TFE 94/6 copolymer crystallised as the β phase this is accompanied by the appearance in the oriented state of sections of the chains in the $TGT\bar{G}$ conformation, which is not characteristic of the given polymorphic modification.^{155, 156} The fraction and nature of the microstructure of the voids formed may be regulated by isometric annealing processes and under certain conditions it is possible to achieve a decrease in, on the one hand, the concentration of the voids and, on the other, in the concentration of 'defective' conformations of the $TGT\bar{G}$ and $T_3GT_3\bar{G}$ types.^{155–157}

The detection by the spectroscopic method of these conformations in the VDF/TFE copolymer,^{114, 129, 130} which crystallises as the polar β phase with the 'planar zigzag' conformation, most probably confirms the concept that conformational defects of the kink bonds are present in the PVDF crystals.^{91–97} The above defects may play a significant role in polymorphic transformations during uniaxial drawing. This has been confirmed, for example, by data¹⁵⁸ according to which the high-temperature drawing of PVDF is accompanied by the formation of an oriented α phase. Electron diffraction patterns reveal certain 'anomalies'. Thus the 110 reflection due to the α phase has the form not of a point but of a strip which coincides with the direction of the c axis. Diffuse halo blurring (from the $hk0$ direction) is characteristic of the 002 reflection. The authors also attributed the observed 'anomalies' to the appearance of kink bonds. Instead of the $TGT\bar{G}TGT\bar{G}TGT\bar{G}$ sequence, one should expect in this case the $TGT\bar{G}TTTGT\bar{G}$ combination, where the conformational defects arise due to cooperative segmental 'flip-flop' motions between the $T\bar{G}TG$ and $TGT\bar{G}$ conformations. Defects of this kind for the oriented α form of PVDF arise also during prolonged isometric annealing.⁹²

It follows from the overall analysis of the data that the kink bonds noted above tend to aggregate into chains, which are disposed in the 001 plane.¹⁵⁸ The observed diffuse halo near the 200, 110 reflection, due to the oriented polar β phase,¹⁵⁹ is also caused by the appearance of bent kink bonds. In this case, this is attributed to the insertion of type GT_nG or $TGT\bar{G}$ sections of the chain into the chain with the 'planar zigzag' conformation. The authors of the concept developed believe that the solid-state transformation $\alpha \rightarrow \beta$ has a two-step mechanism: the $\gamma \rightarrow \beta$ transition takes place initially and is followed by the $\gamma \rightarrow \beta$ stage.⁹⁴ It is postulated that the kink bonds in the initial α phase constitute an intermediate phase between the α and γ modifications and can therefore facilitate significantly the occurrence of the first stage of the transformation.

The presence of chain sections in the $TGT\bar{G}$ and $T_3GT_3\bar{G}$ conformations in the VDF/TFE 94/6 copolymer, which crystallises from the melt or from solution immediately as the polar β phase,¹³⁰ can be regarded as evidence for the presence of kink bonds. Their role in the uniaxial stretching processes involving isotropic films of the above copolymer, unaccompanied by a polymorphic transformation, is also extremely significant. Thus it has been shown that identical stretching conditions for the two films are characterised by a greater deformation energy density in the case of the specimen with a lower content of conformational defects in the initial state.¹³⁰ The structure of the oriented film arising under these conditions is characterised by a higher Young's modulus and a higher deformation-induced acoustic response.¹²⁹ The higher residual polarisations¹⁶⁰ and piezoelectric responses¹²⁹ in such films after treatment in an electric field show that the role of the kink bonds must be taken into account also in the technological development of methods for the preparation of films designed for practical purposes.

The stabilities of various polymorphic modifications of PVDF under the conditions of the operation of uniaxially stretching stresses σ have been justified theoretically and predicted.⁸⁸ Calculation of the free energy taking into account the interchain and intrachain interactions leads to the conclusion that at least five different phases may exist in PVDF: α , β , γ , σ , (α_p) and m (melt). Analysis of the phase diagram for PVDF in a state of mechanical stress has demonstrated the possibility of the existence of a large number of metastable states.⁸⁸ At room temperatures under the conditions of the operation of uniaxially stretching stresses, the α phase may exist only in a metastable state owing to the increased free energy, which agrees well with the characteristics of the $\alpha \rightarrow \beta$ transformation described above.

It has been shown^{161,162} that the above transition under the conditions of uniaxial stretching proceeds in the neck formation stage in the specimen so that the structural studies devoted to the

necking phenomenon in PVDF may extend the ideas concerning the mechanism of the polymorphic transformations $\alpha \rightarrow \beta$. The conclusions of certain investigators on this question are of interest in this connection. Thus according to Kochervinskii,¹⁶³ the variation of the short- and long-range order parameters as a function of T_d led the authors to the conclusion that crystallisation processes should occur in the region of the formation of a neck in PVDF and should be preceded by the passage of the system through a strongly disordered or even fused state. However, in the study of the Raman spectra in the course of the deformation of PVDF it was observed¹⁶² that not only does the $\alpha \rightarrow \beta$ transformation occur in the region of the neck but there a marked increase in the degree of crystallinity (Fig. 14a). At the same time, as can be seen from the figure, the medium is heated intensely in the region of the neck, such heating depending on the rate of deformation. This factor is apparently decisive for the 'anomalous' decrease in the velocity of ultrasound on formation of a neck in the VDF/TFE 94/6 copolymers.^{114,163} The decrease in the velocity of sound under these conditions may reach 15% and the intensity of the transition of the material to the disordered state may depend significantly on its previous thermal history.

Specimen 2, for which the isothermal crystallisation time was five times longer than for specimen 1, has a lower concentration of defective conformers ($TGT\bar{G}$ and $T_3GT_3\bar{G}$), a larger size of the spherulite R_c , a higher density ρ , and an increased fraction of the basic 'planar zigzag' conformations (Table 10).

^b For specimen 2, $\rho = 1.807 \text{ g cm}^{-3}$ and $R_c = 4.6 \text{ }\mu\text{m}$.

Figure 14. Dependence of the degree of crystallinity (α) on the distance (l) to the neck formation boundary at different rates of deformation (v_s) (a) and variation of the temperature in the region of the formation of a neck on uniaxial drawing of PVDF (b).¹⁶²
 v_s (mm min⁻¹): (1) 0.1; (2) 10; (3) 100.

It may be inferred from the values of $\rho(\gamma)$ calculated by Eqn (4) that an increase in the crystallisation time is accompanied by a redistribution of the relative amounts of the conformational defects, i.e. chain sections are enriched in the isomers with the $T_3GT_3\bar{G}$ conformation as a result of their transition from the $TGT\bar{G}$ conformation.

Specimen	$\rho(\gamma)$	$\frac{D_{287}}{D_{300}}$	$\frac{D_{411}}{D_{442}}$	$\frac{D_{214}}{D_{442}}$	$\frac{D_{100}}{D_{70}}$

2	0.70	0.88	0.37	0.04	0.46

An increase in the number of chains in the 'planar zigzag' and $T_3GT_3\bar{G}$ (which are closer to a planar zigzag than $TGT\bar{G}$) conformations is in fact apparently the cause of the weaker disordering in the transitional region involving the formation of the oriented β phase (Fig. 15).

Figure 15. Dependence of the longitudinal velocity of sound on the deformation (a) and the relative change in the velocity of sound as a function of the stress in the region of the formation of a neck in two specimens of the VDF/TFE 94/6 copolymer (b).¹¹⁴ Specimen: (1) 1; (2) 2.

The structure and morphology of the latter for films obtained at different T_d may differ significantly.¹²⁹ This follows also from the consistent changes in the long period L and in the intensity of the small angle meridional maximum on the X-ray diffraction curves (Fig. 16). An increase in T_d is accompanied by an increase in L and in the intensity, as mentioned above, the latter being probably due to the increase in the difference between the densities of the crystalline and amorphous regions along the direction of stretching. As can be seen from the same figure, this is accompanied by consistent changes in the response recorded by acoustic (from the velocity of sound) or optical (from the magnitude of the birefringence) methods. In particular, for the specimen with the highest draw temperature, the optical anisotropy in the film for small deformations hardly changes, while the velocity of sound actually diminishes somewhat. The increased concentration of 'defective' isomers noted for oriented films with a high T_d ¹²⁹ shows that the microstructure of the noncrystallising sections in such systems may determine also the response to external influences (mechanical¹²⁹ or electrical¹⁶⁰). This may prove useful in its turn for the understanding of the mechanism of the piezoelectric response in such systems.

V. Characteristics of the crystallisation of poly(vinylidene fluoride) under the conditions of uniaxial compression and high pressures

The uniaxial stretching effects influence significantly the phase equilibrium in the crystalline PVDF phase and one may therefore expect that the conditions in the uniaxial or all-sided compression also lead to an alteration in the nature of the polymorphic transformations. This hypothesis was confirmed more than 25 years ago in the pioneer studies by Doll and Lando.¹⁶⁴⁻¹⁶⁶ It was shown that isothermal crystallisation from the PVDF melt, which is usually accompanied by the formation of the α modification, leads to the crystallisation of the γ phase (or its mixture with the α phase) on raising the pressure to 2000–5000 atm, the probability of this increasing with decrease in the degree of supercooling.¹⁶⁵ For the VDF/TFE 93/7 copolymer, which usually crystallises as the low-melting β phase (melting point 139 °C), an increase in pressure to 5000 atm leads to the formation of the same modification but with a melting point higher by 20 °C.¹⁶⁶ The same rule holds also for isotropic specimens textured as a result of uniaxial stretching and crystallised at normal and elevated pressures.¹⁶⁶ The results of differential thermal analysis have shown that an increase in pressure at the crystallisation of isotropic specimens is only one of the conditions for the formation of the β phase, the other condition being the maintenance of a low degree of supercooling. It has been shown by electron microscopy that crystallisation under pressure is accompanied by a significant increase in the long period (to 68 nm compared with the usual values of 10–15 nm).¹⁶⁷ An increase in pressure to 3000 atm increases linearly the melting point both of the VDF homopolymer and of its copolymer with TFE, the entropy of fusion diminishing under these conditions.

Similar results have been obtained also in a study whose authors observed the polymorphic transition $\alpha \rightarrow \beta$ in the high-temperature annealing of specimens with the α phase under a pressure of 4000 atm. It was noted (as in the above studies¹⁶⁵⁻¹⁶⁷) that a decrease in the annealing temperature lowers the effectiveness of this transition. It was demonstrated later¹¹⁰ that, by making the conditions for the annealing of the isotropic PVDF specimens more severe (a pressure of 4500 atm and a temperature of 292 °C), it is possible to ensure also the $\alpha \rightarrow \beta$ transformation. The extent of such transformations can be increased by optimising the PVDF crystallisation conditions under high pressure.¹⁶⁹ For this purpose, changes were made both in the temperature (from

Figure 16. Variation of the longitudinal velocity of sound (a) and birefringence (b) as well as small angle X-ray diffraction curves (c) for oriented films of the VDF/TFE copolymer obtained at different temperatures (°C): (1) 60; (2) 80; (3) 100; (4) 120; (5) 140.¹²⁹

Table 11. Characteristics of the crystallisation conditions and the parameters of the PVDF structure during formation under increased pressure.¹⁶⁹

the initial T_i to the final T_f and in the temperature (from the initial T_i to the final T_f) and in the pressure (from the initial P_i to the final P_f) of this process as a result of which it is possible to vary appreciably both the fraction of the β phase and the degree of its crystallinity. This is illustrated by the data in Table 11.

The nature of the changes in the parameters of the unit cells in the PVDF crystals formed under pressure has been investigated.¹⁷⁰ For this purpose, the changes in the interplanar spacings were followed in specimens of the α and β phases under pressure. In the α modification of PVDF, they proved lower in the 110 plane than in polyethylene (PE), whereas along the axis of the macromolecule the opposite was true. The variation of the unit cell parameter of the α phase along the b axis was found to be greater than along the a axis, whereas for the β modification the changes in the interplanar spacings along the normals to the 110, 200, 020, and 310 planes are similar. It has also been shown that the compressibility of the lattice decreases in the direction $PE \rightarrow PVDF_\alpha \rightarrow PVDF_\beta$. The study of the volume compressibility β_v with the aid of physicochemical characteristics in block PVDF specimens crystallised as the β modification evidently makes it possible to obtain definite information about the structure of the nonordered regions.¹⁷¹ Thus, it has been shown that, under the conditions of the crystallisation of PVDF in the form of one modification, β_v for the oriented specimens proved to be always lower than for the isotropic ones. On the assumption that the degree of crystallinity is constant, this can be accounted for solely by the denser packing of the chains of the amorphous phase in the former. The large fraction of the latter phase in PVDF (> 50%) is believed to be the main cause of the abrupt change in Young's modulus with increase in pressure, where the vitrification of the nonordered regions is postulated.¹⁷¹ The role of the latter is manifested also by the dependence of the linear expansion coefficient L of the specimens with a nonoriented phase on the pressure P described by the polynomial

$$L = A + BP + CP^2 + DP^3, \quad (5)$$

where $A = 2.540$, $B = -1.733 \times 10^{-2}$, $C = -1.605 \times 10^{-3}$, and $D = -1.386 \times 10^{-4}$.

The two bends in the temperature variations of the linear expansion coefficient (at -50 and 22 °C) are attributed to transitions in the amorphous phase and the crystal respectively.

In a series of studies Matsushige and coworkers^{127, 171–175} also indicated the possibility of the $\alpha \rightarrow \beta$ transformation on crystallisation (or annealing) under high pressure. The presence of three endothermic fusion peaks for the PVDF specimens crystallised in this way is attributed to the fusion of the residues of the α phase and of the regions of the β phase, which results in the formation of folded-chain crystals and extended chain crystals (ECC).^{171–175} It was noted that such crystals have significantly different morphologies: a spherulite structure was observed for the folded-chain crystals, whereas for the ECC lens-like formations with dimensions of ~ 10 μm were noted. The corresponding melting points (at the normal pressure) are respectively 190 and 207 °C, both increasing linearly with pressure. As the PVDF specimens with the β phase crystallised under a high pressure are heated under normal conditions, the reflections characteristic of the β phase remain unchanged up to 189 °C (which is not the case in the oriented specimens with the β phase). This indicates the high stability of the above modification and the absence of the reverse transition $\beta \rightarrow \alpha$ up to the temperature indicated.¹⁷⁴ The results of

the study of the high-temperature annealing of specimens of the PVDF phase under a pressure of 4000 kg cm⁻² have shown that the virtually complete transition $\alpha \rightarrow \beta$ takes place over a period of 165 min at 278 °C (the melting point of the α phase is 286 °C). A decrease in the annealing temperature lowers the rate of the transformation. The activation energy for the above transition (calculated from kinetic data for the initial stage of the process) has been estimated as 30 kcal mol⁻¹.¹⁷³

When pressure was applied to an oriented PVDF specimen containing a small amount of the residual α phase, a uniaxial deformation arose, which led to the complete disappearance of the α phase.¹⁷⁶ In addition, X-ray photographs at different angles relative to the initial c texture have shown that the $h00$ planes of the β phase crystal lattice are located in the plane of the film, the 001 direction again coinciding with the direction of the initial extension, so that the $h00$ planar texture is produced. It is believed that the 100 and 110 planes in PVDF (as in polyethylene) are the closest packing planes with the maximum interplanar spacing. Slip should occur along the above planes in most cases. The formation of fault bands and twinning are characteristic of the structure formed under these conditions.

In the case of the uniaxial compression of isotropic films with the α phase, it was found that the shape of the pistons may play a significant role in the $\alpha \rightarrow \beta$ transformation.^{175, 177} The rectangular shape is preferable for the chosen conditions (5000 kgf cm⁻² and 125 °C). In this case, the X-ray diffraction pattern proved to be similar to those for the extended specimens, the degree of orientation of the β crystallites reaching 95%.¹⁷⁵ The results of the study of the compression process at variable temperatures have shown that the most complete $\alpha \rightarrow \beta$ transformation takes place at 125 °C. On the other hand, on extension an increase in temperature (under the conditions of constant deformation) leads to a decrease in the extent of the above transformation. It is therefore concluded that the mechanisms of the $\alpha \rightarrow \beta$ transitions on compression and extension are different. With increase in pressure, there is also a change in the mechanism of the transformation on extension. At a temperature above 130 °C, uniaxial stretching proves ineffective for the $\alpha \rightarrow \beta$ transition. However, if it is carried out under a pressure of 4000 kgf cm⁻², then the transition occurs up to draw temperatures in the range 250–265 °C.¹²⁷ The changes in the nonordered phase in high-temperature annealing processes under a high pressure have been investigated in a study¹²⁷ of the $\alpha \rightarrow \beta$ transitions in relation to single crystals of the α phase. In particular, the above transformation goes to completion in such crystals over a period of 15 min at 533 K and a pressure of 400 MPa. Presumably the nonordered phase gives rise to definite hindrance to the $\alpha \rightarrow \beta$ transition, since the annealing at the same pressure of a PVDF specimen with a lower degree of crystallinity requires 165 min and a temperature of 551 K for the 100% yield of the β phase.¹⁷³

The structural transformations for different versions of the uniaxial and all-sided compression should be reflected also in the electromechanical characteristics of the polarised PVDF films.

Table 12 shows that, during annealing at a high pressure, the piezoelectric constants of uniaxially extended films increase by a factor of 3.5–4. Drawing under a high pressure requires the optimisation of the process with respect to temperature. For the variant involving uniaxial compression, the piezoelectric moduli may be increased appreciably by combining the film deformation and polarisation processes.

Table 12. Piezoelectric properties of PVDF specimens obtained by different methods.¹²⁷

Preparation conditions	Piezoelectric stress constant $10^2 d_{31}/\text{C m}^{-2}$	Elastic modulus /GPa	Piezoelectric strain constant $d_{31}/\text{pC N}^{-1}$
1 kgf cm ⁻² drawing and 75 °C	1.0	1.5	6.7
Drawing (annealing) under 4000 kgf cm ⁻² pressure and 278 °C for 30 min	3.5	1.3	27
Drawing under 4000 kgf cm ⁻² pressure at different temperatures /°C			
165	2.7	1.4	20
200	3.0	1.4	21
250	4.1	1.6	26
265	1.7	1.3	13
Uniaxial compression at 5000 kgf cm ⁻² and 125 °C			
Poling after compression	1.5	1.5	8.0
Poling during compression	2.8	1.5	19

For the VDF homopolymer with crystals of the β phase, an increase in pressure to 4.5 kbar increases its melting point by more than 100 °C.¹⁷⁰ For the VDF/TrFE 70/30 copolymer, in which the melting point and the temperature of the ferroelectric–paraelectric transition are different, an increase in pressure is accompanied by an increase (albeit in accordance with different laws) in the regions of both transitions. The nature of the above phenomenon has been investigated in detail in studies^{179–181} of the structural changes under the influence of high pressure in ferroelectric VDF/TrFE copolymers having different compositions. In particular, it has been shown for PVDF/TrFE 54/46 that under normal conditions (room temperature, normal pressure) the crystal structure is characterised by the coexistence of the paraelectric and ferroelectric phases, to which correspond different angular positions of the main intermolecular reflection.¹⁷⁹ An increase in pressure to 450 GPa is accompanied, together with the general shift of the reflections towards larger angles, also by a significant weakening of the paraelectric component, the above changes being reversible.¹⁷⁹ An increase in pressure in the copolymers indicated is accompanied, according to X-ray and electrophysical measurements, by an appreciable shift of the region of the ferroelectric–paraelectric transition towards higher temperatures.¹⁸⁰

A combined study of the structural and electrophysical properties of films of the VDF/TrFE 94/6 copolymer resorting to X-ray diffraction, scanning electron microscopy, and thermal analysis data has shown that crystallisation at high pressures is accompanied by the formation of lamellar crystals of the β phase with hexagonal packing and a thickness of 100–200 nm, which retain their stability at very high temperatures. By generalising these data, the authors¹⁸¹ were able to put forward a phase diagram for the VDF/TrFE 94/6 copolymer (Fig. 17). It follows from the latter, in particular, that the melting point and the Curie point (T_c) increase with pressure according to different laws and that the hexagonal phase may be present only at high pressures. As a result of the analysis of the morphology of the supermolecular structures formed, it was later concluded that the ECC regions are formed when crystallisation from the melt gives rise to a metastable hexagonal phase, which may be subsequently converted into a stable orthorhombic phase.^{182, 183}

VI. The polymorphism of the poly(vinylidene fluoride) induced by strong electric fields

The dipole moment of the monomer unit of the PVDF chain in the 'planar zigzag' conformation is 7×10^{-30} C m,¹⁸⁴ so that it is natural to expect a high sensitivity of this polymer to strong fields. Indeed, numerous experimental data have confirmed this. High fields may affect the crystal lattice, altering the nature of the supermolecular formations in the PVDF and the isomeric composition of its chain. The above changes are usually observed by large- and small-angle X-ray diffraction methods, the method based on the small angle scattering of polarised light, and IR and Raman spectroscopy. Examination of the polymorphic transformations in PVDF under the influence of high fields can be usefully begun with a simpler case where a PVDF specimen crystallised as the β phase, in which a polymorphic should not be expected, is subjected to the action of the field. Such a case has been described in a study¹⁸⁴ where the β phase was obtained as a result of low-temperature drawing and subsequent annealing. The nature of the change in the profile of the principal β phase reflection 200, 110 after poling (in a 60 MV m⁻¹ field) showed that the polar cell uncoils under the influence of the field.

Another variant of the behaviour of PVDF in a high field has been examined in studies,^{185, 186} where crystallisation led to the formation of a mixture of the α and β modifications. Fig. 18 presents X-ray diffraction curves for the initial (biaxially oriented) film and the film treated in a corona discharge. Evidently, poling in the corona discharge even at a potential of 5 kV leads to the disappearance of the 100 and 020 reflections of the α phase and to an increase in the principal 200, 110 reflection of the β phase. The intensity of the latter increases significantly with the simultaneous decrease in yet another reflection (110) of the α phase with increase in the potential to 10 kV, which has been attributed to the polymorphic $\alpha \rightarrow \beta$ transition. Certain details of the structural changes occurring under these conditions may be noted by analysing the data in Table 13. In particular, it is seen that, after the treatment of the film in the field, the principal reflections of both the α and β phases shift towards small angles and are broadened at the same time. The former fact, indicating some 'loosening' of the transverse dimensions of the crystallites, has been attributed to the deformation of the bond angles in the main chain as a result of the interaction of the field with the polar CF₂ bonds. On the other hand, the broadening of the β reflection after

Figure 18. Diffraction curves for the initial PVDF film (1) and the film charged in a corona discharge (2, 3).¹⁸⁵ Potential in the corona discharge (kV): (2) 5; (3) 10.

charging the film is due to the decrease in the size of the crystallites or an increase in their defectiveness.

For oriented PVDF films containing only 5% of the β phase, the effect of the 1.5 MV cm^{-1} field did not lead to the appearance of any new reflections, but a number of those arising from the initial film changed significantly.¹⁸⁷ A similar phenomenon in low fields was noted also in other investigations.^{188, 189} A significant change in the concentration of the groups in the $TGT\bar{G}$ conformation was not then found¹⁸⁷ and it was therefore postulated that a new crystallographic modification α_p (δ -) is formed under these conditions.

The $\alpha \rightarrow \alpha_p$ transition leads to the formation of a new cell in which the dipole moments of two chains are parallel (Fig. 2). This transition requires the rotation of one chain by 180° (as a result of the energy of the external field and temperature) with a translational displacement along the axis of the macromolecule over a distance $c/2$. The identity periods of the new lattice are then found to be the same as in the α phase, but the structure factors for a series of the reflections may differ appreciably (Table 14).

The appearance of the new 110, 200 reflection of the β phase in higher fields^{188, 189} indicates that two stages in the structural rearrangement should be expected for the α phase: in accordance with the scheme $\alpha \rightarrow \alpha_p \rightarrow \beta$. In low fields, the $\alpha \rightarrow \alpha_p$ transition takes place without changes in the chain conformation and in the geometry of the lattice, the unit cell becoming polar under these conditions. The last factor is apparently the reason why certain reflections from the α_p phase undergo a change in intensity or are altogether extinguished (Table 14). However, this transition is not

Table 14. The structure factors for the reflections due to the α and α_p modifications of PVDF.¹⁸⁸

hkl	2θ /deg	Structure factor /rel. units	
		α phase	α_p phase
100	17.88	60	0
020	18.41	86	86

002	38.99	78	78

accompanied by any significant changes in the initial morphology.¹⁹⁰ In higher fields, conformational rearrangements of the type $TGT\bar{G} \rightarrow (TT)_n$ begin, which entail a change in the type of the unit cell. The structural rearrangements noted above are accompanied by the rotation of the dipoles relative to the direction of the field and by a change in the relative intensities of a series of characteristic bands in the IR spectrum.¹⁹¹ It is postulated that the rotations of the dipoles for the chain sections in the $(TT)_n$ conformation proceed with greater difficulty than for the chain sections in the $TGT\bar{G}$ conformation.¹⁹² Analysis of the kinetics of the variation of the intensity of the 512 cm^{-1} band (characteristic of segments with the 'planar zigzag' conformation) after the application of a rectangular electric field pulse permitted the conclusion that there are fast and slow stages in the orientation of the dipoles.¹⁹³ The former is attributed to the rotation of small crystals and the latter to the slow rotation of the chains in the crystal. It is postulated that the slow stage of the orientation process should not reduce solely to 'flip-flop' motions with 180° rotation of the chain, which are inactive in the IR region.¹⁹³

For the cyclic variation of the strength of the field and of its polarity, the orientation processes are in the nature of hysteresis. This can be inferred from Fig. 19, in which the intensity curves for two absorption bands sensitive to the 'planar zigzag' conformation are presented. If A and B are initial points, then the antiparallel nature of the curves is due to the difference between the directions of the transition moment vector for the two bands: for the 512 cm^{-1} band, it is parallel to the dipole moment of the CF_2 group, while for the 446 cm^{-1} band it is perpendicular.¹⁹³ The retention of a definite orientation of the dipoles after the removal of the high field is apparently one of the factors needed for the establishment of a residual poling in PVDF films.

Table 13. X-Ray diffraction data for the initial (biaxially oriented) PVDF film and PVDF film treated in a corona discharge.

Thickness of specimen / μm	Data from Refs 110 and 111			Data from Ref. 186					
				before treatment in discharge			after treatment in discharge

Figure 19. The hysteresis character of the 512 cm^{-1} (a) and 446 cm^{-1} (b) band intensity curves for a variable field in a PVDF film. A and B — initial points.¹⁹²

The above hypothesis that the $\alpha \rightarrow \alpha_p$ transition is not accompanied by a change in the nature of the H_V dispersion pattern¹⁹⁰ was refined to some extent data by the data of Broussoux et al.¹⁹⁴ They observed an increase in the intensity at the centre of the pattern when a PVDF film in the α_p modification was placed in a high field. Since the crystals of the α_p phase are polar, the forces acting on them alter the form of the orientation function $N(\alpha)$ for the crystallites in the spherulite. This should disturb the order in which the crystallites are arranged along the spherulite radius and should increase the scattering intensities at the centre of the pattern. During the repolarisation of the PVDF films in an 800 kV cm^{-1} field, the above changes in intensity occur over several minutes.¹⁹⁴ In high fields, this can be explained only by the influence of the space charge.

In a later study¹⁹⁵ by the same workers, the role of plastic deformation in the $\alpha \rightarrow \alpha_p \rightarrow \beta$ polymorphic transformations on poling of PVDF films was investigated. The change in the nature of the orientation of the β phase crystals under the influence of a high field was estimated (from the 201, 111 reflection) for this purpose. In one case, the poling was carried out after rolling the film and in another both processes were combined. Furthermore, by employing together with the X-ray method yet another variant of the IR spectroscopic distorted total internal reflection method, they estimated the nature of the orientation both in bulk and on the surface. The results demonstrate appreciable differences for the two poling methods. When the rolling and poling are carried out separately, the orientation in bulk proved to be less marked than on the surface and for the latter it is significantly more pronounced on the side of the positive electrode. This difference is attributed to the change in the local field as a result of the injection of carriers from the electrode. On the other hand, when the rolling and poling processes are combined, the difference between the orientations on the surface and in bulk are insignificant, as for different signs of the potential on the surface of the poling film. Owing to the high mobility of the chains, the plastic deformation processes promote an effective 'dissipation' of the space charge of the injected carriers and thereby smoothe out the inhomogeneity of the poling along the film cross-section.

The experimental critical fields for the $\alpha \rightarrow \alpha_p$ ($100\text{--}150\text{ MV m}^{-1}$) and $\alpha \rightarrow \beta$ (500 MV m^{-1}) transitions¹⁸⁸ have been confirmed, as regards order of magnitude, by calculations of the local free energy in terms of the average field approximation.¹⁹⁶ A decrease in the fields with increase in the poling temperature has also been predicted, in agreement with experimental data.¹⁹⁷ On raising the temperature from 20 to 65°C , coercive fields decrease by a factor of 2 as a consequence of the initiation of thermal defects, which should facilitate the above transitions. It is significant that this concerns only conformational defects, since irregularities in the 'head to head' attachment of groups actually increase the intramolecular potential barrier to the transition under consideration.¹⁹⁸ If it is postulated that the conformational defect is produced in the form of a kink of the kind mentioned above, the $\alpha \rightarrow \alpha_p$ transition can be modelled by the motion of a defect along a chain.¹⁹⁹ According to this model, the rate of migration of the kink depends on the field strength. At 373 K and for a field strength of 100 MV m^{-1} , the rate is $\sim 10\text{ m s}^{-1}$. This means that the kink migrates over a lamella 10 nm thick over a period of $\sim 1\text{ ns}$.

Estimates have shown that the proposed mechanism of the $\alpha \rightarrow \alpha_p$ transition requires $\sim 1\text{ ms}$ for the 180° rotation of the chain. For a quantitative justification of the proposed model, it was postulated²⁰⁰ that the motion of the kink along the chain in the form of soliton waves is the basis of the mechanism for the polarisation of the longitudinal component of the dipole moment, observed in PVDF films. Calculations based on the proposed hypothesis yield an activation energy for the migration process of $\sim 10\text{ kcal mol}^{-1}$ in the case of an ideal chain. This is an order of magnitude higher than the value obtained in dielectric relaxation experiments. It is assumed that the difference may be smaller if account is taken of the 'head to head' defects which actually exist in the chains and of the stressed bonds which may arise in the crystal or at its boundary with the nonordered phase. Another mechanism of the growth of the domain disposed most favourably relative to the polarising field has been proposed.²⁰¹ The mechanism is based on the idea of the twisting of the boundaries.²⁰² It has been shown that the additional energy per chain for 180° rotation in the conformation with minimum energy is 42 kJ mol^{-1} . The energy barrier which is overcome during the migration of the boundary along the chain is not less than 7.5 kJ mol^{-1} per repeat unit. This is comparable with the energy gain of 1.45 kJ mol^{-1} on transpolarisation of PVDF in a 2 MV cm^{-1} field.

The above structural transformation occurs only for high field strengths. Indeed, in the crystallisation of PVDF from solution in dimethylformamide in a 100 kV cm^{-1} field, neither the formation of a new phase nor a change in the form of the spherulite were observed.²⁰³ However, even at 115°C appreciable changes in the intensity of the 616 cm^{-1} band are observed only for field strengths in excess of 100 MV m^{-1} .^{204, 205} In the temperature range $50\text{--}70^\circ\text{C}$, the increase in the intensity of the conformational rearrangements occurring in the field (350 MV m^{-1}) agrees qualitatively with the data of Lu et al.¹⁹⁷ The regions of mobility in the PVDF crystal phase observed in this range by the dielectric method necessitate the assumption that above motions should play an important role in structural rearrangement processes under the influence of a field. This has been confirmed by data²⁰⁵ showing that, under the conditions of an identical field, an increase in the poling temperature from 20 to 100°C leads to an increase in the fraction of the β phase formed from 60% to 95%. Data obtained in studies on depolarisation processes in such specimens indicate that the temperature range $50\text{--}70^\circ\text{C}$ is important also for the deorientation processes involving some of the dipoles in polarised PVDF specimens and the β phase formed under these conditions remains stable up to high temperatures.²⁰⁵ The deorientation processes affect also the relaxation of the modulus in PVDF films in the early stages of stress relaxation.²⁰⁶ It must be noted that the mobility in these experiments (mentioned above) may also have a positive effect on the elastic properties,

since after longer times the inverse increase in the modulus is observed, which is most probably attributable to additional crystallisation.

Kepler et al.²⁰⁷ investigated the possibility of the theoretical estimation of the changes in the degree of crystallinity α in PVDF films with the β phase under the influence of an electric field. Estimates have shown that an increase in α with increase in field strength should be linear with a coefficient of $2.8 \times 10^{-11} \text{ V m}^{-1}$. The experimental coefficient was found to be somewhat higher, namely $(1.8 \pm 0.2) \times 10^{-11} \text{ V m}^{-1}$. One of the causes of the difference between the coefficients is, according to the authors, the difference between the relative permittivities of the amorphous and crystalline phases, giving rise to an inhomogeneity in the effect of the field on them. Yet another cause of the above difference may be the irreversible changes in the intermolecular packing of the PVDF chains under the influence of high fields. This can be inferred from the appreciable frequency shift of the characteristic bands in the IR spectra of PVDF on exposure to a strong electric field, which is reflected in Table 15.

Table 15. Variation of the band frequencies in the IR spectrum of PVDF during poling and after poling.²⁰⁸

Bond / cm^{-1}	Type of vibration	Frequency / cm^{-1}		
		before poling	during poling	after poling
976	$\nu(\text{CH}_2)$	975.9	974.8	975.8
796	$\gamma(\text{CH}_2)$	796.4	796.3	796.3
765	$\sigma(\text{CF}_2) + \sigma(\text{CCC})$	765.1	764.3	764.0
614	$\sigma(\text{CF}_2) + \sigma'(\text{CCC})$	614.7	614.0	614.3
530	$\sigma(\text{CF}_2)$	532.3	533.5	532.7
845	$\gamma(\text{CH}_2) + \nu_a(\text{CF}_2)$	843.5	846.0	844
510	$\sigma(\text{CF}_2)$	510.1	510.9	510.4

The same tendency towards a displacement of a series of β phase bands after the poling process towards higher frequencies has been noted also for the VDF/TFE 75/25 copolymer.²⁰⁹ The state of the more ideal packing of the chains after polarisation can be judged from the narrowing of the above bands and from the simultaneous increase in the density from 1.875 to 1.895 g cm^{-3} .²⁰⁹ As in the study of Kepler et al.,²⁰⁷ the polarisation of the VDF homopolymer is accompanied by an increase in α , but this occurs without change in the size of the crystallites. This finding indicates the formation of additional ordered regions from the amorphous phase.²¹⁰

The changes in the intensity of the 510 cm^{-1} band during the cyclic variation of the field applied to a biaxially oriented PVDF

film²¹¹ agree qualitatively with the changes in the intensity of this band found by Naegle and Yoon.¹⁹³ Comparison of the coercive fields obtained from spectroscopic data and from the field dependences of the electric shift showed that in the latter case they are appreciably greater. The 510 cm^{-1} band is characteristic of both the β and γ phases (Table 1). For this reason, Guy and Unsworth²¹¹ believe that one of the causes of the difference between the coercive fields is the presence together with the β phase of small amounts of the γ phase, which may have high coercive fields. Another cause is most probably the fact that the 510 cm^{-1} band is sensitive to the presence of 'planar zigzag' conformations not only in the crystal but also in the amorphous phase. The hysteresis phenomena for the latter should undoubtedly be characterised by lower coercive fields than the domain switching processes in the crystal, which are in fact responsible for the characteristics of the hysteresis in electrophysical experiments.

The influence of the poling temperature on the nature and kinetics of the structural transformations in PVDF in the range $20\text{--}100^\circ\text{C}$ has been investigated.²¹² For films with three different thicknesses, the changes in the intensities of the 510 and 530 cm^{-1} bands, which characterise the 'planar zigzag' and $TGTG$ conformations respectively, were analysed mainly. Fig. 20a presents the dependence of the relative change in the intensity of the 530 cm^{-1} band as a function of the polarising field strength. Evidently an increase in the poling temperature leads to an approximately linear displacement of the structural rearrangement region towards lower fields (Fig. 20b). The kinetics of the variation of the intensity of the 530 cm^{-1} band when a high field (2.1 MV cm^{-1}) acts on a PVDF film shows that the equilibrium value of ΔI_{530} is attained after $40\text{--}60$ min. The domain switching times in such fields should be less than 10^{-3} s.¹²⁷ The considerable differences between the domain switching and structural rearrangement times make it possible to put forward certain considerations about the details of the latter. When a field is applied to a specimen, the reorientation of crystallites takes place initially in the first stage. In the new position, the latter generate an internal field, which promotes the occurrence of orientation processes in the amorphous phase itself and at its boundaries with crystallites. The slowest stage in this process is the diffusion-controlled generation of a space charge both from the free carriers present in the initial state (before the application of the field) and as a consequence of the injection of charges from the electrodes.

A confirmation of the hypothesis of the occurrence of structural rearrangement processes in the amorphous phase may be found in the results of the study of Hsu et al.,²¹² although the authors did not draw attention to this fact. Indeed, during the poling process the 490 and 470 cm^{-1} absorption band intensities are redistributed, a decrease in that of the former and an increase in that of the latter being noted. These bands are attributed to the amorphous regions and their changes imply that poling leads to a

Figure 20. Field dependences of the relative change in the intensity of the 530 cm^{-1} absorption band at different poling temperatures (a) and temperature dependence of the critical fields in the structural rearrangement (b).²¹² T ($^\circ\text{C}$): (1) 20; (2) 40; (3) 65; (4) 80; (5) 100.

decrease in the fraction of the *gauche*-conformation as a result to the transition to the *trans*-conformation.

Yet another rather unpredicted phenomenon was later observed.²¹³ In previous sections, it was shown that the $\alpha \rightarrow \gamma$ transition initiated by prolonged high-temperature annealing of films with crystals of the α phase or by the crystallisation of PVDF from the melt with slight supercooling. The crystallisation of PVDF from the melt with high degrees of supercooling has been investigated in a 0.07 MV cm^{-1} electric field.²¹³ An experiment involving crystallisation with the same degree of supercooling but in the absence of an electric field was carried out as a control. It was observed that in the latter case PVDF always crystallised as the α phase. On the other hand, IR spectroscopic data showed that crystallisation in a weak field is accompanied by the appearance of an appreciable amount of the γ phase. This was inferred from the appearance of the 815, 776, 510, and 430 cm^{-1} bands characteristic of the T_3GT_3G conformation. It is significant that the fraction of the γ phase increases with decrease in the degree of supercooling and reaches 70% in the best cases. This phenomenon may be not only of academic interest but may also find a practical application.

The characteristics of the structural transformations under the influence of strong electric fields have been observed also for the VGF/TrFE 75/25 copolymer, which crystallises immediately as the ferroelectric β phase in the absence of the field.²¹⁴ It was observed by IR spectroscopy that the number of long sections of the chains in the 'planar zigzag' conformation (the 850 and 1290 cm^{-1} bands) changes in different ways following the application of a strong field depending on the temperature. Thus the application of a field at room temperature, which differs markedly from the Curie temperature, leads to a decrease in the concentration of the above sections (this is not observed for the VDF homopolymer), whereas at temperatures close to the Curie point the opposite behaviour is noted. It is believed that the improvement of order occurs only if it has been disturbed in the initial state (in the absence of a field) owing to large thermal fluctuations.

Transitions under the influence of a field on PVDF films obtained by different methods have been observed by X-ray diffraction, IR spectroscopy, and DSC.²¹⁵ Variation of the method of preparation showed that the threshold fields for the structural transformations of the α phase may be 0.6 and 1.6 MV cm^{-1} .

In a series of studies designed to estimate the possible structural changes in PVDF after and during the treatment by operation of strong electric fields, NMR spectroscopy was employed.^{216–210} Significant changes were noted in the direction of the b axis of the lattice in a field of 1 MV cm^{-1} even at room temperature.²¹⁶ Variation of the field strength demonstrated an appreciable decrease in the fraction of mobile protons in fields of $1.5–1.6 \text{ MV cm}^{-1}$,²¹⁷ whilst analysis of the second moment of the absorption line indicates the presence, together with the crystalline phase, of highly oriented chains of the nonordered phase, the fraction of which may reach 0.14.²¹⁸

The distribution function for the b and c axes of the lattice in PVDF films after their poling has been analysed.²¹⁹ Comparison of the intensities of the 111 and 001 reflections for the PVDF β phase before and after poling shows that a high field affects not only the distribution functions for the polar axes of the lattice (b) but also the distribution functions for the axes of the macromolecules (c). At the same time, it was noted that, despite the high fields the distribution of the b axes relatively to the normal to the film surface remains fairly wide. According to the authors²¹⁹, this creates potential possibilities for increasing the residual poling P_r in the ferroelectric PVDF by a factor of at least 2.²¹⁹ In the case of uniaxially extended PVDF films, P_r can be partly increased by selecting the conditions for preliminary isometric annealing. Thus it has been shown that such annealing at high temperatures ($160–180^\circ \text{C}$) is accompanied by an appreciable increase in P_r (from 51.4 to 65.2 mC m^{-2}).²²⁰ This is attributed to a considerable increase (from 45% to 68%) in the degree of crystallinity

under such annealing conditions. Somewhat later, Takase et al.²²¹ showed that such annealing is accompanied by an increase in the chain packing density in the lattice of the β crystallites and by an increase in their perfection. At the same time, these structural changes decrease appreciably (from 67.0 to $41.3 \mu\text{s}$) the domain switching times for a 2 MV cm^{-1} field in the ferroelectric phase.²²¹

The structural transformations in oriented PVDF films, crystallised as a mixture of the α and β phases, have also been investigated by the method of X-ray pole figures.²²² Analysis of the data shows that the distribution of the orientations of the dipoles along the direction of polarisation begins to change appreciably already in fields of 80 MV m^{-1} , although the nature of the distribution is restored after the removal of the field. Such low threshold fields may be associated with the high draw ratio ($\lambda = 6$) of the initial film. A field-induced increase in crystallinity has been observed,²²² which corresponds qualitatively to the data of Kepler and Anderson.¹⁸⁴ The dependence of the additional increment in the degree of crystallinity in PVDF films on the polarising field strength (Fig. 21) indicates nevertheless also certain differences with the above study. Whereas in the latter a monotonic linear dependence was noted in the entire range of fields, it can be seen from the figure that in the range $160–100 \text{ MV m}^{-1}$ an 'anomalous' decrease in the degree of crystallinity takes place. The cause of such decrease is probably the competitive effect of two processes. In low fields, the structures of the crystallites, the polar axis of which assumes a favourable disposition relative to the external field, are built up (using the chains of the amorphous phase). In a higher field, the energy of the latter is sufficient to initiate the rotation of single chains in crystals with an unfavourable disposition. Such rotations may disrupt the crystals, which in fact leads to a decrease in the degree of crystallinity. One should also note that, after the field has been switched off, the degree of crystallinity falls significantly. This finding most probably indicates that the reversible component or the increase in the degree of crystallinity is effected via a transition to an ordered state of some of the chains of the amorphous phase (or of its boundaries with the crystal). After the removal of the electric field, these regions again pass to the disordered state.

The contributions of the dipoles of the crystalline and amorphous phases to the field-induced orientation processes have been divided on the basis of a modified scheme for IR spectroscopic analysis, which provides for the possibility of altering the angle at which the beam enters the textured PVDF films.²²³ Use was made of a uniaxially extended film in which the fraction of the residual α phase was less than 5%, i.e. the polymorphic transformation under the influence of the field could be neglected

Figure 21. Dependence of the additional increment in the degree of crystallinity in PVDF films on the poling field strength.²²² (1) With the field applied; (2) after the removal of the field.

and the changes in the IR spectra could be unambiguously attributed solely to the change in the orientation of the dipoles. Two vibrational bands (at 510 and 445 cm^{-1}), characterising the 'planar zigzag' conformations were selected. The former corresponds to the CF_2 groups in both phases, while the latter corresponds only to the dipoles in the crystallites. Analysis of these data showed that, whereas in the initial state the dipoles form an angle of $42\text{--}44^\circ$ relative to the normal to the film, after the application of a 2.4 MV cm^{-1} field the angle is 27° for the 510 cm^{-1} band and 18° for the 44 cm^{-1} band. The significant difference between these values demonstrates unambiguously that, for the same field, the dipoles are better oriented in the crystal than in the amorphous phase.

A general thermodynamic approach to the quantitative description of the influence of the field on the crystallisation of PVDF (in the α or γ phases) has been developed.²²⁴ The authors of this study began with the concept of homogeneous primary nucleation. The free energy of formation (in the absence of a field) of N cylindrical particles with a length L and an area A may be found from the relation

$$\Delta F_0 = -NLA\Delta f + 2NA\sigma_e + 2L\sqrt{NA\pi}\sigma, \quad (6)$$

where Δf is the free energy of fusion of a crystal with a unit volume and σ_e and σ are the end-face and lateral surface free energies of the nucleus respectively. In order to take into account the contribution of an electric field with a strength E_0 , a modified Guggenheim approximation was used. The free energy function $F(T, V, E_0)$ assumes the following form for the formation of a crystalline nucleus with a volume V_c and a permanent polarisation P_0 :

$$F(T, V, E_0) = F_0(T, V) - V_c P_0 E_0 - \frac{V_c \epsilon_0 \epsilon E_0^2}{2}. \quad (7)$$

where ϵ is the relative permittivity of the system. Experiments designed to investigate the Kerr effect in PVDF demonstrated a weak orientation of the chains in an electric field. On this basis, it was assumed that the induced polarisation is much smaller than the permanent polarisation. Taking this into account, the authors²²⁴ concluded that there is a large difference between the nucleation processes in an electric field for particles with polar and nonpolar phases. The overall free energy equation for crystallisation in nonpolar (α) and polar (γ) phases subjected to a field is

$$\Delta F = -NAL(\Delta f + PE_0) + 2NA\sigma_e + 2L\sqrt{NA\pi}\sigma. \quad (8)$$

For the α phase, in which the permanent polarisation is zero, P has the significance of the induced polarisation P_i :

$$P = P_i = \epsilon_0 \epsilon_a \frac{(\epsilon_c - \epsilon_a)}{(\epsilon_a + \epsilon_c)} E_0. \quad (9)$$

For the polar γ phase, one should consider, for the reason stated above, only the permanent polarisation P_p , which is linked to the polarisation of the crystal P_c and the relative permittivities of the crystal (ϵ_c) and the melt (ϵ_a) by the relation

$$P = P_p = \frac{2\epsilon_a}{\epsilon_a + \epsilon_c} P_c. \quad (10)$$

By differentiating Eqn (10), it is possible to find the values of the critical parameters: the concentration N_c^* , the size L_c^* and the free energy of formation ΔF_c^* of a nucleus with the critical size in an electric field. For temperatures which are not far below the equilibrium melting point T_m^0 the expression for ΔF_c^* is

$$\Delta F_c^* = \frac{\Delta h \Delta T}{T_m^0},$$

where Δh is the enthalpy of fusion and $\Delta T = T_m^0 - T$ is the degree of supercooling.

Taking into account all the above considerations, the rate of nucleation J_e may be found from the equation

$$J_e = K' \exp \frac{-U_0}{k(T - T_\infty)} \exp \frac{-\Delta F_c^*}{kT}, \quad (11)$$

where K' is a constant, U_0 is the activation energy for the transfer of the species comprising the nucleus ($1.5 \text{ kcal mol}^{-1}$), and $T_\infty = T_g - 30 \text{ K}$.

For analysis, it is more convenient to use the relative change in the rate of nucleation in a field (J_e) and in its absence (J_0) rather than Eqn (11). Such relations (in terms of semilogarithmic coordinates) as a function of field strength for different degrees of supercooling ΔT are presented in Fig. 22. In particular, it is seen that the effects of the field on the crystallisation of the polar and nonpolar modifications of PVDF are different. Whereas the field intensifies nucleation in the γ phase, and to a more significant extent for lower degrees of supercooling, the opposite effect is observed for the α phase (with a nonpolar cell). The theory developed has been confirmed qualitatively by the results of experiments^{203,212} and investigation²²⁵. According to the data obtained in the last study, the application of a 0.1 MV cm^{-1} field during crystallisation does indeed accelerate significantly (for the same crystallisation temperatures) the rate of formation of the γ phase, 100% conversion being achieved already at temperatures of $\sim 165^\circ \text{C}$. The field alters significantly also the form of the dependence of the total degree of crystallinity (taking into account the α and γ phases) on the crystallisation temperature.

However, the theoretical ideas which have been developed do not account for a series of new experimental relations. Thus it has been observed²²⁵ that the morphology arising in PVDF specimens crystallised in high fields and at high temperatures is not homogeneous along the film area. Indeed, the spherulites which have appeared during crystallisation at different depths differed both in size and birefringence, on the one hand, and in concentration, on the other. We may note that the sign of the potential on the electrode is an important factor for the formation of crystallites. For example, near the positive electrode the nucleation density is always greater than in the vicinity of the negative electrode. In the light of the theory developed, the latter factor should be most probably attributed to the fact that the permanent polarisation in the vicinity of the positive electrode is always greater than near the negative one.²²⁶ Direct observations of the crystallisation process have shown²²⁵ that the role of the field does not reduce to the direct inhibition of the rate of formation of the α phase, as predicted by the theory.²²⁴ The decrease in the number and

Figure 22. Dependence of the relative change in the rate of nucleation with and without the application of the field with different degrees of supercooling for the γ phase (a) and the α phase (b).²²⁴ ΔT ($^\circ \text{C}$): a: (1) 30; (2) 40; (3) 50; (4) 60; b: (1) 5; (2) 10; (3) 15.

average size of the α spherulites occur as a result of the acceleration of the processes involving the crystallisation of the γ phase spherulites. It has also been noted that, whereas in the absence of the field γ spherulites of approximately equal size are obtained, crystallisation in a field lowers the above homogeneity. The intensity of the depolarisation in the scattered light pattern is also reduced, which has been attributed to the disturbance of the radial disorder of the b axes of the γ phase crystallites in the spherulite under the influence of the field. The fact that disc-shaped spherulites in which the radial direction is in the plane of the film arise near the negative electrode indicates that the field affects not only the processes involving the formation and growth of the nuclei but also the secondary crystallisation processes accompanied by the formation of a supermolecular structure.

This conclusion agrees with the results of a study²²⁷ which confirms, in particular, the theoretical conclusion²²⁴ that the field has an inhibiting effect on the crystallisation of the α phase. However, results which cannot be predicted by the theory have been obtained for γ phase crystals. For example, it has been observed that the nature of the morphology generated may depend significantly on the configuration of the electrodes. An increase in the rate of growth of γ spherulites under the influence of the field has been observed only for direct contact between the specimen and both electrodes. In contrast to the results of Marand et al.,²²⁴ disc-shaped γ spherulites were formed near the positive electrode. Experiments on crystallisation, where one or both electrodes were blocked, showed that such conditions affect appreciably the nature of the morphology produced. Apparently, this can be most reasonably explained by the appearance of local electric fields, arising due to the injection of carriers from the metal into the polymer and captured by traps in the latter.

The VDF/TrFE copolymer exhibits ferroelectric properties most distinctly. The structural transformations in an electric field as a function of the number of triangular pulses applied to the specimen have been investigated for this polymer.²²⁸ The amplitude value of the field strength was 160 MV m^{-1} and the pulse frequency was 0.001 Hz . For an isotropic specimen crystallised as a mixture of the α , β , and possibly γ phases, a virtually complete $\alpha \rightarrow \beta$ transition was observed after only 6–8 pulses and the residual polarisation and the coercive field also attained the equilibrium values. Comparison of the temperature variations of the principal reflections from two polarised specimens in the same investigation made it possible to reach an important conclusion concerning the role of the morphology in the stability of the structure formed under the influence of the field. Isotropic and uniaxially extended specimens were compared, the nature of the X-ray diffraction by both being identical. The former crystallised with formation of thick lamellar crystals with a thickness of $\sim 0.1 \mu\text{m}$, while in the latter a typical fibrillar morphology with the usual ($\sim 100\text{\AA}$) longitudinal dimensions of the crystals was observed. For isotropic specimens, the principal 200, 110 reflection of the β phase remains constant up to $\sim 150^\circ\text{C}$, while for the oriented specimen its intensity begins to change appreciably above $70\text{--}80^\circ\text{C}$. The above differences have also been confirmed indirectly: the higher piezoelectric constant d of the oriented specimen shows that the nature of the structural changes following the application of mechanical loads differs significantly for the isotropic and textured polarised films.

The nature and dynamics of the domain structure were elucidated for the same copolymer (with the composition 65/35) by determining on the real time scale the changes in the structural characteristics during the ferroelectric switching of the specimen.²²⁹ The influence of the poling field strength, primarily on the size of the β phase crystallites and on their perfection, has been tested in relation to the oriented specimen. For this purpose, the integral widths (B) of the 110, 220 and 330 reflections, i.e.

$$B = \frac{1}{L_{110}} + \frac{(my)^2 m^2}{d_{110}}, \quad (12)$$

were estimated for three specimens obtained by polarisation in 60, 90, and 200 MV m^{-1} fields. Here L_{110} is the transverse dimension of the crystallite in the direction of the normal to the 110 plane, m is the diffraction order, $y = \langle d_{110} \rangle / d_{110}$ the degree of defectiveness of the second kind in the crystal, and d_{110} the interplanar spacing.

The analysis showed primarily that the main contribution to B comes from the size of the crystallite, which increases from 19 to 39 nm in the field change indicated above. The defectiveness of the crystal was within the limits of 3% and tended to decrease somewhat on poling. Data on the dynamics of the structural changes in the transposing of a nonoriented specimen, obtained on the real time scale, are valuable and unique. The increase in the electric displacement on switching the poling is accompanied by characteristic changes in the parameters of the 110 reflection of the polar β phase (Fig. 23). The intensity of the reflection at the maximum as well as its integral intensity at the characteristic time pass through a minimum, while the integral width passes through a maximum. Evidently, the parameters of the above reflection vary within the limits of several per cent and in a number of

Figure 23. Time variations of the intensity of the maximum (a), the integral intensity (b), the width (c), and the electric displacement (d) of the 110 reflection during the switching of the poling of the VDF/TrFE copolymer.²²⁹

instances their monotonic variation may be observed. The latter presupposes a large contribution to processes responsible for the characteristic features of the supermolecular structure. The nature of the change of the integral intensity indicates the 180° rotation of the chains on transposing of the specimen, in contrast to the 60° model which is frequently employed.

The new reflections observed by Servet and Rault²³⁰ and later also by Newman and Scheinbeim²³¹ and Weinhold et al.²³², which could not be indexed in terms of the lattices of any of the known polymorphic transformations, are important for the understanding of the details of the mechanism of the structural transformations in PVDF under the influence of strong electric fields. More detailed study showed²³³ that the reflections of the new superlattice in a specimen with the polar α phase are located in the vicinity of the reflections characteristic of the β form: 110, 200, 001, and 111, 201.

We discussed above a series of results indicating the existence in the α phase of kink bonds, which are detected from the characteristic features of the scattering in the vicinity of the reflections mentioned above. Taking this into account, the hypothesis was put forward that the reflections from the superlattice are reflections from ordered regions formed by aggregates of the kink bonds. Thus the new form is intermediate between the polar modification of the α phase and the β phase in the course of the field-induced type $\alpha \rightarrow \alpha_p \rightarrow \beta$ transformation. Calculations showed that the probability of intramolecular rearrangements on formation of the new form may depend significantly on the parity of the number of bonds n passing to the 'planar zigzag' conformation when the conformational defects noted above are formed. As an example, one may consider two schemes of transformations for even and odd values of n :²³³

...TGTGTGTGTGTGTGTG...

...TTTGTGTGTGTGTGTG...

1

...TGTGTGTGTGTGTGTGTG...

...TTTTGTGTGTGTGTGTG...

2

It may be said that the transformation in accordance with Scheme 2 should take place preferentially compared with Scheme 1. Indeed, whereas the rearrangements in the second scheme are effected as a result of transitions of G or \bar{G} bonds to T bonds, in Scheme 1 there are in addition the transitions $G \rightarrow \bar{G}$ and $\bar{G} \rightarrow G$, which require the cooperative motion of the entire chain. Fig. 24 presents two variants of the chain conformations (with an odd number of bonds in the repeat unit) for the new form. The presence of chain sections with the $G\bar{T}\bar{G}$ conformation between the bonds in the 'planar zigzag' conformation makes it possible to regard the polar β phase and the new modification as conformationally incommensurable. Fig. 24 shows that two features are characteristic of the above superlattice. Firstly, the identity period along the axis of the macromolecule is found to be greater than for the β phase with the 'planar zigzag' conformation. Furthermore, the appearance of a definite tilt angle for the axes of the macromolecules forming the triclinic lattice is characteristic of this superlattice.

Partly crystalline polymers, including PVDF, are known to have a heterogeneous structure. The presence of a large volume fraction of a nonordered phase complicates the molecular mechanism of the structural rearrangements in PVDF under the influence of strong electric fields. The elucidation of the role of the amorphous phase and of its microstructure in the above phenomena should be the subject of separate investigations. A series of experimental results indicating the nontrivial role of the microstructure in the changes occurring under the influence of a field are presented below. The paper of Sen et al.²³⁴, who described a study of the influence of added plasticiser (tricresyl phosphate) on the nature of the field-induced structural transformations, should probably be regarded as the first communication of this kind. Despite the fact that the plasticiser molecules should be

Figure 24. Molecular models for the conformations of the chains in the PVDF superlattice.²³³

located predominantly in regions with an increased free volume, i.e. in the amorphous phase, it was found that the plasticiser influences significantly the characteristics of the polymorphic transition which occurs particularly in the crystalline regions. In plasticised PVDF, the $\alpha \rightarrow \alpha_p \rightarrow \beta$ transitions occur in the presence of appreciably lower fields than in the nonplasticised polymer. As a result of this, the fraction of the β phase formed in the plasticised PVDF is found to be higher almost by a factor of 2 under the same polarisation conditions. The accompanying increase in macroscopic characteristics such as the residual polarisation and the relative permittivity leads also to higher values of the piezoelectric constants d_{31} and e_{31} . A qualitatively similar result has been obtained also in a study²³⁵ where the plasticiser for PVDF was poly(ethylene glycol).

Direct evidence for the important role of the nonordered phase in the strong field-induced structural transformations has been obtained in a study¹⁶⁰ where uniaxially extended VDF/TFE 94/6 copolymer films were investigated. It was shown that, in the presence of high fields, hysteresis-type electric displacement and switching current curves arise for the films. These characteristics for two films with draw temperatures of 60 and 140°C (for the same draw ratio $\lambda = 4$) may be compared in Fig. 25. Evidently, the remanent electric displacements (as well as their maximum values) differ appreciably. The current hysteresis curves also differ significantly. Structural studies have shown that the above copolymer forms the β modification with the 'planar zigzag' conformation under the usual crystallisation conditions.^{32, 160} However, taking into account the increased concentration of bonds in the $TGT\bar{G}$ and $T_3GT_3\bar{G}$ conformations of films oriented at high draw temperatures,¹⁶⁰ one may assume that the difference between the current hysteresis curves is caused by the characteristic features of the microstructure of the amorphous regions. This confirms the small angle X-ray diffraction curves (in the meridional direction) for the same films (Fig. 16). The higher intensity of the maximum for films with an increased draw temperature is most probably due to the greater difference between the densities in the amorphous and crystalline regions. If the β modification is produced in all the films, then the foregoing finding must be attributed to the less dense packing of the amorphous regions along the direction of stretching. The characteristics of the microstructure of the amorphous region affect the remanent and maximum electrical displacement for field strengths in excess of the critical values, where a remanent poling appears (Fig. 25). The

Note. The following notation has been adopted: R — dichroic ratios for a series of specific IR bands; L — long period of the crystal; l — longitudinal dimension of the crystal; n — number of chains per unit area in the amorphous phase; N — ditto in the crystal.

increased response to the external field depends significantly on the degree of orientation of the chain in the amorphous regions (Table 16).

Figure 25. The field dependences of the remanent (1–3) and maximum (1'–3') electric displacements for films of the VDF/TFE 94/6 copolymer uniaxially oriented at 60 °C (1, 3, 1', 3') and 140 °C (2, 2').¹⁶³

The dichroic ratios at frequencies of 470, 490, and 600 cm^{-1} are attributed only to the amorphous phase, whereas at a frequency of 508 cm^{-1} they are believed to be due to the 'planar zigzag' conformers in both phases. Evidently the increase in T_d leads to a decrease in R for all the frequencies specified. At the same time, this is accompanied by an increase in the size of the amorphous gaps obtained in the form of the difference between the long period and the longitudinal size of the crystal.

The decrease in size between neighbouring crystallites is accompanied by an increase in the number of stressed chains passing through them [tie-tough-chains (TTC)], which is indicated by acoustic relaxation data.¹²⁹ At the polarisation temperature (in our case, this is 20 °C), the amorphous regions are in the rubber state, i.e. their compliance is an order of magnitude higher than in the crystalline phase. This means that the polar chains of the amorphous phase should respond in the first place to the increase in the external field strength. The presence of 'planar zigzag' conformers, for which the transverse component of the dipole moment is greater than for the $TGT\bar{G}$ and $T_3GT_3\bar{G}$ conformations because the field strength vector is perpendicular to the surface of the film, is of great importance in this connection. The TTC

regions may play a very important role in these phenomena, since the same chain may enter into both regions mentioned above and into the β phase crystal itself. As a result of this, the rotations in the TTC chains arising under the influence of the field should be transmitted also to the chains of the crystal, leading ultimately to their reorientation as a whole.

Thus the response in textured films of PVDF and its copolymers may be intensified by bringing them closer to the texture of the 'ideal single crystal'. As has been seen, this requires a decrease in the conformational heterogeneity along the chain, an increase in the size of the noncrystalline regions, and an increase in the fraction of the TTC within them.

Special attention must be given to the role of the texture in the materials investigated. The creation of a definite texture in films of the VDF/TFE 94/6²³⁶ and VDF/TFE 71/29²³⁷ copolymers, which can be characterised by the average orientation, promotes a decrease in the coercive fields and an increase in the residual polarisation. The reason is probably that, when a texture is formed, there is a tendency for the arrangement of the axes of the macromolecules in the plane, which facilitates the interaction of the field with the transverse component of the dipole moment, rigidly linked to the main chain.

The role of the amorphous phase in ferroelectric response phenomena can also be seen in relation to isotropic films. A common feature has been observed in the copolymers having the above compositions. For films with a lower degree of crystallinity (this was inferred from the densities and relative permittivities) lower coercive fields and hence greater remanent pollings were noted.^{160, 237} This was attributed to the greater compliance of the amorphous phase chains and to the initiation of the intrinsic ferroelectric polarisation in the neighbouring β phase crystals.

VII. The influence of irradiation on the structure of poly(vinylidene fluoride) and its copolymers

The structural-chemical transformations in PVDF have been investigated by spectroscopic methods.²³⁸ It was shown that an increase in the radiation dose promotes the accumulation of both vinyl $-\text{CH}=\text{CF}_2$ (1715 cm^{-1}) and vinylidene $>\text{C}=\text{CF}_2$ (1750 cm^{-1}) groups. Radiation-chemical processes occur more often on irregularities than on ideal chains. Branches and 'head to head' defects are included among the former. The fraction of irregularities was estimated from high-resolution NMR spectroscopic data. At least two types of radicals, detected in the oriented PVDF specimens, may correspond to the α and β modifications present in such specimens. The appearance of intermediate species (carbonium ions), which are manifested in the form of luminescence peak on the temperature curves of radiothermoluminescence has also been detected.

According to empirical rules, chain rupture reactions should predominate on irradiation in polymers with a structure of the type $(-\text{CH}_2\text{CR}_1\text{R}_2-)$; on the other hand, mainly cross-linking has been noted in PVDF chains. The ratio of the probabilities of scission and cross-linking steps on γ -irradiation has been esti-

mated as 0.35, which leads to an increase in the gel fraction to 0.7 rupture for a dose of 10 Mrad.²³⁹ The hypothesis²³⁸ that the dissociation and cross-linking reactions are linked, which should be associated with the migration of a radical centre (charge) along the chain to the location of the irregularity, has also been confirmed by a study²⁴⁰ of the irradiation of PVDF by accelerated electrons. The sequences of another comonomer can also serve as irregularities of this kind. Therefore, an increase in the gel fraction in the copolymer of VDF and hexafluoropropene compared with the homopolymer confirms qualitatively the above hypothesis. Additives promoting the formation of a three-dimensional network also play a significant role in cross-linking processes on irradiation. This can be inferred from the increase (other conditions being equal) in the gel fraction following the introduction of a sensitizer into the irradiated PVDF.^{240, 241}

The form of the energy-carrying species is important for the processes occurring on irradiation. For example, comparison of data concerning the influence of irradiation by electrons and protons on the strength characteristics of PVDF indicates a significant difference between them. It was observed that, in order to reduce the relative elongation at break by a factor of 2, a proton flux smaller by a factor of ~ 20 than the electron flux is needed.²⁴² These results are related to the data obtained in a study²³⁹ where it was shown that irradiation of PVDF with γ -rays and α -particles leads to a significant difference between the initial free radicals formed. The kinetics of the recombination of such radicals also differ significantly: in the case of γ -rays, the radicals begin to recombine already above 77 K, whereas under the conditions of α -irradiation, the radicals are stable up to 240 K. The dependence of the concentrations of the above radicals on the irradiation dose shows that fast recombinations takes place immediately in the region of the tracks formed along the paths traversed by the particles.

The nature of the radiation damage in the case of helium ions may depend significantly on the energy of the incident particles (for the range 0.4–4.5 MeV).²⁴³ For an energy of 0.4 MeV, the helium ions, which have a path length of only 27 μm , are responsible for an 86% decrease in crystallinity relative to the initial value, while the solubility of the irradiated specimen is reduced by 76%. Such changes in characteristics have been attributed to the probability of the formation of a hydrogen atom, which may rapidly diffuse in space.

By following the dielectric relaxation process associated with micro-Brownian motion in the amorphous regions of PVDF, it is possible to refine the nature of the radiation-chemical transformations and their location. Thus a decrease in the intensity of the above process for irradiation doses of 30–40 Mrad suggests that cross-linking occurs in the amorphous regions, which results in the creation of a definite steric hindrance to the reorientation of a chain segment.^{244, 245} The possible appearance of polyene chains may give rise to an increase in the intensity of the process under consideration for lower irradiation doses.²⁴⁵ It is believed that the cross-links appearing on irradiation may be located not only in particularly nonordered regions but also on the surfaces of lamellae, since an increase in the irradiation dose lowers the intensity of the α -process associated with motion in crystalline regions.²⁴⁵ The observations of irreversible changes in dielectric losses are of interest. After the cessation of irradiation, the latter return to the initial values.²⁴⁴ This phenomenon may be associated with the accumulation of carriers, which may then fall into deep traps.

Studies on the structural changes occurring in PVDF and its copolymers on irradiation began as early as the beginning of the 1980s but developed to a greater extent only in the last 15 years. One may name a large number of studies in which it has been shown that the degrees of crystallinity α of a series of polymers increase for low irradiation doses.^{246–253} This behaviour is common to crystallising polymers, including PVDF.^{254, 255} The nature of the above phenomenon has not been discussed by the authors of the studies mentioned, so that analysis of the con-

formational changes in the chains of PVDF during its irradiation may 'throw light' on this effect.^{256, 257} On γ -irradiation in air of uniaxially and biaxially extended films of the PVDF homopolymer, a weakening of the intensities of the bands associated with the $TGT\bar{G}$ conformations and, conversely, the intensification of a series of bands corresponding to the 'planar zigzag' conformation were observed.^{256, 257} This occurred predominantly in the range of irradiation doses up to 50 Mrad, i.e. in the region where an increase in the degree of crystallinity has also been noted. The radiation-induced conformational rearrangements in PVDF chains were most probably located predominantly in amorphous regions of the polymer, since the intensities of the bands attributed to the nonordered phase changed most significantly. This follows from the fact that, after irradiation at a dose of 30 Mrad, the intensity of the 470 cm^{-1} band increased appreciably at the expense of the weakening of the 490 cm^{-1} band. These bands are attributed to the 'planar zigzag' and $TGT\bar{G}$ conformations of the PVDF chains in the nonordered regions.²⁵⁷ The above finding therefore indicates the possibility of conformational rearrangements on irradiation. For a biaxially oriented film, this effect is due to the most marked.²⁵⁶ The intensity of the 600 and 740 cm^{-1} bands, due to the particular amorphous regions in PVDF, decreased after irradiation, which agrees with DSC data.^{256, 257}

The above results are to some extent correlated with the conclusions reached in studies^{258, 259} in which structural changes in irradiated PVDF specimens were recorded by the X-ray method. The authors of these investigations observed a series of interesting effects due to the influence of large irradiation doses. For example, it was shown that powders are more resistant to irradiation than the film prepared from them, which was accounted for by the role of oxygen. For specimens in various polymorphic forms, an increase in the irradiation dose was accompanied by a decrease in the order characteristics. However the stability of the β modification proved greater than that of the α modification. Whereas the initial specimens crystallised as the α form, at doses of 500–600 Mrad the $\alpha \rightarrow \beta$ polymorphic transition took place.

The significant differences between the irradiation doses inducing structural changes found by Kosmynin and Gal'perin,^{258, 259} on the one hand, and a number of other workers,^{254–257} on the other, can be explained by the fact that in the latter the changes concern predominantly the nonordered regions (or regions adjoining the crystal), whereas in the former the crystals proper were considered.

In the case of VDF copolymers with small amounts of added TFE, the trend in the structural changes on irradiation becomes similar to that for the homopolymer. This is confirmed by the nature of the changes in the diffractometer traces for isotropic specimens of the VDF/TFE 94/6 copolymer after irradiation with doses up to 10 Mrad.^{115, 116} After irradiation, the intensity of the 001 and 210, 111 reflections increases, since the order in the above directions is 'improved'. The broadened reflection at $2\theta = 18^\circ$ is due to the presence of highly disordered paraelectric phase in the initial specimen. Therefore the decrease in the intensity of the above reflection after irradiation can be explained by the partial paraelectric–ferroelectric transition. More significant changes in the structures of the above copolymers have been observed in uniaxially extended specimens for which X-ray photographs were taken in the meridional direction. The intensity of the amorphous halo, adjoining the 001 reflection, decreased significantly after irradiation under these conditions. These results are qualitatively correlated with DSC and IR spectroscopic data.^{254–257}

The initial copolymer specimens may be crystallised in a definite metastable state where the crystalline phase consists mainly of the paraelectric α phase^{117, 118} characterised by the 020, 110, and 021 reflections. The structural changes in the copolymer with increase in the irradiation dose are shown in Fig. 26. For the initial specimen, the intensity of the 110, 200 reflection due to the ferroelectric β phase present was found to be appreciably lower than that of the 110 reflection due to the α

phase, where former is manifested by the presence of a shoulder (on the side of larger angles) for the latter reflection. With increase in the irradiation dose, the intensity of the β phase reflection rises and for a dose of 10 Mrad, the reflection is fairly well resolved as a consequence of the decrease in the half-width. On the other hand, the increase in the dose to 40 Mrad leads to the equalisation of the intensities of the above reflections due to the α and β phases, which is manifested by some broadening of the resolved doublet. At high irradiation doses, changes were noted also in the region of the 020 reflection ($2\theta = 18.4^\circ$) due to the α phase, where together with the latter a broadened halo arises, indicating the appearance of perturbations in the paraelectric phase. In conformity with the foregoing and also in view of the increase in the intensity of the intramolecular 201, 111 reflection due to the ferroelectric β phase, one may infer the radiation-induced $\alpha \rightarrow \beta$ transition.^{115, 116}

The mechanism of the above structural transformations in PVDF and its copolymers with TFE is most probably determined by the ferroelectric nature of these polymers. The nature of the changes in the 470 and 490 cm^{-1} absorption bands for the uniaxially extended PVDF after irradiation agrees with those for the film after treatment in a corona discharge.²⁵⁷ In the latter case, the above conformational changes of the type $TGT\bar{G} \rightarrow (TT)_n$ occur under the influence of the field, including the field generated by the surface layer of the injected charges and charges captured by deep traps. The irradiation of PVDF is accompanied by an appreciable increase in the dielectric loss factor, which can be accounted for, with a high degree of probability, by the appearance of additional free carriers.²⁴⁴ Bearing in mind the high penetrating capacity of γ -radiation, their concentration is on average the same throughout the volume, in contrast to the charges in the corona polarisation of PVDF, which are located predominantly on the surface of the film. The decrease in the conductivity of the PVDF films after the cessation of irradiation may be associated with carrier recombination processes. However, bearing in mind their low mobility, capture by deep traps must be regarded as a more likely cause. In the case of the strongly polar ferroelectric β phase crystal, the carriers may be located on charged planes.

Thus local internal fields, sufficiently strong to induce the above conformational transformations, may be generated at these sites. If one begins with this mechanism, then the location planes (in isotropic specimens) are 201, 111, since the intensity of the reflection from them changes most significantly.

The structural transformations under discussion may occur via an epitaxial crystallisation mechanism where sequences of the chain in the $TGT\bar{G}$ conformation, undergoing a transition to the 'planar zigzag' conformation, may undergo additional crystallisation, producing neighbouring regions of the ferroelectric β phase. This mechanism is supported by spectroscopic data, according to which the above conformational transformations are manifested most distinctly in films containing the crystals of the α and β phases.^{256, 257} Naturally, in structural modification processes account must be taken also of the role of the chemical changes in the PVDF chains on irradiation.

As mentioned above, the advantages of the cross-linking processes occurring in the amorphous regions have been confirmed both by the nature of the decrease in the intensity of the dielectric absorption for the micro-Brownian motion in the amorphous regions^{245, 260} and by the decrease in the coefficient of thermal expansion of the lattice in the a and b directions in the cell.²⁶¹ However, the nature of the morphology, which is extremely variable in such systems, may affect the ratio of the yields of the scission and cross-linking reactions. Analysis of the changes in the mechanical characteristics in PVDF and in its copolymers with TFE on irradiation shows that in the oriented state there is an increase in the fraction of tie-tough-chains in the amorphous phase, in which degradation reactions should predominate although the polymer as a whole may remain in the cross-linked state.²⁶² The above significant change in the ratio of the intensities of the amorphous halo and of the 001 reflection after irradiation of a uniaxially extended specimen of the PVDF copolymer also confirms the hypothesis put forward. Indeed, the scission processes on the TTC should facilitate the thermal motion processes in the remaining fragments, as a result of which they may be incorporated in the neighbouring crystals of the β phase, increasing their size and perfection in the direction of the 001 plane.

Copolymers of VDF with TFE in which the fraction of the latter comonomer is low and its chemical structure is similar to that of PVDF were considered in the studies quoted above. This may explain the similarity of the behaviour on irradiation of the above copolymers and PVDF.

Another object for which radiation-induced physicochemical changes have been studied in detail is the copolymer of VDF with trifluoroethene. In contrast to TFE, the latter has a structure differing appreciably from that in the homopolymer. It may be that this factor is one of the reasons why these copolymers behave differently from the homopolymer and the VDF/TFE copolymer.

On γ -irradiation of the VDF/TrFE 65/35 copolymer, it was observed that an increase in the dose is accompanied by the impairment of the structural characteristics.²⁶³ Thus irradiation with a dose of 120 Mrad at room temperature of a specimen consisting of the ferroelectric phase leads to its transition to the paraelectric state, which may be inferred from the shift of the main intermolecular reflection towards lower angles (Fig. 27). If the crystal is in the paraelectric state, irradiation of the specimen is accompanied by significant changes in the initial structure. The ferroelectric-paraelectric transition becomes in this case more diffuse and shifts towards lower temperatures. The latter has been noted also on irradiation of these copolymers by accelerated electrons.²⁶⁴

The results of experiments^{265–268} for the same copolymer but with the composition 70/30 indicate a qualitatively similar conclusion. Irradiation of thin films (7 μm) with a beam of electrons having an energy of 100 keV leads to a smooth displacement of the Curie point with increase in the irradiation dose towards lower temperatures, which, however, are always found to be higher than the glass transition temperature.²⁶⁵ The

Figure 27. The nature of the variation of the profile of the 200, 110 reflection due to the ferroelectric phase on γ -irradiation of the VDF/TrFE 65/35 copolymer.²⁶³ Irradiation dose (Mrad): (1) 120; (2) and (3) 60; (4) 0; (1), (3) and (4) irradiation at room temperature; (2) irradiation at 120 °C.

experiments failed to confirm the conclusion²⁶³ that more intense processes, leading to the impairment of order, take place when the crystal is in the paraelectric phase. According to the temperature dependence of the internal friction, accelerated electrons convert the copolymer into the amorphous form and lead to the accumulation of defects in the crystallites.²⁶⁷

The last conclusion has been confirmed also by X-ray diffraction data, which showed that an increase in the irradiation dose induces a decrease in the packing density in both the paraelectric and ferroelectric phases of the copolymer.²⁶⁶ At the same time, it was established that, for the same irradiation dose, more significant changes are noted for the paraelectric phase. A new phenomenon has been observed: an increase in the energy of electrons (from 100 keV to 3 MeV) leads, under the conditions of the same irradiation dose, to less significant decrements in the melting and Curie points. It is believed that electrons with a higher energy cause the preferential conversion of the copolymer into an amorphous form, whereas particles with a lower energy are mainly responsible for specific defects within the crystals. The decrease in the average size of the crystallite, noted in such processes, is not the main cause of the decrease in the melting and Curie points.²⁶⁸ The process involving a decrease in the energy of the dipole interactions as a result of the increase in the concentration of the double bonds and carbonyl and other new groups arising on irradiation is believed to be more important. The decrease in the melting and Curie points with increase in the irradiation dose is fairly well described by a model taking into account the decrease in the internal pressure.^{268, 269}

Thus one may see a significant difference between the radiation-induced structural changes in the VDF homopolymer and in the VDF/TrFE copolymer, on the one hand, and in the VDF/TrFE copolymers, on the other. One of the reasons for this may be associated with the chemical structure of the TrFE unit (CH_2CFH), which, in contrast to the TFE unit (CF_2CF_2), is 'chemically incommensurate' with the VDF repeat unit (CF_2CH_2). The fact that the glass transition temperatures in PVDF and TrFE (in contrast to PVDF and TFE) differ markedly may be regarded as confirmation of this postulate.

Other causes of the significant differences in behaviour on irradiation of the VDF/TrFE and VDF/TFE copolymers may be associated with the fact that in the former the fraction of TrFE is

fairly large (30–35 mol %). A decrease in the latter (to 20 mol %) does not alter the situation fundamentally, since radiation-induced conformational rearrangements of the type $(\text{TT})_n \rightarrow \text{TGT}\bar{\text{G}}$ and $(\text{TT})_n \rightarrow \text{T}_3\text{GT}_3\bar{\text{G}}$ have been noted in such copolymers on irradiation with γ -rays at doses as low as 1–10 Mrad. In the homopolymer, the opposite rearrangements take place.^{256, 257} Yet another cause of the differences may be that all the VDF/TrFE copolymers were investigated in the isotropic state, whereas the 'anomalous' behaviour on irradiation of the homopolymer and VDF/TFE copolymer was noted in uniaxially or biaxially oriented states. Copolymers in the latter states are known to be metastable systems in which the role of internal stresses may be manifested to a greater extent. It is noteworthy that a more detailed study of the behaviour of the VDF/TrFE copolymers at low irradiation doses is needed.

VIII. Characteristics of the dynamics of the chains in the block state of isotropic and anisotropic poly(vinylidene fluoride) specimens

For the practical employment of PVDF films as the material of the active element in energy transducers, it is necessary to know their stable electrophysical parameters.³ This requirement cannot be met without the knowledge of the characteristics of the molecular mobility and of the mechanism of the relaxation phenomena in films. Taking into account the high degree of heterogeneity of the test materials, it is possible to obtain from the characteristics of the molecular mobility information about the structural features of the nonordered phase, which frequently cannot be achieved by classical structural methods. In this section, attention is concentrated on the analysis of studies predominantly on the dielectric relaxation of the test materials, since this method has recently undergone a new development and proved very informative in the analysis of the microstructures of PVDF-based blends.

As early as the beginning of the 1970s, when the valuable properties of PVDF for practical purposes were not known, a series of studies of the molecular mobility in PVDF copolymers by the dielectric relaxation method appeared.^{270–272} This polymer has a high dipole moment per monomer unit (7×10^{-30} C m) and is superior to others as regards the glass transition temperature. This in fact explains the great early interest in it and the high information content afforded by the dielectric relaxation method. The ferroelectric properties of these polymers, discovered subsequently, led to additional possibilities for the above method.²⁷⁰ The majority of investigators observed three or four types of molecular motion in these compounds. In the α modification of PVDF crystals, these are always four different forms of motion. The forms of molecular mobility are usually designated as δ , γ , $\beta(\alpha_a)$, and $\alpha(\alpha_c)$.[†]

An example of the temperature variations of the real (ϵ') and imaginary (ϵ'') components of the complex relative permittivity in PVDF for different electric field frequencies is presented in Fig. 28. The two separate dispersion regions in order of increasing temperature are attributed to $\beta(\alpha_a)$ and $\alpha(\alpha_c)$ relaxations. The lower-temperature regions of the δ and γ mobilities are not seen, but the nature of the variation of ϵ' and ϵ'' in them is the same. The generalisation of ideas about the mechanisms of the above types of mobility can be more conveniently begun by the analysis of the mobilities in the low-temperature regions (at temperatures below the glass transition region of PVDF).

According to Sasabe et al.,²⁷⁴ the γ mobility is described by the Arrhenius equation with an activation energy of 2.1 kcal mol⁻¹ and is determined by localised kinetic units. There are two contradictory views concerning the location of such units. Thus, according to Yano,²⁷³ they should be located in the amorphous phase. However, in a later study²⁷⁵ the contrary claim was made

[†] Here and henceforth double designations for relaxation are given, since in the literature these processes are designated in different ways.

Figure 28. Temperature dependence of the components of the complex relative permittivities ϵ' (a) and ϵ'' (b) in the region of the β and α dispersions of PVDF.²⁷³

Frequency (Hz): (1) 10; (2) 100; (3) 1000; (4) 10 000; (5) 100 000.

that they should constitute crystalline regions. This was based on the observation of a single low-temperature γ -relaxation process on VDF specimens in the α modification. The region of the δ mobility is located near 50 K.²⁷⁶ A detailed study²⁷⁷ has shown that the δ mobility is due to the defects in the α phase lattice. This conclusion was confirmed by the decrease in the intensity of the δ mobility with increase in the degree of crystallinity as the crystallisation conditions were varied. It is significant that this mobility is generated precisely by the defects in the α phase. In specimens of the VDF/TrFE copolymer, which crystallises as the β modification, the above mobility was not observed.²⁷⁷

A similar conclusion was reached in a study²⁷⁶ where there was no δ process in the PVDF specimens with the β phase obtained as a result of uniaxial stretching. At the same time it was noted that a region of ϵ relaxation is present in such specimens, occurring at still lower temperatures (~ 20 K). The activation energy for this process is ~ 1.9 kJ mol⁻¹, whilst that for the δ process is 12.6 kJ mol⁻¹. It has been shown that poling decreases the intensity of the ϵ process severalfold. This finding indicates that the ϵ process is associated with defects in the β phase lattice. The activation parameters for the δ and ϵ relaxation and the temperature ranges where they are manifested differ significantly, so that the defects in the lattices of the α and β modifications responsible for the mobility under discussion are different.²⁷⁶

The curves for the temperature and frequency dependences of ϵ' and ϵ'' for one of the VDF/TFE copolymers have been discussed.²⁷⁸ A characteristic feature of the β relaxation is the increase in the loss factor to a maximum with increase in temperature. The characteristics of this process in the above copolymer are common also to PVDF (Fig. 28) and one may therefore consider them in greater detail.

Analysis of the shape of the above curves shows that they are described satisfactorily by the Williams–Watts equations.²⁷⁹ The

experimental frequency dependences of ϵ'' correspond to those calculated from the relation

$$\epsilon' - \epsilon_\infty - i\epsilon'' = (\epsilon_0 - \epsilon_\infty) \sum_{n=1}^{\infty} (-1)^{n-1} \frac{\Gamma(n\beta + 1)}{\Gamma(n+1)} (i\beta\tau)^{-n\beta}, \quad (13)$$

where i is an imaginary number, ϵ_0 and ϵ_∞ are the limiting relative permittivities at low and high frequencies, β is the parameter of the distribution of the relaxation times ($1 \geq \beta > 0$), $\Gamma(n+1)$ is the gamma function, and τ is the relaxation time. The temperature dependences (in terms of the Arrhenius coordinates) of the frequencies corresponding to the ϵ'' maxima are not linear and it has been shown²⁷⁸ that they can be described by a modified Williams–Lundell–Ferry (WLF) equation in the form proposed by Brereton:²⁸⁰

$$\lg f_{\max} = A + \frac{C_1(T - T_g)}{C_2 + (T - T_g)} + \lg\left(1 - \frac{T_g}{T}\right), \quad (14)$$

where A , C_1 , C_2 , and T_g are numerical constants.

The above form of the curve is characteristic of processes occurring in the glass transition of polymer. The dispersion region under discussion should therefore be associated with the micro-Brownian motion of the chains in the nonordered regions. A series of experimental facts may be regarded as confirmation of this conclusion. For example, the intensity of the above process decreases steadily with increase in the degree of crystallinity of PVDF and its copolymers.^{273, 274, 281} The constant T_g in Eqn (14) agrees with the point corresponding to the characteristic break on the temperature dependences of the coefficient of thermal expansion²⁷⁸ or the specific volume.²⁸¹ The significant decrease in the intensity of the micro-Brownian motion of the chains after irradiation²⁸² may also serve as confirmation of the validity of the assignment of the above process.

Indeed, as shown above, irradiation is accompanied by cross-linking predominantly in the nonordered regions, which should lead to an increase in the steric hindrance to the reorientation of the segments. The enthalpies ΔH and entropies ΔS of relaxation are usually determined from the temperature variations of the relaxation times. For the given process in PVDF with the α phase, ΔH varies from 22 to 41 kcal mol⁻¹ while ΔS varies from 50 to 120 e.u. in the temperature range from 3 to -30 °C.²⁷³ Taking into account these values as well as the enthalpy of vaporisation for a monomer unit, equal to 3.8 kcal mol⁻¹, it has been found²⁷³ that the number of repeat units in the kinetic segment is 23.

The presence of crystalline regions in the bulk of PVDF may give rise to a difference in the relaxation behaviour in the vicinity of T_g compared with that in purely amorphous polymers. The significant difference (by almost 30 °C) between the experimental T_g (-38 °C) and its value calculated by the WLF equation (-67 °C), whilst in the amorphous polymers the difference is 5–6 °C, may be regarded as confirmation of this finding. The reason for the appearance of this difference may be that, as the amorphous polymers approach the equilibrium glass transition temperature, the size of the cooperatively rearranged region should approach a microscopic size, whereas in the crystallising polymers it should be restricted to the size of the nonordered region between crystallites. The same anomalies in the glass transition have been explained²⁸⁰ by the influence of the local field effects (allowance for the correlated motion of dipoles).

In order to discover the reasons for the observed increase in ϵ''_{\max} with temperature in the region of the $\beta(\alpha_a)$ dispersion, Nakagawa and Ishida²⁸³ modelled this type of mobility. It was found that the increase in ϵ''_{\max} mentioned above is associated with the increase in the absorption $\Delta\epsilon = \epsilon_0 - \epsilon_\infty$. It was shown in relation to two specimens (quenched and annealed) that $\Delta\epsilon$ passes through a diffuse maximum in the temperature range 30–80 °C. General relations yield

$$\Delta\epsilon = \frac{4\pi N\bar{\mu}^2\xi}{3kT}, \quad (15)$$

where N is the number of repeat units, $\bar{\mu}^2$ the mean square of the effective dipole moment per monomer unit, ξ the local field factor, k the Boltzmann constant, and T the absolute temperature.

Calculation of $\bar{\mu}^2$ on the assumption of an Onsager internal field showed that all its values are higher than μ_0^2 ($\mu_0 = 1.93$ D is the dipole moment of difluoromethane). The quantity μ^2 was expressed in the form $\bar{\mu}^2 = (\mu_s^2/n_s)g_n$, where μ_s is the dipole moment of the 'segment' containing n_s repeat units and g_n is the correlation factor. For $g_n > 1$, the correlated motion of neighbouring dipoles takes place in the nonordered regions and in fact may be responsible for the characteristics of the relaxation behaviour in the vicinity of the glass transition region.²⁸⁰ The passage of $\Delta\epsilon$ for the β relaxation considered through a maximum is known to be characteristic of order-disorder transitions, in particular of the ferroelectric-paraelectric transformation in the test systems. The latter occurs in the crystalline phase of PVDF and its copolymers. However, the observation of the above dielectric anomalies, for example in highly polar vinylidene cyanide/vinyl acetate copolymers, shows²⁸⁴ that in the amorphous phase of such systems there may be regions with an intermediate form of order analogous to that observed in polymeric liquid crystals. If it is assumed that a definite proportion of the amorphous phase of PVDF is in the nematic phase, the local nematic-isotropic liquid transition will be accompanied by the dielectric anomalies noted above.

A reasonable interpretation of a large number of new experimental data for crystallising polymers nevertheless requires ideas concerning the existence of regions with an intermediate order. It may be that the detection of the isotropic and anisotropic components of the amorphous phase in the VDF/TFE 94/6 copolymers constitutes a confirmation of the above hypothesis.¹¹⁵ The above change in the average interplanar spacing in the sections of the anisotropic phase noted above most probably indicates the occurrence of the postulated nematic-isotropic liquid transition.¹¹⁷ The similar postulated transition in the amorphous component of the PVDF with the α phase is significantly more diffuse and is displaced towards lower temperatures compared with the transition in the VDF/TFE copolymer.²⁸³ This can be explained by the higher fraction in the latter of segments in the 'planar zigzag' conformation than in the VDF homopolymer.

Indeed the modelling of the dynamics of the chains in the amorphous phase of PVDF shows that the best agreement between the calculated and experimental temperature variations of μ^2 is observed only if the neighbouring segments in contact are in the GG or $G\bar{G}$ conformations.²⁸³ If the dipole interactions are decisive in the establishment of the above order, it is possible to find an explanation of the lower transition temperature in the homopolymer²⁸³ compared with the VDF/TFE copolymer.^{117, 118} When neighbouring segments are in contact, the transverse component of the dipole moment relative to the axis of the macromolecule is limiting. The transverse component of the dipole moment of the segments with the GG and $G\bar{G}$ conformations is known to be smaller than that for the segments with the predominant 'planar zigzag' conformation (as in the VDF/TFE copolymer). Accordingly, the lower energy of the interaction in the former does actually lead to a displacement of the transition under consideration in the homopolymer towards lower temperatures.

Since the packing of the chains in the amorphous phase is less dense than in the crystal, the presence of a free volume in this phase is postulated. The role of the latter for β -mobility processes may be traced, for example, from the significant increase in the relaxation times in the VDF/TrFE 73/27 copolymer with increase in pressure.^{285, 286} The free volume causes the displacement of the end groups into the amorphous phase and various kinds of chemical perturbations in the chain (branches, etc.) on crystallisation of PVDF. This can explain the changes in the width of the

relaxation times spectrum and in the effective dipole moment per monomer unit in PVDF obtained by the emulsion and suspension polymerisation methods.⁶²

As the glass transition temperature is approached, the frequency dependences of ϵ'' are greatly broadened. The role of the free volume effects in such broadening has been investigated in a series of studies.²⁸⁷⁻²⁹¹ It was postulated that the relaxation time τ obeys the Doolittle equation:

$$\ln \tau = \ln \tau_0 + \frac{1}{f}. \quad (16)$$

Here f is the fraction of the free volume:

$$f = f_0 + \alpha_f(T - T_0), \quad (17)$$

where α_f is the temperature coefficient of the increase in the free volume. Under these conditions, the frequency dependence of ϵ'' can be described by the function

$$\epsilon''(\omega) = \int_0^1 \epsilon_f''[\omega, \tau(f)] F(f) df, \quad (18)$$

where $\epsilon_f''[\omega, \tau(f)]$ is the loss factor corresponding to the segments with the free volume fraction f and $F(f)$ is the normalised free volume distribution function. The latter was specified in the form

$$F(f) = \frac{(f - f_1) \exp[-(f - f_1)/\lambda]}{\lambda}, \quad (19)$$

where f_1 is the minimum volume and λ the parameter of the width of the distribution.

Comparison of the calculated and experimental relations $\epsilon''(\omega)$ shows that, at temperatures approaching the glass transition temperature, the significant broadening of the curves is determined in the first place by the free volume distribution effects whereas at higher temperatures account must also be taken of the distribution of the relaxation times.

Textured PVDF films are usually employed in practice. From the analysis of the influence of, for example, uniaxial stretching on the nature of the micro-Brownian motion in the nonordered regions, one may formulate general relations.^{272, 281, 292} In all cases the uniaxial stretching process did not lead to an appreciable alteration of the relaxation times, but the total absorption $\Delta\epsilon$ increased steadily. This implies [in conformity with Eqn (15)] an increase in the effective dipole moment per monomer unit. There may be several causes of the increase. In a textured film, the chains in the amorphous phase assume a definite preferred orientation, which can be inferred, for example, from the appearance of the IR dichroism of the 600 cm^{-1} absorption band, which is sensitive to the presence of the amorphous phase.¹²⁹ In this case the quantity $3kT$ in Eqn (15) for the isotropic film should be reduced when account is taken of the anisotropy in the disposition of the chains in the amorphous phase. Another cause, apparently decisive, is that the conformation of the sequences of the chain in the amorphous gaps may change in the oriented state. The probability that chain sections entering into the region of higher local mechanical stresses will pass to the 'planar zigzag' conformation increases. The sequences of the TTC mentioned above apparently constitute the 'limiting case' for the scheme mentioned above, since increased mechanical stresses cause their transition to the 'planar zigzag' conformation.¹⁶⁰

For an anisotropic film, one may speak of three components of the relative permittivity. Under the usual conditions of the measurement (electrodes deposited on the surface of the film), one should be dealing with the component ϵ_{33} if the direction 3 coincides with the normal to the surface. If the chain of a textured amorphous phase is located predominantly in the plane of the film, then the values of ϵ_{33} depends significantly on the transverse component of the dipole moment. As mentioned above, this component for the chain sequences in the 'planar zigzag' conformation is greater than for the sequences with the $TGT\bar{G}$

conformation. For this reason, the increase in $\Delta\epsilon$ in the textured films agrees with the increase within the plane of the films in the number of chain sections of the amorphous phase in the 'planar zigzag' conformation. Evidently data concerning the anisotropy of the dielectric desorption in the regions of the β dispersion for specimens of uniaxially extended PVDF may serve as confirmation of this correspondence.²⁹³ After drawing, the specimens were cut out in a way such that in one case the electrodes were located perpendicular and in another parallel to the draw axis. It was found ϵ''_{\max} in the region of β relaxation is almost three times greater in the second case than in the first.

The high-temperature $\alpha(\alpha_c)$ relaxation process is unambiguously associated with motions in the PVDF crystalline phase. This has been confirmed by the observation of the $\alpha(\alpha_c)$ mobility in crystalline mats²⁷⁵ and also by the increase in the intensity of the above process with increase in the degree of crystallinity.²⁷⁴ The majority of investigators assume that this mobility occurs predominantly in the α modification of PVDF crystals. This is based on numerous data showing that, in specimens where the α and β phases coexist, an appreciable decrease in the intensity of the $\alpha(\alpha_c)$ relaxation is observed.^{273, 281, 292} Furthermore, there is evidence that this process is altogether absent from PVDF specimens obtained in the γ phase,²⁹⁴ while in the PVDF copolymers, where the α phase is usually not formed, it is extremely weak.²⁷⁸ There exists also a communication,²⁹⁵ which unfortunately has been confirmed by only one other investigation,²⁹⁶ stating that in specimens with coexisting α and β phases two $\alpha(\alpha_c)$ relaxation regions are observed. The low-temperature region is attributed to the motion of the chains in the crystals of the α phase, while the high-temperature region is attributed to relaxation in β phase crystals.

Analysis of the above studies shows that in all cases the relaxation times are described by Arrhenius equations and the activation parameters are characterised by the quantities $\Delta H = 24 \text{ kcal mol}^{-1}$ and $\Delta S = 23-26 \text{ e.u.}$ ^{273, 281} Detailed analysis of the characteristics of this process shows that they may reflect fine details of the microstructure. For example, it has been observed that the increase in the fraction of 'head to head' defects in PVDF chains reduces the intensity of the α relaxation.²⁷³ The thickness of the lamellae in the above process affects the mobility parameters: an increase in thickness is accompanied by an increase in mobility.^{273, 283} Annealing, which usually leads to the thickening of the lamellae, is also accompanied by an appreciable increase in the average α relaxation times.²⁸³ One of the characteristic features of the process is that it exhibits anisotropy. The results of three different studies^{293, 297, 298} indicate unambiguously that, when the field vector \vec{E} is arranged perpendicular to the draw axis, the intensity of the process is higher than in the case where these directions coincide.

The mechanism of the processes in the above dispersion region has been discussed in greatest detail by Nakagawa and Ishida²⁸³ and Myjamoto et al.²⁹⁸ In the first study, the discussion began with the postulate that motions of two types are possible in folded-chain crystals: the motion in the surface itself (loops and other defects) and rotation of the chain (or of its section) in the bulk phase with a small longitudinal displacement. The number of monomer units in the fold (n_f) was estimated from the thickness of the lamella using electron microscope data. It was found that, for the range $n_f = 50-130$, the reorientation frequencies of the moving segments varied linearly. It was therefore concluded that the rigid rod approximation used in the study is correct for the kinetic unit. Comparison of the calculated and experimental relations shows that the enthalpy of activation for the above transition is determined mainly by the fold in the chain. Analysis of the experimental $\Delta\epsilon(T)$ relations enabled the authors²⁹⁸ to conclude that the rotations of sections of the lamellae within the crystal make the dominant contribution to α relaxation, but with the stipulation that motion within the folds cannot be fully excluded under these conditions. The chains in the folds are more mobile than within the crystal, but the contribution of the

latter to the process is decisive because of the high resultant dipole moment.

The above studies^{293, 297, 298} confirm the conclusion that the chains in the internal regions of the crystal make the main contribution to the α -relaxation process. Indeed, after orientation, the normal to the surface of the folds coincides with the draw axis. Under these conditions, the inner chains of the lamellae are arranged at right angles to the direction of orientation. Taking into account the fact that the perpendicular component of the dipole moment of the PVDF chain in the $TGT\bar{G}$ conformation is greater than the parallel component, the absorption when the field is applied perpendicular to the draw axis should be more intense, which has in fact been observed.^{293, 297, 298}

The mechanism of the α relaxation has also been considered by Myjamoto et al.²⁹⁸ with the aid of the same two positions model. Using the dependence of $\Delta\epsilon$ on the angle between the field vector and the stretch direction and having assumed that the longitudinal component of the dipole moment μ_{11} varies, the authors obtained a reasonable explanation of the relations noted above. Conformational analysis shows that such a case may occur, for example, in the $TGT\bar{G} \rightarrow GT\bar{G}T$ transition within a section of the lamella. This transition is possible, since even when account is taken of the activated state (in the form of the 'planar zigzag' conformation), which requires a 10% deformation along the axis of the macromolecule, the change in the conformation is then local and significant translational migrations of the chain as a whole are not required. Despite the fact that the fluorine atoms should move in such conformational transition along the c axis, the packing of the chains along the a and b axes changes little. The mechanism of the $TGT\bar{G} \rightarrow GT\bar{G}T$ conformational change presupposes the existence between chain sequences with different conformations of a defect (of the 'head to head' or conformational type), which may migrate along the chain as a result of thermal excitation and may induce a change in the dipole moment component μ_{11} .

According to another model, the position of the defect within the chain is fixed and the initiation of the above conformational transformation begins on the surface of the lamella as a result of a 'wormlike' excitation and is then transferred to another surface. In both models, account is taken of the important role of chemical defects, although the importance of conformational defects is not denied. It is assumed that with the aid of the latter one can explain a series of 'anomalous' effects in the characteristics of the α relaxation. Thus, when the relaxation times of the above process were compared for two specimens (isotropic and oriented), it was observed that, although in the former case the long period (and tentatively also the thickness of the lamella) is greater than in the latter (150 and 135 Å respectively), the relaxation time in it is an order of magnitude shorter than in the latter. It is assumed that, owing to the uniaxially stretching, the concentration of conformational defects changes in the second specimen and these in fact influence the rate of the relaxation processes. The proposed two positions model begins with a single relaxation time, whereas experiments yield a distribution of times. This discrepancy may vanish if account is taken of the distribution of the lamellae with respect to thickness and also of the distortions in the form of the potential energy function as a result of the presence of defects.

When α relaxation was observed in the region of high temperatures, usually at low frequencies of the electric field, anomalously high values of the ϵ' and ϵ'' components were noted. This has been attributed to the influence of impurities causing high losses due to dc conductivity. It was observed that they can be significantly reduced by maintaining the PVDF specimens at elevated temperatures in an electric field, where electrolytic processes take place.²⁹⁹ An increase in the electric field strength accelerates the decrease in the above conductivity during the electrolytic process. The imposition of a $\sim 20-30 \text{ kV cm}^{-1}$ electric field lowers the values of ϵ' at high temperatures, this being manifested to the greatest extent at low frequencies.²⁹⁹ After the field has been switched off, the increased conductivity is partly

restored. Nevertheless, it has been shown that, in cases where the α process was masked by losses due to dc conductivity, annealing of the specimens subjected to the field made it possible to observe the above process distinctly. Experiments with mercury electrodes showed that calcium ions make a large contribution to the ionogenic impurity conductivity.²⁹⁹

For theoretical justification of the above experimental facts, it has been suggested³⁰⁰ that the experimental ϵ' and ϵ'' each have two components:

$$\epsilon' = \epsilon'_i + \epsilon'_p, \quad (20)$$

$$\epsilon'' = \epsilon''_i + \epsilon''_p, \quad (21)$$

where the components with subscripts i and p denote the contributions of the ionic impurities and the polymer itself respectively. Taking into account the fact that only some of the impurities dissociate, their contributions to the components of the complex relative permittivity are defined by the relations³⁰⁰

$$\epsilon'_i = \frac{2v_0q^2}{lkT\pi^{0.5}} \left(\frac{D_0}{f}\right)^{3/2} \exp\left[-\left(\frac{3E_d}{2} + \frac{W}{2\epsilon_0}\right)/kT\right], \quad (22)$$

$$\epsilon''_i = \frac{2v_0q^2}{kT} \left(\frac{D_0}{f}\right)^{3/2} \exp\left[-\left(E_d + \frac{W}{2\epsilon_0}\right)/kT\right], \quad (23)$$

where v_0 is the concentration of mobile ions, l the thickness of the specimen, q the ionic charge, D_0 the diffusion coefficient of the ion, f the field frequency, E_d the activation energy for the diffusion of the ion, and W the ion dissociation energy.

Taking into account the relations obtained, a series of quantitative characteristics were found for the ionogenic impurities in PVDF. Thus at 160 °C the diffusion coefficient proved to be $D_0 = 4.36 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$, which (on the assumption that the ions are univalent) corresponds to their mobility $\mu = 1.2 \times 10^{-5} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ ($\mu = qD_0/kT$) and the concentration $v_0 = 6.8 \times 10^{14} \text{ cm}^{-3}$ (at a concentration of monomer units of $1.7 \times 10^{22} \text{ cm}^{-3}$). The activation energies for the dissociation of ions and their diffusion have been estimated as 342 and 34 kcal mol⁻¹ respectively. An interesting fact was noted: prolonged (10 days) annealing at 160 °C of PVDF specimens leads to an appreciable decrease in the contribution of the ionic impurities to the low-frequency dielectric characteristics.

The anomalously high values of ϵ' and ϵ'' at low frequencies in the region of fusion of the PVDF α phase crystals have also been noted by Yano et al.³⁰¹ It was shown that there is a sharp fall of ϵ' and an increase in ϵ'' in the range 153–155 °C (according to DSC data the melting point is 157 °C). Analysis of the conductivity in this system before and after fusion indicates significant differences. In particular, the independence of the conductivity of the electric field frequency was noted for the melt. It was proposed that the melt be regarded as a homogeneous medium and that the nature of the conductivity in it is similar to that in an electrolyte solution. In this case, the dielectric parameters depend on the characteristics of the electrical double layer at the electrolyte–electrode boundary and Eqns (22) and (23) should be valid. According to the equations, the conductivity should be frequency-independent and the relations between ϵ'_i and $\lg f$ should be characterised by a coefficient of 3/2. Interpretation of the experimental data confirmed the validity of the chosen model: the conductivity indeed proved to be frequency-independent and the above coefficient was close to the predicted value, namely 1.67–1.79. At temperatures below the melting point, the homogeneous medium model was not confirmed. This may be inferred if only from the fact that the conductivity proved to be a function of the field frequency. The correct interpretation of experimental data can be achieved if account is taken of the differences between the values of ϵ' and of the conductivities of the crystalline and amorphous regions.

Similar anomalies in the behaviour of ϵ' and ϵ'' in the fusion region have been observed also on VDF/TFE copolymers.²⁷⁸ The loss factors in this region vary in accordance with the law

$$\epsilon'' = A\omega^{-m}, \quad (24)$$

where A is an empirical constant and m is a constant which varied in the range 0.3–0.5 as a function of temperature and the conductivity of the specimen. Eqn (24) is characteristic of the polarisation of the space charge of ionogenic impurities³⁰² and it too confirms the necessity to take into account the heterogeneity (in terms of the electrical characteristics) in systems based on PVDF at elevated temperatures.

The Maxwell–Wagner polarisation process under discussion has also been detected in uniaxially extended PVDF films³⁰³ and its characteristics (mainly the loss factor at the maximum) proved to be extremely sensitive both to the phase ratio in PVDF and to the state of orientation of the chains in its nonordered regions. It is noteworthy that the characteristics of the electrical heterogeneity for the ordered and nonordered regions have been found to be sensitive to the polarisation process in the corona discharge, since under these conditions the intensity of the interlayer polarisation process diminishes significantly.³⁰³

This process has been investigated in greater detail in a study³⁰⁴ where the high-temperature transition $\alpha \rightarrow \gamma$ was considered. If the crystals are obtained in the γ modification, the low-frequency dependences of ϵ' are found to differ significantly from those for the case where PVDF crystallises as the α phase (Fig. 29). Indeed, in the former case the values of ϵ' at low

Figure 29. Frequency dependences of the high-temperature relative permittivity for PVDF films crystallised as the γ modification (1) and the α modification (2) at 160 °C.³⁰⁴

frequencies are significantly higher and do not obey the law $\epsilon' (f^{-3/2})$, as happens in the case of α PVDF. As already mentioned above, this law is characteristic of electrode polarisation and this mechanism is therefore inapplicable to crystals of the PVDF γ phase. This conclusion is confirmed also by the dependence of ϵ' for PVDF films in both modifications on the thickness of the specimen (Fig. 30). Evidently, in the case of crystals of the α modification an explicit dependence of ϵ' on thickness is observed (which is characteristic of electrode polarisation, whereas for films with the γ modification ϵ' remains approximately constant. The interlayer (Maxwell–Wagner) polarisation mentioned above may serve as another possible explanation of the observed relaxation process with an activation energy of 627 kJ mol⁻¹. For spherical crystals with a conductivity σ_2 and a relative permittivity ϵ_2 , immersed in an amorphous matrix with the corresponding values of σ_1 and ϵ_1 , the frequency f of the loss maximum can be found from the equation³⁰⁵

$$f = \frac{2(\sigma_1 + \sigma_2)}{2\epsilon_1 + \epsilon_2}. \quad (25)$$

Figure 30. Dependence of the high-temperature relative permittivity on the thickness of PVDF films crystallised as the γ modification (1) and the α modification (2) at 165 °C.³⁰⁴ Frequency (Hz): (1) 0.2; (2) 0.1.

Since the γ phase crystals have an uncompensated dipole moment per unit cell, $\sigma_1 \gg \sigma_2$ and $\epsilon_2 \gg \epsilon_1$ and Eqn (25) may be replaced by

$$f = \frac{4\sigma_1}{\epsilon_2} \quad (26)$$

The equilibrium value $1.5 \times 10^{-10} \Omega^{-1} \text{ cm}^{-1}$, obtained after 15-h maintenance of the specimen at 185 °C in a 400 V cm^{-1} field, was used as σ_1 . The frequency f calculated by Eqn (26) is 0.6 Hz, which differs by more than two orders of magnitude from the experimental value.

The possibility of orientational motions of the γ crystals as a whole was considered as an alternative mechanism of the high-temperature relaxation process mentioned above. This is based on the linear dependence of ϵ''_{max} for the process on the heat of fusion of the γ phase crystals (DSC data), which indicates that the magnitude of the absorption is determined mainly by the volume fraction of the γ phase crystals. The possibility of the motion of the crystals as a whole in this process does not lack justification. Indeed, with increase in the long period (linked directly to the size of the crystalline lamella), the maximum of the mechanical loss modulus shifts towards higher temperatures. Finally, yet another argument in support of the hypothesis that the crystal moves as a whole follows from estimates $\Delta\epsilon$ by Eqn (15) using the experimental numbers of monomer units per kinetic unit. It proved to be 6×10^3 repeat units. This number exceeds by more than an order of magnitude the number of monomer units in a lamella of the usual size ($\sim 10^2$ units). Osaki et al.³⁰⁴ does not discuss the reason for this discrepancy but the latter may indicate the involvement in the given transition of motions accompanying a ferroelectric–paraelectric transition in which cooperative effects should prevail.

Indeed the above relaxation region is in the vicinity of the melting point, where a ferroelectric–paraelectric transition has been postulated for the VDF homopolymer in a polar form (as in the given instance). The relation between the mobility in the crystalline phase and the motions in a ferroelectric transition may be inferred from the nature of the temperature variation of the dielectric parameters in the VDF/TrFE copolymer, which is known to be ferroelectric³⁰⁶ and for which the temperature of the above transition differs from the melting point. Here too one observes a high-temperature mobility in the crystalline phase, which is characterised by high values of $\Delta\epsilon$. Analysis of the temperature variation of the latter shows that its increase with increasing temperature represents the onset of the anomalous rise in $\Delta\epsilon$ in the region of the ferroelectric transition.³⁰⁶

Mention should be made of the results of a study³⁰⁷ of the mechanism of the high-temperature relaxation in PVDF. The low-frequency dielectric characteristics of PVDF films with α -phase crystals were investigated. Here attention was concentrated on the role of the material of the electrodes. Aluminium and gold, for

which different temperature variations of the components of the complex conductivity had been found, were employed. The authors explained the highly intense $\tan \delta$ maximum (amounting to 12–25!) at low frequencies by the manifestation of the space charge at the material–electrode interface. However, in contrast to other investigators, they believe that the majority carriers are the F^- and H^+ ions. This presupposes the presence in the bulk of the film of a finite number of HF molecules which should be partly dissociated. This hypothesis is confirmed by a whole series of facts. For example, one of them is that the presence of excess fluorine has been observed in the bulk of PVDF by the method of reverse Rutherford scattering.³⁰⁷ A finite number of the $(-\text{CH}=\text{CF}-)$ groups have been found in the initial state of different PVDF films from the characteristic IR absorption bands. Such groups may be formed by the reaction

initiated by thermal energy or irradiation.³⁰⁰ A sufficient amount of HF may be formed by this reaction already at ~ 60 °C.³⁰⁹ Thus taking into account the presence of the H^+ and F^- ions in the bulk phase, the low-frequency $\tan \delta$ maximum should be attributed to the behaviour of these ions in a variable electric field.³⁰⁷ It is believed that the mobility of the hydrogen cations is significantly greater than that of the fluoride ions, so that the former accumulate near the negative electrode at ultralow frequencies, creating a space charge, which is in fact responsible for the relaxation process under discussion.

The less mobile fluoride ions are captured by traps, but their role may vary significantly for different electrode materials. If the electrode material is aluminium, then, under the influence of the combined action of a high temperature and a weak variable field, the fluoride ions, having reached the electrode, may diffuse into the latter. This is confirmed by the detection of fluoride ions in the surface of the electrode after the application of the combined influence mentioned above.³⁰⁷ X-Ray photoelectron spectroscopic data demonstrate that the fluoride ions which have migrated into the electrode can react with the aluminium atoms to form new compounds.^{310,311}

Thus analysis of data on the high-temperature relaxation shows that the mechanism of the above processes may be fairly complex. A number of workers have noted the dependence of its characteristics on experimental parameters such as the magnitude and duration of the effect of the field.³¹²

Information about the relaxation process can be obtained by the method of thermostimulated depolarisation currents, with the aid of which processes involving local and segmental mobility at low temperatures can also be detected.³¹³ Above room temperature, it is possible to detect even two interlayer polarisation processes. One of them (the low-temperature process) is attributed to the formation of a space charge at the boundaries between the amorphous phase and the nonpolar crystals of the α modification, whilst the other 'senses' these boundaries with the polar (β , α_p) modifications.^{314,315} In a later study³¹⁶ on specimens with crystals of both the polar and nonpolar phases, only one relaxation process, associated with the space charge, was detected. However, at high temperatures three additional current maxima, the temperatures of which are correlated with the melting points of the α , β , and γ modifications of the PVDF crystals, were noted.

Despite the high information content of the electrical methods for the assessment of relaxation process, there have been a number of studies where it was shown that certain forms of mobility in PVDF are inactive. For example, according to the results of McBrierty et al.,³¹⁷ the relaxation process, associated with the motion of the folds on the surface of the lamellae and noted in experiments on dynamic mechanical relaxation by the dielectric method, was not observed. A similar conclusion was reached in a study³¹⁸ where two mechanical relaxation regions (α_1 and α_2) were found in all the PVDF specimens (isotropic and oriented with the crystals of the α and β modifications) at high temperatures, the higher-temperature region (α_2) being assigned to the

motions preceding the fusion of the crystal. It follows from the results of the study that the mechanisms of the relaxation in mechanical and electric fields in the region of the glass transition of the oriented specimens may differ. This is indicated, in particular, by the finding that, in a mechanical field, the β process is more intense in the case of a parallel disposition of the force vector and the orientation axis,³¹⁸ whereas in an electric field the opposite behaviour obtains.^{293, 297}

An attempt has been made at a detailed comparison of the relaxation processes in PVDF and polyethylene on the basis of the results obtained by mechanical spectroscopy.³¹⁹ In the region lying below the glass transition temperature, two relaxation processes (γ_1 and γ_2) were observed in polyethylene, their parameters being close to those of the γ and δ relaxation processes (discussed above) obtained by dielectric measurements. A reasonable agreement between the activation energies and the normalised relaxation time spectra for the processes in both polymers made it possible to postulate that the mechanisms of the γ and δ processes in PVDF are similar to those of the γ_1 and γ_2 processes in polyethylene. According to the results of Yamada et al.,³²⁰ the γ_1 relaxation should be attributed to the local modes of motion of the nonordered chains in the interlamellar regions, whilst the lower-temperature relaxation region (γ_2) should be assigned to the motion in the surfaces of the lamellae.

The same situation occurs also for the region of the high-temperature α relaxation of PVDF, for which the normalised relaxation time spectra agree well with those for the α_2 relaxation in polyethylene. The similarity in the relaxation behaviour of PVDF and polyethylene is also supplemented by the fact that two transitions (α_1 and α_2) can be noted in the high-temperature region for both polymers.³¹⁹

IX. Structural characteristics in the crystallisation of poly(vinylidene fluoride) in blends with other polymers

Examination of the questions associated with the structural characteristics in the crystallisation of PVDF in blends with other polymers will be useful for a number of reasons. One of them is related to the possibility of supplementing and expanding the ideas concerning the characteristic features of the modification of the structure and properties of polymer blends in which one or both components are crystallisable. By crystallising PVDF in blends with other polymers, it is possible to regulate specifically the conformational structure of its chains, which is important in the practical employment of PVDF-based materials for piezoelectric and pyroelectric sensors. The possibility of the modification in such blends of the morphology and optical properties of PVDF is regarded as their additional advantage when they are used as materials with nonlinear optical properties.

Since the blends of PVDF with polymethacrylates have been studied in greatest detail, it is more convenient to begin the analysis of the results precisely with studies in which these blends were investigated. The orientation process in polymeric materials is frequently used to impart improved mechanical properties to the latter. For PVDF, this process is frequently used also for the formation of the ferroelectric β phase, which determines practically important phenomena such as the piezoelectric effect and the second-order optical nonlinearity. However, the orientation of a polymeric material is accompanied by the appearance of birefringence Δn , the magnitude of which is determined by the difference between the refractive indices along (n_1) and across (n_2) the direction of stretching. When a textured material is used for optical elements (windows, discs, lenses, etc.), the birefringence effect is undesirable. One of the possible ways of suppressing this effect has been noted in relation to blends of atactic poly(methyl methacrylate) (PMMA) with PVDF. Such blends are known to be compatible in the melt and cooling of the latter affords a homogeneous optically transparent material.³²⁰ When the com-

position of the blend was varied, it was shown that the refractive index of the isotropic phase varies linearly with increase in the fraction of PVDF.³²¹ This follows from the Lorentz–Lorenz relation for multiphase mixtures, in which the characteristic dimensions of the regions corresponding to different components are smaller than the light wavelength. PVDF is present in a partly crystalline state and is characterised by the densities $\rho_c = 2.0 \text{ g cm}^{-3}$ and $\rho_a = 1.6 \text{ g cm}^{-3}$ in the crystalline and amorphous states; the refractive indices of these phases have been estimated as $n_c = 1.48$ and $n_a = 1.37$. The value of n_c for PVDF is close to that for the amorphous PMMA (1.49). Therefore a decrease in the light scattering effects and an improvement of transparency compared with pure PVDF are to be expected for crystallisable PVDF/PMMA blends with a high content of the first component.

The effect of the deformation-induced birefringence has been observed on noncrystallisable blends with a PVDF content not exceeding 60 mass %. In this case Δn proved to be a linear function of the draw ratio λ , the slope of which depended significantly on the composition of the blend. In the PVDF/PMMA 40/60 and 20/80 blends, Δn was surprisingly low even for high draw ratios. The reason for this may be found by analysing the dependence of Δn on the composition of the blend for $\lambda = 2$ (Fig. 31). For a certain composition of the blend (for $\lambda = 2$, this is a blend having the composition 17/83), Δn proves to be zero. A further decrease in the PVDF concentration leads to negative values of Δn . The components of the above blend have different signs of the double refraction, so that, by varying their ratio, it is possible to select a composition such that the birefringence is compensated for a certain value of λ .

The foregoing is valid for amorphous blends with a particular previous thermal history. These questions have been investigated in detail in a study,³²² where the composition of the components blended in the melt was varied within wider limits. When the components are fully compatible in given proportions in the melt, the cooling of the latter may lead to the crystallisation of PVDF,^{323–336} the characteristic features of which may depend also on the annealing temperature.³²² In particular, if the annealing is carried out at temperatures in the range between the glass transition temperatures of PMMA and PVDF crystallisation may be observed in blends containing more than 10% of PVDF.³²² The amorphous phases of both components are apparently fairly compatible since a single glass transition temperature has been noted in the blends. It decreases monotonically with increase in the fraction of PVDF in conformity with the mixing rule for a two-component mixture^{337, 338}

Figure 31. Dependence of the birefringence on the blend composition in amorphous oriented ($\lambda = 2$) specimens.³²¹

$$\lg T_g = \frac{M\Delta C_p \ln T_g + M'\Delta C_p' \ln T_g'}{M\Delta C_p + M'\Delta C_p'} \quad (27)$$

where T_g , M , and ΔC_p are respectively the glass transition temperature, the mass fraction, and the difference between the heat capacities of VDF in the region of the glass transition of the components; the primed quantities refer to PMMA.

A decrease in the fraction of PVDF in the blend hardly affects the thickness of the lamellae formed (Fig. 32). Under the conditions of reduced crystallinity, this implies that the introduction of PMMA promotes mainly a decrease in the rate of nucleation. It follows from the relations presented in Fig. 32 that, for blends enriched in PMMA, the morphology of the structural elements formed is characterised by an increase in the intercrystallite spacings.

Figure 32. Dependence of the large period (1), the size of the amorphous layers (2), and the thickness of the lamellae (3) on the fraction of PVDF in PVDF/PMMA blends annealed at 140 °C.³²²

The satisfactory compatibility of PVDF with PMMA is confirmed by the negative value of the Flory-Huggins parameter (B). According to numerous data,^{330,339-341} blends of PVDF with poly(ethyl methacrylate) (PEMA) are also compatible. The polymers PMMA and PEMA are incompatible and it is therefore difficult to predict the nature of the compatibility of PVDF with PMMA/PEMA copolymers. This problem has been solved in experiments involving the study of the fusion of PVDF in blends with PMMA/poly(ethyl methacrylate) (PEMA) copolymers over a wide range of compositions.³⁴² The parameter B was estimated from the equation^{324,339}

$$T = T_0 + B \frac{V}{\Delta H} T^0 \Phi^2 \quad (28)$$

where T_0 and T are respectively the melting points of pure PVDF and in the blend, $\Delta H/V$ is the heat of fusion of PVDF per unit volume (44.0 cal cm⁻³), and Φ is the volume fraction of the noncrystallisable polymer in the blend.

According to the pair interaction model,³⁴³ the parameter B for such blends may be estimated with the aid of the relation

$$B = B(\text{MMA/VDF})\Phi(\text{MMA}) + B(\text{EMA/VDF})\Phi(\text{EMA}) + B(\text{MMA/EMA})\Phi(\text{MMA})\Phi(\text{EMA}). \quad (29)$$

The experimental values of B for blends of PVDF with the copolymers PMEMA of different composition are presented in Fig. 33. Evidently, with increase in the amount of MMA in the copolymer, B diminishes. Positive values of $B(\text{MMA/EMA})$ in Eqn (29), indicating the repulsive nature of the intramolecular interactions between neighbouring units in the copolymer, yield

Figure 33. Dependence of the Flory-Huggins parameter for the PVDF/PMEMA blend on the composition of the copolymer. (1) $B(\text{MMA/EMA}) = 0$ (2) $B(\text{MMA/EMA}) = 3.25 \text{ cal cm}^{-3}$.

the best agreement between the calculated curve and the experimental points.

The compatibility of PVDF with low homologues of the methacrylate series (PMMA and PEMA) breaks down for higher homologues of this series.³⁴⁴ Since the concentration of carbonyl groups in the latter diminishes, it has been suggested that these groups in the methacrylates actually play a significant role in the compatibility processes. In this connection, a study has been made³⁴⁵ of the influence on the compatibility processes of both these and other functional groups and elements, for example oxygen or sulfur in ether groups. For this purpose, questions concerning the compatibility of PVDF with poly(methoxymethyl methacrylate) (PMOMMA) and poly(methylthiomethyl methacrylate) (PMTOMA) were examined. For the former, the existence of a single glass transition temperature indicates the compatibility of the components. The parameter B found from Eqn (28) is -14.5 J cm^{-3} . This is an intermediate value for blends of PVDF with PMMA and PEMA. It was shown that the upper critical miscibility temperature (determined from the turbidity temperature) diminishes almost by 100 °C with increase in the fraction of PMOMMA to 0.5. The PVDF/PMTOMA blends are turbid at all temperatures and two glass transition temperatures are observed for them regardless of composition. This means that these blends are incompatible. The melting point of the PVDF crystals in the blends diminishes slightly with increase in the fraction of PMOMMA, which indicates some change in the dimensions and perfection of the crystals. One may assume that the role of PMTOMA in these blends reduces mainly to the effective suppression of nucleation, since the degree of crystallinity (for a PMTOMA fraction of 0.5) decreases almost by a factor of 2 according to measurements of the heat of fusion. The reasons for such a striking difference in the behaviour of the blends of PVDF with methacrylates, is seen by the authors of the study in the increased volume of the side group in PMTOMA compared with PMOMMA. Yet another cause of the above difference is attributed to the lower electronegativity of the sulfur atom compared with the oxygen atom.

The amorphous phase in a blend with a crystallisable polymer is known to decrease the rate of crystallisation of the latter in all cases.^{346,347} This law is valid also for the PVDF/PMMA³²⁸ and PVDF/poly(ethyl acrylate)³⁴⁰ blends. The details of this phenomenon have been investigated in a study³⁴⁹ where the rate of growth of the spherulites was investigated with variation of both the crystallisation temperature of the PVDF/PMMA blend and of the molecular mass of the second component. It was found that, depending on the temperature, the crystallisation can occur in three regimes, which differ in the rates of secondary nucleation and surface growth. At the same crystallisation temperature, an increase in the molecular mass of PMMA in a blend of one composition leads to a decrease in the rate of growth of the

spherulite. The experimental data are best described within the framework of the modified Hoffman–Lauritzen theory, which takes into account the two-step diffusion-controlled mechanism.

The high-resolution nuclear magnetic resonance (NMR) technique with spinning of the specimen at the magic angle is nowadays frequently employed to analyse the microstructures of polymers in the block state. Potentially this method can be used also for the analysis of the details of the interaction in blends if blending at the molecular level is accompanied by a change in the electronic states for the resonating nuclei. The approximate similarity of the magnetisation parameters for these nuclei in the PMMA and PVDF chains has been demonstrated³⁵⁰ on the basis of the characteristics of the resonance of the ^{13}C nuclei. When this was taken into account, the experiments involving the ^{13}C and ^{19}F nuclei with cross-polarisation showed that PMMA and PVDF are at least partly blended at the molecular level. This method has been developed (in relation to the blends under consideration) in a study³⁵¹ where data involving the resonance of not only the ^{19}F and ^{13}C nuclei but also ^1H nuclei were employed.

For PVDF/PMMA blends with a wide range of compositions, the experimental data are best described in terms of the model which takes into account the presence of four different phases. The presence of pure PVDF is postulated in the first phase. On the experimental time scale, the presence of protons arising from PMMA is not detected. The second phase includes the regions in which the chains of both components are mixed at the 'truly molecular' level and the main transfer of magnetisation from protons to fluorine is ensured directly by the ^1H – ^{19}F -depolarisation processes. The third phase is close to the previous one but, in contrast to the latter, it should be controlled to a greater extent by spin diffusion processes. Finally, the fourth phase includes regions of pure PMMA, manifesting depolarisation and spin diffusion processes. On the basis of their experiments, the authors³⁵¹ were able to calculate the fractions of the first and fourth phases and also to estimate the dimensions and ratios of the components in the domains comprising the second and third phases for blends with a wide range of ratios of the initial components.

Table 17 shows that in the blend with 20% of PMMA the latter is wholly in the blended state. In virtually all the blends, the mixed second and third phases have virtually the same composition as regards the monomer ratio. The 80/20 blend is an exception, which is due to the dilution effect. The dimensions of the domains comprising the above phases also vary only slightly with composition and are respectively 7 and 6 Å.³⁵¹

Later Papavoine et al.³⁵² demonstrated in relation to the PMMA/PVDF 60/40 blend that the method being developed has a high information content also for the assessment of the kinetics of phase separation. In the experiments, the initial blends were heated under pressure at 200 °C (i.e. above the melting point of the PVDF crystals where the components are fully compatible) and were then rapidly cooled to 77 K. The kinetics of the phase separation were then followed in the isothermal annealing regime (at 120 and 140 °C) by the method described above (the increase in the fractions of the first and fourth phases was estimated). It was found that at both annealing temperatures the attainment of the equilibrium value occurs at approximately the same time in terms

of the fractions of both the first and fourth phases. The accumulation of the first phase, i.e. of the regions of pure PVDF, should be accompanied by the crystallisation of the latter. This has been confirmed qualitatively by DSC data (the appearance of the fusion endotherm for annealed specimens). Comparison of the increase in the degree of crystallinity during annealing at 140 °C on the basis of the results obtained by both methods shows that, according to DSC, these values are systematically lower by approximately the same amount. The authors believe that this is not fortuitous and attribute it to the fact that in the NMR method the first phase must include also the interfacial regions at the crystal–amorphous phase boundaries, the presence of which has been demonstrated by numerous dielectric relaxation experiments.

Shilov et al.³⁵³ investigated the differences between the phase ratios in bulk and on the surfaces of PVDF/PMMA blends. The X-ray photoelectron spectroscopic method, yielding information about the microstructure at depths of 4–5 nm, was employed. Specimens of two types were investigated, one of which consisted of a thin (0.2 µm) film of the 50/50 blend. Heating of the specimen in 40 °C steps directly in the spectrometer chamber demonstrated that up to 373 K the form of the XPES spectra does not change. Annealing at a temperature $T \geq 413$ K leads to an increase in the intensities of the lines corresponding to the carbon in the CF_2 bond and, conversely, to a decrease in the intensities of the lines due to the carbon in the $\text{C}=\text{O}$ group. On fusion of the blend, this process intensifies to an even greater extent as a result of the weakening of the specific interactions between the blend components. All the foregoing considerations can be accounted for solely by a redistribution of the blend components in the above annealing regimes, as a result of which the surface is enriched in PVDF at depths of 5 nm.

This conclusion is confirmed by the results of the study of specimens of the second kind which were of the 'sandwich' type: a thin layer of PMMA was deposited on top of a layer of PVDF. In the initial state, the lower PVDF layer in the specimen was almost fully covered by PMMA, but thermostatic treatment of the specimen at 413 K leads to the redistribution of the intensities of the components of the lines due to carbon in the CF_2 and $\text{C}=\text{O}$ groups mentioned above. The kinetics of this process are described by a power relation with the exponent $n \approx 0.5$, which is characteristic of diffusion-controlled processes. Since the density of PVDF is higher than that of PMMA the direction of the processes involving the inversion of the distribution of the components in the surface must be opposed to the direction of the force of gravity gradient. According to the authors,³⁵³ a surface energy minimum should correspond to the state of equilibrium, since one is dealing with the structure of the surface. The surface tensions of PMMA and PVDF are respectively 40.2 and 32.7 mN m⁻¹.³⁵⁴ The surface energy minimum therefore requires the emergence of PVDF onto the surface, which has been noted experimentally.³⁵³

In connection with the possible formation of polymorphic modifications in PVDF crystals, a test of the influence of the amorphous phase of the blend on the crystallisation of PVDF in a particular modification is of current interest. If PVDF crystallises with formation of α and γ spherulites for low degrees of supercooling, the addition of PMMA leads to a decrease in the concentration of the large (α) spherulites, which in addition become loosely packed.⁸⁶ Thus isotropic films become enriched in spherulites formed by the γ phase. According to other data,³⁴⁵ PMMA can influence also the form of the polymorphic modification of the PVDF crystals produced in the isothermal annealing regime at temperatures above the glass transition temperature of the blend after its quenching from the melt.

DSC, IR spectroscopic, and X-ray diffraction data have shown that the crystallisation of PVDF/PMMA blends leads mainly to the formation of the α phase, but, if the component ratio is 70/30, the ferroelectric β phase is produced. These questions have been investigated in detail for textured films. In

Table 17. The fractions of the first and fourth phases and the monomer ratio in the second and third phases for PVDF/PMMA blends of different composition.³⁵¹

PMMA/PVDF	Fraction of first phase	Fraction of fourth phase	Monomer ratio	Monomer ratio in second and third phases
20/80	0.75	0	0.16	0.65
40/60	0.35	0.10	0.43	0.59
60/40	0.15	0.30	0.96	0.75
80/20	0.10	0.30	2.56	1.99

particular the role of PMMA in polymorphic changes has been investigated in the formation of PVDF films under the conditions of a high longitudinal gradient in the flow of the melt.³⁵⁶ It was shown that, under the above conditions, pure PVDF crystallises as a mixture of the α and β modifications, the fraction data of the former amounting to 62%. Scanning electron microscopic data indicate that this entails the formation of lamellar crystals. When 20 mass% of PMMA is introduced into PVDF, the fraction of the β phase increases by 20% under the same crystallisation conditions, while the morphology becomes mixed, i.e. acicular crystals appear together with lamellar ones. A similar conclusion was reached also in a later study¹⁰² where it was shown that the addition of PMMA also increases the fraction of the β phase formed, while the morphology changes from lamellar to fibrillar. A new feature is the finding that the number of fibrillar β phase crystals increases with increase in the molecular mass of the polymethacrylates.

The influence of the form and concentration of the amorphous component in the blend with PVDF on the nature of the morphology generated on crystallisation of the latter has been investigated in detail.³⁵⁷ Blends of PVDF with PMMA, the styrene/MMA copolymer (S-MMA), and poly(methyl acrylate) (PMA) were studied. It was noted that, whereas the lower critical miscibility temperature (LCT) in PVDF/PMMA blends is $\sim 350^\circ\text{C}$, it is significantly reduced for the PVDF/S-MMA system with increase in the amount of styrene in the copolymer. When the styrene content reaches ≥ 0.15 , the blend becomes incompatible, since the LCT becomes comparable to the equilibrium melting point of the α modification of PVDF. As in an earlier study,⁸⁶ pure PVDF crystallised at low degrees of supercooling with formation of the α and γ spherulites, but, in contrast to the study quoted, when polymethacrylates were added, fine differences were noted in the supermolecular structures produced. The α spherulites of pure PVDF have a fine fibrillar structure, which the γ spherulites lack.

For the PVDF/S-MMA blends, the α phase spherulites are converted into dendrites, the size of which diminishes, other conditions being equal, with increase in the fraction of the amorphous component. An even higher content of the latter leads to the crystallisation of PVDF in the form of small circular spherulites. The formation of dendrites is explained by the appearance in the growing front of fluctuations in the concentration of PVDF chains and by the transition of the crystallisation process to the diffusion-controlled region. Only circular spherulites are usually observed for PVDF/PMA blends. This is attributed to the lower glass transition temperature of PMA (and hence also of the blend) compared with PMMA, which should lead, other conditions being equal, to the acceleration of the stages involving diffusional control during crystallisation. The last blend is interesting also because it is possible to observe in it the crystallisation of PVDF under the conditions of very high 'dilution', i.e. when its volume fraction is only 0.3.

The above changes in the properties of blends of PVDF with polymethacrylates suggest the occurrence of specific interactions in these components. Their nature has been investigated by IR spectroscopy.³⁵⁹ Attention was concentrated in the above study³⁵⁹ on the analysis of the form and frequencies of the stretching vibrations of the carbonyl (C=O) group of PMMA. Preliminary studies on solutions of low-molecular-mass homologues of PMMA in the form of methyl acetate (MAC) and methyl pivalate (MPA) have shown that the solvent polarity may alter significantly the characteristics of the above band up to its splitting. The occurrence of significant interactions may be deduced by analysing the form of the absorption band due to the vibrations of the carbonyl group in MAC and MPA, which were introduced into the matrices of different polymers (Fig. 34). Evidently in the case of inert matrices (PE, PTFE) the absorption bands remain narrow and are displaced towards higher frequencies. In contrast to this, bands due to the PVDF matrix are significantly broadened and are displaced appreciably towards

Figure 34. The form and position of the band due to the stretching vibrations of the C=O group of methyl acetate (a) and methyl pivalate (b) in various matrices.³⁵⁹ (1) PTFE; (2) PE; (3) PVDF.³⁵⁹

low frequencies. The authors formulated in greater detail the mechanism of the specific interactions in blends, having considered the system comprising the VDF/chlorotrifluoroethene copolymer swollen in deuterated MAC.

By following the doublet absorption in the region of symmetrical and antisymmetrical stretching vibrations of the methylene groups in PVDF in the copolymer, it was shown that the swelling of the copolymer in MAC leads to a significant bathochromic shift of the bands. It was therefore concluded that the C=O groups may form hydrogen bonds with VDF units. When account is taken of similar data for low-molecular-mass compounds, the enthalpy of such bonds, calculated from the frequency shift of the absorption bands, is found to be $\sim 1 \text{ kcal mol}^{-1}$. This conclusion has been confirmed also on passing from model systems to polymer blends. The changes in the region of the absorption bands due to the carbonyl group for pure PMMA and PMMA in the PVDF/PMMA 50/50 blend show that in the latter case the band shifts somewhat towards lower frequencies, which can be seen distinctly from the difference spectra for specimens of the annealed and quenched blends, having the same composition. The excess absorption on the high-frequency side and the negative absorption on the lower-frequency side imply in this case that this annealing, leading to the crystallisation of PVDF, diminishes the number of specific contacts between PMMA and PVDF.

It was possible to demonstrate the occurrence of specific interactions also in relation to other functional groups, in particular for the methyl ether group $\text{O}-\text{CH}_3$ and the α -methyl group of PMMA. An increase in temperature leads to a decrease in the intensities of the above absorption bands for pure PMMA. The addition of 15 mass % of PVDF leads to exactly the same change. As a result of specific interactions, the latter effectively weakens the intermolecular interactions in PMMA chains. This is reflected also by the decrease in the glass transition temperature of the blends with increase in the fraction of PVDF noted above [see Eqn (27)]. Shilov et al.³⁵³ also concluded that specific interactions occur in PVDF/PMMA blends, where the carbonyl group of PMMA should be involved. This conclusion is based on the analysis of the X-ray photoelectron spectral lines.

The specific interactions between PMMA and PVDF may be the cause of an unusual phenomenon noted for the PVDF/PMMA 80/20 blend. The study by Tsutsumi et al.³⁶⁰ was devoted to the estimation of the internal field E_i in the polarised specimen. The method involving the introduction of small amounts of a dye (dimethylaminonitrostilbene) was used and measurements were made of the differences between the absorption spectra in the visible region before and after poling in a field with a strength E . For sufficiently high poling fields, the internal field proved to be higher than the poling field (Fig. 35 a). In the highest poling fields,

Figure 35. Dependence of the internal field E_i on the strength of the poling field (a) and the annealing temperature (b) in PVDF/PMMA 80/20 blends.³⁶⁰

the field ratio may be more than two, this conclusion being confirmed also for another type of dye.³⁶¹

As a result of the specific interactions between the PVDF and PMMA chains in the amorphous phase, the glass transition temperature in the blend of the above composition becomes 60 $^{\circ}\text{C}$.³⁶⁰ At a poling temperature of 80 $^{\circ}\text{C}$, these interactions are weakened and the poling field causes the preferential orientation of not only the ferroelectric crystals but also of the polar segments in the amorphous phase. Cooling of the specimen after poling in the presence of a field to room temperature creates a new situation for the blend compared with the VDF homopolymer. Indeed, since $T_g = -40$ $^{\circ}\text{C}$ for the latter, it follows that at room temperature the ordered dipoles in the amorphous phase should undergo depolarisation after the removal of the field and the internal field is then generated only by crystallites. In contrast to this, for the above blend at room temperature the ordered dipoles of the amorphous phase should be frozen, since its glass transition temperature is 60 $^{\circ}\text{C}$. For this reason, the resultant internal field at room temperature is generated in this case, in contrast to PVDF, both by the polar crystals and by the ordered domains in the amorphous region. This hypothesis is confirmed by the data presented in Fig. 35b. Evidently heating of the specimen of the poling blend lowers E_i precisely in the region of the glass transition temperature, where the specific interactions between the PVDF and PMMA chains are effectively weakened. It can also be seen from the same figure that the main contribution to the depolarisation process comes nevertheless from crystals in which the appearance of mobility at temperatures above 100 $^{\circ}\text{C}$ leads to a more significant decrease in E_i .

The study of Tsutsumi et al.³⁶⁰ was also concerned with the problem of the influence of PMMA on the polymorphism of PVDF. X-Ray diffraction data have shown that, whereas the homopolymer crystallises as the α phase, its blends with PMMA having the composition specified above are characterised by the presence of the β phase after quenching from the melt. This has also been noted in other studies.^{345,357} However, it would be premature to reach an unambiguous conclusion concerning the role of PMMA as regards polymorphism, since many results indicate some uncertainty. For example, when the blend is prepared by deposition from a compatible polar solvent (dimethylacetamide), then, as for the pure homopolymer, it crystallises as the γ modification.³⁶² In the absence of α phase crystals, it is impossible to observe the high-temperature $\alpha(\alpha_c)$ relaxation. However, later data³⁶³ showed that the form of the crystallographic modification may depend also on the type of the support on which the film is deposited. In particular, the case of the PVDF/PMMA 60/40 blend from solution onto an aluminium support promotes crystallisation as the α modification.

Together with indirect data on the polymorphism in PVDF, the dielectric relaxation method applied to blends can also yield

new information about the details of the morphology produced. This is illustrated by the results of a series of studies where the relaxation processes in compatible PVDF blends were investigated by the dielectric method. The temperature dependences of the loss factor at a frequency of 100 kHz were analysed for pure PVDF and its blends with PMMA having different compositions.^{365–367} Two relaxation regions can be clearly distinguished for the homopolymer. They are attributed, in order of increasing temperatures, to the $\beta(\alpha_a)$ and α_c processes. For blends, the kinetics of both processes are the same as the fraction of PMMA increases to 60% their intensity diminishes steadily without a change in the temperature of the ϵ'' maximum. The latter factor for the high-temperature process can be readily accounted for from the standpoint of the mechanisms of the α_c relaxation in PVDF. Indeed, as already mentioned, it can be attributed to motions of the chains in the crystals of the α modification of PVDF. A decrease in the fraction of the latter is therefore equivalent to a decrease in the number of crystals, which should lead to the observed decrease in the intensity of the peak without its displacement as regards temperature. The $\beta(\alpha_a)$ process is unusual. As mentioned above, according to the unanimous view of all investigators this process is attributed to the micro-Brownian motion of the chains in the amorphous region during glass transition. If the low-temperature peak for blends is also related to the glass transition, then it is impossible to account for the independence of the temperature of the above process as the fraction of PMMA in the blend increases. If the amorphous phase of PVDF is compatible with that in PMMA (this is indicated by the presence of a single glass transition temperature), then, as the fraction of the latter increases, the glass transition region should shift towards higher temperatures, as indicated by Eqn (27). The observed constancy of the low-temperature relaxation peak clearly conflicts with these conclusions.

This factor as well as the fact that the $\beta(\alpha_a)$ relaxation is observed distinctly only when the α_c process is detected made it necessary to postulate that the observed low-temperature process has to be related not to glass transition but to the motion in the interfacial region along the crystal–amorphous PVDF phase boundaries. The same idea has been developed in a study³⁶⁸ in which compatible PVDF blends were investigated, but this time with PEMA. Fig. 36 presents the temperature variations of the loss factor ϵ'' for this blend at a frequency of 200 kHz.

In contrast to PMMA, poly(ethyl methacrylate) has a lower glass transition temperature (60 $^{\circ}\text{C}$), so that yet another relaxation region (β_1) is observed together with the $\beta(\alpha_a)$ and α_c dispersions for blends with a high PVDF content. Comparison of DSC data shows that this relaxation region has to be attributed to the glass transition process in the mixed regions of the amorphous phase of PVDF and PEMA. It was found that the temperature variations of the relaxation frequencies for the

Figure 36. Temperature dependence of the loss factor at a frequency of 200 kHz in PVDF/PEMA blends.³⁶⁸ The numerals on the curves represent the fraction of PVDF in the blend.

homopolymer and the slowly cooled blends enriched in PVDF fit satisfactorily on a single relation. This made it possible to claim that the low-temperature relaxation region in PVDF and in its crystallisable blends with PEMA is associated with the mobility in the interfacial regions of the crystal. Furthermore, the fraction of such regions W_i may be estimated from the relation³⁶⁸

$$W_i = W - (W_c - W_m), \quad (30)$$

where W is the overall fraction of PVDF in the blend, W_c the fraction of the crystalline phase, and W_m the fraction of PVDF in the blended state. The last was estimated from T_g for the blend, while W_c was calculated from the enthalpy of fusion. The values of W_i were compared with the relaxation force $\Delta\epsilon$. It was shown that there is a linear relation between them. The maximum value of $\Delta\epsilon$ (5.5) corresponds to the relaxation in the homopolymer, for which the fraction of interfacial regions reaches 0.35. As can be seen, this value may constitute more than half the degrees of crystallinity in PVDF usually reported.

However, the view of Yoon et al.³⁶⁷ and Ando et al.³⁶⁸ concerning the nature of the low-temperature relaxation region in PVDF blends is not shared by everyone. Thus Saito and Stuhn³⁶⁹ questioned the validity of the conclusions reached. This is based on, for example, the temperature variations of the loss factor ϵ'' at two frequencies for pure PVDF and in blends with PMMA having the 60/40 composition (Fig. 37). Evidently the regions of the ϵ'' maximum for low-temperature relaxation at a high frequency are approximately the same for the homopolymer and the blend, as mentioned in the earlier studies.^{367, 368} However, at a frequency of 100 Hz the differences between the temperatures of the maxima are very striking. This served as a basis for the conclusion that it is not the α_a process but some other process which contributes to the low-temperature relaxation.

Fig. 38 presents comparative frequency dependences of ϵ'' in the glass transition region for pure PVDF and its blend with PMMA. Evidently, the peak for the homopolymer exhibits a high-frequency asymmetry, which was attributed to the contribution by the local mobility in the region of $\beta(\gamma)$ relaxation. The overall curve was subdivided into two components (α_a and β) by adjusting the experimental points to agree with the calculated ones with the aid of the empirical Havriliak–Negami relation:

$$\epsilon^*(\omega) = \epsilon_\infty + \frac{\epsilon_0 - \epsilon_\infty}{[1 + (i\omega\tau)^2]^\gamma}, \quad (31)$$

Figure 37. Temperature dependence of the loss factor in PVDF (1, 2) and in the PVDF/PMMA 60/40 blend (3, 4) at frequencies of 100 Hz (1, 4) and 10 kHz (3, 2).³⁶⁹

where the parameters $0 \leq \alpha$ and $\gamma \leq 1$ describe respectively the broadening and asymmetry of the relaxation time distribution function, while ϵ_0 and ϵ_∞ are the extrapolated static and high-frequency relative permittivities. At the temperature indicated in Fig. 38, the curve for the β process in PVDF is described satisfactorily by the parameters $\Delta\epsilon = 0.69$, $\lg v_m = 4.0$, $\alpha = 0.32$, and $\gamma = 1$.

The same frequency dependences of ϵ'' for the blend at the same temperature are presented in Fig. 38b, where the high-frequency maximum is described (after separation from the postulated low-frequency maximum) by the parameters $\Delta\epsilon = 0.43$, $\lg v_m = 4.3$, $\alpha = 0.34$, and $\gamma = 1$. As can be seen, the parameters of the β process for the homopolymer and the blend are virtually identical. This justifies the assumption that the low-temperature relaxation in PVDF/PMMA blends is determined by the contribution not of the α_a process but of the local mode of motion (β process). The temperature dependence of the relaxation frequencies in the blend and in the homopolymer are presented in Fig. 39. They confirm the above conclusion, since in both cases the relaxation frequencies and the activation energies (determined from the slopes of the relations presented) for the β and α_c process are virtually identical.

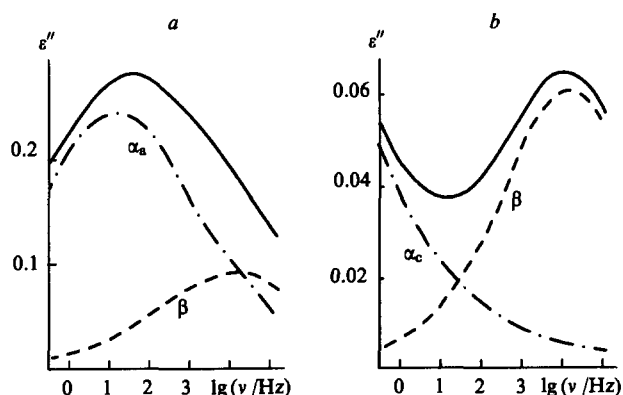

Figure 38. Frequency dependences of the loss factor at -40°C for pure PVDF (a) and for the PVDF/PMMA 60/40 blend (b).³⁶⁹ α_a , α_c , β — contributions of the corresponding relaxation regions.

Figure 39. Temperature dependences of the relaxation frequencies in pure PVDF (1, 3, 4) and in the PVDF/PMMA 60/40 blend (2, 5, 6).³⁶⁹ α_a , α_c , β , MW — contributions of the corresponding relaxation regions.

The α_a process in the homopolymer cannot be described by the Arrhenius relation, as noted also by Ando et al.³⁶⁸ Ando et al.³⁶⁸ thought that one of the main arguments in support of their hypothesis is the agreement between the correlation frequencies for the homopolymer and the blend, which cannot be observed in the case of PVDF/PMMA according to the data of Saito and Stuhn.³⁶⁹ However, one can assume that there are no special contradictions in the experimental data of the two studies.^{368, 369} Indeed, the sections of the curve corresponding to the relaxation frequencies in the ranges $\nu > 10^4$ Hz and $\nu < 10^4$ Hz were discussed in the first and second studies respectively (Fig. 39). Evidently, with increase in frequency, the α_a and β relaxation processes approach one another and one may expect that they would coincide. Despite the rigorous quantitative analysis of the results for the low-temperature relaxation in PVDF/PMMA blends, the conclusions reached by Saito and Stuhn³⁶⁹ are nevertheless regarded as controversial. Indeed, if the low-temperature relaxation in the PVDF/PMMA blend is induced mainly by the contribution of the local β process in PVDF, then, under the conditions of the compatibility of the amorphous phases of both components, one has to postulate that the $\beta(\gamma)$ process in PVDF is associated with the local mobility precisely in the amorphous regions. However, this conclusion is not always confirmed experimentally, since there are data (see, for example, Osaki and Ishida²⁷⁵) showing that this process has to be related to the crystalline phase.

The demonstration by Saito and Stuhn³⁶⁹ that the characteristics of the interfacial regions at the amorphous phase–crystal boundary in the homopolymer and in the PVDF/PMMA blend differ significantly is more valuable. This is confirmed by the frequency dependences of ε'' at 90 °C for the PVDF/PMMA blend and the homopolymer (Fig. 40). Evidently they differ significantly: a maximum associated with the α_c relaxation, on which an intense rise in ε'' due to the occurrence of a vigorous low-frequency relaxation process via the Maxwell–Wagner (MW) interlayer polarisation mechanism is superimposed, has been observed for PVDF. As can be seen from Fig. 40a, the above relaxation process can be distinguished in the case of a blend, since the experimental ε'' points in the low-frequency region are satisfactorily fitted for the superposition of the MW process and when account is taken of the dc-conductivity. Compared with the homopolymer, the MW polarisation process in the blend is displaced towards higher frequencies. This made it possible to describe the given relaxation process in terms of the parameters of Eqn (31): $\Delta\varepsilon = 22.5$, $\lg\nu_m \approx 0.3$, $\alpha = 0.72$, and $\gamma = 1$.

Figure 40. Frequency dependences of the loss factor at 90 °C in the PVDF/PMMA 60/40 blend (a) and in pure PVDF (b).³⁶⁹ Components: dc — dc conductivity; M = Maxwell–Wagner relaxation; α_c — α_c relaxation.

Thus the difference noted between the parameters of the MW polarisation in the homopolymer and in its blend with PMMA makes it possible to assume that, owing to the increased affinity of the chains of both components, PMMA fragments are inserted not only in the PVDF amorphous phase proper but also into the regions of the interfaces noted above. Only this hypothesis can explain (at least qualitatively) the observed differences, since the ratio of the relative permittivities and the mobility of the carriers in the region of the interfaces, which in fact control the MW polarisation processes, should change under these conditions.

It is of interest to examine the characteristics of the blending of PMMA not only with PVDF but also with its copolymers. In the first place, attention was turned to the VDF/TrFE copolymer, which gives rise to a ferroelectric phase immediately on crystallisation from the melt.³⁷⁰ The VDF/TrFE 78.5/21.5 copolymer was used and the blends were prepared by precipitation from solution in dimethylacetamide. As for the PVDF/PMMA blend, in the case of the copolymer an increase in the fraction of the amorphous component lowers the melting point of the PVDF crystals formed. Taking this into account, the Flory–Huggins parameter was estimated from Eqn (29) as -0.329 , which is less than in the case of the homopolymer. This means that the introduction of TrFE into the VDF chain of the monomer promotes an intensification of the interaction between these blend components. It may be that this accounts for a series of the features noted below.

X-Ray diffraction data have shown that an increase in the fraction of PMMA in the blend with the copolymer hardly affects the unit cell parameters of the ferroelectric phase and leads merely to a decrease in its volume fraction. Crystallisation persists even in 65/35 blends and both the Curie and melting points change little under these conditions. The degree of crystallinity diminishes linearly with increase in the fraction of PMMA to 40% and for its higher values the blend is obtained in the amorphous state. Comparison of IR spectroscopic data and the concentrations of the groups of the copolymer in the 'planar zigzag' and $TGT\bar{G}$ conformations showed that the introduction of PMMA into the copolymer promotes an increase in the concentration of the former.

The copolymer considered comprises two polar comonomers. It is of interest to proceed to the consideration of a VDF copolymer in which the second comonomer is nonpolar. A fairly high fraction of this comonomer may affect the mechanism of the interaction of the blend components, since specific interactions between the PMMA chains and a nonpolar comonomer may be disturbed. The most suitable compound for this purpose is the copolymer of VDF with tetrafluoroethylene, which, like the

previous copolymer, can give rise to a ferroelectric phase in the isotropic state.³⁷¹

The use of the VDF/TFE 80/20 copolymer, the properties of which are similar to those of the VDF/TrFE copolymer, made it possible to test the role of the polarity of the second monomer. The monotonic variation of the refractive index and the single glass transition temperature obtained on varying the composition ratio indicate that the above blends are compatible. Analysis of X-ray data has shown that crystallisation ceases when the fraction of the copolymer is less than 70%. Evidently this corresponds approximately to the critical value for VDF/TrFE copolymer in a blend with PMMA (~65%). This similarity is most probably associated with the fact that in both copolymers crystallisation proceeds with formation of the polar ferroelectric β phase. For higher contents of PMMA in the blend with the VDF/TFE copolymer, the latter no longer crystallises. The nature of the amorphous halo indicates the compatibility of the components in the nonordered state: with increase in the fraction of PMMA, the angular position of the halo shifts monotonically towards lower angles as a consequence of the increase in the average distances between the molecules.

The different chemical composition of the second comonomer is, however, manifested in a different way. Yet another endotherm, associated with the phase separation process, which is recorded also from the appearance of the turbidity point, has been noted on the DSC curves in the range of temperatures above the melting point. Both methods yielded approximately similar characteristic temperatures, but, what is most interesting, the turbidity point varied very significantly. The variation may be described by a curve with a minimum as a function of the increase in the fraction of the copolymer in the blend. It has been shown that a maximum variation of the enthalpy of phase separation corresponds to the region of the minimum in the phase separation point. The Flory-Huggins parameter is then found to depend on the composition, but remains negative over the entire concentration range. The increase in this parameter as the concentration of the copolymer is reduced shows that PMMA-enriched blends are characterised by a weaker interaction of the components. This has also been noted for the PVDF/PMMA blend³³² on the basis of small angle X-ray scattering data. The specific role of the nonpolar comonomer TFE in PVDF chains most probably attributes to the fact that the lowest values of B are found to be higher than for the blend of pure PVDF and PMMA.

From the practical point of view, it is important to have compatible PVDF blends with a high glass transition temperature. For this purpose, it is of interest to consider as the blend component the noncrystallising highly polar polyvinylpyrrolidone (PVP), the glass transition temperature of which is ~200 °C. The above components are satisfactorily compatible in the melt.^{372,374} It was observed that the introduction of PVP greatly reduces the melting point of the PVDF crystals, the formation of which is fully inhibited for a PVP content of ~40 mass %. The melting point depends on the molecular mass of PVP and decreases with increase in the fraction of the latter. Analysis of the details of the dynamic relaxation in the above systems shows that a decrease in the fraction of PVP in noncrystallising heterogeneous blends with PVDF leads to a significant decrease also in the glass transition temperature: for a PVP fraction of 0.4, it diminishes to ~120 °C.³⁷⁴

If the PVDF/PVP blends crystallise, then the presence of three-phases is noted: the crystals of PVDF, homogeneously blended domains with a quasi-constant composition, and the purely amorphous PVDF phase. In view of the very low Flory-Huggins parameter, very strong interactions are postulated between the components of the blend in the second phase.

The possibility of regulating the energy of the specific interactions of the components can be ensured by introducing ions into the polymer chain. In this connection, it is of interest to examine the questions concerning structure formation in a blend of PVDF with the tetrafluoroethene-perfluorovinyl ether copolymer with a sulfonic acid group at the end [Nafion (NAF)].³⁷⁵ In the study of

the morphology on crystallisation of PVDF in such a blend, obtained by precipitation from dimethylacetamide and dimethylformamide, it was shown that the average size of the spherulite is always greater when the component ratio is approximately equal. Mixed spherulites of the α and γ modifications have been observed for the PVDF/NAF 40/60 and 60/40 blends, as in pure PVDF under certain crystallisation conditions. The size and shape of the spherulites formed depend not only on the blend composition but also on the film deposition temperature. α Spherulites grow predominantly at 150 °C, whereas the small spherulites of the γ phase grow mainly at 70 and 90 °C. The latter property is new compared with pure PVDF and is apparently due to the presence of the ionomer.

An increase in temperature in a film of a blend with a spherulitic morphology to 185 °C is accompanied by the disappearance of spherulites when the system melts. However, a further increase in temperature leads to a catastrophic growth of scattering intensity (for parallel polarisers) and a displacement of the scattering region towards small angles. This is attributed to the thermoinduced phase separation of the spinodal type. By resorting to dielectric relaxation data in the region of the α_c transition, it was possible to establish that the temperature of the maximum increases linearly with increase in the fraction of NAF. On this basis, it is concluded that this pair of components is partly compatible as a result of the specific interactions between the PVDF groups and NAF ions. A detailed study of the kinetics of the phase separation (above the melting point of PVDF) showed that the characteristic point may depend significantly on the heating rate. At a constant heating rate (0.2 K min⁻¹), the turbidity point varies as a function of blend composition along a curve with a minimum for a blend with 60 mass% of NAF. Treatment of the experimental data from the standpoint of the scaling theory has shown that, for a small thickness of the blend films (10 μ m), the growth of domains with concentration fluctuations in the region of the phase separation is more likely to be two-dimensional in character.

One may deal separately with the results of several studies in which problems of compatibility in blends of PVDF with an other crystallisable polymer were considered. The blends of PVDF with poly(vinyl fluoride) (PVF) have been investigated in greatest detail in this connection.^{376,377} The results of X-ray analysis have shown that the phenomenon of isomorphism (crystallisation of both components with the same lattice) is characteristic of them for virtually any component ratio.³⁷⁶ The reason for this is apparently the identity of the chemical bonds in the repeat units of the monomers and hence the similarity of the lattices of each polymer. Thus the most intense intermolecular reflection due to the β phase is characterised by the interplanar spacings $d = 4.31$ Å in PVF and 4.39 Å in PVDF. It is significant that even small amounts of PVF added to PVDF stabilise the 'planar zigzag' conformation in the latter.³⁷⁶

The same feature has been noted also for the blend of PVDF with another crystallisable polymer — poly(ethylene glycol).³⁷⁸ The manifestation of cocrystallisation effects has also been observed for the blend of PVDF with the chlorotrifluoroethylene/VDF 77/23 copolymer. Under the conditions of the preparation of blend films from a common solvent, a single melting endotherm due to the fusion of the PVDF crystals is manifested, the melting point shifting insignificantly towards lower temperatures as the PVDF fraction is diminished. At the same time, this leads to an appreciable decrease in the degree of crystallinity and in the size of the spherulites. The authors tend to see the significant difference between the degrees of crystallinity α in the blend with 10% of PVDF compared with the pure homopolymer, taking into account its fraction in the blend, as the manifestation of the cocrystallisation effects in the above blends: whereas $\alpha = 53\%$ for PVDF, for the blend with 10% of the homopolymer (in the case of a noncrystallisable copolymer) α should be 5.3%, but the actually observed value is 9.9%.

The practical tasks in the search for new materials with high piezoelectric characteristics suggest the creation of composite systems with classical inorganic ferroelectric fillers (of the type of BaTiO_3), which are introduced into the organic polymer matrix. In this connection, the specific interactions between PVDF and PMMA, in particular, may be reflected also in the final piezoelectric properties. Indeed, the three-layer dielectric in the form of PVDF combined with PMMA (filled with BaTiO_3) has a high piezoelectric constant d_{33} , which, however, is insufficiently stable. An increase in d_{33} may be attained in another system, where the buffer layer consists of a polyetherurethane elastomer,³⁸⁰ the highly polar groups of which may stabilise the structure and hence the piezoelectric properties as a result of the interaction with the corresponding fragments of the PVDF chains.

The filling of PVDF simply with BaTiO_3 particles is also of practical interest, since the latter have a higher Curie temperature, which makes it possible, in principle, to obtain a combined material not only with high piezoelectric characteristics but also with a wider range of temperatures at which it can be employed. Possible structural modifications both in PVDF and in the particles of the added filler have been suggested for this purpose.^{381,382} The X-ray diffraction method, employed for the same purpose, has been applied over a wide range of scattering angles in order to isolate nonoverlapping reflections from individual blend components. Pure PVDF crystallised as the α modification while the introduction of even 10% of BaTiO_3 greatly reduced the intensity of the corresponding reflections, which can be explained by a decrease in the degree of crystallinity. The observation of the characteristic reflections for BaTiO_3 with increase in its content in the blend indicates that they are somewhat displaced into the region of smaller angles. This is treated as evidence for the appearance of internal stresses in such composites.

Finally, one should deal with yet another study on PVDF blends with inorganic fillers. This concerns PVDF composites with $\gamma\text{-Fe}_2\text{O}_3$ particles.³⁸³ The author's aim was to test the occurrence of the thermal decomposition of $\text{Fe}(\text{CO})_5$ in a chemically inert matrix. However, this study may be regarded as a contribution to the development of a new method for the preparation of materials with an interesting combination of electrical and magnetic properties.

The formation of fine $\gamma\text{-Fe}_2\text{O}_3$ particles as a result of the decomposition reactions of the initial compounds is accompanied primarily by the formation of an insoluble polymer. These processes are most probably actually responsible for the fact that, on crystallisation of PVDF, the large spherulites (which arise in the homopolymer) are no longer observed in the blend, while the mechanical characteristics of the latter change significantly in the region of the high elasticity plateau. Optical microscope and small angle X-ray scattering data indicate that the degree of crystallinity in blends diminishes significantly. Analysis of the morphology of the blends produced clearly indicates the occurrence of processes involving the phase separation of the components. The cluster structure was typically analysed by the method of X-ray probes and it was found that the concentration of iron within the particles is higher than in the surrounding polymer matrix. Analysis of X-ray and electron diffraction indicates the possibility of the occurrence of reactions between the magnetic particles and PVDF with formation of FeF_2 compounds. It is believed that the latter are produced in the course of the formation of a three-dimensional network in the polymer matrix. On the other hand, most of the disperse phase has the $\gamma\text{-Fe}_2\text{O}_3$ structure. The proposed method is promising for the preparation of organic materials containing small magnetic particles (the size of the latter is 50–100 Å).

X. Conclusion

The possibilities of the polymorphic transformations in PVDF and in its copolymers under the influence of various external factors have been analysed in the present review. It has been

shown that a particular crystallographic modification may be obtained not only as a result of the operation of various physical factors but also as a result of the introduction into the PVDF chain of, for example, 'head to head' defects or certain comonomers. It is significant that the specific effects of the solvent can also be used as an effective factor in the formation of particular structure of PVDF films from appropriate solutions. It is emphasised that the concentration and type of ionogenic impurities in solution can then affect the type of the polymorphic modification formed.

The operation of factors such as high pressure and tensile deformation are used for practical applications, where one needs to obtain polar modifications of PVDF, for example for pyro- and piezo-electric transducers. Examination of the polymorphism in PVDF induced by high electric fields may be used, on the one hand, to discover the fundamental characteristics of the behaviour of polymeric dielectrics in electric fields and, on the other, for recommendations concerning the practical preparation of the active elements used in the energy converters mentioned above. It has been shown in relation to a series of recent studies that yet another (nontraditioned) method for the modification of the structure of PVDF and crystallising polymers in general is irradiation.

The characteristics of the dynamics of polymer chains in PVDF and its copolymers may serve as a basis for the prediction of the occurrence of relaxation processes in the systems considered, which is important for the creation of materials with stable and specified properties.

It is shown that specific modification of the structures of the polymer systems considered may be achieved also with the aid of blends with polymers and nonpolymeric components. In a number of cases, it is possible to improve by this procedure certain optical characteristics of the materials formed, which makes them competitive in relation to other materials used in elements with nonlinear optical properties.

Abstract. The current state of gas adsorption chromatography on open tubular capillary columns is analysed. The history of the development of this method and its role in gas chromatography are considered. The preparation of open tubular adsorption capillary columns, fundamentals of the theory of retention and of broadening of chromatographic zones, and the use of columns of this type in practical analytical chemistry are discussed. The bibliography includes 148 references.

I. Introduction

Gas chromatography is among the main analytical methods; it is used successfully in various branches of industry such as the petrochemical, chemical, and gas industry, etc., in pharmaceuticals, in the control of environmental pollution, in medicine, in agriculture, and also in scientific research.^{1–6}

Currently, capillary gas chromatography is used most frequently. Indeed, according to a bibliometric study,⁷ 83% of the publications devoted to chromatography refer to the use of capillary columns and, according to McNair's data,⁸ capillary columns account for 80% of all gas-chromatographic columns purchased. In recent years, a new type of capillary column, namely, open tubular gas adsorption (or gas-solid) capillary columns have been used advantageously in analytical practice. This makes it possible to solve numerous practically important analytical problems that cannot be solved with the use of conventional gas-liquid columns.

The aim of the present review is to analyse critically the data on capillary gas adsorption chromatography, in particular, studies by Russian scientists, who have made a substantial contribution to the development of this technique.

The vigorous development of capillary chromatography during the last 10–15 years is due to a number of advantages of capillary columns over the conventional packed columns. Firstly, open tubular capillary columns are 10–1000 times more efficient than the classical packed columns. Secondly, capillary columns

permit separation of a wider range of heavy (high-boiling) compounds, since chromatography on these columns is carried out at lower temperatures than on packed columns. Thirdly, with the open tubular capillary columns, a substantially higher rate of separation can be achieved. Fourthly, the decrease in the size of columns ensures a more reproducible regime of separation. Finally, the procedures for working with capillary columns became much simpler when flexible quartz columns with polymeric coatings^{9,10} or with a more thermostable metallic coating^{11,12} have been introduced into the chromatographic practice. The latter columns were proposed for the first time in Russia.¹¹ The above advantages have stimulated the development of not only gas-liquid but also gas-solid capillary chromatography.

The separating capacity of a chromatographic column (R) is determined by three factors:

$$R = \frac{\alpha - 1}{\alpha} \frac{\sqrt{N}}{4} \frac{k}{1 + k} = SEC, \quad (1)$$

where α is the relative retention of two components that form a pair, critical for separation; N is the number of theoretical plates; k is the capacity factor of the second component being separated; and S is the selectivity index of the column (of the sorbent used)

$$S = \frac{\alpha - 1}{\alpha}; \quad (2)$$

E is the efficiency index of the column

$$E = \frac{\sqrt{N}}{4}; \quad (3)$$

C is the capacity index of the column

$$C = \frac{k}{1 + k}. \quad (4)$$

The capacity index C plays an important role when the capacity factors of the compounds being separated are small; for large k values, the capacity index approaches unity.

When the operation of open tubular capillary columns is analysed, their high efficiency is usually noted; however, the fact that the high selectivity of the sorbent used is also a very important factor having a considerable influence on the chromatographic separation, is often neglected.

Received 19 March 1996

Uspekhi Khimii 65 (11) 991–1012 (1996); translated by Z P Bobkova

The selectivity index [see Eqn (1)] has the greatest influence on the degree of separation. In the case of poorly separable peaks ($\alpha \approx 1.0$), the selectivity index increases proportionally to $(\alpha - 1)$

$$S = \frac{\alpha - 1}{\alpha} \approx \alpha - 1, \quad (5)$$

hence,

$$R = (\alpha - 1)EC. \quad (6)$$

The selectivity of a sorbent is usually the most significant criterion for its possible use. Selective sorbents used in gas chromatography include not only absorbents (stationary liquid phases) but also adsorbents. A special place among the latter belongs to geometrically ordered solids (for example, molecular sieves) or adsorbents with specific properties (for example, organic hydrophobic adsorbents) or adsorbents with extended surface, etc.

In view of this, it is natural to extend the use of solid adsorbents to capillary gas chromatography, i.e. to develop gas adsorption (gas-solid) capillary chromatography.

Gas adsorption chromatography has the following advantages.¹³

1. Enhanced selectivity and sorption capacity of adsorbents, which make it possible to separate organic or inorganic compounds having similar physicochemical properties. Examples are provided by the separation on molecular sieves, graphitised carbon black, or organic polymeric adsorbents.
2. The higher efficiency of separation compared to that in gas-liquid chromatography (GLC), which is due to the fact that mass exchange processes occur more rapidly than those in GLC.
3. The sufficiently high thermal stability of adsorbents.
4. The possibility of separating gases and volatile compounds at 40–50 °C with conventional gas chromatographs.
5. The lower 'noise' of the detector, which is due to the fact that the adsorbents are usually non-volatile.

The unique features of gas adsorption chromatography have also attracted the attention of Giddings,¹⁴ who has written: 'One immediate advantage of gas-solid chromatography resides in the fact that a surface coated with any reasonable degree of uniformity will exhibit a coefficient of the resistance to mass transfer substantially smaller than the corresponding coefficient for a liquid adsorption layer in gas-liquid chromatography. The second immediate advantage of gas-solid chromatography resides in the great potential selectivity of the adsorption process. Surface adsorption is potentially capable of offering the most versatile and selective characteristics of any of the known retentive mechanism. The rigidly fixed forces of a solid surface contrast sharply with the fluid forces of a liquid phase.'

Of course, the gas-solid chromatography is not free from certain drawbacks. These are the following:

1. Some non-reproducibility of sorption and chromatographic characteristics of the adsorbents used (compared to those of stationary liquid phases).
2. Asymmetry of chromatographic zones resulting from some non-linearity of adsorption isotherms.
3. A higher probability (compared to that in GLC) of irreversible adsorption and catalytic transformations of the compounds being analysed on the surface of an adsorbent.
4. The narrow range of commercially available adsorbents for gas-solid chromatography.

Juxtaposition of the advantages and drawbacks of gas adsorption chromatography shows that the advantages of this variant are much more significant than its drawbacks. This is also supported by the fact that columns with such adsorbents as alumina, silica, graphitised carbon black, molecular sieves, organic polymers, etc. are widely used in practice.

The advantages of gas adsorption chromatography can be fully realised by using its capillary variant.

II. The discovery of capillary gas chromatography and its development

The author of capillary chromatography Golay was the first to point out the theoretical possibility of preparing open tubular capillary columns with a sorbent layer arranged on the inner walls. In 1960 he wrote: 'Why not make a semipacked column with a large open passage in the centre, say, nine-tenths as large as the column inside diameter, and with a large thin layer of packing material in the remaining space on the periphery? The answer is why not indeed? I believe that such columns constitute nearly ideal columns for a wider range of analysis than present-day smooth tubular columns.'¹⁵ Note that the researcher did not indicate what particular variant of chromatography, i.e. gas-liquid or gas-solid chromatography, it would be expedient to accomplish on a capillary column with porous walls.

Some years later, open tubular gas adsorption capillary columns with their inner walls coated by an adsorbent layer were produced independently by several researchers in Russia and Germany. For example, in 1961, Kalmanovskii *et al.*,¹⁶ who studied the modification of glasses with chlorotrimethylsilane during the production of various glass capillary columns have noted that: 'the separation on non-modified capillaries proved poor (Fig. 1a), the retention time of acetone being much longer than those for other compounds and its peak being markedly asymmetrical. This indicates that the capillary surfaces contain a large number of polar sites. When the surface of these non-modified capillaries was coated with a silicone oil film, the separation became better (Fig. 1b). The modification of the capillary surface with chlorotrimethylsilane (Fig. 1c) led to clear-cut separation and to a change in the order of elution (acetone emerged first!) with respect to that with the unmodified capillary made of the same glass (*cf.* Fig. 1a). Modified capillaries can be used for analytical purposes directly in the gas adsorption version of the capillary chromatography.'¹⁶

Further, the researchers noted that the application of a silicone oil film to the surface of a modified capillary improved the separation to a greater degree (Fig. 1d) than its application to a non-modified capillary (see Fig. 1b). It is also noteworthy that the modification of the capillary surface with chlorotrimethylsilane was performed by an unusual procedure during the production of the capillary. The initial tube, from which the capillary was to be drawn, was filled with liquid chlorotrimethylsilane. At high temperature (~700 °C), chlorotrimethylsilane apparently decomposed, and interaction of the products thus formed with the glass surface yielded an adsorption layer on the inner walls of the capillary column. The chromatograms shown in Fig. 1 were obtained at 25 °C with glass capillaries with a length of 15–20 m and with an inner diameter of 0.3 mm.

Mohnke and Saffert^{17,18} have prepared a gas adsorption capillary column with a silica layer by prolonged (30 h) etching of the inner surface of a Jena glass capillary by aqueous ammonia at 170–180 °C. This yields a 10–20 µm thick silica layer. Note that Mohnke and Saffert were the first to point to a very important application of capillary gas chromatography, namely, to the separation of isotopes and nuclear-spin isomers of gases. A good degree of separation of nuclear-spin isomers and isotopes of hydrogen was achieved even in the first studies on capillary gas adsorption chromatography (Fig. 2).¹⁸

A fundamentally new suspension method for the preparation of open tubular absorption columns, based on the deposition of an adsorbent layer on the inner walls of a capillary from a suspension, has been proposed by Halasz and Horvath.^{19,20} The preparation of an adsorbent in columns of this type is independent of the material of the inner walls of the column and does not involve any transformations of it. Fig. 3 presents a chromatogram of a fast separation of aromatic hydrocarbons on graphitised carbon black layered onto the inner walls of a copper capillary. Kirkland²¹ manufactured for the first time an open tubular capillary column (75 m × 5 mm) with boehmite (Al₂O₃) and

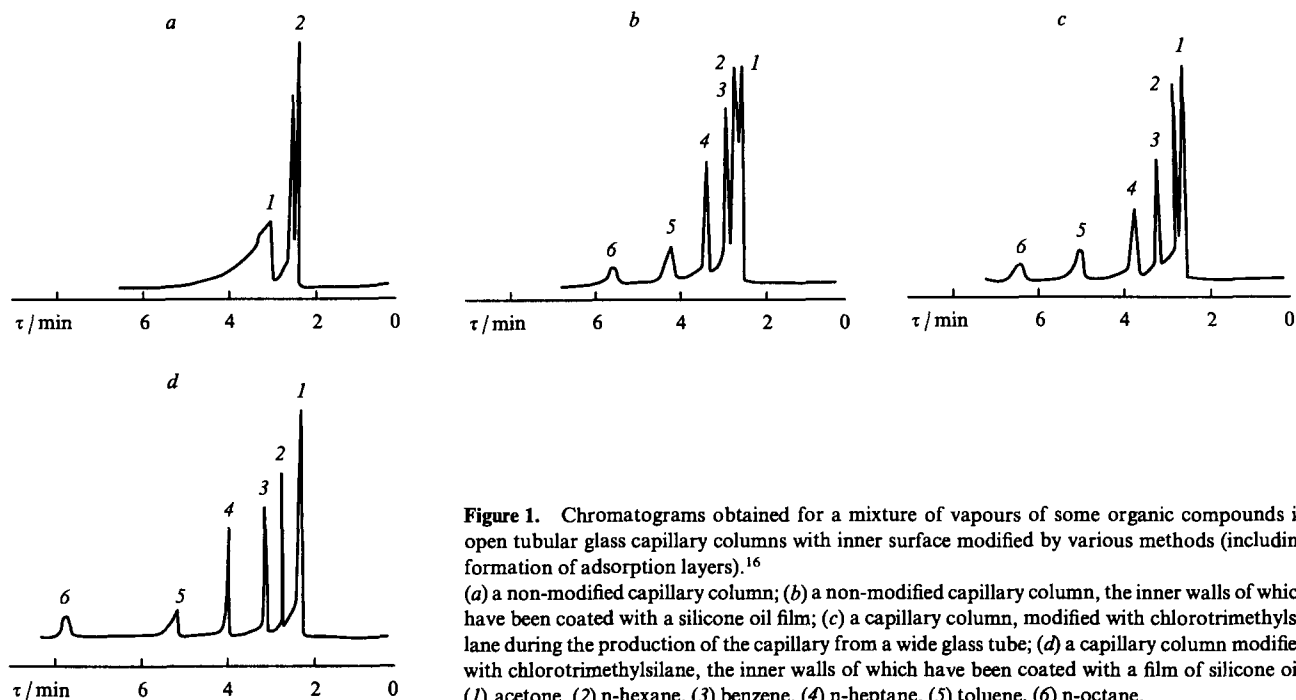

Figure 1. Chromatograms obtained for a mixture of vapours of some organic compounds in open tubular glass capillary columns with inner surface modified by various methods (including formation of adsorption layers).¹⁶

(a) a non-modified capillary column; (b) a non-modified capillary column, the inner walls of which have been coated with a silicone oil film; (c) a capillary column, modified with chlorotrimethylsilane during the production of the capillary from a wide glass tube; (d) a capillary column modified with chlorotrimethylsilane, the inner walls of which have been coated with a film of silicone oil; (1) acetone, (2) n-hexane, (3) benzene, (4) n-heptane, (5) toluene, (6) n-octane.

showed the possibility of using this column for the fast separation of Freons.

Among the pioneering studies dealing with the adsorption capillary chromatography, the works of Weiher,²² Petitjean and Leftault,²³ Schwartz,²⁴ Liberti and coworkers,^{25–29} and of Ilkova and Mistryukov³⁰ should be mentioned.

An important role in the development of the capillary chromatography in columns with a porous layer on the inner walls (capillary columns with adsorbent layers constitute a particular case), has been played by the studies of Ettre and coworkers^{31–33} and, especially, by their review³⁴ devoted to the theory, methods for production, practical application, and prospects of the development of surface-layered open tubular capillary columns for gas-liquid chromatography.

Thus, the results of the very first studies on the adsorption capillary columns demonstrate, firstly, the high resolving power of the method, which is manifested most clearly in the separation of isotopes, and, secondly, the fact that separation takes little time.

During the last 10–15 years, interesting studies and important practical applications of open tubular gas-adsorption columns have been accomplished by de Nijs, de Zeeuw, Mohnke, and coworkers;^{35–40} the 'Chrompack' company (the Netherlands) has

begun the commercial manufacture of some types of these columns based on alumina, molecular sieves, and polymeric adsorbents (see for example Ref. 41).

In our opinion, classification of capillary columns is important in gas chromatography. It has been noted (see for example Ref. 42) that some researchers confuse the term 'open tubular capillary columns with a porous layer on the inner walls' (PLOT) with the term 'open tubular capillary columns with inner walls coated with a layer of a solid material' (WCOT). It is expedient to distinguish various types of columns according to the following features: first, the presence (or absence) of a porous layer on the inner walls of a capillary column and second, the presence (or absence) of a layer of a stationary liquid phase on the inner walls of a column (Fig. 4).

Figure 2. Chromatogram for the separation of nuclear spin isomers and isotopes of hydrogen in an open tubular adsorption glass capillary column.¹⁸

The 80 m long open tubular capillary column contained a 20 μ m thick silica layer as an adsorbent; $T = 77.4$ K; neon was used as the carrier gas; (1) helium, (2) *p*-protium, (3) *o*-protium, (4) DH, (5) *o*-deuterium, (6) *p*-deuterium.

Figure 3. Chromatogram obtained for the separation of aromatic hydrocarbons in an open tubular capillary column containing graphitised carbon black.¹⁹

A 15 m \times 0.25 mm silver-plated copper column was used, the concentration of graphitised carbon black was 5.4 mg m^{-1} ; $T = 245$ °C; hydrogen was used as the carrier gas;

(1) benzene, (2) toluene, (3) ethylbenzene, (4) *m*-xylene, (5) *o*- and *p*-xylenes.

Figure 4. Various types of open tubular capillary columns.

(1) Open gas adsorption (gas-solid) column with smooth walls (an adsorbent); (2) open gas adsorption (gas-solid) column with inner walls coated with an adsorbent layer; (3) open gas-liquid-solid column with smooth walls (a solid support); (4) open gas-liquid-solid column with inner walls coated with an adsorbent layer (a solid support).

In the case of open tubular capillary columns with smooth walls (i.e. containing no porous layer), in which non-porous inner walls of the capillary are used as the adsorbent, an equilibrium in the system 'gas-planar adsorbent' under consideration is established quite rapidly; however, unfortunately, the capacity of these columns is relatively low. The theoretical possibility of using these columns was noted for the first time by Berezkin and Volkov.⁴³

Columns, the inner walls of which are coated with a layer of a solid adsorbent, are most widely used in the analytical practice. Columns containing a solid adsorbent layer modified with small amounts of non-volatile liquid phases should also be classified as adsorption columns. Characteristics of open tubular capillary columns modified with non-volatile liquid phases can be found, for example, in the following studies.⁴⁴⁻⁴⁶

The contribution of an adsorption mechanism to the retention can also be significant in the classical columns with a layer of a stationary liquid phase on smooth walls. For example, this is the case with the chromatography of n-alkanes in open tubular capillary columns with a poly(ethylene glycol) layer.^{47,48}

This review is mostly devoted to open tubular capillary columns, the inner walls of which are coated with a layer of a solid adsorbent (gas-solid chromatography).

III. Retention of compounds subjected to capillary gas-solid chromatography

Retention in gas adsorption chromatography is determined both by the nature of the surface of the adsorbent and by its structure. The mechanism of retention is discussed in detail in a number of monographs.⁴⁹⁻⁵⁴ Kiselev^{13,51} has shown that the retention volume V_N is directly proportional to the surface area (S_{ad}) of the adsorbent in the column (it has been assumed that at relatively low coverages, the accessibility of the adsorbent surface does not change):

$$V_N = K_s S_{ad}, \quad (7)$$

where K_s is the coefficient of distribution of the substance subjected to chromatography between the adsorbent surface and the gas phase.

Note an important specific feature of the gas-solid chromatography, namely, the fact that the retention of compounds depends on the nature of the mobile phase. The replacement of light carrier gases by heavy gases leads to dynamic modification of the adsorbent surface, to a decrease in the coefficients of distribution of compounds being analysed in the 'solid adsorbent-gas' system, and, hence, to a decrease in retention times.

Figure 5. Chromatograms for a mixture of hydrocarbons separated in an open tubular capillary column with alumina using helium (a) and carbon dioxide (b) as carrier gases.

(1) Methane, (2) ethane, (3) propane, (4) isobutane, (5) n-butane. A 50 m × 0.32 mm column with Al_2O_3/KCl was used; $T = 100^\circ C$, flame ionization detector, flow splitting 1/50.

The chromatograms of gaseous hydrocarbons obtained on a column with alumina using two carrier gases (helium and carbon dioxide) are presented in Fig. 5. It is seen that the retention times, especially those of heavy compounds, decrease in the case where the heavy carrier gas (carbon dioxide) is used. An influence of water vapour on the modification of the adsorbent (Al_2O_3) and on the retention in the capillary adsorption chromatography has been noted by de Nijs.³⁵

A further important specific feature of the capillary adsorption chromatography is the dependence of retention on the pressure of the carrier gas. The influence of the average carrier gas pressure in a column on retention values (for example, on the capacity factors) of compounds subjected to high-performance gas-solid capillary chromatography was studied systematically for the first time by Berezkin et al.⁵⁵ for various carrier gases and for the pressure range used in the conventional capillary gas chromatography (1–5 atm at the inlet of the capillary column). It is noteworthy that owing to the high resolving power of open tubular capillary columns, the experimental conditions that can have an influence on the retention are especially significant in capillary chromatography.⁵⁶ For example, in order to decrease the time required for separation by increasing the velocity of the carrier gas in the column, it is necessary to change the pressure at the inlet of the column (and, consequently, the average pressure in the column within the pressure range specified above).

The results of a study of the dependence of the capacity factor on the average pressure of the carrier gas in the column are presented in Table 1. It follows from these data that retention depends both on the nature of the carrier gas and on its pressure in the column.

To explain this, we shall use the known regularities of the adsorption of mixtures. If we assume that the adsorption of molecules of volatile compounds A and C occurs upon their collision with an unoccupied adsorption site on the surface of a solid adsorbent and that the rate of desorption of these molecules is proportional to the surface area occupied by the adsorbed molecules, the adsorption isotherm can be described by the following equations:⁵⁷

$$a_A = \frac{K_{AC} a_C}{1 + K_{CC} c_C + K_{AC} a_C}, \quad (8a)$$

Table 1. Dependence of the capacity factors of gaseous hydrocarbons on the average pressure of the carrier gas in a capillary column.⁵⁵

\bar{P} /atm	Propene	Butane	But-1-ene	\bar{P} /atm	Propene	Butane	But-1-ene
H₂ as the carrier gas				He as the carrier gas			
1.0	0.80	1.51	3.27	1.0	0.88	1.68	3.66
1.6	0.81	1.52	3.29	1.6	0.89	1.71	3.73

3.4	0.81	1.53	3.22	3.4	0.89	1.71	3.71
4.1	0.84	1.56	3.24	4.1	0.88	1.69	3.63
N₂ as the carrier gas				CO₂ as the carrier gas			
1.0	0.87	1.65	3.61	1.0	0.64	1.17	2.46
1.6	0.88	1.68	3.64	1.6	0.59	1.08	2.24
2.8	0.87	1.65	3.58	2.8	0.54	0.95	1.91
3.4	0.86	1.62	3.52	3.4	0.49	0.88	0.80
4.1	0.85	1.59	3.45	4.1	0.44	0.80	1.58

$$a_C = \frac{K_C c_C}{1 + K_C c_C + K_A c_A}, \quad (8b)$$

where a_A and a_C are concentrations (g g^{-1}) of the adsorbed compounds A and C, respectively; K_A and K_C are adsorption coefficients of the compounds A and C; and c_A and c_C are the concentrations (g l^{-1}) of A and C in the gas phase. Subsequently, A stands for the compound being chromatographed and C stands for the carrier gas.

From Eqns (8), the following equation has been derived,⁵⁵ which relates the capacity factor (k) to the average pressure of the carrier gas in the column (\bar{P}):

$$\frac{1}{k} = a + b\bar{P}, \quad (9)$$

where

$$a = \frac{\beta}{K_A}, \quad (10a)$$

$$b = aK_C, \quad (10b)$$

β is the ratio (v/v) of the phases occurring in the column, a_p and b_p are coefficients from Eqn (9). By using the above equations, one can determine the parameters of Eqn (8) for adsorption of a gas mixture.

The experimental data obtained are adequately described by Eqn (9) (Fig. 6). Such a processing of experimental results makes it possible to find the parameters of Eqn (9); i.e. in this case, gas chromatography can be used as a physicochemical method for determining parameters of the equation describing the adsorption of mixtures. Note that a variation of the pressure of a carrier gas at the inlet of the column is associated with a variation of its linear velocity; therefore, in this case, a dependence of the capacity factor (i.e. of the retention of a substance) on the linear velocity of the carrier gas can be manifested.

The nature of the carrier gas exerts a substantial influence on the retention of compounds in the capillary gas adsorption chromatography. It is clear that the rules that make it possible to pass from the retention values observed with one carrier gas (G_1) to the values characterising retention of the same compounds when another carrier gas is used (G_2) are of practical interest. Recently[†] the following correlation has been established:

$$k(G_2) = Ak(G_1) + B, \quad (11)$$

where $k(G)$ is the capacity factor of a compound with carrier gas G, and A and B are constants. It was shown in the same study that the efficiency of separation is substantially improved by using carbon dioxide, passed at the optimal velocity, as the carrier gas.

Figure 6. Dependence of $1/k$ on the average pressure of a carrier gas (carbon dioxide) in the column.

(1) Propylene, (2) butane, (3) but-1-ene. Experimental conditions: a $50 \text{ m} \times 0.32 \text{ mm}$ column; $\text{Al}_2\text{O}_3/\text{KCl}$ as the adsorbent; $T = 90^\circ \text{C}$.

The above features characterising the dependence of the retention of compounds being analysed on the properties of the mobile phase should also be taken into account in the practical use of capillary adsorption columns.

IV. Broadening of chromatographic zones in open tubular gas adsorption capillary columns

Broadening of chromatographic zones during their migration along the column is influenced by the character of movement of the carrier gas in the column, by the diffusion of the substances being separated in mobile and stationary phases, by the rate of interfacial mass transfer, and by characteristics of the adsorption layer used.^{13, 34, 51–53, 58–64}

Already in first studies on capillary chromatography, Golay^{58–60} proposed that, in order to increase the capacity index of the column, one should apply a layer of stationary liquid phase onto a porous layer of a solid support located on the inner walls of

[†] See V G Berezkin, I V Malyukova, V R Alishoev, J de Zeeuw *J. High Resol. Chromatogr.* **19** 272 (1996).

a capillary column rather than directly onto the smooth walls of the column. If the thickness of the film formed by the stationary liquid phase on separate particles of the solid support is the same as that formed on the smooth walls of the capillary, then the amount of the stationary liquid phase per unit length of the column becomes much higher, since the interior surface of the solid support is much greater in this case. This results in a decrease in the ratio of the phase volumes

$$\beta = \frac{V_g}{V_l}$$

(where V_g is the volume of the gas phase in the column and V_l is volume of the stationary liquid phase in the column), in an increase in the capacity factor k , and, hence, enhances the separation.

To describe broadening of chromatographic zones in open tubular capillary columns with walls coated by a porous layer, Golay has obtained the following equation:^{14,15}

$$H = \frac{2D_g}{u} + \left[\frac{1+6k+11k^2}{(1+k)^2} + \frac{(8+32k)a_2}{(1+k)^2} + \frac{8k^2}{(1+k)^2} \frac{a_1^2}{a_2} \right] \frac{r^2 u}{24D_g} + \left[\frac{k^3}{6(1+k)^2} \frac{1+2a_2}{F} \right] \frac{r^2 u}{K_D^2 D_l}, \quad (12)$$

where H is the height equivalent to a theoretical plate (HETP); D_g is the coefficient of diffusion of the compound under analysis in the gas phase; u is the linear velocity of the carrier gas; k is the capacity factor of the compound under analysis; $a_1 = d_i/r$ (d_i is the average length of the tortuous channels in the porous layer covering the inner walls of the column); $a_2 = d_g/r$ (d_g is the effective thickness of the gas layer in the porous layer covering the inner walls of the column); r is the internal radius of the column; F is the ratio of the surface area of the liquid phase to the surface area of the capillary walls; K_D is the coefficient of distribution of the substance under analysis between the mobile and stationary phases; and D_l is the diffusion coefficient in the liquid phase.

The last term in Eqn (12) reflects the resistance to the mass transfer in the liquid phase and it is inversely proportional to F . This implies that the efficiency of a capillary column should increase with an increase in the degree of porosity of the near-surface layer (H decreases with an increase in F). Thus, the idea of a capillary column with a porous layer of a solid support has already been included in the derivation of this equation. However, it should be noted that this equation, like other Golay equations, was obtained first of all for gas-liquid-solid (or gas-liquid) chromatography.⁴⁸

An equation relating HETP to the linear velocity of the carrier gas for gas adsorption chromatography has been proposed by Giddings.^{65,66} The first terms in the Giddings equation virtually coincide with those in the Golay equation. These equations differ, firstly, in the term that reflects the resistance to the mass transfer in the adsorption layer located on the inner walls of the capillary column and, secondly, in the allowance for the influence of the carrier gas pressure differential along the column on the broadening of chromatographic zones. The Giddings equation can be represented in the following way:

$$H = \frac{2D_g}{u_0} + \left[\frac{1+6k+11k^2}{24(1+k)^2} \right] \frac{r^2 u}{D_g} f_1 + \frac{8}{a_k u_m} \left(\frac{k}{k+1} \right)^2 \frac{V_g}{S} f_n u_0 f_0, \quad (13)$$

where u_0 is the linear velocity of the carrier gas at the outlet of the column.

$$u_0 = \frac{L}{t_m f_2}, \quad (14)$$

where L is the length of the column; and t_m is the 'dead time' of the column;

$$f_1 = \frac{9}{8} \frac{(P^4 - 1)(P^2 - 1)}{(P^3 - 1)}, \quad (15)$$

$$f_2 = \frac{3}{2} \frac{(P^2 - 1)}{(P^3 - 1)} \quad (16)$$

($P = P_i/P_0$, P_i and P_0 are carrier-gas pressures at the inlet and outlet of the column, respectively), a_k is the accommodation coefficient; u_m is the average velocity of the molecules of the substance under analysis in the gas phase, S is the overall surface area of the adsorbent layer in the column, and f_n is a factor reflecting the heterogeneity of the adsorbent.

If we neglect the influence of the pressure differential on the broadening of chromatographic zones (i.e. $f_2 \approx 1$, $f_1/f_2 \approx 1$), the Giddings equation for an adsorption capillary column assumes the form:

$$H = \frac{2D_g}{u} + \left(\frac{C_{gp}}{D_g} + C_{ad} \right) u \quad (17)$$

or

$$H = \frac{2D_g}{u} + Cu, \quad (18)$$

where

$$C = \frac{C_{gp}}{D_g} + C_{ad} = C_g + C_{ad}, \quad (19)$$

$$C_{gp} = \frac{1+6k+11k^2}{24(1+k)^2} r^2, \quad (20)$$

$$C_{ad} = \frac{8}{a_k u_m} \frac{V_g}{S} f_n \frac{k}{(1+k)^2}, \quad (21)$$

$$C_g = \frac{C_{gp}}{D_g}. \quad (22)$$

To verify whether Eqn (18) is in agreement with experimental results, it is convenient to write it in the following form:

$$Hu = 2D_g + Cu^2. \quad (23)$$

The D_g values can be calculated from the equation proposed by Fuller et al.⁶⁷ or by another theoretical method (see, for example, a published study⁶⁸). If we find the values for the resistance to mass transfer C for compounds subjected to chromatography with two carrier gases in an open tubular adsorption capillary column, then we can determine the real coefficients of resistance to the mass transfer in the gas phase (C_g) and in the adsorption layer (C_{ad}). The theoretical methods have been developed earlier by Perrett and Purnell for gas-liquid chromatography.⁶⁹

The first estimate of the coefficients of resistance to mass transfer from the Golay-Giddings equation was carried out by the Dutch researchers de Nijs and de Zeeuw.³⁶ They considered the chromatography of buta-1,3-diene in an open tubular adsorption capillary column (with alumina as the adsorbent) with helium and nitrogen as carrier gases and obtained the following values for $C \times 10^4$: C_g (butadiene in helium) = 1.3; C_g (butadiene in nitrogen) = 4.6; C_{ad} = 1.8. Thus, C_g and C_{ad} are of the same order of magnitude.

For comparison, we present the coefficients of resistance to mass transfer C_g and C_l reported by Cramers et al.⁷⁰ for the chromatography of tridecane in an open tubular capillary column with the inner walls coated with a stationary liquid phase layer. For a $24.7 \text{ m} \times 0.55 \text{ mm}$ column (with the CP-Sil 5-CB silicone as the stationary liquid phase, $T = 150^\circ \text{C}$), the following values have been reported, $C \times 10^4$: the coefficients of resistance to mass transfer in the gas phase C_g (tridecane in helium) = 2.8; C_g (tridecane in nitrogen) = 10.6; the coefficient of resistance to mass transfer in the liquid phase $C_l = 4.1$. It follows from these data that the coefficients of resistance to mass transfer for the gas-solid and gas-liquid variants of capillary chromatography are of the same order of magnitude.

A similar study has been carried out for a capillary gas adsorption column of the 'Chrompack' company (the Netherlands), the inner walls of which have been coated with a layer of the adsorbent $\text{Al}_2\text{O}_3/\text{KCl}$.⁴³ The results of this study are presented in Table 2. The values listed were determined from the linear Eqn (18). The results obtained are in good agreement with the experimental data.

Table 2. Coefficients of the Golay–Giddings equation for the separation of gaseous hydrocarbons in a capillary column with alumina.

Carrier gas	Calculation		Experiment	
	$D_g^a / \text{cm}^2 \text{ s}^{-1}$	$B^b / \text{cm}^2 \text{ s}^{-1}$	$B / \text{cm}^2 \text{ s}^{-1}$	C / s
For the analysis of ethane				
He	0.68	1.4	1.2	2.4
N ₂	0.22	0.44	0.45	6.8
CO ₂	0.175	0.35	0.36	8.0
For the analysis of propane				
He	0.56	1.11	0.96	3.0

CO ₂	0.11	0.22	0.22	24.0

^a Calculated by the Fuller–Schettler–Giddings method.⁶⁷ ^b $B = 2D_g$.

The coefficients of diffusion of compounds subjected to chromatography in a carrier gas can be found from the coefficient B and calculated from the Fuller–Schettler–Giddings equation.⁶⁷

Thus, the values found using the Golay–Giddings equation are in satisfactory agreement with the experimental results for open tubular capillary columns both in the type of functional dependence and in the magnitudes of the diffusion coefficients for substances in the gas phase, which are determined from the experimental chromatographic data. For example, the coefficient

of diffusion for butane in helium, found from the Golay equation, is $0.40 \text{ cm}^2 \text{ s}^{-1}$, while the corresponding diffusion coefficient calculated from the Fuller–Schettler–Giddings equation is $0.44 \text{ cm}^2 \text{ s}^{-1}$.

It is noteworthy that the experimental data obtained by Goretti et al.⁷¹ have also been in good agreement with Eqn (18). These investigators used open tubular glass capillary columns, the inner walls of which were coated with a graphitised carbon black layer. The parameters B and C determined from their experimental results are listed in Table 3. It follows from these data that when the velocity of a carrier gas is more than 30 cm s^{-1} , the major contribution to the broadening of the zones corresponding to the compounds under analysis is made by the term reflecting the resistance to mass transfer.

To describe the dependence of HETP on the linear velocity of the carrier gas for open tubular gas adsorption columns, the following equation has been proposed⁷² (which is valid provided that the thickness of the porous adsorbent layer σ is much smaller than the radius of the column r (i.e. $\sigma/r \ll 1$):

$$H = \frac{2D_g}{u} + \frac{11k^2 + 6k + 1}{24(k+1)^2} \frac{r^2}{D_g} u + \frac{1}{3} \left(\frac{k}{k+1} \right)^2 \frac{\sigma r}{D_p \chi} u, \quad (24)$$

where D_p is the diffusion coefficient of the substance being analysed in the porous layer of the adsorbent (note that normally $D_p < D_g$), and $\chi = V_{pg}/V_p$, where V_{pg} is the pore volume in the adsorbent and V_p is the volume of the whole porous layer.

This equation implies that the H value decreases (the efficiency of the column increases), firstly, as the radius of the capillary column decreases and, secondly, as the degree of porosity of the adsorption layer increases. These dependences agree qualitatively with the experimental results.

In conclusion, it should be mentioned that the authors of some recent studies (see for example Ref. 73) have noted that the dependences of HETP on the linear velocity of the carrier gas observed experimentally for adsorption capillary columns do not agree with the Golay–Giddings equation.

V. Methods for the preparation of open tubular gas adsorption capillary columns

Methods for the preparation of open tubular adsorption capillary columns have some specific features which distinguish them from the known techniques used for the production of capillary columns with a stationary liquid layer.

Only methods for the production of adsorption capillary columns with a porous adsorbent layer have been reported. Columns of this type are characterised by high capacities and stable performance.

A method for the preparation of open tubular columns has to meet fairly stringent requirements.

(1) A method should ensure uniform distribution of the layer of an adsorbent over the whole inner surface of a capillary;

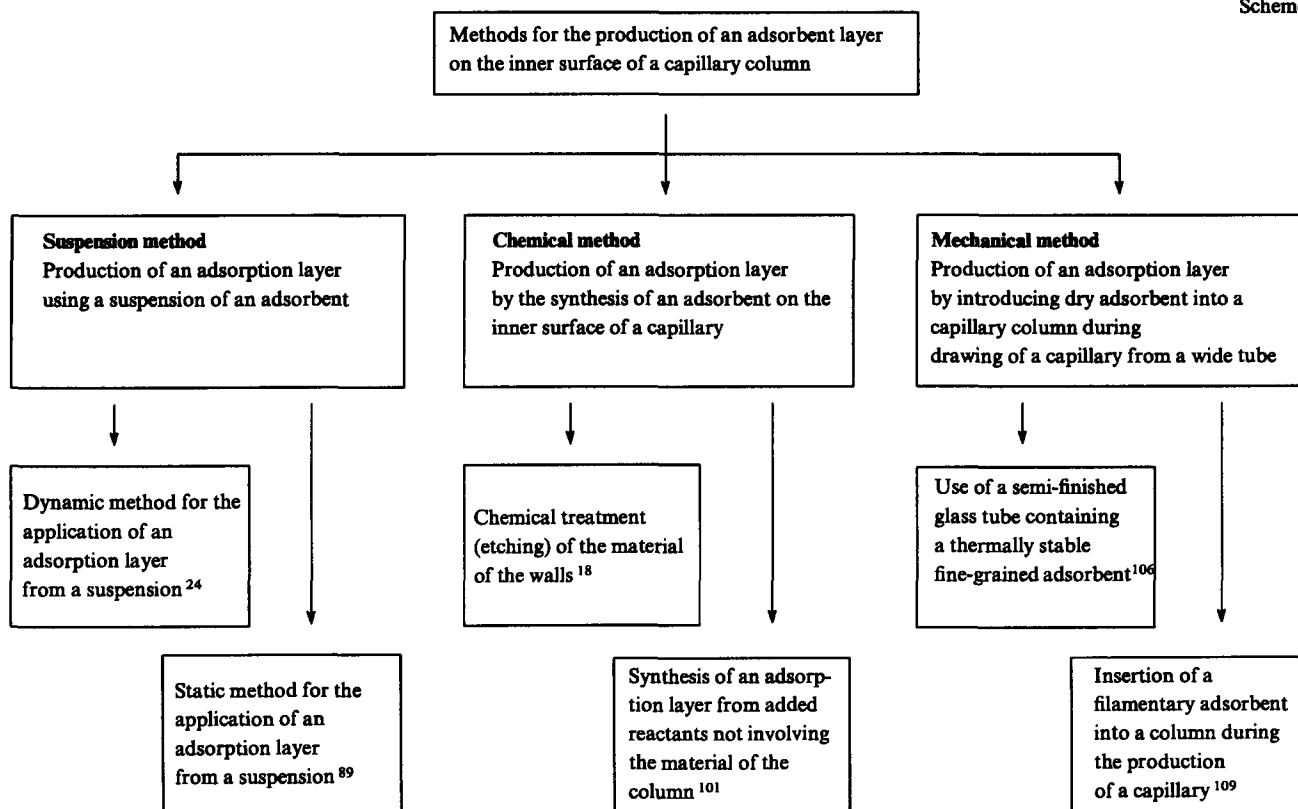

(2) the particles of the adsorption layer should be fixed fairly rigidly on the surface of the capillary;

Table 3. Characteristics of the processes of chromatography of isobutane (I) and n-butane (II) on gas adsorption capillary columns with graphitised carbon black of the MT type ($7 \text{ m}^2 \text{ g}^{-1}$).

Size of the column ^a /m × mm	Thickness of the sorbent layer/μm	K		$B / \text{cm}^2 \text{ s}^{-1}$		$10^3 C / \text{s}$		$H_{\text{min}} / \text{mm}$	
		I	II	I	II	I	II	I	II

Scheme 1

(3) a method should ensure the possibility of preparing capillary columns with reproducible characteristics;

(4) a method should be suitable for producing adsorption layers based on various adsorbents;

(5) the procedure involved should take little time.

Development of a procedure satisfying all these requirements is a fairly complicated task involving various aspects.

The characteristics of the known methods for the preparation of open tubular adsorption capillary columns are shown in Scheme 1. It can be seen that three main techniques have been described to date, namely, suspension, chemical, and mechanical (construction) technique in which dry sorbent is introduced into a glass tube during the production of a capillary.

1. Suspension technique

The suspension method is similar to that used to apply a stationary liquid phase onto the inner walls of a capillary column. An adsorbent is dispersed in an appropriate liquid medium and introduced into a column as a suspension, and the volatile liquid is then removed. As in the 'classical' procedure for the deposition of a stationary liquid phase, dynamic and static versions of the suspension method have been developed. The main specific feature of the latter is heterogeneity (or microheterogeneity) of the system introduced into a capillary in order to prepare an open tubular adsorption column. In this case, the suspension which migrates along the capillary is a non-newtonian liquid, which often exhibits clear-cut thixotropic properties. During the flow of this liquid, the particles are segregated according to their sizes, in conformity with the regularities of flow chromatography in a force field.⁷⁴⁻⁷⁸ As a result, the rheological properties of the suspension vary during the application or during the filling of the column and hence, it is difficult to obtain an adsorbent layer which is uniform over the whole length of the capillary.

Nevertheless, the suspension method has been used even in the earliest works on the capillary adsorption chromatography. For example, silica has been applied onto the inner surface of polymeric, copper, or steel capillaries with lengths ranging from

4 m to 400 m and with an internal diameter of ~ 0.5 mm.^{24,75,79} It was noted that the use of suspensions containing micron-size particles is associated with some difficulties and that colloidal solutions of silica are preferred. Schwartz et al.²⁴ used a 22% sol of silica in a water-isopropyl alcohol system. After removal (evaporation) of the dispersion medium, a thin layer of solid silica remained on the inner walls of the capillary. The workers²⁴ did not mention whether a suspension stabiliser, which is usually present in systems of this sort, has remained on the silica particles after drying. Apparently, surfactants, which are used as stabilisers of suspensions, modify the surface and, consequently, have an influence on the retention.

The particle size in these sols does not exceed $0.02 \mu\text{m}$; therefore, the adsorption layer has a large specific surface area. A column produced by the suspension method was used to separate pentane and hexane isomers. However, the specific efficiency of the column, calculated from the chromatograms, did not exceed 100 theoretical plates per metre. In all probability, this low efficiency is due to the fact that the solid sorbent particles are nonuniformly distributed over the inner surface of the column. This is a result of the disadvantages peculiar to the dynamic method (fluctuations of the velocity at which the suspension meniscus moves and instability of the film formed), as well as of some specific features of the suspension.

Schwarz et al.⁷⁹⁻⁸¹ have prepared adsorption columns using larger silica particles ($\sim 4 \mu\text{m}$) with the surface modified with an organic surfactant, because the use of adsorbent particles with a size not exceeding that of colloidal particles can lead to the formation of a dense adsorption layer, which substantially hampers mass transfer.

The modified silica was applied by the dynamic method as a 7.5% suspension in *n*-hexane. The glass capillary column thus formed with a length of 120 m and with an inner diameter of 0.5 mm permitted separation of 13 isomeric C_5 - C_7 hydrocarbons over a period of 18 min. The specific efficiency of the column determined in relation to 2,4-dimethylpentene was 550 theoretical plates per metre.⁷⁹⁻⁸¹

In the early 60s, the dynamic method for the application of a solid support was used by the Perkin-Elmer company for the commercial production of copper gas-liquid capillary columns with a length of 15–30 m and 0.5 mm in diameter, meant for quick analysis of light gaseous hydrocarbons.⁸²

Capillary adsorption columns with graphite have been obtained by application of graphitised carbon black by the dynamic method.^{19,20} 15 m long copper columns with an internal diameter of 0.25 mm, the inner surface of which was coated with silver, were treated with a suspension of carbon black preliminarily graphitised at 3000 °C. The suspension was prepared by intense stirring (8000 rpm) of a mixture consisting of 15 g of carbon black, 220 ml of trichlorotrifluoroethane, and 30 ml of tetrachloromethane. Thus, the dispersion medium of this suspension had a density of $\sim 1.5 \text{ g cm}^{-3}$. The high density of the dispersion medium made it possible to obtain a fairly stable suspension, which passed through a column without aggregation of particles. The surface area of the capillary column thus obtained was 0.2–0.8 m², which made it possible to separate all the isomers of heptane at 245 °C.¹⁹

Ultrasonic treatment of graphite suspensions has been proposed in order to increase their stability.^{71,83,84} A suspension consisting of 0.25 g of Carboxpack A, 5 ml of dichloromethane, and 20 ml of tetrachloromethane was sonicated (frequency 20 to 24 kHz and amplitude 2 μm). The optimal time of irradiation was 40 min. The suspension thus prepared was passed through a column at a velocity of 0.6 ml min⁻¹ in both directions. The glass capillary column used was 10–15 m long and 0.4–0.5 mm in diameter.

A suspension of graphitised carbon black 'Sterling MT' prepared in a similar way has also been used for the production of an adsorption capillary column. The suspension was passed through a column with a reduced pressure at the outlet. This was possible, because the suspension had a low viscosity, due to the fact that its concentration did not exceed 1%.⁸⁴ However, the amount of the sorbent applied in this way proved insufficient to be used efficiently in the adsorption variant of chromatography. Therefore, the layer thus formed was used as a solid support for a stationary liquid phase, i.e. in the absorption–adsorption variant of chromatography.

Purcell⁸⁵ has used the dynamic method to prepare a column coated from the inside by a layer of 5 Å molecular sieves with a particle size of up to 20 μm . Later, the 'Chrompack' company has started the production of columns with molecular sieves applied by the dynamic method.⁴¹ The most interesting results on the application of an adsorbent layer by the dynamic method have been obtained with alumina suspensions.

The first attempt along this line was undertaken by Kirkland,²¹ who used Al₂O₃ as the fibrous mineral boehmite. Microscopic studies have shown that an elementary fibre of this mineral has a length of $\sim 1000 \text{ Å}$ and a diameter of 50 Å; the fibres are joined in aggregates $\sim 2 \mu\text{m}$ in diameter. The specific surface area of this sorbent is 275 m² g⁻¹. To prepare an adsorption column, a 7% aqueous sol of boehmite was injected into a glass (or stainless-steel) capillary of length 10 m and with an inner diameter of 0.25 mm (or 0.5 mm). When the suspension was passed and the adsorption layer was dried, the capillary column was ready for use. This column made it possible to separate a number of Freons; however, its efficiency was not very high.

The dynamic method for the application of Al₂O₃ has been developed further by Schneider et al.⁸⁶ They noted the following advantages of glass capillary columns, the walls of which are coated by an alumina layer, over metallic capillaries: (1) the adsorption activity of the walls of the columns is low; (2) finely powdered alumina is readily applied onto a glass surface without any fixing agents and forms thin layers, which do not fall off the walls even when the capillary is deformed within its elasticity limits; (3) the process of application and the quality of the column can be monitored visually; (4) glass capillaries of any size can be easily produced in a laboratory.

The following procedure can serve as an example of filling a capillary column. The suspension is prepared by mixing 20 g of alumina (obtained by calcination of aluminium hydroxide with particles no larger than 2 μm) with 70 ml of a 5% colloidal solution of Al₂O₃ and with 0.3 ml of glacial acetic acid. The resulting suspension is exposed to ultrasound, filtered through 300 mesh sieves, and allowed to stand for 24 h for maturing. The suspension thus obtained possessed thixotropic properties.

The use of a colloidal solution of alumina provides a dispersion medium with high density and viscosity, which increases the stability of the suspension. In addition, colloidal particles of alumina cement large particles of the sorbent and thus fix them additionally on the capillary surface.

Prior to the application of Al₂O₃, the capillary column is washed with 1% acetic acid. For the deposition of an alumina layer onto the inner walls of the column, the suspension is pressed through a capillary at a velocity of 4 ml min⁻¹. At this rate, 0.6 ml of the suspension is sufficient to coat 15 m of the column. As the final stage of the process, the column is stored for 10 h and is subsequently dried at room temperature in a flow of nitrogen. A 65 m long column of diameter 0.4 mm is dried for a week at a nitrogen pressure of 0.3 MPa at the inlet.

After drying, the column is activated for 3 h at 300 °C. The column thus obtained has been reported⁸⁷ to contain $\sim 6 \text{ mg}$ of Al₂O₃ per metre. The quantity of the sorbent can be varied over a relatively wide range by varying the viscosity of the suspension, the velocity at which it is pressed through the column, or the volume of the suspension introduced in one portion.

To decrease the adsorption activity, the column is washed twice with a 2% solution of potassium chloride. After repeated drying and heating, the column is ready for use. The columns obtained in this way are sufficiently efficient for the separation of various substances. For example, their efficiency with respect to the peak for 3-methylbut-1-yne (the capacity factor is 7.1) is 700 tp m⁻¹. Altogether more than 50 light hydrocarbons present in a gas mixture in concentrations of about 1 part per billion each, were separated under isothermal conditions at 130 °C. A similar procedure for the application of an adsorbent onto inner walls of the column has been employed by de Nijs³⁵ to prepare quartz capillaries, which have been widely used for capillary columns in recent years. The application by virtue of the dynamic method requires using concentrated suspensions, since the amount of an adsorbent remaining in the column is only that contained in the thin film formed after passing the suspension. It is of interest that when a suspension prepared from spherical silica gel particles with a diameter of $\sim 5 \mu\text{m}$, meant for high performance liquid chromatography (HPLC), is passed through a column, only a loose monolayer of silica gel particles covering only 50% of the whole inner surface of the capillary is formed.

Preparation of capillary columns containing a barium sulfate layer (a solid adsorbent) on the surface has been reported.⁸⁷ Barium sulfate (which is an ionic adsorbent) is known to exhibit high selectivity in the separation of polar organic compounds.⁸⁸

The barium sulfate used as the adsorbent in open tubular capillary columns was prepared separately by the reaction between 1.5 M solutions of barium chloride and sodium sulfate. The precipitate was filtered off and washed, until chloride ions were no longer detected ($S = 10.2 \text{ m}^2 \text{ g}^{-1}$). Barium sulfate was applied onto the inner walls of a capillary column (Pyrex) by the dynamic method. The solvent was removed and then the columns were conditioned at a temperature programmed to increase to 250 °C. Since the asymmetry A_s of the columns obtained amounted to 4.5 with respect to benzene, they were modified by a dynamic method using small amounts of poly(ethylene glycol) (Carbowax 3000) and polydimethylsiloxane (E-301). After modification, the efficiency of the columns sharply increased (from 900 to 2500 tp m⁻¹) and the chromatographic zones became more symmetrical. The retention of compounds in this column is caused by both adsorption and absorption processes.

Figure 7. Arrangement for the production of open tubular adsorption capillary columns by applying an adsorbent to their inner walls using a high-pressure static method.⁸⁹

(1) Air thermostat, (2) heater, (3) thermometer, (4, 4') reels, (5) electric motor, (6) connection, (7) capillary tube, (8) heated metallic unit.

To increase the thickness of the layer, attempts have been made to use the static variant of the suspension technique. Horvath⁸⁹ has constructed a special device (Fig. 7) for this purpose. A metallic capillary column was completely filled with a suspension of a sorbent in a volatile solvent; then one of the ends of the column was closed, while the other end was introduced into an air thermostat heated to 90–150 °C (through a metallic unit heated to 200–250 °C). The volatile liquid was evaporated in the metallic unit, and its vapour did not condense owing to the high temperature.

A similar device modified by Mistryukov et al.³⁰ has been used by Guiochon et al.⁹⁰ for the preparation of an open tubular capillary column containing 'Sterling FTG' graphitised carbon black. Initially, a 5% suspension of carbon black in dichloromethane was prepared. When squalane (0.05%) was used as the stabiliser, this suspension was stable over 24 h. This procedure makes it possible to apply 10 mg m⁻¹ of the sorbent. A mixture of *o*-, *m*- and *p*-xylenes was separated at 165 °C in columns (19 m × 0.5 mm). The use of a 20% suspension of carbon black and a high-pressure static method made it possible to increase the thickness of the layer to 20 µm.⁹¹

A simple method for the production of adsorption capillary columns has been proposed.⁹² Silica particles (5 µm) and carbon particles were suspended in a solvent, together with polydimethylsiloxane. The suspension was passed through a column (25 m × 0.32 mm), then the column was dried and heated. This gave a very stable layer.

Using the device proposed by Horvath,⁸⁹ Ettre et al.³¹ have manufactured a capillary column containing a layer of Johns-Manville diatomite with an average thickness of 60 µm. In view of the fact that a sorbent with a particle size of 10 µm was used, it can be inferred that it was possible to deposit ~6 layers of the sorbent in one entry. Apparently, this result could not be achieved by the dynamic method. However, the static procedure also suffers from some drawbacks. First of all, the necessity to fill capillaries with a suspension should be regarded as being a drawback, i.e. this method, too, does not make it possible to avoid movement of a suspension along the tube. Consequently, the structure of the suspension is disturbed, particles are combined into aggregates, which are nonuniformly distributed along the column, and this leads to the formation of an inhomogeneous layer and decreases the efficiency of the separating system. In addition, this method is applicable only to volatile dispersion media, which usually possess low densities.

2. Chemical synthesis of an adsorbent on the inner surface of a capillary column

Conduction of chemical reactions yielding adsorbents directly in a column has been employed already in the early papers dealing with the preparation of open tubular capillary columns. A possible advantage of this method is that the preparation of an adsorption layer does not require using suspensions and involves only homogeneous reagents, which easily fill the whole column and can be easily removed from it. In addition, this technique provides the possibility of repeating the reaction in order to increase the thickness of the adsorption layer.

a. Etching of a capillary

The first attempts to use the technique under consideration involved preparation of a sorbent by a chemical transformation of the material from which the column was produced. This approach has been used most widely in relation to glass columns; in this case, etching or leaching of the walls by various procedures affords layers of adsorption-active silica gel.

The first results obtained by this approach have been published in a number of papers.^{16–18, 93} Kiselev et al.⁹³ have separated gaseous hydrocarbons C₁–C₄ in column (10 m × 0.5 mm), which had been preliminarily treated for a short period with 0.1 M HCl and then washed with distilled water.

Mohnke and Saffert^{17, 18} have filled a capillary of length 80 m with a diameter of 0.27 mm with a 17% solution of ammonia, sealed both ends of the column, and kept it for 70 h at 170 °C. After that, the liquid was removed, and the column was dried at 190 °C in a flow of a carrier gas. This procedure yielded a ~20 µm thick adsorption layer on the inner surface of the capillary. The column thus produced was used for the separation of isotopes and nuclear spin isomers of hydrogen.

Alkaline etching of glass has also been used by other researchers.^{28, 94–96} Their procedure involved treatment of the walls of a column with a 20% solution of NaOH for 6 h followed by activation in a flow of nitrogen at 200 °C. The columns thus produced proved suitable for the separation of oxygen and nitrogen isotopes.

The production of open tubular capillary columns, containing an internal porous layer with a fixed thickness, by etching has been patented.^{97, 98} Initially, a two-layer column was produced from a two-layer half-finished article consisting of two coaxial tubes. The outer tube was made of a chemically stable glass, while the inner tube was made of a chemically less stable sodium borosilicate glass. The resulting two-layer capillary was treated with alkali, which led to almost complete leaching of the inner glass layer. The porous glasses thus obtained were used as adsorbents in a capillary column. Porous glasses are known to be used successfully in gas chromatography (see for example Ref. 99).

Similar procedures have been proposed for covering the inner surface of a column with alumina (keeping aluminium capillaries in a flow of oxygen²³) or with copper(II) oxide (treatment of copper capillaries with 40% HNO₃ followed by oxidation with dry oxygen).¹⁰⁰

The known methods for chemical treatment of capillary walls are facile but not versatile and are limited only to glass (or, more rarely, to metallic) columns. In addition, the composition and properties of the resulting adsorption layer are markedly dependent on the composition of the material of the column, which can vary.

b. Synthesis of an adsorbent inside the column

A variety of adsorbents (and capillary adsorption columns) can be obtained by synthesising them inside the columns. The walls of the column are not involved in these processes. An example is provided by the reported¹⁰¹ synthesis of an inorganic adsorbent, crystalline barium carbonate, on the walls of a capillary, which makes it possible to obtain a markedly more extended surface. This method has been applied successfully to a quartz capillary column.¹⁰²

Apparently, a similar method can also be used for the preparation of capillary columns containing barium sulfate (as an adsorbent). First, barium hydroxide is applied to the inner surface of a column and then gaseous sulfur trioxide is passed through it.

Recently, a method for the production of a capillary column containing an adsorption silica layer has been proposed. The method is based on hydrothermal treatment of a sol of silica directly in a capillary column.¹⁰³ A capillary is filled with a silica sol, then a part of the sol (15%–20% in the case of glass columns) is displaced from the column by a compressed gas, in order to avoid damage of the column during its subsequent heating; then both ends are hermetically closed, and the column is kept in a thermostat at 180–210 °C for several hours. Under these conditions, a silica film forms on the inner surface of the column; this results from two processes occurring in parallel, namely, dissolution of small particles of the sol and polymerisation of silica gel on the surface of the column having a large radius of curvature. Washing and drying afford a stable and relatively uniform coarse-pored layer of silica, which is not washed out from the walls. The thickness of the layer depends on the concentration of the sol and on the duration of treatment. The optimum concentration of the sol is 0.1%–1.5%. At higher concentrations, the thickening of the silica film on the surface ceases, and coagulation of the sol in the bulk occurs instead. When the sol concentration is lower than 0.1%, dissolution predominates, and the silica film does not form at all. Under the conditions specified, the treatment of the column should last for 5–11 h. Heating for a longer period does not lead to any substantial increase in the layer thickness, since the rate of polymerisation markedly decreases at the end of heating. Shorter heating results in the formation of a very thin layer with low adsorption activity. The columns obtained in this way can be used advantageously for quick analysis of light hydrocarbons.¹⁰³

Volkov et al.¹⁰⁴ have proposed a simple method for producing an adsorption layer based on magnesian cement.

It is noteworthy that the technique involving synthesis of an adsorbent inside a capillary has also been used to produce adsorption capillary columns with organic hydrophobic adsorbents.¹⁰⁵

3. Mechanical method (formation of an adsorption layer during production of a glass capillary)

When a glass capillary is manufactured, a ready-for-use sorbent can be introduced into it without being converted into a suspension. Since a capillary is drawn from a relatively wide tube, a sorbent can be easily placed into it before drawing.

Halasz and Heine¹⁰⁶ have produced in this way columns with alumina. In order to preserve an open passage inside the column, they inserted a steel wire 1 mm in diameter into it. As the tube was drawn, alumina particles were captured by the softened glass. The resulting 2 m long column was an intermediate version between a packed column and an open tubular capillary column and exhibited a relatively high efficiency, 3500 tp m^{-1} with respect to ethylene.

In a later modification of this technique, the diameter of the wire was diminished to the size of the inner passage in the column, and the wire itself passed through the area of softening and ended in the capillary (Fig. 8). This design permitted the diameter of the inner tube in the column and, hence, the thickness of the layer to be exactly specified. For example, Grant¹⁰⁷ has manufactured a column with an inner diameter of the capillary of 0.3 mm and with a 100 μm thick alumina layer by using a 0.1 mm thick tungsten wire. In this study, lithium chloride was used as a binding agent in the preparation of the adsorption column. The height equivalent to a theoretical plate for this column was ~ 0.5 mm.

Since this technique involves heating of adsorbents to high temperatures (700–800 °C), the range of adsorbents used is limited to thermally stable substances withstanding temperatures up to the temperature of glass softening. Therefore, apart from alumina, graphitised carbon black has been used. Goretti et al.¹⁰⁸ has produced by this method capillary columns with a length of ~ 10 m containing 50–100 μm thick layers of graphitised carbon

Figure 8. Arrangement for the production of open tubular adsorption columns during drawing of a capillary from a wide tube.¹⁰⁷

(1) Pyrex tube (outer diameter 9 mm, inner diameter 5 mm) filled with particles of a solid packing material (support or adsorbent) and with particles of anhydrous lithium chloride, (2) tungsten wire (diameter 0.3 mm), (3) the point of fastening of the tungsten wire, (4) feeding rollers, (5) electric furnace, (6) the column with a sorbent layer on the inner walls being produced, (7) pulling rollers.

black. The efficiency of the columns obtained was $\sim 1500 \text{ tp m}^{-1}$, their permeability being relatively high.

According to the interesting method proposed by Liberti et al.,¹⁰⁹ a graphitised fibre (7.5–10 μm in diameter) was inserted into the initial tube. When this tube was drawn into a capillary by the usual procedure, the fibre reeled out of the spool and entered the capillary; as this occurred, a gap of 0.2–0.3 mm remained inside the capillary. The length of the column thus obtained varied from 1.5 to 10 m, and the inner diameter varied from 0.4 to 0.5 mm.

In our opinion, application of an adsorption layer during the production of a glass capillary from a wide tube is among the most promising techniques; however, it also suffers from some drawbacks. Firstly, it is applicable only to thermally stable adsorbents (for example, polymeric adsorbents cannot be used in this method). Secondly, to obtain a tightly fixed adsorption layer, a specific binding material should be selected for each type of adsorbent and for each material of the column. Thirdly, in the case of sorbents, which are unstable in air at high temperatures, the process must be conducted under an inert atmosphere, which complicates the apparatus used.

The method for the production of open tubular adsorption capillary columns by synthesising sorbents directly in the capillary permits the simultaneous solution of two problems — preparation of the sorbent and its fixing to the walls. However, it is applicable to a limited range of adsorbents.

In our opinion, the suspension method is most universal as regards the preparation of open tubular capillary columns. However, in this method, too, the problem of fixing an adsorbent on the inner walls of a capillary column has not been solved. The way of fixing and the substance suitable for this purpose should be specially selected. What particular method is optimum in each case depends apparently on the type of sorbent used and on the material of the column.

In conclusion, it should be noted that the problem of the preparation of open tubular capillary columns with walls coated by an adsorption layer cannot be regarded as already solved. This delays somewhat the application of the adsorption capillary chromatography. Elaboration of new methods for the preparation of highly efficient open tubular capillary columns is a basic challenge in the development of capillary gas adsorption chromatography.

VI. The use of open tubular gas-solid capillary columns

At present, gas-solid capillary chromatography is widely used in analytical practice. The area of application of gas adsorption capillary columns is constantly extending. In 1995, columns of this type were presented at the Pittcon-95 workshop by four well-known companies from the USA alone (Table 4). However, the

Table 4. Some characteristics of new capillary gas adsorption columns presented at the Pittcon-95 workshop.¹¹⁰

Sorbent	Thickness of the sorption layer / μm	Dimensions of the column ^a /m \times mm	Notes
Carboxen-1006 column from Supelco			
Carbon molecular sieves, $S = 750 \text{ m}^2 \text{ g}^{-1}$	—	$30 \times 0.32 (0.53)$	Separation of permanent gases and $\text{C}_1 - \text{C}_3$ hydrocarbons, temperatures of up to 250°C
Gas-Pro-GSC column from Astec			
Not indicated	—	$(5-60) \times 0.32$	C_{10} and lighter hydrocarbons; carbon, sulfur, and nitrogen oxides; sulfur and halogen-containing organic compounds, permanent gases
HP PLOT Molsieve column from Hewlett-Packard			
5A Molecular sieves	12.50	Various	Permanent gases, separation of argon and oxygen at ambient temperatures, separation of krypton and nitrogen
RT Molsieve 13X column from Restek			
13 X Molecular sieves	1.2-4.0	$(15; 30) \times (0.32; 0.53)$	Permanent gases, 13X molecular sieves ensure faster and more effective separation than 5A molecular sieves
RtD PLOT column from Restek			
Divinylbenzene	2	30×0.53	Permanent gases and hydrocarbons, separation of air, carbon dioxide, light hydrocarbons, natural gas
Supel Q PLOT column from Supelco			
Divinylbenzene	—	$30 \times (0.32; 0.53)$	$\text{C}_1 - \text{C}_{10}$ hydrocarbons, chlorofluorohydrocarbons, sulfur-containing gases

^a The length (m) and the diameter (mm) of the columns are given.

current level of practical application of open tubular capillary columns is far from their real potential. While developing new analytical procedures, one should take into account the advantages and the limitations of the gas-adsorption chromatography (see above). The adsorption capillary chromatography is a hybrid method combining the advantages of the adsorption and capillary versions of chromatography.

Considering the advantages of capillary columns over packed columns, only the higher efficiency of the former is often mentioned. At the same time, capillary columns are also characterised by higher rates of separation (quicker analysis), by more reproducible temperature regimes, by small sizes of the apparatus

needed, and by lower consumption of carrier gases and sorbents; they also extend the field of application of gas adsorption chromatography, due to lower separation temperatures.

In order to select the optimum conditions while developing a procedure for separation, it is expedient to consider a plot that makes it possible to estimate quickly the number of theoretical plates needed (and, hence, the length of the column), if the selectivity and capacity of the adsorbent used are known.

Figure 9 shows the dependence of the number of theoretical plates needed for separation (N_r) on the selectivity of the sorbent used (α) for compounds characterised by different capacity factors (k):

$$N_r = \varphi[(\alpha-1), f^2]. \quad (25)$$

The influence of the capacity factor is reflected in this plot by the following function

$$f^2 = \left(\frac{k+1}{k} \right)^2 = \left(1 + \frac{\beta}{K_D} \right)^2, \quad (26)$$

each f^2 value being matched by a particular curve:

$$N_r = \varphi[(\alpha-1), f^2] = \text{const}. \quad (27)$$

Let us consider an example of practical application of the plot shown in Fig. 9. Assume that we have to determine the number of theoretical plates needed to separate two components with $\alpha = 1.05$ and $K_D = 100$ in a column with $\beta = 40$. For this pair of compounds, $f^2 = 2$. For the characteristic curve $f^2 = 2$, the point $\alpha-1 = 0.05$ on the abscissa in Fig. 9 corresponds to the point $N_r = 16000$ theoretical plates on the ordinate. Thus, we determined the desired efficiency of the column, which is needed to separate the pair of compounds in question.

Figure 9. Graphical determination of the number of theoretical plates N_r , needed to separate a pair of compounds, depending on the selectivity of the sorbent α and the parameter f^2 , which is determined by the capacity factor k .¹¹¹

The numbers on the curves give the magnitudes of f^2 .

An important field of practical application of gas chromatographic analysis is the analysis of impurities.^{13,52,61,63,112} Sensitivity (detection limit) is often a crucial characteristic of a method used for this kind of analysis. As samples become larger, the sensitivity of determination increases, but the efficiency of the column simultaneously decreases. Therefore, the dependence of the efficiency (i.e. of the HETP) on the size of the sample being analysed is of practical interest regarding the optimisation of the separation conditions, since to achieve a higher sensitivity, the samples subjected to analysis should be as large as possible.

The dependence of HETP on the size of the sample in the capillary chromatography determines whether a capillary column without a flow splitter can be used, and also whether the use of a particular column in the traditional methods for the determination of impurities would be expedient. The dependence of the chromatographic zone broadening on the size of the sample under analysis has been discussed in a number of studies (see for example Refs 61,63,112).

It would be convenient to evaluate this dependence quantitatively using a linear equation relating HETP to the size of the sample. An equation of this type has been proposed.¹¹³ It is in satisfactory agreement with the experimental results obtained for open tubular capillary columns containing a stationary liquid layer (as an adsorbent) and for packed capillary columns.¹¹⁴

The dependence of the efficiency of a column on the size of the sample under analysis has been studied in relation to an open tubular gas adsorption column with alumina-coated inner walls (produced by 'Chrompack').⁴³ The experimental results were processed in terms of the following equation:¹¹³

$$\sqrt{H} = \sqrt{H_0} + \lambda W, \quad (28)$$

where H_0 is the limiting HETP value corresponding to the sample size approaching zero, λ is a constant determined by characteristics of the system in question; W is the size of the sample injected into the column (or a quantity proportional to it). Eqn (28) makes it possible to determine both the H_0 value and the variation of H as a function of W .

The dependences $\sqrt{H} = \Psi(W)$ corresponding to Eqn (28) and obtained in experiments with the same open tubular capillary column but using different methods for the injection of the sample (with and without a flow splitter), are shown in Fig. 10. The plots of HETP against the size of the sample in these coordinates are linear, which experimentally confirms Eqn (28). When the sample is introduced with a flow splitter, the efficiency of the column increases (the \sqrt{H} value decreases). However, as regards the increase in the sensitivity, the least flow splitting (i.e. the least possible discharge) or even no splitting are desirable.

Figure 10. Dependence of \sqrt{H} on the size of the sample under analysis for *n*-butane in an open tubular capillary adsorption column with inner walls coated with alumina, the sample being injected without a flow splitter (1) and with a flow splitter (2).⁴³

A 50 m \times 0.32 mm quartz column from Chrompack (Netherlands) with an alumina layer and a flame ionisation detector were used; $T = 100^\circ\text{C}$.

Note that irrespective of the method used for the injection of samples (with or without a flow splitter), the limiting value of the efficiency of the column H_0 is nearly the same. This specific feature of the dependence observed is additional evidence for the validity of Eqn (28).

The results obtained indicate that an open tubular packed column with inner walls coated with an adsorption layer can also be used in a gas chromatograph without a flow splitter (although in this case, the efficiency markedly decreases). However, the decrease in the efficiency is not very significant for a fairly broad range of analytical procedures.

At present, gas adsorption chromatography is used most frequently for the analysis of volatile compounds with various isotope compositions, of inorganic and organic gases, of volatile organic polar compounds, and of aqueous solutions of organic compounds.

The separation of nuclear spin isomers and isotopes of hydrogen¹⁸ was the first prominent example of the practical application of the adsorption capillary chromatography (see Fig. 2). Later, it has been shown that the time required for the separation of the nuclear isomers of protium and deuterium could be shortened by decreasing the temperature of the column to 47 K.¹¹⁵

Oxygen isotopes ($^{16}\text{O}_2$ and $^{18}\text{O}_2$) have been separated in an adsorption capillary column⁹⁶ (Fig. 11). The adsorption layer on the inner walls of a glass column was produced by etching the walls with 20% NaOH for several hours at 100°C . When this process was prolonged enough (more than 4 h), clear separation of the isotopes was achieved. The efficiency of the capillary columns used was $\sim 350\,000$ theoretical plates. A mixture of nitrogen (65%) and helium (35%) was used as the carrier gas.

Figure 11. Chromatogram for the separation of a mixture of $^{16}\text{O}_2$ and $^{18}\text{O}_2$ isotopes in an adsorption glass capillary column (175 m \times 0.3 mm) at 77 K, and with the N_2 (65%)–He (35%) binary carrier gas.⁹⁶

Nitrogen isotopes ($^{14}\text{N}_2$ and $^{15}\text{N}_2$) have been separated by Cartoni and Possanzini⁹⁴ in an open tubular gas adsorption glass capillary column, the inner walls of which had been etched in order to produce an adsorption layer. The procedure for the preparation of this column has been reported.⁹⁵

Figure 12 shows the chromatogram for the separation of the nitrogen isotopes. The experiment lasted for ~ 3 h; however, only partial separation was achieved. It is obvious that the separation can be markedly improved, for example, by optimising its conditions.¹¹⁶

It is noteworthy that the nitrogen isotopes have been separated on a sorbent with a very low selectivity ($\alpha = 1.006$). A mixture of helium and carbon dioxide (45%) was used as the carrier gas, the latter also acting as a modifying agent for the adsorption layer of silica coating the walls of the column.

A sharp separation of neon isotopes (^{20}Ne and ^{22}Ne) has been achieved by Purer et al.¹¹⁶ at a low temperature (19 K). The height equivalent to a theoretical plate for the glass column used (82 m \times 0.28 mm) amounted to 0.8 mm at $k = 0.8$ and $\alpha = 1.06$.

Figure 12. Chromatogram for the separation of nitrogen isotopes.⁹⁴

An open tube glass capillary column (175 m × 0.28 mm) with walls coated by an adsorption layer obtained by etching and a mixture of helium and carbon dioxide (45%) as the carrier gas were used; $T = 77$ K.

Complete separation of neon isotopes can be achieved if a shorter column (45 m) is used.

To obtain the adsorption layer on the walls, the initial capillary was etched with 10% sodium hydroxide for 6 h at 100 °C according to the procedure proposed by Brunner and Cartoni.²⁸ It has been reported¹¹⁶ that mixtures containing ²¹Ne can also be separated by this procedure.

The separation of hydrogen isotopes¹⁸ has certainly stimulated studies aimed at the separation of isotopically substituted molecules of organic compounds.

Figure 13 presents a chromatogram obtained for the separation of methanes with different isotopic compositions.²⁷ It is of interest that not only the methane molecules containing different hydrogen isotopes but also those with different carbon isotopes were separated in this experiment. Thus, we can agree with the opinion stated sometimes that a chromatograph is also a simple and cheap mass spectrometer.

Figure 13. Chromatogram for the separation of deuterated and tritiated methanes.²⁷

The separation of methanes (see Fig. 13) was carried out using an open tubular adsorption capillary column containing a silica layer, which had been etched with a sodium hydroxide solution, according to a previously described procedure.²⁸ The column used was fairly effective (70 000 theoretical plates), and the peaks were symmetrical even at low temperatures. A mixture of helium (30%) and nitrogen (70%) was used as the carrier gas. A clear separation of tritiated methanes in a substantially more prolonged experiment has been also reported.¹¹⁷

In our opinion, the use of adsorption capillary columns with molecular sieves as the adsorbent holds the greatest promise for the separation of isotopically substituted molecules. Separation of molecules of gaseous compounds differing in the isotope composition is a promising branch of capillary gas adsorption chromatography.

Some progress has been achieved in the separation of isotopically substituted liquid organic compounds. For example, separation of benzene and deuteriobenzene and of toluene and

deuteriotoluene has been reported.¹⁰⁸ This was accomplished on a capillary column with a layer of graphitised carbon black.

The above examples indicate that adsorption capillary columns can be successfully used for the separation of isotopically substituted compounds. Further studies along this line will substantially simplify tracer techniques.

The separation of inorganic and organic gases in capillary columns is of great practical significance. In our opinion, capillary columns with molecular sieves are the most promising. Purcell⁸⁵ was the first to use columns of this type for the separation of permanent gases. An interesting example of using 13 Å molecular sieves for separation of hydrocarbons of various types in capillary columns has also been reported.^{118–120}

The procedure used currently for the separation of permanent gases in an open tubular flexible quartz capillary column with molecular sieves was apparently described for the first time by de Zeeuw and de Nijs,¹²¹ Verga,¹²² who has used a similar column, has demonstrated that columns of this type are suitable for solving a number of practically important problems. He used a highly sensitive helium ionisation detector. Fig. 14 shows the results of separation of a standard mixture of permanent gases in helium and of determination of carbon monoxide present in air in a concentration of 2–3 ppm. It is noteworthy that oxygen and argon (3 ppm) are clearly separated under these conditions at 35 °C.

Figure 14. Chromatogram for the separation of a mixture of permanent gases in helium at 35 °C (a) and for determination of carbon dioxide in air at 80 °C (b).¹²²

A 25 m × 0.32 mm column with 5 Å molecular sieves was used.

Oxygen and argon as well as samples of methane differing in the hydrogen isotope composition have been separated¹²³ in a capillary column with 5 Å molecular sieves at room temperature.

Among the numerous fields of application of open tubular adsorption capillary columns, space research should be mentioned. For example, for the studies dealing with the atmosphere of Titan (a satellite of Jupiter), a procedure for the analysis of a gas

Figure 15. Chromatogram for the separation of a mixture of inorganic and hydrocarbon gases in a quartz adsorption column.⁷³ A 10 m × 0.53 mm column with 5 Å molecular sieves was used (the adsorption layer was 50 μm thick); $T = 90^\circ\text{C}$; hydrogen with a velocity of 2 ml min^{-1} at the outlet of the column was used as the carrier gas, the flow spitting was 1 : 40, and a katharometer was used as the detector.

mixture simulating qualitatively the suggested composition of the atmosphere of this satellite has been developed by Vanssay et al.⁷³ (Fig. 15).

Analysis of mixtures of gaseous hydrocarbons and light hydrocarbons is a practically important problem. Alumina is widely used for the separation of these compounds. The analytical potential of columns containing alumina was demonstrated for the first time by Schneider et al.⁸⁶

A significant contribution to the perfection of columns of this type has been made by researchers of the 'Chrompack' company.^{35-37, 41, 124} In recent years, this company has been manufacturing open tubular capillary columns based on metallic capillaries with an inert inner surface coated with a layer of an inert material (Ultimet column). Two modifications of these columns containing alumina are produced; they differ in the salt used for the modification.¹²⁵ The columns containing $\text{Al}_2\text{O}_3/\text{KCl}$ are less polar than those with $\text{Al}_2\text{O}_3/\text{Na}_2\text{SO}_4$. Chromatograms obtained in the separation of a mixture of C_1 – C_4 hydrocarbons using columns of both types are shown in Fig. 16. It is advisable to use the columns with $\text{Al}_2\text{O}_3/\text{Na}_2\text{SO}_4$ as the adsorbent for the separation of a mixture of butenes.

Capillary columns with alumina are also used for the separation of light halocarbons. The data on retention obtained experimentally for halo-derivatives of hydrocarbons in a capillary adsorption column with Al_2O_3 (60 m × 0.32 mm) have been supplemented by the data on the retention obtained by calculations.¹²⁶ The calculations have been mostly carried out by two methods — correlation equations^{127,128} and additive schemes.¹²⁹ High resolving power of adsorption capillary columns with Al_2O_3 has been noted;¹²⁶ the researchers were able to separate such isomers as $\text{CF}_2\text{ClCF}_2\text{Cl}$ and CF_3CFCl_2 (previous attempts to separate these isomers in gas-liquid capillary columns have failed).

Adsorption capillary columns possess relatively high capacities; therefore, they are suitable for the analysis of impurities.

While considering the range of practical application of capillary columns with alumina, one should mention the possibility of conducting fast analysis of gaseous hydrocarbons (the analysis can take no more than 100 s).¹²⁴ This is of special interest for the purposes of industry.

Adsorption capillary columns are successfully used in complex chromatographic systems for fast separation of mixtures containing components with different boiling points.

The separation of complex multicomponent mixtures can be substantially improved if sorbents, optimum for the selective separation of individual fractions of the mixture (or even of individual groups of compounds) are specially selected for each particular case. Therefore, gas chromatographic systems with adaptable structures have been used for a fairly long period in

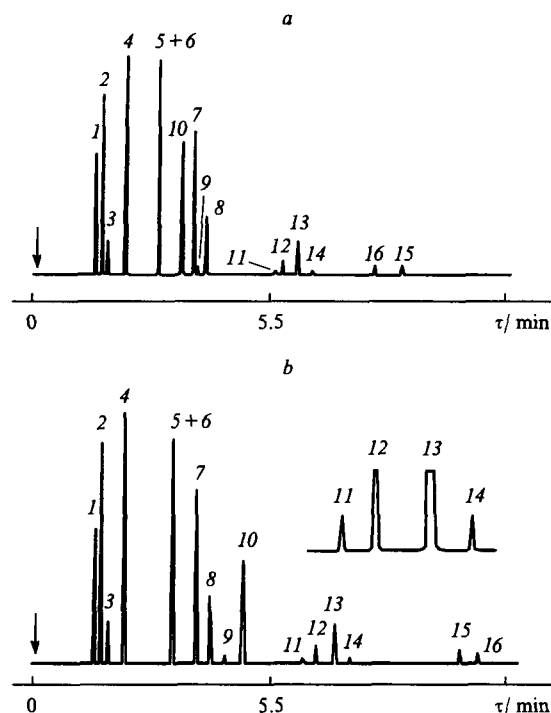

Figure 16. Chromatogram for the separation of C_1 – C_4 hydrocarbons in special metallic capillary columns with $\text{Al}_2\text{O}_3/\text{KCl}$ (a) and $\text{Al}_2\text{O}_3/\text{Na}_2\text{SO}_4$ (b).¹²⁵

Peaks: (1) methane, (2) ethane, (3) ethene, (4) propane, (5) cyclopropane, (6) propene, (7) isobutane, (8) butane, (9) propadiene, (10) acetylene, (11) *trans*-but-2-ene, (12) but-1-ene, (13) isobutene, (14) *cis*-but-2-ene, (15) buta-1,3-diene, (16) methylacetylene. A 50 m × 0.32 mm column and hydrogen as carrier gas were used, the temperature increased from 70 to 130°C at a rate of 5°C/min .

gas chromatography on packed columns, especially for industrial purposes. These schemes make it possible to change automatically, during the analysis, the order in which the columns are connected and the direction of the carrier-gas flow in the individual sections (or in the whole scheme) and also to include individual columns into the scheme or to exclude them from it. Thus, the conditions for the separation of individual groups of compounds can be optimised, the time required for the analysis can be shortened, and the stability of the operation of the columns used can be increased.

The use of such schemes also in the capillary chromatography would certainly be expedient and would markedly improve the separation. The first gas chromatograph 'Siechromat' based on an adaptable multicolumn scheme was developed by Siemens (Germany). Fig. 17 shows two chromatograms obtained in the separation of a mixture of C_1 – C_8 hydrocarbons in *n*-pentane with this instrument. The boiling points and chromatographic characteristics of the components of this mixture were essentially different. Initially, this mixture was separated at 75°C in an open tubular capillary column (24 m × 0.27 mm), the inner walls of which were coated with a modified clay (Bentone-34) impregnated with di-*iso*-decyl phthalate. This main column ensured clear separation of benzene (11), toluene (12), ethylbenzene (13), *p*-xylene (14), *m*-xylene (15), and *o*-xylene (16). The C_1 – C_5 light hydrocarbons were rapidly eluted from the column; therefore, they were responsible for one common peak in the chromatogram.

Fast separation of light hydrocarbons was achieved by injecting them into another open tubular capillary column (80 m × 0.4 mm), the inner walls of which were coated with a layer of alumina modified with potassium chloride. The separation in this column was carried out at 15°C . Light hydrocarbons — methane (1), propane (2), propene (3), isobutane (4),

Figure 17. General chromatogram for the separation of C_1 – C_8 hydrocarbons in an open tubular capillary column (a) and the partial chromatogram for the fraction of C_1 – C_5 hydrocarbons (b).¹³⁰ Experimental conditions 24 m \times 0.27 mm columns with Bentone-34 impregnated with diisodecyl phthalate as adsorbent (a) and a 80 m \times 0.4 mm column with alumina (b).

n-butane (5), but-1-ene (6), *trans*-but-2-ene (7), butadiene (8), isobutene (9), and *cis*-but-2-ene (10) — were separated in this column. The separation in the two capillary columns occurred simultaneously, the time required for the process in each column not exceeding 6 min. This example clearly illustrates the advantages of using adaptable multicolumn schemes in gas chromatography and the possibility of increasing markedly the separating capacity of capillary chromatography. These schemes make it possible to gain a larger amount of chromatographic information than a traditional single analysis.

Chromatographic schemes in which adsorption capillary columns are used together with packed columns have also been reported (see for example Ref. 131). Poy and Cobelli¹³¹ have shown experimentally that the use of a gas chromatograph with a flame-ionisation detector ensures fairly high reproducibilities of the retention values and of the proportions of the components determined for a mixture subjected to the analysis (Table 5). The results obtained by these workers can be regarded as experimental justification for using open tubular capillary columns for analytical and physicochemical purposes.

At present, porous organic polymers are used fairly frequently as adsorbents in adsorption chromatography (especially for polar compounds).^{132, 133} Capillary columns with porous organic adsorbents have been used¹²⁵ for the analysis of the following classes of compounds: C_1 – C_5 alcohols, C_2 – C_7 fatty acids, C_1 – C_2 haloalcohols, C_1 – C_5 hydrocarbons, solvents, C_1 – C_5 aldehydes, gases, mixtures of gases with water, C_3 – C_8 ketones, and C_1 – C_9 thiols.

The use of porous organic polymers as adsorbents offers a number of advantages; the main of them are high homogeneity of the surface with controllable (within certain limits) porosity and hydrophobicity of particular types. Therefore, porous polymers can be figuratively regarded as organic polymeric phases that have come to a standstill.

Open tubular capillary columns containing a polymeric layer on the inner walls were produced for the first time by Hollis,¹⁰⁵

Table 5. Reproducibility of retention values and concentrations of components found in a mixture being analysed for an open tubular gas adsorption capillary column from Chrompack.

^a R — mean square deviation from the average value. ^b The numbers above the bar refer to a packed column, those below the bar refer to a capillary column. The statistical data were obtained from 10 experiments (calculations were carried out by the internal normalisation method).

while the modern variant of these columns based on flexible quartz capillaries has been developed by Dutch researchers of the 'Chrompack' company;^{39, 125, 134} the same researchers have also developed special metallic capillary columns with polymeric adsorbents.³⁸ Fig. 18 presents three chromatograms obtained for the separation of C_1 – C_4 hydrocarbons using three different types of columns. It is seen that the retention of hydrocarbons on the organic adsorbent differs sharply from that on methylsilicone and alumina; in the case of the organic adsorbent, groups of hydrocarbons differing in the number of carbon atoms in their molecules can be clearly distinguished. Examples of successful separation of polar organic compounds in columns of this type have been reported.^{38, 39, 123, 125}

Note that natural organic adsorbents can also be used in capillary columns. Fig. 19 shows the results of the separation of organic acids of natural origin on a natural polymer, *Staphylococcus aureus* cells. A quite satisfactory degree of separation was achieved. The use of natural adsorbents seems promising.

Gas capillary chromatography has been used for the separation of hydrocarbons and nitriles.^{136, 137} Porapak Q and Al₂O₃/KCl were used as adsorbents, a thin layer of which covered the inner walls of a capillary column. Good results were achieved with the PoraPLOT Q column (10 m \times 0.32 mm); in the case of the PLOT Al₂O₃/KCl column, nitriles are held tightly, some of the peaks being asymmetrical.

Determination of buta-1,3-diene in air carried out using a PLOT capillary column containing Al₂O₃/KCl (50 m \times 32 mm) has been described by Finnish researchers.¹³⁸

Columns with traditional adsorbents, for example, with graphitised carbon black, also find practical application. 'Structural sensitivity', which is manifested in the separation of isomers, is a specific feature of graphitised carbon black used as an adsorbent. This feature, which is very attractive for an analyst, can be illustrated by the separation of hydrocarbons, the chromatogram for which is shown in Fig. 20. All the three isomers of xylene were separated in a capillary column with

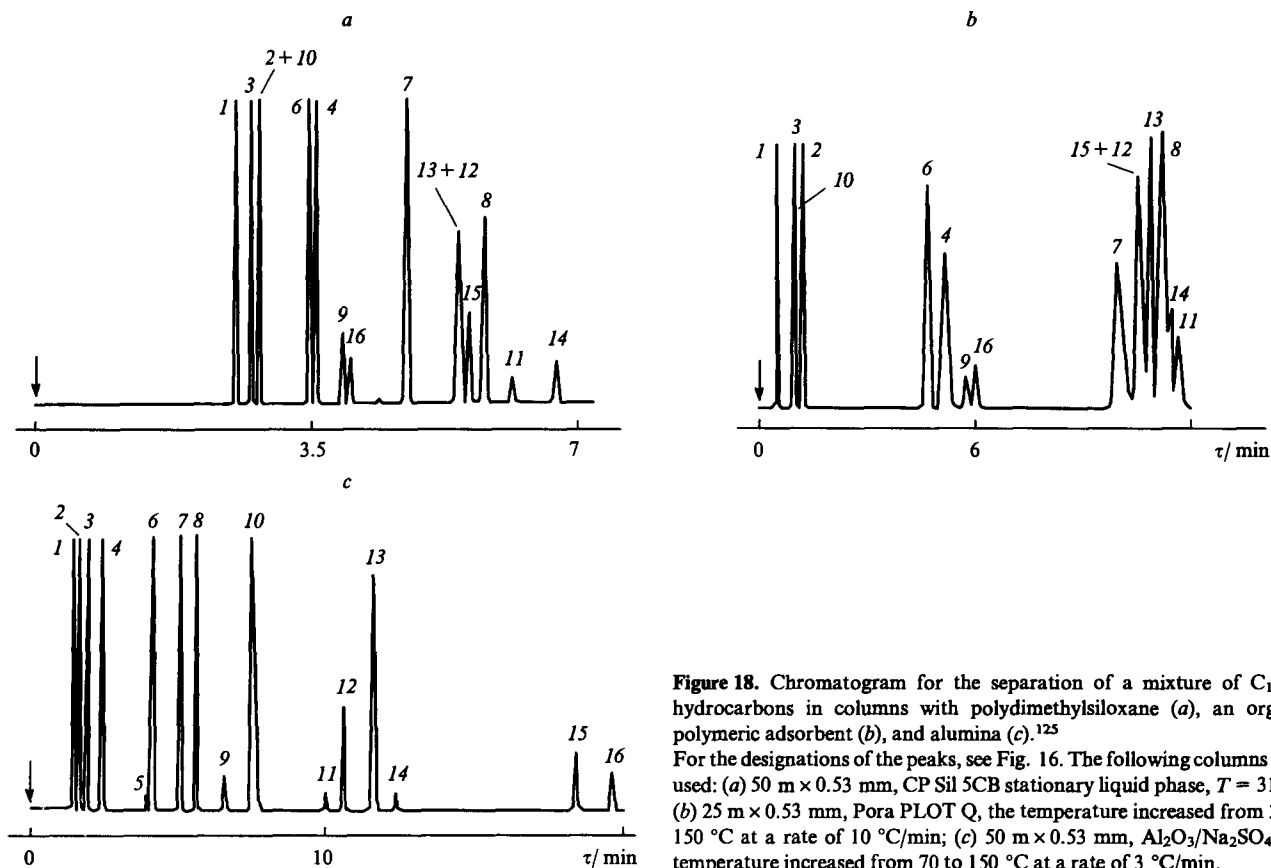

Figure 18. Chromatogram for the separation of a mixture of C_1 – C_4 hydrocarbons in columns with polydimethylsiloxane (a), an organic polymeric adsorbent (b), and alumina (c).¹²⁵ For the designations of the peaks, see Fig. 16. The following columns were used: (a) 50 m \times 0.53 mm, CP Sil 5CB stationary liquid phase, $T = 31^\circ\text{C}$; (b) 25 m \times 0.53 mm, Pora PLOT Q, the temperature increased from 35 to 150 °C at a rate of 10 °C/min; (c) 50 m \times 0.53 mm, $\text{Al}_2\text{O}_3/\text{Na}_2\text{SO}_4$, the temperature increased from 70 to 150 °C at a rate of 3 °C/min.

graphitised carbon black. In another study,¹³⁶ adsorption columns with Carbo-pack B modified with a non-volatile liquid phase have been used; these columns are usually called Carbon Layer Open Tubular (CLOT) columns.

Graphitised carbon black can be used for the analysis of mixtures of halohydrocarbons. The results of separation of some halohydrocarbons in an adsorption capillary column (Carbo-pack B + 1% SP 1000) are shown in Fig. 21.

Figure 19. Chromatogram for the separation of unsaturated acids in an open tubular capillary column in which *Staphylococcus aureus* cells were used as the adsorbent.¹³⁵

Acids: (1) 14:1 tetradecenoic; (2) 14:0 myristic; (3) 15:0 pentadecanoic; (4) $c\Delta^8$ 16:1 *cis*-hexadec-8-enoic; (5) $c\Delta^9$ 16:1 *cis*-hexadec-9-enoic (palmitic); (6) $c\Delta^{10}$ 16:1 *cis*-hexadec-10-enoic; (7) $c\Delta^{11}$ 16:1 = $t\Delta^9$ 16:1 *cis*-hexadec-11-enoic and *trans*-hexadec-9-enoic; (8) $t\Delta^{10}$ 16:1 *trans*-hexadec-10-enoic; (9) $t\Delta^{11}$ 16:1 *trans*-hexadec-11-enoic; (10) $t\Delta^{12}$ 16:1 *trans*-hexadec-12-enoic; (11) 16:0 palmitic; (12) $c\Delta$ 17:0 *cis*-methylene-hexadecanoic; (13) $t\Delta$ 17:0 *trans*-methylenehexadecanoic; (14) 18:0 octadecenoic; (15) 18:0 stearic.

Columns with graphitised carbon black are used mostly for the separation of gaseous and relatively light hydrocarbons; however, Brunner et al.¹⁴¹ have shown that they can also be used for the determination of some herbicides in water.

A practically significant separation of halo-derivatives of hydrocarbons in open tubular capillary columns containing a layer of solid adsorbents on the inner surface of the capillary has been studied by de Zeeuw et al.¹⁴² They showed that the PLOT columns with $\text{Al}_2\text{O}_3/\text{KCl}$ are very selective towards the separation of volatile compounds of this type; however, proportions of some of these compounds in the mixture changed during the elution.

Figure 20. Chromatogram for the separation of a mixture of aromatic hydrocarbons in a capillary column with graphitised carbon black.¹³⁹ (1) n-Octanol; (2) benzene; (3) n-nonane; (4) toluene; (5) *p*-xylene; (6) *m*-xylene; (7) *o*-xylene. A 30 m \times 0.32 mm column with Carbo-pack B was used; $T = 60^\circ\text{C}$; helium was used as the carrier gas.

Figure 21. Chromatogram for the separation of a mixture of halohydrocarbons in a capillary column with Carboxpack B modified with 1% of a stationary liquid phase.¹⁴⁰

(1) CFC 12; (2) CFC 114; (3) CFC 11; (4) $C_2H_2Cl_2$; (5) CFC 113; (6) CH_3CCl_3 ; (7) CCl_4 ; (8) C_2Cl_4 . A 32 m \times 0.53 mm column was used; hydrogen was used as the carrier gas, $T = 30^\circ C$ (2 min) followed by heating to $180^\circ C$ at a rate of $20^\circ C/min$.

The use of capillary columns with the PoraPLOT Q adsorbent is promising for the analysis of chlorofluoro-derivatives of hydrocarbons.

Bruner et al.¹⁴³ have developed a procedure for the determination of hydrocarbons and amines in a capillary column with graphitised carbon black modified with various liquid phases.

Stationary liquid phases are widely used for the modification of solid adsorbents in gas adsorption chromatography. The retention in these systems can be described in terms of the additive absorption-adsorption theory.¹⁴⁴ In recent years, colloidal stationary liquid phases have been used in order to increase the capacity of the columns and to change their selectivity.^{145,146}

The field of application of gas adsorption capillary columns is progressively extending, and the number of companies producing these columns is increasing.¹⁴⁷

Unfortunately, the use of open tubular adsorption capillary columns in Russia is still limited, although these columns can be manufactured in almost any chromatographic laboratory.¹⁴⁸

* * *

The use of capillary gas adsorption chromatography makes it possible to improve markedly the main characteristics of chromatographic separation of volatile compounds (selectivity, efficiency, speed, the area of application, etc.). Capillary gas-adsorption chromatography is a modern version of the adsorption chromatography, which makes it possible to take full advantage of this earliest version of gas chromatography.

The wide experience accumulated by researchers from various countries forms a strong basis for the extensive use of adsorption capillary columns for solving numerous important routine problems.

From our viewpoint, in the future, attention should be concentrated on the following branches of gas adsorption capillary chromatography: the theory and optimisation of the separation conditions, reproducible methods for the manufacture of capillary columns, and the extension of the number of various selective adsorbents used in the capillary variant of chromatography.

The author is grateful to Academician I I Moiseev for useful discussion and to the Scientific Council of the subprogramme 'Priority Branches of the Chemical Science' for supporting this work.

IV. Reactions of fluoroalkyl phosphites	948
V. Conclusion	966

Abstract. The review surveys and gives a systematic account of the electronic structures, syntheses, and chemical properties of fluoroalkyl derivatives of trivalent phosphorus (phosphites, thiophosphites, and amidophosphites). The methods of preparation and reactivities of fluoroalkyl phosphites are compared with those of unsubstituted phosphites. The bibliography includes 420 references.

I. Introduction

Derivatives of trivalent phosphorus are of key importance in the synthesis of a wide variety of organophosphorus compounds with different coordinations at the phosphorus atom and exhibit in most cases pronounced nucleophilic properties. This is associated with the accessibility of the lone pair (LP) of the phosphorus atom in the above derivatives and with the ease of their conversion into compounds with a phosphoryl group.

Various aspects of the influence of alkyl-, alkoxy-, amido-, etc. substituents on the reactivity of trivalent phosphorus compounds have been described in fair detail in the literature, but there have been no surveys of the influence of fluorine atoms, although a number of questions, concerning, for example, the electronic structures of fluorinated derivatives of P(III), have been discussed in monographs.^{1–3}

A systematic description of the syntheses and chemical properties of fluoroalkoxy-derivatives of trivalent phosphorus and the identification and possible explanation of their characteristic features compared with the unsubstituted analogues are the subject of the present review.

II. The influence of fluorine-containing substituents on the properties of the P(III) atom. Photoelectron spectroscopic and electrochemical data

The introduction of a fluorine atom into trivalent phosphorus compounds almost always alters the properties of the derivatives obtained compared with their nonfluorinated analogues, although as a rule the fluorine atom in such derivatives is not a reaction centre or a leaving group. In order to give a systematic account of data concerning the influence of fluorine on the properties of the P(III) atom, it is useful to examine four conventional groups of compounds containing P and F atoms: (1) compounds with a P–F bond; (2) compounds containing the P–C–F fragment (the F atom occupies the α -position relative to the P atom — these are usually CF_3 derivatives); (3) compounds containing the P–E–C–F fragment, where E = C, O, S, Se, N, etc. (the F atom occupies the β -position relative to the P atom); (4) compounds with the P–E–C–C–F fragment (the F atom occupies the γ position relative to the P atom). The available information about the reactivities of the first two groups of compounds have been surveyed.^{4–9} The chemistry of the compounds belonging to the third group, in which E = S, Se, or Te, has been scarcely investigated. Among the compounds with E = C, the pentafluorophenyl derivatives have been most thoroughly investigated.¹⁰ In compounds with P–E–C–C–F fragments, the fluorine and phosphorus atoms are separated by four bonds and the inductive effect of the fluorine atom on phosphorus in them should be minimal. Nevertheless, experimental data indicate an appreciable influence of the fluorine atoms on the phosphorus centre in such compounds.

According to X-ray photoelectron spectroscopic data, the replacement of a hydrogen atom by fluorine in an organic compound leads to profound perturbations of the electronic core of the molecule as far as the 1s level of carbon. The binding energy of the electrons of the carbon atom $E(\text{C}1s)$ in the $\text{CF}_n\text{H}_{4-n}$ molecule then increases by ~ 2.7 eV for each fluorine atom introduced.¹ On passing from ethane to trifluoroethane ($\text{C}_2\text{H}_6 - \text{CF}_3$), an additive increase in the binding energy for the β -carbon $E(\text{C}\beta 1s)$ is also observed, although to a lesser extent than in methane (from 290.7 to 292.1 eV).

The additivity breaks down when an oxygen atom is introduced at the β -carbon atom. Thus, on passing from ethanol to trifluoroethanol, $E(\text{C}\beta 1s)$ changes by only 0.3 eV (from 292.5 to 292.8 eV), while on replacement of one hydrogen atom in

$C_\alpha F_3 C_\beta H_3$ by OH groups, $E(C_\alpha 1s)$ does not change [$E(C_\alpha 1s) = 297.8$ eV]. It follows from these data that the manifestation of the inductive effect for $C_3 1s$ on passing from ethane to trifluoroethane is almost five times greater ($\Delta = 1.4$ eV) than on passing from ethanol to trifluoroethanol ($\Delta = 0.3$ eV). This phenomenon is classified as the β -effect of the fluorine atom.¹¹

Calculations¹² yield a negative charge on the carbon atom in the β -position relative to fluorine. Thus in ethane the charge on the carbon atom is zero, while in CF_3CH_3 we have $q^{C_\alpha} = 0.60 - 0.72$ e and $q^{C_\beta} = (-0.09) - (-0.11)$ e, i.e. the presence of the fluorine atom increases the electron density on the β -carbon atom and diminishes it on the C_α atom. The consequences of the β -effect of the F atom are particularly strikingly manifested, as will be seen below, in the case of fluorinated alkoxy-derivatives of P(III). In order to explain it, the concepts of hyperconjugation,^{11,13-15} antibonding orbitals,^{16,17} and the perfluoro-effect¹¹ have been resorted to.

According to Davis et al.¹² and Bock et al.,¹⁸ the effect can be accounted for by the fact that the strong acceptance of electronic charge by fluorine via the system of σ -bonds is accompanied by the reverse polarisation of the π -electron system or the σ^* orbitals. Overall, if the charges on the carbon atoms of ethane are zero, the substitution of a hydrogen atom by fluorine leads to the appearance of an effective positive charge of 0.24 e at the α -carbon atom and of a negative charge of -0.03 e at the β -atom; the charge on the fluorine atom is -0.23 e. These features are fully retained for ethene and benzene.¹

By virtue of its small size (the van der Waals radius of fluorine is 0.14 nm), close to that of the hydrogen atom (0.12 nm), the fluorine atom is capable of substituting all the hydrogen atoms in linear molecules. When all the valences of the carbon atom in the carbon chain are saturated by fluorine atoms, the carbon skeleton passes from the zigzag to the helical shape, whereupon the electronegative fluorine atoms fully protect the carbon skeleton against attack by nucleophiles.^{19,20} The helix exhibits a 180° twist for each 13 carbon atoms. In a weakened form, this effect is probably manifested also in fluoroalkyl phosphites, particularly those with long fluorinated carbon chains.

In order to estimate the quantitative influence of fluorine on various properties of the molecule, photoelectron spectroscopy (PES) has been widely used together with X-ray spectroscopy.²¹⁻²³ A characteristic feature of the photoelectron spectra of organofluorine compounds is the absence of narrow (without a vibrational structure) bands, typical for ionisation with participation of nonbonding MOs, although formally the molecules contain a large number of fluorine lone pairs (n_F), whereas such narrow bands are observed for the chloro- and bromo-derivatives. The broad bands present in the spectra of organofluorine compounds, frequently with vibronic structures, indicate that in the organofluorine compounds there are no true n_F orbitals. The photoelectron spectra of fluoroalkanes, fluoroalkenes, and fluoromethyl derivatives of nitrogen subgroup elements, i.e. simple and planar molecules, almost fully reproduce the photoelectron spectra of hydrocarbon analogues, although they are displaced towards higher ionisation potentials (IP). However, the effect of the perfluoroalkyl substituent, postulated²⁴ and defined as a shift towards higher IP (without changes in the sequence, energy differences, and symmetry type of the MO for the n and σ MO of the central atom) when alkyl groups are replaced by perfluoroalkyl groups, is not a general rule for fluorinated molecules, because it requires a correspondence between the nature of the MO and the energies and symmetries of the fluorinated and hydrocarbon analogues. This is possible only subject to the condition of the complete localisation of the orbitals n_F on the fluorine atoms, which in its turn conflicts with the nature of the photoelectron spectra.

The ionisation potential of the molecule is a measure of the difference between the energies of formation of the molecule and the molecular ion (radical-cation). The replacement of a hydrogen atom by an alkyl group with electron-donating properties leads to

the stabilisation of the radical-cation, while the replacement by a fluorine atom or a fluorinated alkyl (σ -acceptors) results in destabilisation. The σ -acceptor effect of the CF_3 group is then intensified by its weak π -acceptor effect, while the effect of the F atom is weakened by the donor influence.³

The complex nature of the effect of the CF_3 group has been demonstrated recently.²⁵ Thus, when a F atom is replaced by the CF_3 group in fluoroalkenes, the π levels of the molecule are strongly stabilised with some destabilisation of the σ levels. For example, on passing from $CF_2=CF_2$ to $(CF_3)_2C=C(CF_3)_2$, the π -type HOMO energy diminishes by 3.8 eV, while the LUMO (π^*) energy decreases by 2.1 eV. Under these conditions, the occupied π - and σ -type MO approach one another. The CF_3 group induces a marked alternation of the charge (the appearance of a negative charge on the β -carbon atom and of a positive charge on the α -carbon atom). Thus the overall effect of the CF_3 group in perfluoroalkene is electron-donating (M-acceptor, σ -donor). Evidently, the electronic effects of the CF_3 group on the F atom can change depending on the nature of the fragment to which they are attached. Thus, using the LCAO-MO SCF methods supplemented by the optimisation of the geometrical parameters, it has been shown that the $C_\alpha - C_\beta$ distance decreases with increase in the number of CF_3 groups at the α -atoms of the carbanions $CF_3CH_2^-$, $(CF_3)_2CF^-$, and $(CF_3)_3C^-$, which indicates the existence of negative hyperconjugation at the fluoroalkyl substituents.²⁶

In simple, planar molecules, the substitution of hydrogen by fluorine leads to a more pronounced stabilisation of the σ MO than the π MO. The preferential σ -stabilisation on fluoro-substitution is called the perfluoro-effect. The ranges of the π -electron IP then overlap markedly and the composition of the fluorinated derivatives changes qualitatively compared with that of the nonfluorinated analogues.²⁷

The photoelectron spectra of fluorinated alcohols have a complex form with broad overlapping bands.²⁸⁻³⁰ Overall, they are subject to the effect of the perfluoroalkyl group, i.e. they have the same band sequence as in the spectra of the usual alcohols which has undergone an almost parallel shift into the region of higher potentials; furthermore, quantum-chemical calculations^{28,29,31} yield the same sequence of the MO. The highest occupied molecular orbital of alkanols and their fluoro-derivatives is not a pure n_O orbital. The contributions of the $2p$ AOP of oxygen to the HOMO in the series CH_3CH_2OH , CH_2FCH_2OH , $(CF_3)_3COH$ are 43%, 41%, and 27% respectively. This suggests that the n_O orbitals, like the n_F orbitals, are not fully localised on oxygen and fluorine.

In trifluoroethanol, the CF_3 group is separated from the oxygen atom by the CH_2 unit, which weakens both the σ_1 -effect and the conjugation effect.

Extremely interesting data have been obtained in the study of fluorinated alcohols by the ^{17}O and ^{13}C NMR methods.³² It was found that the influence of fluorine in the β - and γ -positions ($F_\beta - C - O$, $F_\gamma - C - C - O$) is manifested much more strikingly in the ^{17}O NMR spectra than in the ^{13}C NMR spectra. Bearing in mind that the quantity $\delta_O(\delta_C)$ is linearly related to the charge on the corresponding atom and hence to the electron density,³³ one may reach certain conclusions about its distribution. The fluorine atoms in the β -position relative to the oxygen (and carbon) atom exert a powerful deshielding effect ($\Delta_O = 36 \pm 5$ ppm) on the oxygen atom (the β -effect), whereas the F_γ atoms exert a weak shielding effect ($\Delta_O = 10 \pm 3$ ppm). The above effects may be accounted for by the different manifestations of the effect due to the field of the fluorine atom.³⁴

The vertical IP for fluorine-containing phosphites have been determined.³⁵⁻³⁷ It was shown that the replacement of hydrogen atoms by fluorine increases significantly IP_1 , which largely corresponds to ionisation with participation of the n_P orbital. Thus the IP_1 for the phosphites 2 and 4 exceed the IP_1 for the phosphites 1 and 3 by 1.33–1.37 eV (Table 1). Finally, the IP_1 for tris(hexafluoroisopropyl) phosphite 5 is greater than IP_1 for phosphorus trichloride by 0.29 eV, i.e. the electron-accepting

Table 1. Photoelectron spectroscopic data for certain P(III) derivatives.

PCl ₃	10.52	—	40
PBr ₃	9.35	—	40

effect of the hexafluoroisopropyl substituent exceeds that of the chlorine atom. Overall, the photoelectron spectra of the fluorinated phosphites resemble those of the usual phosphites, but they are displaced towards higher ionisation potentials, i.e. the perfluoroalkyl effect rule holds in this case, since the sequence and symmetry of the MO (*n*_P, *n*_O, σ_{CC}) are retained.

It has been shown⁴⁰ that the IP₁ in the PX₃ series increase in proportion to the IP₁ of the functional hydrides HX (the fluorinated phosphites 2, 4, and 5 are not an exception). The relation between IP(PX₃) and IP(HX) is linked to the parallel manifestation of the inductive effect of the substituent X and the mixing of the orbitals *l*_P and *n*_X.⁴⁰ Thus the contribution of the 3*p* AO LP of phosphorus to the HOMO increases in the sequence C₆F₅P(NEt₂)₂ < C₆F₅P(NCS)₂ < C₆F₅P(OMe)₂ in conformity with the increase in the IP₁(HX): HNEt₂ (8.15) < HNC (9.94) < HOMe (10.96).⁴¹ The IP(*n*_P) for the phosphites 2, 4, and 5 exceed those for the phosphonites enumerated, like the IP(*n*_O) of fluorinated alcohols, so that the contribution of the phosphorus 3*p* AO to the HOMO increases, with an overall increase in IP(*n*_P), on passing from the phosphites P(OR)₃ and the phosphonites C₆F₅PX₂ to the fluorinated phosphites 2, 4, and 5 and P(OC₆F₅)₃. Under these conditions, the *n*_P orbital to which the 3*p* AO of phosphorus contributes significantly (from 75% to 87% according to different estimates),⁴⁰ is also capable of *n*_P– σ_{C-O}^* conjugation.

The electron-accepting nature of the C–O σ^* -bond increases as a result of the introduction of the fluorinated substituent at the carbon atom. In the usual compounds, the *n*_P– σ_{C-O}^* interaction in the P(III)–O–C fragment is weak, since the excitation is localised mainly on the carbon atom.^{42,43} In fluorinated phosphites, such interaction is apparently more effective; here there is a partial delocalisation of the *n*_P electrons to the C–O σ -bond. An appreciable delocalisation of the *n*_P electrons has been noted for the compound P(OC₆F₅)₃, which has been investigated by X-ray emission spectroscopy (PK _{β}).⁴¹

The enhancement of the electron-accepting properties of the OR_F substituents via the σ_1 mechanism is accompanied by an increase in the electrophilicity of the P–O σ^* -bonds, the electron deficiency occurring predominantly on the phosphorus atom, because it is less electronegative than oxygen. Bearing in mind the electronic interaction occurring in the O–CH₂–CF₃ fragment and enhancing the electron-accepting properties of the orbital σ_{CO}^* , one may postulate that the conjugation of the P–O σ^* -bond and the *n*_O electrons, characteristic of the usual P(III) compounds, is unlikely in compounds with this fragment.

Thus, by virtue of the strong electron-accepting effect of the fluoroalkoxy-groups, a significant electron density deficiency arises on the phosphorus atom, which imparts electrophilic properties to the latter. Hence one should expect a greater reactivity of R_F phosphites in reactions with nucleophiles compared with R_H phosphites.

One of the consequences of the replacement of the H atoms by F atoms in phosphites is the strengthening of the C–O bond, i.e. an increase in its energy. This change in the bond energy may be explained on the basis of the orbital model of *n*_O– σ_{C-C}^* hyperconjugation.^{16,42,43} The introduction of fluorine atoms lowers the energy of the σ_{C-C}^* orbital, which is localised predominantly on

the terminal carbon atom of the C–CF₃ fragment and increases the effectiveness of its interaction with *n*_O.

The transfer of electron density from the oxygen atom to the fluorinated alkyl group is possible both via the σ_1 mechanism and via a mechanism involving *n*_O– σ_{C-C}^* and σ_{C-O} – σ_{C-F}^* conjugation. Furthermore, the substituent CF₃(R_F) exhibits a π -acceptor effect,³ which may occur via the mechanism involving the hyperconjugation of the antibonding MO of the CF₃ group localised on the carbon atom with the π -type MO of the CH₂ fragment. All this strengthens the C–C and C–O bonds, i.e. stabilises the σ levels and enhances the electron-accepting properties of the alkoxy-fragment OR_F.

The photoelectron spectra of cyclic phosphites containing electron-accepting substituents (CF₃)₂CH have been investigated.³⁷ The results are presented in Table 2.

The first two potentials, IP₁ and IP₂, in the photoelectron spectra of benzodioxaphospholanes 6–9 and the salicyl derivatives 13 and 14 correspond to the ionisation of two π orbitals of the benzene ring, *a*₂(π) and *b*₁(π), perturbed by the effective interaction with the antisymmetric (*n*_O[–]) and symmetrical (*n*_O⁺) combinations of the group orbitals of oxygen. Under these conditions, the *a*₂(π)–*n*_O⁺ orbital is the HOMO.

The ionisation potential IP₃ of the benzophospholanes 6–9 corresponds to the ionisation of the *n*_P orbital, exceeding the IP₁(*n*_P) for the analogous phospholanes 10–12 by 0.35–0.6 eV. The reason for the increase in IP₃(*n*_P) in the benzophospholanes 6–9 is the effective interaction. The replacement of one oxygen atom in compounds 6 and 7 by an ester group (compounds 13 and 14) leads to an appreciable increase in the energies of the *a*₂(π) and *b*₁(π) orbitals, but at the same time facilitates the ionisation of the *n*_P orbital. This is consistent with the M effect of the C(O)O group.

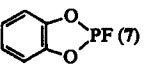

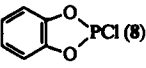

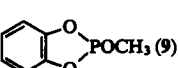

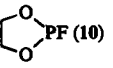

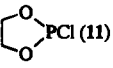

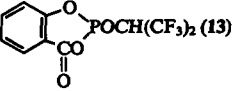

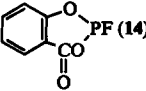

Naturally the *n*_O⁺–*a*₂(π) and *n*_O⁺–*b*₁(π) conjugation is just as effective as the *n*_O⁺– π interaction. The *n*_O– π^* conjugation shifts electron density from the oxygen atom to the ring.

It follows from the foregoing that cyclic benzodioxaphospholanes and unsubstituted dioxaphospholanes contain an extremely electrophilic phosphorus atom, the positive charge on which is comparable to that for acyclic fluorinated phosphites (the ionisation potentials of such compounds are very high). If weak electron-accepting substituents, such as NR₂, OMe, or OSiMe₃, are present at the phosphorus atom in the phospholane, then the σ_{PO}^* orbitals, localised mainly on the phosphorus atom, behave as acceptors in the σ_{PO}^* –*n*_X conjugation,⁴⁴ the electrophilicity of the σ_{PO}^* orbitals of the cyclic fragment increasing after the introduction of the benzene ring owing to *n*_O– π^* conjugation. On the other hand, if there are strong π -acceptor substituents, for example OC₆F₅, OCH(CF₃)₂, or OCH₂CF₃, at the phosphorus atom, then the nature of the electronic interactions of the cyclic fragment with the exocyclic substituent changes. In this case, the electrophilicity of the σ_{PO}^* orbital weakens, and the *n*_O– σ_{PX}^* interactions are intensified, which diminishes somewhat, in its turn, the *n*_O– π^* conjugation. Thus the IP₁(π_1) and IP₂(π_2) for compounds 6 and 7 increase by ~0.45 and ~0.30 eV compared with the corresponding ionisation potentials of compound 9 (Table 2).

The photoelectron spectroscopic data for fluorinated phosphites examined above show that the IP₃(*n*_P) for these compounds are higher by 1.3–2 eV compared with the ionisation potentials of the unsubstituted phosphites, which should undoubtedly be reflected in the electrochemical properties of fluoroalkyl phosphites. The study of the electrochemical behaviour of fluoroalkyl phosphites^{37,45–47} has shown that acyclic derivatives are not oxidised in the accessible range of potentials (for example, compounds 2, 4, and 5), which is fully consistent with photoelectron spectroscopic data. Table 2 presents also the half-wave oxidation potentials (*E*_{1/2}/V) of some of the fluorinated P(III) derivatives investigated. They were obtained by the voltammetric method at a platinum electrode in acetonitrile (25 °C).⁴⁷

The value of *E*_{1/2} quoted^{48,49} for tris(tetrafluoropropyl) phosphite 4 (0.85 eV) is erroneous and has not been reproduced.

Table 2. Photoelectron spectroscopic data for certain cyclic phosphites (IP/eV).³⁷

Compound	IP ₁ (π_1) $a^2(\pi) - n_O^+$	IP ₂ (π_2) $b_1(\pi) - n_O^-$	IP ₃ (n_P)	$E_{1/2}/V$
 (6)	8.89	9.58	10.75	1.59, 2.03
 (7)	8.90	9.53	11.11	1.58, 1.85
 (8)	8.86	9.57	10.55 ($n_P - n_O - n_{Cl}$)	—
 (9)	8.45	9.26	10.33	1.29, 1.99
 (10)	10.74(n_P)	11.19(n_O)	12.51(σ_{CC})	—
 (11)	10.20(n_P) ⁴⁸	—	—	—
 (12)	9.55(n_P) ⁴⁸	—	—	—
 (13)	9.42(π_1)	9.80(π_2)	10.30 ($n_P + n'_O$)	2.34
 (14)	9.54	10.04	10.43	—

This is understandable because the value of $E_{1/2}$ determined by the above workers^{48,49} is actually lower than $E_{1/2} = 1.68$ V for $P(OEt)_3$.⁵⁰ One-electron and (according to cyclic voltammogram data) irreversible waves were observed on the voltammograms for fluoroalkyl phosphites derived from catechol and salicylic acid. The reaction centre in these compounds is the benzene ring and an electron is abstracted from the HOMO which is the $a_2(\pi) - n_O^*$ orbital.

The calculated number of electrons for cyclic fluoroalkyl phosphites is less than integral values, which may be associated with the interaction of the radical-cation formed with the initial phosphite. This leads to the formation of dimeric species, for example in the case of bis(trifluoroethyl) phenylphosphonite.⁵¹

The shift of the potential $E_{1/2}$ to the negative region for compound 13 and its analogues⁴⁷ is associated with the presence of the electron-accepting substituent $C(O)O$ in the ring, which agrees with the higher ionisation potential of the $a_2(\pi)$ orbital.

Thus electrochemical oxidation, photoelectron spectroscopic, NMR spectroscopic, and calculated data clearly indicate that the phosphorus in fluorinated cyclic and acyclic phosphites has a very high $IP(n_P)$, carries an appreciable effective positive charge, and exhibits (together with nucleophilic properties) pronounced electrophilic properties. As a result of the characteristic features of the electronic interactions in the fluoroalkoxy-group, it is difficult to split off R_F from phosphonium centres compared with the splitting off of R_H . For this reason, one should expect the ready elimination of this group in the corresponding nucleophilic reactions, i.e. the easier cleavage of the $P-OR_F$ bond compared with the $P-OR_H$ bond. The easier elimination of the CF_3CH_2O group compared with CH_3CH_2O has been noted⁵² in relation to the aminolysis of the esters $RCOOCH_2CF_3$. In this sense, the chemistry of fluoroalkyl phosphites resembles that of P(III) halides, which is known to reduce largely to nucleophilic substitution reactions at the phosphorus atom. Furthermore, the chem-

istry of fluoroalkyl phosphites is significantly richer and is not restricted solely to the nucleophilic reactions indicated above. The difference in the behaviour of fluoroalkyl phosphites and P(III) halides, having similar $IP(n_P)$, may be due to the difference in the hybridisation of the phosphorus lone pairs, which has predominantly s character in the case of phosphorus halides and is distinguished by a significant contribution of p character in the case of trialkyl phosphites.^{2,40} Finally, the formation of products with a phosphoryl group from fluorinated phosphites should be more convenient than their formation from unsubstituted phosphites.

III. Synthesis of fluoroalkoxy-derivatives of P(III)

1. Reactions of P(III) halides with fluorine-containing alcohols

Various methods of synthesis of P(III) derivatives containing fluorinated substituents have been developed: reactions involving phosphorylation of fluorinated alcohols by P(III) acid halides and amides, alcoholysis and transamination reactions, interaction of P(III) derivatives with hexafluoroacetone, etc.

The interaction of P(III) halides with fluorinated alcohols is one of the most frequently employed approaches to the synthesis of fluoroalkyl phosphites. As we have already noted, fluorinated alcohols are relatively weak nucleophiles. They are less basic than the usual alcohols.³¹ Being fairly acidic ($pK \approx 4-12$),^{53,54} R_F -alcohols react with difficulty with P(III) chlorides, in contrast to R_H -alcohols. They are unusually inert in reactions proceeding via the intermediate formation of carbonium ions, which indicates a strong interaction of the oxygen lone pair with the fluoroalkyl fragment (the 'mesomeric' nature of the bonds).⁵⁵ Quantum-chemical calculations,³¹ carried out for CF_3CH_2OH , $CF_3CH_2O^-$, $(CF_3)_2CHOH$, and $(CF_3)_2CHO^-$, indicate shortening of the C-O bond in fluoroalcohol anions (compared with

R_F -alcohols) and a corresponding increase in the length of the C–F and C–C bonds and an increase in the effective negative charge on the CF_3 and $(CF_3)_2CH$ fragments, which is interpreted as the manifestation of the field effect.³¹ The nucleophilicity of $P(OR_F)_3$ differs little from that of PX_3 ($X = Cl, Br$). This probably explains the inertness of fluoroalkyl phosphites when acted upon by hydrogen halides so that in the synthesis of R_F phosphites from PX_3 there is no need to employ bases in order to bind the HX.

Phosphites based on fluorinated alcohols — tris(2-fluoroethyl) phosphite and tris(2,2,2-trifluoroethyl) phosphite — were first obtained from PCl_3 .^{56,57} It was noted that, in the interaction of PCl_3 with linear R_F -alcohols, mainly trialkyl phosphites are formed together with a small amount of R_F -dialkyl chlorophosphites.^{57–59} Further studies^{60–62} demonstrated that the result depends on the ratio of the initial compounds, the reaction conditions, and the catalyst. At 80 °C and for the ratio $PCl_3 : R_FOH = 1:1$, it is possible to isolate dichlorophosphites, the yield of trialkyl phosphites increasing with increase in temperature. The latter are formed almost quantitatively if the initial alcohol is employed in (2–3)-fold excess. We have frequently noted that the acid phosphite $(R_FO)_2PHO$ is frequently formed as a side product, i.e. the reaction of fluoroalkyl phosphites with PCl_3 does nevertheless occur to a slight extent (up to 10%–15%). It becomes the main reaction in the case of 2-fluoroethanol, which affords bis(2-fluoroethyl) phosphites in a high yield on treatment with PCl_3 .⁶³ The addition of a catalyst (pyridine) accelerates the reaction significantly and improves the yield of the trialkyl phosphite.^{60,61}

The catalytic role of pyridine is seen in relation to the synthesis of tris(hexafluoroisopropyl) phosphite **5**: at 25 °C, hexafluoroisopropyl alcohol does not react with PCl_3 (1:1), on prolonged heating the phosphite **5** is formed in 70% yield,⁶⁴ while in the presence of pyridine the reaction ends after 2 h and the yield of the phosphite **5** is almost quantitative.⁶⁵ Tertiary alcohols such as $(CF_3)_2MeCOH$, do not react with PCl_3 even at 90 °C,⁶⁴ whereas the alcohols R_FMe_2COH [$R_F = CF_3, CHF_2CF_2, CHF_2(CF_2)_3$], taken in an appropriate amount, interact with PCl_3 in the presence of pyridine as catalyst, affording high yields of the dichloro- and monochloro-phosphites $Cl_{3-n}P(OCMe_2R_F)_n$ ($n = 1, 2$).⁶⁶ Pentafluorophenol reacts with PCl_3 on heating to form (depending on the initial reactant ratio) predominantly $C_6F_5OPCl_2$ or a mixture of $(C_6F_5O)_2PCl$ and $P(OC_6F_5)_3$, all three compounds being separated by distillation.⁶⁷

Numerous studies (see, for example, Refs 57 and 68–73) have been made of the interaction of PBr_3 with fluorinated alcohols, but their results are contradictory. On the whole, PBr_3 reacts more readily with fluoro-alcohols than PCl_3 , but the reaction proceeds via several paths. For the ratio $PBr_3 : R_FOH = 1:3$, fluorine-containing trialkyl phosphites are formed in high yields.^{57,73} Attempts to obtain bromo- and dibromo-phosphites were unsuccessful. The preparation of the dibromophosphite $CHF_2(CF_2)_3CH_2OPBr_2$ has been reported in only one study.⁷² In the case of trifluoroethanol and the fluoroalkanols $CH_2F(CH_2)_nOH$ ($n = 1, 2, 5, 7$), an appreciable amount of the fluoroalkyl bromide is produced.^{68–71} Such results are associated both with the greater tendency of P(III) bromides to disproportionate compared with the chlorides and with the more effective

dealkylation of fluoroalkyl phosphites by HBr. Tris(fluoroalkyl) phosphites, dialkyl chlorophosphites, chlorophosphonites, and chlorophosphinites, their fluorinated analogues, asymmetric fluoroalkyl phosphites, and amidophosphite have been obtained in high yields by Arbuzov's method via alkoxides.^{58,64,74} These reactions proceed smoothly and, depending on the initial reactant ratio, lead to mono-, bis-, or tris-(fluoroalkyl) phosphites. However, here too dismutation occurs in certain cases, particularly in the synthesis of fluoroalkyl phosphites with linear groups.

Lithium alkoxides are usually employed in the synthesis of fluoroalkyl phosphites.^{64,74–88} Sometimes (see, for example, San et al.⁷⁴) lithium alkoxide is obtained beforehand from R_FLi [$R_F = CF_2CF_2OCF(CF_3)_2$] and hexafluoroacetone.

Bis(fluoroalkyl) chlorophosphites show a much greater tendency to disproportionate than dialkyl chlorophosphites. Nevertheless they have been obtained in a number of studies from PCl_3 and the corresponding alcohols both in the presence^{59,89,90} and absence^{58,59,66} of a base. Other approaches to the synthesis of bis(fluoroalkyl) chlorophosphites have also been proposed: the exchange reactions of $P(OCH_2CF_3)_3$ with BCl_3 and PCl_3 ,⁵⁸ as well as the exchange reactions of PX_3 with lithium R_F -alkoxides.^{76,89}

Fluoroalkyl difluorophosphites and bis(fluoroalkyl) fluoro-phosphites are obtained by the reactions of PF_3 with R_F -alcohols or R_FOLi and R_FONa ^{77,78,82,91} by fluorinating bis(fluoroalkyl) chlorophosphites and fluoroalkyl dichlorophosphites with SbF_3 .^{81,92,93} The synthesis of the phosphite containing mobile halogen atoms [$(Pr^iO)_2POCCl(CCl_3)CF(CF_3)(SO_2F)$] described by Eleev et al.,⁹⁴ gives rise to doubts owing to the presence of extremely reactive fragments in this compound.

Table 3 presents acyclic P(III) compounds obtained by phosphorylating fluorinated alcohols or their alkoxides by P(III) halides; it also lists cyclic phosphites containing an exocyclic fluoroalkoxy-substituent, as well as compounds obtained from fluorinated diols and their lithium derivatives.^{53,54,56–165}

An extremely interesting example of phosphorylation leading to the isomeric azaphospholines **15** and **16** has been described.¹⁶⁶ On heating, 1,3,5-oxazaphospholine **15** ($\delta_P = 166$ ppm) is converted into 1,3,2-oxazaphospholine **16** ($\delta_P = 112$ ppm)

Phosphorylation of the potassium and silver salts of 2,3,4,5-tetrakis(trifluoromethylthio)pyrrole (HetM) by treatment with PCl_3 , $PhPCl_2$, Ph_2PCl , PI_3 , and PBr_3 afforded fluorinated heterocyclic amidophosphites:¹⁶⁷ Het_2PCl , $PHet_3$, Het_2POEt , Het_nPPh_{3-n} ($n = 1, 2, 3$). The chemistry of these compounds has been surveyed by Weiss.¹⁶⁸

Another interesting type of fluorinated P(III) amides comprises phosphorylated derivatives of hexafluoroacetone imine **17**.¹⁶⁹

$n = 1, 2, 3.$

Table 3 (continued).

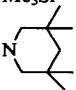

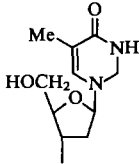

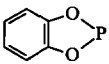

Compound	R _F	R (or NR ₂)	R' (or X)	Ref.
	—	—	—	150

The 1,3,2-diazaphospholines **18** and **19**, containing trifluoroethyl groups, have been obtained from PCl_3 and $(\text{CF}_3\text{CH}_2\text{OC}=\text{NH})_2$.¹⁷⁰

2. Transesterification, transamination, alcoholysis, and acidolysis

Certain R_F phosphites and amidophosphites have been obtained by the transesterification of phosphites with trifluoroethanol.¹⁷¹ Transesterification proceeds more readily in the case of P(III) derivatives with 'acid' residues, whereas the transesterification of $\text{P}(\text{OMe})_3$ is difficult.¹⁷¹

There are few examples of the alcoholysis of P(III) amides by R_F -alcohols.^{113, 143, 144, 172, 173} Bearing in mind that fluorinated alcohols are extremely acid reagents, one may expect that alcoholysis with their participation would be facilitated by virtue of protophilic cooperation.¹⁷² Indeed, the alcoholysis of amides by R_F -alcohols proceeds under comparatively mild conditions^{113, 173} and, depending on the ratio of the P(III) amide and $\text{R}_F(\text{OH})$, leads to full phosphites and mono- and di-amidophosphites, i.e. $\text{P}(\text{OR}_F)_3$, $\text{Et}_2\text{NP}(\text{OR}_F)_2$, and $(\text{Et}_2\text{N})_2\text{POR}_F$, where $\text{R}_F = \text{CHF}_2(\text{CH}_2)_3\text{CH}_2$ or $\text{CHF}_2(\text{CF}_2)_{11}\text{CH}_2$ and also to cyclic phosphites, for example to 1,3,2-dioxaphosphorinane with the exocyclic substituent $\text{OCH}_2\text{C}_3\text{F}_7$.¹⁷²

The alcoholysis of cyclic amides by hexafluoroisopropyl alcohol also takes place under mild conditions at 20 °C in CH_2Cl_2 .^{143, 147}

The interaction of trifluoropropanol with *o*-phenylene trifluoroacetyl phosphite affords a high yield of the corresponding full phosphite.¹⁷⁴

The transamination reaction has been used¹⁷⁵ to obtain fluorinated diazadiphosphetides **20**.

$\text{R} = \text{Et}, \text{Me}$; $\text{Ar} = 2\text{-CF}_3\text{C}_6\text{H}_4, 2,4\text{-F}_2\text{C}_6\text{H}_3, 2\text{-CF}_3\text{-4-ClC}_6\text{H}_3, 2\text{-Me-3-FC}_6\text{H}_3$.

Examples of the acidolysis of the amides $(\text{R}_F\text{O})_2\text{PNEt}_2$ and $(\text{R}_F\text{O})(\text{R}'_F)\text{PNEt}_2$ ($\text{R}_F = \text{C}_2\text{F}_5, \text{C}_3\text{F}_7$; $\text{R}'_F = \text{CF}_3, \text{C}_3\text{F}_7$) by HCl in order to obtain the corresponding R_F chlorophosphites are available in only one communication.¹⁰⁰

3. Reactions involving the addition of dicoordinate phosphorus to alcohols

The R_F phosphites **21** have been synthesised from dicoordinate phosphorus compounds $\text{R}_2\text{N}-\text{P}=\text{NR}$ **22**.¹⁷⁶

$\text{R} = \text{Me}_3\text{Si}, \text{Bu}^t$.

The diamidophosphite **21** is in equilibrium with the amide **23**, the stability of which increases by virtue of the presence of the electron-accepting group R_FO .

4. Reactions of P(III) derivatives with hexafluoroacetone

The reactions of P(III) derivatives with hexafluoroacetone are extremely diverse. The products of these reactions are usually compounds with the phosphorane structure. The reactions of hexafluoroacetone with chloro-, bromo-, and pyro-phosphites, as well as acyl phosphites, in which the final products are P(III) derivatives, are therefore of special interest. The insertion of hexafluoroacetone in a $\text{P}-\text{Hal}$ bond without change in the coordination at the phosphorus atom was first described in 1967.¹⁰⁴ The phosphite **24** ($\text{X} = \text{I}$) formed in this reaction was reduced to compound **25**.

It was later shown that hexafluoroacetone may also be inserted in the $\text{P}-\text{P}$ bond of tetrafluorodiphosphine.¹⁷⁷

A whole range of compounds are formed in the reactions of the diphosphines Me_2PPMe_2 and $\text{Me}(\text{Bu}^t)\text{PPMe}(\text{Bu}^t)$ with hexafluoroacetone owing to the instability of the phosphinites $\text{R}_2\text{PC}(\text{CF}_3)_2\text{OPR}_2$ formed initially.¹⁷⁸

The reactions of phosphines containing a $\text{P}-\text{H}$ bond with hexafluoroacetone have been examined in reviews.^{179, 180}

The interaction of chlorophosphites with $(\text{CF}_3)_2\text{CO}$ was first described by Knunyants and coworkers,¹⁸¹ who obtained σ^4 -dioxaphospholane **26**.

Later the reactions of dialkyl chlorophosphites with $(\text{CF}_3)_2\text{C}=\text{O}$ were investigated in greater detail.^{182, 183} It was shown that at -40°C the insertion products **28** are formed almost quantitatively, whereas on raising the temperature to 20°C a mixture of products **26**–**28** is formed.

It has been suggested that the first reaction step involves one-electron transfer from the phosphite to the ketone, i.e. a radical mechanism operates.[†] When cyclic chlorophosphites are made to react with hexafluoroacetone, only the insertion products **28a**, which are more stable than the phosphites **28**, are obtained.

R = H, Me.

The authors of the studies quoted, suggest that the phosphites **28** enter into the Arbuzov reaction with trimethyl phosphite, forming compound **29**, whereas the phosphites **28** afford compounds **30**.

We believe that the product **30** cannot be obtained from the phosphite **28**. Careful analysis of the experimental part of the study of Heine and Rosenthaler¹⁸² confirms our view. Apparently the first reaction stage is the interaction of hexafluoroacetone with the more nucleophilic trimethyl phosphite. The resulting dipolar ion P^+OC^- **31** reacts as a C-nucleophile with $(\text{RO})_2\text{PCl}$, affording the salt **32**. The elimination of MeCl from the latter leads to the phosphonite **30**.

Bearing in mind the greater electrophilicity of cyclic chlorophosphites compared with the acyclic ones, it is logical to assume that they have sufficient time to 'capture' the dipolar ion P^+CO^- :

The treatment of the mechanism of the formation of compounds **29** and **30** presented here has been confirmed, from our point of view, by results¹⁸⁴ which show that hexafluoroacetone and fluoral react with triethyl phosphite to form compounds **34** and **35** with different types of substitution at the phosphorus atom, because the $\text{P}(\text{OEt})_2$ group migrates in different dipolar ions **36** and **37**. Thermolysis of compound **35** leads to the fluoro-phosphite **30** and the vinyl phosphate **39**.

The reaction of the acyl phosphonite $(\text{EtO})_2\text{PC}(\text{O})\text{R}$ (R = Prⁱ, Bu^t, OMe) with hexafluoroacetone apparently proceeds via the same path.¹⁸⁵ If hexafluoroacetone is taken in excess, the σ^5 -1,3,2-dioxaphospholane **42** is formed.

[†] The proposed mechanism was taken from data presented in Professor Rosenthaler's lecture delivered in Tallin in 1989. More detailed data have not been published.

The complex phosphites **43–45**, incorporating heterocyclic fragments, have been obtained from hexafluoroacetone and phosphines containing the $\text{N}=\text{C}=\text{S}$ and $\text{C}\equiv\text{N}$ groups.^{186–188} It was noted that the interaction of the above reactants entails the isomerisation of the isothiocyanate group to the thiocyanate group and of the nitrile group to the isonitrile group. The structure of compound **43** ($\delta_{\text{P}} = 89.3$ ppm) has been demonstrated by X-ray diffraction.¹⁸⁸ The hexafluoroacetone dimer reacts similarly with $\text{P}(\text{CN})_3$.¹⁸⁹

5. Other approaches to the synthesis of fluoroalkoxyfluoroalkylamino-derivatives of P(III)

Amido- and amino-phosphites are obtained by the interaction of silylated amides and amines with P(III) chlorides:^{155, 188, 190}

The reactions of aminophosphines with R_F -esters of perfluorocarboxylic acids proceed with retention of configuration at the phosphorus atom.¹⁹¹

The interaction of phosphorus trichloride with perfluoro-*tert*-butyl hypochlorite is accompanied by the formation of tris(perfluoro-*tert*-butyl) phosphite.¹⁹²

The chlorine liberated does not then react with the phosphine. Attempts to employ this approach in order to obtain $\text{P}(\text{OCF}_3)_3$ from CF_3OCl and PCl_3 proved unsuccessful, since in this case CF_3OCl behaves as a fluorinating agent, being converted into the very stable COF_2 .¹⁹²

The compounds $(\text{CF}_3\text{O})_3\text{PO}$, $(\text{CF}_3\text{O})\text{P}(\text{O})\text{Cl}$, and $(\text{CF}_3\text{O})\text{P}(\text{O})\text{Cl}_2$ have been detected among the reaction products by mass spectrometry. It was not possible to detect any kind of P(III) derivatives.

Apart from the reactions listed above, the rearrangement $\text{PCO} \rightarrow \text{POC}$ in the series of α -hydroxyphosphines is also used to obtain fluorinated phosphines. This reaction was first described in 1974 for (1-hydroxyperfluoroisopropyl)diphenylphosphine **47** — the product of the reaction of diphenylphosphine with hexafluoroacetone.¹⁷⁷

It was found that the rearrangement of the phosphine **47** is effectively catalysed by tertiary phosphines and that the higher the nucleophilicity of the phosphine the faster the rearrangement. The possibility of the occurrence of this reaction for the products of the reaction of bis(*tert*-butyl)phosphine and *tert*-butylmethylphosphine with hexafluoroacetone has been indicated,¹⁹³ but more detailed information has not been published.

It has been suggested¹⁶⁰ that $\text{CF}_3\text{CH}_2\text{OSiMe}_3$ be used for the synthesis of fluoroalkyl phosphites. The corresponding phospholane was obtained in a high yield.

6. Bis(fluoroalkyl) phosphites

The classical method of synthesis of dialkyl phosphites — the reaction of P(III) chloride with alcohols — cannot be extended to fluorine-containing dialkyl phosphites. The only exception is the reaction of P(III) chlorides with $\text{FCH}_2\text{CH}_2\text{OH}$.⁶³ The synthesis of phosphites containing a large number of fluorine atoms by this method is impossible because of the difficulty of splitting off the fluorinated alkyl group. Indirect approaches to the synthesis of bis(fluoroalkyl) phosphites by the reaction of $\text{R}_\text{F}\text{OH}$ with PCl_3 were therefore developed. Thus bis(fluoroalkyl) phosphites have been obtained by the reaction of PCl_3 with $\text{R}_\text{F}\text{OH}$ in the presence of methanol¹⁹⁴ or *tert*-butyl alcohol.

The products **52–54** are liquids, which are separated by distillation at the usual pressure. A quartet ($\delta_P = 194.4$ ppm, $^3J_{\text{PF}} = 24$ Hz), a septet ($\delta_P = 143$ ppm, $^3J_{\text{PF}} = 22$ Hz), and a decet ($\delta_P = 85$ ppm, $^3J_{\text{PF}} = 20$ Hz) correspond to them respectively in the ^{31}P NMR spectra.²¹⁷

$\text{CF}_3\text{SP}(\text{CF}_3)_2$,^{218, 219} $\text{CF}_3\text{SeP}(\text{CF}_3)_2$,²¹⁸ CF_3SPF_2 ,²²⁰ CF_3SePF_2 ,²²¹ $\text{PhP}(\text{SeCF}_3)_2$,²²² $(\text{CF}_3\text{Se})_2\text{P} - \text{P}(\text{SeCF}_3)_2$,²²² $\text{P}(\text{SeCF}_3)_3$,²²² and $\text{PhP}(\text{SCF}_3)_2$ ²²³ were synthesised similarly. The initial compounds employed were the corresponding phosphorus iodides. $\text{Hg}(\text{SeCF}_3)_2$ was used to synthesise the selenides. In the ^{31}P NMR spectrum, a decet with $\delta_P = 65$ ppm ($^3J_{\text{PF}} = 14.9$ Hz) corresponds to the selenophosphite $\text{P}(\text{SeCF}_3)_3$.²²⁰ This compound is unstable, its decomposition resulting in the segregation of $\text{CF}_3\text{SeSeCF}_3$ and the formation of a polymer. The ^{19}F and ^{31}P NMR spectra of the selenophosphinite $(\text{CF}_3)_2\text{PSCF}_3$ have also been described.²²⁴

Subsequently several approaches were developed for the synthesis of fluorinated thio- and seleno-phosphites. Thus it has been suggested that the reaction of polyphosphines with CF_3SSCF_3 ^{225, 226} and $\text{CF}_3\text{SeSeCF}_3$ ²²² be used for the synthesis of CF_3E derivatives of $\text{P}(\text{III})$, in which $\text{E} = \text{S}$ or Se .

Fluorinated thiophosphines have been obtained by the reaction of R_FSCl with white phosphorus.²¹⁷

The synthesis of an organoboron derivative of thiophosphine has been described.^{225, 226}

The reaction of trifluoromethanesulfonyl chloride with methyl dichlorothiophosphite involves the substituent CH_3S .²²⁷

The interaction of PCl_5 with $\text{Pb}(\text{SC}_6\text{F}_5)_2$ constitutes yet another unusual approach to the synthesis of thiophosphites. Tris(pentafluorophenyl) thiophosphite **55** has been obtained by this procedure.^{97, 228} The phosphorane **56** formed initially in this reaction is extremely unstable and decomposes to the thiophosphite **55** and a disulfide.

The chemistry of the CF_3E derivatives of $\text{P}(\text{III})$ has been only slightly developed. The reactions with S_8 ,^{219, 223, 229} EtOH ,²¹⁶ and

$\text{CF}_n\text{Cl}_{3-n}\text{SCl}$ ($n = 1, 2, 3$)²¹⁷ and the oxidation of the phosphite **54**²²⁹ have been studied. The complexes of perfluoroalkyl-substituted phosphites $(\text{CF}_3)_2\text{PECF}_3$ ($\text{E} = \text{S}, \text{Se}$) with molybdenum and manganese carbonyls have been synthesised.^{230, 231}

c. Perfluoroalkyl amidophosphites

Perfluoroalkylaminophosphines **57** ($n = 1, 2, 3$) have been obtained by the exchange reactions of tris(trifluoromethyl)phosphine with $[(\text{CF}_3)_2\text{N}]_2\text{O}$.²³²⁻²³⁴

The interaction of the stable bis(trifluoromethyl)nitroxyl radical with $\text{E}(\text{III})$ ($\text{E} = \text{P}, \text{As}, \text{Sb}$) derivatives has been investigated.²³⁵⁻²³⁹ $\text{P}(\text{III})$ compounds were obtained only when phosphorus hydrides,²³⁵ iodides,^{236, 237} and cyanides²³⁸ were used as the initial compounds. It is suggested that the reactions proceed via a radical mechanism.

The amidophosphite $(\text{Me}_2\text{N})_2\text{PON}(\text{CF}_3)_2$ can be obtained from hexamethylphosphorous triamide and bis(trifluoromethyl)nitroxyl.²⁴⁰

The analogous arsenic and antimony compounds are more stable than the phosphorus compounds.^{239, 241}

Other perfluoroalkyl and nitrogen derivatives, for example $(\text{CF}_3)_2\text{NONO}$ and CF_3NO , are not only inserted into the $\text{CF}_3 - \text{P}$ bond but also oxidise the compounds formed to $\text{P}(\text{V})$ derivatives.²⁴¹⁻²⁴³ Bis(trifluoromethyl)phosphine adds to CF_3NO with retention of the coordination at the phosphorus atom, forming the amidophosphine $(\text{CF}_3)_2\text{PN}(\text{OH})\text{CF}_3$.²⁴³

IV. Reactions of fluoroalkyl phosphites

As a result of the presence of the fluorinated substituent R_F , fluoroalkyl phosphites and related compounds (phosphonites, phosphinites, etc.) exhibit a reduced reactivity in nucleophilic reactions and an enhanced reactivity in electrophilic reactions compared with alkyl phosphites. The characteristic features of the chemical behaviour of the R_F -derivatives of $\text{P}(\text{III})$ are caused by the difficulty of cleaving the $\text{O} - \text{R}_F$ bond owing to the strong electron-accepting properties of polyfluorinated groups. The inertness of the polyfluorinated radicals derived from the fluoroalkanol $\text{CHF}_2(\text{CF}_2)_n\text{CH}_2\text{OH}$ ($n = 1, 3$)²⁴⁴ in reactions involving the formation of polyfluoroalkylcarbenium ions^{60, 245} provides grounds for the hope that stable phosphoranes may be obtained from them. The chemistry of the latter has been developed vigorously precisely as a result of the introduction of fluorinated substituents at the phosphorus atom.²⁴⁶⁻²⁴⁸

1. Reactions of fluoroalkyl phosphites with retention of the coordination the phosphorus atom

Reactions involving nucleophilic substitution at the phosphorus atom, which behaves as an electrophilic centre, must take first place among the reactions involving retention of the coordination at the phosphorus(III) atom. Such reactions are extremely characteristic of R_F -phosphites. They include alcoholysis, trans-

Dimethyl 1-hydroxymethylphosphonate interacts readily with tris(tetrafluoropropyl) phosphite, forming the phosphite $(\text{MeO})_2\text{P}(\text{O})\text{CH}_2\text{OP}(\text{OCH}_2\text{CF}_2\text{CHF}_2)_2$.¹¹³ Tris- and bis-(fluoroalkyl) phosphites proved to be exceptionally mild phosphorylating agents in the synthesis of oligonucleotides.^{88, 114, 249–256} It has been suggested that tris(hexafluoroisopropyl) phosphite be used as the most convenient reagent for the synthesis of DNA oligomers by the phosphite method. Various type **58–61** phosphites are obtained initially from the deoxyribonucleoside phosphite.

A mild synthesis of oligodeoxyribonucleotides employing the phosphites **62**–**64** as key intermediates has been described.¹¹⁴

The ready hydrolysis of phosphites or the reactions with nucleosides are used in the synthesis of *H*-phosphonate-nucleotides and oligonucleotides. Data on the phosphorylation of oligonucleotides by certain fluorinated P(III) derivatives can be found in a recently published review.²⁵⁷ It has also been suggested that bis(hexafluoroisopropyl) phosphite,^{199, 201} bis(trifluoroethyl) phosphite,^{195, 196, 198, 258, 259} and bis(trifluoroethyl) trimethylsilyl phosphite²⁶⁰⁻²⁶³ be used for the phosphorylation of oligonucleotides and natural and common alcohols. The P(III) derivatives **65** and **66** are formed initially in the phosphorylation of nucleosides by bis(trifluoroethyl) trimethylsilyl phosphite.²⁶⁰

The nucleophilic substitution reactions of a series of phosphites containing the perfluoropinacol fragment have been investigated.^{264, 265} The electrophilicity of the phosphorus atom in these systems is so high that it was possible to obtain the relatively stable bicyclic phosphoranide intermediate **67**.

The reactions involving the phosphorylation of the alcohols by R_F phosphites proceed under very mild conditions (20 °C). Thus the reaction of the amidophosphite $(Pr_2N)_2POCH(CF_3)_2$ **69** with deoxyribonucleosides takes place selectively with formation of diisopropylamine.¹²¹

In certain studies, bases such as pyridine have been used as catalysts of the phosphorylation by R_F phosphites,¹⁹⁹⁻²⁰¹ while triethylamine has been used as the catalyst for reactions involving the addition of bis(fluoroalkyl) phosphites to carbonyl compounds such as CF_3CHO , $CF_2ClCOCFCl_2$, $(ClCF_2)_2C=O$, $(CF_3)_2C=O$,²⁶⁶ and $PhC(O)CHCl_2$ ²⁶⁷ and the alkylation of such phosphites by halogen-containing crown-ethers.^{268,269} In the alkylation of bis(trifluoroethyl) phosphite by functionally substituted alkyl bromides, sodium hydride is added to the reaction mixture.²⁷⁰ In many cases, the reaction is carried out for a long time at a high temperature (80–140 °C).

Sulfur adds to tris- and bis-(fluoroalkyl) phosphites with much greater difficulty than to the corresponding alkyl phosphites. The reaction takes place only after prolonged heating in dioxane^{61, 62, 164, 292} or pyridine.²⁹³ Only one reaction involving the addition of selenium to a phosphite, leading to the selenophosphate $\text{CF}_3\text{CH}_2\text{OP}(\text{Se})(\text{OCH}_2)_2$, has been described in the literature.²⁹⁴

2-Nitro-1,1,3,4,4-pentachlorobuta-1,3-diene, which has electrophilic properties and contains fairly mobile terminal chlorine atoms, reacts fairly readily with fluoroalkyl phosphites, but, in contrast to other types of nucleophiles (for example, amines), only its nitro-group is involved. This results in the oxidation of phosphites to phosphates in high yields.²⁹⁵ The rate of reaction increases with increasing nucleophilicity of the phosphite.

b. The Staudinger reaction

Fluoroalkoxy-derivatives of P(III) enter into the Staudinger reaction with greater difficulty than the R_H analogues, the type 75 iminophosphoranes formed are stable and do not undergo imide-amide rearrangement.²⁹⁶⁻³⁰¹

$$R_F = CF_3CH_2.$$

This course of the reaction becomes understandable in the light of data obtained recently on the imide–amide rearrangement,³⁰² which proceeds via an intermolecular chain mechanism with the intermediate formation of carbonium ions. Thus the rearrangement of the iminophosphorane **76** takes place on heating.^{107, 108}

It was found that the result of the Staudinger reaction for the cyclic fluoroalkyl phosphites **77** — derivatives of salicylic acid — depends significantly on the nature of the exocyclic substituent R_F at the phosphorus atom.^{103,303} If $R_F = C_6F_5$, then the intermediate iminophosphorane **78** readily undergoes the imide — amide rearrangement, affording σ^4 -1,3,2-oxazaphosphorinane **79**, but, if $R_F = CF_3CH_2$ or $CHF_2(CF_2)_nCH_2$ ($n = 1, 3$), then the intermediate **78** is almost fully converted into the diazadiphosphetidine **80**. When catechol derivatives are used, only the diazadiphosphetidines **80** are formed.

$$X = O, COO; R_F = CF_3CH_2, CHF_2(CF_2)_nCH_2 (n = 1, 3), C_6F_5.$$

c. The Arbuzov reaction and its nonclassical variants

Tris(perfluoroalkyl) phosphites do not isomerise even at 250 °C.^{60, 62} The Arbuzov reaction of tris(tetrafluoropropyl) phosphite with MeI (1 : 1 ratio) takes place at 220 °C in a stainless steel test tube,^{60, 62, 304} whilst the iodide $\text{CHF}_2\text{CF}_2\text{CH}_2\text{I}$ does not react with the above phosphite.⁶² The kinetics of such reactions have been investigated³⁰⁵ and it has been shown that the rate-determining stage is nucleophilic attack on the P(III) atom. The decrease in the nucleophilicity of the latter is apparently more important for the Arbuzov reaction than the enhancement of the electrophilicity of the C_α atom in the $\text{R}_\text{F}\text{CH}_2\text{O}$ group, which favours elimination via an $\text{S}_{\text{N}}2$ mechanism. It is of interest to note that, in the reaction of the phosphite $(\text{EtO})_2\text{POCH}_2\text{CH}_2\text{F}$ with EtI, a mixture of the phosphonates $(\text{EtO})_2\text{P}(\text{O})\text{Et}$ and $(\text{EtO})(\text{CH}_2\text{FCH}_2\text{O})\text{P}(\text{O})\text{Et}$ is formed, whereas the reaction with MeI affords only the phosphonate $(\text{EtO})(\text{CH}_2\text{FCH}_2\text{O})\text{P}(\text{O})\text{Me}$.⁶³ The reaction temperature decreases after the addition of MeOH,³⁰⁴ which is associated with the fact that, not the initial phosphite, but the transesterification product interacts with RI.

In the presence of two alkyl substituents at the P(III) atom, its fluoro alkoxy-derivatives form the quasi-phosphonium salts **81–83** with MeI.^{122, 125, 177, 178, 306}

$$R^1, R^2 = \text{Me, Et, Ph, Bu}^t.$$

These salts do not decompose up to 100–140 °C, which is due, according to the authors, to the electron-accepting influence of the CF₃ groups on the α -carbon atom.

However, it is known that electron-accepting substituents accelerate the substitution reaction via an S_N2 mechanism,³⁰⁷ so that, for example, the stability of compound **83** may be associated either with the effective shielding of the C_α atom in the hexafluoroisopropyl group or with the fact that the elimination stage has significant features of an S_N1 process.³⁰⁸

The preparation of the salt **84**, stable up to 150 °C, has been reported.³⁰⁶

For the salt **84**, the exchange processes do not occur even at 100–150 °C.

The stable quasi-phosphonium salt **86** has been obtained by the interaction of MeI with the imine **85**.^{125, 306} The authors believe that the stability of the salt **86** and its analogues **87** is due to the delocalisation of the positive charge on the phosphorus atom.

$\text{R}^1 = \text{Me}_2\text{N}$, $\text{R}^2 = \text{CF}_3\text{CH}_2\text{O}$ or Ph , $\text{R}^3 = \text{CF}_3\text{CH}_2\text{O}$.

In the quasi-phosphonium salts examined above, an electron-donating amide or alkyl group was always present together with the fluorinated substituent at the phosphorus atom, stabilising the positive charge on the latter.

It has been shown³⁰⁹ that tris(fluoroalkyl) phosphites are capable of forming the quasi-phosphonium salts **88** with methyl triflate.

$\text{R}_\text{F} = \text{CF}_3\text{CH}_2$, $\text{CHF}_2\text{CF}_2\text{CH}_2$, $\text{CHF}_2(\text{CF}_2)_3\text{CH}_2$.

The latter are converted into the phosphoranes **89** in a high yield. The interaction of R_F phosphites is much slower than that of R_H -phosphites.^{310–312} The phosphite **5** with $\text{R}_\text{F} = (\text{CF}_3)_2\text{CH}$ reacts at 120–150 °C,¹⁰³ while the phosphites **2** and **4** with $\text{R}_\text{F} = \text{CF}_3\text{CH}_2$ and $\text{CHF}_2(\text{CF}_2)_n\text{CH}_2$ ($n = 1, 3$) react at 20 °C. The salts **88** formed have significantly weaker alkylating properties than R_H -phosphonium triflates. This follows from the inertness of tris(fluoroalkyl) phosphites in relation to fluoroalkylphosphonium triflates. Even in the presence of 50 mass % of the triflates **88** in the reaction mixture, the latter do not react with the initial phosphites, whereas R_H phosphites react via a cationic chain mechanism at an exceptionally high rate.^{310–312} Another significant difference between the R_F -quasi-phosphonium salts and the R_H -salts is the ability to react with R_F -alcohols at the phosphorus atom, i.e. to phosphorylate alcohols, whereas R_H -phosphonium triflates alkylate alcohols.³¹³

In contrast to acyclic fluoroalkyl phosphites, the cyclic phosphites **90** — derivatives of salicylic acid — react more slowly with methyl triflate. This has been established^{37, 103} in a study of

the competing reaction of the phosphites **4** and **90** ($\text{R}_\text{F} = \text{CHF}_2\text{CF}_2\text{CH}_2$) with $\text{MeOSO}_2\text{CF}_3$ by the ^{31}P NMR method. The stability of the cyclic salts **91** was found to be lower than that of the acyclic analogues **88**.

$\text{R}_\text{F} = \text{CF}_3\text{CH}_2$, $\text{CHF}_2\text{CF}_2\text{CH}_2$.

The salts **91** behave in this reaction merely as acylating agents, forming the phosphonate **92** in the reaction with tetrafluoropropanol.

The reactions of carbon tetrachloride with fluoroalkyl phosphonites^{105, 314} take place after prolonged heating in CH_3CN , while those with tris(fluoroalkyl) phosphites do not occur at all. The interaction of the silyl amidophosphonite **93** with CCl_4 leads to the PCl -iminophosphine **94**.³¹⁵

It has been noted that the elimination of CHCl_3 in this reaction is promoted by nonpolar solvents and by the absence of steric shielding of the protons of the CH_2Si fragment in compound **93**.

The interaction of N -benzoyltrifluoroacetimidoyl chloride **95** with tris(tetrafluoropropyl) phosphite proceeds with formation of σ^5 -1,4,2-oxazaphospholine **96** ($\delta_\text{P} = -41.7$ ppm) and the phosphonate **97**.³¹⁶

$\text{R}_\text{F} = \text{CHF}_2\text{CF}_2\text{CH}_2$.

Striking differences between cyclic and acyclic fluoroalkyl phosphites, on the one hand, and the corresponding unsubstituted phosphites, on the other, have been observed in the reactions of these compounds with the halogens, which lead, depending on the structure of the $\text{P}(\text{III})$ derivative, to different products —

halophosphates **98**, *P*-haloimines **99**, and the phosphoranes **100** and **101**.^{57, 64, 65, 76, 77, 83, 87, 96, 98, 284, 317–319}

$\text{X} = \text{Cl}, \text{Br}; \text{R}_\text{F} = \text{CF}_3\text{CH}_2, \text{CF}_3\text{CMe}_2, (\text{CF}_3)_2\text{CMe}, \text{CF}_3\text{MeCH},$
 $\text{CHF}_2\text{CF}_2\text{CH}_2, \text{CHF}_2(\text{CF}_2)_3\text{CH}_2$; ^{57, 284, 315}

$\text{R}_\text{F} = \text{CF}_3\text{CMe}_2$,⁶⁴ $\text{CHF}_2\text{CF}_2\text{CH}_2$,²⁸⁴

$\text{R}_\text{F} = (\text{CF}_3)_2\text{CH}$ ^{65, 76, 77, 96, 317}; C_6F_5 , ^{98, 316}

It is noteworthy that the compounds containing the $\text{CH}(\text{CF}_3)_2$ substituent react with the halogens to form the stable phosphoranes **100** and **101**.

The interaction of tris(tetrafluoropropyl) phosphite with bromine has been investigated by the dynamic ³¹P NMR method (Scheme 2).²⁸⁴ As in the case of triethyl phosphites,^{320, 321} this results in the formation of the quasi-phosphonium intermediate **102**. A further three quasi-phosphonium salts **103–105** were detected in the reaction mixture, and, depending on the ratios of the reactants and the order in which they were mixed, different phosphates **106–108** and the bromophosphite **109** were obtained.²⁸⁴

Scheme 2

$\text{R}_\text{F} = \text{CHF}_2\text{CF}_2\text{CH}_2$.

Despite the presence of electron-accepting substituents destabilising the phosphonium centre, the stability of the bromide **102** is higher than that of its close analogue $(\text{EtO})_3\text{P}^+\text{Br}^-$ **110**. In this case, it is impossible to explain the greater stability of the fluorinated salt by the increase in the fraction of the phosphorane formed in the possible phosphonium \rightleftharpoons phosphorane equilibrium because, according to ³¹P NMR spectroscopic data, the chemical shifts, which are very sensitive to the position of equilibrium

between phosphonium salts and phosphoranes, are virtually identical for the two salts **102** and **110** ($\delta_\text{P} = 13–15$ ppm).[†] This effect is apparently due to the fact that substitution at the C_α atom has certain features characteristic of an $\text{S}_\text{N}1$ process. Only in this case would fluorinated radicals reduce the rate of cleavage.

Another specific difference in the behaviour of the salts **102** and **110** is the ability of the former to enter into disproportionation reactions with the initial phosphites.

The tricyclic phosphites **111** also afford the phosphoranes **112**.^{48, 49}

$\text{X} = \text{Cl}, \text{Br}; \text{R}_\text{F} = \text{CF}_3, \text{CHF}_2\text{CF}_2, \text{CHF}_2(\text{CF}_2)_3$.

The stability of the phosphoranes increases significantly if a perfluoropinacol fragment is introduced at the phosphorus atom.^{155, 157, 158, 160, 162} It effectively stabilises the bipyramidal phosphorus structure.^{162, 319, 322} The stabilisation effect is so strong that it is actually possible to obtain halophosphoranes with substituents such as CH_2Ph ,¹⁵⁷ NH_2 , NHBu^t , $\text{N}(\text{SiMe}_3)_2$, NMe_2 , and OSiMe_3 .^{155, 160} The thermolysis of these compounds proceeds in an extremely unusual manner:

$\text{R} = \text{Me}, \text{Bu}^t$.

In the case of compound **113**, the latter initially disproportionates to the phosphoranes **114** and **115** after which the phosphorane **115** is converted into the phosphate **116**.¹⁶⁰

The catechol derivative **117** reacts with bromine to form the relatively stable phosphorane **118**, its stability being significantly higher than that of the bis(ethoxy)derivative,³²⁰ which readily decomposes to the phosphate via the Arbuzov reaction. In an excess of bromine, the phosphorane **118** forms the quasi-phosphonium salt **119**. When the phosphorane **118** is allowed to stand (at 20 °C), it disproportionates with formation of P(III) and P(V) derivatives.³²³

[†] The value $\delta_\text{P} = 2$ ppm quoted ⁴⁸ for compound **102** is erroneous.

The hexafluoroisopropyl derivative **120** disproportionates to the phosphoranes **121** and **122**, the latter being subsequently converted into a mixture of the phosphoranes **121** and **123**.³²⁴

The fluorination of acyclic fluoroalkyl phosphites by fluorine,¹³² the azide $\text{CF}_3\text{CHFCF}_2\text{N}_3$,³²⁵ or perfluoroepoxypropane³²⁶ leads to difluorophosphoranes. The reaction of bis(tetrafluoropropyl) phosphite with the perfluoroepoxypropane dimer and trimer proceeds with the preferential formation of the tetrafluoropropyl ester of monofluorophosphorous acid and bis(tetrafluoropropyl) fluorophosphate.³²⁷

Bromocyanogen reacts slowly with R_F -alkyl phosphites, forming the dicyanophosphoranes **124** and the bromophosphates **107**,^{328, 329} whereas only phosphates are obtained from the R_H phosphites.³³⁰ It has been suggested that the process proceeds via the intermediate **125a**.

$\text{R}_F = \text{CHF}_2\text{CF}_2\text{CH}_2, \text{CHF}_2(\text{CF}_2)_3\text{CH}_2.$

The nature of the intermediate (**125a** or **125b**) was established when the above reaction was carried out in the presence of a third reagent — chloral.³³¹ The phosphates **126** and **127** and the phosphorane **128** were obtained in this case, indicating the initial appearance of the quasi-phosphonium intermediate **125b**, which may react with the initial bromocyanogen. The interaction of the intermediates **124**, **125b**, and **102** with chloral leads to the final compounds **126**–**128**. The formation of the phosphates **126** and **127** includes the initial appearance of the salts **129** and **131** and their subsequent conversion via ligand exchange into the phosphonium salts **130** and **132**.

It has been shown^{329, 332, 333} that *N*-chloroamines react with R_F -alkyl phosphites to form iminophosphines, but the intermediate monochlorophosphoranes were not detected.

$\text{X} = \text{CF}_3\text{CH}_2\text{O}; \text{CHF}_2\text{CF}_2\text{CH}_2\text{O};$

An interesting approach to the synthesis of fluoroalkoxyphosphoranes has been proposed.^{334–337} It consists in the successive treatment of tris(trifluoroethyl) phosphite with diisopropylchloroamine and bisphenol, the role of a base being assumed by the amine produced during the reaction. The eight-membered heterocyclic compounds **133**–**135** were obtained in this way.

The structure of compound **134** was demonstrated by X-ray diffraction. The determination of the conformations of these phosphoranes was important for the understanding of the interaction of phosphates with the active sites of enzymes in the presence of sulfur-containing aminoacids.³³⁸

The interaction of P(III) derivatives with the halogens and sulfur(II, IV, VI) halides has many features in common and represents a nonclassical variant of the Arbuzov reaction.^{330, 339} In contrast to the halogens, sulfur halides have two different centres (the sulfur and halogen atoms), which are readily polarisable and are accessible to nucleophilic attack by the P(III) atom.³³⁹

Considerable attention has been devoted in the literature (see, for example, Refs 148 and 340–345) to the reactions of sulfur(II, IV, VI) chlorides with R_F -derivatives of P(III). Thus benzenesulfonyl chloride interacts with R_F -phosphites to form mixtures of compounds.³⁴²

$R_F = CHF_2(CF_2)_nCH_2$, $n = 1, 3$;

(a) 20 °C; (b) –50 °C, R_FOH , NEt_3 .

The intermediate **136** was not detected, but its presence was deduced from the formation of the unstable monothiophosphorane **137** as a result of the treatment of the reaction mass with a mixture of the corresponding alcohol and triethylamine at –50 °C.

The interaction of acyclic and cyclic fluoroalkyl phosphites with dialkyl phosphonosulfonyl chlorides **138** is accompanied by the deoxygenation of the latter.^{103, 148, 344, 345} The catechol derivatives **117** also react similarly with compounds **138**^{148, 344, 345} with the preferential formation of the phosphate **139** and the chlorothiophosphate **140**.

$R = Me, Et, Pr$; $R_F = CHF_2CF_2CH_2, CF_3CH_2, CHF_2(CF_2)_3CH_2$.

The reaction probably begins with halogenophilic attack on the phosphorus atom and the formation of the quasi-phosphonium salt **141**, which is in equilibrium with the phosphorane **142**. The latter is converted via the salt **143** into the main products **139** and **140**. The formation of small amounts of the phosphorylated phosphoranes **144** and of the *o*-phenylene phosphite **145** during the disproportionation process, which has been investigated in detail in relation to the reactions of the phosphites **117** with bromine, also constitutes evidence in support of the formation of the chlorophosphorane **142**.³²³

The mechanism of the reaction of the neopentyl *o*-phenylene phosphite **146** with the sulfonyl chloride **138** ($R = Et$), which also leads mainly to the phosphates **140** ($R = Et$) and **147**, has been recently investigated by dynamic ³¹P NMR (from 100 °C).³⁴⁶ The authors were able to detect the intermediate **148**, which is analogous to the phosphorane **142** postulated above. On this basis, it was concluded that the sulfur atom in compound **138** is initially attacked with subsequent two-step ligand exchange.

However, despite such a low reaction temperature, the intermediates **149**–**151** were not detected. In our view, the data presented in no way disprove the halogenophilic deoxygenation mechanism and cannot serve as proof that the sulfur atom is attacked. The high rates of the reactions of the sulfonyl chloride **138** with both the usual and fluorinated phosphites may indicate orbital control in these reactions or initial one-electron transfer from the phosphorus atom to the $\sigma_{\text{S-Cl}}^*$.

In the reactions of sulfonyl chloride with fluoroalkyl phosphites, the formation of chlorophosphates is accompanied by oxidation to phosphates.³⁴⁴ It has been suggested that the chlorophosphonium salt **152** formed initially enters into nucleophilic substitution reactions either at a carbon atom [path (a), intermediate **153**] or at the phosphorus atom [path (b), intermediate **154**].

It has been noted³⁴⁴ that the high electronegativity of the $\text{R}_\text{F}\text{O}$ [$\text{R}_\text{F} = \text{CHF}_2(\text{CF}_2)_n\text{CH}_2$] group hinders the elimination of R_F in the reaction with SO_2Cl_2 and promotes the formation of oxidation products. However, if the elimination stage were bimolecular, as described above, then the electron-accepting substituent R_F would be split off easily. It has to be assumed that the formation of the $\text{P}=\text{O}$ bond in the given reaction must take place before the attack by the Cl^- ion on R_F , i.e. the process should possess features of an $\text{S}_\text{N}1$ mechanism of fission of an alkyl group, which is naturally hindered by electron-accepting substituents such as fluorine atoms. It is doubtful if the intermediate **154** has the character of a phosphorane. Monochlorophosphoranes have been obtained only for $\text{R}_\text{F} = \text{CH}(\text{CF}_3)_2$ ³⁴¹ and in all the remaining cases only quasi-phosphonium salts are formed from acyclic fluoroalkyl phosphites. Ligand exchange in the salt **152** and nucleophilic attack on the sulfur atom are therefore more probable, as shown in relation to trifluoroethyl chlorosulfate.

where $\text{R}_\text{F} = \text{CF}_3\text{CH}_2, \text{CHF}_2\text{CF}_2\text{CH}_2, \text{CHF}_2(\text{CF}_2)_3\text{CH}_2, (\text{CF}_3)_2\text{CH}, \text{C}_6\text{F}_5$.

The reactivity of trifluoroethyl chlorosulfate towards fluoroalkyl phosphite is lower than that of sulfonyl chloride.^{103, 344}

According to the authors, the reactions involve the initial formation of the chlorophosphonium salt **155** and subsequent ligand exchange with formation of the intermediate **156**, the decomposition of which leads exclusively to a phosphate (the yield is quantitative).

The fact that the first stage in the reaction of trifluoroethyl chlorosulfate with R_F -phosphites is nucleophilic attack on the chlorine atom is confirmed by the results of the reaction of trifluoroethyl chlorosulfate with the silyl phosphite **157**, which leads to a bis(fluoroalkyl) chlorophosphate.³⁴⁴

In contrast to the reactions examined above, the interaction of trifluoroethyl chlorosulfate with fluoroalkyl *o*-phenylene phosphites **117** takes place with formation of the phosphoranes **158** and the phosphates **139**. The phosphoranes **158** are obtained as a result of ligand exchange between the initial phosphite and the intermediate chlorophosphorane **159**. However, the main path in the reaction of the latter is transition via the salt **160** to the phosphate **139**.

The chlorosulfurane **161** readily reacts with R_F phosphites to form the phosphoranes **162** and **163**,^{340,344} which are converted into compounds **164**–**166** as a result of exchange reactions with the initial chloride **161** and disproportionation.

Thus the reactions of fluoroalkyl phosphites with sulfur chlorides and bromine have shown that a whole series of characteristic features, associated primarily with the low nucleophilicity of the P(III) atom and the hindrance to the elimination of the fluoroalkyl group from quasi-phosphonium intermediates, are typical of fluorinated P(III) derivatives. This leads to new reaction paths and unusual ways in which halophosphoranes and quasi-phosphonium salts are stabilised, such as transition to P(V) and P(III) compounds via exchange and disproportionation reactions.

It is known from theoretical studies and data on the stability of phosphorus(V) compounds^{246,248} that electronegative groups stabilise the phosphorane molecule. As we have already noted, fluoroalkoxy-groups have electron-accepting properties and effectively stabilise phosphorane structures and this is the reason why much attention has been devoted in the literature to the synthesis of stable phosphoranes from R_F -phosphites.

The stable phosphoranes **167** have been synthesised^{95–97,135,140,150} via the reaction of R_F -phosphites with sulfenic acid esters (Scheme 3).

Scheme 3

R^1	R^2	R^3
CF_3CH_2O	CF_3CH_2O	CF_3CH_2O
Ph	CF_3CH_2O	CF_3CH_2O
Ph	Ph	CF_3CH_2O
C_6F_5O	C_6F_5O	C_6F_5O
$(CF_3)_2CHO$	$(CF_3)_2CHO$	$(CF_3)_2CHO$
$(CF_3)_2CHO$	$(CF_3)_2CHO$	Ph
$(CF_3)_2CHO$	Ph	Ph
	$-OCH_2CH_2O-$	$(CF_3)_2CHO$
	$-SCH_2CH_2S-$	$(CF_3)_2CHO$
	$-MeNCH_2CH_2NMe-$	$(CF_3)_2CHO$

It was suggested that, in the interaction of R_F -phosphites with sulfenic acid esters, the P atom is inserted in the S–O bond with formation of the alkoxythiophosphorane **168**. Such mixed phosphoranes have been obtained for $R^1 = R^2 = R^3 = CF_3CH_2O$ and $(CF_3)_2CHO$ ^{95,96} ($\delta_P = 50–54$ ppm). Next, the phosphorane **168** reacts via path (a) with yet another $PhSOR_F$ molecule, forming the pentaalkoxyphosphorane **168**. Path (b) operates for substituents at the phosphorus atom with more pronounced electron-donating properties.

The interaction of the hexafluoroisopropyl ester of sulfoxylic acid with fluoroalkyl phosphites results in the formation of a mixture of products.³⁴¹

3. Reactions of fluoroalkoxy-derivatives of P(III) with carbonyl compounds and their aza-analogues

The reactions of fluoroalkoxy-derivatives of P(III) with carbonyl compounds have been investigated for a comparatively small number of carbonyl compounds, among which most attention has been devoted to hexafluoroacetone. This is not fortuitous, because the latter forms with various P(III) derivatives σ^5 -1,3,2- or σ^5 -1,4,2-dioxaphospholanes, which are of great interest in view of their stability and the possibility of studying the structures of pentacoordinate phosphorus compounds, the role of which in biochemical processes is very important.^{143,347} The importance of fluoroalkoxyphosphoranes in organic synthesis has also been increasing.³⁴⁸

a. Bis(fluoroalkyl) phosphites

Bis(fluoroalkyl) phosphites are stronger acids than dialkyl phosphites.⁴⁷ The nucleophilicity of phosphorus in the P(III)-tautomeric form of bis(fluoroalkyl) phosphites is lower than in dialkyl phosphites.

The products of the phosphonate–phosphate rearrangement (hexafluoroisopropyl phosphates) have been obtained in the interaction of bis(fluoroalkyl) phosphites with $(CF_3)_2C=O$ in the presence of NEt_3 .^{160,266} Fluorodialkyl phosphites readily add to fluoral and chloral with formation of 1-hydroxyphosphonates,^{62,208} which are converted into phosphates or vinyl phosphates on heating in the presence of NEt_3 . Hexafluoroacetone *N*-benzenesulfonylimine reacts with bis(tetrafluoropropyl) phosphite to form a stable 1-aminoalkylphosphonate.³⁴⁹

The kinetics and mechanism of the addition of bis(fluoroalkyl) phosphites to benzylideneacetone, chalcone, butyl cinnamate and *p*-methoxycinnamate, and also to a phenylglyoxylic acid ester have been investigated.^{350,351} The reduced reactivity of bis(fluoroalkyl) phosphites in the Abramov and Pudovik reactions as well as certain specific features of their behaviour uncharacteristic of the usual dialkyl phosphites have been noted. For example, an excess of bis(fluoroalkyl) phosphite in the reaction of benzylideneacetone in the presence of R_FONa lowers the rate of reaction compared with the rate of reaction of

dialkyl phosphites, which the authors attribute to the formation of fairly stable hydrogen-bonded complexes between the free acid and its anion.

The esters of α -ketocarboxylic and mesoxalic acids react with bis(fluoroalkyl) phosphites to form the 1-hydroxyphosphonates **169**. The phosphonate obtained from ethyl pyruvate ($R = Me$) partly undergoes the phosphonate-phosphate rearrangement during distillation, while the analogous phosphonate synthesised from the phenylglyoxylic acid ester ($R = Ph$) is fully converted into the rearrangement product **170**.^{99, 352}

$$R_F = CF_3CH_2, CHF_2CF_2CH_2; R = Me, Ph, COOEt.$$

The fluoroalkyl groups at the phosphorus atom in the 1-hydroxyalkyl phosphonate obtained from bis(tetrafluoropropyl) phosphite and 2-acetoxyethyl methyl ketone promote a more ready occurrence of the phosphonate-phosphate rearrangement compared with the fluoroalkyl groups in the 1-hydroxyalkyl-phosphonate obtained from diethyl phosphite.¹¹⁶

The reactions of bis(fluoroalkyl) phosphites with ethylideneacetylacetone and ethyl acetoacetate and benzylidenemalonate are exothermic. In the presence of a catalyst, they lead to the phosphonates **171**.³⁵³ On heating, compounds **171** cyclize (probably via the enolic form **172**) to the $\sigma^{\alpha-1}$ -2-oxaphospholenes **173**.

$$R = \text{Me, Ph}; R^1, R^2 = \text{MeCO, COOEt}; R_F = \text{CF}_3\text{CH}_2, \text{CHF}_2\text{CF}_2\text{CH}_2.$$

An analogue of the phosphonates **171**, containing OEt substituents instead of OR_F, cyclises under much more severe conditions than compounds **171**, which is associated with the greater leaving capacity of the fluoroalkoxy-group compared with the ethoxy-group. The phosphonate **171**, obtained from benzyldienemalonic ester which is incapable of enolisation, does not give rise to the phospholene **173**.

b. Fluoroalkyl phosphites, phosphonites, phosphinites, and amidophosphites

Fluoroalkyl phosphites, amidophosphites, phosphinites, and phosphonites have been allowed to react with hexafluoroacetone,^{84-86, 118, 122, 130, 141, 155, 161, 177, 178, 354, 355} diacetyl,¹⁶¹ perfluorodiacetyl,^{137, 140, 143, 144, 147} carboxylic α -ketoacid esters,³⁵¹ benzoynitrile,⁹⁰ *o*-anthraquinone,¹³³ diethyl mesoxalate,³⁵⁶ *o*-chloranil,^{357, 358} halogen-containing esters of di- and trifluoro-

acetoacetic^{356,359} and pyruvic³⁶⁰ acids, 1,1-dichloroacetophenone,²⁶⁶ pentafluorophenylbromoacetophenone,³⁶¹ dimethyl trichloroacetylphosphonate,⁹⁰ fluorinated aldehydes,^{49,208} and chloral and bromal.^{362,363}

Hexafluoroacetone reacts with fluorinated P(III) derivatives to form phospholanes of three types: σ^5 -1,3,2- and σ -1,4,2-dioxaphospholanes **174**^{85, 86, 118, 122, 130, 141, 142, 161, 177, 178, 355} and **175**^{14, 86} respectively, as well as σ^5 -1,2-oxaphosphetanes **176**^{84, 86, 122, 130, 155, 177, 178, 354}. In the case of fluoroalkyl phosphites, mainly the σ^5 -1,3,2-dioxaphospholanes **174** are formed.

$$R^1, R^2, R^3 = \text{Ph, Et, Me, RO, (CF}_3)_2\text{CHO.}$$

It has been suggested that P(III) initially attacks the carbon atom of the carbonyl group with formation of the dipolar ion 177, which is converted into the zwitterion 179 via the phosphorane 178.

If one of the substituents at the P atom contains protons at the α -carbon atom, such a proton may be transferred to the carbanionic centre of the dipolar ion 179 with formation of the ylide 180.

The addition of a second acetone molecule to the intermediates 177, 179, and 180 leads to the final reaction products 174–176. The intermediates 177–179 were not detected by any methods.

It is noteworthy that analysis of the available data on the reactions of P(III) derivatives with hexafluoroacetone, in which σ^5 -1,4,2-dioxaphospholanes are formed,^{86, 122, 181, 364–369} does not reveal the causes of the formation of the latter and the factors promoting the appearance of 1,3,2-dioxaphospholanes. 1,4,2-Dioxaphospholanes have been obtained from cyclic and acyclic P(III) derivatives containing both electron-donating (NR_2) and electron-accepting [F , $\text{OCH}(\text{CF}_3)_2$] substituents, as well as bulky groups. A particularly effective example is quoted in a study³⁶⁶ in which the synthesis of the phosphorane **181** is described.

The structure of compound **182** is interesting as a model of the intermediate **178** containing a three-membered ring.³⁷⁰

The reactions of cyclic fluoroalkyl phosphites with perfluoro-diacetyl have been investigated^{143, 144, 147} and it has been shown that they proceed stereospecifically — with retention of configuration at the phosphorus atom. The authors believe that this is a consequence of the attack by P(III) on the oxygen atom.

It has been suggested that the phosphorane **183** be used as a phosphorus-containing model of the P(V)-intermediate cyclic nucleotide for enzymic reactions. It has been shown by NMR (500 MHz) that the phosphorinane ring exists predominantly in the twist-conformation.

Fluoral and tetrafluoropropanal react with fluoroalkyl phosphites^{49, 208} and fluoroalkyl chlorophosphites^{49, 136} to form σ^5 -1,4,2-dioxaphospholanes. For example, the chlorophosphite **184** forms an unstable intermediate monochlorophosphorane **185** ($\delta_P = -40$ ppm), which is readily converted into the σ^5 -1,4,2-dioxaphospholane **186**:

R_F = CF₃CH₂, R'_F = CHF₂CF₂.

Diethyl mesoxalate,³⁵⁶ *o*-chloranil,^{356, 357} and the ethyl ester and nitrile of phenylglyoxylic acid³⁵² react with fluoroalkyl

phosphites to form σ^5 -1,3,2-dioxaphospholanes; the reactions take place under more severe conditions than those with alkyl phosphites.

A single example of the interaction of the fluoroalkyl phosphites **117** with α -diimines³⁷¹ to form the σ^5 -1,3,2-diazaphospholine **187** has been described.

R_F = (CF₃)₂CH, CF₃CH₂.

It is noteworthy that alkyl phosphites do not interact with mono- and di-imines.³⁷²

Carbonyl compounds containing a mobile halogen atom have been less studied in reactions with fluoroalkoxy-derivatives of P(III) — there have been only a few communications on this topic. Thus tris(tetrafluoropropyl) phosphite undergoes the Perkow reaction with chloral (in a stainless steel tube at a temperature > 200 °C),^{60, 62} with halogen-containing esters of di- and tri-fluoroacetoacetic³⁵⁸ and pyruvic⁹⁰ acids, with 1,1-dichloroaceto-phenone,²⁶⁷ with pentafluorophenylbromoacetophenone,³⁶¹ and with dimethyl trichloroacetylphosphonate.⁹⁰ Tris(tetrafluoropropyl) phosphite also undergoes the Perkow reaction with polychloronitrosoethanes.³⁷³

R_F = CHF₂CF₂CH₂, R = ClCH₂, Me.

A detailed reinvestigation of the reaction of tris(fluoroalkyl) phosphites with chloral showed³⁶³ that it begins even at 20 °C and leads mainly to the σ^5 -1,4,2-phosphorane **188**, the phosphate **189**, and small amounts of the vinyl phosphite **190**.

The fundamental results obtained in the study of the reactions of fluoroalkyl phosphites with chloral are briefly surveyed below.^{103, 362, 363, 374, 375} In the first place, it was possible to demonstrate the reversibility of the formation of the phosphorane **188**, which decomposes at 100 °C into the initial compounds and is reformed at 20 °C.³⁶⁰ In the case of tris(trifluoroethyl) phosphite, the corresponding phosphorane **191** was isolated in the form of one diastereoisomer;³⁷⁵ the stereoselectivity of the reaction is > 90%.

An extremely unusual fact was noted in the reaction of the phosphite P(OR_F)₃ with chloral in the presence of the alcohol R_FOH: together with the phosphate **189**, the fraction of which increases, the phosphorane **188** is also produced.^{103, 363} The

product of the Perkow reaction — the vinyl phosphate **192** — is formed only at 160 °C.^{60, 62, 363} Hence it follows that fluoroalkyl phosphites react with chloral predominantly at the carbonyl group, but the dechlorination of the CCl₃ substituent also takes place to a slight extent.

Chloral proved to be an effective catalyst of the oxidation of fluoroalkyl phosphites by oxygen.³⁶²

The initial attack on the carbon atom of the carbonyl group has been confirmed also by the results of the reaction of chloroalkyl phosphites with chloral in the presence of Lewis acids.³⁷⁴ When SbCl₅ was used, the betaine **193** with a P—C bond, stabilised by coordination to the Lewis acid at the anionic centre, was obtained. At 20 °C, the betaine **193** is slowly converted into the quasi-phosphonium salt **194** with a P—Cl bond.

The betaine **195** ($\delta_\text{P} = 26$ ppm), obtained by the interaction of tris(fluoroalkyl) phosphite with chloral in the presence of BF₃·OEt₂, undergoes various reactions on heating, one of which is intramolecular fluorination to the difluorophosphorane **196** ($\delta_\text{P} = -57.9$ ppm, $^1J_\text{PF} = 894$ Hz).³⁶³

The asymmetric fluoroalkyl phosphites (R_FO)₂POR, containing one nonfluorinated substituent, react with chloral to form σ⁵-1,4,2-phospholanes with a P—C bond [R = Et, (EtO)₂P(O)CH₂], which are stable at 20 °C.¹¹³ We obtained the same result for cyclic fluoroalkyl phosphites.^{138, 139} The reaction with chloral led to the isolation for the first time of both σ⁵-1,4,2-dioxaphospholanes **197** and σ⁵-1,3,2-dioxaphospholanes **198**, the structures of which were confirmed by NMR data ($\delta_\text{P} = -20$ to -30 ppm for compound **197** and -42 to -50 ppm for compound **198**). Bromal gives rise to 1,4,2-dioxaphospholanes **197** only.

There exist two points of view in the literature concerning the mechanism of the rearrangement $\text{P}^+ - \text{C} - \text{O}^- \rightarrow \text{P}^+ - \text{O} - \text{C}^-$. One of them is that of Ramirez,³⁷⁶ who believes that the rearrangement proceeds via the formation of a six-membered cyclic diphosphorane, i.e. is bimolecular. This cyclic diphosphorane has been recently obtained from PhCHO and ethyl pinacol phosphite,³⁷⁷ which confirmed this mechanism.

According to the second point of view, the rearrangement involves the formation of a three-membered transition state (or intermediate) on the path to the POC adduct, i.e. follows a unimolecular path.^{378, 379} Theoretically, one cannot rule out also the possibility of a direct electrophilic attack by P on the oxygen atom of the C=O group.³⁷⁹

When σ⁵-1,3,2- and σ⁵-1,4,2-dioxaphospholanes are formed simultaneously, their ratio should be affected by the dilution. When the C=O group is attacked simultaneously at the O and C atoms, the dilution of the reaction mixture should not lead to a significant change in the ratio of the phospholanes **197** and **198**. Where the rearrangement follows a bimolecular mechanism, dilution should diminish the fraction of the phospholane **198**. When the P atom attacks the C=O group at the C atom with an intramolecular rearrangement, the fraction of the phospholane **198** should increase with dilution. The experimental data obtained¹³⁹ for *d*, *l*-2,3-butylene tetrafluoropropyl phosphite and chloral have shown that the fraction of the phospholane **198** increases with dilution, whilst that of the isomer **197** falls, which confirms the intramolecular character of the rearrangement $\text{P}^+ - \text{C} - \text{O}^- \rightarrow \text{P}^+ - \text{O} - \text{C}^-$ in the case of chloral.

The results obtained in the study of the reaction of bromal with fluoroalkyl phosphites differ from those for chloral.^{363, 375} Bromal is much more reactive than chloral. When bromal is employed, the vinyl phosphate **199** and the phosphate **189** are formed as the main products. The dibromovinyl phosphite **200** was also detected in a small amount.

When this reaction is carried out in the presence of an alcohol, the phosphate **189** (yield ~97%) and the aldehyde CHBr_2CHO are formed. This reaction has been proposed in the literature as a test reaction for the halogenophilic mechanism.^{380, 381} Under these conditions, even the use of a much less acid alcohol (propanol) affords more than 90% of the phosphate **189**.^{103, 363}

Taking into account the difference between the reactivities of chloral and bromal and also the fact that the rate-determining stage in the Perkow reaction is the nucleophilic attack by the phosphorus atom, a halogenophilic mechanism has been proposed for the reactions of fluoroalkyl phosphites with bromal.^{103, 363}

The use of a third reagent (a Lewis acid) in the reaction with bromal on the whole confirms that the bromine atom is attacked, but in this case the shielding of both the carbonyl group and of the phosphorus atom by bulky substituents plays a certain role. Thus, when SbBr_5 is used as the Lewis acid, the quasi-phosphonium salt **201** with a P—Br bond is formed. The salt **202** is obtained similarly from the branched tris(hexafluoroisopropyl) phosphite and SbCl_5 .¹⁰³ On the other hand, the interaction of the complex $\text{CBr}_3\text{CHO} \cdot \text{SbCl}_5$ with tris(tetrafluoropropyl) phosphite leads to the formation of the betaine **203**.³⁷⁴

The betaine **204**, stabilised by coordination to BF_3 , is converted into the difluorophosphorane **205** ($\delta_\text{P} = -77.9$ ppm, $^1J_\text{PF} = 729.6$ Hz) after being kept at 20°C .

When oxygen is bubbled through a mixture of a phosphite and bromal, the oxidation product — the phosphate **189** — is formed in 100% yield.³⁶²

This is an extremely important result, indicating the appearance of radical species during the reactions of fluoroalkyl phosphites with bromal, i.e. the occurrence of a one-electron transfer. Only in this case is there a possibility of catalysis of the reactions of phosphites with paramagnetic oxygen. A possible mechanism of the interaction of fluoroalkyl phosphites with bromal is presented below.¹⁰³

We may note that the appearance of small amounts of vinyl phosphite as well as bromophosphites in reactions with bromine is associated with ligand exchange between the quasi-phosphonium intermediates and the initial fluoroalkyl phosphite.

The interaction of the phosphite **117** with chloral and bromal is complex.^{103, 382, 383} P(III) derivatives, formed on cleavage of the CCl_3 group and representing disproportionation products, were detected together with σ^5 -1,3,2- and σ^5 -1,4,2-dioxaphospholanes in the reaction with chloral.³⁸³

The replacement of chloral by bromal increases the contribution of the processes accompanied by the partial reduction of the CBr_3 group. The reaction products are the monocyclic pentaalkoxyphosphorane **206**, the phosphate **139**, and a small amount of the vinyl phosphite **207** (Scheme 4).³⁸² It was also possible to make the interesting observation that the above reaction is accelerated on UV irradiation.¹⁰³ These data as well as the results of the interaction of oxygen with the phosphite **117** in the presence of bromal, leading to the phosphate **139**, indicate the occurrence of one electron transfer in the reaction with bromal. The interaction of the phosphite **117** with bromal in the presence of $\text{R}_\text{F}\text{OH}$ leads to the phosphate **139**, the phosphorane **208**, and dibromoacetaldehyde, which also confirms that the phosphorus atom attacks the bromine atom of bromal. When the last reaction is carried out in the presence of a base, the phosphorane **208** becomes the only phosphorus-containing reaction product.³⁸²

On heating, the phosphorane **206** decomposes to the vinyl phosphate **210**; when it is kept for a long time at room temperature in an acid medium, symmetrisation results in the formation of various phosphoranes containing both one and two catechol fragments and different acyclic substituents.

Thus the reaction of the phosphite **117** with bromal proceeds via a halogenophilic mechanism with the intermediate formation of the bromophosphorane **209**, which adds to the $\text{C}=\text{O}$ bond of bromal, affording the phosphorane **206**. The monobromophosphorane **209** is unstable and decomposes to the vinyl phosphate **210** at 20°C .

$R = \text{CF}_3\text{CH}_2, \text{CHF}_2\text{CF}_2\text{CH}_2, \text{Me}, \text{Bu};$

$R^1 = \text{H}, X = \text{Br}; R^1 = (\text{MeO})_2\text{P(O)}, X = \text{Cl}.$

Fluoroalkyl salicyl phosphites **211** interact readily with imines to form 1,4,2-oxazaphosphhepanes **217**.³⁹² It has been suggested that the imine nitrogen atom behaves as a nucleophile.

$R_F = (\text{CF}_3)_2\text{CH}_2, \text{CF}_3\text{CH}_2.$

Dibenzoyl reacts with the phosphite **211** ($R_F = \text{CF}_3\text{CH}_2$) to form the unstable σ^5 -1,3,2-dioxaphospholene **218**, which readily eliminates the salicylic acid fragment on heating and is converted into σ^4 -1,3,2-dioxaphospholene **219**.^{390,391}

Despite the presence of the electron-accepting pentafluorophenyl substituent, 1-pentafluorophenyl-3-phenylprop-2-en-1-one (the *trans*-isomer) reacts with salicyl trifluoroethyl phosphite only on heating.^{390,391} As in the case of dibenzoyl, the final product is a σ^4 -1,2-oxaphospholene **221**, which does not contain a salicylic acid fragment. The 1,4-adduct (the phosphorane **220**) formed initially is unstable and decomposes to the phospholene **221** under the reaction conditions.

The esters of halogen-substituted acetoacetic acids undergo the Perkow reaction with the salicyl phosphites **211**, the process being accompanied by the regioselective cleavage of the anhydride fragment (in the case of fluoroalkyl salicyl phosphites) or partial elimination of the acyclic group (in the case of alkyl salicyl phosphites).^{358,359} The reactions are highly stereoselective and, when a dibromo-ester is used, lead to the isomers **223** with the *trans*-disposition of the ester group and the phosphorus-containing fragment (yield more than 90%), whereas in the case of the chloro-ester they lead to the thermodynamically more stable *cis*-isomers **224** (yield 60%–80%). The phosphates **223** and **224** cyclise on heating with formation of compounds **225** and **226**. Taking into account the greater reactivity of the dibromo-ester compared with the chloro-ester, one may assume that, when the former is employed, a halogenophilic mechanism operates (the intermediate **227** is formed), whereas in the case of the chloro-ester there is attack on the carbon atom of the carbonyl group (the intermediate **238** is formed).

R = Et, CF₃CH₂, CHF₂CF₂CH₂;

R = Et, CF₃CH₂, CHF₂CF₂CH₂.

d. Bis(fluoroalkyl) isocyanatophosphites

The introduction of fluorinated substituents into the molecules of isocyanatophosphites not only lowers the nucleophilicity of the phosphorus atom in these compounds in reactions with carbonyl compounds and their aza-analogues but also determines a whole series of specific features of the behaviour of these isocyanates: the formation of the products of the dimerisation of σ⁴-1,3,2-oxazaphospholines and the complete absence of the products of the imide-amide rearrangement, cycloaddition to the P=N bond, and the formation of stable phosphoranes.^{89, 90, 117, 233, 352, 393} Certain aspects of the influence of fluoroalkyl groups on the reactivity of isocyanatophosphites in reactions with carbonyl compounds have been demonstrated.³⁴⁵

Thus the formation of stable σ⁴-1,3,2- and σ⁴-1,3,4-oxazaphospholines and **231** is characteristic of the interaction of fluoroalkyl isocyanatophosphite **229** with phenylglyoxylic and

pyruvic acid esters.^{117, 361} The oxazaphospholines obtained from unsubstituted isocyanatophosphites are unstable and undergo rapidly the imide-amide rearrangement.^{394, 395}

R_F = CHF₂CF₂CH₂; R¹ = Me, Ph; R² = Me, Et.

It has been suggested that in the case of compound **229** the phosphorus atom attacks initially the carbon atom of the carbonyl group with formation of the dipolar ion **232** which subsequently undergoes either intramolecular cyclisation with formation of the product **231** or the phosphonate-phosphate rearrangement to the dipolar ion **233** and subsequent cyclisation to the azaphospholine **230**.

The reduced reactivity of fluoroalkyl isocyanatophosphites compared with the nonfluorinated analogues in the reactions with ethyl phenylglyoxylate and dibenzoyl has been demonstrated by differential thermal analysis.¹¹⁷

In the reactions of the isocyanatophosphite **229** with trifluoroacetoacetic ester^{393, 396} and benzoyltrifluoromethylacetone,³⁹⁷ the corresponding intermediate 1,3,4-oxazaphospholine **234** dimerises in the former case with formation of diphosphatricyclodecane **235** [path (a)], while in the latter it is converted into the bicyclooctene **236** as a result of intramolecular cyclisation via the enolic form **237** [path (b)].

R_F = CHF₂CF₂CH₂.

Bis(tetrafluoropropyl) isocyanatophosphite and diphenyl isocyanatophosphite react with trifluoropyruvic acid esters to form the dimers **238** (σ⁴-1,3,2-oxazaphospholines **239** are intermediates in these reactions, whereas the interaction of dimethyl isocyanatophosphite with the above esters leads to a mixture of σ⁴-1,3,2- and σ⁴-1,4,2-oxazaphospholines.³⁹⁸

R = CHF₂CF₂CH₂, Ph; R' = Me, Et.

In contrast to trifluoropyruvic acid esters, hexafluoroacetone adds to the intermediate azaphospholine **240** with formation phosphabicycloheptanes **241**.^{361, 398}

R = CHF₂CF₂CH₂, CF₃CH₂.

The relatively stable intermediate σ⁵-1,2-oxaphospholenes **242** have been detected by ³¹P NMR in reactions of fluoroalkyl isocyanatophosphite **229** (R_F = CHF₂CF₂CH₂) with alkylidene-β-dicarbonyl compounds.³⁹⁹

R¹ = Me, Ph; R² = Me, OEt; R_F = CHF₂CF₂CH₂.

Fluorinated substituents stabilise the structure of σ⁴-1,2-azaphospholine **243**, formed in the reaction of the phosphite **229** with ethylidenecyanoacetic ester.

R_F = CHF₂CF₂CH₂.

Such stabilisation is due to the high resistance of the R_F-O bond to cleavage, which occurs readily in the imide-amide rearrangement of R_H-isocyanatophosphites.

Bis(tetrafluoropropyl) and diphenyl isocyanatophosphites react with *N*-trichloroethylidenecetamine to form substituted diphosphatricyclodecanes **244**,⁴⁰⁰ whereas dimethyl isocyanatophosphite affords the phosphabicycloheptane **245**.

e. Fluoroalkyl-substituted alkenyl and alkynyl phosphonites

Fluoroalkyl-containing alkenyl and alkynyl phosphonites, first obtained by Erofeeva and coworkers,⁴⁰¹⁻⁴⁰³ have been allowed to react with nitrilimines. The reactions of the usual alkenyl phosphonites with nitrilimines proceed with participation of phosphorus as the reaction centre and lead to cyclic [3 + 3]-adducts.⁴⁰⁴ The fluorinated phosphonite **246** undergoes [3 + 2]-cycloaddition without the incorporation of the phosphorus atom in the heterocycle. The pyrazolines **247** formed (δ_P = 187-189 ppm) are unstable and are converted on heating into pyrazole derivatives **248**.

Ar = Ph, 4-O₂NC₆H₄, R_F = CF₃CH₂.

The alkynyl phosphonite **249** as well as its fluorine-free analogue undergo [3 + 3]-cycloaddition to the nitrilimine with formation of σ⁴-1,2,4-diazaphosphorine derivatives **250**. It has been suggested that the reaction proceeds via the intermediate formation of the phosphonium salts **251**.⁴⁰²

R_F = CF₃CH₂.

4. Reactions of fluoroalkyl phosphites with aldehyde hydrates

Since the reactions of fluoroalkyl phosphites with aldehyde hydrates have a number of characteristic features, they are considered in a separate section. It has been shown in a series of studies^{124, 405–414} that, when fluoroalkyl phosphites react with aldehyde hydrates, phosphates and α -hydroxyphosphonates are formed. For example, the hydrates $\text{CF}_3\text{CH}(\text{OH})_2$ and $(\text{CF}_3)_2\text{C}(\text{OH})_2$ give rise to phosphates,⁴⁰⁵ while chloral hydrate and $\text{H}(\text{CF}_2\text{CF}_2)_n\text{CH}(\text{OH})_2$ ($n = 1, 2, 3$) afford predominantly α -hydroxyphosphonates.^{408, 410, 411} This reaction has been considered in detail in relation to chloral hydrate.⁴¹² The authors⁴¹² believe that the 'molecular association complex' **252** arises in the first stage, where there is either attack by the phosphorus atom on a carbon atom (A) or by an oxygen atom on the phosphorus atom (B), which lead to an α -hydroxyphosphonate and phosphate respectively.

It is noteworthy that not only the structure of the 'molecular association complex' **252** but also the path leading to the formation of the phosphate **254** [path (b)], presupposing the elimination of HCl from trichloroethyl phosphate **253**, give rise to doubts, since it is known that P(III) and P(V) compounds with the OCH_2CCl_3 substituent are extremely stable (for example the quasi-phosphonium salts,^{46, 211, 415}) while the oxygen atom in the $\text{P}-\text{O}-\text{R}_\text{F}$ group is a very weak electron donor (the electron density on this atom is reduced by the electron-accepting effect of the substituent R_F).

5. Complex formation

There have been several studies^{294, 416–418} in which the use of fluoroalkoxy-derivatives of P(III) in the synthesis of iron and nickel complexes has been described.

The proposed structure of complex **255**⁴¹⁶ was questioned¹⁸⁸ in view of the complexity of the IR spectra (more than seven $\nu_{\text{C}=\text{O}}$ bands), which is associated with the occurrence of side reactions and hydrolysis.

V. Conclusion

The above analysis of the reactivities and the systematic description of the syntheses and properties of fluoroalkyl derivatives of P(III) revealed, on the one hand, a whole series of characteristic features of the syntheses and chemical behaviour of fluoroalkyl phosphites, associated with the influence of fluorinated substituents on the phosphorus atom, and, on the other hand, it made it possible to obtain many new data concerning the mechanisms of known reactions, such as the interactions with the halogens, sulfur halides, halocarbonyl compounds, etc. On the whole, the introduction of fluorine atoms diminishes the nucleophilicity of the P(III) atom and lowers the rate of reaction, because in most of the cases considered nucleophilic attack by the phosphorus atom is probably the rate-determining stage of the reaction. However, the introduction of electron-accepting fluorinated substituents does not affect the rate of interaction with bromine and dialkylphosphonosulfonyl chlorides, which in our view is associated with the ready polarisability of the chlorine and bromine atoms.

The appreciable deficiency of electron density on the phosphorus atom in fluoroalkyl phosphites and the presence of a lone pair with a fairly high ionisation potential impart to these compounds the character of a biphilic reagent, capable of both nucleophilic and electrophilic attack. In certain reactions, it is actually difficult to determine the kind of species that phosphorus represents (electrophilic or nucleophilic), which from our point of view may be associated with orbital control in these reactions, where the initial step is a two-sided exchange interaction of the $n_\text{P}-\pi^*$ and σ^*-n types; here n_P is the lone pair of the phosphorus atom and σ^* is an antibonding orbital of the $\text{R}_\text{F}\text{O}-\text{P}$ bond localised on phosphorus and constituting the LUMO, whereas π^* and n are the LUMO and the HOMO of the organic reactants.⁴¹⁹ The possibility of applying orbital control rules to the reactions of phosphines with alkyl halides and carbonyl compounds is discussed in a recently published communication.⁴²⁰

The study of fluoroalkyl phosphites as potential biphilic reagents in reactions with different nucleophiles and electrophiles is promising not only because there is a possibility of new varieties of the reactions and of new ways of stabilising the intermediates but also in terms of a purely practical aspect — for the very mild phosphorylation of natural alcohols and for the synthesis of new types of phosphorylating agents and phosphorus derivatives with diverse useful properties.⁵⁵

One of the most important and interesting differences between fluoroalkyl phosphites and the R_H derivatives is the reduced rate at which the fluoroalkyl group is split off from the phosphonium centre and the stabilisation of intermediate structures of the phosphorane and phosphonium types. The increase in the stability of quasi-phosphonium compounds is due to the stability of the $\text{O}-\text{R}_\text{F}$ bond. In certain cases, the $\text{R}_\text{F}-\text{O}$ bond is not cleaved at all, although for the R_H derivatives of P(III) the dealkylation stage takes place fairly readily and on the whole obeys the rules governing nucleophilic substitution at a carbon atom via an $\text{S}_\text{N}2$ mechanism (the Perkow and Arbuzov reactions and the nonclassical variants of the latter). In this sense, the weakening of the nucleophilic properties of the P(III) atom is more significant than the increase in the electrophilicity of the CH_2 carbon atom in the $\text{R}_\text{F}\text{CH}_2\text{O}$ fragment.

The appearance of new paths in the interaction of P(III) derivatives with halogen-containing reagents is a consequence of the retardation or complete suppression of the elimination of the

fluoroalkyl group from phosphonium intermediates. These include reactions with retention of the coordination on the phosphorus atom, the disproportionation of haloquasi-phosphonium or phosphorane intermediates in the presence of the initial P(III) derivatives, and the very ready conversion of P(III) compounds into P(V) compounds. In the reactions considered, R_H derivatives of P(III) are as a rule converted into compounds with a phosphoryl group.

Abstract. Data on the dependence of the extraction ability of the principal classes of organic compounds on their structure are surveyed. Mono- and bi-dentate neutral organophosphorus compounds (NOPC), sulfoxides, amines, quaternary ammonium, arsonium, and phosphonium bases, amine and arsine oxides, organophosphorus acids and their salts, and crown-ethers are examined. It is shown that the extraction ability of the NOPC in relation to any metal increases with increase in the basicity of the extractant and diminishes when electronegative substituents are introduced into its molecule. With increase in the basicity of neutral extractants, qualitative changes in the complex formation mechanisms are observed. The influence of diluents on the extraction ability of organic compounds is analysed. Methods for predicting extraction ability are considered. Examples of the use of the above rules for the development of new extractants are presented. The bibliography includes 157 references.

I. Introduction

The search for highly effective extractants is an important scientific and practical problem. The understanding of the dependence of the extraction ability (EA) of organic compounds on their structure has played the role of a compass in this search.

Such a dependence is of interest also when the general problem of the reactivity of compounds is considered.

The extraction of metal salts and acids is based on the chemical interaction (complex formation) of these substances with the extractant and may be regarded as a heterogeneous

chemical reaction. The effective extraction constant K_{ex} (the abbreviated term describing the equilibrium constant of the extraction reaction) is a quantitative characteristic of the extraction ability. For example, for the reaction

where TBP = tributyl phosphate, K_{ex} is determined from the Law of Mass Action taking into account the activity coefficients of the extracted compound in the aqueous phase (γ_{\pm}):

$$K_{ex} = \frac{\bar{K}_{ex}}{\gamma_{\pm}^v},$$

$$\bar{K}_{ex} = \frac{[\text{UO}_2(\text{NO}_3)_2(\text{TBP})_2]}{[\text{UO}_2^{2+}][\text{NO}_3^-]^2[\text{TBP}]^2},$$

where \bar{K}_{ex} is the concentration extraction constant and v the number of ions into which the metal salt dissociates in the aqueous phase ($v = 3$). The distribution coefficient (D) can be used as the characteristic of the EA, but only when the compounds present in the aqueous phase at macroconcentrations are not extracted. Otherwise, the changes in D when the structure is varied can reflect not only the changes in the EA of the extractant but also the changes in the concentration of the free extractant.[†] If the salt extracted from the aqueous phase is the same, the changes in the extraction constant when the structure of the extractant is varied reflect the changes in the constant for the complex formation

[†] This happened, for example, in a pioneer study where an apparent linear correlation between the distribution coefficients of uranyl nitrate in extraction from nitric acid solutions by a series of NOPC and the P=O bond vibrational frequency was obtained solely due to experimental errors, which were discovered when the results of the above study¹ were compared with more accurate data.² In addition, the extraction constant is much more informative than the distribution coefficient: knowing \bar{K}_{ex} , it is possible to reproduce the extraction isotherm and to find the dependence of D on the process conditions.

reaction between the salt and the extractant. Admittedly in the traditional approach to the description of extraction (see, for example, Sekine³) this is not quite correct. In this approach, the transfer of the extractant to the aqueous phase is considered as the first stage of the process, the formation of a complex with a metal or an exchange reaction with the latter in the aqueous phase is the second stage (or the third, if the extractant dissociated in the aqueous phase), while the transfer of the compound formed from the aqueous phase to the organic phase is considered to be the last stage. Under these conditions, the extraction constant is related in a complex manner to the complex formation constant in the aqueous phase β_{aq} and also depends on the distribution constants of the extractant and the complex, the last being usually unknown.

This approach arose in the initial period of the use of extraction when water-soluble extractants were employed (especially in analytical chemistry). However, extractants which are sparingly soluble in the aqueous phase are usually employed nowadays. The approach based on the consideration of complex formation in the organic phase⁴ is therefore more useful.

For neutral sparingly soluble extractants, the Gibbs free energy of extraction ΔG_{ex} represents the difference between the Gibbs free energies of the solvation and hydration processes:^{5,6}

$$\Delta G_{ex} = \Delta G_{solv} - \Delta G_{hydr}, \quad (1)$$

and since $\Delta G_{ex} = -RT \ln K_{ex}$ and $\Delta G_{solv} = -RT \ln \beta_{org}$, where β_{org} is the complex formation constant in the organic phase, we find

$$K_{ex} = \beta_{org} \exp \frac{\Delta G_{hydr}}{RT}, \quad (2)$$

i.e. K_{ex} is proportional to the complex formation constant in the organic phase β_{org} and characterises the stability of the complex.

The thermodynamic parameters of the hydration of many metals have been published⁵⁻⁸ and most fully in the last of the studies quoted (examples are presented in Table 1). Evidently the hydration energies increase when the nitrate ion is replaced by the chloride ion, and with increase in the charge and with decrease in the radius of the cation. Extraction becomes correspondingly more difficult. For extraction to be effective (K_{ex} of the order of unity), it is necessary to compensate for the hydration energy, i.e. the complex formation energy in the organic phase must be of the same order as G_{hydr} . In principle, such complex formation energies may be attained if the process proceeds via an electron donor-acceptor (EDA) mechanism. However, for the extraction of alkaline earth elements, a high electron-donating capacity of the extractants is necessary and for $AlCl_3$ it is altogether impossible to select effective extractants. To a certain extent, it is possible to obviate the difficulties associated with hydration by choosing salts with a reduced hydration of the anion; it is also possible to extract the ion with its hydration shell (the hydrate-solvate extraction mechanism⁹).

On the other hand, the most effective procedure involves the transition from the solvate to the cation-exchange mechanism of extraction:

Table 1. The Gibbs free energies and enthalpies of hydration of salts of metals (kcal mol⁻¹).

Compound	$-\Delta G_{hydr}$	$-\Delta H_{hydr}$	Compound	$-\Delta G_{hydr}$	$-\Delta H_{hydr}$
HCl	10.7	14.8	ThCl ₄	—	56.7
NaCl	2.1	-0.9	HNO ₃	7.3	7.95
MgCl ₂	30.3	37.2	NaNO ₃	1.5	-4.9
CaCl ₂	15.5	19.8	Mg(NO ₃) ₂	21.2	21.8
LaCl ₃	21.0	33	Ca(NO ₃) ₂	12.8	4.5
AlCl ₃	61.1	78.1	LiNO ₃	5.6	0.6
UO ₂ Cl ₂	16.4	28.1	UO ₂ (NO ₃) ₂	6.1	20.3

where HY is an organic acid. In the aqueous phase, the salt molecule MA_z is replaced by z molecules of the inorganic acid HA. Depending on the sign of the transhydration energy,

$$\Delta \Delta G_{hydr} = z\Delta G_{hydr}(HA) - \Delta G_{hydr}(MA_z)$$

it is actually possible to achieve a gain in extraction energy, which intensifies extraction.

The most correct method for predicting EA is the quantum-chemical calculation of the complex formation energy with subsequent determination of the partition functions and entropies of the components.[†] Unfortunately, this approach is possible only in a semiempirical approximation for inorganic acids or organic compounds.^{10,11} In most cases, especially for d and f elements, the direct (especially nonempirical) quantum-chemical calculation for extraction complexes is impossible. Therefore, correlations between the extraction constant and various characteristics of the extractant associated with its reactivity are widely used for predicting EA. The following are usually employed: (1) the characteristics of the structural groups, for example the electronegativities of the groups in substituents,¹² the reaction constants of these groups [the Taft (σ^*)¹⁸ and Kabachnik (σ^p)^{13,14} constants] on the assumption that the influence of these groups is additive: (2) the characteristics of an isolated extractant molecule as a whole — the electron density (charge) on the functional atom, the ionisation potential¹⁵, and the energy of the core $1s$ levels;¹⁶ (3) the characteristics of the reactivity of the molecule as a whole — basicity, determined experimentally from the energies of test reactions with simplest electron acceptors¹⁷⁻²¹ or by quantum-chemical calculations of the energies of complex formation with a proton [proton affinities (PA)], Li^+ , LiH , etc.^{16,22}

The dependences of EA on the structure of the extractants and the possibility of predicting it on the basis of various correlations are analysed in the present review. The dependences were established mainly in relation to the extraction of the actinides, but are nevertheless of a general character.[§]

II. Monodentate neutral organophosphorus compounds

At the time of the publication of the first studies on extraction using alcohols, ethers, and ketones, the chemical nature of the process was still obscure. Owing to the low EA of the reagent, the extraction isotherms obtained in these investigations did not in the main have a saturation section characteristic of the formation of compounds (Fig. 1, curves 1 and 2). The relation between extraction ability and structure was not traced and it was only noted that EA diminishes with increase in the C/O ratio, i.e. as the hydrocarbon chain is lengthened.^{23,24} The introduction of tributyl phosphate in the 1950s²⁵⁻³⁰ led to revolutionary changes both in the technology (EA increased by 5-6 orders of magnitude and it became possible to extract uranyl and plutonium nitrates without employing salting-out agents) and in the theory of the processes [a saturation section, frequently indicating the formation of compounds (Fig. 1, curves 3 and 4), appeared on the extraction isotherms].³⁰

† Strictly speaking, a calculation taking into account the influence of the solvent is necessary. However, it has been established in a number of studies that a weakly polar solvent exerts a comparatively weak influence on the complex formation and extraction energies which is due to the compensation of diluent-extractant and diluent-extracted complex interactions (see below).

§ The review is based largely on the results of studies carried out under the supervision of A M Rozen during the last 30 years. Z I Nikolotova, N A Kartasheva, E I Moiseenko, Z I Nagnibeda, Yu I Murinov, B V Martynov, A S Skotnikov, L P Kharkhorina, V G Yurkin, and B V Krupnov participated actively in these investigations. Studies by other workers are naturally also discussed.

Figure 1. Isotherms for the extraction of Pu(IV) by neutral organic compounds ($x_H = 0.1$ M).

Extractant: (1) dibutyl ether (DBE); (2) diethyl ether (DEE); (3) TBP; (4) diisopentyl methylphosphonate (DPMP); AB — initial section of the isotherm determined by dissociation into ions; BC — section corresponding to moderate nonideality; CD — saturation section.

Neutral organophosphorus compounds are the first class of compounds for which the dependence of EA on the structure has been studied systematically. For phosphates, phosphonates, phosphinates, and phosphine oxides, the reaction centre (RC) is the PO group and the composition of the complexes remains unchanged (for example, the disolvates of tetravalent and hexavalent actinides, the trisolvates of trivalent actinides and lanthanides), while extraction ability increases appreciably. A correlation has been proposed¹² between $\ln K_{ex}$ for uranyl nitrate and nitric acid, on the one hand, and the sums of the electronegativities of the groups of the substituents (X) in the above series:

$$\ln K_{ex} = A - B \sum X - \rho \sum l, \quad (4)$$

where A is a constant which depends on the reaction series (the class of the extractant and the individuality of the compound extracted), B is the coefficient of the sensitivity to electronegativity, ρ the coefficient of the sensitivity to the length of the hydrocarbon chain, l the effective length of the hydrocarbon chain of the substituent (in the case of normal groups, $l = n_C$), and the values of X are determined from the spectral scale (Table 2).

The following considerations also lead to Eqn (4).³¹ On the one hand, since the complexes are formed via an EDA mechanism, one can suppose that EA is greater the greater the electron density on the donor atom. Rozen and Denisov³¹ put forward more logical considerations, which may make it possible to estimate the coefficient B :

Table 2. The electronegativities and Taft constants for certain substituents.^{6, 12}

Substituent	X	σ^*
F	4.0	—
Cl	3.0	—
CCl ₃	2.95	2.65
ClCH ₂	2.60	1.05
Cl(CH ₂) ₂	2.32	—
C ₆ H ₅	2.34	0.6
CH ₃	2.07	0.0
Alk	2.0	-0.13
RO	2.9, 2.4*	1.50, 0.75*
H	2.3	0.49

* Effective values.

$$\ln K_{ex} = a + b|q|,$$

where a and b are constants and q is the charge. On the other hand, according to the results of approximate quantum-chemical calculations,^{32, 33}

$$|q| = a'' - b'' \sum X,$$

where a'' and b'' are constants. When account is taken of these relations, Eqn (4) is obtained. When calculations are made relative to a standard compound, Eqn (4) leads to the Hammett-Taft equation.¹⁴

$$\ln \frac{K_{ex}}{K_0} = -B \sum (X - X_0) - \rho \sum (l - l_0) = r^* \sum \sigma^* + d \sum E_s. \quad (5)$$

Here the subscript 0 refers to the characteristics of the standard state, r^* and d are coefficients, and E_s is the steric hindrance constant.

In fact it has been found¹⁴ that $X = 2.07 + \sigma^*/2$, i.e. the Taft constants represent relative electronegativities.

Figure 2. Dependence of EA on the sum of the electronegativities of the substituents (ΣX) and the stretching vibrational frequencies (ω_{PO}) in the extraction of certain compounds by monodentate NOPC.

Compound extracted: (1) manganese nitrate; (2) potassium permanganate; (3) nitric acid; (4) americium nitrate; (5) uranyl chloride; (6) uranyl nitrate; (7) plutonium nitrate. ODOP = octyl dioctylphosphinate; TOPO = trioctylphosphine oxide.

The following conclusion follows from Eqn (4): the EA of monodentate NOPC decrease after the introduction of electronegative substituents. This conclusion is fairly general, being valid for any metals (Fig. 2). However, in order to obtain a general correlation when a wider class of NOPC, including the C_6H_5 , CCl_3 , $ClCH_2$, and $Cl(CH_2)_2$ groups, is considered (Fig. 3), Eqn (4) had to be refined.^{12, 34} Effective (reduced) electronegativities were introduced for the alkoxy-groups ($X_{ef} = 2.4$ and $\sigma_{ef}^* = 0.75$). The possible reason for this is that X and σ^* describe only the inductive effect, whereas for RO the resonance effect is also observed.[†]

† One cannot rule out also the explanation based on the jump in entropy on passing from one subclass to another (for example, from phosphates to phosphonates).¹⁴

Figure 3. Dependence of the extraction ability of NOPC on the sum of the effective electronegativities (a), the effective Taft constants (b), and the Kabachnik constants (c) of the substituents.

Extractant: (I) TOPO; (2) ODOP; (3) DPMP; (6) TBP; (7) trioctyl phosphate; (4), (5), (8), and (9) (iso-C₅H₁₁O)₂RPO, R = C₆H₅ (4), Cl(CH₂)₂ (5), ClCH₂ (8), or CCl₃ (9); substance extracted: (I) UO₂(NO₃)₂; (II) HNO₃.

Instead of Eqn (4), one can write

$$\begin{aligned} \ln K_{\text{ex}} &= A - B\Sigma X_{\text{ef}} - \rho\Sigma l = \\ &= A - B\Sigma X + B'\Sigma\sigma_{\text{res}} - \rho\Sigma l, \end{aligned} \quad (6)$$

where σ_{res} is the resonance interaction constant and $X_{\text{ef}} = X - \sigma_{\text{res}}B/B'$.

Eqn (6) is equivalent to the use of Kabachnik constants:

$$\lg \frac{K_{\text{ex}}}{K_0} = r^P \Sigma \sigma^P,$$

where $\sigma^P = \sigma_{\text{ind}}^P + \sigma_{\text{res}}^P$ is the Kabachnik constant taking into account the resonance effect, and including also the term $\rho\Sigma l/r^P$. The correlation with σ^P does not therefore require the introduction of effective quantities.

The advantage of electronegativity over the constants σ^* and σ^P is a more clear-cut physical significance. Electronegativities may be determined independently of any reactions. Unfortunately, there are no independent methods for the determination of σ_{res}^P . The energy of the 1s orbitals is an independent quantum-chemical parameter characterising the molecule as a whole and equivalent to ΣX_{ef} . The decrease in EA with increase in the electronegativities of the substituents is characteristic of any class of neutral compounds (the only exception, in the case of bidentate NOPC, is discussed below).

III. Organic sulfoxides

Systematic studies on extraction by sulfoxides (in which the reaction centre is the SO group) began and developed vigorously at the beginning of the 1970s. The research groups led by Rozen, Mikhailov, and Torgov published more than 20 papers. They have been reviewed by Nikitin et al.³⁵

It was established that, in terms of their extraction ability, aliphatic sulfoxides approach phosphonates. Cyclic sulfoxides are obtained by oxidising petroleum sulfides. Their EA is higher by a factor of 2–3 (owing to the contribution by the entropy factor) than that of aliphatic sulfoxides. The dependence of EA on the

structure of the sulfoxide is described by Eqns (4) and (5). The difference from NOPC consists in a higher sensitivity of EA to the influence of substituents (higher values of B in the above equations). Thus the replacement of a single alkyl group by the phenyl group in NOPC lowers the degree of extraction of uranium by a factor of 17, while in the case of sulfoxides the decrease is by a

Figure 4. Dependence of the uranyl nitrate extraction constant on the basicity (I) and the sum of the electronegativities of the substituents or the Taft constants (II) of the extractants.

Extractant: (I) diphenyl sulfoxide; (2) hexyl phenyl sulfoxide; (3) dihexyl sulfoxide; (4) cyclohexyl hexyl sulfoxide; (5) hexyl tolyl sulfoxide; (7) 2-amyltetrahydrothiopyran sulfoxide; (8) DPMP; (9) TBP.

factor of 40. Fig. 4 presents the dependences of the extraction constant of uranyl nitrate (K_U) on the basicity and on the sum of the electronegativities or Taft constants of the sulfoxides.

IV. Variation of extraction ability and the complex formation mechanism as the reaction centre is varied and the basicity of the extractants increases

The dependence of extraction ability on the structure of organic compounds has also been investigated for carbonyl compounds and arsine and amine oxides (the reaction centres are the CO, AsO, and NO groups respectively). The extraction by compounds of this type is associated with the formation of electron donor-acceptor complexes, so that the more marked the electron-donating properties of the extractants (characterised by their basicity) the higher the EA. A linear correlation between $\ln K_{ex}$ and the basicity is frequently observed under these conditions [see, for example, Refs 34–37 (Fig. 5)]:

$$\ln K_{ex} = a + bpK \quad (7)$$

We may note that the dependence of EA on the electronegativity of the substituents in the extracting molecule examined above is a special case of the dependence of EA on the basicity. It has been shown in relation to extraction by sulfoxides that the extraction of uranyl nitrate and the basicity of sulfoxides depend on the sum of the electronegativities of the substituents:

$$\ln K_{ex} = 3.04 - 5.23\Sigma(X - 2); \quad (8a)$$

$$pK = 2.67 - 0.94 \Sigma(X - 2), \quad (8b)$$

which is equivalent to the dependence of the EA in relation to uranium on the basicity:

$$\ln K_{ex} = -11.38 + 5.6pK, \quad (8c)$$

i.e. Eqns (4) and (7) are equivalent for a class of extractants with a single reaction centre. Eqn (8b) implies that, when electronegative substituents are introduced into the extractant molecule, the electron-donating capacity of the latter (its basicity) diminishes and there is corresponding decrease also in the EA [Eqns (8a) and (8c)].

There exist several basicity scales which are determined experimentally [for example by titration with perchloric acid in nitromethane (pK),¹⁷ by the reaction with pentachlorophenol,^{8,19} and by the calorimetry of the interaction with antimony pentachloride (Gutmann donor numbers) and other Lewis acids].^{20,21} In connection with the development of quantum chemistry and the ion cyclotron resonance spectroscopic methods, gas-phase basicity and proton affinity scales,^{41,42} which are free from the influence of the solvent, are increasingly used at the present time.[†] Table 3 gives an idea about the above scales.

Table 3. Extractant basicity scales.

Compound	Proton affinity / kcal mol ⁻¹	Donor number ^{43,44}	Energy of H bond with H ₂ O ⁴⁵	Taft–Rozen basicity ¹⁹ (C ₆ Cl ₅ OH)

R ₃ NO	238.0	—	6.9	—

† It has been shown^{38,39} that considerable differences are observed between the proton basicities in the gas phase and in solution. At the same time, it has been found⁴⁰ that the differences between the energies of the complex formation reactions with metal salts in the gas phase and in weakly polar solvents are small.

Figure 5. Dependence of the extraction constants of nitric acid (I), americium (II), and uranyl (III) nitrates (a) and of the monosolvates (IV) and disolvates (V) of perchloric and pertechnetic (VI) acids (b) on the basicity of neutral extractants. Extractant: a: (1) Ph₃PO; (2) R₃PO; (3) Ph₃AsO; (4) Ph₂RAsO; (5) PhR₂AsO; (6) R₃AsO; (7) R₃NO; b: (8) TBP; (9) Ph₃PO; (10) TOPO; (11) R₃AsO; (12) R₃NO.

The above scales, based on allowance for the donor–acceptor interactions in solution, have a certain advantage in the prediction of complex formation constants in solutions. Here it is desirable that the nature of the interactions underlying the scale should not vary over the entire basicity range. This condition is not satisfied by the basicity scale based on the titration of the extractant with perchloric acid in nonaqueous media. Only the basicities of strong electron donors (ranging from R_3PO to R_3NO) have been determined by this procedure, while weak bases are not protonated under these conditions. Unfortunately the scales constructed using the interaction energy with weak proton donors (water or phenol) exhibit a low sensitivity to changes in the electron-donating capacities of the extractants. A more sensitive scale is based on the interaction energy with a stronger proton donor — pentachlorophenol. This scale has been used successfully in establishing correlations with EA for a wide range of extractants — from the weakest (alcohols, ethers, and ketones) to fairly strong (sulfoxides and NOPC).[‡] The above condition is most readily fulfilled when the scale is constructed on the basis of the interaction with a metal salt. This is in fact the reason why the Gutmann donor number scale has come to be widely used.

With increase in the basicity of the extractant, not only is there an increase in the stability of the complex observed but the complex formation mechanism also changes. Thus in the extraction of nitric acid, the hydrate solvate mechanism [the coordination of an extractant molecule via a water molecule, for example $HNO_3 \cdot H_2O_2 \cdot (TBP)_2$] is readily replaced by the solvate mechanism (the formation of a molecular hydrogen-bonded complex with a direct bond between the donor atom of the extractant and the proton of the acid extracted, for example $TBP \cdot HNO_3$ and $TOPO \cdot HNO_3$). On further increase in basicity, complexes involving proton transfer are formed ($R_3XOH^+ \cdot NO^-$, where $X = As$ or N).³⁴ A similar complex formation mechanism has been found also in the extraction of strong acids (HCl , H_3ClO_4 , $HReO_4$, $HTcO_4$, etc.) with formation of both monocomplexes $[LH]^+ A^-$ and dicomplexes $[LHL]^+ A^-$.^{46–48} The extraction constants for the latter are especially high (Table 4). The stronger the inorganic acid, the lower the basicity of the extractant for which the transition to the new mechanism takes place.

Table 4. The extraction constants of inorganic acids in the form of the proton-transfer complexes $[LH]^+ A^-$ (K_1) and $[LHL]^+ A^-$ (K_2).

Acid	Extractant			
	R_3AsO		R_3NO	
	K_1	K_2	K_1	K_2
HNO_3	—	—	8.0×10^7	4.0×10^{11}
HCl	—	—	5.0×10^5	3.0×10^7
$HReO_4$	1.0×10^{10}	4.8×10^{15}	3.6×10^{11}	7.2×10^{17}
$HTcO_4$	3.0×10^{10}	2.4×10^{16}	1.0×10^{12}	2.8×10^{18}

A change in the extraction mechanism leads to significant alterations of the extraction ability. The nature of the dependence of the degree of extraction of acids on the basicity of the extractant is then determined to a considerable degree by the strength of the acid being extracted. Torgov and Nikolaeva[§] found that, in the

extraction of weak acids (phenols, phosphoric or acetic acid), the extraction mechanism (the formation of a hydrogen bond) does not change over the entire range of basicities of the extractants and lgK_{ex} varies linearly with the donating capacity of the extractant. Amine oxides possess the highest extraction ability in relation to weak acids. It is of interest that amines are not included in these correlations: having a gas-phase proton affinity similar to that of amine oxides and a higher protonation energy in solution, amines form hydrogen-bonded complexes, the stability of which does not exceed that of complexes formed by phosphine oxides which are less basic in protonation reactions. Furthermore, amines extract weak acids with even lower distribution coefficients than phosphine oxides (for example 3.11 for the extraction of phenol with TOPO and only 1.23 for its extraction with trioctylamine); this may be associated with steric hindrance.

The dependences of lnK_{ex} on the basicity of the extractant for moderately strong acids (for example, nitric acid) have a break on passing from complexes with an intermolecular hydrogen bond to those involving proton transfer (Fig. 5).³⁶ Quantum-chemical calculations have shown⁵¹ that this break is due to the increase in the sensitivity of the energy of the complex to the basicity of the extractant after the change in the complex formation mechanism. We put forward the hypothesis¹¹ that, by altering the 'threshold' of the transition through the selection of the extractant and the diluent, it is possible to obtain a significant increase in the separation coefficients for acids in their mixtures.

The lgK_{ex} of strong acids (for example, perchloric and pertechnetic), which form proton-transfer complexes over the entire range of basicities of the extractant, increases almost linearly (by 15–18 units) with increase in basicity as the substituents and the reaction centre are varied (SO , PO , AsO , NO) (Fig. 5b).^{37, 46, 47}

The formation of proton-transfer complexes in the extraction of metal salts results in the manifestation, together with coordination to the oxide oxygen and the formation of a solvate [for example $UO_2(R_3XO)_2(NO_3)_3$], also of coordination to the cation LH^+ , for example $R_3XOH^+ UO_2(NO_3)_3^-$ (Rozen et al.³⁶ called this the amine mechanism). Attempts to separate the contributions of the oxygen and amine mechanisms have been undertaken.^{36, 47}

The discovery of the amine (anion-exchange) mechanism of the extraction of actinides by the oxides R_3AsO and R_3NO made it possible to explain the similarity of the distribution coefficients of uranium and plutonium in extraction by amines and amine and arsine oxides (Fig. 6).[¶]

For arsine oxides, a transition to the cation-exchange mechanism is observed in the region of low acidity.⁴⁹

In the extraction of metal salts, the changes in the complex formation mechanism are similar to the changes in the mechanism of the formation of complexes by acids over a wide range of basicities of neutral extractants. In extraction by weakly basic extractants (for example, by ethers or ketones), the hydrate-solvate mechanism is favourable. In this case, the extractant is unable to displace a water molecule from the first hydration shell and the metal ion is extracted together with the latter, since the separation of the hydrated ion from the outer hydration shell requires less energy than its separation from the inner shell. Under these conditions, the extractant is in the outer sphere of the complex and is coordinated to the metal ion via a water molecule.[†]

Stronger extractants decompose the first hydration shell and extract the metal without water molecules.

The most basic extractants (arsine and amine oxides) extract the metal via the amine mechanism.

‡ One cannot be certain that the complex formation mechanism does not change for the strongest bases — for example, arsine and amine oxides. A change in this mechanism would lead to considerable errors in prediction.

Author's abstract of Candidate Thesis in Chemical Sciences, Institute of Inorganic Chemistry, Siberian Branch of the Russian Academy of Sciences, Novosibirsk, 1996.

¶ For R_3NO , such similarity was observed as early as 1964⁵⁰ but until the publication of the study of Rozen et al.³⁶ was not understood.

† For the characteristic features of the extraction via the hydrate-solvate mechanism, see Yu A Zolotov.⁹

Figure 6. Dependence of the distribution coefficients of Pu^{4+} (I), and UO_2^{2+} (II) on acidity in extraction by trioctylamine oxide (I), trioctylamine (2), and trioctylarsine oxide (3) (extractant concentration in benzene 0.1 M).

V. Characteristic features of extraction by amine and arsine oxides

In the extraction of metals by arsine and amine oxides, the formation of proton-transfer complexes $(LH^+)A$ between the extractant and the inorganic acid, similar to amine salts, is accompanied also by complex formation via the anion-exchange mechanism. For example, the complexes $LH^+[UO_2(NO_3)_3]^-$ and $(LH^+)_2[Pu(NO_3)_6]^{2-}$ where $L = R_3AsO$ or R_3NO , are formed.³⁴ Thus at high basicities the boundary between neutral extractants and amines is obliterated.

At a low acidity of the aqueous phase, yet another change in the extraction mechanism is observed. It is particularly pronounced in the case of arsine oxides. Fig. 6 shows that, at HNO_3 concentrations less than 1.5 M, the distribution coefficient of uranium increases with decrease in x_H , i.e. R_3AsO begins to extract like an organic acid.³⁶ The dependence of the distribution coefficient on the pH (Fig. 7) characteristic of extraction by organic acids, i.e.

$$\lg D = a + zpH \quad (9)$$

(z is the valence of the cation), is observed. One may conclude³⁶ that the arsine oxide molecule rearranges and tentatively is converted into the acid $R_3As(NO_3)OH$. The reaction proceeds via the cation-exchange mechanism, for example via the reaction

where Y is apparently $R_3As(NO_3)O$. Such rearrangement may account also for the surprising phenomenon observed in a number of studies:^{52–55} in the weakly acid region, the degree of extraction of $Pu(IV)$ and $Pu(VI)$ increased after the replacement of the alkyl groups in the arsine oxide by the more electronegative phenyl groups, which, as we have seen above, leads to a weakening of extraction when NOPC and sulfoxides are employed. However, when account is taken of the 'acid rearrangement', everything becomes clear, since in extraction by organic acids an increase in the electronegativity of the substituents leads to an increase in the

Figure 7. Dependence of the distribution coefficients of U(VI) (1, 2), Pu(VI) (3, 4), and Np(VI) (5, 6) on the pH in extraction by arsine oxides Ph_3AsO (1, 3, 5) and R_3AsO (2, 4, 6).⁵²

strength of the acid and in the degree of extraction by the cation-exchange mechanism.

We may note yet another, albeit less striking, anomaly, which has been observed in the extraction of nitric acid by arsine oxides.⁵⁶ In the weakly acid region, the extraction constant K_{1H} for the first acid molecule depends on the electronegativity of the substituents and on the basicity of the arsine oxides in conformity with Eqns (4) and (7) (for Ph_3AsO , $Ph_2AlkAsO$, $PhAlk_2AsO$, and Alk_3AsO , the constant is 3×10^2 , 3×10^3 , 5×10^4 , and 5×10^5 respectively); in the strongly acid region, the isotherms for the extraction of HNO_3 by all four arsine oxides are virtually identical [see Rozen et al.⁵⁶ (Table 3)].

If inorganic acids are extracted by R_3AsO and R_3NO with extraction constants in the range 10^6 – 10^{10} , they immediately become actual competitors of the metals and are no longer salting-out agents (like HNO_3 in the extraction of metal salts by TBP).

In conclusion we may note that, by varying the substituents and the reaction centre (SO, PO, AsO, NO), it is possible to alter the EA of organic oxides in any required direction by 15–18 orders of magnitude (Fig. 5b).³⁷

VI. Salts of amines and quaternary onium bases

Inorganic acids are extracted by amines via an addition reaction⁵⁵ with extraction constants of 10^5 – 10^7 , characteristic of the formation of proton-transfer complexes, i.e. the amine salts, for example $(R_3NH)^+A^-$. Amine salts are in their turn effective extractants for acids and metal salts. In the latter case, extraction can be described either as anion exchange or as an addition reaction: the two types of reaction are thermodynamically indistinguishable. In the complexes formed [for example, $(R_3NH)^+(UO_2A_3)^-$ or $(R_3NH)_2^+(PuA_6)_2^{2-}$], the metal is present in the anion and the extractant is in the outer sphere of the complex.⁵⁷ However, in the extraction of platinum metals, very stable complexes with a direct metal–amine nitrogen atom coordinate bond, called insertion complexes, were detected together with the anion-exchange complexes.⁵⁸

The electronegativity of hydrogen (2.3) is higher than that of an alkyl group (2.0), so that EA increases in the series primary amine salts < secondary amine salts < tertiary amine salts < quaternary ammonium (QA) salts (Fig. 8). The difference

Figure 8. Dependence of EA on the electronegativities sum and the Taft constants of the extractants in the extraction of Pu(VI) (1), U(VI) (2), and HNO₃ (3) by salts of primary amines — quaternary ammonium bases series [R_iNH_{4-i}]⁺NO₃⁻, where *i* = 1, 2, 3, 4.⁶⁰

between amines and NOPC consists in a higher sensitivity to changes in EA ($B_{Pu} = 6.8$ instead of 4.8 for NOPC) and the length of the substituents. The question of the influence of association requires separate discussion. One should only note that, owing to the differences between the degrees of polymerisation, the above series is sometimes found to break down: primary amines extract more effectively than tertiary amines.

The correlation for the EA of amine salts may be represented also in the form of the dependence on the basicity; a linear increase in $\lg K_{ex}$ with increase in pK is observed in the above series. When the nature of the substituents in the amine molecules is varied widely, linear correlations are observed for the EA within the limits of each subclass of amines — primary, secondary, etc. (the corresponding straight lines are parallel). The increase in EA with increasing pK is characteristic of the anion-exchange extraction mechanism while on formation of coordination insertion complexes the opposite relation holds: the stability of the complexes increases in the series tertiary amines < secondary amines <

< primary amines, i.e. as the steric hindrance to coordination is weakened.

The extraction ability of amine salts depends also on the nature of the anions. Shmidt⁵⁹ proposed a two parameter correlation of the extraction constant with the hydration parameter ΔG_{hydr} and the influence of the diluent (ID):

$$\lg K_{ex} = \lg K_{ex 0} + a\Delta G_{hydr} + bBP. \quad (10)$$

The extraction ability of quaternary onium salts $R_4X^+NO_3^-$ (where R = octyl) in the series with X = N, As, or P has been investigated in relation to the extraction of nitric acid and uranyl and plutonium nitrates.³⁶ It was found that EA varies little in the above series. Thus the isotherms for the extraction of nitric acid by the nitrate salts of all three bases virtually coincide (Fig. 9a), while for uranyl and plutonium nitrates (Figs 9b and 9c) a slight decrease in EA is observed [for example, the concentration constants for the extraction of the uranyl monocomplex $R_2X^+(UO_2(NO_3)_3)^-$ are respectively 5.3, 5.0, and 4.7 for the above extractant salts] Fig. 9 shows that significant changes occur only when a second organic phase is formed: in the series N—As—P, the compatibility of the complexes formed with the diluent (CCl₄) increases appreciably. Apparently the polarity and hence the degree of polymerisation of the extractants and complexes decrease somewhat in the above series. The first factor leads to a decrease in EA, whilst the second results in the improvement of the compatibility of the complexes with the solvent. The smallness of the changes in EA in the above series confirms the generally accepted idea that the interaction between the bulky cation in the outer sphere of the complex and the MA_{2-i}^{n-i-} anion is predominantly electrostatic. The important role of the cation-anion hydrogen bond is indicated by the fact that the smallness of the changes in EA in the series N > As > P does not correspond to the change in the size of the central atom (N < P < As), but coincides with the EA series for the oxides R_3XO .

VII. The influence of the length and degree of branching of substituents on the extraction ability of organic compounds

The overall steric effect of the substituents in extraction by neutral and ion-exchange compounds is determined by at least five factors. An increase in the bulk and degree of branching of the substituents leads as a rule to a decrease in the electronegativity of the substituent, a decrease in the solubility of the extractant in the aqueous phase, an increase in the steric hindrance to complex formation, a decrease in the degree of polymerisation of the extractant, and a decrease in the rotational partition function.⁶¹

Figure 9. Extraction isotherms of nitric acid (a) and uranyl (b) and plutonium (c) nitrates by onium nitrates $R_4X^+NO_3^-$, where X = N (1), P (2), and As (3) (extractant concentration in CCl₄ 0.1 M); dashed curves — extraction of water.

The first two factors promote an increase in EA, while the others tend to decrease it. Evidently, for a moderate length of the alkyl substituents, the first two factors exert the greatest influence, whilst the importance of the remaining factors increases as a rule for bulky and branched substituents.

The length of the hydrocarbon chain of the substituent n_C particularly for the normal structure, influences comparatively slightly the extraction ability of NOPC and amine salts. Weak maxima have been noted on the $K_{ex} = f(n_C)$ curves for $n_C = 5-8$ (Fig. 10). These can be readily accounted for by the operation of the factors listed above. For NOPC, the coefficient ρ in Eqn (4) is small: $\rho(\text{UO}_2) = \rho(\text{Pu}) = 0.01$; for amine salts, it is appreciably higher: $\rho(\text{Pu}) = 0.12$ (see also Fig. 10 *b*).

Figure 10. The influence of the length of the hydrocarbon chain in symmetrical trialkylamines on the extraction of uranyl and plutonium nitrates (*a*) and plutonium nitrate and nitric acid (*b*).

Substance extracted: (1) and (4) Pu(VI); (2) and (3) U(VI); (5) HNO₃. Extractant: (1), (3), and (5) amines; (2) and (4) phosphonates.

In the early studies on extraction (see, for example, Glueckauf and coworkers^{23, 24}) a marked decrease in the extraction constant with increase in the length of the hydrocarbon substituent was noted when extraction by undiluted alcohols and ethers was investigated. This relation could not be explained since the chemical nature of extraction was not yet understood. At the present time, the explanation is evident: when account is taken of the formation of complexes, the extraction constant (or more precisely the distribution constant) is proportional to L_0^q , where L_0 is the initial concentration of the extractant (on the molar scale) and q is the solvation number. The initial extractant concentration diminishes with increase in the length of the hydrocarbon chain and in the molecular mass ($L_0^q = 9.8, 7.5$, and $5.9 \text{ mol litre}^{-1}$ for diethyl, dipropyl, and dibutyl ethers respectively). The third factor apparently also plays a role, because hydrocarbon chains are attached directly to the donor centre — the oxygen atom.

The influence of steric hindrance is clearly manifested in the extraction of uranyl and trivalent lanthanide and actinide nitrates by the amides of alkylphosphoric acids. Very high EA of such compounds have been reported, in particular of the hexabutyl phosphorous trisamide (HBTA), which greatly exceeds the EA of trialkylphosphine oxides.[‡] A careful check of the extracting properties of HBTA⁶⁶ led to unexpected results. It was found that, in extraction by nitric acid, where monosolvates are formed both with HBTA and TOPO, the extraction isotherms virtually coincide (Fig. 11); a slight excess (in favour of HBTA) was observed only at a high HNO₃ concentration, i.e. in the region

where semisolvate and one-third solvates are formed. On the other hand, in extraction by hydrochloric, perchloric, and sulfuric acids, where disolvates are formed, HBTA extracts much less effectively than TOPO (Fig. 12, Table 5). A decrease in extraction occurs also in the extraction of uranyl nitrate, where disolvates are also

‡ The greater complex-forming capacity of the amides is indicated also by the higher Gutmann donor number, although the gas-phase basicities of the amides and phosphine oxides are practically identical.⁴¹

Table 5. Constants for the extraction of acids by solutions of TOPO and HBTA in benzene in the form of disolvates (K_2), monosolvates (K_1), hemisolvates ($K_{1/2}$), and one-third solvates ($K_{1/3}$).

Acid	Extractant	K_2	K_1	$10^3 K_{1/2}^a$	$K_{1/3}^a$
HNO ₃	TOPO	0	18.5	1.7	1.4×10^{-5}
	HBTA	0	18.5	2.9	3.3×10^{-5}
HClO ₄	TOPO	1620	0.98	0	0
	HBTA	112	0.91	0.0048	2
HCl	TOPO	0.146	0.02	2.2×10^{-4}	—
	HBTA	0.014	0.0049	—	2.34×10^{-2}
H ₂ SO ₄	TOPO	29.7	0.27	2.8×10^{-4}	—
	HBTA	1.42	0.07	3.5×10^{-4}	—

^a The increased constants $K_{1/2}$ and $K_{1/3}$ for HBTA may be associated with coordination to the nitrogen atom.

formed. The lowest degree of extraction (lower by 3–4 orders of magnitude) is that of the trivalent americium and cerium, which are extracted in the form of disolvates. These results can be explained solely by the influence of the steric hindrance generated by the amide groups, the steric effect increasing non-linearly. For example, for uranyl nitrate, we have

$$\lg K_{\text{ex}}[(\text{NR}_2)_n\text{R}_3\text{—}_n\text{PO}] = \lg K_{\text{ex}}(\text{R}_3\text{PO}) - 0.15n^2.$$

The steric and electronic structures and the electron-donating capacities of a series of carbonyl compounds with amide groups, namely the ketone–carboxylic acid amide–urea series, have also been investigated. It was found that the nonadditivity of the influence of the amide groups in these systems (the strong influence of the first amide group and the weak influence of the second) is due to the geometrical hindrance to the conjugation in substituted amides and ureas. This hindrance increases with increase in the number of amide groups and in the length of the hydrocarbon groups (this system is examined in greater detail below). A characteristic feature of extraction with participation of amides is the strong influence of the length of the amide groups on the compatibility with HNO₃ solutions and even on the stoichiometry of the complex-formation reaction.⁶⁷ Thus, whereas, in the extraction of uranyl nitrate by the amide OctC(O)NR₂, where Oct = C₈H₁₇, the disolvate ($K_2 = 9.6$, $K_3 = 0.7$) is formed preferentially for R = Bu, in the case where R = C₁₂H₂₅ the main product is the trisolvate ($K_3 = 6.3$, $K_2 = 1.2$). Taking into account the increase in steric hindrance, one may postulate that the extractant molecule in the trisolvate is coordinated via a water molecule.

VIII. The use of quantum-chemical calculations for predicting extraction ability

It was shown above that equations similar to Eqns (4) and (5) have been obtained for neutral oxygen-containing compounds, amine salts, and quaternary ammonium salts. At the same time, the electronegativities and constants of the substituents may be used to predict EA only for short series of compounds with one reaction centre. The employment of these parameters is also limited by the assumption that the influence of the substituent is additive. This assumption is in many cases invalid.^{67, 68} Thus in the series of ketone–amide–urea carbonyl compounds, the effects of the first and second amide groups are not equivalent⁵⁴, i.e. there is no additivity. It is therefore useful to employ characteristics calculated by quantum-chemical methods, which are free from the assumption that the influence of the substituents is additive.

Examination of the correlation of EA with quantum-chemical parameters in different series of neutral compounds permits certain conclusions. It is possible to test the hypothesis put forward in early studies that EA is determined by the electron density (charge) on the functional atom. For this purpose, the effective charges on the oxygen atom of the phosphoryl group in a series of NOPC have been calculated. It was found that in the general case the accuracy of the estimates of the effective charges by different molecular orbital methods may be insufficient for a reliable prediction (which is aggravated also by the arbitrary features of the method of analysis of the Mulliken populations itself.)

A more reliable characteristic of the distribution of electron density in the molecule is the energy of the molecular core levels, the values of which not only depend on the effective charge on the atom but also take into account the influence of the field of other atoms.

The correlation between the energy of the 1s core levels of the donor oxygen atom ($E_{1s,O}$) and EA is characteristic for a large series of extractants with different reaction centres (Fig. 13). The nonlinearity of the dependence of $\lg K_{\text{ex}}$ on $E_{1s,O}$ is apparently due to the changes in the complex formation mechanism (noted above) with increase of the extractant basicity. On the other hand, the deviation of the points corresponding to amides and ureas indicates the restricted nature of the correlations deduced from the characteristics of isolated extractant molecules. The point is that in compounds of this kind an appreciable stabilisation of the system occurs directly on complex formation as a result of the conjugation of the bonds. The use of the energies of test reactions for prediction of EA therefore appears more justified. In addition, such energies make it possible to take into account simultaneously components of the energy of the EDA interactions such as the electrostatic, charge-transfer, geometrical ligand rearrangement, and polarisability components. Indeed, the points corresponding to amides and ureas, which deviate in Fig. 13, in Fig. 14 are found to be close to the overall correlation describing the dependence of EA on the energy of the simplest test reaction, namely protonation.

Figure 13. Dependence of the uranyl nitrate (I) and nitric acid (II) extraction constants on the energy of the 1s core levels of the oxygen atom and the effective charge on the oxygen atom. Extractant: (1) R₂CO; (2) (NR₂)₂RCO; (3) (NR₂)₂CO; (4) (RO)₃PO; (5) R₂SO; (6) (RO)₂RPO; (7) (RO)R₂PO; (8) R₃PO; (9) R₃NO.

Figure 14. Dependence of the uranyl nitrates (I) and nitric acid (II) extraction constants on the proton affinity calculated by the AM1 method. Extractant: (1) R_2CO ; (2) $(NR_2C)RCO$; (3) $(NR_2)_2CO$; (4) $(RO)_3PO$; (5) R_2SO ; (6) $(RO)_2RPO$; (7) $(RO)R_2PO$; (8) R_3PO .

The ketone-carboxylic acid amide-urea series (three points in Fig. 15) merits a more detailed consideration because this is one of the examples of the nonadditivity of the influence of the substituents. The effects arising from the introduction into the ketone molecule of the first and second amide groups are non-equivalent. The introduction of the first group increases the degree

Figure 15. Dependence of the distribution coefficient of uranyl nitrate (I), the proton affinity (II), and the effective charge on the oxygen atom (III) on the structure of the extractants. Extractant: (1) ketone; (2) carboxylic acid amide; (3) urea.

of extraction of uranyl nitrate by three orders of magnitude, whilst the second contributes little.⁶ The frequencies of the carbonyl group vibration (ν_{CO}), the solvate shift of the frequency of the hydroxy-groups of phenol on complex formation ($\Delta\nu_{OH}$), the Gutmann donor number (D_N), and the entropy of formation of a complex with BF_3 (ΔH) also change in steps (Table 6). It is clear that, since the standard correlation approaches presuppose the additivity of the influence of the substituents, they are ineffective in this case. On the other hand, the characteristics calculated by the quantum-chemical method — the charges on the oxygen atom, the energies of the core levels, and the proton affinity (PA) — also vary stepwise in the above series, like the physicochemical properties (Fig. 15), and may be used for correlation with extraction data (PA is employed for correlation within a large series of compounds with different reaction centres). The advantages of the quantum-chemical approach to the interpretation and prediction of EA have been strikingly manifested for the series of compounds considered.^{68, 69}

Table 6. Properties of carbonyl compounds.

Compound	$10^2 D$		ν_{CO} /cm ⁻¹	$\Delta\nu_{OH}$ /cm ⁻¹	D_N	ΔH /kcal mol ⁻¹
	U(VI)	Pu(VI)				
R_2CO	0.037	0.068	1730	74	17.0	18.2
$NR_2C(O)R$	88.5	26.0	1640	200	27.8	26.8
$(NR_2)_2CO$	89.0	56.4	1642	208	29.6	26.0

Together with protonation, reactions with the simplest Lewis acids — H_2O , HNO_3 ,¹⁶ Li^+ , LiH , $LiCl$, $AlBr_3$, AlH_3 , etc. — may also be used as the test reactions.²² The thermodynamic parameters of the complex formation reactions between NOPC and the above acceptors have been calculated quantum-chemically by the modern semiempirical MNDO and AM1 methods.⁶⁹ It was found that the above reaction series is isentropic, which demonstrates the validity of the correlation between EA and the enthalpies of complex formation.

An advantage of the prediction of EA from the values of PA is the relative simplicity of the calculation of EA. At the same time, limitations have also been discovered. Calculations have shown that, in the case of complexes with a weak EDA interaction, alkylphosphine oxides form more stable complexes than their phenyl-substituted analogues, i.e. the phenyl group behaves as an electronegative substituent.²² This is manifested also in all the known cases of the extraction of metals by monodentate NOPC.^{6, 12, 34} For example, in the NOPC series, the introduction of one phenyl group instead of an alkyl group diminishes the extraction constant by a factor of 17 for uranyl nitrate and a factor of 8 for americium nitrate. On the other hand, in the formation of more stable complexes with a proton an inversion is observed: phenyl substituents become electron donors. Therefore in the presence of amphoteric substituents in the reaction series, reactions not with a proton but with a weaker acceptor must be used as the test processes. The test reaction with water, which is ideal from this standpoint, suffers from a significant disadvantage — a small variation of the enthalpy of complex formation within the limits of the reaction series.

§ The main cause of the weak influence of the second amide group is the steric hindrance to the conjugation of the lone pair on the nitrogen atom of the amide group with the π -electron system of the carbonyl bond.

IX. Bidentate neutral organophosphorus compounds and the anomalous aryl stabilisation effect

Bidentate neutral organophosphorus compounds (BDNOPC) are powerful extractants. Analysis of the dependences of the distribution coefficients of americium presented in Figs 16 and 17 shows that in extraction by BDNOPC these coefficients are higher by 3–6 orders of magnitude than in extraction by monodentate NOPC. In particular, they are promising for the extensive extraction of the actinides from waste in radiochemical industries. At the same time, they are of considerable interest because of the unusual dependence of EA on the structure of the extractants. Deviations of relations (4) and (7) have been observed in the study of the extraction ability of alkylendiphosphine dioxides $R'_2P(O)(CH_2)_nP(O)R''_2$,⁷¹ and carbamoylmethylphosphine oxides $R'R''P(O)CH_2C(O)NR'''$ (abbreviated to $R'R''/R'''$). Admittedly, on formation of complexes with monodentate coordination, characteristic of the extraction of inorganic acids (HNO_3 , $HClO_4$),^{70,71} relations (4) and (7) hold qualitatively. The introduction of electronegative substituents at the phosphorus atom in place of alkyl groups lowers the degree of extraction [in particular, in the 4Oct–2Oct2Ph–4Ph series (Fig. 18)].

Eqn (4) then holds quantitatively for HNO_3 : the dependence of the logarithm of the extraction constant on the sum of the electronegativities or the Taft constants of the substituents is linear.⁷⁰ Deviations from linearity have been observed for $HClO_4$ (Fig. 19): the introduction of the first two phenyl groups greatly reduces EA, while the introduction of the next two groups has a smaller effect. In the extraction of trivalent actinides and lanthanides, complexes with bidentate coordination are formed. In this case, the replacement of alkyl groups by more electronegative groups such as $AlkO$ or $Cl(CH_2)_2$ also lowers EA (Table 7). However, when phenyl (or other aryl) group which have the electronegativity like $Cl(CH_2)_2$ are introduced into molecules of

¶ The following abbreviations have been adopted below: if $n = 1$ and $R' = R''$ the extractant is designated by 4R, if $R' \neq R''$ the designation is $2R'2R''$, and if $n > 1$ and $R' = R'' = Ph$ the designation of the extractant is 4Ph(CH_2)_n.

Figure 16. extractants Nos 1 and 4, instead of alkyl groups, relations (4) and (7) are infringed. Despite the increase in the electronegativity of the substituents and the decrease in the basicity of the methylenediphosphine dioxides, the distribution coefficients and extraction constants of trivalent americium and the lanthanides increase almost by two orders of magnitude (Figs 16 and 20). This effect, first observed by Rozen et al.⁷⁴ and discussed in a number of communications,^{22,72–79,81–87} has been called the anomalous aryl stabilisation (AAS). The data presented in Table 7 indicate

Table 7. The effective constants for the extraction of americium(III) from nitric acid solutions of $R'_2P(O)CH_2P(O)R''_2$ in the form of disolvates (determined by a method involving dilution in dichloroethane).^{72–74}

that the effect is associated not with the electronegativity but with the chemical nature of the aryl groups.

Yatsimirskii, Kabachnik, and coworkers⁸⁰ found in their conductimetric study of the formation of complexes by methylenediphosphine dioxide with certain metals in acetonitrile that the constant for the formation of a complex between NaI and 4Ph is somewhat higher than for the alkyl-substituted dioxide. However,

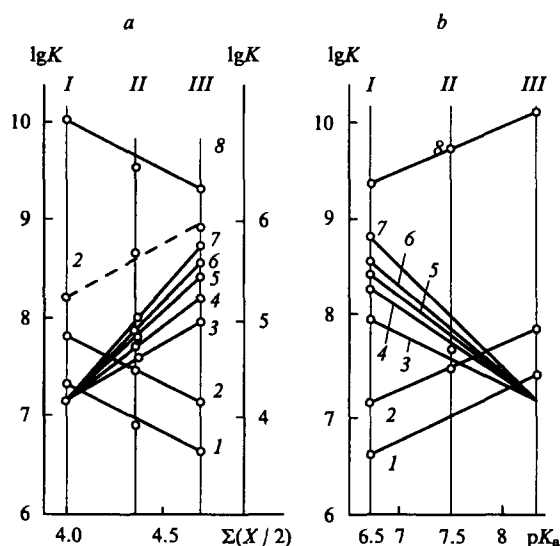

Figure 20. Dependence of the extraction constants for the actinides and lanthanides by extraction with solutions of methylenediphosphine dioxides on the sum of the electronegativities of the substituents (a) and the basicity (b).

they did not pay attention to this result, did not point it out in their conclusions, and did not note the anomaly. This may have been because the dependence of the complex formation constant on the basicity of the ligand was not investigated (and possibly also because the effect differs little from the experimental error, which in view of the abundance of assumptions made in the method, the authors estimated very optimistically as within the limits of 20%). The authors confined themselves to the hypothesis that an exotic compound is formed: a six-membered ring is not closed via two oxygen atoms through a metal cation but via an anion — through phosphorus. After more than a decade since the anomaly had been discovered by Rozen et al.⁷⁴, Yatsimirskii et al.⁸⁰ carried out a systematic study in which they replaced acetonitrile by tetrahydrofuran and found⁸¹ that the AAS effect is observed on formation of complexes of alkali metal and copper ions with methylenediphosphine dioxides and carbamoylmethylphosphine oxides in ionising solvents (Table 8).

The AAS effect is observed in various media [HNO_3 (Fig. 16), HCl , and H_2SO_4 (Fig. 21)] and is particularly large in perchloric acid solution (Fig. 22), which we believe can be accounted for by the increase in the solvation number as a consequence of the decrease in the denticity of the metal-anion bond (the extraction constant for the trisolvate is $\sim 10^{13}$). The increase in lgK_{ex} as phenyl groups are introduced is nonlinear (the first two groups make the main contribution).⁷⁷ The AAS effect depends also on the nature of the trivalent element (Fig. 20).^{74,78} In the case of tetravalent and hexavalent actinides, the distribution coefficients increase following the replacement of alkyl groups by phenyl groups, while the extraction constants diminish slightly [there is 'apparent' stabilisation (Fig. 23)]. This can be explained by the

Figure 21. Dependence of the distribution coefficient of americium in extraction by solutions of diphosphine dioxides in dichloroethane (0.01 M) from sulfuric acid (1, 3) and hydrochloric acid (2, 4) solutions on the acidity: (1) and (3) 4Oct; (2) and (4) 4Ph.

fact that the increment in ΔG due to the AAS ($\sim 3 \text{ kcal mol}^{-1}$ for two phenyl groups according to the estimate by Rozen et al.⁷⁸) is insufficient for the given elements to overcome the negative inductive effect of the phenyl groups (we may recall that the coefficients of the sensitivity to electronegativity B in extraction by NOPC are 3.1 for americium and 4.6 for tetravalent and hexavalent actinides, i.e. are much greater). On the other hand, the increase in the distribution coefficient is attained as a result of the suppression of the extraction of HNO_3 by electronegative aryl groups and the corresponding increase in the concentration of the free extractant.⁸²

When chloroform is used as the diluent, true AAS is observed for tetravalent and hexavalent actinides (Fig. 20a). This can be explained by the enhancement of the oxygen–chloroform interaction in the 4Ph–2Ph2Oct–4Oct series with a corresponding decrease in the EA for oxygen. When chloroform is employed, the solvation number probably increases from two to three^{5,76} as a consequence of the depolymerisation of the extractant.⁷⁶ Nor can

Figure 23. Dependence of the distribution coefficients of uranium in the extraction of uranyl nitrate by methylenediphosphine dioxides (apparent AAS). Extractant: (1) 4Ph; (2) 2Oct2Ph; (3) 4Oct.

one rule out the interaction of chloroform with the methylene bridge of the dioxide.⁷⁸

An unexpected result was observed in the extraction of macroamounts of europium nitrate by solutions of tetraalkyl- and tetraphenyl-methylenediphosphine dioxides in dichloroethane. Whereas in the extraction of microamounts of americium or europium by the above extractants in dichloroethane the formation of disolvates was observed (according to data concerning the influence of dilution in dichloroethane), in the extraction of europium nitrate the distribution coefficient diminishes rapidly as the extractant is saturated with europium, owing to the formation of a trisolvate [a small plateau is observed on the extraction isotherm (Fig. 24)], after which the distribution coefficients for the extractants are the same.⁷⁶

The anomalous aryl stabilisation in the extraction of americium has been noted also for carbamoylmethylphosphine oxides (Fig. 17);^{84–87} as for methylenediphosphine dioxides, the effect is enhanced in perchloric acid solution.^{88–90} However, owing to the lower extraction ability of carbamoylmethylphosphine oxides compared with methylenediphosphine dioxides, extraction from sulfuric acid solutions was not observed. Finally, the AAS has been observed⁸¹ in the formation of complexes of alkali metal ions and CuCl with carbamoylmethylphosphine oxides and methylenediphosphine dioxides (Table 8).

The occurrence of the AAS and the breakdown of relations (4) and (7) in extraction with BDNOPC indicate a significant rearrangement of the extractant molecule on complex formation. Therefore, as in extraction by amides, the prediction of EA on the basis of the characteristics of an isolated extractant molecule becomes incorrect.

The question arises of the nature of the AAS. Calorimetric measurements (unfortunately there has only been one such study⁷⁶) indicate the bonding nature of the effect. A possible explanation, first put forward by ourselves,²² is the amphoteric nature of the aryl groups. Depending on the electron-accepting capacity of the group to which the phenyl group is attached, the latter may function both as an electron donor and acceptor.²² Quantum-chemical calculation has shown²² that in a complex of a monodentate NOPC with a proton (structure 1), the phenyl group is an electron donor. When the proton is replaced by a metal cation (structure 2) or an acid molecule, the phenyl group behaves as an electronegative substituent.

This means that the electron accepting capacity of the group attached to the phenyl substituent in structure 2 is lower than in structure 1 and is insufficient for the conversion of Ph from an electron-accepting into an electron-donating substituent. The same has been observed in the formation of a complex by a BDNOPC with monodentate coordination for example, in the extraction of nitric acid (structure 3).

On the other hand, for the bidentate coordination of the extractant to the metal (structure 4), the six-membered ring formed has a reduced electron-accepting capacity and the phenyl group is converted from an electron acceptor into an electron donor.

The disappearance of the AAS when the phenyl group is separated from the phosphorus atom by a CH_2 group (in the extraction of the tetraenzyl derivative of methylenediphosphine dioxide) indicates the π - π conjugation of the Ph group with the PO group, arising on formation of the complex (a six-membered ring) and also on delocalisation of the electron density from the Ph group to the ring. The decrease in the AAS almost by three orders of magnitude when the methylene bridge between the phosphorus atom is replaced by an ethylene group, its complete disappearance after the introduction of a propylene bridge (Fig. 25), and its restoration when a vinylene bridge is introduced (despite the expansion to a seven-membered ring), as well as the high mobility of the protons of the methylene bridge[†] in the complex also

[†] Shcherbakova has shown⁷⁶ that these protons acquire the capacity for deuterium exchange, which is absent in the isolated extractant molecule.

Figure 25. The influence of the length and structure of the bridge on the extraction of americium by $\text{cis-R}_2\text{P}(\text{O})\text{CH}=\text{CHP}(\text{O})\text{R}_2$ and $\text{Ph}_2\text{P}(\text{O})(\text{CH}_2)_n\text{P}(\text{O})\text{Ph}_2$. Extractant: (I) cis-4Tol with a vinylene bridge; (II) cis-4Ph with a vinylene bridge; (1)–(3) $4\text{Ph}(\text{CH}_2)_n$, where $n = 1$ (1), 2 (2), 3 (3).

indicate the chemical nature of the effect. One may postulate that the ring is 'aromatised' — the formation of a single system of conjugated bonds.

Thus there are arguments in support of the chemical (electronic) nature of the AAS effect. On the other hand, some evidence indicates its entropic character. Firstly, this conclusion has been reached⁷⁴ on the basis of the determination of the enthalpy of extraction from the temperature variation of the concentration extraction constant for trivalent americium in the series $4\text{Oct}-2\text{Oct}2\text{Ph}-4\text{Ph}$ (Table 9). Secondly, the changes in the extraction of HNO_3 , in the IR spectra of the PO group, and in X-ray photoelectron spectra indicate a decrease in the electron-donating capacity of the oxygen atom in the phosphoryl group in the above series (which, admittedly, does not rule out stabilisation on complex formation and cyclisation via the metal cation).

Table 9. The americium extraction constants and the enthalpies of extraction calculated from their temperature dependence (0.01 M solutions of the extractants in dichloroethane).⁷⁴

Parameter	4Oct	2Oct2Ph	4Ph	4Ph(CH ₂) ₂

$-\Delta H$ (calc) /kcal mol ⁻¹	15.0	14.2	13.0	11.6

In their study of the extraction of Am(III) by carbamoylmethylphosphine oxides, Chiarizia and Horwitz⁹¹ noted that the AAS is observed only for a high polarity of the diluent (when the diluent parameter $\text{ID} > 3$, for example, nitrobenzene, nitromethane, and chloroform). In weakly polar media (tetrachloroethene, carbon tetrachloride, and *o*-xylene) the effect is absent; the solvation number then increases from 2 to 3. Taking into account these data, the authors concluded that the AAS is an effect of the diluent. However, by analysing our results,⁸³ we found that in extraction by methylenediphosphine dioxides the AAS effect is observed also when a weakly polar solvent (benzene) is employed (Fig. 26). It may be that the results of the above study⁹¹ can be accounted for by the loss of bidentate coordination with increase in the solvation number. At the same time Japanese investigators,^{92,93} who studied the NMR spectra, showed that carbamoylmethylphosphine oxides in trisolates are coordinated as bidentate species to cerium and europium atoms. Admittedly, the highly polar deuteriochloroform was used as the diluent, which may be the reason for the retention of the bidentate coordination.

Figure 26. Isotherms for the extraction of americium(III) by 0.01 M solutions of methylenediphosphine dioxides in benzene (a) and chloroform (b). Extractant: (1) 4Ph; (2) 2Ph2Oct.

Thus the causes of the AAS have not been fully established and the contributions of the electronic and entropic effects have not been separated. Despite this, the AAS effect is useful in practice. In contrast to monodentate NOPC, including phosphine oxides which extract effectively tetravalent and hexavalent actinides but are ineffective in the extraction of trivalent actinides and lanthanides, the bidentate NOPC, especially those containing aryl groups, extract trivalent actinides with very high distribution coefficients.

The extraction ability of BDNOPC is influenced by the length and structure of the alkylene bridge. It was found that this influence depends both on the nature of the substituents in the BDNOPC molecule and on the properties of the compound extracted. For example, in the extraction of uranyl nitrate by alkylendiphosphine dioxides with alkyl substituents, the influence of the length of the bridge is small and the highest EA is observed in the case of the ethylene bridge (Fig. 27a).⁹⁴ The chelation effect is then small (<10), but, if uranyl nitrate is replaced by the perchlorate, the chelation effect is 10^5 and is suppressed on lengthening the bridge, i.e. the AAS effect, which is suppressed following an increase in the length of the bridge, is observed. In the case of aryl substituents, the effect of the bridge length is very strong (Figs 25 and 27) probably because the AAS effect is suppressed; in the case of the propylene bridge, the EA is lowest and corresponds to the electronegativity of the aryl

Figure 27. The influence of the length and structure of the bridge on the extraction of U(VI) by diphosphine dioxides.

(a) Extraction by tetrahexylalkylendiphosphine dioxides; the numerals opposite the curves indicate the length of the alkylene bridge; (0) extraction by TOPO; (b) extraction by dioxides with vinylene and alkylene bridges.

substituents. As we have already mentioned, when a vinylene bridge is introduced in the *cis*-position, the conjugation and the AAS are restored but in the case of uranyl nitrate an appreciably higher EA is attained than for the dioxide 4Ph,⁹⁵ while in the extraction of americium the EA is lower⁸⁸ (Figs 27b and 25) by an order of magnitude in nitric acid and by as much as three orders of magnitude in perchloric acid. The dioxide with a vinylene bridge 'catches up' with the dioxide 4Ph only when the phenyl substituents are replaced by tolyl substituents (Fig. 25). Apparently the electronic and steric effects also play a role in this case. We may note that the difference between the shapes of the $D = f([HNO_3])$ curves for UO_2^{2+} and Am^{3+} can be explained by the difference between the stoichiometries: in the reaction with UO_2NO_3 , the monosolvate is formed together with the disolvate,⁹⁵ which lowered the displacing effect of HNO_3 and shifts the maximum in the distribution coefficient towards higher nitric acid concentrations.

The study of the influence of the replacement of hydrogen in the methylene bridge of methylenediphosphine dioxides and carbamoylmethylphosphine oxides by various substituents, for example, in the compounds $Ph_2P(O)CHY(O)PPh_2$ ($Y = C_3H_7$, CH_3 , or Cl) in the extraction of the actinides, showed that in all cases such replacement lowers appreciably the distribution coefficients.^{87,97,98} We found⁹⁷ that the AAS vanishes for $Y = C_6H_5$, i.e. both protons of the methylene bridge are needed for the appearance of the effect. Despite the decrease in EA, which is particularly marked (by four orders of magnitude) in perchloric acid solution, the selectivity diminishes. However, in the case of the methylenediphosphine oxide 4Ph, the introduction of a pyridine group into the methylene bridge increases significantly the distribution coefficient for the transplutonic element/lanthanide element pair.¹⁰⁰ For alkali metals, the introduction of methyl groups into the bridge increases the stability of the complexes.⁸¹ Steric effects apparently play an important role.

The influence of substituents in the benzene ring on the EA of the tetraaryl-methylenediphosphine dioxides 4Ar in chloroform has been investigated¹⁰¹ in relation to the extraction of uranium (trisolvates are extracted; $K_U = 0.7 \times 10^8$ may be found from the data¹⁰¹ for 4Ph). On passing from the unsubstituted phenyl group to *p*-tolyl (i.e. after the introduction of the CH_3 group into the benzene ring), the extraction constant increased by a factor of 1.5; after the introduction of a p - CH_3O group, the increase was by two orders of magnitude; the CH_3O group in the *meta*-position does not increase the degree of extraction. The replacement of CH_3O by C_4H_9O causes an additional increase in the constant by a factor of ~ 2 . The introduction of halogen-containing groups diminishes the solvation number from 3 to 2 and leads to a very marked decrease in the degree of extraction: for $Ar = ClC_6H_4$, BrC_6H_4 , p - $CF_3C_6H_4$, and *m*- $CF_3C_6H_4$, the extraction constants are respectively 130, 110, 70, and 14, i.e. diminish with increase in the electronegativity of the groups introduced. When alkyl groups attached to phosphorus atoms were introduced into the benzene rings of carbamoylmethylenephosphine oxides,¹⁰² an increase in the degree of extraction was observed, as for methylene diphosphine dioxides. The influence of the substituent at the nitrogen atom on the EA of carbamoylmethylphosphine oxides has also been investigated;¹⁰³ it proved to be weak and, when a phenyl group was introduced, there was no AAS effect.

Chmutova, Myasoedov, and coworkers^{104,105} investigated the extraction of nitric acid, americium, uranium, and plutonium by bidentate organophosphorus compounds with a rigid bridge (a benzene ring fragment) — the *ortho*- and *meta*-isomers of xylylenediphosphine dioxides (see also Rozen's review⁷⁹). It was found that the introduction of two $CH_2P(O)Ph_2$ groups in the *ortho*-position increases the selectivity of the separation of the U/Pu and Pu/Am pairs: the separation factor reaches 10^3 – 10^4 . This result has no practical significance (such separation factors are obtained also in extraction by TBP), but it is important because it indicates a possible way of increasing the selectivity by employing steric hindrance or rigid units †.

† The idea that rigid units should be used to improve selectivity is due to Kabachnik.¹⁰⁰

It is of interest that the *meta*-isomer of tetraphenylxylylenediphosphine **6** exhibits a much lower selectivity and basicity than the *ortho*-isomer **5**,^{194, 105} but it extracts actinides with appreciably greater distribution coefficients. The degree of extraction of americium by the *meta*-isomer is higher by three orders of magnitude — for example, $K_{ex\ o} = 3.26 \times 10^2$ and $K_{ex\ m} = 4.9 \times 10^5$ for tetra(*p*-tolyl)xylylenediphosphine dioxide. On the other hand, the degree of extraction of uranium and plutonium increases only severalfold on passing from the *ortho*- to the *meta*-isomers. The uranium/americium separation factor therefore diminishes by two orders of magnitude. These surprising results were explained¹⁰⁶ by the fact that, owing to steric hindrance, in the extraction by the *ortho*-isomer only complexes involving monodentate coordination are formed with the actinides. Under these conditions, the trivalent elements are poorly extracted (as in extraction by TBP), so that the An(IV)/An(III) or An(VI)/An(III) separation improves. On the other hand, in extraction by the *meta*-isomer complexes involving bidentate coordination are formed as a consequence of the decrease in steric hindrance, the degree of extraction of americium increases, and the Am/U and Am/Pu separation is less effective.

Judging from data on the extraction of nitric acid by tetraphenylxylylenediphosphine dioxide, the *meta*-isomer should be more basic: $K_{1o} = 0.0336$, $K_{1m} = 0.51$. This has also been confirmed by the AM1 quantum-chemical calculation: the *meta*-isomer forms more stable complexes with nitric acid than the *ortho*-isomer ($\Delta H = -8.6$ and -7.1 kcal mol⁻¹ respectively), which agrees with the observed difference between the extraction constants. It has been suggested¹⁰⁶ that, in the determination of *ortho*-isomer basicity by titrating the reagent with perchloric acid in nitromethane, a complex involving the bidentate coordination of the proton is formed. This in fact leads to an increased formal basicity. Indeed, our calculations by the AM1 method have shown that the *ortho*-isomer effects the bidentate coordination of the proton (the distance between the oxygen atoms of the phosphoryl groups is $R = 2.3$ Å) and with a much higher interaction energy ($PA = 256.2$ kcal mol⁻¹) than the *meta*-isomer, for which the coordination of the proton is monodentate ($R_{O...O} = 6.1$ Å, $PA = 224.1$ kcal mol⁻¹). On the other hand, the *meta*-isomer forms a more stable complex with the lithium cation than the *ortho*-isomer ($R_{O...O} = 2.8$ and 3.9 Å, $\Delta H = -41.8$ and -6.8 kcal mol⁻¹).

A phenomenon resembling the true AAS has been observed in such systems for a ten-membered ring.¹⁰⁵ The americium extraction constants have been determined for tetra(*p*-tolyl)-*m*-xylylenediphosphine and tetrabutyl-*m*-xylylene dioxides as 4.89×10^5 and 2.5×10^5 respectively. However, an americium extraction constant of 1.45×10^4 has been found for tetraphenyl-*m*-xylylenediphosphine dioxide, i.e. there is no true aryl stabilisation. Apparently for this ring size the energy increment corresponding to the AAS (~ 1 kJ per mole of Ph) is small and is insufficient to overcome the negative inductive effects of the phenyl group; the operation of steric factors may also prove to be important.

Carboxylic acid diamides are also effective bidentate extractants, for example, $CH_2[C(O)NOctMe]_2$, which has been proposed as an extractant for the actinides.¹⁰⁷ The tridentate dicarbamoylphosphine oxides **7** are interesting because the AAS effect is observed when the methyl group is replaced by the phenyl group.¹⁰⁸

The study of extraction by polyphosphine oxides containing three and four phosphoryl groups showed that the increase in EA compared with that of the dioxides was insignificant.¹⁰⁹

X. Polydentate neutral extractants — crown-ethers

Polydentate extractants (crown-ethers) are known to be stereospecific. The stereospecificity is manifested predominantly (not always owing to the flexibility of the rings) in the electrostatic interaction occurring in processes involving the extraction of alkali and alkaline earth metals. In the extraction of acids and metal salts (strong electron acceptors), electronic effects, especially EDA interaction play an important role.^{110–113}

In order to obtain quantitative data necessary for the determination of the dependence of the EA of crown-ethers on the structure, a study was made⁹⁸ of the extraction of nitric acid and plutonium, neptunium, uranyl, and thorium nitrates by crown-ethers of the type 18-crown-6 with different substituents. 18-Crown-6, dibenzo-18-crown-6, dicyclohexyl-18-crown-6, as well as dibenzo-ethers with alkyl or alkoxy-groups introduced into the benzene ring were used.⁵

The data obtained permit the conclusion that the rules characteristic of extraction by monodentate compounds hold. Thus, with increase in acidity, curves with a maximum (Pu) are observed. These are due to the combination of the salting-out and displacing effects of the acid.²⁷ The concave initial section of the uranium and thorium extraction isotherms is due to the dissociation of the salts in the aqueous phase. Plutonium and thorium form disolvates with crown-ethers, whilst uranium and HNO₃ form monosolvates. The extraction of actinides by crown-ethers depends greatly on their oxidation state as, in the case where monodentate extractants, for example, TBP, are used. The extraction ability increases in the sequence Th(IV) < Np(IV) < Pu(IV), etc.

At the same time, the equilibria involving crown-ethers are more complex than those involving monodentate extractants. The intense extraction of HNO₃ by crown-ethers is noteworthy: for an acidity > 6 M, it is much more pronounced than the extraction employing the most 'powerful' extractant among the NOPC — the phosphine oxide TOPO (Fig. 28 a). The complexes (HNO₃)_h(H₂O)_h·L, containing from one to twenty or more acid molecules per ligand molecule, are formed. The equilibrium has been described¹¹⁰ as the formation of a polymer chain with attenuation (a decrease in the constant for the addition of the last acid molecule with increase in its number). The usual description with the aid of a single constant¹¹¹ is inappropriate here. The first extraction constants observed for crown-ethers are higher than for ordinary ethers by two–three orders of magnitude, which indicates polydentate coordination. The thorium extraction isotherm was found to be complex. For thorium, dilution yields an apparent solvation number of 1, whereas according to saturation data it is 2. This contradiction has been explained¹¹⁰ by the dissociation of the complex in the organic phase. The constants for extraction by crown-ethers are presented in Table 10.

§ The extraction of HNO₃ and actinide nitrates has been investigated by Yakshin and coworkers.^{111, 112} Unfortunately the complexity of the equilibria in systems with crown-ethers (especially in the extraction of HNO₃, see below) was not taken into account in the above studies, the extraction constant was determined from one point, and a check was not made to make sure that the isotherm as a whole is described for this value of the constant (distribution data are not presented by Yakshin et al.¹¹¹). As a result, the quantitative extraction characteristics found by Yakshin and coworkers^{111, 112} and quoted in a review¹¹⁴ are only qualitative and may differ from the true values severalfold.

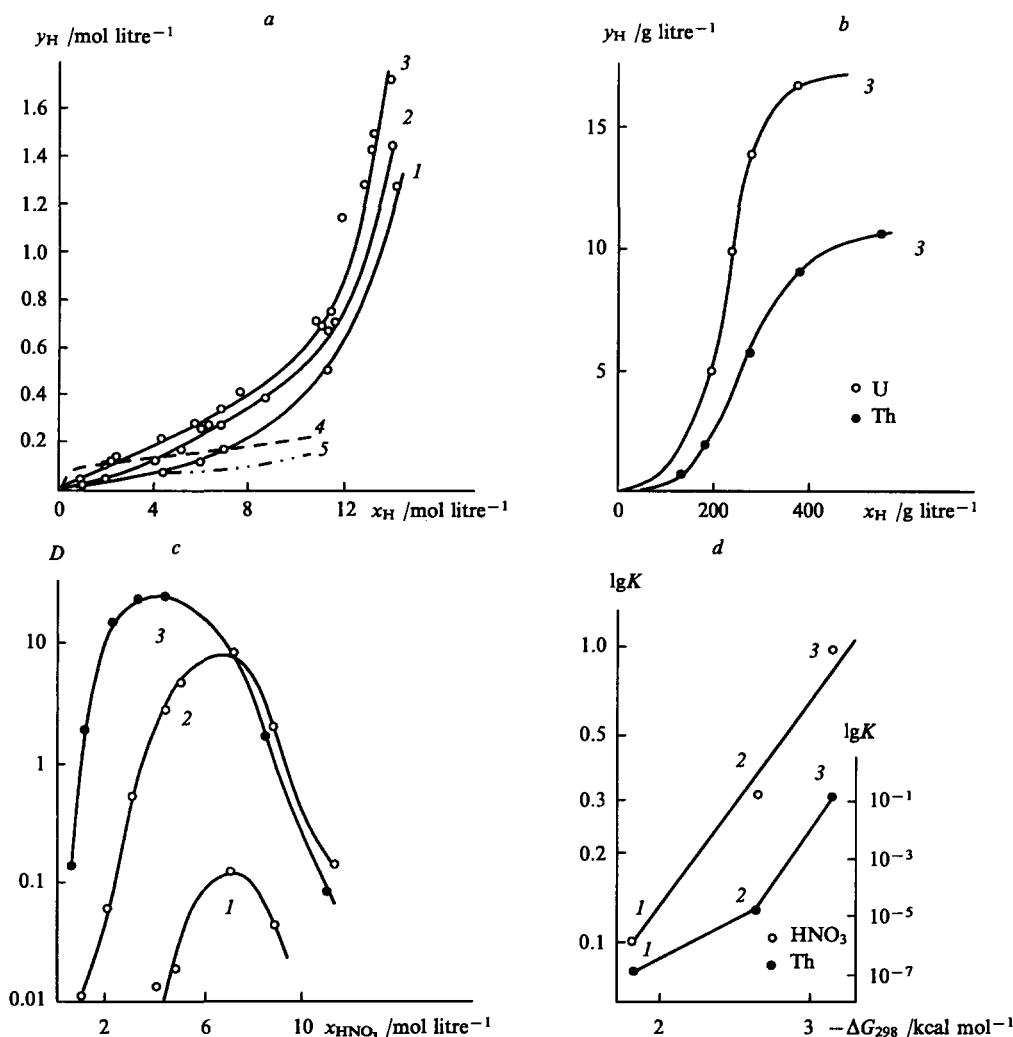

Figure 28. Isotherms for the extraction of HNO₃ (a), uranium and thorium (b), and plutonium (c) by solutions of crown-ethers in dichloroethane (0.1 M) and dependence of the extraction constant on the basicity (the energy of the interaction with phenol) (d). Extractant: (1) dibenzo-18-crown-6; (2) 18-crown-6; (3) cyclohexyl-18-crown-6; (4) TOPO; (5) TBP.

The dependence of the extraction ability of crown-ethers on structure is similar to that for neutral monodentate compounds. In particular, it is possible to control the EA of crown-ethers by varying the substituents. According to Eqns (4) and (7), EA increases with decrease in the electronegativity of the substituents (phenyl < alkyl < cyclohexyl) and the corresponding increase in

the basicity of the crown-ether (for example, the energy of the reactions of the ethers with phenol¹¹³) in the series dibenzo-18-crown-6 < 18-crown-6 < dicyclohexyl-18-crown-6 (Fig. 28 d).

The nonlinearity of the correlation may be associated with an insufficiently correct allowance for the solubility of 18-crown-6 in the aqueous phase. The introduction of alkyl groups into the benzene ring of dibenzo-18-crown-6 has little effect on its EA, while an alkoxy-group increases the EA to the level of the EA of 18-crown-6 (i.e. the same rules are observed as in extraction by BDNOPC, but they are less stringent).

The results constitute fairly convincing proof of the important role of electronic factors. A detailed survey of data on the extraction properties and the complex-forming capacities of crown-ethers may be found in a monograph.¹¹⁴ Different contributions to the complex-formation energy have been analysed.^{115, 116}

Unfortunately crown-ethers extract trivalent actinides and lanthanides very weakly (the basicity of the oxygen in the ether group is low). It would be useful to develop macrocyclic extractants for the extraction and fine separation of trivalent actinides and lanthanides.

XI. Organic acids

Organophosphorus acids (R^1R^2POOH) and carboxylic acids ($RCOOH$) are frequently used as extractants. The presence of the functional groups PO and OH in the organophosphorus acids and of CO and OH in carboxylic acids permits the extraction of a metal via both the cation-exchange and solvate or mixed mechanisms. We shall consider these mechanisms in relation to organophosphorus acids (OPA).

1. Extraction via the cation-exchange mechanism

The cation-exchange extraction mechanism predominates in the weakly acid region. When account is taken of the dimerisation of the acid, the process is described by Eqn (3) and the extraction ability is characterised by the equilibrium constant of this reaction. The metal cation extracted replaces the proton of the organic acid and is at the same time coordinated to the oxygen atom of the phosphoryl group.

Thus both functional groups (PO and OH) participate in the coordination. This is the reason for the characteristic feature of the influence of the structure of the OPA on their extraction ability in extraction via the cation-exchange mechanism. The change in the electronegativity of the substituents X has the opposite effect on the reactivity of the groups PO and OH: with increase in the electronegativity, the strength of the acid and the EA of the OH group increase, but the electron-donating capacity and the extraction ability of the oxygen atom of the phosphoryl group diminish.³⁴ As a result, in contrast to NOPC for which the dependence of EA on the structure is universal, in extraction by OPA the nature of the influence of the structure depends on the nature of the element extracted and on the way in which this element reacts with each centre. Thus the acid strength and the degree of extraction of trivalent actinides and lanthanides, which form predominantly an ionic bond and are weakly coordinated to the oxygen atoms of the PO group, increase in the series $R_2POOH - R(RO)POOH - (RO)_2PCOH$ (i.e. with increase in the electronegativity of the substituents). Conversely, the degree of extraction of tetravalent and hexavalent actinides, which are strongly coordinated to the PO group (they form predominantly a covalent bond) weakens in this series (Fig. 29). One may assume that^{6,34,49}

$$\lg \tilde{K}_{ex} = A' + (B_{OH} - B_{PO}) \Sigma X. \quad (11)$$

In the extraction of trivalent actinides and lanthanides, $B_{OH} > B_{PO}$ and the extraction ability of OPA increases with

Figure 29. Dependence of the extraction ability of organophosphorus acids [the $(RO)_2POOH$ (1)– $RORPOOH$ (2)– R_2POOH (3) series] on the sum of the effective electronegativities.

(a) Constants for the extraction of UO_2^{2+} (I) and Am^{3+} (II) via the ion-exchange mechanism; (b) constants for the extraction of UO_2 via the ion-exchange (K_1), exchange-solvate (K_{12}), and solvate (K_2) mechanisms.

increase in the electronegativity of the substituents. $B_{OH} < B_{PO}$ in the extraction of uranyl, so that the opposite dependence of EA on the electronegativity holds.

The above explanation was confirmed also by semi-empirical AM1 and PM3 quantum-chemical calculations.¹¹⁷ We used the enthalpy (ΔH_{exch}) of the gas-phase exchange reaction as a characteristic of the EA

In the determination of ΔH_{exch} (in contrast to the determination of the enthalpy of the extraction reaction), no account was taken of the hydration energies of protons and cations (transhydration energies), which remain unchanged if only the extractant is varied. The assumption that the nonspecific solvation has only a slight effect on the process energy relations is therefore fully justified. The overall process may be represented as consisting of two stages: (1) deprotonation of the acid dimer molecule; (2) formation of cyclic complexes. ΔH_{exch} is the sum of the enthalpies of these reactions. The acids R^1R^2POOH , where $R^1, R^2 = R, RO$ ($R = \text{Alk}$), and Cl, were examined and model ions were chosen as the acceptor (Kat^+) — 'hard' $AlBr_2^+$ and 'soft' (HgH^+). According to Pearson's theory, the former ion should form predominantly ionic bonds and the latter predominantly covalent bonds.

As can be seen from Fig. 30, the calculated ΔH_{exch} increases for $AlBr_2^+$ and decreases (slightly) for HgH^+ with increase in acid strength in the series $R_2POOH - RORPOOH - (RO)_2POOH - Cl_2POOH$, which agrees with the experimental extraction data presented above.

Figure 30. Dependence of the enthalpy (ΔH_{exch}) of the exchange reaction between organophosphorus acids and $AlBr_2^+$ (1, 2) and HgH^+ (3, 4) on the enthalpy of the organophosphorus acid deprotonation reaction (ΔH_d). Calculation by the AM1 (1, 3) and PM3 (2, 4) methods.

Figure 31 presents the variation of constants for the extraction of trivalent americium and promethium by organophosphorus acids over a wide range of variation of ΣX and the acid strength (pK).¹¹⁸ Evidently, by increasing the electronegativity of the substituents and hence the acid strength, it is possible to increase the extraction of trivalent lanthanides and actinides by several orders of magnitude. Alkylphenylphosphoric acid has the highest EA ($pK = 1.4$);[†] a further increase in EA could probably be achieved by the replacement of the alkoxy-group by PhO ($pK = 0.8$) and ClC_6H_4O ($pK = 0.2$).

[†]The quality of the correlation is unsatisfactory possibly because we employed old data; as in the case of NOPC, an effective electronegativity ($X_{ef} = 2.2$) had to be introduced for the RO group.

Figure 31. Dependence of the constants for the extraction of promethium (I) and americium (II) by the organophosphorus acids R^1R^2POOH on the Kabachnik (a) and Taft (b) substituent constants and pK (c) over a wide range of basicities.

Together with the increase in EA, an important aspect of the improvement of OPA as extractants is, firstly, an increase in the phase stability of their complexes as a result of the suppression of polymerisation which leads to the formation of gels insoluble in the diluent and reducing the capacity of the extractant; secondly an increase in selectivity, especially in the separation of lanthanides and actinides. Both problems can be solved by optimising the hydrocarbon chain. About 30 years ago, diethylhexylphosphoric acid (D2EHPA) began to be used. It exhibits a higher selectivity and phase stability than di-n-octylphosphoric acid as a result of the branching in the β -position. However, it has been recently observed that free D2EHPA and some of its complexes are polymerised to an extent exceeding dimerisation.^{119,120} A further improvement of the properties of OPA by lengthening the hydrocarbon chain is possible, but a better solution has been proposed¹²¹ — the replacement of alkyl substituents by the bulky ethylcyclohexyl [diethylcyclohexylphosphoric acid (DiECHPA)] or cyclohexylcyclohexyl [dicyclohexylcyclohexylphosphoric acid (DiCHCHPA)] substituents:

The bulky substituents suppress polymerisation in the extraction of the lanthanides; the formation of gels was not observed and the capacity c_M/c_{HR} increased (for example to 40% and 35% respectively in the case of neodymium instead of 25% for D2EHPA) and the total energy of the complexes $Nd(HR_2)_3$, calculated by the molecular modelling method, increased by a factor of 2 and 3 — from 550 for D2EHPA to 1120 for DiECHPA and 1700 kcal mol⁻¹ for DiCHCHPA. There was also a significant increase, compared with D2EHPA in the extraction ability for DiCHCHPA (by 1–2 orders of magnitude) (Fig. 32) and in the selectivity (especially for the La/Ce and Gd/Ho pairs).

It has been shown¹²² that the monobasic acid (a D2EHPA analogue)

is a more effective extractant than D2EHPA. It was shown in the above study that dibasic acids having the general formula

are effective for the extraction and separation of the lanthanides. Here X may be $-(CH_2)_2-$, $o\text{-C}_6\text{H}_4$, or $p\text{-C}_6\text{H}_4$. The dibasic acid containing a phenyl group in the *para*-position (*p*-DA) in the middle of the bridge proved to be the most effective and selective (predominantly in relation to the heavy lanthanides). The authors explain their results by the steric hindrance generated by the bridge and the advantage of *p*-DA by the rigidity of the bridge with a phenyl group in the *para*-position. It is noted that *p*-DA is

present in solution as the trimer (the remaining dibasic acids are dimerised).¹²²

Interesting results have been obtained in the study of Yuan et al.¹²³ The influence of steric factors was investigated in relation to the extraction of the lanthanides by alkylphosphonic acids $R(RO)POOH$ with different structures of the alkyl and alkoxy-chains. It was noted that, for a virtually identical basicity ($pK = 4.1-4.5$), the acids differ by an order of magnitude as regards both their EA and selectivity (Table 11). The branching of the alkyl chain increases the degree of separation predominantly of the heavy lanthanides, while the branching of the alkoxy-chain increases the separation of the light lanthanides. The influence of branching is greater the closer it is to the central phosphorus atom.

In the same study,¹²³ an attempt was made to discover by the molecular mechanics and quantum-chemical methods the optimum conformation of the acids and to investigate the influence of their structure on electronic characteristics.

2. Extraction by the exchange-solvate and solvate mechanisms

We have already mentioned that the extraction by OPA is not confined to the cation-exchange complex-formation mechanism. With increase in the acidity of the aqueous phase, this mechanism is suppressed and new mechanisms arise. We shall examine this problem in relation to the extraction of uranyl as example.

In the weakly acid region, the cation-exchange extraction mechanism predominates; for example, for uranyl we have

Under these conditions, the distribution coefficient of uranium (like those of other metals) rapidly diminishes with increasing acidity ($D_U \sim x_{HNO_3}^{-2}$). However, as can be seen from Fig. 33, this decrease is replaced by an increase — a minimum and then a maximum in the distribution coefficient is observed (at acidities of 3 and 6 M respectively for D2EHPA).^{49,127} This indicates a change in the complex formation mechanism. It has been

Figure 33. The contributions of different mechanisms to the extraction of U(VI) by diheptylphosphoric (a), phosphonic (b), and phosphinic (c) acids (0.0005 M in *o*-xylene).

(1) Experimental data; (2) ion-exchange mechanism; (3) exchange-solvate mechanism; (4) solvate mechanism.

suggested^{125, 126} that the cation-exchange extraction mechanism is replaced by the solvate mechanism:

However, it has been shown^{124, 127} that the ideas of the above workers^{125, 126} are too simplified and that the description of the result is erroneous. Agreement with experiment was achieved on the assumption that the activity coefficients of uranyl nitrate in the aqueous phase γ_{\pm} are constant, whereas they increase from 0.5 to 2.5, i.e. by a factor of 5, as the ionic strength is raised from 0.5 to 10, while the value of γ_{\pm}^3 in the equation of the Law of Mass Action increases by a factor of 100.

In reality it was found that, as the acidity increases, the second extraction reaction is not reaction (12) but the formation of an exchange-solvate complex containing one inorganic and one organic anion:

On the other hand, reaction (12) hardly occurs for D2EHPA: $K_{11} = 10^4$, $K_{12} = 3 \times 10^4$, and $K_{22} < 10$, possibly owing to steric hindrance (for di-n-octyl phosphoric and di-n-heptylphosphoric acids, $K_{22} = 5 \times 10^2$, i.e. an appreciable albeit relatively small value).

The role of solvate formation by reactions (12) and (13) increases in the series alkylphosphoric–phosphonic–phosphinic acids, i.e. with increase in the electron-donating capacity of the oxygen atom of the phosphoryl group.^{34, 49} The 'sensitivity' of the extraction constant to changes in the structure of the substituents (their electronegativity) in the course of the transition from the ion-exchange to the exchange-solvate and solvate mechanisms intensifies (Fig. 29).

In the extraction of ions of higher valence, the picture becomes more complicated, since there is a possibility of the appearance of several exchange-solvate complexes, for example, the formation of MY_3NO_3 , $\text{MY}_2(\text{NO}_3)_2$, and $\text{MY}(\text{NO}_3)_3$ for Pu(IV). The hypothesis has been put forward⁴⁹ that the symmetrical exchange-solvate complex $\text{MY}_2(\text{NO}_3)_2$ exists, but no evidence was quoted. We may note that the extraction of Pu(IV), which is effectively coordinated by the oxygen atom in the phosphoryl group,³⁰ weakens, like that of uranyl, in the series phosphinic–phosphonic–phosphoric acids, i.e. with increase in the electronegativity of the substituents and with decrease in the EA of the PO group.⁴⁹

3. Extraction by bidentate phosphonitrilic acids

The extraction ability of OPA is greatly reduced by dimerisation, which results in the binding of both reaction centres — PO and OH. Accordingly there is a possibility of a new way of controlling their EA: the creation of obstacles to dimerisation, for example, the employment of multiunit polyphosphonitrilic acids. These acids have been proposed as extractants by Laskorin et al.¹²⁸ Indeed, it has been found^{129, 130} that the constants for the extraction of americium and europium by polyphosphonitrilic acids are 8 orders of magnitude higher than the constants for the extraction of these elements by D2EHPA. For the tetravalent and hexavalent actinides, the increase in EA was comparatively small. This can be accounted for by the fact that the intensification of the extraction of Am(III) and Eu(III) was assisted by the imide rearrangement

since the number of OH groups, successfully coordinating trivalent elements, increased, but at the same time the PO groups, which coordinate tetravalent and hexavalent actinides most effectively, disappeared.

An advantage of the polydentate phosphonitrilic acids as extractants is a very high EA, whilst their disadvantage is a low selectivity.

XII. Organic acid salts

The acid salts of certain metals (Zr, Hf, Ti, etc.) are known to exhibit higher EA than the corresponding phosphoric acids.^{131–133} This phenomenon is usually explained by the enhancement of the acid properties; the salt [for example, $\text{ZrY}_4(\text{HY})_2$] may be regarded as a strong metalloid acid (for example, H_2ZrY_6), assuming implicitly that the dependences of EA on the structures of the acids and their salts obey common rules. In this case, one may postulate that the possibilities for increasing the EA of the salts (and hence of increasing the concentration of the inorganic acid at which these extractants are capable of extracting radionuclides effectively) are far from exhausted. Stronger organic acids, for example, sulfonic acids, may be used.

At the same time we do not believe that this is the only explanation, since an increase in acidity may be accompanied by the simultaneous decrease in the energy of the complex formation reaction with the metal cations. Quantum-chemical calculation has shown that OPA salts are indeed stronger extractants than the acids themselves,¹¹⁷ but the main reason for the differences between the extraction abilities of the OPA and their acid salts with metals are the differences between the energies of the steric strain in the ligands.¹³⁴

The salts of organic acids with inorganic bases, for example R_4NY (binary extraction proposed by Khol'kin^{135, 136}) are of great interest as extractants. The binary extractant belongs to the neutral group. For example, the extraction reaction of the acid H_mB takes place in accordance with the equation:

However, the initial section of the extraction isotherm is linear and the distribution coefficient is approximately constant,^{135–137} whereas in the extraction by the usual neutral extractants at $x \rightarrow 0$, $D \rightarrow 0$.²⁷ It can be shown that the binary process is analogous to extraction by neutral extractants with dissociation of the compounds in the organic phase:

In both cases the number of species (ions) does not change in the extraction process, so that we have $D(0) = \text{const}$, when $x \rightarrow 0$.^{137, 140} However, there are incomparably greater possibilities for controlling the binary process. In particular, the EA of the binary extractant may be increased by employing a weaker acid HY; the extraction constant $K(\text{H}_m\text{B}) \approx K_a^{-m}$, where K_a is the dissociation constant of the acid HY. This fact has been confirmed in the extraction of inorganic acids and platinum metals.¹³⁸ In the latter case, the binary extractants have a great advantage over inorganic salts of amines and quaternary ammonium bases because they do not form insertion complexes and make it possible to achieve back-extraction readily.

We may note that the EA of binary extractants may be determined not only by the strength of the acids but also by the operation of steric factors. For example, the degree of extraction of H_2PdCl_4 by tetraoctylammonium alkyl(alkoxy)sulfonates increases in the series of the following anions derived from sulfonic acids of similar strength:

i.e. it increases with increase in the number of substituents and in the length of the chains of the alkyl groups.¹³⁸

Cobalt dicarbollides, which effectively extract caesium (at HNO_3 concentrations up to 4–6 M), strontium, and trivalent actinides and lanthanides, are unusual acid extractants.¹³⁹

XIII. The influence of diluents on the extraction ability of organic compounds

The nature of the diluent has a comparatively weak influence on extraction by monodentate neutral compounds, for example, NOPC, but has a strong influence on extraction by BDNOPC. What is the explanation? We may recall that the effective extraction constant is ^{5, 34, 140}

$$K = \frac{K_T \gamma_L^q}{\gamma_c}, \quad (14a)$$

where K_T is the thermodynamic extraction constant, γ_L and γ_c are the activity coefficients of the extractant and the complex respectively, and q is the solvation number. The thermodynamic constant is independent of the nature of the diluent and its influence is determined by the parameter

$$\text{dil} = \frac{\gamma_L^q}{\gamma_c}. \quad (14b)$$

The activity coefficients of the extractant and the complex in basic diluents (saturated and aromatic hydrocarbons, aprotic chloroderivatives) have been determined experimentally in relation to the extraction of uranyl nitrate by TBP [the complex $\text{UO}_2(\text{NO}_3)_2\text{L}_2$]^{141, 142} and the uranyl salt of D2EHPA [the complex $\text{UO}_2(\text{HY}_2)_2$].¹⁴³ Table 12 presents the values of γ_L and γ_c at zero concentrations of the extractants complexes and also the values of $\text{dil}(0)$ and $\text{dil}/\text{dil}_{\text{CCl}_4} = D/D_{\text{CCl}_4}$. Comparison of the measured values of dil with experimental extraction data indicates satisfactory agreement. The coefficients γ_L for various diluents differ markedly (for example, by an order of magnitude for benzene and hexane). Since in the above systems $q = 2$, one might have expected differences between the parameters dil and D by two orders of magnitude. However, as can be seen from Table 11, the activity coefficients of the complex change 'in the same direction' as γ_L and a compensation takes place — the values of dil and D for various diluents differ little from one another (dilution with chloroform, where dil and D are significantly reduced, is an exception).

In order to understand the results, one has to take into account the fact that the activity coefficients and dil are determined by the operation of three factors:³⁴ (1) the athermal effect (the increase in entropy on mixing molecules differing in size and shape); (2) van der Waals forces; (3) chemical interaction (the last factor dimin-

Table 12. Characteristics of diluents based on measurements of the activity coefficients and extraction data.⁵

Parameter	CCl_4	C_6H_6	C_6H_{14}	CHCl_3

$\text{dil}/\text{dil}_{\text{CCl}_4}$	1.0	0.95	4.2	0.16
D/D_{CCl_4} (experiment)	1.0	0.97	4.7	0.14

ishes both γ_L and γ_c). It can be shown that the effects of the first two factors on γ_L and γ_c cancel out even for the opposite sign of nonideality (for example, for hexane and benzene). The compensation is most complete on formation of monosolvates (in particular, this is why HNO_3 is most sensitive to the nature of the diluent) and is satisfactory on formation of disolvates, but when trisolvates are formed the athermal effects for benzene and CCl_4 cancel out incompletely; since $\gamma_L^3 \ll 1$, dil and D decrease compared with saturated hydrocarbon diluents. On the other hand chemical reactions do not cancel out at all. They are in fact decisive, the interaction with the extractant diminishing dil and D while that with the complex increasing them. The chemical interactions with the diluents CCl_4 and C_6H_6 are comparatively weak and do not play any role; in the case of C_6H_{14} , they are altogether absent. On the other hand, the interaction with CHCl_3 is significant (a hydrogen bond having an energy of $\sim 5 \text{ kcal mol}^{-1}$ is formed with TBP) and is stronger with the extractant than with the complex because in the latter the oxygen of the PO group is blocked by the metal extracted. There is a corresponding significant decrease in γ_L^2 and in the degree of extraction [by a factor of 30 for TBP (Table 11)].

In the absence of appreciable chemical interactions, the activity coefficients of the extractants and the complex are correlated,³⁴ which makes it possible to describe the influence of the diluent by means of one parameter.¹⁴⁴

Thus in the extraction of metals and acids by monodentate extractants, the inert diluent does not usually affect the dependence of EA on the structure of the extractants. Hence in the vast majority of the systems investigated, the degree of extraction by the organic oxides R_nXO increases in the sequence $\text{TBP} < \text{dioctyl sulfoxide (DOSO)} < 2\text{-nonylpyridine-}N\text{-oxide (2-NPO)} < \text{triisopentylphosphine oxide (TPPO)}$ regardless of the nature of the diluent and the compound extracted. The extraction of acids by solutions of 2-NPO and TPPO in diluents with different solvating capacities constitutes the few existing exceptions.^{145, 146} The relative extraction abilities of these extractants are determined by the form in which the complexes extracted exist, the latter depending on the nature of the acid and the diluent.^{145, 146} For example, in the extraction of moderately strong acids (HNO_3) in weakly solvating diluents (heptane, CCl_4 , benzene), hydrogen-bonded complexes are formed for both extractants, their extraction constants being higher for TPPO than for 2-NPO. In more strongly solvating diluents (chloroform, 1,2-dichloroethane), the state of the complex with TPPO does not change whereas the complex with 2-NPO exists as an ion pair. Owing to

the increased solvation of the ion pair by the diluent, the extraction constants for 2-NPO are higher than those for TPPO.

For bidentate extractants (diphosphine dioxides and carbamoylphosphine oxides), the influence of the diluent proved very strong (see, for example, Fig. 26). When chloroform, which interacts with the reaction centres of BDNOPC is used, the degree of extraction is reduced, as in the case of monodentate extractants. However, when a polar diluent (dichloroethane), which reacts weakly with oxygen, is employed, a marked increase (almost by two orders of magnitude) in the degree of extraction is observed. Apparently dichloroethane reacts with the complex (possibly with the protons of the methylene group⁸³), which, as stated above, leads to an increase in the degree of extraction. When different substituents are introduced into the methylene bridge of methylenediphosphine dioxides and carbamoylmethylphosphine oxides in place of one of the hydrogen atoms, not only does the degree of extraction diminish and the AAS disappear, but the influence of diluents is also significantly weakened.¹⁴⁷ Apparently diluents do indeed interact with the bridge protons⁸³ and their acidity falls sharply on substitution.

We may note that diluents capable, like chloroform, of reacting with the reaction centres and of blocking them may alter qualitatively the dependence of EA on the extractant structure. If this dependence is described by Eqn (4) and the extractant-diluent interaction constant (K_{Ld}) is described by a similar equation but with other values of the coefficients A' and B' , the following equation is valid:

$$\lg K = \lg \frac{K_0}{K_{Ld}} = A - A' + (B - B')\Sigma X, \quad (15)$$

where K_0 is the extraction constant in the absence of interaction of the extractant with the diluent. If $B' > B$, the dependence of $\lg K$ on ΣX may change sign, which is in fact observed in the extraction of tetravalent and hexavalent actinides by methylenediphosphine dioxides when dichloroethane is replaced by chloroform (Fig. 20 a).

XIV. Examples of the development of new extractants

The regularities described above were used to solve two problems of practical importance in the radiochemical technology.

1. Improvement of the first principal extraction cycle in the regeneration of spent fuel from atomic power plants. Development of an extractant as a substitute for tributyl phosphate

Tributyl phosphate, which is widely used in the radiochemical technology, has optimal extraction properties. It extracts uranium and plutonium very effectively and there is no need for salting-out agents. The second essential operation — back-extraction (stripping) of the above elements — is also carried out comparatively readily if TBP is used; here there is no need for the introduction of additional reagents and it is sufficient to alter the acidity and the temperature of the medium. However, TBP suffers from a series of disadvantages. The main one is the comparatively low solubility of plutonium dissolved by TBP in saturated hydrocarbons. For 30% solutions of TBP in alkanes (with a hydrocarbon chain length $n_C = 12-14$) at room temperature, the solubility exceeds only slightly 30 g litre⁻¹ in terms of plutonium. Therefore, in the processing of mixed uranium-plutonium fuel with a high plutonium concentration and also in the refining of plutonium, there is a risk of the formation of a second organic phase and danger of inadmissible process perturbations (in particular, the loss of nuclear safety). Furthermore, TBP is comparatively readily soluble in the aqueous phase, which leads to loss of the extractant, and in refining it can lead to contamination of the product with phosphorus.

In the search for new extractants (taking into account the results described above), it was endeavoured to retain the extraction ability at the level of that of TBP but at the same time to alter the physical properties of the extractant.

It has been shown that EA changes markedly following a change in the chemical nature of the substituents in the extractant molecule and only slightly when the hydrocarbon chain is altered. Consequently, it is necessary to retain the chemical nature of the substituents, i.e. to employ trialkyl phosphates (if phosphonates, even those containing only the electronegative phenyl substituent, are used, difficulties arise with back-extraction). On the other hand, the physical properties may be 'regulated' by optimising the hydrocarbon chain — by increasing its length and by employing branching (this lowers the tendency towards polymerisation, improves compatibility with diluents, and at the same time lowers the solubility in the aqueous phase).

In accordance with these recommendations, the extraction properties of certain trialkyl phosphates, in which the overall length of the hydrocarbon chain varied from 12 (TBP) to 21 (triheptyl phosphate), were investigated. Triisopentyl phosphate (TIPP, $n_C = 15$) and diisobutyl isooctyl phosphate (DIBIOP, $n_C = 16$) proved to be best.¹⁴⁸⁻¹⁵⁰

The use of TIPP solves the problem of the extraction of plutonium from concentrated solutions, because a second organic phase is not formed even after the complete saturation of the extractant by plutonium. On the other hand, if one goes over to DIBIOP, i.e. the hydrocarbon chain is increased by one more atom, then the second organic phase is ruled out also in the presence of thorium nitrate (Fig. 34). The distribution coefficients differ little from one another when TIAP, TIBIOP, and TBP are used (Fig. 35) and the rates of phase separation are comparable. An advantage of both extractants is reduced (by a factor greater than 10) solubility in the aqueous phase, which diminishes the contamination of the products with phosphorus subject to the condition that mechanical losses have also been eliminated.

Triisopentyl phosphate and diisobutyl isooctyl phosphate have undergone successful tests on the highly irradiated fuel (100 GW d t⁻¹) in fast reactors (the activity of the solutions was up to 10³ Ci litre⁻¹ and the concentration of plutonium was up to 30 g litre⁻¹). The risk of radiation damage to the extractant was prevented by employing centrifugal extractors with a short phase contact time.

The parameters of the extraction and purification of valuable components were better than in the case where TBP was employed (including its use on a cascade of mixing-settlers).¹⁵¹ Under the

Figure 34. Isotherms for the extraction of thorium by 30% TBP (1), 33% TPAP (2), and 35% diisobutyl isooctyl phosphate (DIBIOP) (3) in *n*-tetradecane. Concentration of extractant in *n*-tetradecane (%): (1) 30, (2) 33, (3) 35; A — region corresponding to separation into two phases.

Figure 35. Dependence of the distribution coefficients of Pu(IV) (1, 2) and U(VI) (3–5) on acidity in extraction by solutions of TBP (1, 4), TPAP (2, 5), and DIBIOP (2, 3) in n-tetradecane.

supervision of Nikiforov, Zakharkin, Smelov, and others, triisooamyl phosphate has been used successfully, instead of TBP, on an industrial scale under factory conditions for the regeneration of the spent fuel from water–water power reactors (more than 100 m³ of the 33% extractant in a hydrocarbon diluent was employed).^{152–154} As expected, the new extractant did not introduce negative aspects into the technology: the uranium, plutonium, and neptunium separation factors as well as the decontamination coefficients from radionuclides characteristic of systems with TBP were consistently reproduced. At the same time, it made it possible to reduce appreciably (by a factor of 1.5) the losses of the extractant. This effect is more pronounced if the mechanical loss of the organic phase, which is the same for TIPP and TBP, is eliminated. The employment of TIPP in the refining extraction of plutonium fundamentally expanded the technological possibilities in this stage of the process: the degree of concentration of plutonium was increased and the monitoring of its accumulation in different stages within extractors was simplified.

2. Extractants for the deep extraction of transplutonic elements from radiotechnological waste

Monodentate organophosphorus extractants (even the strongest phosphine oxides, for example, TOPO) are relatively unsuitable for the extraction of transplutonic elements from waste. When TBP is used, it is necessary to introduce a salting-out agent, while phosphine oxides extract americium effectively, but only at a low acidity (up to 0.3 M)¹⁵⁵ and their use requires the neutralisation of the solution. The decrease in the degree of extraction with increase in acidity is associated with the competition by nitric acid for the free extractant: the nitric acid extraction constant is high and the concentration of the free extractant is inversely proportional to it.

Thus an extractant with an increased EA in relation to trivalent actinides and at the same time with a reduced EA in relation to HNO₃ is needed. Surprisingly, these seemingly incompatible requirements can be met by employing the unusual properties of the bidentate organophosphorus compounds — methylenediphosphine dioxides and carbamoylmethylphosphine oxides. Indeed, when electronegative aryl substituents are introduced into the molecules of these compounds, an AAS effect is observed and the extraction of americium and other actinides, involved in bidentate coordination, is enhanced; at the same time, these substituents suppress the extraction of HNO₃, which is involved in monodentate coordination. As a result, a double gain is achieved (Figs 16 and 17): the distribution coefficients of americium increase (compared with the distribution coefficients

Figure 36. Dependence of the distribution coefficient of Am(III) on acidity in extraction by solutions of 2Tol2Ph (1) and Tol₂/Bu₂ (2) in trichlorobenzene. Concentration of lanthanides in the aqueous phase 10 g litre⁻¹; concentration of the extractant in the organic phase 0.3 M.

when phosphine oxides are used) by 3–5 orders of magnitude and a possibility is created for extensive extraction of the actinides from solutions of any acidity without any kind of preparation of the latter.

The extractants recommended in Refs 156 and 177 — carbamoylphosphine oxide and diphosphine dioxides — have undergone a successful test in the processing of the highly irradiated fuel mentioned above (the activity of the initial aqueous solution was ~ 10³ Ci litre⁻¹).¹⁵¹ The distribution coefficients are presented in Fig. 36. (In order to simulate the conditions in the extraction from the vaporised refined product in the first cycle, 10 g litre⁻¹ of lanthanides was introduced into the aqueous phase.)

The above developments are protected by patents.^{148, 156}

Abstract. The literature data on the electrochemical synthesis of phosphorous acid and phosphoric acid esters from elemental phosphorus are surveyed. The possible mechanisms of the electrode processes are discussed. The procedures for the employment of electrolysis in the preparation of various derivatives of phosphorous acid esters are examined. The bibliography includes 63 references.

I. Introduction

The syntheses of phosphorus-containing compounds based on elemental phosphorus have become important because they make it possible to reduce significantly the amount of industrial waste compared with the classical methods employing phosphorus chlorides. The review of Dorfman et al.¹ published in 1993 contains information about the chemical methods for the syntheses of phosphorus-containing compounds from elemental phosphorus, but electrochemical methods are not considered although numerous studies demonstrating that this aspect is promising have been published during the last decade. It has been established that phosphorus exhibits an electrochemical activity in both anodic and cathodic processes. This makes it possible to obtain various phosphorus-containing compounds in a single stage and under mild conditions. Electrochemical methods have been used successfully also for the syntheses of various phosphorous acid esters. Although in many cases the details of the mechanisms of the electrode processes occurring remain obscure, the synthetic possibilities of the electrochemical methods are evident. The aim of the present review is to survey the experimental data which have accumulated hitherto in this field.

II. Syntheses based on the anodic oxidation of phosphorus

It has been found that in alkaline and acid solutions white phosphorus gives rise to a distinct oxidation wave at a carbon paste anode at a potential of 1.08 V.² According to coulometric

measurements, between 12 and 16 electrons are consumed in the oxidation of a phosphorus molecule in acid solutions. On these grounds, it is concluded that the anodic oxidation of phosphorus results in the formation of a mixture phosphoric and phosphorous acids. In an alkaline medium, the process is complicated by the oxidation of PH_3 — the product of the interaction of phosphorus with water.

The development of a process for the preparation of phosphorous acid by oxidising a suspension of white phosphorus in the presence of hydrogen halide solutions constitutes an interesting attempt at the practical employment of the anodic oxidation of phosphorus.³ The best yield of phosphorous acid is attained in the presence of hydriodic acid. Hydrobromic acid yielded somewhat poorer results. It is postulated that the anodic process includes several stages: the generation of the free halogen, the interaction of the latter with phosphorus, and finally the hydrolysis by water of the phosphorus trihalide formed in the second stage to phosphorous acid.

The hydrogen halide is not consumed in the process but acts as a homogeneous catalyst. It is recommended that a two-phase electrolyte, constituting a mixture of water and benzene, be employed.

This method makes it possible to obtain only relatively dilute solutions of phosphorous acid, since the accumulation of the acid during electrolysis leads to its partial oxidation to phosphoric acid. Furthermore, the phosphorous acid formed contains a small admixture of the hydrogen halide, the complete elimination of which is difficult.

The direct synthesis of phosphoric acid is of much greater interest. The possibility, in principle, of obtaining phosphoric acid esters by electrolysis suspensions of red phosphorus in an aliphatic alcohol was first demonstrated by Varshavskii et al.⁴ The electrolysis was carried out in a diaphragm-free electrolyser with an anode and cathode made of graphite. During electrolysis, the solution containing a suspension of red phosphorus in an aliphatic alcohol was saturated with dry hydrogen chloride. It was noted that the change in current density in the range from 400 to 1000 A m^{-2} and at temperatures from 20 to 50 °C hardly affects the yield of trialkyl phosphates. It is suggested that the overall anodic oxidation process proceeds in accordance with the equation

Received 19 July 1995

Uspekhi Khimii 65 (11) 1080–1088 (1996); translated by A K Grzybowski

However, the amount of alkyl chloride isolated proved to be much smaller than might have been expected from the above equation. The following phosphoric acid esters have been obtained by this method:

Ester	(MeO) ₃ PO	(EtO) ₃ PO	(BuO) ₃ PO	(C ₅ H ₁₁ O) ₃ PO
Yield (%)	77.5	55.0	88.3	83.1

Subsequently, the direct synthesis of alkyl phosphates was investigated at a greater depth. The reports that other transfer catalysts have been used instead of hydrogen chloride merits attention. Thus the employment of copper(II) chloride as the transfer catalyst has been described.⁵

It was shown that CuCl₂ oxidises white phosphorus:

The anodic process reduces to the regeneration of CuCl₂ by the oxidation of copper(I) chloride. The introduction of HCl lowers the yield of trialkyl phosphate and promotes the formation of a dialkyl phosphite. The electrolysis is carried out in an electrolyser with a diaphragm and, in order to increase the solubility of phosphorus, toluene-alcohol mixtures and not pure alcohol are used. Under optimum conditions [current density $(2-6) \times 10^{-3} \text{ A cm}^{-2}$, $CuCl_2 : P_4 \geq 20$], the yield of alkyl phosphates is nearly quantitative. One cannot rule out the possibility of the formation in this process of copper phosphide as an intermediate, since it has been reported that triethyl phosphate has been obtained in a high yield by the anodic dissolution of copper phosphide in ethyl alcohol.⁶

The anodic oxidation of a suspension of white phosphorus in an acetonitrile-alcohol mixture in the presence of tetrabutylammonium iodide as the supporting electrolyte has been studied in detail.⁷⁻¹⁰

Interesting studies have been carried out by Romakhin et al.,¹⁰ who followed the changes in the outward appearance of the catholyte. It was noted that, soon after the current has been switched on, the state of the white phosphorus changes. It is converted into a dark-yellow deposit with a high phosphorus content, which is insoluble in organic solvents. It is postulated that oligomeric structures are formed in this stage, decomposing in the course of electrolysis (Fig. 1).

This accounts for the low rate of formation of monomeric phosphorus-containing products at the beginning of the electrolysis, the rate increasing significantly towards the end of the process.

It has been found that, under the conditions of diaphragm electrolysis, alkyl phosphates are formed only in an insignificant yield and the presence of trialkyl phosphites was also detected.

Figure 1. Dependence of the amount of electricity (Q_{prod}) consumed in the formation of triethyl phosphite on the total amount of electricity (Q_{tot}) in the electrolysis of a suspension of phosphorus in acetonitrile in the presence of ethanol.¹⁰

The diaphragm-free electrolysis,⁸ where the trialkyl phosphate is formed with participation of both the cathodic and anodic reactions, proved to be more effective.

After the theoretical amount of electricity has been passed, more than 95% of the phosphorus taken is converted into monomeric products. In the electrolysis of a suspension of white phosphorus in the aliphatic alcohol-acetonitrile-tetrabutylammonium iodide system, dialkyl alkylphosphonates $(RO)_2P(O)R$ and dialkyl phosphites $(RO)_2P(O)H$ are formed in addition to trialkyl phosphates. The yield of the former depends significantly on the electrolysis conditions, particularly on the presence of moisture.¹¹ Unfortunately, the mechanism of this reaction is not discussed in the above study.¹¹ Thus, in the electrolysis of a suspension of white phosphorus in the presence of ethanol at 18–25 °C and a current density of 5 A cm^{-2} , the following dependence of the yield of the electrolysis products on the water content in the reaction mass was obtained:

H ₂ O : P ₄ (in moles)	Yield (%)	
	(EtO) ₃ PO	(EtO) ₂ P(O)H
In the absence of water	81.1	8.9
0.255	73.0	13.8
0.328	70.1	18.8
1.000	72.5	27.0
3.125	50.1	17.4

Thus an increase in the water content lowers appreciably the yield of trialkyl phosphate. In the absence of water, the electrolysis of white phosphorus in the alcohol-acetonitrile-tetrabutylammonium iodide system is accompanied by the formation of a mixture of phosphoric acid esters,⁸ the yield of which varies as a function of the nature of the alcohol.

Alcohol	Yield with respect to phosphorus (%)		
	(RO) ₃ PO	(RO) ₂ P(O)H	(RO) ₂ P(O)R
MeOH	70	11	3
EtOH	69	9	14
BuOH	66	7	15

The yields quoted were not obtained under optimum conditions and can be improved when the process is optimised.

The employment of tetraalkylammonium iodides as the supporting electrolytes has the advantage that the alkyl iodide formed during electrolysis is reduced at the cathode, affording the corresponding hydrocarbon and generating the supporting electrolyte at the same time. Ultimately, the overall process scheme may be formulated as follows:

This method is inapplicable to the synthesis of triaryl phosphates, because phenol and its derivatives interact with phosphorus under these conditions, giving rise to a mixture of triaryl phosphates and triaryl phosphites.¹²

Alcohol	Yield with respect to phosphorus (%)	
	(ArO) ₃ PO	(ArO) ₃ P
PhOH	20	46
<i>o</i> -MeC ₆ H ₄ OH	32	38
<i>p</i> -ClC ₆ H ₄ OH	32	11

The process is accompanied by the passivation of the anode. The addition of pyridine eliminates the passivation, but in this case the main product of the electrolysis becomes the triaryl phosphite. Thus in the presence of pyridine the yield of $P(OPh)_3$ increases to 78%, whilst that of $(PhO)_3PO$ remains 20%.

The question of the mechanism of the formation of trialkyl phosphates in the electrolysis of a suspension of phosphorus in the

presence of an aliphatic alcohol and a halide salt merits separate consideration.

According to Budnikova et al.,¹¹ the first step in the electrochemical process is the reduction of an alcohol molecule at the cathode and the formation of alkoxide ions.⁹

The P–P bond in the phosphorus molecule is ruptured by the alkoxide ions generated at the cathode (in the presence of a large excess of phosphorus, there is a possibility of the formation of polymeric structures) and the resulting ROP_4^- anion is protonated and subsequently interacts with the alkyl hypophosphite generated at the anode:

Subsequent alkoxylation ultimately leads to a full phosphorous acid ester, which is oxidised to an alkyl phosphate at the anode. On the basis of the above considerations, a mechanism has been proposed for the possible processes occurring during electrolysis in a single-solution electrolyser of alcoholic solutions of tetrabutylammonium iodide in the presence of white phosphorus:¹¹

In the case of phenols, a triaryl phosphite is formed in the first stage of the electrolysis. It reacts with the iodide and phenol generated at the anode, affording a pentaphenoxyphosphorane; the latter is partly converted into a triaryl phosphate at the anode:¹²

The above data demonstrate that the electrolysis of a suspension of phosphorus in aliphatic alcohols (when halide salts are used as the supporting electrolyte) may be regarded as a way of obtaining phosphoric acid esters, bypassing the stage involving the formation of phosphorus halides. In the study of the formation of alkyl phosphates, the cathodic activation of white phosphorus and the possibility of the anodic oxidation of phosphites to phosphates were observed. These two possibilities merit independent consideration.

III. Cathodic activation of phosphorus

As already mentioned, the electrochemical synthesis of trialkyl phosphates from white phosphorus may be achieved with a satisfactory yield only in an electrolyser without a diaphragm, i.e. the cathodic process plays in this case a significant role, inducing the activation of phosphorus molecules.

The formation of active phosphorus species in chemical processes has been frequently discussed in the literature. For example, in a study of the reactions of elemental phosphorus with electrophiles in a highly basic medium, it was suggested that the P–P bond is ruptured by the base:¹³

Phosphorus is also activated by amines.¹⁴ Thus in the presence of triethylamine, white phosphorus reacts with epoxyethane.

The high reactivity of red phosphorus in the presence of copper halides has also been explained by the dissociation of the P–P bond:¹⁵

We shall now consider the possible paths leading to the activation of white phosphorus molecules in cathodic processes.

White phosphorus is known to be electrochemically active and gives a wave in the region of -1.90 V.¹⁶ The process involves the transfer of 12 electrons to the P_4 molecule and the final reduction product is phosphine.^{17,18} However, in a study of the electrochemical reduction of a suspension of white phosphorus in 50% acetic acid (with addition of potassium acetate in order to increase the electrical conductivity), it was noted that part of the phosphorus (12.3%) in the cathodic compartment is converted into phosphorus acids. Thus, phosphorous, hypophosphorous, and orthophosphoric acids were detected among the reaction products in proportions of 45:55:5 by weight.¹⁹ Particular experiments demonstrated that white phosphorus does not react with the catholyte.

Another interesting fact was observed in the electrochemical reduction of a suspension of white phosphorus in an acid solution at a lead cathode.²⁰ In the first instants of the electrolysis, gaseous products are hardly evolved at the cathode (Fig. 2), the joint evolution of hydrogen and phosphine being observed only after some time. The yield of phosphine increases sharply, exceeding 100% relative to the amount of electricity passed through the system. As phosphorus is consumed, the yield of hydrogen increases and reaches the theoretical value. This experiment demonstrated that involatile phosphorus compounds are formed initially and are converted during electrolysis into phosphine.

There are different views on the nature of the active phosphorus species formed initially at the cathode. The formation of partly hydrogenated phosphorus molecules, arising in the course of its reduction, appears most probable. For example,

Another path, involving the generation of nucleophilic species in the cathodic compartment, is also possible. For example,

Yield with respect to current (%)

Figure 2. The formation of phosphine (1) and hydrogen (2) in the electrolysis of a suspension of phosphorus in sulfuric acid solution.²⁰

The radical species produced in both cases can give rise, in the presence of an excess of phosphorus, to polymeric structures of the type

where X = H or OH. Such structures are usually formed in the first stage of the electrolysis.

The example of the reduction of phosphorus at a lead cathode described above agrees well with the first mechanism, according to which higher phosphorus hydrides are formed initially, whereas the formation of phosphorus acids in the cathodic compartment would be more logically explained on the basis of the second mechanism. This mechanism also demonstrates the role of the cathodic process in the synthesis of trialkyl phosphates. One may postulate that the mechanism of the activation of phosphorus depends on the electrolysis conditions and principally on the material on the cathode. On metals with a high hydrogen overpotential, the reduction of P_4 and the formation of lower phosphorus hydrides (the first mechanism) are more likely, whereas on metals with a low hydrogen overpotential the activation of phosphorus by the nucleophile generated at the cathode is more probable. In particular, in the preparation of trialkyl phosphates, phosphorus is activated by the alkoxide ions formed at the cathode.

The electrochemical activation of phosphorus molecules may be used for various synthetic purposes. For example, the possibility of obtaining phosphites by the electrolysis of a suspension of red phosphorus in an aqueous solution of ethylenediamine has been demonstrated.²¹ The phosphite is formed in the cathodic compartment of the electrolyser, the yield with respect to the red phosphorus taken amounting to ~40%. Under the same conditions but in the absence of ethylenediamine, the only product of the reduction of red phosphorus is phosphine.²² Since phosphorus does not react chemically in an aqueous solution of ethylenediamine, it remains to postulate that phosphites are formed as a result of the interaction of electrochemically activated phosphorus molecules with water. When this process is carried out in an electrolyser with a platinum anode but without a diaphragm, the yield of the phosphite increases slightly.²³ This shows that the phosphite is formed exclusively from cathodically activated phosphorus.

The formation of organophosphorus compounds in the electrolysis of suspensions of white phosphorus in aprotic solvents in the presence of alkyl halides^{24,25} and unsaturated compounds²⁶ can apparently be also accounted for by the cathodic activation of phosphorus. In all cases, the formation of the corresponding phosphines was observed. For example, the electrolysis of a suspension of white phosphorus in acetonitrile in the presence of styrene afforded a series of compounds, the main one being the monosubstituted phosphine $\text{PhCH}_2\text{CH}_2\text{PH}_2$ (26%). The other reaction products were the di- and tri-substituted phosphines $(\text{PhCH}_2\text{CH}_2)_2\text{PH}$ (0.5%) and $\text{P}(\text{PhCH}_2\text{CH}_2)_3$ (2.5%) and also the diphosphine $[(\text{PhCH}_2\text{CH}_2)_2\text{P}]_2$ (1.0%).²⁶

In the presence of alkyl halides, tertiary phosphines are formed preferentially, reacting with the excess alkyl halide to form quaternary phosphonium salts:

IV. Anodic oxidation of phosphorous acid and electrochemical syntheses based on it

Free phosphorous acid in 0.5 N H_2SO_4 gives rise to a distinct oxidation wave at a potential of +0.52 V relative to the saturated calomel electrode (s. c. e.) at a palladium electrode.²⁷ It is suggested that under these conditions phosphorous acid is oxidised via a catalytic dehydrogenation mechanism:²⁸

Orthophosphoric acid is the product of the oxidation of phosphorous acid. At a platinum anode in an alkaline medium, the oxidation takes place with a current yield of ~40%.^{29,30} The addition of potassium iodide to the solution increases the yield of orthophosphoric acid to 66%.³¹ At a graphite anode in the presence of 0.5 N HCl, phosphorous acid is oxidised fairly effectively, but this requires the passage of 180% of electricity relative to the theoretical amount, whereupon phosphorous acid is almost fully oxidised (97%).

In an alkaline solution, the oxidation takes place effectively even at a nickel anode, but a fully defined ratio of disodium hydrogen phosphite and sodium hydroxide is then necessary. The optimum ratio disodium hydrogen phosphite:sodium hydroxide = 1.6:1.0 makes it possible to attain a degree of oxidation of 99% with a current yield of 43%. The process can be carried out also in a diaphragm-free electrolyser, since the losses in reduction do not exceed 1%–3%.³²

The sodium salts of phosphorous acid are polarographically active. Thus sodium dihydrogen phosphite has a reduction wave with $E_{1/2} = -0.605$ V ($n = 0.4$), whereas disodium hydrogen phosphite has one with $E_{1/2} = -0.42$ V ($n = 0.7$).³³ Unfortunately the nature of these waves has not been discussed.³³

In an aqueous solution, the product of the electrochemical reduction of phosphorous acid is phosphonous acid:³⁴

The formation of phosphine has also been observed.³²

Electrochemical synthesis based on acid phosphite esters merits separate consideration. The characteristic features of their electrochemical behaviour are determined by the equilibrium

which is almost fully displaced towards four-coordinate phosphorus.

In the accessible range of potentials, dialkylphosphorous acids are not oxidised,³⁵ but in aprotic media they give rise to a reduction wave at transition metal cathodes.³⁶ Thus, in acetonitrile in the presence of quaternary ammonium salts as supporting electrolytes, dimethyl phosphites have the following reduction potentials (in V) at different cathodic materials:

Phosphine	Pt	Ni	Fe	Cu
$(\text{MeO})_2\text{P(O)H}$	1.88	1.88	1.90	2.00
$(\text{EtO})_2\text{P(O)H}$	1.89	—	2.06	2.04

It is suggested that the cathodic process leads to the formation of anions, since the evolution of hydrogen is observed at the cathode:

Four-coordination of the phosphorus atom in the anion is indicated by the finding that diaphragm-free electrolysis with a soluble anode leads to dialkyl phosphite salts with a metal–phosphorus bond.³⁶ In this case, the anodic process consists in the dissolution of the anode material and its transition to an ionic state:

The interaction of the phosphite anions generated at the cathode with the metal cations leads to the formation of salts:^{36,37}

The formation of the corresponding platinum salt has been described in a study³⁷ where a platinum electrode was employed.

In aqueous solutions of alkali metal halides, dialkyl phosphites are oxidised to dialkyl phosphates at a graphite anode:^{38,39}

The oxidation is carried out at a current density not exceeding 0.01 A cm^{-2} and a temperature of $30\text{--}35^\circ\text{C}$. The yield of phosphates is 75%–80%. In the electrolysis of lower dialkyl phosphites ($\text{Alk} = \text{C}_1\text{--C}_3$), the process is accompanied by partial hydrolysis with formation of monoalkylphosphoric acids.

In the electrolysis of an aqueous solution of dialkylphosphorous acid with an aluminium anode, aluminium alkyl phosphate was obtained in a yield of 90%–95%:⁴⁰

This process was used as a basis for the industrial preparation of the Russian-produced systemic fungicide EFAL'-50.⁴¹ The technological scheme is significantly simplified as a result of the employment of a diaphragm-free electrolyser fitted with aluminium electrodes. The electrolysis is carried out with an alternating current at a frequency of 50 Hz.⁴²

The aluminium salt can be obtained similarly from methylphosphonic acid.⁴³

The electrolysis of dialkyl phosphites in a nonaqueous medium using an insoluble graphite anode leads to a complex mixture of products, more than 60% of which comprises tetraalkyl pyrophosphate $(\text{RO})_2\text{P}(\text{O})\text{OP}(\text{O})(\text{OR})_2$.⁴⁴ The mechanism of its formation is not clear. It has been suggested that, since hydriodic acid is used as supporting electrolyte, the acyl iodide formed at the anode reacts with water, giving rise to a dialkyl phosphite; the latter reacts with a second acyl iodide molecule:⁴⁵

However, from our point of view this mechanism is unlikely, since the use of even thoroughly dried acetonitrile does not lower the yield of pyrophosphate. A similar reaction occurs in the electrolysis of acetonitrile solutions of alkyl alkylphosphonates, leading to the formation of dialkyl dialkylpyrophosphonates $(\text{RO})\text{RP}(\text{O})\text{OP}(\text{O})\text{R}(\text{OR})$.⁴⁴ Data on the electrosynthesis of pyrophosphates and pyrophosphonates from phosphorous acid esters are presented below (the mechanism of this reaction has not been investigated):

$(\text{RO})_2\text{POP}(\text{OR})_2$						
R	Et	Pr ⁿ	Bu ⁿ			
Yield / $10^3 \text{ mol A}^{-1} \text{ h}^{-1}$	12.2	11.1	11.0			
$(\text{RO})\text{MePOPMe}(\text{OR})$						
R	Et	Pr	Pr ⁱ	Bu	Bu ⁱ	n-C ₃ H ₁₁ iso-C ₃ H ₁₁
Yield / $10^3 \text{ mol A}^{-1} \text{ h}^{-1}$	12.3	8.8	11.6	7.9	10.4	6.3 10.1
$(\text{RO})\text{EtPOPEt}(\text{OR})$						
R	iso-C ₃ H ₇	iso-C ₄ H ₉				
Yield / $10^3 \text{ mol A}^{-1} \text{ h}^{-1}$	11.2	10.2				

Although, as already mentioned, the acid phosphite esters themselves do not undergo anodic oxidation, they react readily with the halogens generated at the anode, forming reactive acyl

halides. This reaction has been used successfully for the synthesis of compounds with P–N, P–S, and P–O bonds. The possibility of the electrochemical formation of the P–C bond was later demonstrated.

The overall mechanism of the electrochemical phosphorylation reactions of organic compounds can be represented as follows:

We shall examine these reactions in greater detail.

1. Synthesis of amidophosphates

The formation of amidophosphates in a high yield has been noted in the electrolysis of acetonitrile solutions of dialkyl phosphites containing an alkali metal iodide as the supporting electrolyte to which a secondary amine has been added. The process is carried out in a diaphragm-free electrolyser with platinum electrodes. The yields of the amidophosphates as a rule exceed 75%. For example, when dimethyl phosphite was coupled with dipropylamine, the yield of the amidophosphate was 76%, while the yields in the reactions with dibutylamine and morpholine were 83% and 80% respectively.⁴⁶

The most probable reaction path involves the anodic iodination of the phosphite:

An alternative path involving the anodic iodination of the amine is also possible:

The iodoamine formed as a result of this reaction reacts subsequently with the phosphite:

On the basis of voltammetric measurements and quantum-mechanical calculations, preference is given to the first path.⁴⁷

This reaction has been used successfully for the phosphorylation of various alkaloids. For example, cytosine has been phosphorylated electrochemically:

The reaction was carried out in the presence of tetraethylammonium bromide with added free iodine as the supporting electrolyte. The following yields of the phosphorylation products were obtained depending on the nature of R:⁴⁸

R	Me	Et	Pr	Pr ⁱ	Bu ^t
Yield (%)	53	84	78	73	70

L-Ephedrine,⁴⁹ lupinine,⁵⁰ pyrazidol,⁵¹ salsolidine,⁵² and anabasine^{48, 53} have been phosphorylated in 85%–91% yields.

The phosphorylation of anabasine is represented by the following overall equation:

The yield of the phosphorylated product depends on the nature of the group R:

R	Me	Et	Pr ⁿ	Pr ⁱ	Bu ⁿ
Yield (%)	79.0	91.2	86.4	86.0	87.1

In the phosphorylation of quinine, it was established that the hydroxy-group is initially oxidised to the carbonyl group with formation of the corresponding quinone, which is then phosphorylated to the α -hydroxyphosphonate.⁵⁴

As already mentioned, the phosphorylation of amines takes place with iodine as the transfer catalyst. Other halogens proved to be appreciably less effective. Thus the following dependence of the yield of the target product on the nature of the halogen-containing additive has been obtained in the synthesis of the diethylamide of ethylphosphorous acid:¹⁴

Additive	I ₂	NaI	NaBr	NaCl
Yield (%)	94	92	36	4

It is of interest to note that lupinine is most effectively phosphorylated in the presence of crown-ethers to which lithium chloride has been added.⁵⁰ The presence of surfactants has apparently a favourable effect on the process.

2. Synthesis of thioamides

If during the electrolysis of acetonitrile solutions of dialkyl phosphites in the presence of secondary amines ammonium thiocyanate is used instead of sodium iodide, the nature of the products changes significantly. The synthesis of *N*-phosphorylated thioamides has been observed. Cyclic voltammetric data and quantum-mechanical calculations have shown that the most probable mechanism for the simplest dimethyl phosphite–dimethylamine system involves the interaction of the phosphite with the iodine thiocyanate formed at the anode:⁵⁵

The thiocyanato-derivative obtained as a result of this reaction then reacts with the amine, affording *N*-phosphorylated thioamides:

This reaction has been used successfully for the phosphorylation of ephedrine alkaloids. The corresponding phosphorylated thioamides were obtained in 48%–53% yield. The phosphorylated quinine and lupinine thioamides are formed in approximately the same yield.⁵⁶

3. Synthesis of thiophosphates

The electrochemical generation of the halogens makes it possible to achieve the coupling of dialkylphosphorous acid with disulfides, which results in the formation of compounds with a P–S bond. The following process mechanism has been proposed on the basis of polarisation measurements for the initial components:

Best results were obtained in the presence of bromide salts; the reactions with other halides are less successful (see, for example, Torii et al.⁴⁵):

Additive	NaI	NaBr	NaCl
Yield of $(\text{EtO})_2\text{P}(\text{O})\text{SPh}$ (%)	73	91	59

The coupling of diethyl phosphite with diphenyl disulfide is carried out in an electrolyser without a diaphragm, which made it possible to obtain coupling products with entirely satisfactory yields. For example, in the coupling of dimethyl phosphite with diphenyl disulfide, dibenzyl disulfide, and bis(ethoxycarbonylmethyl) disulfide, the yields of the coupling products were 61%, 71%, and 75% respectively.

4. Synthesis of trialkyl phosphates

The anodic oxidation of dialkyl phosphites in an alcoholic solution in the presence of chloride ions makes it possible to obtain trialkyl phosphates in high yields.⁵⁷ It has been suggested that in the first stage the phosphite undergoes anodic chlorination to the acyl chloride, which then reacts with the alcohol, affording the corresponding trialkyl phosphate:

This method made it possible to obtain phosphoric acid esters with various substituents. Although the yield of the esters synthesised in this way is somewhat lower than in the syntheses examined previously, the method is nevertheless preparatively important. Thus, when dimethyl phosphite was coupled with methyl, ethyl, and propyl alcohols, the yields of the corresponding trialkyl phosphates were 46%, 57%, and 63% respectively. The syntheses were carried out using perchloric acid with added lithium chloride as the supporting electrolyte. The anode was made of vitreous carbon and a diaphragm electrolyser was used, although the need for a diaphragm in this process can hardly be justified.

5. Synthesis of phosphonates

The cathodic reduction of dialkyl phosphites in the presence of halogen-containing compounds leads to phosphonates. The mechanism of this process differs significantly from those examined above. The primary process is apparently the cathodic reduction of the dialkyl phosphite with formation of the anion $(\text{RO})_2\text{P}(\text{O})^-$:³⁶

The anion reacts further with the halogen-containing compound:³⁶

The electrochemical synthesis of phosphonates was first described by Petrosyan and Niyazymbetov.⁵⁸ The process was carried out in a diaphragm electrolyser at a platinum anode in acetonitrile at a current density of 0.003–0.005 A cm⁻² at 20 °C. A 0.3 M solution of tetraethylammonium bromide was used as the supporting electrolyte.

The starting compounds were dimethyl, diethyl, and diphenyl phosphites as well as methyl and benzyl iodides and chlorides. The yields of the corresponding phosphates were in the range 55%–65%.

An interesting modification of this reaction has been proposed.⁵⁸ In it, methylene chloride containing 0.3 M tetraethylammonium bromide and 0.015–0.03 M phosphite (Pt cathode) was used as the catholyte, while the anolyte was a 0.3 M solution of tetraethylammonium bromide in methylene chloride to which

cyclohexene had been added to bind the bromine evolved. The reaction proceeds in accordance with the equation:

R = Me, Et, Ph.

The yields of the products **A** and **B** depend on the amount of electricity passed through the system. Thus, when three Faradays are passed per mole of the phosphite, mainly product **A** is formed, its yield amounting to 75% for dimethyl phosphite, 72% for diethyl phosphite, and 51% for diphenyl phosphite. It was later shown⁵⁹ that the alkylation of phosphites in the presence of small amounts of water proceeds more successfully than in the anhydrous solvent. The following composition of the catholyte has been recommended for alkylation: solution containing 2 mmol of the phosphite and 3 mmol of the alkyl halide in 25 ml of dimethylformamide containing 4 mmol of tetrabutylammonium as the supporting electrolyte and 4 mmol of water.

For example, the coupling of diethyl phosphite with butyl iodide has been achieved under these conditions in 74% yield, but in the reactions with butyl bromide, benzyl bromide, and benzyl chloride the yields were 49%, 60% and 55% respectively. These data show that compounds containing a sufficiently mobile halogen atom must be used as the coupling component. In other examples, the yields of the phosphonates vary in the range 56%–58%.

The electrochemical alkylation of *cis*-2-hydro-4-methyl-2-oxo-1,3,2-dioxaphosphorinane **1** with equatorially oriented methyl and oxo-groups proceeds stereoselectively and leads to 2-benzyl-4-methyl-2-oxo-1,3,2-dioxaphosphorinane in 60%–70% yield.⁶⁰ Together with the phosphonate **2**, the phosphate **3** was isolated. The mechanism of the formation of the latter has not yet been investigated.

In contrast to dialkyl phosphites, the sodium salts of dialkylphosphorous acids are readily oxidised at a platinum anode in solution in acetonitrile in the presence of sodium perchlorate as the supporting electrolyte.⁶¹

R in (RO) ₂ PONa	Et	Pr ⁱ	Pr ⁿ	Bu ⁿ
<i>E</i> _{1/2} /V	0.45	0.50	0.63	0.63

It is suggested that the oxidation proceeds in accordance with the equation:

The electrolysis of such a system in the presence of aromatic and heterocyclic compounds leads to the corresponding phosphonates, for example,

Apart from thiophene, furan, quinoline, and naphthalene have been introduced into this reaction. The yield of the phosphorylation products varied in the range 25%–30%, the reaction

being accompanied by the formation of a number of side products, such as $(\text{RO})_2\text{P}(\text{O})\text{H}$, $(\text{RO})_2\text{P}(\text{O})\text{R}$, and $(\text{RO})_3\text{PO}$.⁶¹

In the presence of secondary amines, amidophosphite diesters were synthesised at the oxidation potential of sodium dialkyl pyrophosphite.⁶² It is suggested that the reaction proceeds via the following path:

In the presence of a large excess of the amine in the solution, the following process may occur:⁶³

The following amidophosphites have been synthesised electrochemically: $(\text{EtO})_2\text{PNet}_2$, $(\text{BuO})_2\text{PNet}_2$, and $(\text{BuO})_2\text{PNBu}_2$ in 30%, 20%, and 32% yields respectively.

* * *

The data presented in this review show that electrolysis can be used successfully for the synthesis of trialkyl phosphates from white and red phosphorus. Data on the catalytic influence of copper halides on the synthesis of alkyl phosphates merit attention. The study of the characteristic features of the formation of trialkyl phosphates demonstrated the possibility, in principle, of the direct synthesis of phosphites from elemental phosphorus and also the possibility of the electrochemical oxidation of phosphites and dialkyl phosphites to the corresponding phosphates and pyrophosphates. It is noted that electrolysis is a promising procedure for the preparation of various derivatives of dialkyl phosphites.

The authors thank the International Scientific-Technical Centre (grant No. 136) for financial support in the writing of this review.

Abstract. Alkyl vinyl chalcogenides show a complex picture of rotational isomerism and are characterised by the presence of several qualitatively different types of stable conformers. The features of conformational structure of these compounds can be understood only by considering the stationary states altogether. Conformational analysis of divinyl chalcogenides indicates that the potential energy surface of internal rotation should be considered not as just a source of information on rotational isomerism; rather, it is a tool in a search for stationary states corresponding to definite intervals of variation of internal molecular coordinates. The principal details of the orbital structure of allenyl ethers and vinyl chalcogenides including a weak dependence of the structure and relative location of higher occupied π -MOs of alkyl vinyl chalcogenides on the nature of the heteroatom and the structure of the alkyl substituent are discussed. The common feature of chalcogenides is the presence of a low energy excited state of σ -symmetry. The excited states of π -symmetry are always located higher on the energy scale than the states of σ -symmetry. The bibliography includes 198 references.

I. Introduction

The interest in electronic and conformational structures of vinyl systems of the type $\text{CH}_2=\text{CHXR}$ ($\text{X} = \text{O}, \text{S}, \text{Se}, \text{Te}$, $\text{R} = \text{Alk}$, and $\text{CH}=\text{CH}_2$) stems from a number of important features specific to rotational isomerism in compounds of this class. First of all, the number of existing rotamers may exceed the number expected on the basis of canonical concepts about the nature of rotational isomers. In the majority of cases, the deviation of atoms from their equilibrium position are small, and the observed properties of the molecular system can be satisfactorily described in terms of the harmonic oscillator approximation. In the case of large deviations from equilibrium in molecules existing in several rotameric forms, quantum mechanical analysis leads to a revision of conclusions on the nature and the number of stable conformers.

According to traditional concepts, hindered internal rotation about $\text{C}_{sp^2}-\text{X}$ ($\text{X} = \text{O}, \text{S}, \text{Se}, \text{Te}$) bonds in molecular systems of alkyl vinyl chalcogenides provides three conformations, namely, *s-cis*-, *s-trans*-, and *gauche*- (non-planar).[†] The reason for hindered rotation about the $\text{C}_{sp^2}-\text{X}$ bonds can be both the interaction of the multiple bond π -electrons with the lone electron pair on the chalcogen atom (p, π -interaction) and purely steric interaction of substituent R with the hydrogen atoms of the vinyl group. For these types of molecules, the most important information on rotational isomerism is the number of stable conformers and their parameters. Mutual counterbalance between the changes in structural parameters in internal rotation and the electron distribution in different conformations opens the way to understanding both the properties of the compounds and the effect on them of external factors, such as electric and magnetic fields, medium, and temperature.

Typical of vinyl chalcogenides are rotameric forms characterised by torsional intramolecular motion of large amplitude. The peculiarities of the conformational structure of these compounds can be understood by considering the whole ensemble of stationary states. The most comprehensive information on rotational isomerism in alkyl vinyl chalcogenides can be gained from the internal rotation potential curve, and in divinyl chalcogenides, from the corresponding potential surface constructed as a function of rotational angles about $\text{C}_{sp^2}-\text{X}$ bonds. Alkyl vinyl chalcogenides are characterized by rotation about the $\text{C}_{sp^3}-\text{X}$ bond, in addition to the rotation about the $\text{C}_{sp^2}-\text{X}$ bond; for R other than Me, internal rotation in the alkyl substituent also takes place. This increases the number of rotational states and hampers the use of many methods of investigation. In this connection, an increased interest in the simplest analogues of compounds under study such as vinyl alcohol and ethenethiol is well understood.

The problem of the relationship between conformational isomerism, electronic structure, physicochemical properties, and reactivity in vinyl heteroatomic systems has first been formulated for vinyl ethers and sulfides in generalising papers.^{1,2} In these studies, the main achievements in this field were summed up, and novel approaches (and solutions) were contemplated. These studies have stimulated systematic investigations in this field carried out in the last two decades^{3–21} including also vinyl compounds of selenium,^{9,11,13} tellurium,^{4,9,11,13} and nitrogen.^{16–20} A significant part of these investigations was performed by the NMR method on various nuclei. Large areas of this

[†] Hereinafter, the terms *cis*- and *trans*-conformers refer to *s-cis*- and *s-trans*-conformers of chalcogenides.

research are summarized in theses^{9,13,16,18} and reviews.^{3,4,6-8} However, recent results obtained by other methods have not been considered altogether except for a thesis,²¹ in which the results of the study of the electronic and spatial structures of vinyl and allenyl chalcogenides by IR, Raman, UV, and PE spectroscopy methods, conformational analysis, quantum-chemical calculations, and normal coordinate analysis have been summarized.

The present review gives a systematic account and critical examination of investigations of the electronic and conformational structures of vinyl and allenyl chalcogenides carried out by complementary theoretical and experimental methods (gas electronography, microwave, vibrational, UV and PE spectroscopy, dipole moments).

II. Rotational isomerism in vinyl and allenyl chalcogenides

1. Vinyl alcohol and ethenethiol

For a long time, vinyl alcohol has not been available for experimental studies and has been considered as an unstable tautomeric form of acetaldehyde. Only in 1967 was vinyl alcohol identified by its mass spectrum in the analysis of the products of oxidation of dideuteroacetylene.²² The NMR spectrum of vinyl alcohol (without its isolation from the products of photolysis of acetaldehyde) was reported.²³ The molecular structure of vinyl alcohol was elucidated from the MW spectra.^{24,25} The analysis of the MW spectra favours the preferential planar *cis*-conformation of the molecule having the following geometric parameters: $r(\text{C}=\text{C}) = 1.33 \text{ \AA}$, $r(\text{C}-\text{O}) = 1.37 \text{ \AA}$, CCO bond angle is equal to 120° . Experimental parameters of the less stable *trans*-conformer of vinyl alcohol were obtained later by MW spectroscopy.²⁶ The analysis of rotational constants for the *trans*-rotamer and its deuterioisotopomer ($\text{CH}_2=\text{CHOD}$) gave the following geometry: $r(\text{C}=\text{C}) = 1.32 \text{ \AA}$, $r(\text{C}-\text{O}) = 1.38 \text{ \AA}$, the COD bond angle is 122° . The C=C bond distance in vinyl alcohol is somewhat shorter than the corresponding bond lengths in ethene²⁷ and propene.²⁸ Shortening of the C—O bond length and an increase in the CCO bond angle is observed in vinyl alcohol as compared to saturated alcohols (1.43 \AA and 120° , respectively).²⁹ The energy difference of 4.5 kJ mol^{-1} was calculated for *cis*- and *trans*-conformers of vinyl alcohol from the variation of relative intensities in the MW spectrum.²⁶

The characteristics of vinyl alcohol derived from IR, UV, and NMR spectra³⁰⁻³² are useful for the detection of this alcohol and other simple enol compounds among intermediates of chemical reactions. The absorption bands for the *cis*-rotamer and for all by-products formed in its synthesis were assigned based on the analysis of the IR spectra of vinyl alcohol and nine of its isotopomers and from normal coordinate analysis.³² Five absorption bands are observed in the photoelectron spectrum of vinyl alcohol.^{33,34} The low-energy band has a fine structure with a vibrational interval of 1400 cm^{-1} . The low-frequency component of this band is assigned to the *cis*- and the high-frequency component is assigned to the *trans*-conformer.³³

According to the IR and MW spectra, the sulfur analogue of vinyl alcohol, ethenethiol, is also a mixture of two conformers.³⁵⁻⁴⁰ A detailed analysis of the IR spectra of ethenethiol^{36,37} in the gas phase, crystal state (at 300 K), and in argon and nitrogen matrices has shown that the molecule exists as *cis*- and *trans*-conformers, the *cis*-form being more favourable in energy, as in the case of vinyl alcohol. The normal coordinate analysis for *cis*- and *trans*-conformations indicates that the stretching C—S, bending C=C—H, and torsional S—H vibrations depend most of all on conformations.³⁷

The planar *cis*- and 'quasi'-*trans*-conformers of ethenethiol and its deuterated isotopomers have been studied by MW spectroscopy.^{35,36,38,40} The following geometric parameters were obtained for the most stable *cis*-conformer: $r(\text{C}=\text{C}) = 1.34 \text{ \AA}$, $r(\text{C}-\text{S}) = 1.76 \text{ \AA}$, bond angles CCS and CCH are equal to 126.9 and 95.8° , respectively.⁴⁰ Internal rotation about the

Figure 1. The potential function of internal rotation for the *trans*-conformer of vinylthiol.³⁹

$\text{C}_{sp^2}-\text{S}$ bond results in a decrease in the CCS angle by 5° and in an increase in the C—S bond length by 0.02 \AA . The characteristics of an ethenethiol rotamer and its SD-isotopomer differing from the *cis*-form in the ground and three excited vibrational states were also obtained from the MW spectra.³⁹ The dipole moments and rotational constants corresponding to the CCS and CSH bond angles equal to 122 and 98° , respectively, were determined. The potential curve of internal rotation for *trans*-ethenethiol was obtained in this work (Fig. 1). The ground vibrational state of this 'quasi'-*trans*-conformer (according to the authors' terminology) is above the barrier of 19 cm^{-1} at 26° separating the two minima relative to the zero of the planar conformation.

Considerable progress in studies of the conformational properties of α,β -unsaturated ethers and sulfides has been achieved with the use of *ab initio* calculations, which allow one to estimate the population of one conformation or another and the probability of the interaction of a lone electron pair of a heteroatom with the π -electron system.⁴¹⁻⁴⁶ One of the first theoretical studies of this type was the calculation on vinyl alcohol and ethenethiol,⁴² which confirmed that both compounds have two rotational isomers, the *cis*-conformer being more stable. The maximum in the potential curve of internal rotation for vinyl alcohol corresponds to a dihedral angle (ϕ) of 90° , and for ethenethiol it corresponds to 60° (Fig. 2). The second minimum for ethenethiol corresponds to a torsional angle of 150° .

ab initio Calculations for vinyl alcohol have been performed with full optimization of the geometry of vinyl alcohol using STO-3G and 4-31G basis sets.⁴³⁻⁴⁵ These calculations have also confirmed that the molecule exists in two planar conformations: *cis*- and *trans*-. For a series of substituted vinyl alcohols $\text{XCH}=\text{CHOH}$ ($\text{X} = \text{H}, \text{CN}, \text{F}$),⁴⁶ the potential as a function of the internal rotation about the $\text{C}_{sp^2}-\text{S}$ bond calculated in the 4-21G basis set appeared to depend substantially on the nature of substituent X (Fig. 3) Internal rotation in these molecules is

Figure 2. The potential functions of internal rotation for vinyl alcohol (1) and vinylthiol (2).⁴²

Figure 3. The potential functions of internal rotation for molecules $\text{XHC}=\text{CHOH}$.⁴⁶ X = H (1), CN (2), F (3).

accompanied by changes in the CCO angle and the C–O bond length.^{45, 46}

The energy difference between the conformers of vinyl alcohol is equal to 9.4 (STO-3G),⁴⁴ 9.0 (4-31G),⁴⁴ 7.1–7.9 (3-21G),⁴⁵ and 11.8 (4-21G)⁴⁶ kJ mol^{-1} , which agrees with the value of 7.9 kJ mol^{-1} (*spd*) obtained from the calculation using a partial geometry optimization.⁴² The barrier to internal rotation separating the *cis*- and *trans*-forms of vinyl alcohol is equal to 17.3,⁴⁶ 17.6,⁴² and 17.9 kJ mol^{-1} .⁴⁵

The internal rotation potential curves for ethenethiol obtained by *ab initio* calculations in various basis sets (STO-3G, 3-21G, 44-31G, and *spd*) were compared with those obtained by molecular mechanics (MM) methods (Fig. 4).^{47, 48} The *cis*-conformation is the most stable in all basis sets. The planar *trans*-form is the second stable conformer of ethenethiol in the STO-3G basis while in the 44-31G, 3-21G, and *spd* basis sets, the second stable conformer is a *gauche*-rotamer with a rotational angle about the C_{sp^2} –S bond of 120–135°. The rotational barrier obtained by the MM method (3.8 kJ mol^{-1}) is lower somewhat compared to those determined by other methods (5.9 (44-31G),⁴⁷ and 7.9 kJ mol^{-1} (*spd*).⁴² The value of the barrier calculated using the STO-3G basis appeared to be significantly higher (16.7 kJ mol^{-1})⁴⁶ than those calculated in other basis sets. For this reason the prediction that the *trans*-form is the second stable conformation, most probably, cannot be considered to be correct.

Potential curves for internal rotation about the C_{sp^2} –S bond in ethenethiol obtained from the MW spectroscopy data⁴⁹ are presented in Fig. 5a. In the region corresponding to the *trans*-conformation, there are two minima with torsional angles of about 156° (0.87 π) and 204° (1.13 π) separated by a barrier of about 0.14 kJ mol^{-1} . The ground vibrational state of the *trans*-conformer is above that small barrier. The *cis*-conformer of

Figure 4. The potential functions of internal rotation for vinylthiol⁴⁷ obtained by different methods: (1) STO-3G, (2) *spd*, (3) MM, (4) 44-31G, (5) 3-21G.

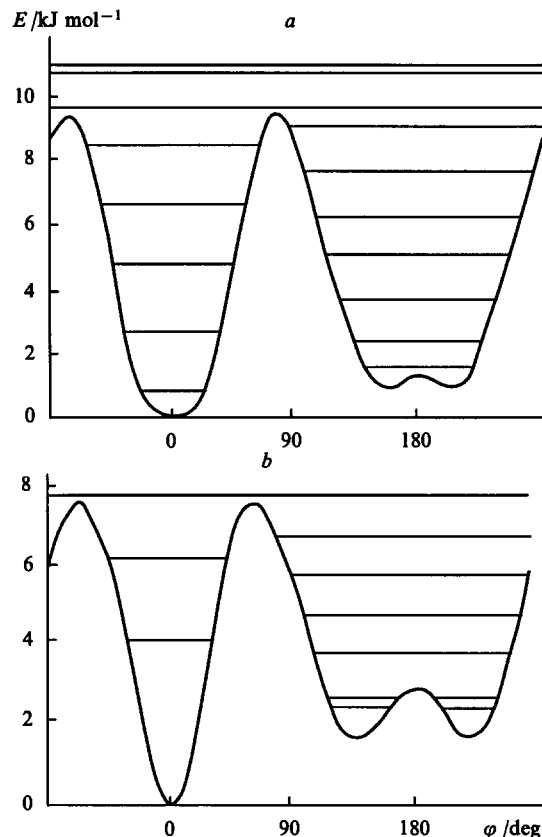

Figure 5. The experimental (a) and theoretical (b) functions of internal rotation for vinylthiol.⁴⁰

vinylthiol is 0.6 kJ mol^{-1} more stable, and the rotational barrier separating the *cis*- and *trans*-conformers is equal to 9.5 kJ mol^{-1} . The *ab initio* calculation in the 4-21G basis gave the internal rotation potential and the positions of stationary energy levels corresponding to the planar *cis*- and 'quasi'-*trans*-states as well as to the non-planar *gauche*-form (Fig. 5b).⁴⁹

The potential function for internal rotation about the C_{sp^2} –S bond in ethenethiols $\text{XCH}=\text{CHSH}$ (X = H, CN, Me, F are *trans* oriented with respect to the sulfur atom) depends substantially on the nature of the substituent (Fig. 6).^{49, 50} The relative stability of the planar *cis*-conformer increases as the electron acceptor

Figure 6. The potential functions of internal rotation for molecules $\text{XHC}=\text{CHSH}$.⁴⁹ X = H (1), CN (2), CH_3 (3), F (4).

properties of the substituent increase; for $X = F$, the acceptor properties of which are lowered due to the competitive p, π -interaction in the $F-C=C$ system, only the *gauche*-rotamer exists in the system.

2. Alkyl vinyl ethers

The existence of rotational isomerism in vinyl ethers was first established from Raman and IR spectroscopy^{1,52-59} and was confirmed later by studies of ultrasonic relaxation⁵¹ and microwave spectroscopy.⁶⁰ From the very beginning, there were different opinions about the number and structure of stable conformers. The study of the temperature dependence of absorbance of triplet components in the range of double bond stretching vibrations allowed one to conclude⁵⁶ that the most stable conformation is characterised by two bands (1613 and 1650 cm^{-1}) whereas the less stable form is characterised by one maximum at 1642 cm^{-1} . The appearance of the third band in the 1600 cm^{-1} region (with the highest frequency) in the vibrational spectra of alkyl vinyl ethers is explained by Fermi resonance between the $\nu(C=C)$ and $\omega(CH_2=)$ vibrations.⁶¹ The temperature dependences of integral intensities of the components of the same triplet in the Raman spectrum of *n*-butyl vinyl ether allowed one to assign each of the three components to a particular rotamer and to calculate the difference between their energies.⁶² Assuming the existence of three possible conformations (two planar, *cis*- and *trans*-, and one non-planar, *gauche*-), one could calculate the frequencies and eigenvectors of the normal modes for methyl vinyl ether, which were in a satisfactory agreement with experimental data.⁵⁸ At the same time, the relaxational behaviour of methyl, ethyl, and 2-chloroethyl vinyl ethers indicates that there is an equilibrium between the planar conformations (*cis*- and *trans*-).⁵¹ Vibrational spectra of methyl vinyl ether and its deuterio-isotopomers have been studied and the band assignment according to symmetry and eigen vectors has been proposed.⁶³ It is noted that this molecule exists at room temperature in the planar *cis*-form, and at lower temperature it exists in the planar *trans*-form (or nearly *trans*-), which follows from the appearance of a number of new bands in the spectra. From the analysis of Raman and IR spectra of methyl vinyl ether it also follows that the *s-trans*-conformation is less stable.⁶⁴⁻⁶⁶ The same conclusions have been derived from the analysis of PE spectra of alkyl vinyl ethers⁶⁷⁻⁶⁹ with normal alkyl substituents.

Analysis of the rotational structure of $CH_2=$ out-of-plane bending modes (820 cm^{-1}) has led to a conclusion^{61,70,71} that the most stable conformation in methyl and ethyl vinyl ethers has a sickle-like (*cis*-) form. It was suggested^{61,70} that the other conformation should have a non-planar structure. These conclusions^{61,70,71} have received additional and independent support from the analysis of MW,⁶⁰ Raman and IR⁷²⁻⁷⁴ spectra of methyl vinyl ether. The study of vibrational spectra of methyl vinyl ether in the gas phase allowed the identification of a less preferred 'skew' rotamer with a torsional angle of 144°.⁷²

The IR spectra of vinyl ethers are very useful in determining the conformer ratio. An analysis of extensive experimental data and literature assignments allowed the major bands of the vinyloxy group to be ascribed to particular conformations. For example, the following maxima correspond to the planar conformer: a low-frequency component of a band in the region of $\sim 820 \text{ cm}^{-1}$ [$\omega(CH_2=)$];^{61,70,75,76} a high-frequency component of a band at $\sim 960 \text{ cm}^{-1}$ [$\omega(CH=)$];^{61,70,76} a very strong broad band around 1200 cm^{-1} [$\nu(C-O)$];^{56,61,70} a narrow band of medium intensity at 1320 cm^{-1} [$\delta(CH=)$];^{61,70} a low-frequency component of a triplet in the 1600 cm^{-1} region (usually, $\sim 1620 \text{ cm}^{-1}$) [$\nu(C=C)$];^{56,61,62,70} The following peaks correspond to the non-planar conformer: a high-frequency shoulder on the band at 820 cm^{-1} ,^{61,70,75,76} a low-frequency component of a doublet in the region of 950 cm^{-1} [$\omega(CH=)$];⁶⁶ weak peaks in the region of 1150–1050 cm^{-1} [$\nu(C-O)$] (for example, 1138 cm^{-1} in methyl vinyl ether⁶⁴ and 1143, 1100, 1081,

1048 cm^{-1} in ethyl vinyl ether⁷⁰); the middle component of a triplet in the range of 1640 cm^{-1} [$\nu(C=C)$].^{56,61,62,70}

The aim of the studies⁷⁷⁻⁷⁹ was to elucidate, using the IR spectra of alkyl vinyl ethers, the influence of the structure of alkyl substituent on the relative intensities of bands belonging to different conformations without going into details of their spatial structure. A comparative analysis of IR spectra of ethyl vinyl ether indicates that the conformation ratio depends very strongly on the degree of branching of the substituent at the α -carbon atom.⁷⁷ For methyl and alkyl vinyl ethers with normal substituents the planar conformers dominate, whereas the relative intensities of the bands of the planar conformer decrease abruptly with an increase in branching in the substituent up to the disappearance of some of them; simultaneously, the bands of the non-planar conformer appear and their intensities increase. *tert*-Butyl and *tert*-pentyl vinyl ethers exist virtually as one non-planar conformer. Indeed, all the vibrational bands of the planar conformer in the spectra of these ethers decrease in intensity or disappear. This is most clearly illustrated in the 1600 cm^{-1} region, where only one high-frequency component of the very strong multiplet remains, which belongs to the non-planar conformation.

The possibility to apply *ab initio* calculations to analyse the vibrational spectra of methyl vinyl ether has been shown.⁸⁰ A theoretical force field has been composed and corrected by scaling factors, which have been either transferred from simpler molecules $CH_2=CHF$ and Me_2O or selected by calculation of the rotation about the $C_{sp^2}-O$ bond. The method of stepwise determination of scaling factors gave a satisfactory agreement between the calculated and experimental data.

The molecular structure of methyl vinyl ether was also studied by electron diffraction.^{42,81} Along with the problem of the determination of the molecular geometry of the major rotamer, an attempt was made to solve the problem of the existence of a second less-preferable form. In an earlier paper⁸¹, the *gauche*-conformer with an angle between the $C=C-O$ and $C-O-C$ planes between 80–110° has been favoured. Later, the results of *ab initio* calculations referring to the planar *s-trans*-structure of the second stable rotamer have convinced the authors to reconsider their experimental data and to conclude that these data do not contradict the supposition about the planar structure of the second rotamer in methyl vinyl ether.⁴²

Important results concerning the spatial and electronic structure of alkyl vinyl ethers were obtained from the study of their dipole moments.¹ For alkyl vinyl ethers $CH_2=CHOR$, unprecedented dependences of dipole moments on the structure of the alkyl substituent⁸² and temperature⁸³ were established. The reason for these features is a close relationship between p, π -interaction and conformational isomerism. Mere consideration of the dipole moment vectors for dimethyl and methyl vinyl ethers leads to the conclusion that the dipole moment of the latter depends on the torsional angle provided that the p, π -interaction is accompanied by polarisation of the double bond (Scheme 1):

Scheme 1

The existence of this polarisation follows from the consideration of the dipole moment values of alkyl vinyl ethers with normal and branched alkyl substituents (Table 1).⁸⁴⁻⁸⁶

In methyl vinyl ether, which exists preferentially as the *s-cis*-conformer,⁸⁵ the directions of π and σ constituents are opposite. Therefore, in this case, it is worth estimating the π -constituent as the difference (0.36 D) between the moments of dimethyl ether and methyl vinyl ether (as in Ref. 87). Of course, one should bear

in mind that the π -moment value obtained in this way includes the induced π -moment and the contribution due to the difference in the moments of the C_{sp²}-O and C_{sp²}-O bonds. However, estimations of dipole moments of other conformations by the addition of π and σ vectors⁸⁷ are erroneous in principle, because they do not take into account the changes in the degree of p,π -interaction (and therefore, the π -constituent) due to violation of coplanarity. For a non-planar *gauche*-conformation (where the angle is 90°) the π -constituent should be absent or, at least, should be much less than that for the planar conformation. The consideration of the molecular model shows that for such a conformation, the σ -moment vector forms an angle of ~55° with the double bond plane, and the directions of its projection to this plane and the C_{sp²}-O bond coincide.

A significant difference between the dipole moments of conformers of alkyl vinyl ethers could be rationalised in terms of electronegativity of a substituent R.⁸⁸ The validity of this supposition follows from a close linear dependence of the dipole moment on inductive (σ^*) and steric (E_s) constants of the substituent R. The study of temperature dependence of dipole moments⁸³ allowed one to choose between the inductive and conformational nature of the difference in dipole moments in the series of alkyl vinyl ethers in favour of the latter.

The dielectric behaviour of alkyl vinyl ethers with non-branched substituents was shown to differ substantially from that of vinyl ethers with bulky branched substituents. In the former case, the dipole moment increases markedly with temperature, and in the latter case it decreases. For methyl vinyl ether, the dipole moments measured in a broad temperature interval are in line with the concept about the equilibrium of two rotamers in octane and benzene solutions.^{83,89} It was concluded⁸³ that a decrease in the dipole moments of alkyl vinyl ethers with Prⁱ, Bu^t, Pent^t substituents as temperature increases is caused, not by an increase in the population of the less polar form, but rather by violation of coplanarity of the molecular fragment CH₂=CHO during torsional vibrations. It is evident that an increase in the population of excited torsional vibrational states can affect significantly the experimental dipole moment only if the torsional mode has a sufficiently large amplitude. A W-shaped potential curve of internal rotation has been proposed,⁸³ which can explain qualitatively the dielectric behaviour of all the alkyl vinyl ethers studied.

In addition to the experimental studies of rotational isomerism in vinyl ethers discussed, numerous publications concerning theoretical considerations^{42,45,63,64,80,90-101} indicate that the

planar *cis*-conformation is the most favourable in energy, while the structure of a second less stable conformer is still disputable. The potential curve of internal rotation for methyl vinyl ether was obtained in the CNDO/2 approximation; its shape depends significantly on the COC angle.^{90,91} According to these calculations, the second less stable conformer has a non-planar *gauche*-structure. It is also possible that coplanarity in the *trans*-form is violated.^{42,92}

One of the first *ab initio* calculations⁹⁴ yielded the potential curve of internal rotation for methyl vinyl ether. The minima of the potential function correspond to torsional angles of 0° (*s-cis*-form) and 180° (*s-trans*-form). The conformer energy difference was calculated as 2.2 kJ mol⁻¹.⁹⁴ The potential curve of internal rotation for methyl vinyl ether was calculated using the STO-3G and 4-31G basis sets.^{95,96} The potential curve obtained is shown in Fig. 7.⁹⁶ The geometry optimization was performed in the STO-3G basis. The calculations predict two stable conformations for methyl vinyl ether: planar *cis*- and planar *trans*-. The conformer energy differences of 4.02 kJ mol⁻¹⁹⁵ and 4.2 kJ mol⁻¹⁹⁶ calculated in the STO-3G basis, are in satisfactory agreement with the experimental value (4.8 kJ mol⁻¹) obtained by gas electronography;⁴² the values of 10.3 kJ mol⁻¹⁹⁵ and 9.6 kJ mol⁻¹⁹⁶ calculated in the 4-31G basis appeared to be twice as high.

Figure 7. The potential function of internal rotation about the C_{sp²}-O bond in vinyl methyl ether.⁹⁶

The method of calculation: (1) 4-31 G, (2) STO-3G.

The potential as a function of internal rotation for methyl vinyl ether was calculated in the 6-31G and 6-31G* basis sets with full geometry optimization.⁹⁷ A region in the potential curve with two flattened minima (torsional angle CCOC is 156.7–159.4°) and a barrier between them corresponds to a less favourable conformer (Fig. 8). The stationary state energies are located above the barrier; they are associated with the vibration of the Me group with large amplitude relative to the equilibrium position

Figure 8. The potential function of internal rotation for vinyl methyl ether in the region of location of the *trans*-conformer and the positions of the steady energy levels (the calculation using the 6-31 G* basis set).⁹⁷

corresponding to the planar *trans*-form. The energy difference between the lowest energy levels of the *cis*- and *trans*-forms, 8.3 kJ mol^{-1} (6-31G) and 9.9 kJ mol^{-1} (6-31G*), is in agreement with the experimental value (7.1 kJ mol^{-1}) obtained for the gas phase by IR spectroscopy.⁷⁴

An *ab initio* calculation in the 4-21G basis with full geometry optimisation gave comprehensive data on the structure of three conformers, *s-cis*- (0°), *s-trans*- (180°), and skew (168°).⁹⁸ The population of the skew conformer is 1–5%, the energy difference between *s-cis*- and *s-trans*-rotamers is equal to 12.4 kJ mol^{-1} . However, according to other *ab initio* calculations for methyl vinyl ether,⁴⁵ torsional angles of 0° (*s-cis*-) and 150° (*gauche*-) correspond to the stable states, the first being more favourable by 7.9 – 8.8 kJ mol^{-1} .

Hence, most of the studies on rotational isomerism in vinyl ethers show that these ethers exist as two stable conformers. One of them is planar (*cis*-), the other is characterised by a relative motion with large amplitude of the molecular fragments and an effective non-coplanarity, which depends on the structure of the vinyl substituent.

3. Allenyl ethers

Allenyl ethers ($\text{CH}_2=\text{C}=\text{CHOR}$) are close analogues of vinyl ethers. Their unsaturated fragment is represented by two orthogonal π -systems. The spatial structure of allenyl methyl ether has been investigated by various physico-chemical methods.^{102–112} The interest in allenyl ethers is easily understandable because they are both valuable initial substances for organic syntheses and convenient models for investigations of the relationship of, and mutual influence between, conformational isomerism and p, π -interaction. Experimental data obtained by gas electronography indicate that at room temperature allenyl methyl ether exists only in the planar *cis*-conformation; the second conformer was not detected.¹⁰² This conclusion was confirmed by an analysis of coupling constants in the ^1H NMR spectrum of allenyl methyl ether.^{103, 104}

According to these data, alkyl allenyl ethers with non-branched substituents possess preferential planar *cis*-conformation, and homologues with branched substituents exist essentially in the planar *trans*-conformation. Conformational analysis of vinyl and phenyl allenyl ethers¹⁰⁴ allowed one to conclude that the planar *trans*-conformation predominated and the content of the *cis*-conformer was $\sim 10\%$.

The molecular structure of allenyl methyl ether was also studied by MW spectroscopy.¹⁰⁵ The overall dipole moment was determined in the ground state ($\mu = 0.96\text{D}$). The barrier to internal rotation of the methyl group was obtained from the splitting of transitions in the excited state ($V_3 = 11.86 \text{ kJ mol}^{-1}$). The values obtained were assigned to the planar *cis*-form. PE spectroscopic data and semiempirical MNDO/3 calculations showed that allenyl methyl ether exists as two conformers *s-cis*- and *s-trans*-, the former dominating.¹⁰⁶ Raman and IR spectra of allenyl methyl ether were studied using *ab initio* calculations within the 3-21G and 6-31G* basis sets. From the data obtained it was concluded that allenyl methyl ether has two conformers, viz, the planar *cis*-form and the non-planar *gauche*-form with a torsional angle of 140° . The energy difference of 11.2 kJ mol^{-1} for conformers was calculated from the temperature dependence of intensities of the bands sensitive to conformations. The potential curve of internal rotation for allenyl methyl ether was obtained¹¹³ (Fig. 9). In the range of the second stable conformer, there are two small minima separated by a barrier of 1.42 kJ mol^{-1} , which correspond to enantiomeric forms. Large amplitude intramolecular motion of fragments of the molecule relative to the planar *trans*-form corresponds to the stationary energy states arranged above the barrier.

Rotational isomerism and the breakdown of local C_3 , symmetry of the methyl group have been studied using vibrational spectra [IR (gas, liquid), Raman (liquid)] of allenyl methyl ether and its deuterio-isotopomer, $\text{CH}_2=\text{C}=\text{CHOCD}_3$.¹¹⁴ Specific

Figure 9. The potential function of internal rotation for allenyl methyl ether.¹¹³

interactions in the fragments $\text{CH}_2=\text{C}=\text{CHO}$ and COC can manifest themselves in vibrational spectra due to the orthogonal arrangement of the π -systems in allenyl methyl ether. It is difficult to estimate the coupling of these vibrations directly from experimental spectra. It became possible only by comparing experimental results and *ab initio* calculations.

The calculation of the equilibrium geometry and the force field was carried out by the gradient method using the 4-21G basis assuming the *cis*-conformer to be the most stable.¹¹⁴ Scaling factors were transferred from simpler dimethyl ether and allene molecules, and for the rotation about the $\text{C}_{sp^2}-\text{O}$ bond these were selected from calculations. The scaling factors were determined by fragments, which gave a satisfactory agreement of calculated and experimental frequencies.¹¹⁴

Similar to Fermi resonance between $\nu_s(\text{CH}_3)$ and $2\delta_s(\text{CH}_3)$, there is a resonance between the $\nu_{as}(\text{CH}_3)$ and $2\delta_{as}(\text{CH}_3)$ modes. Comparative analysis of a splitting value of the degenerate $\nu_{as}(\text{CH}_3)$ mode of C_3 , symmetry and the frequency shift for this mode upon isotopic substitution indicates that asymmetry of the C–H bond lengths in the methyl group of allenyl methyl ether is the same as in methyl vinyl ether.^{115, 116}

The antisymmetric stretching mode of the allenyl fragment $\nu_{as}(\text{C}=\text{C}=\text{C})$ at 1960 cm^{-1} is not coupled and localised in double bonds, while the $\nu_s(\text{C}=\text{C}=\text{C})$ mode at 1054 cm^{-1} is coupled with the vibrations of the COC and CH_3 groups. The frequencies of $\text{C}=\text{C}=\text{C}$ bending modes occur in the low-frequency range at 270 and 170 cm^{-1} ; the bending mode of the COC group contributes largely to the band at 170 cm^{-1} . The band responsible for the torsional motion relative to the CCC axis (612 cm^{-1}) is intense in the Raman spectrum and weak in the IR spectrum. This is explained by substantial changes in the molecular polarisability and a weak dependence of the dipole moment on the torsional motion of the allenyl fragment. Apparently, the perturbation introduced by the orthogonal π -system to the interaction of the lone pair electron with π -electrons of the double bond of the $=\text{C}=\text{C}(\text{H})\text{O}$ fragment does not influence significantly the effects of electron density delocalisation.

Analysis of experimental spectra of allenyl methyl ether and its deuterio-isotopomer allowed one to identify the bands corresponding to the stretching modes of the CH and CH_2 groups. A band of medium intensity in the IR spectrum and a strong line in the Raman spectrum with a frequency of 3046 cm^{-1} were assigned to the stretching mode of the C–H bond.¹¹⁴ It is identical in frequency and eigenvector with that of the analogous group in methyl vinyl ether.

The feature distinguishing allenyl methyl ether from methyl vinyl ether is an anomalous intensity ratio of the vibrational bands $\nu_s(\text{CH}_2)$ and $\nu_{as}(\text{CH}_2)$. The intensity of $\nu_{as}(\text{CH}_2)$ in methyl vinyl ether is significantly higher than that of $\nu_s(\text{CH}_2)$, while, according to the calculation for allenyl methyl ether, confirmed by experimental results, the derivative of the dipole moment with respect to the normal coordinate is by an order of magnitude larger for

$\nu_s(\text{CH}_2)$ than for $\nu_{as}(\text{CH}_2)$. A similar picture is observed in the spectra of other molecules containing the allenyl group,¹¹⁷ which might be rationalised in terms of peculiar features of the electronic structure of the allene framework.

In the IR spectrum of allenyl methyl ether in the gas phase, the A-type band with a frequency of 1430 cm^{-1} belongs to the bending mode $\delta(\text{CH}_2)$.¹¹⁴ This assignment differs from the assignment¹¹³ of this band to $\delta(\text{CH}_3)$, which has been made without analysis of the rotational structure of the deuterio-isotopomer. A low intensity δ_{CH_2} bending mode at 1015 cm^{-1} manifests itself as a C-type band in the IR spectrum. According to calculation, it contains a contribution from a wagging mode, which features a departure of the α -hydrogen atom from the plane of the $\text{C}=\text{C}-\text{O}$ fragment.¹¹⁴

Analysis of rotational contours in the IR spectrum of allenyl methyl ether allowed one to assign the bands in the $850\text{--}920\text{ cm}^{-1}$ range since in this range, the stretching COC mode gives rise to a band of the A type at 918 cm^{-1} , which is coupled with the wagging modes of the CH_2 group (895 cm^{-1}) and the bending mode of the allene framework.

In order to investigate rotational isomerism in allenyl methyl ether and in its deuterio-isotopomer, their IR spectra in various solvents (CCl_4 , C_7H_{16} , $\text{C}_4\text{H}_9\text{Br}$, MeCN) were measured over a wide temperature range.¹¹⁴ A normal coordinate analysis was carried out for various orientations of the COC and CCO fragments specified by the COCC torsional angle. The bands in the vibrational spectrum sensitive to conformations were identified by calculation. For allenyl methyl ether in the condensed state, two weak bands at 572 cm^{-1} (Raman) and 960 cm^{-1} (IR) were revealed, which, probably, belong to the modes of a second conformer differing from the *cis*-conformer in population and geometry. No features of the second conformer were detected in the gas-phase spectra. The splitting of the $\nu_s(\text{C}=\text{C}=\text{C})$ and $\nu_{as}(\text{C}=\text{C}=\text{C})$ bands cannot originate from conformational changes because it remains in the spectra of the gas phase, condensed and solid states. The bands observed on the high-frequency side of $\nu_{as}(\text{C}=\text{C}=\text{C})$ and on the low-frequency side of $\nu_s(\text{C}=\text{C}=\text{C})$ seem to belong to a series of so-called 'hot' transitions.

It follows from the above account that the planar *cis*-conformer with the methyl group of distorted C_{3v} local symmetry is the most preferable in energy for allenyl methyl ether. The splitting value of the degenerate $\nu_{as}\text{CH}_3$ mode of C_{3v} symmetry and the position of the low-frequency component of the Fermi resonance lead to the conclusion that the structures of methyl vinyl and allenyl methyl ethers are similar.

4. Alkyl vinyl sulfides

The molecular structure of the sulfur analogue of methyl vinyl ether, methyl vinyl sulfide, has been studied by both experimental and theoretical methods. The conclusions made from these investigations concerning the nature of possible stable conformers and their energy characteristics do not always coincide.^{42, 118–124} Thus the data of MW¹²⁰ and PE spectroscopy¹²⁵ indicate that methyl vinyl sulfide exists at room temperature only in the *cis*-conformation, whereas electronography shows that methyl vinyl sulfide exists as two conformers, *cis*- and *gauche*-, in the ratio of 33:66¹²¹ and 38:62.⁴² The content of the *gauche*-conformer was estimated as 11%–21%.¹²² The electronographic data reported^{42, 121, 122} and the MW and Raman spectra of methyl vinyl sulfide were analysed¹²³ using a static (considering small amplitude modes) and a dynamic (including large amplitude modes) models. The differences observed were explained by the fact that the use of the static model is incorrect because this model cannot be applied to high-temperature measurements as well as in the cases when the barrier separating the conformers is relatively high as is the case for methyl vinyl sulfide.

Dipole moments of alkyl vinyl sulfides appeared to be very much similar to those of alkyl vinyl ethers. In the series $\text{CH}_2=\text{CHSR}$ ($\text{R} = \text{Me}, \text{Et}, \text{Pr}^i, \text{Bu}^i$) a significant increase in

dipole moments is observed with an increase in branching of alkyl substituent.¹²⁶

However, the difference in dipole moments of *tert*-butyl vinyl sulfide and methyl vinyl sulfide at 298 K is only 0.35 D, which is more than twice as low as that of *tert*-butyl vinyl and methyl vinyl ethers (0.74 D). A smaller dipole moment value for methyl vinyl sulfide than that of the saturated analogue, ethyl methyl sulfide (1.60 D), as in methyl vinyl ether, indicates the same direction of polarization due to p, π -conjugation.

The temperature dependence of the dipole moments of alkyl vinyl sulfides is analogous to that observed for alkyl vinyl ethers with the only difference that the variation range is substantially narrower.⁸³ For alkyl vinyl sulfides with normal substituents, the temperature dependence originates from a change in the populations of *s-cis*- and *gauche*-conformations; for branched substituents, it is due to a change in the vibrational level populations of the *gauche*-conformation, i.e. the temperature dependence is determined by a different degree of deviation of the SR group from the equilibrium position as the planar form is approached.

Methyl vinyl sulfide was intensively studied by IR spectroscopy.^{3, 5, 124, 127–131} A detailed investigation of IR-active vibrations of the molecule has been given.^{118, 124, 127} The bands sensitive to conformational changes were revealed. The results of these studies agree except for the assignment of the band at 1430 cm^{-1} , which has earlier been assigned to the bending mode of the vinyl groups ($\text{CH}_2=$).¹¹⁸ In more recent studies,^{124, 127} it was assigned to the out-of-plane bending vibration of the methyl group, and the $\delta(\text{CH}_2=)$ mode was associated with the bands in the range of $1360\text{--}1390\text{ cm}^{-1}$.

Out-of-plane bending ($\text{CH}_2=$) ($860\text{--}880\text{ cm}^{-1}$) and C–S stretching ($600\text{--}750\text{ cm}^{-1}$) modes are sensitive to rotational isomerism and give rise to several bands, the number and intensity of which vary with the change in the structure of the alkyl substituent at the sulfur atom.^{124, 127, 128} The band at 860 cm^{-1} was assigned¹²⁴ to the planar *cis*-conformer, and the higher-frequency band ($\sim 880\text{ cm}^{-1}$), to the *gauche*-rotamer. A trend of increasing frequency of $\omega(\text{CH}_2=)$ (860 cm^{-1}) with increase in the electron-acceptor properties of the substituent was noted¹³¹ in the spectra of substituted vinyl sulfides. Bearing in mind the IR spectra of vinyl ethers,^{77–79} one can relate these changes to the increase in the population of the less conjugated non-planar conformer due to the shift of the lone electron pair of the sulfur atom toward the acceptor.

It is noticed¹²⁸ that the band at 678 cm^{-1} [$\nu_s(\text{C}-\text{S})$], which dominates in the spectra of alkyl vinyl sulfides with non-branched substituents, becomes less intense in the spectra of *sec*-alkyl vinyl sulfides and is absent in the spectra of *tert*-alkyl vinyl sulfides. The latter have the only band at 730 cm^{-1} assigned to *gauche*-rotamer modes.¹²⁸ A comparison of relative intensities of the bands in the ranges mentioned shows that vinyl sulfides are irregular as regards to conformation, and the proportion of the dominating stable *cis*-rotamer decreases with an increase in substituent branching. *tert*-Alkyl vinyl sulfides exist virtually completely in the *gauche*-conformation.

The band due to the double-bond stretching mode exhibits a doublet with absorption maxima in the range of $1575\text{--}1585\text{ cm}^{-1}$ (Fig. 10).¹²⁹ As the alkyl substituent branching increases, the intensity of the low-frequency component decreases and that of the high-frequency component increases. In the spectrum of *tert*-butyl vinyl sulfide, the low-frequency band is absent. A similar picture is observed in the IR spectra of vinyl ethers.^{1, 77} Hence, IR spectra of alkyl vinyl sulfides adequately reflect changes in the conformer ratio depending on the substituent structure.

Figure 10. The band contour of the stretching vibration of the double bond in the IR spectra of compounds $\text{CH}_2=\text{CHSAlk}$.¹²⁹ Alk = Me (1), Et (2), Pr^i (3), Bu^i (4).

IR spectroscopic data and quantum mechanical consideration of rotational isomerism gave the potential energy curve for internal rotation in methyl vinyl sulfide.¹²⁹ In the spectrum the doublet band of the double bond stretching mode has maxima at 1577 and 1581 cm^{-1} . The relative intensity of the low-frequency component decreases and that of the high-frequency component increases with temperature. The effect of alkyl substituent branching in a series of alkyl vinyl sulfides as well as the existence of a temperature dependence of relative intensities of the doublet components permitted their assignment to different conformations of the vinylthio group.¹²⁹ Since the intensity of the C=C bond stretching mode due to the substituent resonance effect is independent of the inductive effect influence and since the σ constants are equal in the substituent series AlkS ,¹³⁰ the extinction for methyl vinyl sulfide in the *gauche*-conformation may be assumed to be equal to that for *tert*-butyl vinyl sulfide.

The temperature dependence of the $\nu(\text{C}=\text{C})$ band contour has been analysed. The relationship between $\ln(c_{\text{cis}}/c_{\text{gauche}})$, obtained using the temperature dependence of *tert*-butyl vinyl sulfide, and $1/T$ gives the following enthalpy and entropy difference for the rotamers: $\Delta H = 6.1 \text{ kJ mol}^{-1}$, $\Delta S = -1.74 \text{ J K}^{-1} \text{ mol}^{-1}$. The energy difference obtained for methyl vinyl sulfide conformers is close to those found earlier (kJ mol^{-1}): 9.63,¹³² 5.86,¹²⁴ 7.95,¹²³ 3.3–3.7,¹²² 7.9.¹³³

Based on the quantum model of conformational isomerism, the internal rotation potential curve parameters were selected so as to correlate the number and energies of all the stationary states with the observed temperature behaviour of the conformer ratio (Fig. 11).¹²⁹ The stationary energy spectrum of the molecular rotation is found from the solution of the Schrödinger equation:¹²⁹

$$\left[-\frac{\hbar^2}{2J} \frac{\partial^2}{\partial \varphi^2} + U(\varphi) \right] \phi(\varphi) = \epsilon \phi(\varphi)$$

with the potential $U(\varphi)$ in the form:

$$U(\varphi) = U_n(\varphi) + \frac{1}{2} \sum_{k=1}^3 V_k (1 - \cos k\varphi),$$

where $U_n(\varphi)$ is the energy of steric hindrance, V_k is the characteristic internal rotation barrier about the $\text{C}_{\text{sp}^2}-\text{S}$ bond, J is the reduced moment of inertia of the molecule, and φ is the rotation angle.

Figure 11. The potential function of internal rotation for vinyl methyl sulfide and the positions of the stationary energy levels. States: *cis* (1), *gauche* (2), 'quasi'-*trans* (3), and free rotation (4).¹²⁹

As is seen from Fig. 11, the methyl vinyl sulfide molecule is an ensemble of four types of rotamers corresponding to four types of stationary states, namely, planar *cis*-states (1), *gauche*-states with rotation angles about the $\text{C}_{\text{sp}^2}-\text{S}$ bond of $132 \pm 3^\circ$ (2), the states above the *trans*-barrier ('quasi'-*trans*-states) associated with a large amplitude intramolecular mode having the equilibrium position in the planar *trans*-form (3), and the states of free rotation (4). The bands of the *gauche*- and 'quasi'-*trans*-states seem to differ somewhat in frequency, therefore, the width of the band at 1581 cm^{-1} is, on the average, 1.35 times larger than that of the band at 1571 cm^{-1} . A maximum in the potential curve corresponding to the planar *s-trans*-conformation is typical of the methyl vinyl sulfide molecule. The barrier separating the *gauche*-forms is equal to 2.5–2.9 kJ mol^{-1} .¹²⁹ There are two or three energy levels in the potential well of the *gauche*-conformer. The energy difference between lower *gauche*- and *cis*-levels (3.8–4.2 kJ mol^{-1}) differ substantially from the formal enthalpy difference of rotamers obtained on the basis of the static model of rotational isomerism (6.1 kJ mol^{-1}). The barrier to *cis-gauche*-transition is equal to 9.8–10.6 kJ mol^{-1} .

Optimal parameters of the potential V_k were obtained,¹²⁹ which correspond to the minimum of the fitness criterion F

$$F = \left\{ \frac{1}{K} \sum_{i=1}^2 \left[\ln \left(\frac{c_{\text{cis}}}{c_{\text{gauche}}} \right)_{\text{calc}} - \ln \left(\frac{c_{\text{cis}}}{c_{\text{gauche}}} \right)_{\text{exp}} \right]^2 \right\}^{1/2}.$$

The value of $V_1 = 2.7 \pm 0.1 \text{ kJ mol}^{-1}$ means that the energy of the interaction between the lone electron pair on the sulfur atom and π -electrons of the double bond differs for planar *cis*- and *trans*-conformations. The interaction is more effective for the *cis*-form than that for the *trans*-rotamer. A value of $V_2 = 7.9 \pm 0.8 \text{ kJ mol}^{-1}$ is an average estimate of the interaction energy. The value of $V_3 = 6.3 \pm 0.4 \text{ kJ mol}^{-1}$ appeared to be unexpectedly high, probably, due to hybridisation intermediate between sp^2 - and sp^3 -hybridisations of the sulfur valence electrons.

The potential function for methyl vinyl sulfide (Fig. 11)¹²⁹ is qualitatively similar to that of ethenethiol (Fig. 5).⁴⁰ The barriers to *cis-gauche*-transitions are practically the same, while the barrier separating two *gauche*-forms is significantly higher for methyl vinyl sulfide (2.9 kJ mol^{-1}) than that for ethenethiol (0.14 kJ mol^{-1}). As a result, there are several (2 or 3) energy

levels in the potential well for the *gauche*-conformer of methyl vinyl sulfide.

The spatial structure of methyl vinyl sulfide was the subject of semiempirical and *ab initio* calculations. Semiempirical calculations were used for the analysis of the correlation between the structure of sulfur compounds and their various experimental characteristics such as electronic and PE spectra, and dipole moments. An analysis of publications⁴¹ of this type leads to the conclusion that the interaction between the lone electron pair on the sulfur atom and the double bond π -electrons should be taken into account to interpret practically all the experimental data. CNDO/2 calculations of methyl vinyl and divinyl ethers and sulfides have been performed in *sp* and *spd* approximations in order to compare the electronic transfer effect through the hetero atom.¹³⁴ It was concluded that the transfer is more effective in the case of the sulfur atom due to $p\pi-d\pi$ interaction. Vacant orbitals were taken into consideration in the calculation though the question of whether it is necessary to include these into the basis set is still being debated.^{135,136} For vinyl sulfides, the passage from the *sp* to the *spd* approximation leads to a basically different conclusion on the nature of the sulfur atom: the sulfur atom is a π -donor within the *sp* basis, while it becomes a π -acceptor within the *spd* basis.¹³⁴ The CNDO/2 calculation in the *sp* approximation yielded the energies of *cis*- and *trans*-conformers for β -substituted methyl vinyl sulfides ($XCH=CHSMe$, $X = Me, OMe, SMe$)¹³⁷ with a fixed geometry.¹²¹ It was shown that the *cis*-rotamer is more favourable in energy. The energy differences between conformers are as follows: 2.8, -3.6, and 2.4 kJ mol⁻¹ for $X = Me, OMe$, and SMe , respectively. The corresponding enthalpy differences obtained from the equilibrium constants are 1.9 kJ mol⁻¹, 9.9 kJ mol⁻¹, and 2.8 kJ mol⁻¹.¹³⁷ An analysis of the interactions in $XCH=CHX$ ($X = OMe, SMe$) has been carried out by the CNDO/2 method.¹³⁸ For these systems the *trans*-conformer appeared to be more favourable than *cis*-conformer. The calculated conformer energy differences are: 20.4 and 1.7 kJ mol⁻¹ for $X = SMe$ and OMe , respectively.

Considerable progress has been made in the analysis of conformational transitions in α,β -unsaturated sulfides using *ab initio* calculations. The efficiency of these calculations depends upon the approximation used, upon the type and set of the basis functions. *ab initio* Calculations are used for the analysis of the role of *nd*-AOs in the formation of chemical bonds by the sulfur atom in different valence states. It was concluded¹³⁵ that a meaningful, in quantitative terms, population of the 3*d*-AO is observed only for compounds with an increased coordination number of sulfur. The authors¹³⁵ believe that the 3*d*-AOs should be always taken into account as polarisation corrections in *ab initio* calculations; for compounds with a higher valence, they might play the role of real orbitals. The solution of a conformational problem requires that sulfur 3*d*-AOs should also be included in the basis for the correct representation of the wave function geometry.

Potential functions for internal rotation about the $C_{sp^2}-S$ bond for vinyl sulfides have been obtained by *ab initio* calculations.^{47,48,92,123,139} The internal rotation potential for methyl vinyl sulfide was shown to depend strongly on the basis set used (Fig. 12).^{47,48} The *cis*-conformation was found to be the more stable regardless of the basis used, whereas the next conformation might be either *trans*- (STO-3G) or *gauche*-form with different values of the CCSC torsional angle (3-21G, 44-31G). The potential obtained by the MM method is analogous to that calculated within the 44-31G basis.⁴⁸ For a long time, the preference of the *cis*-conformer in methyl vinyl sulfide and in methyl vinyl ether was considered as an experimental fact. Later in theoretical studies,^{95,140,141} it was suggested that the preference can result from the interaction between the σ -orbitals of two methyl hydrogen atoms and π -orbitals of the double bond. In the range of *trans*-conformation in the potential curve of methyl vinyl sulfide, there is a small maximum separating two *gauche*-forms (Fig. 12).⁴⁷ The barrier height is equal to 0.84 kJ mol⁻¹, which is

Figure 12. The potential functions of internal rotation about the $C_{sp^2}-S$ bond in vinyl methyl sulfide.⁴⁸

The method of calculation: (1) STO-3G, (2) 44-31 G, (3) 3-21 G, (4) MM.

insufficient for the existence of a stationary state of the *gauche*-type.

The energy differences calculated for methyl vinyl sulfide conformers, 2.9 kJ mol⁻¹ (44-31G),⁴⁷ 0.8 kJ mol⁻¹ (3-21G),⁴⁸ and 0.8 kJ mol⁻¹ (MM),⁴⁸ are markedly lower than the experimental values obtained from the IR spectra (4.9 kJ mol⁻¹ and 6.7 kJ mol⁻¹).^{124,129} A higher value (9.6 kJ mol⁻¹) is obtained from a temperature dependence study of the PE spectra of methyl vinyl sulfide.¹³² Electronography^{42,121} gives the energy difference as close to zero.

5. Allenethiol and allenyl sulfides

ab initio Calculations for allenethiol and allenyl methyl sulfide have been performed.⁴⁷ The calculation for allenethiol within the STO-3G basis⁴⁷ revealed two stable forms, *cis* and *trans*. The potential curves of internal rotation for allenethiol and ethene-thiol are similar. The conformer energy differences for these molecules are practically the same and are equal to ~4.6 kJ mol⁻¹.⁴⁷

The calculations for allenyl methyl sulfide and methyl vinyl sulfide within the STO-3G and 44-31G basis sets give similar results.⁴⁷ Both calculations predict the greater stability of the *cis*-conformation for allenyl methyl sulfide. According to the calculation within the STO-3G basis, the next conformation is *trans*, while the calculation within the 44-31G basis gives a *gauche*-conformation as the next stable one (Fig. 13). The internal rotation potential curve for allenyl methyl sulfide is more flattened (44-31G, Fig. 13) than that for methyl vinyl sulfide (44-31G, Fig. 12), and the energy maximum corresponds to a dihedral angle of 65–70°. The rotational barrier for allenyl methyl sulfide is 5.5 kJ mol⁻¹, which is 3.3 kJ mol⁻¹ lower than that for methyl vinyl sulfide (8.8 kJ mol⁻¹).

The corresponding barriers obtained in the STO-3G basis⁴⁷ are 12.6 kJ mol⁻¹ for allenyl methyl sulfide and 16.4 kJ mol⁻¹ for methyl vinyl sulfide.

The energy minimum in the potential curve for allenyl methyl sulfide corresponds to a torsional angle of ~120°. In the range of

Figure 13. The potential functions of internal rotation for allenyl methyl sulfide.⁴⁷

The method of calculation: (1) STO-3G, (2) 44-31G.

trans-conformation, there is a low barrier of 4.2 kJ mol⁻¹ separating two *gauche*-forms. The energy difference between *cis*- and *trans*-conformers is higher for allenyl methyl sulfide than that for methyl vinyl sulfide (4.6 kJ mol⁻¹ and 1.2 kJ mol⁻¹ in the STO-3G basis and 7.5 kJ mol⁻¹ and 3.8 kJ mol⁻¹ in the 44-31G basis, respectively).⁴⁷ This seems to be due to the difference in spatial interaction between the Me group and the β -hydrogen, which is of a repulsive character in methyl vinyl sulfide and is absent in allenyl methyl sulfide.

ab initio Calculations⁴⁷ predict two stable conformers for allenyl methyl sulfide. PE spectroscopic data and semiempirical quantum calculations of allenyl methyl sulfide suggest two planar conformers, *cis* and *trans*.¹⁰⁶ At the same time, an electronic investigation of allenyl methyl sulfide indicates only one planar *cis*-conformation.¹⁰² The same follows from the ¹H NMR study of alkyl allenyl sulfides.¹⁰³

6. Methyl vinyl selenide and methyl vinyl telluride

Analysis of vibrational spectra of methyl vinyl selenide and methyl vinyl tellurides suggests the presence of rotational isomers: it makes it possible to estimate the torsional angles between the CXC and XCC planes (X = Se, Te) and to assess the degree of interaction of the heteroatom with the double bond. Band assignments in the IR and Raman spectra of methyl vinyl selenide and methyl vinyl telluride were proposed based on a normal coordinate analysis.^{142–144} The starting point for the discussion of the spectra of the molecules under study was a normal coordinate analysis of methyl vinyl sulfide and its deuterio-isotopomers.¹²⁷ The force fields of the vinyl and methyl groups of these molecules are mutually transferable, which indicates that their electronic structures are similar. While the force constant matrices are consistent, the frequencies of C–X modes differ significantly, which might be due to the difference in heteroatom masses, geometry and force constants of the C–S–C, C–Se–C, and C–Te–C groups. The C_{3v} local symmetry of the methyl group breaks down^{127, 142, 143} in the case of methyl vinylchalcogenides. Analysis of the IR spectra of liquids and solutions in a temperature range of 193–353 K allowed one to suppose that methyl vinyl selenide^{142, 145, 146} and methyl vinyl telluride^{143, 147, 148} have rotational isomers.

Normal vibration frequencies calculated for various values of the CXCC torsional angle were correlated with the experimental frequencies.^{142, 143} The bending $\delta(\text{XCC})$ and $\delta(\text{CXC})$ modes are sensitive to changes in the torsional angle. Rotational isomers should manifest themselves most distinctly in the range of the stretching $\nu(\text{CXC})$ modes. Unfortunately, in the case of methyl vinyl selenide, it was impossible to analyse the frequency changes in this region due to the overlap of bands of the stretching (CSeC) and out-of-plane bending (Se–C_{sp²}–H) modes.¹⁴²

According to the calculation for methyl vinyl telluride, the 500–600 cm⁻¹ region should contain the bands due to out-of-plane bending modes of the vinyl group as well as the symmetric and antisymmetric stretching C–Te modes. Only one band is observed in the IR (at 519 cm⁻¹) and Raman spectra (at 530 cm⁻¹) of liquid methyl vinyl telluride at 298 K, whereas in the IR spectrum¹⁴³ of a CS₂ solution of methyl vinyl telluride at 193 K, this band is composed of three components at 512, 521, and 527 cm⁻¹. The band due to double bond stretching vibrations appears as a doublet with absorption maxima at 1582 cm⁻¹ and 1585 cm⁻¹ for methyl vinyl selenide and 1572 cm⁻¹ and 1577 cm⁻¹ for methyl vinyl telluride (in heptane solutions). The temperature dependence of the relative intensities of doublet components is analogous to that for methyl vinyl sulfide.¹²⁹ The intensity of the low-frequency band decreases, and that of the high-frequency band increases with a rise in temperature. Obviously, the doublet nature of the $\nu(\text{C}=\text{C})$ band of methyl vinyl selenide and methyl vinyl telluride is due to the presence of several rotamers in solution.

The enthalpy and entropy differences have been calculated¹⁴⁷ for rotamers of methyl vinyl telluride: $\Delta H = 4.6$ kJ mol⁻¹,

$\Delta S = -11.1$ J K⁻¹ mol⁻¹. The ΔH value reflects the lowering of the rotational barrier from sulfur to tellurium. The high-frequency doublet component in the spectra of methyl vinyl selenide and methyl vinyl telluride corresponds, as for methyl vinyl sulfide, to several rotamers with large amplitude torsional motion or with above-barrier free rotation. A significant ΔS value indicates the presence of a large number of stationary energy levels corresponding to the high-frequency absorption band.

The data presented point to a similarity of the conformational structures of methyl vinylchalcogenides. It is reasonable to suppose that the low-frequency doublet component in the spectra of methyl vinyl selenide and methyl vinyl telluride, as in the case of the corresponding sulfide, belongs to the planar *s-cis*-form. This is confirmed by comparison of half-widths of the high-frequency doublet components.^{129, 142, 147} The half-widths of the low-frequency components are virtually the same for all the chalcogenides considered, whereas the half-widths of the high-frequency doublet components are different: 5.5 cm⁻¹ for methyl vinyl telluride, 8.0 cm⁻¹ for methyl vinyl selenide, and 10.2 cm⁻¹ for methyl vinyl sulfide. Evidently, the high-frequency doublet component of methyl vinyl telluride belongs preferentially to one type of stationary state. Apparently, the contribution of the *p*, π -interaction stabilising planar conformations is less, and the barrier separating two *gauche*-forms seems to be higher for methyl vinyl telluride than those for methyl vinyl sulfide.

In order to solve the problem of possible *p*, π -interaction in methyl vinyl telluride and methyl vinyl sulfide, the conformational energy has been calculated as a sum of energies of interaction between atoms separated by more than two bonds¹⁴⁷ and energies of bond angle strains.^{149–151} The dependence of the conformational energy on the angle of rotation about C_{sp²}–Te and C_{sp²}–S bonds is presented in Fig. 14. It is seen that steric hindrance is practically absent in the *s-cis*-form of methyl vinyl telluride. The difference in the energies of steric hindrance between the planar *cis*- and *trans*-forms is 0.7 kJ mol⁻¹ (for the sulfide it is 4.4 kJ mol⁻¹). The planar *s-cis*-form in methyl vinyl telluride is stabilised by electronic interactions of the same type as in the case of methyl vinyl sulfide, i.e. due to *p*, π -interaction. The energy of this interaction is 5.3 kJ mol⁻¹, which is twice as low as the energy of the same interaction in methyl vinyl sulfide (10.4 kJ mol⁻¹).

Thus, investigations of rotational isomerism in vinyl chalcogenides have revealed unexpected, and remarkable in many respects peculiarities of their molecular and electronic structure. Alkyl vinyl chalcogenides have two qualitatively different types of stable conformers. One of them is characterised by a definite torsional angle and small deviations from the global minimum of potential energy. The other is associated with a large amplitude relative motion of the fragments of the molecule within a flat-bottomed potential well. This motion can include more than one minimum in the internal rotation potential curve.

Figure 14. The dependence of the energy of steric strain on the angle of internal rotation for vinyl methyl telluride (1) and vinyl methyl sulfide (2).¹⁴⁷ For the planar *s-trans*-form $\phi = 0$.

III. Rotational isomerism in divinyl chalcogenides

The presence of two unsaturated fragments in the immediate vicinity of the heteroatom in divinyl chalcogenides poses new problems of the competition in the interaction of the double bond π -electrons with the lone electron pair, of the possibility of a 'through' conjugation of the π -systems of the vinyl groups, and of a correlation between the barriers to internal rotation in alkyl vinyl and divinyl compounds. The most comprehensive information about rotational isomerism in divinyl chalcogenides can be gained from the potential surface composed as a function of angles of rotation about $C_{sp^2}-X$ bonds. In the case of divinyl chalcogenides, the internal rotation potential energy surface should be considered not only as source of information on rotational isomerism, but as a tool for a search for the stationary states corresponding to changes in the internal molecular coordinates.

A method of build up and analysis of potential energy maps was used to determine the number and the nature of rotational isomers of divinyl chalcogenides.⁵ The most essential component of the potential energy, the energy of steric hindrance, was calculated by the MM method (Table 2).⁵

Table 2. The energies of steric strain U_n in various conformations for molecules $CH_2=CHXCH=CH_2$ ($X = O, S, Se, Te$).⁵

Conformation	$U_n/\text{kJ mol}^{-1}$			
	O	S	Se	Te
A (<i>trans-trans</i>)	3.8	2.5	2.0	1.8
B (<i>cis-trans</i> , planar)	14.5	12.9	8.4	5.1
C (<i>cis-trans</i> , deviation by 15°)	11.3	9.0	5.5	3.2
D (<i>cis-cis</i> , planar)	52.7	53.5	41.4	31.8
E (<i>cis-cis</i> , deviation by 38°)	9.4	5.3	2.7	1.0
F (<i>cis-cis</i> , deviation by 45°)	7.6	3.2	1.3	0.3

1. Divinyl ether

Electron diffraction study of the molecular structure of divinyl ether has led to the conclusion that the planes of the double bonds are turned by about 20° relative to the plane of the symmetrical *trans-trans*-conformation.¹⁵² However, the analysis of MW spectroscopic data for divinyl ether¹⁵³⁻¹⁵⁵ revealed a non-planar *cis-trans*-conformer. A deviation from the planar structure is supposed to be due to strong repulsion between the hydrogen atoms in the α - and β -positions of the *trans*- and *cis*-vinyl groups, respectively. The special feature of the *cis-trans*-conformation is the existence of a tunnel transition through an insignificant potential barrier, which manifests itself as a splitting of rotational transitions.¹⁵⁴ Taking into account tunnel splitting of rotational transitions made it possible to increase the accuracy of the calculation of frequencies of *cis*- and *trans*-conformers in the MW spectrum of divinyl ether.¹⁵⁵

A study of the vibrational spectra of gaseous and liquid divinyl ether has provided evidence for the preferential planar *cis-trans*-conformation of C_s symmetry, however, the possibility of the existence of a second, less stable conformation having no symmetry elements (C_1) is also not ruled out.¹⁵⁶ Divinyl ether was shown¹⁵⁷ to exist as an equilibrium mixture of two conformers with an energy difference of 2.5 kJ mol⁻¹. Analysis of relative band intensities in the IR and Raman spectra and line polarisability in the Raman spectra leads to the conclusion that the planar *trans-trans*-conformer is the most stable, while the second conformer has no elements of symmetry.¹⁵⁷ An investigation of the band shapes of the COC stretching modes in the IR spectrum of gaseous divinyl ether has been performed¹⁵⁸ based on a theoretical simulation of profiles of these bands in different conformers. At 300 K, divinyl ether was shown to contain 80% of *cis-trans*-conformer with torsional angles of 13° and 145° and 20% of *trans-trans*-conformer.

ab initio Calculations have been carried out in order to investigate rotational isomerism in divinyl ether.¹⁵⁷⁻¹⁶⁰ Two stable conformations have been predicted:¹⁵⁷ the first energy minimum corresponds to the *trans-trans*-form, and the second belongs to a non-planar conformation with torsional angles of 135° and 20°. A potential energy map has been constructed for divinyl ether,¹⁵⁹ and three stable conformations have been predicted corresponding to the potential energy minima of 0, 11.4, and 10.0 kJ mol⁻¹ (Fig. 15). These conformations are non-planar *cis-trans*- (torsional angles 147.4° and -17.4°; C_1), planar *trans-trans*- (torsional angles 180°, 180°; C_{2v}), and near-planar *cis-cis*- (torsional angles 31.5° and 31.5°; C_2). The conformer geometry was optimised¹⁵⁹ within the STO-3G basis, relative energies were optimized within the basis 4-31G. The geometry of *cis-cis*-, *trans-trans*-, and *cis-trans*-conformers of divinyl ether were obtained by a gradient method within the 4-31G basis.¹⁵⁸ The difference in the conformer energy (0; 6.6, and 4.5 kJ mol⁻¹, respectively) differ from those obtained in another study.¹⁵⁹ The calculation of divinyl ether within the 6-31G** basis yielded two stable conformers:¹⁶⁰ a near-planar *cis-trans*-conformer as the most energy-favourable and the planar *trans-trans*-conformer with an energy difference of 1.5 kJ mol⁻¹.

A steric hindrance map for divinyl ether obtained by the MM method is given in Fig. 16.³ The steric hindrance energy was calculated by varying ϕ_1 from 0° to 360° and ϕ_2 from 0° to ϕ_1 with a step of 15° (ϕ_1 and ϕ_2 are the rotation angles of the first and the second vinyl groups relative to the planar *cis-cis*-structure, respectively). A minimum of steric hindrance (-5.65 kJ mol⁻¹) belongs to a non-planar form, which results from the *trans-trans*-conformation by rotating two vinyl groups in opposite directions by an angle of about 75° (Fig. 16). Steric hindrance energies for other conformations are listed in Table 2.

The potential energy for different conformations of divinyl ether was calculated as a sum of energies of steric hindrance and p,π -interaction. The values obtained from the *ab initio* calculation for methyl vinyl ether⁹⁴ were used as p,π -interaction energies for divinyl ether. Analysis of the potential energy map for divinyl ether (Fig. 17) shows that there are three different conformations corresponding to the minima of potential energy. In two non-planar quasi-degenerate *trans-trans*-forms, the vinyl groups deviate from the COC plane by $\phi_1=130^\circ$, $\phi_2=130^\circ$, and $\phi_1=130^\circ$, $\phi_2=-130^\circ$ (energy -26.1 kJ mol⁻¹). In a non-planar *cis-trans*-form, the rotational angle of one vinyl group is

Figure 15. The map of the potential surface for the internal rotation in divinyl ether.¹⁵⁹

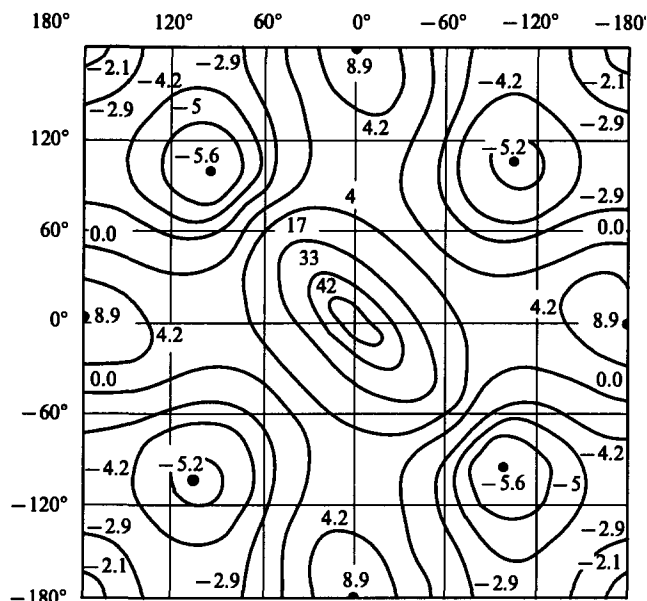

Figure 16. The map of steric hindrance energy for divinyl ether.³

about 10° and that of the other about 50° (energy -28.0 kJ mol⁻¹). These forms are separated by a barrier of -20.9 kJ mol⁻¹. The potential map (Fig. 17) does not take into consideration either effects connected with competition for the interaction of the double bond π -electrons with the lone electron pair of the oxygen atom or 'through' conjugation.

2. Divinyl sulfide

The molecular structure of divinyl sulfide was studied by gas electronography.¹⁶¹ Only one *cis-trans*-conformer with CSCC torsional angles of 32° and -148° having no elements of symmetry was detected in gaseous divinyl sulfide at room temperature. The basic structural parameters of the molecule are as follows: $r(\text{C}-\text{S})=1.758 \text{ \AA}$, $r(\text{C}=\text{C})=1.342 \text{ \AA}$; angles CSC 101.8°, SCC 123.7°. Similar torsional angles were obtained by the MM method (38°, 124°)⁴⁸ and by an *ab initio* calculation within the 3-21G basis (18° and 116°).⁴⁸ Low accuracy in the

electronographic determination of some structural parameters for divinyl sulfide is probably due to large-amplitude intramolecular motion. Therefore the presence of a second (minor) conformer cannot be ruled out.

Rotational isomerism in divinyl sulfide was also studied by vibrational spectroscopy.¹⁶²⁻¹⁶⁴ Analysis of the temperature dependence of intensities of the bands sensitive to conformations in the spectra of gaseous, liquid, and solid divinyl sulfide shows the presence of two conformers.¹⁶³ There is a dynamic equilibrium between the *cis-trans*- and *trans-trans*-conformations in liquid and solution, and in the crystal state only the planar *trans-trans*-conformation exists.¹⁶³ The conformer enthalpy difference is close to zero. Theoretical vibrational spectra of stable conformers of divinyl sulfide have been calculated¹⁶⁰ within the 6-31G** basis. The calculations showed that a non-planar *trans-trans*-conformer is the most favourable, a *cis-trans*-conformer is the next, in which the vinyl group deviates from the CSC plane by 20°; the energy difference between these conformers is 0.71 kJ mol⁻¹. The populations of the individual *trans-trans*-conformer at 300 K was calculated to be 57% and that of the *cis-trans*-conformer, 43% (Table 3).

^a The data of Ref. 158; ^b the data of Ref. 155.

The internal rotation potential curves for divinyl sulfide have been calculated within the STO-3G and 3-21G basis sets and by the MM method with a fixed *trans-trans*-conformation of one vinyl group (Fig. 18).⁴⁸ These potential functions differ significantly from those for ethenethiol (Fig. 4)⁴⁸ and methyl vinyl sulfide (Fig. 12).⁴⁸ The calculation in the STO-3G basis reveals the *trans-trans*-conformation to be the most stable. Two stable conformations, very similar in energy are obtained in the 3-21G basis and by the MM method: *cis-trans*- (0° and 120°, *C_s* symmetry) and *cis-cis*- (120° and 120°, *C₂* symmetry).⁴⁸ ΔE values for the conformers calculated by these methods differ significantly: 5.0 kJ mol⁻¹ (3-21G) and 1.3 kJ mol⁻¹ (MM). The results obtained by the MM method are believed⁴⁸ to be more reliable because the dipole moment (1.48 D) calculated by the MM method fits better the experimental value of 1.07–1.2 D than that calculated within the 3-21G basis (1.9 D).

The conformational energy of divinyl sulfide was calculated^{5,140} as the sum of contributions of the p,π -interaction stabilising the planar arrangement of each of the C–S–C=C fragments and the steric hindrance (Table 2). Minimum steric hindrance is unique to the non-planar *trans-trans*-form with a deviation of the vinyl groups to the both sides of the CSC plane by an angle of ~80°. The planar *cis-cis*-form has a hindrance energy of 53.5 kJ mol⁻¹ (Table 2). Rotation about the C–S bonds in the

Figure 18. The potential functions of internal rotation for divinyl sulfide ($\varphi_2 = 180^\circ$).⁴⁸ The method of calculation: (1) STO-3G, (2) 3-21G, (3) MM.

opposite direction by less than 30° results in a conformation in which steric hindrance changes into stabilization due to Van der Waals interaction.

Quantitative estimation of the p, π -interaction energy in divinyl sulfide was determined¹⁴⁰ from the known internal rotation potential curve for methyl vinyl sulfide.¹²⁹ A part of the internal rotation potential of methyl vinyl sulfide was used in the calculation of the potential energy map for divinyl sulfide:

$$V(\varphi) = V_1 \frac{1 - \cos \varphi}{2} + V_2 \frac{1 - \cos 2\varphi}{2} + V_3 \frac{1 - \cos 3\varphi}{2},$$

where φ is the torsional angle of the rotation about the $C_{sp^2} - S$ bond for methyl vinyl sulfide; V_1 is the first-order barrier connected with the *cis*-preference; V_2 is the second-order barrier numerically equal to a half of the p, π -interaction energy; V_3 is the third-order barrier due to hybridisation of the lone electron pair of the sulfur atom, which is intermediate between sp^3 - and sp^2 -hybridisations. Since the *cis*-preference in divinyl sulfide molecules cannot take place, the p, π -interaction energy can be described by the equation:

$$V(\varphi_1, \varphi_2) = V_2 \left(\frac{1 - \cos 2\varphi_1}{2} + \frac{1 - \cos 2\varphi_2}{2} \right) + V_3 \left(\frac{1 - \cos 3\varphi_1}{2} + \frac{1 - \cos 3\varphi_2}{2} \right),$$

where $V_2 = 7.9 \pm 0.8 \text{ kJ mol}^{-1}$ and $V_3 = 6.3 \pm 0.4 \text{ kJ mol}^{-1}$.

Figure 19. The map of potential energy for divinyl sulfide.¹⁴⁰

The potential energy map for divinyl sulfide is presented in Fig. 19. The planar *trans-trans*-form corresponds to a local maximum rather than to the minimum of potential energy. Two more favourable quasi-degenerate forms have virtually the same energy and correspond to torsional angles $\varphi_1 = 137^\circ$, $\varphi_2 = 137^\circ$ (*trans-trans*-conformer A) and $\varphi_1 = 137^\circ$, $\varphi_2 = -137^\circ$ (*trans-trans*-conformer B). There is also a local minimum at $\varphi_1 = 125^\circ$, $\varphi_2 \sim 0^\circ$ (*cis-trans*-conformer C). The latter conformer is 0.84 kJ mol^{-1} less preferential than the former ones.

Complete understanding of rotational isomerism requires that excited states be taken into account. In the range of excitation energies up to 8 kJ mol^{-1} , there are states in the divinyl sulfide molecule in which torsional angle varies within the limits from -90° to $+90^\circ$ relative to the *trans-trans*-conformation.¹⁴⁰ The stationary state D includes simultaneously potential wells of both *trans-trans*-conformers A and B. Here, large-amplitude intra-molecular motion takes place and the above-barrier states are

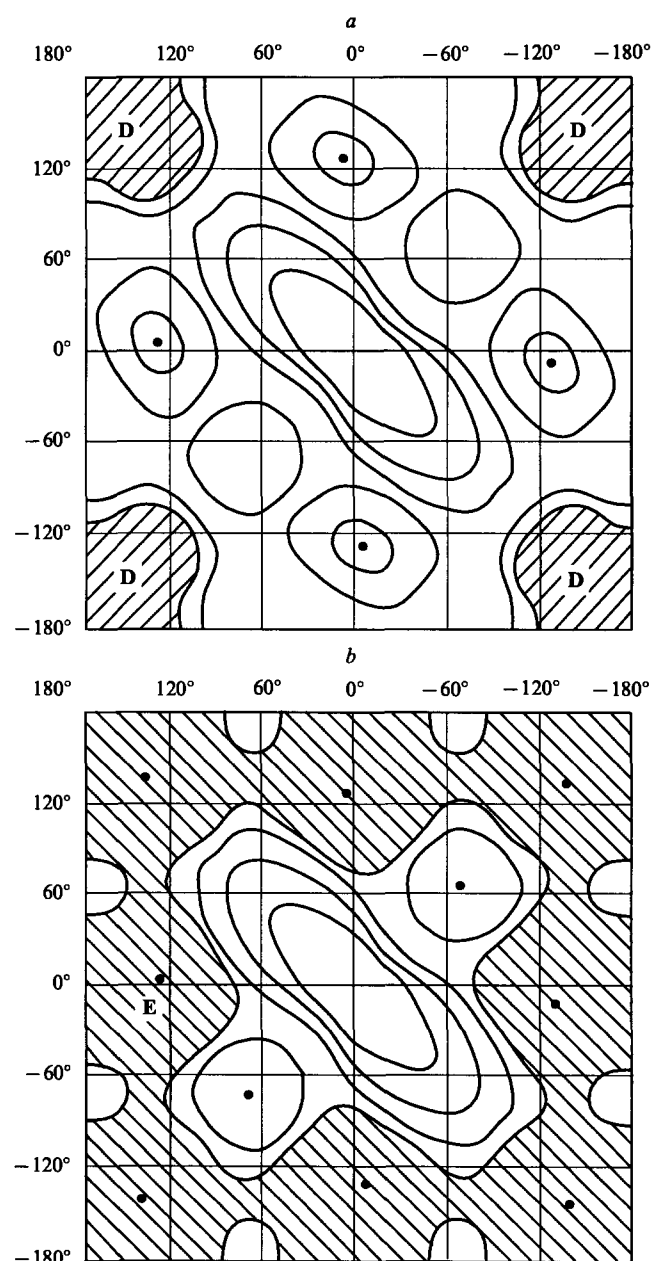

Figure 20. The stationary states of internal rotation¹⁴⁰ for divinyl sulfide: (a) type D with the energy to 8.0 kJ mol^{-1} , (b) type E with the energy above 8.0 kJ mol^{-1} .

becoming occupied. In this range of excitation energies, along with the stationary states of the D type (Fig. 20 a), excited states of the *cis-trans*-conformer C localised near the potential energy minimum are realised.

At excitation energies above 8 kJ mol^{-1} , the stationary state includes conformations that can have, with a few exceptions, practically any values of torsional angles φ_1 and φ_2 (stationary states of the E type, Fig. 20 b).¹⁴⁰ Complete equivalence of the double bonds is characteristic of all the stationary states, except for the *cis-trans*-conformer C in which one of the vinyl groups is practically not involved in the p, π -interaction.

Hence, the potential as a function of the internal rotation about the $C_{sp^2}-S$ bond for methyl vinyl sulfide was transferred (with some corrections) to the rotation about analogous bonds in the divinyl sulfide molecule.¹⁴⁰ Five types of stationary states have been characterised (A-E), two of which have no analogues among stable conformers in a classical sense.

3. Divinyl selenide and divinyl telluride

In this section, the published data on the structure of divinyl selenide and divinyl telluride are presented.^{4, 5, 144, 160, 165} Theoretical vibrational spectra of these molecules have been obtained,¹⁶⁰ the analysis of which revealed two stable non-planar *trans-trans*- and *cis-trans*-conformations. The conformer energy differences and their populations at 300 K are listed in Table 3. A proportion of the more stable *trans-trans*-conformer increases with increase in the mass of chalcogenide. For divinyl sulfide and divinyl telluride, the *trans-trans*-conformer is preferential in energy. Recently the IR spectra of divinyl telluride in the gas, liquid, and solid states and the spectra at low temperatures in various matrices (argon, nitrogen, xenon, and krypton) have been measured and the bands sensitive to conformations have been found.¹⁶⁰

It is interesting to compare the geometrical parameters of conformers for divinyl chalcogenides.¹⁶⁰ With an increase in the chalcogenide mass, the C-X bond length increases and the C-X-C angle decreases, the angle is somewhat less in the *trans-trans*-conformer than that in the *cis-trans*-conformer.

Potential energy maps were obtained for divinyl selenide and divinyl telluride: they were constructed as functions of rotational angles about $C_{sp^2}-X$ (X = Se, Te) bonds.⁵ The steric hindrance energies calculated for different conformations by varying the angles φ_1 from 0° to 360° and φ_2 from 0° to φ_1 with a step of 15° are presented in Table 2.

For all the chalcogenide conformations, steric hindrance energies vary in the series $O > S > Se > Te$. Of the two structural factors, bond lengths and bond angles, exerting opposite influence on steric hindrance, the key role belongs to the increase in the C-X bond lengths. For all vinyl chalcogenides, the planar *cis-cis*-conformation (D) is the most sterically hindered (Table 2), the *trans-trans*-form (A) is the least hindered. The steric hindrance energy of the non-planar *cis-cis*-conformation (F) for divinyl sulfide, divinyl selenide and divinyl telluride is close to, or is lower than that of the *trans-trans*-conformer (A), and only for divinyl ether is it twice higher (Table 3). This conformation results from the planar *cis-cis*-form by rotating the vinyl groups to the opposite directions by an angle of 45° .

Thus, the potential energy maps for divinyl chalcogenides give a comprehensive idea of the steric structure. The potential of internal rotation about the $C_{sp^2}-X$ bonds (X = O and S) in alkyl vinyl chalcogenides can be transferred (with some corrections) to the rotation about analogous bonds in the corresponding divinyl chalcogenides. The latter exist as three non-planar stable conformers: two quasi-degenerate *trans-trans*- and one *cis-trans*-conformer. A complete picture of rotational isomerism in divinyl chalcogenides involves not only the ground, but also excited vibrational states, which are characterised by large-amplitude intramolecular motion encompassing more than one local minima in the potential energy map.

IV. Electronic structure of vinyl and allenyl chalcogenides

1. Photoionisation of vinyl ethers

Interesting and important regularities have been established on the basis of photoelectron investigations of organic compounds.¹⁶⁶ Ionisation potentials of organic molecules depend significantly on the structure of substituents at the atom ionised;^{167, 168} within one class compounds, these are dictated exclusively by the inductive effect.¹⁶⁸⁻¹⁷¹ However, ionisation processes should also be very sensitive to other intramolecular effects of the structure. In particular, considerable contributions to the ionisation energy might be expected from the interaction of a cation radical with neighbouring double bonds and heteroatoms. These contributions can be identified and measured as deviations from a regression line reflecting the relationship between the ionisation potential and inductive effect (for example, by sums of the substituent σ^* constants). Adiabatic ionisation potentials have been obtained for a series of vinyl ethers by the photoionisation method.^{1, 172} By analogy with alcohols and other classes of compounds¹⁶⁸⁻¹⁷¹ in which a linear dependence of the ionisation potential on the σ^* constants is quite unambiguous, a variation of ionisation potentials in the series of vinyl ethers can be supposed to originate primarily from the inductive effect. The correlation between the adiabatic ionisation potentials (I) and substituent inductive constants ($\Sigma\sigma^*$) is presented in Fig. 21; the correlation parameters are somewhat different for saturated (dialkyl and cyclic) (line 1) and divinyl (line 2) ethers.

Figure 21. The correlation of ionisation potentials (I) of ethers with inductive constants of substituents ($\Sigma\sigma^*$).¹⁷² (1) aliphatic and cyclic ethers, (2) vinyl ethers.

The independent correlation for alkyl vinyl ethers can be explained¹⁷² by p, π -conjugation in the radical cation. An energy gap separating lines 1 and 2 indicates an inequivalence in the coupling of the oxygen AOs with the orbitals of the sp^2 - or sp^3 -hybridised carbon atoms. Correlation processing points against multiple correlations with three arguments ($\Sigma\sigma^*$, Δn , and E_a) for diorganyl and vinyl ethers.^{1, 172} One of the reasons for the uncertainty of the regressions is a strong dependence between the arguments.

Analysis of the correlation $I = f(\Sigma\sigma^*)$ has shown^{1, 172} that other effects do not manifest themselves as distinctly as the inductive one. The deviation of the points exceeding significantly the accuracy of the ionisation potential measurement indicates a contribution of structural effects.^{1, 172} It cannot be ruled out that steric interactions might contribute. A linear dependence of the second ionisation potential (I_2) for alkyl vinyl ethers on the ionisation potentials of a standard series of alkyl iodides I_{R1} ¹⁷³ and the existence of two different curves for compounds with linear (Me, Et, Buⁿ) and branched (Prⁱ, Bu^s, Bu^t) substituents has been found.⁶⁸ It was explained by a change in the conformational

state of the vinyl ether with the introduction of a bulky substituent.

2. PE spectra of alkyl allenyl ethers

PE spectra of alkyl allenyl ethers^{106, 112, 174–176} have been studied and interpreted on the basis of the orbital energy values calculated by semiempirical and *ab initio* methods. The electronic structure of alkyl allenyl ethers was compared with that of alkyl vinyl ethers.¹⁷⁵ The latter are formal analogues of alkyl allenyl ethers except for the fact that the allenyl fragment comprises two orthogonal π -systems. The electronic structure of alkyl allenyl ethers is fully dictated by the interaction of the lone electron pair on the oxygen atom with the π -electrons of the double bond. The same interaction affects the steric configuration and, to some extent, the relative stability of the conformers.

The sequence of the π -type occupied molecular orbitals in alkyl allenyl ethers is considered¹⁷⁵ to be a result of the interaction between the fragmentary π - and n -MOs. According to the orbital correlation diagram (Fig. 22), four bands are expected to exist and observed in the low-energy range of the PE spectrum^{87, 93, 174, 175} (Table 4). In the spectra of allenyl methyl and allenyl ethyl ethers, bands 1 and 2 have a fine structure, which corresponds to the stretching $C=C=C$ modes of the radical cation and is therefore considered to be the vibrational structure.^{112, 174} At the same time, the structure of band 1 in the PE spectrum of allenyl methyl ether is supposed¹⁰⁶ to be associated with the presence of *cis*- and *trans*-conformers. However, according to the gas electronography data,¹⁰² the *cis*-conformation dominates at room temperature (other conformers were not detected).

The low-energy band (8.77 eV) is assigned to the MO which involves the p, π -interaction of the oxygen atom with the π -system of the $C_\alpha = C_\beta$ bond. The next band (10.33 eV) corresponds to the π -MO of the $C_\beta = C_\gamma$ allenyl fragment. Consecutive replacement of the Me group by Et, Prⁿ, Prⁱ, Buⁿ, and Bu^t groups leads to a low-energy shift of the first and second band maxima by 0.1–0.3 eV (Table 4).

The third band in the spectra of alkyl allenyl ethers (11.25–11.97 eV) belongs to the π_1 -MO, which is a bonding combination of the oxygen lone electron pair and the π -MO of the $C_\alpha = C_\beta$ group.

The fourth band (12.28 eV) in the PE spectrum of allenyl methyl ether results from the ionisation of the π_1 and $n_O(\sigma)$ levels. The MNDO calculation shows¹⁷⁵ that a level deeper than that of the π_1 -MO corresponds to the lone electron pair on the oxygen atom. For methyl vinyl ether, the band at 12.2 eV is assigned⁶⁹ to the $n_O(\sigma)$ level. For alkyl allenyl ether, this level is associated with the band in the range of 11.5–12.3 eV.¹⁷⁵ For allenyl methyl ether, this band (12.28 eV) originates from the ionisation of a nearly pure lone electron pair of the oxygen atom, whereas for compounds with R = Et, Prⁿ, Prⁱ, Buⁿ, and Bu^t, a strong coupling between the $n_O(\sigma)$ -MO and the σ_{CC} -MO is observed. As the

Bu ^t	8.6	9.9	11.25 ± 0.1	11.5
$CH_2CH=CH_2$	8.8	10.0	11.9	12.4

^a The band assignment is given in parentheses; ^b a system of overlapping bands with an overall maximum at 12.2 eV; ^c the same with a maximum at 12.3 eV.

substituent length and branching increase, the coupling efficiency between the $n_O(\sigma)$ - and σ_{CC} -MOs increases.¹⁷⁵

Since the ionisation potential I_3 for alkyl allenyl ethers is analogous to I_2 for alkyl vinyl ethers,⁶⁹ the relationship between I_3 and the ionisation potentials for a standard series of alkyl iodides (I_{RI}) (I_{RI} values were found by PE spectroscopy¹⁷³) is also true:¹⁷⁵ $I_3 = 1.63$ eV, $I_{RI} = 3.60$ eV. $r = 0.994$, $s_0 = 0.03$ (the standard deviation s_0 does not exceed the experimental error of ~ 0.05 eV). For compounds with R = Prⁱ, and Bu^t, the points deviate from the regression line by a value approximately equal to s_0 , therefore, there is no reason to set apart these compounds from the series of alkyl allenyl ethers (Table 4). The relationship $I_3 = f(I_{RI})$ is entirely determined by the inductive effect of the substituent. In this case, no conformational effects are revealed. Since the ionisation potentials of alkyl iodides are in turn linearly related to the substituent inductive constants (σ^*),^{169–171} which have a more general character, the latter can be used for the correlation of orbital energies.

An MNDO calculation of the angular dependence of orbital energies ($-\epsilon_i$) for allenyl methyl ether has been carried out (Fig. 23).¹⁷⁵ The $\epsilon(\pi_1)$ value is rather sensitive to the departure from planarity and is practically the same for *s-cis*- and *s-trans*-conformations. Therefore, the existence of a common linear dependence $I_3 = f(I_{RI})$ indicates that all the alkyl allenyl ethers studied have a planar conformation. If for allenyl methyl ether it is definitely *s-cis*-, then the *s-trans*-conformation seems to be favoured for $CH_2=C=CHO-Bu^t$.

The comparison of total energies of possible conformers (*cis*-, *trans*-, and *gauche*-) for alkyl allenyl ethers obtained by the

Figure 23. The angular dependence of orbital energies ($-\epsilon_i$) for $CH_2=C=CHOMe$ (the MNDO method):¹⁷⁵ (1) $\epsilon_1(\pi_3)$, (2) $\epsilon_2(\pi_2)$, (3) $\epsilon_3(\pi_1)$, (4) $\epsilon_4(\sigma)$.

MNDO method¹⁷⁵ shows that the *s-cis*-form of the $C=C-C-O-R$ fragment is the most stable in compounds with normal substituents. For compounds with branched substituents, the most stable conformation is the *s-trans*-form.

3. PE spectra of allenyl vinyl ethers

There are no published data on the electronic structure of allenyl vinyl ether $CH_2=C=CHOCH=CH_2$. In this connection, an empirical band assignment in its PE spectrum¹⁷⁷ was based on comparison of the spectrum with those of divinyl ether and allenyl methyl ether.¹⁷⁵ The spectrum of allenyl vinyl ether contains five well-resolved bands in the range of 8.0–16.0 eV (Table 5). The first two bands have fine structure. As in alkyl allenyl ethers,^{112, 174} the fine structure may be ascribed to the vibrational structure of corresponding states of the cation radical. The next band of allenyl vinyl ether has a distinct maximum at ~10.55 eV. The fourth broad band seems to result from the overlapping of several components with maxima at about 12.55 eV. The introduction of a Pr^n substituent into the α -position of the allene group leads to a shift of the band maxima by 0.3–0.4 eV.¹⁷⁷

Table 5. Vertical ionisation potentials for allenyl vinyl ethers.¹⁷⁷

^a Band assignment is given in parentheses.

The orbital correlational diagram based on the interaction of the fragmentary π -orbitals of ethene and the hypothetical allenyl alcohol molecule was used for a quantitative analysis of the PE spectrum of allenyl vinyl ether¹⁷⁷ (Fig. 24). The sequence of one-electron levels for allenyl vinyl ether was determined from the MNDO data.¹⁷⁷ (Fig. 24). The first band (π_4 -MO) corresponds to the HOMO composed of an antibonding combination of the lone electron pair of the oxygen atom, π -orbitals of the vinyl group (π_1 -MO) and the $C_\alpha=C_\beta$ bond of the allene fragment (π -MO). The second band (10.22 eV) is associated with ionisation from the π_3 -MO, which has a node at the oxygen atom and is antibonding. MOs of the vinyl (π_1 -MO) and allenyl $C_\alpha=C_\beta$ (π -MO) groups

Figure 24. The orbital correlational diagram for hypothetical allenyl alcohol, ethylene, and $CH_2=C=CHOCH-CH_2$.¹⁷⁷

contribute decisively to this orbital. A molecular orbital orthogonal to the rest of the π -system ($\bar{\pi}$ -MO) gives rise to the third band (10.55 eV). The fourth band with a maximum at 12.54 eV results from ionisation from two MOs, a π -MO and an almost pure lone electron pair of the oxygen atom, $n_O(\sigma)$. The π_1 -MO is a bonding combination of the lone electron pair of the oxygen and the fragmentary MOs of the vinyl and allenyl $C_\alpha=C_\beta$ groups. Thus, the structure and sequence of occupied π_4 -, π_3 -, and π_1 -MOs are similar to those for divinyl ether¹⁷⁷ (Table 5).

An MNDO calculation of orbital energies for planar conformations¹⁷⁷ has shown that the bands in the PE spectrum of allenyl vinyl ether can be shifted by ~0.1 eV on transition from the *trans-trans*- to the *cis-cis*-conformation. The difference in the orbital energy values for the *cis-cis*- and *trans-trans*-conformations of allenyl vinyl ether is within the experimental errors of the PE spectroscopy method (0.1 eV for potential difference).

4. PE spectra of vinyl sulfides and selenides

The sequence of three higher occupied MOs of dialkyl sulfides and selenides does not depend on the nature of the chalcogenide:¹⁷⁸ $n_X(b_1) < \sigma_1(a_1) < \sigma_2(b_2)$. The effect of the heteroatom is reduced primarily to an increase in the energy of MOs and the contribution of atomic orbitals of the element (X) to these MOs with an increase in the element atomic number. Structural changes (chain length, branching) of the substituent in each series lead also to the expected effects.

The empirical approach to the low-energy range of PE spectra of vinyl derivatives allowed one to conclude that the relative arrangement of MOs in vinyl sulfides and selenides is practically independent of the nature of the heteroatom and the structure of the hydrocarbon substituent¹⁷⁹ (Table 6, Fig. 25): $\pi_2 < \pi_1 < \sigma_1 < \sigma_2$ ($CH_2=CH-X-Alk$), $\pi_3 < \sigma_1 < \pi_1 < \sigma_2$ ($CH_2=CH-X-CH=CH_2$). On going from dialkyl sulfides

and selenides to unsaturated derivatives with the same number of atoms, the stabilisation of the σ_1 - and σ_2 -MOs becomes non-equivalent, which indicates a different efficiency of coupling of the element (S, Se) AOs with the orbitals of the sp^2 - and sp^3 -hybridized carbon atoms. These differences lead to a splitting of the dependence $I(\sigma_2) = f[I(\sigma_1)]$ into two parts. One dependence includes saturated and the other includes unsaturated derivatives (Fig. 25). Analysis of the energies of the MOs of saturated and unsaturated diorganyl sulfides and selenides allowed one to state two general

concepts, which facilitate the assignment of the ' σ '-bands in the PE spectra of alkyl vinyl and divinyl derivatives: i) the energy gap ΔI_{σ} separating the σ_1 - and σ_2 -MOs does not exceed a limiting value corresponding to the simplest representatives of the series and decreases with an increase in the substituent size (Table 6); ii) there is a linear correlation between the σ_1 - and σ_2 -MO energies, its parameters being somewhat different for saturated and unsaturated compounds of sulfur and selenium (Fig. 25).¹⁷⁹

Figure 26. The orbital correlational diagrams for sulfur saturated and unsaturated derivatives.¹⁷⁹

Figure 27. The orbital correlational diagrams for selenium saturated and unsaturated derivatives.¹⁷⁹

The HOMOs also have common features. Comparison of dialkyl, alkyl vinyl, and divinyl sulfides and selenides shows that the first vertical ionisation potential I_1 (Table 6) practically does not change due to a rather weak coupling of p_x -AOs of a heteroatom with fragmentary π -MOs. The localisation of the orbital electron density mostly on the heteroatom and the terminal C_β atom is typical of HOMOs (I_1) of vinyl sulfides and selenides. This order of electron distribution gives reason to suppose that the transition from divinyl chalcogenides to saturated heterocyclic derivatives of sulfur and selenium will be accompanied by a strong stabilisation of the π_3 -MO in the selenium derivatives. This is confirmed by the position of the first band in the PE spectra of divinyl sulfide and thiophene. The stabilisation of the π_3 -MO leads to the inversion of the sequence of the two higher π -MOs. The PE spectra of divinyl selenide and selenophene consisting of a system of overlapping bands, are less indicative. Nevertheless, the mutual position of the first two bands makes it possible to state that the passage from divinyl selenide to selenophene results in, at least, quasi-degeneracy of the boundary π -MOs. The orbital correlational diagrams¹⁷⁹ for saturated and unsaturated sulfur and selenium derivatives indicate that the passage from saturated to unsaturated compounds of sulfur and selenium and to the corresponding cyclic structures leads to the stabilization of σ_1 - and σ_2 -MOs (Figs 26, 27).

For unsaturated sulfur compounds, comparison of results of the empirical approach to the estimation of their orbital structure with the results of the MNDO calculation (Table 7) shows that qualitative and quantitative agreement was obtained for each compound.¹⁷⁹ Calculations have been made for equilibrium planar *s-cis*-, *s-trans*-, *s-trans-s-trans*- (C_{2v}) forms and a non-planar *cis-trans*-form (C_1) of rotamers.¹⁷⁹ π -MO energy differ-

^a The assignment based on the *ab initio* calculation; ^b *s-cis*-form; ^c *s-trans*-form; ^d *cis-trans*- for $(\text{CH}_2=\text{CH})_2\text{S}$ and $\text{CH}_2=\text{C}=\text{CHSCH}=\text{CH}_2$; ^e *s-trans-s-trans*- (C_{2v}) for $(\text{CH}_2=\text{CH})_2\text{S}$ and $\text{CH}_2=\text{C}=\text{CHSCH}=\text{CH}_2$.

ences for these rotamers are extremely small, that is why the problem of rotational isomerism cannot be solved at the level of the first band in the PE spectrum. In the PE spectrum observed, the shape of the first band rules out the existence of a remarkable concentration of a less favourable rotamer differing from the major rotamer in torsional angles.

Adiabatic potentials for a series of diorganyl sulfides have been measured by the photoionisation method,^{1,180} and conjugation energies in radical cations have been estimated by correlation analysis. Two-parameter approximation¹⁸⁰ yielded the plots (Fig. 28) showing that saturated and unsaturated representatives of the series correlate with the inductive Taft constants to form two independent regressions. The contributions of hyperconjugative and steric effects into the ionisation potential value were found with the requisite statistical accuracy: they make up ~20% of the contribution of the inductive effect.¹⁸⁰ At the same time, conjugation effects contribute significantly to the ionisation potentials, too (Fig. 28). The existence of independent linear dependences for saturated and unsaturated representatives of the series (Fig. 28, lines 1 and 2, respectively) is due to the conjugation between the radical-cation centre and the adjacent double bond. The energy of this conjugation can be estimated^{1,180} by deviations of the points for α,β -unsaturated sulfides from the basic correlational curve. For vinyl sulfides, it is equal to 1.0–1.3 eV.

Figure 28. The dependence of ionisation potentials (I) of diorganyl selenides on inductive constants of substituents ($\Sigma\sigma^*$).¹⁸⁰ (1) Unsaturated and cyclic organylthiols and sulfides, (2) vinyl sulfides.

5. Allenyl methyl sulfide and allenyl vinyl sulfide

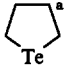

Among unsaturated sulfides, allenyl methyl sulfide and allenyl vinyl sulfide occupy a somewhat unusual position (Table 7).¹⁷⁹ It might be expected that their orbitals, except for an additional π -MO localised at the $C_\beta=C_\gamma$ fragment (9.7 eV for allenyl methyl sulfide and 9.9 eV for allenyl vinyl sulfide) would follow the regularities found for vinyl sulfides. The similarity was, however, found only for allenyl vinyl sulfide (Fig. 25, Table 7). According to the data obtained by the MNDO method, which has shown a good performance in the case of other α,β -unsaturated sulfides, the energies of the σ_1 - and σ_2 -MOs of allenyl methyl sulfide fit the correlational curve of saturated sulfides (Fig. 25). The σ_2 -MO energy for allenyl methyl sulfide is only 0.45 eV higher than the corresponding MO for methanethiol.¹⁷⁸ Unlike other analogous compounds, the σ_2 -MO of allenyl methyl sulfide seems to be localised to a significantly greater extent within the $\text{S}-\text{C}_{sp^3}$ fragment. Other MOs of allenyl sulfides, except for the π -MO localised within the $C_\beta=C_\gamma$ fragment, are qualitatively the same as those for vinyl sulfides. The band assignment in the PE spectra of allenyl sulfides is given in Table 7.

6. PE spectra of vinyl tellurides

PE spectra of dimethyl telluride and some other dialkyl chalcogenides have been described.^{181,182} An analysis of their orbital structure has been performed for model dimethyl derivatives of C_{2v} symmetry.¹⁸² Three lowest-energy bands in the PE spectra of these compounds are associated with electron removal from the antibonding MO of the lone electron pair of the chalcogen atom and from two $\sigma_{1,2}$ bonds.

In the PE spectra of dialkyl tellurides in the range of 7.5–11.4 eV, as well as in the case of analogous sulfides and selenides, there are three bands (Table 8, Fig. 29a). The lowest-energy and the narrowest band is unambiguously assigned to the MO with the major contribution of the tellurium p_z -AO. Two broader bands result from the ionisation of the σ -bonds (Fig. 29a). Successive elongation of the hydrocarbon chain leads to a low-energy shift of all the bands. For saturated tellurides as well as for other dialkyl chalcogenides, there is a linear dependence between the higher σ -MO positions (Fig. 30).¹⁸³ An energy gap value ΔI_σ separating σ_1 - and σ_2 -MOs decreases systematically with an increase in alkyl substituent length and branching (Table 8). In other words, the behaviour of σ -MOs in dialkyl tellurides is completely similar to that of the corresponding sulfides and selenides.

^a The data of Ref. 178.

Analysis of PE spectra of vinyl tellurides has been carried out¹⁸³ using the empirical approach.¹⁷⁹ The PE spectra of vinyl tellurides contain four well-resolved bands (Table 8, Fig. 29b, c). The low-energy band remains narrow. Moreover, for vinyl tellurides its position is practically the same as for dimethyl telluride. The replacement of an alkyl group by the vinyl group in the diorganyl telluride does not lead to a significant interaction of the fragmentary π -orbital with the p_z -AO of the tellurium atom, i.e. the first band relates to the MO localised primarily on the heteroatom. The second and the fourth bands belong to σ -MOs. Unlike saturated and unsaturated sulfur and selenium compounds, in tellurium compounds, the σ -MO energies correlate in the same manner (Fig. 30). The correlation extends also to the σ -MOs of divinyl telluride and tellurophene, thus indicating an equivalent coupling of the tellurium AOs with the orbitals of the sp^2 - and sp^3 -hybridized carbon atoms.¹⁸³ The third MO of vinyl tellurides is responsible for a slightly bonding combination of the π -MO of the vinyl fragment and the tellurium p_z -AO with a lesser contribution of the latter.

More detailed information on the structure of π -MOs in divinyl telluride can be obtained by comparing them with those of tellurophene. The π -MO of tellurophene can easily be com-

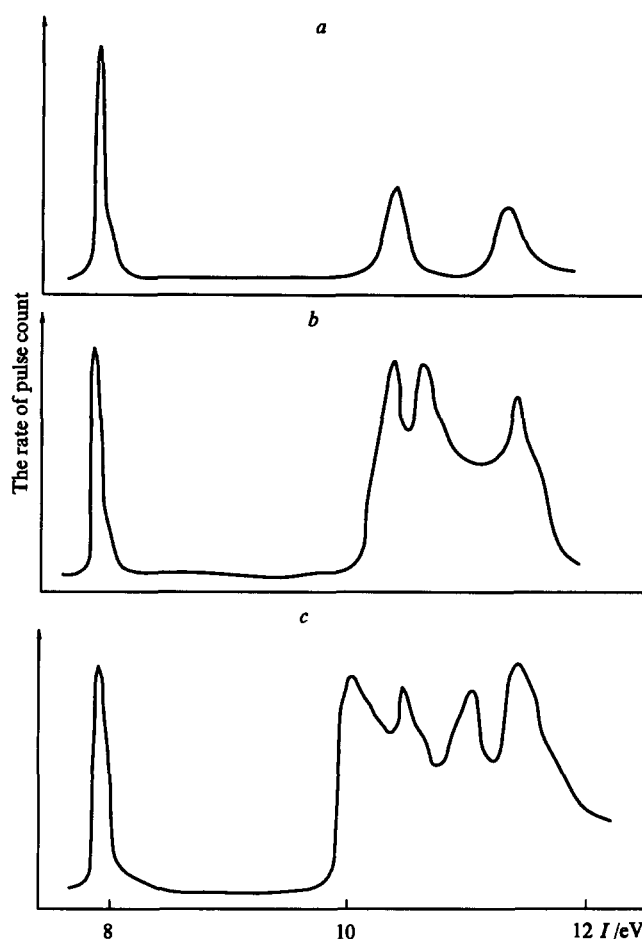

Figure 29. The PE spectra of dimethyl telluride (a),¹⁸² vinyl methyl telluride (b), and divinyl telluride (c).¹⁸³

posed from symmetry considerations.¹⁸³ The PE spectroscopic data (Table 8, Fig. 31) indicate that the passage from divinyl telluride to tellurophene leads to a remarkable increase in the first ionisation potential (0.5 eV). This is not due to the formation of the ordinary bond between the terminal carbon atoms of divinyl telluride, because the analogous structural variation for saturated compounds (tetrahydrotellurophene¹⁸⁴) affects only slightly this

Figure 30. The correlation between the energies of σ -MOs for unsaturated (1) and saturated (2) organyl tellurides.¹⁸³

Figure 31. The orbital correlational diagrams for tellurium saturated and unsaturated derivatives.¹⁸³

value. Apparently, stabilising interactions arise upon heterocyclisation. These interactions can be adequately rationalised only assuming that the HOMO structure for tellurophene is of the same type as that for the preferential rotamer of divinyl telluride. The correlation of the other π -MOs (Fig. 31) leads to the conclusion that the second occupied π -MO of divinyl telluride is an antibonding combination of orbitals of the vinyl fragment, and the lowest MO is, naturally, completely bonding.

Thus, the analysis of the PE spectral features of dialkyl, alkyl vinyl, and divinyl tellurides altogether gave the rationale for the nature of their MOs and allowed the empirical assignment to be made: the low-energy band for alkyl vinyl tellurides results from the ionisation of the MO with the dominating contribution of the tellurium p_z -AO, the second and the fourth bands correspond to the σ -MOs, the third band belongs to the π -MO. The orbital structures of divinyl telluride and tellurophene are of the same type.

7. UV absorption spectra of alkyl vinyl sulfides

UV absorption spectra are the subject of a large number of studies.^{69, 132, 185–191} Nevertheless up to now, there is no unequivocal understanding of the nature of electronic transitions observed in liquid and in the gas phase. A discussion^{69, 132, 185–191} about the band assignment in the near UV range for methyl vinyl sulfide is remarkable. The most long-wave transition was assigned to the first transition of the Rydberg series $\pi \rightarrow n_s$, and the next to the $\pi \rightarrow \pi^*$ -type.⁶⁹ However, according to other data¹⁹¹ the first long-wave band originates from the $n \rightarrow \sigma$ or $\sigma \rightarrow \sigma^*$ excitation, and the second band is associated with the $\pi \rightarrow \pi^*$ transition. Both

transitions are considered^{133, 190} to belong formally to the same ($\pi \rightarrow \pi^*$) type, but to correspond to two rotamers. Experimental data accumulated to date allowed one to perform systematic analysis of UV spectra of alkyl vinyl sulfides.¹⁹² An empirical analysis of the full spectrum of gaseous methyl vinyl sulfide has been carried out.⁶⁹ In addition to the $\pi \rightarrow \pi^*$ transition, the spectrum of methyl vinyl sulfide is represented by three Rydberg series: $\pi \rightarrow n_s$, $\pi \rightarrow np$, and $\pi \rightarrow nd$. Rydberg transitions fall primarily in the vacuum ultraviolet range and are inaccessible for comparative investigations in solutions. In the near UV range there are $\pi \rightarrow \pi^*$, $\pi \rightarrow 4p$, and $\pi \rightarrow n_s$ transitions, the latter is believed⁶⁹ to be of the lowest energy in the series. Comparison (cf. with¹⁹³) of the UV spectrum of methyl vinyl sulfide in the gas phase with those of solutions^{189, 191} in hexane, dioxane, and ethanol, in which no narrow peaks of sufficient intensity were found at 204 nm, indicates that the most short-wave transition is largely of the Rydberg character. The quantum defect δ for this transition is relatively low, $\delta \sim \pm 0.59$ where

$$\delta = n - \left(\frac{R}{T}\right)^{1/2},$$

here R is the Rydberg constant, $T = I_1 - n$, n is a quantum number. Therefore, indeed, this transition can be assigned to the Rydberg transition of the $\pi \rightarrow 4p$ type.¹⁹² An interesting feature of this transition is a dependence of the relative intensity of the corresponding band on the substituent structure, which decreases as the length of a hydrocarbon substituent and branching increase (Fig. 32); for compounds with $R = \text{tert-butyl}$ and tert-pentyl , Rydberg transitions cannot be reliably assigned.¹⁹⁴

The most long-wave band of methyl vinyl sulfide broadens on passage from the gaseous state to solution. It also broadens upon substitution of the methyl group for another alkyl substituent. Bulky substituents increase its absolute intensity (in solution). Sometimes even a slightly pronounced fine structure appears (Fig. 32, Table 9). For $R = \text{tert-butyl}$ and tert-pentyl the intensity of this band increases, and a separate peak is observed (Fig. 32). An isotope effect was quite unexpected. In the case of methyl vinyl sulfide and its deuterio-isotopomer $\text{CD}_2 = \text{CDSMe}$, the absorbance ratio of the maxima of the long-wave band and the neighbouring ' π ' band (D_{244}/D_{225}) in the gas phase is 0.225, while in the spectrum of $\text{CH}_2 = \text{CHSCD}_3$ this ratio is 1.35 times larger. The band half-width also increases (from 1540 cm^{-1} to 2130 cm^{-1}). Data on the deuteration effect also show that the methyl group orbitals (σ -symmetry) take part in the first excited state of methyl vinyl sulfide. The long-wave band of methyl vinyl sulfide might therefore be supposed to belong to the $\pi \rightarrow \sigma^*$ transition.

CNDO/C calculations indicate that yet another $\pi \rightarrow \sigma^*$ -transition should exist in the UV range separated from the first one by an interval of $\sim 1300 \text{ cm}^{-1}$ (Scheme 2; s -AOs are marked with a dotted line). The band at $\sim 196 \text{ nm}$ in the spectrum of methyl vinyl sulfide in solution corresponds to the second $\pi \rightarrow \sigma^*$ -transition (Fig. 32, Table 10). In the spectrum of gaseous methyl vinyl sulfide, the band corresponding to this transition coincides with the components of a vibrational progression of the Rydberg $\pi \rightarrow 4p$ transition. A complex contour of the short-wave absorption band in gaseous methyl vinyl sulfide does not allow vibrational modes of this transition to be reliably identified.¹⁹²

Scheme 2

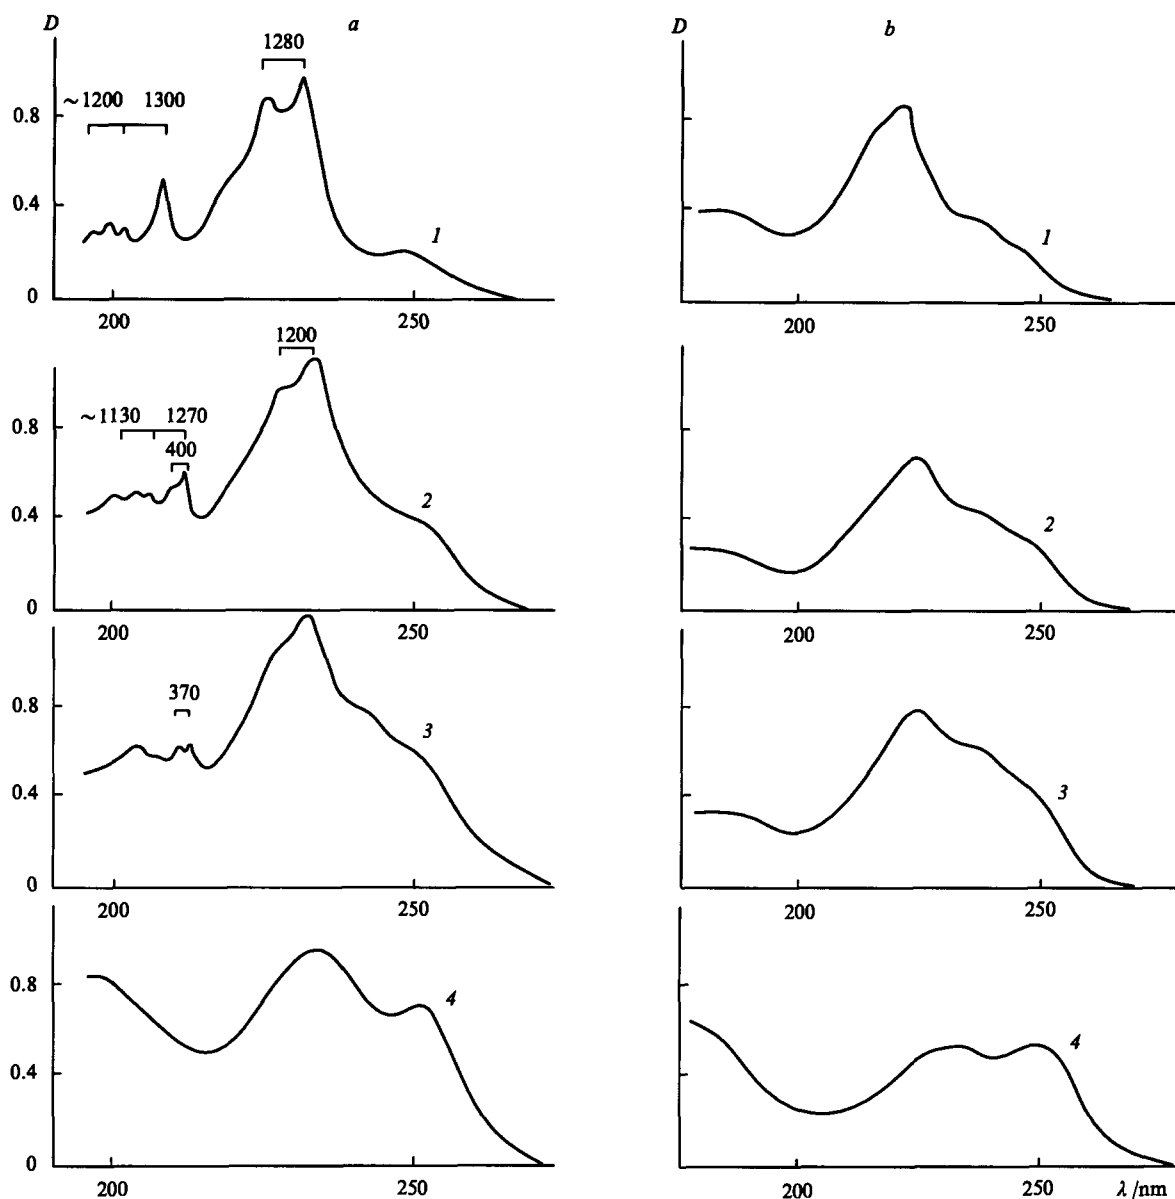

Figure 32. The UV absorption spectra of sulfides $\text{CH}_2=\text{CHSR}$, where $\text{R} = \text{Me}$ (1), Et (2), Bu^i (3), Pent^i (4), in the gaseous state (a) and in a hexane solution (b).¹⁹²

The $\pi \rightarrow \pi^*$ transition band with peaks in the range of 225–236 nm in the spectrum of gaseous methyl vinyl sulfide has a fine structure (the distance between the components is $\sim 1000\text{--}1300\text{ cm}^{-1}$), which disappears in the solution spectra.¹⁹²

Thus, the following energy sequence of transitions is observed in the UV spectra of alkyl vinyl sulfides:¹⁹² $\pi \rightarrow \sigma^* < \pi \rightarrow \pi^* < \pi \rightarrow np < \pi \rightarrow \sigma^*$.

8. UV absorption spectra of alkyl vinyl selenides

UV spectra of vinyl selenides have been studied.^{191,192} The type and the sequence of electronic transitions have been determined (Fig. 33). Comparison of UV spectra of methyl and ethyl vinyl selenides in the gaseous and condensed state identifies the Rydberg transition at $\lambda = 202\text{ nm}$ and 204 nm , respectively. A relatively low magnitude of the quantum defect (0.48) makes it possible to assign these bands to the $\pi \rightarrow 5p$ type (Table 9). $\pi \rightarrow \sigma^*$ transitions in alkyl vinyl selenide are red-shifted as compared to those in the corresponding sulfides, on the average, by 4600 cm^{-1} and occur in the range of 265–270 nm and at 220 nm (Table 10). In the spectrum of methyl vinyl selenide (Fig. 33), the band corresponding to the $\pi \rightarrow \pi^*$ transition has fine structure (1000,

600, $\sim 600\text{ cm}^{-1}$), which differs from that for the analogous sulfur compounds (Fig. 32). Moreover, substitution of the methyl group for the ethyl group leads to a change in the Franck–Condon contour of the absorption band (Fig. 33). This gives grounds to suppose that the ‘ π ’ band of methyl vinyl selenide coincides with the band of the Rydberg transition ($\lambda = 236\text{ nm}$), which distorts the profile of the absorption band in the gas phase. In solution, the Rydberg band disappears or decreases in intensity (Fig. 33, Table 10). The quantum defect of the Rydberg transition (0.88) corresponding to the band at 236 nm allowing one to assign it to the $\pi \rightarrow 5s$ type.

This assignment has further support. The first ionisation potentials for dimethyl and methyl vinyl selenides (to which Rydberg series converge) are close: 8.33 eV and 8.29 eV, respectively.¹⁷⁹ Therefore, their Rydberg $n_{\text{Se}} \rightarrow 5s$ and $\pi \rightarrow 5s$ transitions will also be close. In the spectrum of gaseous Me_2Se there is a narrow peak at $\lambda = 236\text{ nm}$, which is not registered in solution.¹⁹¹ Its quantum defect ($\delta = 0.94$) is in full accord with the Rydberg transition from the series $n_{\text{Se}} \rightarrow n_{\text{S}}$.¹⁹⁶ The following sequence of electronic transitions was found for alkyl vinyl selenides:¹⁹² $\pi \rightarrow \sigma^* < \pi \rightarrow \pi^* \sim \pi \rightarrow ns < \pi \rightarrow \sigma^* < \pi \rightarrow np$ (Tables 9, 10).

9. UV absorption spectra of alkyl vinyl tellurides

Alkyl vinyl tellurides absorb in the range of 200–330 nm (Table 9, 10, Fig. 34).¹⁹² The $\pi \rightarrow \sigma^*$ transitions in the UV spectrum of methyl vinyl telluride are strongly (by $\sim 7100 \text{ cm}^{-1}$) red-shifted even in comparison with those in methyl vinyl selenide, and are located at 259 and 329 nm in the gas phase. For methyl vinyl sulfide band intensities of $\pi \rightarrow \sigma^*$ transitions are of the same order ($\sim 10^3$), whereas dramatic redistribution takes place on going to vinyl telluride, i.e. with an increase in the mass of the heteroatom (Fig. 33). In the spectrum of a heptane solution of methyl vinyl telluride, the extinction ratio of long-wave and short-wave bands of $\pi \rightarrow \sigma^*$ transitions is $\sim 6 \times 10^{-2}$. This is probably due to localisation of the MOs of methyl vinyl telluride within the CTeC fragment having high symmetry (C_2 or C_{2v}). For the ground state of methyl vinyl telluride such a supposition is confirmed by PE spectroscopic data. In contrast to sulfides, the higher occupied π -MO in unsaturated tellurides contains a dominating contribution from the tellurium p_z -AO (I_1 values are the same for Me_2Te and $\text{CH}_2 = \text{CHTeMe}$).¹⁸³ UV spectra show that it is true of the excited state with an electron in the σ_1^* -MO and the vacant π -MO.

As was already noted, the long-wave σ band profile in the spectra of vinyl sulfides is dictated by the phase state and the structure of the alkyl substituents. In the spectra of alkyl vinyl tellurides, the contours of both σ -bands depend on none of these. Irreducible representations b_1 , a_1 , and b_2 correspond to the HOMO of the π -type and to two low-lying vacant σ^* -orbitals of the ground state of methyl vinyl telluride. Hence, it follows that the transitions will be one-configurational, and one of them [$^1A_1 \rightarrow ^1B_1$ ($^1b_1^1a_1^*$) or $^1A_1 \rightarrow ^1A_2$ ($^1b_1^1b_2^*$)] is symmetry-forbidden (in the absence of electronic-vibrational interactions).

A transition of the $\pi \rightarrow \pi^*$ -type is responsible for the band at $\lambda = 243 \text{ nm}$ (gas) with a vibrational splitting of $\sim 800 \text{ cm}^{-1}$ in the UV spectrum of methyl vinyl telluride. The splitting is significantly higher than the frequency of the CTeC stretching mode in the ground state,¹⁴³ thus indicating that the bond becomes stronger upon excitation. The passage from gas to solution causes a red shift (1000 cm^{-1}) in the respective spectra.

It is known that in the UV spectrum of Me_2Te , the first Rydberg transitions of the series $n\text{Te} \rightarrow 6s$ and $n\text{Te} \rightarrow 6p$ are observed at 250 nm and 216 nm. Comparison of the spectra of methyl vinyl telluride in the gas phase and in solution and the fact that the first

Figure 34. The UV absorption spectra of diorganyltellurides Et_2Te (1), $\text{CH}_2=\text{CHTeEt}$ (2), and $(\text{CH}_2=\text{CH})_2\text{Te}$ (3) in a heptane solution. The spectrum of $(\text{CH}_2=\text{CH})_2\text{Te}$ in the gaseous phase is shown in a dotted line.¹⁹⁷

ionisation potentials of this compound¹⁸³ and Me_2Te are practically the same (7.90 and 7.89 eV) made it possible¹⁹² to assign the bands at 250 nm and 214 nm to the $\pi\rightarrow 6s$ and $\pi\rightarrow 6p$ Rydberg transitions, respectively.

Hence, the following sequence of electronic transitions is observed in the UV spectra of alkyl vinyl tellurides:¹⁹² $\pi\rightarrow\sigma^* < \pi\rightarrow\sigma^* < \pi\rightarrow\pi^* < \pi\rightarrow\pi^* < \pi\rightarrow\pi^*$.

Thus, the common feature of the simplest unsaturated compounds of S, Se, and Te is the presence of a low-energy excited state¹⁹² in which an electron occupies the σ_1^* -MO, and a vacancy arises on the π -MO. From the practical point of view, it is important that in the UV spectra of alkyl vinyl chalcogenides, the energies of $\pi\rightarrow\sigma_1^*$ transitions are approximately constant: for sulfides it is 9970 cm^{-1} in the gas phase, for selenides and tellurides it is $\sim 8000\text{ cm}^{-1}$. Quite different behaviour is typical of two higher occupied σ -MOs of the ground state: an energy gap between the transitions decreases with complication of the structure.^{179,183} With the increase in the atomic number of the chalcogen, the $\pi\rightarrow\sigma^*$ and $\pi\rightarrow\pi^*$ transitions exhibit a systematic red shift, the former being more sensitive to the nature of the element than the latter.¹⁹²

10. UV absorption spectra of divinyl chalcogenides

The following concepts^{179,183} were used in the assignment of electronic transitions in the UV spectra of divinyl chalcogenides (Figs 34, 35):¹⁹⁷ a) the energy gap between the σ band maxima is practically independent of the alkyl substituent length and branching and somewhat decreases with an increase in the heteroatom atomic number; and b) the energies of two higher occupied σ -MOs of organyl chalcogenides are linearly related. These properties of $\pi\rightarrow\sigma^*$ transitions could make the band assignment in the absorption spectra of divinyl chalcogenides substantially easier if data were available on similar transitions in the series $\text{CH}_3-\text{CH}_2\text{XCH}_2-\text{CH}_3$, $\text{CH}_2=\text{CHXCH}_2-\text{CH}_3$, $\text{CH}_2=\text{CHXCH}=\text{CH}_2$ (for saturated compounds, the $\pi\rightarrow\sigma^*$ transitions are actually identical to the $n_x\rightarrow\sigma^*$ ones). Unfortunately, only long-wave $n_x\rightarrow\sigma^*$ transitions are known for saturated cyclic sulfides, which have an extremely low intensity because they are symmetry-forbidden.¹⁹⁴ For dialkyl sulfides, these bands overlap with an intense band associated with the $\sigma\rightarrow\sigma^*$ excitation.¹⁹⁴ For dialkyl sulfides in the gas phase and in solution, both $n_{\text{Te}}\rightarrow\sigma^*$ transitions are shown¹⁹⁷ to have an intensity quite sufficient for reliable detection, and are located in a more long-wave region than the transition of the $\sigma\rightarrow\sigma^*$ type (Table 11,

Figure 35. The UV absorption spectra of diorganylsulfides Et_2S (1), $\text{CH}_2=\text{CHSEt}$ (2), and $(\text{CH}_2=\text{CH})_2\text{S}$ (3) in the gaseous phase.¹⁹⁷

Fig. 34). It can be seen from Table 11 that the $\Delta\sigma^*$ values for saturated and unsaturated tellurides differ insignificantly.

The energies of two higher occupied σ -MOs of diorganyl chalcogenides are known^{179,183} to be linearly interrelated. Similar relationship can also be true of two low-lying vacant σ^* -MOs because in the molecules of high symmetry they are rearrange by the same irreducible representations as the higher occupied σ -MOs do. Analysis of UV spectra of diorganyl chalcogenides in which both $\pi\rightarrow\sigma^*$ -transitions are satisfactorily resolved (Table 11), reveals indeed a linear correlation of their energies, which is true for all the compounds considered regardless of the chalcogen type and the number of unsaturated fragments (Fig. 36).¹⁹⁷ Taking this into account, the following energy sequence was obtained for electronic transitions in the UV absorption spectra of divinyl chalcogenides:¹⁹⁷

for Te: $\pi\rightarrow\sigma^* < \pi\rightarrow\sigma^* < \pi\rightarrow\pi^* < \pi\rightarrow\pi^*$;

for S and Se: $\pi\rightarrow\sigma^* < \pi\rightarrow\pi^* < \pi\rightarrow\pi^* < \pi\rightarrow\sigma^*$.

Changes in the Franck-Condon absorption profile for divinyl telluride with regard to the phase state (Fig. 34) indicate

^a Extinction coefficient (lg ε) is given in parentheses; ^b the bands of the $\sigma \rightarrow \sigma^*$ transition and the Rydberg transition overlap.

that in the gas phase the short-wave $\pi \rightarrow \pi^*$ transition overlaps with the Rydberg $\pi \rightarrow ns$ transition. Among $\pi \rightarrow \pi^*$ transitions in divinyl chalcogenides, the most short-wave transition is the least intense. A great difference in intensities of the σ -bands for divinyl telluride (Fig. 34) can be easily rationalised on the assumption of its planar conformation (C_{2v}). For a non-planar form (C_2) of divinyl chalcogenides, an $^1A < ^1B$ sequence corresponds to π^* excited states. The 1B state is associated with the electronic configuration $a^2b^1b^*a^1$, and the position of the a -symmetry orbitals depends slightly on the central atom, therefore, there is a

near-linear correlation between the energy (E^*) of the $^1A \rightarrow ^1B$ transition in divinyl chalcogenides and their first ionisation potentials (Fig. 37).¹⁹⁷

11. UV absorption spectra of allenyl ethers

Electronic transitions in the UV spectra of alkyl allenyl and allenyl vinyl ethers have been analyzed.^{175,177} Two bands were observed in the spectra of heptane solutions, which had a tendency for a blue shift ($\sim 2-3$ nm) on going to a polar solvent (Table 12). The bands of alkyl allenyl ethers belong to the $\pi \rightarrow \pi^*$ and $\bar{\pi} \rightarrow \pi^*$ transitions partially allowed due to electronic-vibrational interaction in the allene group.¹⁷⁵ In allenyl vinyl ethers, the long-wave band corresponds to the transition localised within the allene fragment, and the short-wave band belongs to the $\pi \rightarrow \pi^*$ transition.¹⁷⁷

In a series of alkyl allenyl ethers, the most significant changes in the UV spectra were observed for $\text{CH}_2=\text{C}=\text{CHOBu}^t$.¹⁷⁵ The electronic transition corresponding to the long-wave band appeared to be the most sensitive. In addition to a blue shift of this band by ~ 16 nm relative to its position in allenyl methyl ether, its half-width nearly doubles.

In order to study the possible influence of stereoisomerism in alkyl allenyl ethers on the nature and position of electronic transitions, CNDO/C calculations for the molecules $\text{CH}_2=\text{C}=\text{CHOMe}$ and $\text{CH}_2=\text{C}=\text{CHOBu}^t$ have been carried out.¹⁷⁵ The one-configurational long-wave transition appeared to be symmetry-forbidden (it belongs to the $\pi \rightarrow \pi^*$ type). The next $\bar{\pi} \rightarrow \pi^*$ transition occurs at 4.83–4.86 eV. The energy gap between the bands observed in the ranges of 255–275 nm and 208–213 nm in the spectra of alkyl allenyl ethers corresponds to the difference in the calculated energies of the $\pi \rightarrow \pi^*$ and $\bar{\pi} \rightarrow \pi^*$ transitions. A blue shift of the long-wave band in $\text{CH}_2=\text{C}=\text{CHOBu}^t$ as compared to that in allenyl methyl ether can be explained by a difference in the conformations of these

molecules. However, the calculations for *cis*- and *trans*-rotamers in allenyl methyl ether show that the electronic transition energies depend little on the nature of the planar conformation. Violation of the orthogonal character of the π -systems of the allene fragment does not substantially affect spectral characteristics as well.¹⁷⁵ The calculated electronic spectrum of CH₂=C=CHOBu^t, in which

the *tert.* butyl substituent is rotated relative to the C_{sp}²—O bond by 30–60° (from the planar *s-trans*-form), indicates that the long-wave band is 3–9 nm blue-shifted. It should be borne in mind that for this compound C₂ symmetry might break if there is the only minimum in the internal rotation potential curve corresponding to the *s-trans*-rotamer. Presumably, the shape of the internal rotation potential ensures significant population of the excited torsional-vibrational states, for which large-amplitude motion is typical. It explains a larger width of the long-wave band in CH₂=C=CHOBu^t as compared to that in allenyl methyl ether but does not explain a spectral shift because a vibration amplitude of 60° can hardly be supposed.

Another possible reason is the presence of a non-planar *gauche*- or near-*gauche*-form along with the planar *s-trans*-form. In this case, however, the extinction for the *gauche*-conformer should be, at least, two orders of magnitude higher than that for the planar one. This situation does not seem probable since the long-wave transition is symmetry-forbidden for alkylallenes. Thus, the reason for a blue shift of the long-wave band in CH₂=C=CHOBu^t as compared to that in the spectrum of allenyl methyl ether remains obscure.

The most short-wave electronic transition was calculated¹⁷⁵ to have an energy > 6 eV and corresponds to the $\pi \rightarrow \pi^*$ transition observed for alkyl vinyl ethers in the range of 190–200 nm.¹⁹⁸

According to CNDO/C calculations for allenyl vinyl ether,¹⁷⁷ the long-wave transition is located at 308.6 eV ($f=0$) and belongs to the $\pi \rightarrow \pi^*$ type. The next transition belongs to the $\bar{\pi} \rightarrow \pi^*$ type of the allene fragment. Unlike the corresponding transitions in allenyl methyl ether, the long-wave transitions in allenyl vinyl ether are two-configurational (Table 13).¹⁷⁷ The short-wave transition in allenyl vinyl ether is mostly one-configurational. The calculation shows that the corresponding band is located in the range of 210–215 nm and originates from the $\pi \rightarrow \pi^*$ excitation.

V. Conclusion

The investigations of rotational isomerism in vinyl and allenyl chalcogenides summarised in the present review have revealed remarkable peculiarities of the molecular and electronic structure of this group of compounds. Two qualitatively different types of stable conformers exist. One of them is characterised by a definite torsional angle and small deviations from the global minimum of potential energy. The other is associated with large-amplitude relative motion of molecular fragments encompassing not one, but several local minima in the internal rotation potential curve. Methyl vinylchalcogenides represent an ensemble of stationary

states corresponding to planar *cis*-, *gauche*-, free rotational, and 'quasi'-*trans*-states, in which large-amplitude molecular motion occurs relative to the planar *trans*-form. The existence of three non-planar stable forms, viz, two quasi-degenerate *trans-trans*- and one *cis-trans*-, as well as large amplitude intramolecular motion at high temperatures and, occupancy of above-barrier states under these conditions are typical of internal rotation in divinyl chalcogenides.

The following features are typical of the ground state of alkyl vinyl chalcogenides: a) a weak dependence of the structure and the relative arrangement of higher occupied π -MOs on the nature of the heteroatom and the structure of substituent; b) the existence of a linear correlation between the energies of higher occupied σ -MOs, the parameters of which are dictated by the nature of the heteroatom and the number of unsaturated groups. For alkyl vinyl and divinyl chalcogenides, the lowest energy corresponds to the state, in which an electron migrates to the σ^* -MO and a vacancy arises in the π -MO. Excited states of π -symmetry are located higher on the energy scale as compared to those of σ -symmetry. The latter are more sensitive to the nature of the heteroatom.

Abstract. The thermodynamic properties of polyethylene, polydeuteroethylene, polypropylene, polybut-1-ene, polyprop-1-ene, poly-3-methylbut-1-ene, polyhex-1-ene, polyisobutylene, poly-4-methylpent-1-ene, and polydec-1-ene as well as the thermodynamic parameters of their formation reaction in the temperature range 0–600 K are considered. The recommended thermodynamic quantities are presented. The characteristic feature of the variation of the thermodynamic properties and parameters of the formation reactions of polyolefins are described in terms of the compositions and structures of the initial monomers and polymers and their physical state and temperature at the standard pressure. The bibliography includes 115 references.

I. Introduction

The use of olefins of various composition and structure in polymerisation and copolymerisation reactions has led to considerable possibilities for the synthesis of polyolefins with new valuable operating properties.¹ Extensive theoretical and applied studies have been carried out in this connection on the synthesis of the initial monomers and on the properties of the polyolefins formed and their applications.^{1–4} One of the dominant aspects of such studies at the present time is the search for appropriate catalytic systems, the study of the kinetics and mechanisms of the polymerisation and copolymerisation reactions, and the determination of the influence of the method of synthesis of polyolefins on their physical properties.^{1–5} The effectiveness of the theoretical and applied developments is significantly improved if use is made of the advances in the thermodynamics of polymers and polymerisation. In the foreword to the American edition of H Sawada's book 'Thermodynamics of Polymerisation', the Editor, Prof. O'Driscoll, noted justifiably that any description of polymer-

isation which does not include thermodynamics is incomplete and the solution of certain problems is altogether impossible without a thermodynamic analysis.⁶ It is noteworthy that the role of thermodynamics in the understanding of polymerisation processes has now been recognised and the thermodynamic aspects of polymerisation have been used systematically for the solution of current problems in polymer chemistry. Unfortunately, suitable data on the thermodynamic properties of polymers and the corresponding monomers are not always available. These data may be obtained mainly as a result of specific and laborious precise calorimetric studies. The majority of such studies have not been systematic. Because of this, the results obtained are scattered through scientific periodicals. The thermodynamic foundations of the technology of the synthesis of polymers may be used in theoretical and applied developments (see, for example, Lebedev and coworkers^{7,8}). The discovery of the dependence of the thermodynamic properties and parameters of reactions on the compositions and structures of the reactants is particularly valuable because they can be used successfully for the estimation of the corresponding quantities for polymers and polymerisation reactions which have not yet been investigated (for example, those described by Vasil'ev⁹ and Lebedev and Yevstropov¹⁰).

The aim of the present review is the analysis, critical selection, and survey of the thermodynamic properties of polyolefins and the parameters of their formation reactions over a wide temperature range and the determination of the dependences of the above properties and reaction parameters on the compositions and structures of the reactants and their physical states and on temperature at the standard pressure.

General information about the polymers considered in this review is presented in Table 1. All polyolefins are high-molecular-mass compounds, which rules out influence of molecular mass on their thermodynamic properties and on the parameters of the polymerisation reactions of the initial monomers. The calculations and estimations of the thermodynamic properties refer to 1 mole of the monomer repeat units of the macromolecules. In the tables of the thermodynamic properties and processes, the values quoted usually refer to the amorphous and crystalline states; if necessary, they can be readily estimated for any degree of crystallinity.

Table 1. General information about the polyolefins under consideration.

Name	Monomer repeat unit		Micro-structure (tacticity)
	formula	mass	
Polyethylene	—C ₂ H ₄ —	28.054	—
Polydeutero-ethylene	—C ₂ D ₄ —	32.086	—
Polypropylene	—C ₃ H ₆ —	42.080	Atactic, isotactic, syndiotactic
Polybut-1-ene	—C ₄ H ₈ —	56.104	Isotactic
Polyisobutylene ^a	—C ₄ H ₈ —	56.104	—
Polypent-1-ene	—C ₅ H ₁₀ —	70.134	Isotactic
Poly-3-methyl-but-1-ene	—C ₅ H ₁₀ —	70.134	"
Polyhex-1-ene	—C ₆ H ₁₂ —	84.163	"
Poly-4-methyl-pent-1-ene	—C ₆ H ₁₂ —	84.163	"
Polydec-1-ene	—C ₁₀ H ₂₀ —	140.268	"

^a Amorphous specimen; in all the remaining cases, the specimens were partly crystalline.

II. Elements of the thermodynamics of polymerisation and polymers

In any physical state, real polymers exist in a state of metastable thermodynamic equilibrium,¹¹ so that the methods for the investigation of classical thermodynamics¹² are applicable to them, as well as other metastable systems. In particular, the theory of the occurrence of chemical reactions and their equilibria based on the Second Law of Thermodynamics is fully applicable to polymerisation processes.^{13,14} The following characteristics are the thermodynamic parameters of polymerisation reactions: the thermodynamic constant of the polymerisation-depolymerisation process K_{pol}° and the equilibrium concentration of the monomer $[M]_e^{\circ}$ in the equilibrium reaction mixture; the enthalpy $\Delta_{\text{pol}}H^{\circ}$, the entropy $\Delta_{\text{pol}}S^{\circ}(T)$, and the Gibbs free energy $\Delta_{\text{pol}}G^{\circ}(T)$ of polymerisation; the upper (T_{cel}°) and lower (T_{low}°) limiting polymerisation temperatures.^{6,13-15} The circle in the superscript position indicates that the thermodynamic parameters of the polymerisation process occurring at the standard pressure $p^{\circ} = 101.325$ kPa are considered.

The Law of Mass Action is expressed by the following relation for the polymerisation reaction:

$$K_{\text{pol}}^{\circ} = \frac{1}{[M]_e^{\circ}} \quad (1)$$

In their turn, K_{pol}° and $[M]_e^{\circ}$ are related to the standard Gibbs free energy of polymerisation by the van't Hoff equation.

The equilibrium concentration of the monomer can be expressed in terms of the enthalpy and entropy of polymerisation:

$$\ln [M]_e^{\circ} = \frac{\Delta_{\text{pol}}H^{\circ}(T)}{RT} - \frac{\Delta_{\text{pol}}S^{\circ}(T)}{R},$$

where R is the gas constant.

This equation is frequently used to obtain the values of $\Delta_{\text{pol}}H^{\circ}(T)$ and $\Delta_{\text{pol}}S^{\circ}(T)$, assuming that the enthalpy and entropy are independent of temperature in the experimental range of the latter. Subject to this condition, $\ln [M]_e^{\circ}$ is plotted against $1/T$ on the basis of the values of $[M]_e^{\circ}$ measured at several temperatures. This is usually a straight line, so that

$$\Delta_{\text{pol}}H^{\circ}(\Delta T) = -R \operatorname{tg} \alpha,$$

$$\Delta_{\text{pol}}S^{\circ}(\Delta T) = R \lim_{(1/T) \rightarrow 0} (\ln [M]_e^{\circ}),$$

where α is the slope of the straight line. The enthalpy and entropy of polymerisation are the averages of the quantities in the temperature range of measurement of $[M]_e^{\circ}$.

The temperature variations of K_{pol}° and $[M]_e^{\circ}$ are expressed by the van't Hoff equation of the reaction isobar.

The influence of temperature on $[M]_e^{\circ}$ is determined by the numerical value and sign of the enthalpy of polymerisation. The greater the numerical value of $\Delta_{\text{pol}}H^{\circ}$, the more marked is the variation of $[M]_e^{\circ}$, and, if $\Delta_{\text{pol}}H^{\circ} < 0$, then $[M]_e^{\circ}$ increases with increasing temperature and conversely. All the formation reactions of polyolefins are exothermic, so that the equilibrium yield of the polymer produced by them increases with decrease in temperature.

The influence of pressure on the polymerisation-depolymerisation equilibrium constant K_N , expressed in terms of the mole fraction of the monomer in the reaction mixture, is described by the equation^{11,16}

$$\left(\frac{\partial \ln K_N}{\partial p} \right)_T = - \frac{\Delta_{\text{pol}}V}{RT},$$

where $\Delta_{\text{pol}}V$ is the difference between the molar volumes of the polymer and the monomer at the specified temperature and pressure. For moderate pressure (p), one can use the approximate relation

$$\ln K_N = \ln K_N^{\circ} - \frac{\Delta_{\text{pol}}V^{\circ}p}{RT},$$

where $\Delta_{\text{pol}}V^{\circ}$ is the difference between the molar volumes of the polymer and the monomer at the standard pressure. Since $\Delta_{\text{pol}}V^{\circ} < 0$ in the polymerisation of olefins, an increase in pressure is favourable as regards the yield of the polymers. This equation is applicable to the case where the pressure amounts to tens and even hundreds of atmospheres.

The temperature dependences of the enthalpy, entropy, and Gibbs free energy are expressed by the Kirchhoff and Gibbs-Helmholtz equations.¹⁶

The influence of temperature on $\Delta_{\text{pol}}H^{\circ}(T)$ and $\Delta_{\text{pol}}S^{\circ}(T)$ is determined by the numerical values and signs of $\Delta_{\text{pol}}C_p^{\circ}(T)$ and $\Delta_{\text{pol}}H^{\circ}$, while its influence on $\Delta_{\text{pol}}G^{\circ}(T)$ is determined by the numerical value and sign of $\Delta_{\text{pol}}H^{\circ}(T)$. For the polymerisation reactions of olefins, $\Delta_{\text{pol}}C_p^{\circ}(T)$ and $\Delta_{\text{pol}}H^{\circ}(T)$ are usually negative. As a result of this, the numerical values of $\Delta_{\text{pol}}H^{\circ}(T)$ and $\Delta_{\text{pol}}S^{\circ}(T)$ increase with increasing temperature but remain negative, while $\Delta_{\text{pol}}G^{\circ}(T)$ diminishes with a consequent decrease in the yield of the polymer corresponding to thermodynamic equilibrium; on the other hand, it increases with decrease in temperature.

The dependences of the enthalpy, entropy, and Gibbs free energy on pressure are expressed by the following equations:¹⁷⁻²⁰

$$\Delta_{\text{pol}}H = \Delta_{\text{pol}}H^{\circ} + \int_{p^{\circ}}^p \Delta_{\text{pol}}V(p)dp - T \int_{p^{\circ}}^p \left[\frac{\partial \Delta_{\text{pol}}V(p)}{\partial T} \right]_p dp,$$

$$\Delta_{\text{pol}}S = \Delta_{\text{pol}}S^{\circ} - \int_{p^{\circ}}^p \left[\frac{\partial \Delta_{\text{pol}}V(p)}{\partial T} \right]_p dp,$$

$$\Delta_{\text{pol}}G = \Delta_{\text{pol}}G^{\circ} + \int_{p^{\circ}}^p \Delta_{\text{pol}}V(p)dp,$$

where p° is the standard pressure.

$\Delta_{\text{pol}}H^{\circ}(T)$ and $\Delta_{\text{pol}}S^{\circ}(T)$ for the polymerisation of olefins are negative, whilst the entropy factor $T\Delta_{\text{pol}}S^{\circ}(T)$ increases faster with temperature than $\Delta_{\text{pol}}H^{\circ}(T)$, so that at the upper limiting temperature T_{cel}° the enthalpy and the entropy factor are equalised and $\Delta_{\text{pol}}G^{\circ}(T_{\text{cel}}^{\circ}) = 0$. It can be shown that at moderate pressures

$$\ln T_{\text{cel}} = \ln T_{\text{cel}}^{\circ} + \frac{\Delta_{\text{pol}}V^{\circ}(T_{\text{cel}}^{\circ})p}{\Delta_{\text{pol}}H^{\circ}(T_{\text{cel}}^{\circ})}.$$

Pressure can amount to tens and in certain cases even thousands of atmospheres.¹¹ At $T < T_{\text{ceil}}^{\circ}$, the equilibrium in the polymerisation reaction is displaced towards the formation of the polymer, whereas at $T > T_{\text{ceil}}^{\circ}$ it is actually displaced towards the initial monomer. At temperatures close to T_{ceil}° and higher, the polymer rapidly depolymerises to the initial monomer under kinetic conditions.^{13–15} Since $\Delta_{\text{pol}}V^{\circ}(T_{\text{ceil}}^{\circ})$ and $\Delta_{\text{pol}}V^{\circ}(T_{\text{ceil}}^{\circ})$ for the polymerisation reaction are negative, their ratio is positive and T_{ceil}° accordingly increases with increase in pressure. This leads to the expansion of the range of temperatures favouring polymerisation and to the thermodynamic stability of the polymer.

Heat capacity is one of the most important thermodynamic quantities entering into key thermodynamic relations.^{16, 21, 22}

A series of quantum theories of the heat capacities of chain structures — linear polymers have now been developed: the Stockmayer–Hecht theory²³ based on the analysis of the vibrational spectrum of the lattice formed by the polymer chains; Tarasov's theory of the heat capacities of chain structures²⁴ based on the analysis of the vibrational spectrum of a one-dimensional continuum (rigid string); Lifshits's theory²⁵ also based on the consideration of the vibrational spectrum of a one-dimensional continuum. In contrast to Tarasov, Lifshits chose thin rods (needles) as the one-dimensional continuum. All the above theories of heat capacity have been analysed critically by Godovskii,²⁶ who demonstrated convincingly that Lifshits's theory of heat capacity has the greatest physical justification. However, Tarasov's theory has nevertheless found extensive practical application.²⁴ It is expressed analytically by the following equation:

$$C_{v1,3} = D_1 \left(\frac{\theta_1}{T} \right) - \frac{\theta_3}{\theta_1} \left[D_1 \left(\frac{\theta_3}{T} \right) - D_3 \left(\frac{\theta_3}{T} \right) \right], \quad (2)$$

where D_1 and D_3 are symbols for the Tarasov and Debye heat capacity functions respectively, θ_1 and θ_3 are the characteristic Tarasov and Debye temperatures, and θ_3/θ_1 expresses the degree of interaction of the chains. The generalised expression for the Tarasov and Debye heat capacity functions assumes the form²⁴

$$C_{v,m} = 3mR \left(\frac{T}{\theta_m} \right)^m \int_0^{\theta_m/T} \frac{(\theta_m/T)^{m+1} \exp(\theta_m/T)}{[\exp(\theta_m/T) - 1]^3} d \frac{\theta_m}{T},$$

where $m = 1$ or 3 .

Chernoplekov²⁷ compiled tables of the heat capacities of chain structures, which greatly facilitate practical calculations of the skeletal contribution to the heat capacities of chain polymers. The characteristic temperatures θ_1 and θ_3 are usually determined by an inverse calculation from the experimental measurements of the heat capacities of specific polymers over a temperature range. Eqn (2) has been used particularly fruitfully by Wunderlich and coworkers, for example, in two studies^{28, 29} for the calculation of the heat capacities of linear polymers over a wide temperature range (frequently from 0 to 1000 K). The contribution of atomic vibrations to the heat capacities of polymers has been calculated from vibrational spectroscopic data using the Einstein heat capacity function.

The absolute value of the entropy $S^{\circ}(T)$ of a polymer is expressed by the following equation:

$$S^{\circ}(T) = S^{\circ}(0) + \int_0^T C_p^{\circ}(T) d \ln T + \sum \Delta_{\text{tr}} S^{\circ},$$

where $S^{\circ}(0)$ is the zero-point (residual) entropy of the polymer at $T = 0$ K, $C_p^{\circ}(T)$ is the temperature dependence of the heat capacity, and $\Delta_{\text{tr}} S^{\circ}$ is the entropy of phase transitions.

For vitreous and partially crystalline polymers, $S^{\circ}(0)$ is non-zero owing to the imperfection of the crystals, the thermodynamically nonequilibrium configurations of the macromolecules frozen at the glass transition temperature of the polymer T_g° , and certain other possible factors. The attempts at a theoretical

estimation of $S^{\circ}(0)$, undertaken in a number of studies,^{30–32} usually lead to values ranging from 10 to 20 J mol^{−1} K^{−1}. Strictly speaking, the zero-point entropy of a crystalline polymer is nonzero also owing to the imperfection of the crystals and because the polymer is a mixture of macromolecules having different masses.^{11, 33} However, it has been shown³¹ that the corresponding entropy of mixing of polymers in any physical state is close to zero in cases where the average degree of polymerisation is greater than 100. It has been suggested that the quantity $S^{\circ}(0)$ could be neglected without significant error for polymers with a degree of crystallinity of 100%.

A number of investigators^{34–36} developed a method for the estimation of $S^{\circ}(0)$ for polymers in the amorphous state from calorimetric measurements for partially crystalline polymers. The values of $S^{\circ}(0)$ for more than 100 vitreous polymers of different chemical composition and structure have now been obtained from the results of the corresponding calorimetric measurements. These results have largely confirmed the theoretical estimates. It was found that in most cases $S^{\circ}(0)$ is $\sim 10\%$ of $S^{\circ}(298.15 \text{ K})$ for the corresponding polymers in the amorphous state. It is also of interest that $S^{\circ}(0)$ amounts to between 10% and 80% (in most cases $\sim 50\%$) of the entropies of fusion of the corresponding polymers with $\alpha = 100\%$.^{11, 13} It is not permissible to neglect $S^{\circ}(0)$ in accurate thermodynamic calculations.

It has been established^{37–39} that the configurational entropy S_{conf}° makes the main contribution to $S^{\circ}(0)$ and that frequently we have $S_{\text{conf}}^{\circ} \approx S^{\circ}(0)$. It has also been shown that S_{conf}° can be readily estimated from the formula³⁷

$$S_{\text{conf}}^{\circ} = \int_{T_2^{\circ}}^{T_g^{\circ}} \Delta C_p^{\circ}(T_g^{\circ}) d \ln T, \quad (3)$$

where $\Delta C_p^{\circ}(T_g^{\circ})$ is the increase in heat capacity on devitrification of the polymer at T_g° , while T_2° is the Kauzmann temperature^{37, 40} and $T_g^{\circ}/T_2^{\circ} \approx 1.29$. The quantities in Eqn (3) may be determined experimentally.

Thus the methods developed for the estimation of $S^{\circ}(0)$ made it possible to overcome the significant difficulties in the calculations of $S^{\circ}(T)$ and $\Delta_{\text{pol}} S^{\circ}(0)$, which in its turn opened a way to the full employment of calorimetric data for the calculation of the polymerisation–depolymerisation equilibrium.

III. Calorimetric research methods

1. Combustion calorimetry

The enthalpies of polymerisation of olefins have been calculated mainly from the experimental combustion energies of the monomers and the corresponding polymers. The reactants were combusted in bomb calorimeters.^{41–45} Typical conditions in the measurements of combustion energies have been published.⁴⁶ A calorimeter with an isothermal jacket and a static bomb was used. The design of the calorimeter and the experimental method were similar to those described by Skuratov et al.⁴²

2. Adiabatic vacuum calorimetry

The temperature dependences of the heat capacity and of the temperatures and enthalpies of physical transformations at low and moderate temperatures have been investigated in adiabatic vacuum calorimeters.^{47–51} A number of olefins and polyolefins have been investigated in an adiabatic fully automated vacuum calorimeter, the design and method of employment of which have been described.^{51–53}

3. Dynamic calorimetry

An automated differential calorimeter, working in accordance with the triple thermal bridge principle, is usually employed for measurements by dynamic calorimetry.⁵⁴ The design and method of employment of the calorimeter have been described.^{55, 56} A characteristic feature of the measurements of C_p° in this calorimeter is that it is calibrated for each individual measurement.

The sensitivity of the calorimeter has been raised to $1.3 \times 10^{-2} \text{ J K}^{-1}$ and the error of the heat capacity measurements has been reduced to 1%–4%. However, since in the experiments of Lebedev et al.⁵⁷ the heat capacities of the test substances in the temperature range 250–340 K were measured in an adiabatic vacuum calorimeter subject to an error of 0.2% and the conditions of the measurements in a dynamic calorimeter were chosen so that the values of C_p° obtained in the above temperature range were the same in both calorimeters, it was assumed⁵⁷ that, at $T > 340 \text{ K}$, C_p° measured in the dynamic calorimeter is subject to an error within the range 0.5%–1.5%.

It was shown that the temperature and method of measurement make it possible to obtain C_p° for solid and liquid substances with an error up to 1%, the temperatures of physical transformations can be measured with an error up to 1.0 K, while the enthalpies of the transformations are subject to an error up to 0.8%.³⁰

IV. Heat capacity

The heat capacities C_p° of polyolefins in the range from 5–10 to 350 K have been investigated as a rule in adiabatic vacuum calorimeters, while those at $T > 350 \text{ K}$ have been determined in dynamic calorimeters. In adiabatic vacuum calorimeters, between 90 and 150 experimental C_p° values were obtained in 10–25 series. The calorimeter tube was charged with between 2 and 6 g of the test substance. The heat capacity of the specimens was 50%–70% relative to the overall heat capacity of the calorimeter tube with the test substance. The experimental values of C_p° were averaged by the method of least squares. The scatter of the points around the corresponding averaging curves was 0.7% in the range 5–30 K, 0.07% in the range 30–150 K, and 0.02% in the range 150–340 K. In the study of substances in the dynamic calorimeter, the C_p° measurements were performed under the conditions of continuous heating of the calorimeter with the test substance. The rate of heating was varied from 16.7×10^{-3} to $8.3 \times 10^{-3} \text{ K s}^{-1}$ for the same substance in different series. The duration of a single measurement was ~ 20 –25 s.

All the polyolefins investigated are partly crystalline polymers with the exception of the fully amorphous polyisobutylene and polyhex-1-ene.

Figure 1 presents a typical temperature dependence of the heat capacity of a partly crystalline polymer. Evidently, the heat capacity of a mixture of the vitreous and crystalline polymers increases smoothly in the range from the temperature at the beginning of the measurements from 6 K to the temperature of the onset of devitrification of the amorphous part of the specimen of 260 K (AR). In the range of devitrification temperatures, C_p° increases comparatively sharply with increase in temperature (RN) and then rises smoothly up to the temperature of the onset of the fusion of the crystalline part of the polymer (NQ). The fusion of the crystals is responsible for the anomalous variation of the heat capacity in the fusion range (QSHUE). The heat capacity of the polymer melt increases with increasing temperature (EF). Before proceeding to the analysis of the published data on the heat capacities of polyolefins, we shall make several remarks concerning the methods for the determination of the degree of crystallinity of polymers.

The degree of crystallinity of polyolefins α is determined as a rule from calorimetric data with the aid of the following equations:^{26, 58, 59}

$$\alpha = 100 \left(1 - \frac{\Delta C_p^\circ(\alpha)}{\Delta C_p^\circ(\alpha = 0)} \right), \quad (4)$$

$$\alpha = 100 \frac{\Delta_{\text{fus}} H^\circ(\alpha)}{\Delta_{\text{fus}} H^\circ(\alpha = 100\%)}, \quad (5)$$

Figure 1. Typical temperature variation of the heat capacity of a partly crystalline polymer for isotactic polybut-1-ene as an example.^{69–71} State of the polymer: ABC — crystalline, $\alpha = 100\%$, AB — vitreous, LD — highly elastic, DEF — liquid, AR — partly crystalline (form I, $\alpha \approx 77\%$; amorphous component in the vitreous state), RNQ — ditto, but with the amorphous component of the polymer in the highly elastic state; QSHUE — apparent heat capacity in the melting range of the crystals of form I.

where $\Delta C_p^\circ(\alpha)$ and $\Delta C_p^\circ(\alpha = 0)$ are respectively the increase in the heat capacity at the glass transition temperature T_g° of the partly crystalline and fully amorphous ($\alpha = 0$) polymer, while $\Delta_{\text{fus}} H^\circ(\alpha)$ and $\Delta_{\text{fus}} H^\circ(\alpha = 100\%)$ are the enthalpies of fusion of the polymer with a degree of crystallinity α and of the fully crystalline polymer.

$\Delta C_p^\circ(\alpha)$ and $\Delta C_p^\circ(\alpha = 0)$ were obtained graphically (sections BM and BL in Fig. 1). Point B was found by the linear extrapolation of the temperature dependence of the heat capacity of the partly crystalline polymer between $T < T_g^\circ$ and T_g° . Point B corresponds to the heat capacity of a mixture of the vitreous and crystalline materials, but C_p° is assumed to be equal at this point to the heat capacity of the polymer in the vitreous state. This is based on the experimentally observed equality of the heat capacities of the same polymer in the vitreous, partly crystalline, and even fully crystalline states at $T < T_g^\circ$ within the limits of the error of the measurements (differences between the values of C_p° less than 0.2%).^{36, 60} Point M corresponds to the heat capacity of the same mixture of crystals with the amorphous component of the polymer in the highly elastic state. It was obtained by extrapolating the $C_p^\circ = f(T)$ relation (section NQ) between the end of the devitrification of the amorphous component and the onset of the prefusion of the crystalline component of the polymer. The increase in C_p° (section B) is associated with the devitrification of the amorphous component of the polymer. Point L was found by the linear extrapolation of the relation $C_p^\circ = f(T)$ for the liquid polymer (EF) into the region of its T_g° . Section BL corresponds to the increase in heat capacity owing to the segmental mobility of the macromolecules, which appeared in the course of the devitrification of the polymer in the amorphous state (the α -transition).⁶¹

On slow stepwise cooling, it is possible to measure the heat capacities of certain polymers in the range from point E to L (for example the heat capacity of the polymer in the highly elastic state in Fig. 1), whereupon the deviations of the C_p° points from the corresponding straight line DL are comparable to the error of the measurements of the heat capacity. Depending on the cooling conditions, the polymers are obtained in both amorphous and partly crystalline states. It is sometimes possible to measure C_p° in both states,^{62, 63} whereupon the $C_p^\circ = f(T)$ relation for the polymer in the highly elastic state is located as a rule on the prolongation of the temperature variation of the heat capacity of the liquid (FE) to point L. Clearly the ratio of the sections BM/BL is equal to the fraction of the amorphous component of the polymer, while the

difference $1 - BM/BL$ represents the fraction of the crystalline component of the polymer. The degrees of crystallinity of the polymers found from calorimetric and X-ray diffraction data agree subject a discrepancy which is usually within the limits of 3%–5%.⁶⁴

In conclusion, we may note that the calorimetric method for the determination of the degree of crystallinity from the increase in the heat capacity at T_g° yields satisfactory results for low and moderate degrees of crystallinity, but may lead to significant errors for higher values of α .²⁶

Polyethylene (PE) is one of the most thoroughly investigated polymers. Approximately 50 studies have been published in which the results of calorimetric investigations on ~100 polyethylene specimens having linear and branched structures, different molecular masses (from 2.5×10^4 to 8×10^6), and different degrees of crystallinity (from 25% to 97%) have been published for temperatures ranging from 0.16 to 570 K. All the published investigations have been thoroughly analysed and surveyed by Wunderlich and coworkers.⁶⁵ They obtained as a result the temperature variations of the heat capacity of PE in the crystalline, vitreous, highly elastic, and liquid states at temperatures in the range 0–600 K. It was shown that C_p° for crystalline PE increases smoothly with increase in temperature in the range from 0 to 360 K, after which there is a sharp rise in heat capacity owing to the onset of fusion, which occurs in the range 360–414 K. An anomalous $C_p^\circ = f(T)$ relation corresponds to the fusion process.

The heat capacity of vitreous PE also increases smoothly with increase in temperature from 0 to 200 K, after which the rise of C_p° becomes appreciably faster owing to devitrification, which is completed at 250 K. In the highly elastic and liquid states, the heat capacity of PE is a linear function of temperature. In the region of very low temperatures, C_p° of crystalline PE obeys the Debye T^3 law (in the range 1–9 K), while C_p° of vitreous PE is described by the equation

$$C_p^\circ = aT^3 + bT,$$

where a and b are constants. A similar relation is characteristic also of other amorphous solids. At temperatures in the ranges from 0 to 60 K and from 150 to 414 K, the heat capacities of amorphous and crystalline PE differ markedly, that of amorphous PE being higher. An additive dependence of the heat capacity on the degree of crystallinity of PE is manifested. In the range 60–150 K, the heat capacities of crystalline and amorphous PE are close: the differences do not exceed $\pm 2\%$. The heat capacity of branched PE is always slightly higher than that of the linear polymer. Differences between the heat capacities were not discovered in a study of PE specimens having different molecular masses (from 6×10^4 to 1×10^6) in the same physical state.

Polydeuteroethylene (PDE). The results of the study of the temperature variation of C_p° of polydeuteroethylene have been published.^{66,67} Rabinovich et al.⁶⁶ investigated in an adiabatic vacuum calorimeter a PDE specimen with a degree of deuteration of 93% and a degree of crystallinity of 72% in the range 80–310 K. The molecular mass of the polymer is not indicated. The results of experimental measurements of C_p° were extrapolated to 100% crystallinity on the basis of the proportionality of the differences between the heat capacities of the polymer in the amorphous and crystalline states. The values of C_p° of the fully crystalline PDE were in their turn extrapolated to 100% degree of deuteration assuming that the difference between the heat capacities of PDE and PE at a specified temperature is proportional to the deuterium content. The heat capacity of PDE has been investigated⁶⁷ in adiabatic vacuum and dynamic calorimeters in the temperature ranges 5–330 and 330–450 K respectively. The degree of deuteration of the test specimen was 98%, its degree of crystallinity was ~92%, and its molecular mass was 2×10^5 . The error of the measurements was ~0.2% in adiabatic vacuum calorimeters^{66,67} and from 0.5 to 1.5% in a dynamic calorimeter.⁶⁷ The results obtained by Lebedev and Smirnova⁶⁷ are presented in Fig. 2. Evidently there are several characteristic

Figure 2. Heat capacities of polydeuteroethylene (ABSCFE)⁶⁷ and polyethylene (ALMNP).⁶⁵

State of the polymer: ABSC — crystalline, $\alpha = 92\%$, EF — liquid, CD — apparent heat capacity in the melting range; AL — crystalline, $\alpha = 100\%$, NP — liquid, LMN — apparent heat capacity in the melting range; T_{fus}^{CD} and T_{fus}^{CH} — melting points of polydeuteroethylene and polyethylene respectively, RN — increase in heat capacity on fusion of polyethylene; for the explanation of the remaining symbols, see text.

sections on the $C_p^\circ = f(T)$ curve corresponding to the variation of the heat capacity with increasing temperature: 0–60 K (AB) — along this section, C_p° increases rapidly; 60–200 K (BS) — the range in which C_p° is a linear function of temperature, which occurs for all chain polymers; 200–350 K (SC) — the section along which the rate of change of C_p° is higher than along the preceding section, which may be associated with the devitrification of the amorphous component of the specimen; $T > 350$ K (CD) — along this section, C_p° increases sharply owing to the fusion of the polymer crystals. The heat capacity of the polymer melt (EF) is a linear function of temperature and a very weak one at that.

Comparison of the heat capacities C_p° found in the above two investigations^{66,67} shows that, according to the data of Lebedev and Smirnova,⁶⁷ the heat capacity in the range 20–220 K is 3%–10% higher than in the study of Rabinovich et al.,⁶⁶ in the temperature range 220–260 K the heat capacities virtually coincide, while in the range 260–310 K the heat capacities are 3%–6% lower according to the data of Rabinovich et al.⁶⁶ The above discrepancies between the values of C_p° are apparently a consequence of the different degrees of deuteration and crystallinity of the test specimens and also of the above assumptions in the extrapolations.

Polypropylene (PP). More than 25 studies have been published in which the results of calorimetric measurements of the heat capacities of 34 specimens of atactic, isotactic, and syndiotactic PP are presented. Specimens with molecular masses from 8.9×10^3 to 6.4×10^5 and degrees of crystallinity from 10% to 65% were investigated. The heat capacity was determined in the temperature range 0.5–600 K. Atactic PP specimens are amorphous, while those of isotactic and syndiotactic PP are partly crystalline. All the published results have been thoroughly analysed and surveyed by Gaur and Wunderlich.⁶⁸

The heat capacity of vitreous atactic PP increases smoothly with increasing temperature in the range from 0 to 230 K; at 230 K, a more rapid rise of the heat capacity is observed, apparently owing to the onset of devitrification. The heat capacity of crystalline PP also increases smoothly with temperature in the range 0–280 K. At $T > 280$ K, the growth of C_p° accelerates, which may be associated with the onset of the fusion of the polymer. In the highly elastic and liquid states, C_p° is a linear function of temperature.

In the crystalline state, the heat capacities C_p° of isotactic and syndiotactic PP are virtually identical; in the liquid state, the heat capacities of atactic, isotactic, and syndiotactic PP are identical in the experimental temperature range.

The heat capacity of vitreous PP is higher throughout than that of crystalline PP. In the range from 20 to 150 K, the difference between the values of C_p° diminishes from 30% to 5%, in the range 150–200 K it is within the limits of 5%, while in the range 260–460 K the difference between the C_p° of highly elastic and crystalline PP is 25%. In the range 20–150 K and also between the glass transition temperature and the melting point, C_p° of partly crystalline PP is linear function of the degree of crystallinity. The heat capacity of a partly crystalline specimen is higher the lower its degree of crystallinity.

Polybut-1-ene. The temperature variation of C_p° of isotactic polybut-1-ene specimens in the partly crystalline and liquid states has been investigated in the range 5–630 K.^{69–71} The degree of isotacticity of the test specimens was ~90% and the degree of crystallinity of the polymer varied from 44% to 83% depending on the crystallisation conditions. The crystalline component of polybut-1-ene formed under these conditions consisted of one crystalline modification or a mixture of two or three possible crystalline modifications: rhombohedral, tetragonal, and hexagonal structures, which are designated as forms I, II, and III respectively.⁷²

Lebedev and coworkers⁶⁹ investigated a specimen of isotactic polybut-1-ene with a degree of crystallinity of 77%. The crystalline component of the specimen consisted of form I. The heat capacities of the specimen were measured in the temperature ranges 6–35 and 200–304 K. Dainton et al.⁴⁷ investigated C_p° of a polybut-1-ene specimen with a degree of crystallinity of 44%, the crystalline component of the polymer consisting of a mixture of two crystalline modifications: 37% of form I and 7% of form II. The heat capacity measurements were performed in the range 22–310 K. Bares and Wunderlich⁷¹ published C_p° data for polybut-1-ene in the vitreous, highly elastic, and liquid states in the temperature range 10–600 K.

Wilski and Grever⁷⁰ investigated C_p° of the polymer in the range 250–430 K, but do not quote numerical values, confining themselves to a plot of the temperature variation of C_p° .

A common feature of all the polybut-1-ene specimens investigated is the equality of the heat capacities virtually within the limits of the errors of measurement at temperatures below T_g° for the polymer. The values of C_p° of the melt, found by Lebedev and coworkers,⁶⁹ also agree with those published by Bares and Wunderlich.⁷¹ In the range 22–33 K, the data of Dainton et al.⁴⁷ and Lebedev et al.⁶⁹ differ only within the limits of 1%, but in the range 0–22 K the heat capacities are significantly higher according to the results of Dainton et al.⁴⁷ However, one should bear in mind that Dainton et al.⁴⁷ obtained then by extrapolating the dependence of the measured values of C_p° on T in accordance with the Debye heat capacity function. In the range 200–220 K, which precedes the devitrification of the amorphous part of the polymer, the heat capacity according to the results of Lebedev et al.⁶⁹ is ~1.5% smaller than that measured by Dainton et al.⁴⁷ This can apparently be accounted for by the influence of the difference between the degrees of crystallinity (44% and 77%) on the heat capacity of polybut-1-ene in the given temperature range and, in particular by the difference between the effects of the reinforcement^{11,73} of the vitreous component of the polymer by the crystals which hinder the excitation of the segmental mobility of the macromolecules. Overall, the temperature dependence of the heat capacity of polybut-1-ene is a typical $C_p^\circ = f(T)$ relation for partly crystalline polymers.

In order to obtain the temperature dependence of the heat capacities of polybut-1-ene in the crystalline and amorphous states from the experimental heat capacities of a partly crystalline polymer, use was made of the method described in detail by Lebedev.^{11,60} This method is based on the fact that the C_p° of partly crystalline polymers at $T < T_g^\circ$ virtually agrees with the

heat capacity of the polymers in the vitreous and crystalline states within the limits of the error of the measurement; the linear relation $C_p^\circ = f(T)$ in the range from 50–60 K up to the glass transition temperature is observed for all the chain polymers investigated hitherto.²⁶ The authors assumed that the extrapolation of C_p° of a partly crystalline polymer from T_g° to T_{fus}° correctly reflects the heat capacity of the polymer in the crystalline state, while the linear extrapolation of the heat capacity of the polymer in the liquid state to T_g° describes correctly, in its turn, the heat capacity of the polymer in the highly elastic state. All the above extrapolations are presented in Fig. 1. In order to obtain the temperature dependence of the heat capacity of the polymer in the highly elastic state (EDL), Bares and Wunderlich⁷¹ extrapolated the temperature dependence of the heat capacity of liquid polybut-1-ene (FE) to T_g° .

Polyisobutylene. The results of calorimetric studies on the temperature dependence of the heat capacity of polyisobutylene in the vitreous and highly elastic states have been published by Ferry and Parks⁷⁴ and Furukawa and Reilly.⁷⁵ The measurements of C_p° were performed in adiabatic vacuum calorimeters. Ferry and Parks⁷⁴ studied the C_p° of a low-molecular-mass ($M_n = 49 \times 10^3$) polymer specimen in the range 118–295 K. Furukawa and Reilly⁷⁵ investigated a high-molecular-mass ($M_n = 1.35 \times 10^6$) polymer with a narrow molecular mass distribution ($M_w/M_n = 1.16$). Comparison shows that the heat capacity of the low-molecular-mass polyisobutylene is always 1%–2% higher than that of the high-molecular-mass polymer, apparently as a consequence of the difference between the molecular masses of the test specimens (by a factor greater than 3000). The nature and characteristics of the variation of the heat capacities of the low- and high-molecular-mass polyisobutylenes do not exhibit any differences: the heat capacities C_p° of the polymer in the vitreous and crystalline states increase smoothly with increase in temperature; in the vitrification ranges, $C_p^\circ = f(T)$ varies in the usual way.¹¹ Wunderlich and Baur²¹ averaged the values of C_p° quoted by Ferry and Parks⁷⁴ and Furukawa and Reilly⁷⁵ and published a table of the heat capacities of polyisobutylene in the range 0–380 K.

Polypent-1-ene. The temperature variation of the heat capacity of isotactic polypent-1-ene has been investigated by Wunderlich and coworkers⁷⁶ in the range 220–430 K and by Lebedev et al.⁷⁷ in the range 9–500 K. The degree of isotacticity of the test polymer specimens was 80%–95% and their degree of crystallinity was 0%⁷⁶ and 60%.⁷⁷ The experimental values of C_p° quoted in the above studies^{76,77} agree to within 1%. The temperature variation of the heat capacity of polypent-1-ene is typical for partly crystalline polymers. In the range 220–260 K, the amorphous component devitrifies, whilst in the range 330–390 K the crystalline component melts. The heat capacities of the polymer in the crystalline and amorphous states were found by extrapolation, as for polybut-1-ene (see above).

Poly-3-methylbut-1-ene. The temperature variation of the heat capacity of isotactic poly-3-methylbut-1-ene has been investigated by Lebedev and coworkers⁷⁸ in the range 8.5–650 K. The degree of isotacticity of the test specimen was ~95% and its degree of crystallinity 70%. On cooling melts of the initial specimen, the degree of crystallinity changed from 50% to 88% during their crystallisation and annealing. The amorphous component of the polymer devitrified in the range 300–370 K and the crystalline component melted in the range 500–610 K. Some irregularity in the temperature variation of C_p° in the range 370–500 K is probably associated with the recrystallisation processes during the heating of the polymer. The temperature variation of the heat capacity in the range 8.5–300 K exhibits no singularities of any kind: C_p° increases smoothly with increasing temperature. Immediately after the end of fusion, small endothermic effects were noted on the temperature variation of the heat capacity. For example, such an effect occurred for the initial poly-3-methylbut-1-ene specimen in the range 605–620 K. The maximum heat capacity $C_{p,max} = 230.0 \text{ J mol}^{-1} \text{ K}^{-1}$ corresponds to 612 K. The

deviation of the heat capacity from its normal value at this temperature is $\sim 8 \text{ J mol}^{-1} \text{ K}^{-1}$.

It is noteworthy that the disposition of the $C_p^\circ = f(T)$ curves for the melt depended on the previous history of the specimens. This can apparently be accounted for by the retention of a certain amount of structure in the polymer after the fusion of its crystalline component and its subsequent decomposition, which requires an energy expenditure. A similar phenomenon has been observed also for poly-4-methylpent-1-ene.

Polyhex-1-ene. Bourderiat et al.⁴⁹ published the results of a study of the temperature variation of the heat capacity of polyhex-1-ene in the range 20–300 K. The measurements were performed in an adiabatic vacuum calorimeter. The test polymer specimen exists in the above temperature range in the vitreous and highly elastic states (Fig. 3). Devitrification occurs in the range 200–225 K. In other respects, the temperature dependence of the heat capacity of polyhex-1-ene exhibits no singularities, increasing smoothly with temperature. The error of the measurements of C_p° was 0.2%–0.4%. We may note that this type of $C_p^\circ = f(T)$ relation is typical for fully amorphous polymers.

Figure 3. Typical temperature dependence of the heat capacity of an amorphous polymer for isotactic polyhex-1-ene as an example.⁴⁹ State of the polymer: *AB* — vitreous, *CE* — highly elastic; *BC* — increase in heat capacity on devitrification.

Poly-4-methylpent-1-ene. The temperature variation of the heat capacity of isotactic poly-4-methylpent-1-ene was investigated by Karasz et al.⁴⁸ in the range 77–540 K, by Melia and Tyson⁷⁹ in the range 80–320 K, and by Lebedev et al.⁸⁰ in the range 7–670 K. The degree of isotacticity of the test specimens was ~ 95 and the degree of crystallinity was 30%,⁴⁸ 65%,⁷⁹ and between 35% and 40%.⁸⁰ The experimental values obtained by Lebedev et al.⁸⁰ in the range 77–300 K are smaller by $\sim 1\%$ than the data published by Karasz et al.⁴⁸ and higher by 0.5%–1.7% than the results quoted by Melia and Tyson,⁷⁹ the scatter of the experimental points being $\sim 2\%$.

Figure 4 presents the temperature variation of the heat capacity of poly-4-methylpent-1-ene. The amorphous component of the polymer devitrified in the range 270–320 K and the crystalline component melted in the range 470–557 K for the initial specimen and 450–550 K for specimens obtained on cooling and crystallisation of the initial specimen.

Apart from devitrification and fusion, two additional anomalies in the heat capacity were manifested on the $C_p^\circ = f(T)$ curve for the initial polymer specimen: one in the range 360–390 K (between the glass transition temperature and the melting point) and the other in the range 575–600 K (at temperatures above the melting temperature range, i.e. in the polymer melt). In all the

Figure 4. Heat capacity of isotactic poly-4-methylpent-1-ene.^{48, 79, 80} State of the polymer: *ABC* — crystalline, $\alpha = 100\%$, *AB* — vitreous, *GF* — highly elastic, *FQE* — liquid (isotropic melt). *AOVLMNPHRS* — heat capacity of the initial specimen (after synthesis and purification): *AB* — partly crystalline, $\alpha = 35\%$, amorphous component of the polymer in the vitreous state; *OVL* — partly crystalline, $\alpha = 35\%$, amorphous component in the highly elastic state; *MNP* — apparent heat capacity in the melting range; *PHRS* — heat capacity of a melt containing condiscrystals, *HRS* — apparent heat capacity in the melting range of the condiscrystals, *AOZ* — heat capacity of the polymer with $\alpha = 40\%$ (obtained by cooling the melt of the initial specimen), amorphous component of the polymer in the vitreous state from 0 K to T_g° , amorphous component of the polymer in the highly elastic state from T_g° to 440 K (point *Z*); *ZWQ* — apparent heat capacity in the melting range.

subsequent experiments, these anomalies were not reproduced. The dependences of the heat capacity in the temperature range corresponding to the end of devitrification and up to the temperature of the onset of fusion coincided within the limits of 1.5%. The errors of the measurements were approximately the same. In each of the experiments, the heat capacity of the melt increased smoothly with rising temperature from T_{fus}° to 610–670 K, but the positions of the $C_p^\circ = f(T)$ curves relative to one another fell systematically from experiment to experiment becoming stabilised only in the fourth–fifth experiments (*QE*). At 600 K, C_p° decreased by $\sim 5.5\%$ from the first to the fourth and fifth experiments. The anomaly in the heat capacity in the range $T_g^\circ - T_{fus}^\circ$ was discovered by Karasz et al.⁴⁸ Its appearance was attributed to the presence in the poly-4-methylpent-1-ene specimens, together with the main crystalline modification, of a small amount of another crystalline modification formed in the synthesis of the polymer. Hitherto five different crystalline modifications are known for this polymer.^{81, 82} The anomaly in C_p° in the poly-4-methylpent-1-ene melt is apparently caused by the presence in the latter of mesomorphic formations,⁸³ which gradually decompose from experiment to experiment during the measurements of the heat capacities of the melts. In the fourth and fifth experiments,⁸⁰ the melt probably becomes fully isotropic.

Polydec-1-ene. The temperature variation of the heat capacity of isotactic polydec-1-ene has been investigated in adiabatic vacuum and dynamic calorimeters in the range 5–450 K.^{78, 84} The degree of isotacticity of the test polymer was 90% and its degree of crystallinity was 35%. Approximately 200 experimental values of C_p° were obtained in 20 series reflecting the sequence of the measurements. The averaged $C_p^\circ = f(T)$ curves are presented in Fig. 5. The amorphous component of the polymer devitrified in the temperature range 190–230 K (*NP*).

The fusion of the crystalline component of polydec-1-ene was observed in the range 240–315 K; it occurred in two stages, to each of which corresponded an apparent temperature variation of the heat capacity: *RZQM* and *MUSF*. It was found that polyolefins with bulky side substituents form crystals, like other polymers with a similar structure,⁸⁵ as a result of the crystallisation of the main polymer chains and the crystallisation of the side substituents;⁸⁶ for polydec-1-ene, they are designated by crII and

Figure 5. Heat capacity of isotactic polydec-1-ene.⁸⁴

State of the polymer: *ABC* — crII and crI crystals, *CD* — crI crystals; *AB* — vitreous, *HLE* — highly elastic, *EJ* — liquid; *ANPR* — partly crystalline ($\alpha = 35\%$); the amorphous component of the polymer in the vitreous state along section *AN* and in the highly elastic state along section *PR*; *NP* — heat capacity in the vitrification range; *RZQM* — apparent heat capacity in the melting range of crII crystals; *MUSF* — apparent heat capacity in the melting range of crI crystals.

crI respectively. On slow cooling of the polymer melt, it was possible to measure its heat capacity in the supercooled (highly elastic) state between 270 K and a temperature below the melting points of crII and crI crystals. The attempts at a more extensive supercooling terminated in each case by the spontaneous crystallisation of the polymer with the simultaneous formation of crI and crII crystals, after which the heat capacity was described by the *RZQMUSF* curve (Fig. 5). The temperature variation of the heat capacity of the polymer in the partly crystalline (*AN*), supercooled liquid (*LE*), and liquid (*EFJ*) states exhibits no singularities of any kind: it increases smoothly with increasing temperature.

V. Thermodynamic parameters of fusion

The thermodynamic parameters of fusion have been obtained for all the polyolefins investigated (Table 2) with the aid of dynamic calorimeters. The temperature corresponding to the maximum apparent heat capacity in the melting range of the polymer was adopted as the melting point T_{fus}^0 . For example, for polybut-1-ene this is the temperature at point *H* in Fig. 1. The results of

experiments with the lowest rate of heating of the calorimeter with the test substance ($< 2.7 \times 10^{-2} \text{ K s}^{-1}$) were normally employed for this purpose in accordance with the recommendations of Bernshtein and Egorov.⁸⁷ The enthalpies of fusion $\Delta_{fus}H^0(\alpha)$ were measured as a rule in three experiments and the average result with an arithmetical mean deviation was adopted as $\Delta_{fus}H^0(\alpha)$. In a separate experiment, $\Delta_{fus}H^0(\alpha)$ was calculated as the difference between the integrals of the temperature variations of C_p^0 in the melting range, obtained from the apparent (*QSHUT*) and normal (*QPDE*) heat capacity curves (Fig. 1). All the polymers investigated were partly crystalline with the exception of the fully amorphous polyisobutylene and polyhex-1-ene. The enthalpies of fusion $\Delta_{fus}H^0(\alpha)$ were obtained in experiments for a degree of crystallinity α . The molar enthalpies of fusion of the fully crystalline polymers were calculated from the formula⁸⁸

$$\Delta_{fus}H^0(\alpha = 100\%) = 100 \frac{\Delta_{fus}H^0(\alpha)}{\alpha} \quad (6)$$

The entropy of fusion $\Delta_{fus}S^0(\alpha = 100\%)$ was calculated from the values of $\Delta_{fus}H^0(\alpha = 100\%)$ and T_{fus}^0 by the formula

$$\Delta_{fus}S^0(\alpha = 100\%) = \frac{\Delta_{fus}H^0(\alpha = 100\%)}{T_{fus}^0} \quad (7)$$

We shall now consider the characteristic features of the behaviour of certain polyolefins on fusion and crystallisation. Depending on the conditions in the crystallisation of polybut-1-ene (the nature of the solvent, the rate of cooling of the melts, etc.), crystals of forms I, II, and III are produced. On heating, the crystals usually melt without interconversions, but Clampitt and Hughes⁸⁹ observed a spontaneous transition of the crystals of form II into those of form I, which occurred at $\sim 300 \text{ K}$ in the course of seven days. The temperatures and enthalpies of fusion of crystals of forms I–III, measured calorimetrically, have been published by Lebedev et al.⁶⁹ and those of crystals of forms I and II have been published by Wilski and Grever.⁷⁰

As an example, we shall consider the results of an experiment designed to determine the thermodynamic parameters of the fusion of polybut-1-ene published by Lebedev et al.⁶⁹ Fig. 6 presents the temperature variations of the heat capacity of the initial polymer specimen (curve 1) and the specimens obtained by crystallising its melt directly in the calorimeter on cooling from 500 to 200 K at different rates: 5×10^{-2} (curve 2) and $1.5 \times 10^{-2} \text{ K s}$ (curve 3). The initial specimen was crystallised from solution in isooctane during its precipitation with isopropyl alcohol, whereupon the crystalline form III was formed. Crystals of form III melted in the range 280–385 K and their fusion was completed by the onset of the crystallisation of the melt in form II. This is indicated by an exothermic process which completes the

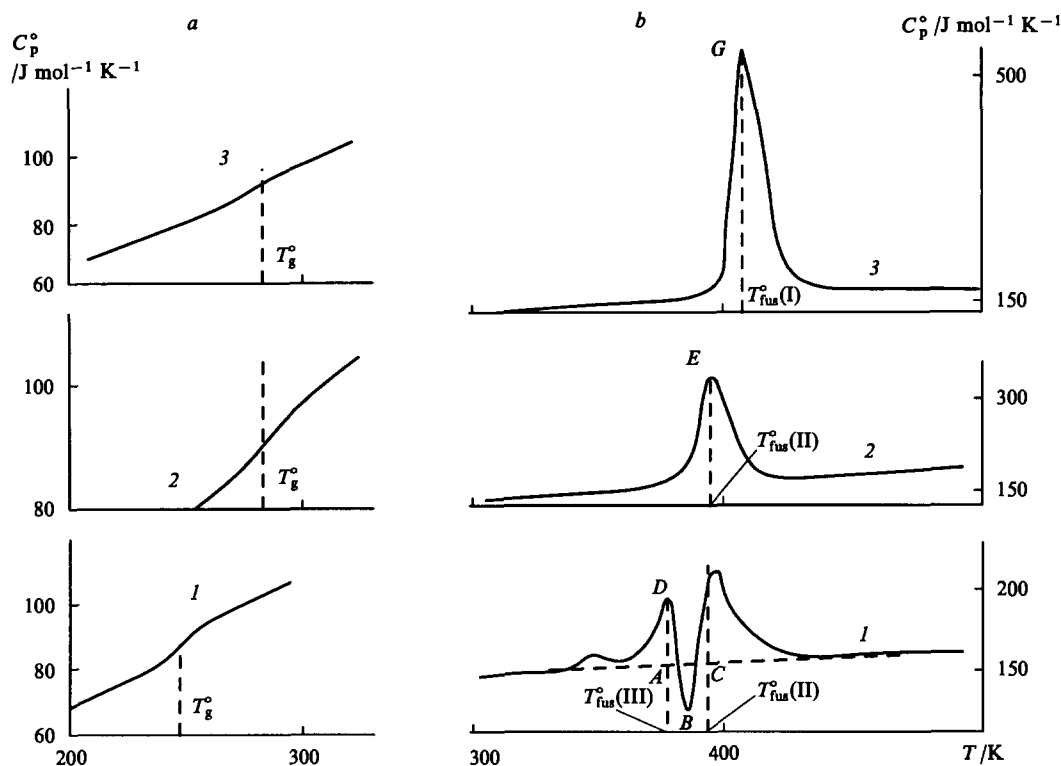

Figure 6. Heat capacity of isotactic polybut-1-ene in the temperature ranges 200–300 K (a) and 300–600 K (b) (according to dynamic calorimetric data, heating rate $1.7 \times 10^{-2} \text{ K s}^{-1}$).

(1) Specimen containing 65% of crystals of form III (with a hexagonal structure) and after their fusion and crystallisation of the amorphous component—crystals of form II (with a tetragonal structure); (2) specimen containing 83% of crystals of form II; (3) specimen containing 77% of crystals of form I (with a rhombohedral structure).

fusion of crystals of form III and precedes the fusion of crystals of form II (the ABC exotherm in Fig. 6b, curve 1). The crystals of form II produced melted in the range 340–420 K (the endotherm in the same figure). We may note that, on crystallisation from solution, the initial specimen had a degree of crystallinity of 65% (crystals of form III).

On cooling of the melt at a rate of $5 \times 10^{-2} \text{ K s}^{-1}$, crystals of form II, constituting 83% of the mass of the specimen, were formed. Crystals of form II melted in the range 340–420 K (Fig. 6b, curve 2), as for the initial polybut-1-ene specimen (curve 1). When the melt was cooled at a rate of $1.5 \times 10^{-2} \text{ K s}^{-1}$ (approximately three times lower than in the previous case), crystals of form I were produced, the degree of crystallinity amounting to 77%. The crystals melted in the range 350–450 K (curve 3). We may note that at this or slightly higher rate of cooling of the melt, a mixture of crystals of forms I and II was formed (10% and 40% respectively). This has also been observed by Dainton et al.⁴⁷ on slow cooling of the melt, a mixture consisting of 7% of crystals of form I and 37% of those of form II was obtained. The degree of crystallinity of the test polymer specimens was determined by Eqn (4) from the values of $\Delta C_p^\circ(\alpha)$ at the glass transition temperature. The values of $\Delta C_p^\circ(\alpha)$ were found graphically from the curves describing the temperature variation of the heat capacity and incorporating devitrification regions (Fig. 6a, curves 1–3). $\Delta C_p^\circ(T_g^\circ)$ is $9.7 \text{ J mol}^{-1} \text{K}^{-1}$ for the specimen containing crystals of form III, $4.3 \text{ J mol}^{-1} \text{K}^{-1}$ for the specimen with crystals of form II, and $58 \text{ J mol}^{-1} \text{K}^{-1}$ for the specimen with crystals of form I. The increase in heat capacity on devitrification of polybut-1-ene in the amorphous state is $\Delta C_p^\circ(\alpha = 0) = 27.5 \text{ J mol}^{-1} \text{K}^{-1}$ (section BL in Fig. 1).

The melting temperature ranges were determined graphically as the temperatures of the onset and end of the anomalous changes in heat capacity caused by fusion (apparent heat capacity endo-

therms in Fig. 6b, curves 1–3). The temperatures corresponding to the maximum heat capacity in the melting range were adopted as the melting points (points D, E, and G on curves 1–3). The enthalpies of fusion $\Delta H^\circ(\alpha)$ were determined by the method involving the continuous injection of energy: for the crystalline forms II and I in three experiments in each case and for form II in one experiment. This yielded $\Delta H^\circ(\alpha = 65\%) = 1.735 \text{ kJ mol}^{-1}$ for form III, $\Delta H^\circ(\alpha = 83\%) = 2.754 \text{ kJ mol}^{-1}$ for form II, and $\Delta H^\circ(\alpha = 77\%) = 5.475 \text{ kJ mol}^{-1}$ for form I. The molar enthalpies of fusion of each form were calculated by Eqn (5) from the corresponding values of $\Delta H^\circ(\alpha)$ and α . The entropies of fusion were calculated by Eqn (6) from the enthalpies of fusion and the melting points. All the thermodynamic parameters of fusion are listed in Table 2. The data of Lebedev et al.⁶⁹ and Wilski and Grever⁷⁰ agree satisfactorily. Judging from the entropy of fusion, the crystalline form I (rhombohedral crystals) is most ordered, while form III is least ordered. Wilski and Grever⁷⁰ established that form III is thermodynamically least stable. We may note that form III cannot be obtained under the conditions of calorimetric experiments on crystallisation of melts of isotactic polybut-1-ene. Furthermore, the determination of the melting temperature range for crystals of form III, crystallised from solution, is complicated by the onset of the crystallisation of the melt in form II, which masks the termination of the fusion of form III. All these factors preclude accurate measurements of the enthalpy of fusion of form III. The enthalpy and entropy of fusion of form III listed in Table 2 must therefore be regarded as only estimates.

According to data quoted by Andrianova⁷² and Raff and Doak,⁹⁰ polybut-1-ene can exist in two crystalline modifications: I (crystals with a monoclinic lattice) and II (crystals with an orthorhombic lattice). It was established that polybut-1-ene usually exists in the crystalline modification I, while modification II is formed extremely rarely. The melting points of modifications I and II are respectively 403 and 348 K. The enthalpies of fusion of

the polymer have been published.^{48,76,77} Their numerical values vary from 3.98 to 6.28 kJ mol⁻¹. The results of calorimetric measurements of the thermodynamic parameters of fusion⁷⁷ are listed in Table 2.

The thermodynamic characteristics of the fusion of poly-3-methylbut-1-ene were determined in four experiments.⁷⁸ In all the experiments, the fusion of the polymer began in the range from 500 to 540 K and ended at 610 K. The melting temperatures corresponding to the maximum apparent heat capacity varied in the melting range from 576.8 to 584.9 K from experiment to experiment. The rates of heating of the calorimeter with the test substance increased under these conditions from 1.7×10^{-2} to 3.3×10^{-2} K s⁻¹. Table 2 lists the value of T_{fus}^0 for the initial specimen (heating rate 1.7×10^{-2} K s⁻¹). For poly-3-methylbut-1-ene specimens with degrees of crystallinity of 50%, 70%, 81%, and 88%, the values of $\Delta_{fus}H^0(\alpha) = 3.04, 4.23, 4.91$, and 5.31 kJ mol⁻¹ respectively were obtained. They were recalculated for the polymer with 100% crystallinity by Eqn (6). The melting range of poly-3-methylbut-1-ene has been published as 513–583 K.⁹¹ Minsker et al.⁹² give $T_{fus}^0 = 545$ K for a specimen of isotactic poly-3-methylbut-1-ene with a degree of crystallinity of 90.5%.

Lebedev et al.⁸⁰ carried out five experiments on the fusion of poly-4-methylpent-1-ene (heating rate $\sim 3 \times 10^{-2}$ K s⁻¹) and obtained a series of melting points ranging from 521.7 K in the first experiment for the initial specimen to 508.5 K in the fifth experiment. A decrease in T_{fus}^0 from experiment to experiment was noted. In the fourth and fifth experiments, the values of T_{fus}^0 virtually coincided. A similar phenomenon has also been observed by Andrianova.⁷² The arithmetical mean of the values of T_{fus}^0 found in the fourth and fifth experiments was adopted as T_{fus}^0 for poly-4-methylpent-1-ene (Table 2). The enthalpy of fusion of the crystalline component of the specimen, obtained in the first experiment, is lower than in the fourth and fifth experiments (in the latter experiments the values of $\Delta_{fus}H^0$ are virtually identical). The value found by Karasz et al.⁴⁸ was adopted as the enthalpy of fusion of the polymer with a crystallinity of 100%.

The apparent heat capacities in the melting range of crystals of forms II and I of isotactic polydec-1-ene were measured with continuous heating of the calorimeter containing the test substance at a rate of 8×10^{-3} K s⁻¹.⁸⁴ The temperature corresponding to the maximum apparent heat capacity $C_{p,max}^0 = 555.3$ J mol⁻¹ K⁻¹ in the melting range was adopted as the melting point $T_{fus}^0(II)$ of the crystals formed by the main chains; the temperature corresponding to $C_{p,max}^0 = 495.3$ J mol⁻¹ K⁻¹ in the melting range of crystals of form I was adopted as the melting point $C_{p,max}^0(I)$ of the crystals formed by the side substituents. The enthalpies of fusion were found to be $\Delta_{fus}H^0(\alpha = 35\%; II) = 2.25$ kJ mol⁻¹ and $\Delta_{fus}H^0(\alpha = 35\%; I) = 2.53$ kJ mol⁻¹. These values were recalculated for 100% crystallinity. The degree of crystallinity was calculated by Eqn (4) from calorimetric data:⁸⁴ $\Delta C_p^0(T_g^0; \alpha = 0) = 60$ and $\Delta C_p^0(T_g^0; \alpha) = 39$ J mol⁻¹ K⁻¹. In the calculations of the degree of crystallinity, it was assumed that the value α found refers to

crystals of both form II and I. This means that, on crystallisation of the main chains of the polymer, the corresponding amount of side substituents crystallises simultaneously. In several consecutive measurements of $\Delta_{fus}H^0(II)$ and $\Delta_{fus}H^0(I)$ for different degrees of crystallinity α , it was found that the ratio

$$\frac{\Delta_{fus}H^0(II)}{\Delta_{fus}H^0(I)} = 0.7 \pm 0.2.$$

is approximately constant.

VI. Parameters of vitrification and of the vitreous state

The parameters of the vitrification and the vitreous state of the polyolefins investigated are listed in Table 3. The glass transition temperature T_g^0 was determined from the point of inflection in the plots of the temperature variation of the entropy $S^0(T) = f(T)$ in the vitrification range. The error of the determination of T_g^0 by this method is usually 0.5–1.0 K.

The availability of the relations $C_p^0 = f(T)$ for the amorphous and crystalline states and also of the temperatures and enthalpies of the physical transformations made it possible to estimate the differences between the enthalpies of the polymers in the vitreous and crystalline states $H_g^0(0) - H_{cr}^0(0)$ at $T = 0$ K and the residual (zero-point) entropy in the vitreous state $S_g^0(0)$. The corresponding calculations were performed by means of published equations,^{11,33,93} which assumed the following form for polyolefins:

$$H_g^0(0) - H_{cr}^0(0) = \int_0^{T_{fus}^0} [C_p^0(cr) - C_p^0(g)] dT + \Delta_{fus}H^0,$$

$$S_g^0(0) = \int_0^{T_{fus}^0} [C_p^0(cr) - C_p^0(g)] d \ln T + \Delta_{fus}S^0,$$

where $C_p^0(cr)$ and $C_p^0(g)$ are the temperature functions of the heat capacities of the polymer in the crystalline and vitreous states respectively.

The configurational entropy S_{conf}^0 of the vitreous polymer was calculated by Eqn (3). The Kauzmann temperature T_2^0 was found graphically from the entropy diagram, as had been done, for example, for polybut-1-ene (Fig. 7). The ratio T_g^0/T_2^0 for the polymeric and monomeric glasses is usually 1.29,^{37,38} so that S_{conf}^0 was estimated from the formula³⁷

$$S_{conf}^0 = \Delta C_p^0(T_g^0) \ln 1.29.$$

It is especially convenient for the estimation of S_{conf}^0 for vitrifying but not crystallising polymers.

According to dynamic calorimetric data,⁶⁹ the devitrification of polybut-1-ene specimens (Fig. 6) with degrees of crystallinity of 65%, 77%, and 83% occurred in the temperature ranges 230–255 K, 265–270 K, and 270–295 K respectively. The glass transition temperatures of these specimens were found to be 249 K for the first and 282 K for the other two. A dependence of

the vitrification temperature ranges and of the glass transition temperatures on the degree of crystallinity of the test specimens was traced. The higher the values of α , the higher the temperature range to which the temperature range of vitrification and T_g° are displaced. This is apparently caused by the effect due to the reinforcement of the vitreous component of the polymer by crystals,⁷³ as a consequence of which difficulties arise in the excitation of the segmental mobility of the polybut-1-ene macromolecules. The temperature T_g° obtained for poly-3-methylbut-1-ene agrees satisfactorily with $T_g^\circ = 327$ K published by Andrianova.⁷² It is of interest that the zero-point entropy of this polymer in the vitreous state was found to be zero. Strictly speaking, within the limits of experimental error and the errors associated with the assumptions made in calculations, it is equal to the zero-point entropy of the polymer in the crystalline state. It has been shown^{11,93} that $S_{cr}^\circ(0) = 0$ for polymers in the crystalline state. Apparently, the same features are characteristic of poly-3-methylbut-1-ene as for poly-4-methylpent-1-ene.⁸⁰ With decrease in the degree of crystallinity, the density of the amorphous part of the polymer increases, i.e. short-range order becomes more marked with decrease in the long-range order in the disposition of the units of the macromolecules in the crystal lattice.⁸⁰ As a result of the operation of these two effects (the increase in entropy on breakdown of long-range order and its diminution on enhancement of short-range order), the entropy changes are compensated because the above factors act in opposition.

For polyolefins at 0 K, the difference between the enthalpies of the vitreous and crystalline states varies from 1.9 kJ mol⁻¹ (for poly-3-methylbut-1-ene) to 8.4 kJ mol⁻¹ (for polydec-1-ene). The error in the values of $H_g^\circ(0) - H_{cr}^\circ(0)$ is $\sim 10\%$. Vitreous polymers, which are in principle capable of crystallising, exist in a metastable state owing to the high activation energy for the rearrangement and the extremely long relaxation times associated with this fact. Clearly the difference between the Gibbs free energies of the vitreous and crystalline states $\Delta G^\circ(a; cr)$ constitutes an estimate of the metastability of the amorphous polymer under the given conditions. For the temperature range between 0 K and T_{fus}° , the above quantity may be calculated from the difference between the enthalpies $\Delta H^\circ(a; cr)$ and the entropies $\Delta S^\circ(a; cr)$ of the amorphous and crystalline states at any temperature within the above range by the formula¹¹

$$\Delta G^\circ(a; cr) = \Delta H^\circ(a; cr) - T \Delta S^\circ(a; cr),$$

$\Delta H^\circ(a; cr)$ and $\Delta S^\circ(a; cr)$ can be readily calculated in their turn from the values of $H_g^\circ(0) - H_{cr}^\circ(0)$ and ΔS° and the temperature variations of the heat capacities of the polymer in the amorphous (vitreous and highly elastic) and crystalline states in the above

Figure 8. Temperature dependences of the enthalpy (1), entropy (2), and Gibbs free energy (3) of the transition of polybut-1-ene from the amorphous to the crystalline state in the temperature range from 0 K to T_{fus}° .

temperature range, as has been done, for example, in the studies of Lebedev and coworkers.^{7,94} Typical temperature variations of $\Delta G^\circ(a; cr)$, $\Delta H^\circ(a; cr)$, and $\Delta S^\circ(a; cr)$ are presented in Fig. 8 in relation to polybut-1-ene.

VII. Thermodynamic functions

The thermodynamic functions of polyolefins in the range 0–600 K have been calculated with the aid of their experimental heat capacities and the temperatures and enthalpies of the physical transformations. For this purpose, the heat capacity of the polymer was usually extrapolated from 5–10 to 0 K using the Debye function⁵⁹

$$C_p^\circ = nD\left(\frac{\theta_D}{T}\right), \quad (8)$$

where n and θ_D are specially selected parameters. They are usually chosen so that Eqn (8) describes the experimental heat capacities C_p° , or the average heat capacities for the range 5–15 K obtained from them, subject to an error not exceeding 1%–1.5%. In the calculation of the functions, it was assumed that at $T < 5$ –10 K the above equation reproduces the heat capacity of the polymer with the same error. Wunderlich⁹⁵ usually employed the two-parameter Tarasov heat capacity function [see Eqn (2)] to extrapolate the heat capacities of polymers. For example, the corresponding characteristic temperatures for polyethylene in the crystalline state are $\theta_1 = 519$ K and $\theta_3 = 158$ K.

The heat capacity of polyhex-1-ene was extrapolated from 20 to 0 K in terms of the specially selected equation⁹⁶

$$C_p^\circ = 0.0258T + 0.02950T^2 + 0.000417T^3.$$

Since virtually all the polymers investigated are partly crystalline with the exception of polyisobutylene and polyhex-1-ene, their thermodynamic functions were calculated by the method which makes it possible to evaluate the functions of the polymers in the fully amorphous and crystalline states from the experimental data on properties of the partly crystalline polymers.^{11,36}

The functions (Table 4) were calculated on a computer by means of the equations^{11,94}

$$H^\circ(T) - H^\circ(0) = \sum \int_0^T C_p^\circ(T) dT + \sum \Delta_{fus} H^\circ,$$

$$S^\circ(T) = \sum \int_0^T C_p^\circ(T) d \ln T + \sum \Delta_{fus} S^\circ,$$

Note. The thermodynamic functions presented have the following dimensions: $C_p^\circ(T)$ and $S^\circ(T)$ — J mol⁻¹ K⁻¹, $H^\circ(T) - H^\circ(0)$ and $G^\circ(T) - H^\circ(0)$ — kJ mol⁻¹.

$$G^\circ(T) - H^\circ(0) = [H^\circ(T) - H^\circ(0)] - TS^\circ(T),$$

where C_p° is the temperature variation of the heat capacities of the substances in the crystalline, vitreous, highly elastic, and liquid states (see, for example, Fig. 1). In the calculations of the entropy for polyisobutylene and polyhex-1-ene, it was assumed that their zero-point entropy is equal to the configurational entropy. The errors in the calculated functions are on average 1%–1.15% at $T < 20$ K, 0.5% in the range 20–50 K, ~0.2% in the range 50–340 K, and 0.5%–2% in the range 340–600 K.

VIII. Thermochemical characteristics

The thermochemical characteristics of polyolefins are listed in Table 5. The enthalpies of combustion were obtained from the experimental combustion energies $\Delta_c U$ measured calorimetrically. Since all the polymers investigated were partly crystalline, the

$\Delta_c U(\alpha)$ were found in the experiments. The results were recalculated for the standard state and the values of $\Delta_c U^\circ(\alpha)$ were obtained. They were used to calculate the enthalpies of combustion $\Delta_c H^\circ(\alpha)$. The enthalpies of combustion of the polymer in the crystalline and amorphous (vitreous or highly elastic) states were calculated in their turn from the values of $\Delta_c H^\circ(\alpha)$ and the molar enthalpy of fusion of the polymer with $\alpha = 100\%$ (calculated for $T = 298.15$ K) by means of the following relations:

$$\Delta_c H^\circ(\text{cr}) = \Delta_c H^\circ(\alpha) + (1 - \alpha)\Delta_{\text{fus}}H^\circ(298.15 \text{ K}),$$

$$\Delta_c H^\circ(\text{a}) = \Delta_c H^\circ(\alpha) - \alpha\Delta_{\text{fus}}H^\circ(298.15 \text{ K}).$$

Here α is expressed as a fraction. The enthalpy of fusion of the polymer at 298.15 K was calculated by the equation

$$\Delta_{\text{fus}}H^\circ(298.15 \text{ K}) = \Delta_{\text{fus}}H^\circ(T_{\text{fus}}^\circ) + \int_{T_{\text{fus}}}^{298.15 \text{ K}} [C_p^\circ(\text{a}) - C_p^\circ(\text{cr})]dT.$$

Table 5. Thermochemical characteristics of polyolefins at 298.15 K and the standard pressure.

^a The following designations of the states of the polymers have been adopted: cr — crystalline, g — vitreous (glassy), h.e. — highly elastic.

We may note that the application of the Kirchhoff equation is possible subject to the condition that the calculation is performed for a constant pressure. In the present instance, it is carried out at the standard pressure (101.325 kPa).

The thermochemical parameters of the formation reaction (the enthalpies $\Delta_f H^\circ$, the entropies $\Delta_f S^\circ$, and the Gibbs free energies $\Delta_f G^\circ$) of the test compounds were calculated from their calorimetric enthalpies of combustion (Table 5) and the absolute entropies (Table 4) and also the enthalpies of formation of liquid water and gaseous carbon dioxide and the entropies of carbon in the form of graphite and gaseous hydrogen, published in handbooks.⁹⁷ The methods used for the corresponding calculations have been described.^{42, 57} For example, $\Delta_f H^\circ$, $\Delta_f S^\circ$, and $\Delta_f G^\circ$ for polybut-1-ene correspond to the following reaction occurring at 298.15 K and the standard pressure:⁶⁹

The Gibbs free energy was calculated from the values of $\Delta_f H^\circ$ and $\Delta_f S^\circ$ by the equation

$$\Delta_f G^\circ = \Delta_f H^\circ - T \Delta_f S^\circ.$$

IX. Thermodynamic parameters of the formation reactions of polyolefins

The methods used to calculate the thermodynamic parameters of the polymerisation reactions from calorimetric data have been described.^{11, 13, 80} The enthalpy of polymerisation $\Delta_{\text{pol}} H^\circ$ was calculated from the enthalpies of combustion of the monomer $\Delta_c H_M^\circ$ and the corresponding polymer $\Delta_c H_P^\circ$ at 298.15 K and 101.325 kPa.

$$\Delta_{\text{pol}} H^\circ = \Delta_c H_M^\circ - \Delta_c H_P^\circ.$$

For other temperatures, the enthalpies of polymerisation were found from the Kirchhoff equation:

$$\Delta_{\text{pol}} H^\circ(T) = \Delta_{\text{pol}} H^\circ(298.15 \text{ K}) + \Delta[H^\circ(T) - H^\circ(298.15 \text{ K})], \quad (9)$$

where $\Delta[H^\circ(T) - H^\circ(298.15 \text{ K})]$ is the difference between the enthalpies of heating of the polymer and monomer in the range 298.15 K–T.

The entropy of polymerisation $\Delta_{\text{pol}} S^\circ(T)$ was calculated from the entropies of the polymer $S_P^\circ(T)$ and the monomer $S_M^\circ(T)$ at the corresponding temperatures:

$$\Delta_{\text{pol}} S^\circ(T) = S_P^\circ(T) - S_M^\circ(T).$$

The Gibbs free energy was calculated from the values of $\Delta_{\text{pol}} H^\circ(T)$ and $\Delta_{\text{pol}} S^\circ(T)$

$$\Delta_{\text{pol}} G^\circ(T) = \Delta_{\text{pol}} H^\circ(T) - T \Delta_{\text{pol}} S^\circ(T).$$

The concentrations of the monomer $[M]_e^\circ$ and the polymer $[P]_e^\circ$ in the equilibrium reaction mixture, corresponding to thermodynamic equilibrium, were estimated from the relations

$$[M]_e^\circ = \exp \frac{\Delta_{\text{pol}} G^\circ(T)}{RT},$$

$$[P]_e^\circ = 1 - \exp \frac{\Delta_{\text{pol}} G^\circ(T)}{RT}.$$

The limiting polymerisation temperatures T_{cel}° of the processes investigated were found from the point of intersection of the relations

$$\Delta_{\text{pol}} H^\circ(T) = f(T) \quad (10a)$$

and

$$T \Delta_{\text{pol}} S^\circ(T) = f(T) \quad (10b)$$

or estimated by Dainton's method.¹³

The results of the calculations are presented in Table 6. The standard enthalpy of polymerisation of gaseous ethene to partly crystalline polyethylene at 298.15 K, published by Sawada,⁹⁸ the thermodynamic functions of polyethylene,⁶⁵ the temperature dependence of the heat capacity, and the temperatures and enthalpies of the physical transformations of the monomer^{99, 100} were chosen as the initial data for the calculation of the thermodynamic parameters of the polymerisation of ethene. For propene, use was made of the value of $\Delta_{\text{pol}} H^\circ(\text{gas; cr and gas; a})$ at 298.15 K obtained by Joshi and Zvolinskii⁴⁵ and Richardson and Parks,¹⁰¹ its thermodynamic functions⁶⁸ and $C_p^\circ = f(T)$, and the temperatures and enthalpies of the phase transitions.^{102, 103}

The enthalpies of the polymerisation of isobutene have been published.^{104–107} In order to determine the thermodynamic parameters of the polymerisation, the value of $\Delta_{\text{pol}} H^\circ(\text{gas; a})$ at 298.15 K, given by Parks and Mocher,¹⁰⁷ was selected. All the other data necessary for the calculations were found in publications describing the temperature variations of the heat capacities and the temperatures and enthalpies of the physical transformations for polyisobutylene^{74–76} and isobutene.^{103, 108}

The limiting polymerisation temperatures, estimated from Eqns (10), amounted to 670 K for ethene and 550 K for propene; the estimation of this parameter for isobutene by Dainton's method¹³ yielded 390 K.

The thermodynamic parameters of the processes leading to the formation of isotactic polybut-1-ene (Scheme 1) for the temperature range 0–600 K under standard pressure have been published by Lebedev et al.⁶⁹ The enthalpies of the processes at 298.15 K and 101.325 kPa were calculated from the standard enthalpies of formation of the monomers, taken from Stull et al.,¹⁰³ and the enthalpies of formation of the polymer (Table 5). For other temperatures, the enthalpies of the processes $\Delta_r H^\circ$ were calculated from the temperature variation of the heat capacity and the temperatures and enthalpies of the phase transitions of the reactants quoted in the literature^{69, 109} and in Tables 2 and 5. The entropies of the processes $\Delta_r S^\circ$ were calculated from the absolute entropies of the reactants, while the Gibbs free energies $\Delta_r G^\circ$ were evaluated from the values of $\Delta_r H^\circ$ and $\Delta_r S^\circ$ for the corresponding temperatures.

Scheme 1

The upper limiting temperatures T_{cel}° for the direct conversion of but-1-ene, *cis*- and *trans*-but-2-enes, and ethene into isotactic polybut-1-ene (processes 1, 3, 4, and 2) were estimated by Dainton's method¹³ from the quantities $\Delta_r H^\circ$ and $\Delta_r S^\circ$ for the polymerisation reaction. They are respectively 520, 500, 490, and 640 K.

The following relations hold at different temperatures:

$$\Delta_r G^\circ < 0 \text{ at } T < T_{\text{cel}}^\circ,$$

$$\Delta_r G^\circ = 0 \text{ at } T = T_{\text{cel}}^\circ,$$

$$\Delta_r G^\circ > 0 \text{ at } T > T_{\text{cel}}^\circ.$$

This means that at $T < T_{\text{cel}}^\circ$ the equilibria in the processes are displaced towards the formation of the polymer and the polymer produced is thermodynamically stable in relation to depolymerisation to the initial monomer; at $T > T_{\text{cel}}^\circ$, the polymer is unstable in relation to the above monomers and rapidly depolymerises under kinetic conditions. In contrast to processes 3 and 4, processes 5 and 6 have lower limiting temperatures — 830 and 910 K respectively. It has been shown^{3, 110} that isotactic polybut-1-ene can be obtained from *cis*- and *trans*-but-2-enes after their

isomerisation to but-1-ene, the yield of the polymer being low. This can be explained by the fact that, since $\Delta_r G^\circ$ for processes 5 and 6 is positive, the equilibrium concentration of but-1-ene in the reaction mixture is low. The reaction equilibrium is displaced towards an increase in the concentrations of but-1-ene with increase in temperature, since $\Delta_r G^\circ$ diminishes. This should increase the yield of polybut-1-ene.

The poly-pent-1-ene formation reactions may be represented by the Scheme 2:

Scheme 2

Chao and Hell¹¹¹ calculated the thermodynamic parameters of processes 1–5 for the temperature range 0–500 K from the results of Lebedev et al.⁷⁷ and the corresponding data on the initial monomers,^{77,111} the enthalpies of the processes at 298.15 K from the enthalpies of formation of the reactants (see Table 5 and Lebedev et al.⁷⁷ and Chao and Hell¹¹¹), and the enthalpies of the processes at other temperatures from the Kirchhoff formula [Eqn (9)]. The temperature variations of the heat capacities and the temperatures and enthalpies of the physical transformations of the reactants were used in the calculations (see Tables 2–4 and Lebedev et al.⁷⁷ and Chao and Hell¹¹¹). The results show that the monomer \rightleftharpoons polymer equilibria in processes 1–3 are displaced towards the formation of poly-pent-1-ene: over the entire temperature range investigated, $\Delta_{\text{pol}} G^\circ < 0$; the absolute values of $\Delta_{\text{pol}} G^\circ$ for the processes decrease with increase in temperature. The enthalpies and entropies of these processes are also negative, which is the reason for the existence of the upper limiting polymerisation temperatures T_{ceil}° . Estimation by Dainton's method¹³ yielded the following values: 590 K for process 1, 560 K for process 2, and 550 K for process 3. Evidently, the thermodynamic characteristics of the polymerisation reactions of the isomeric pentenes diminish in the sequence pent-1-ene > cis-pent-2-ene > trans-pent-2-ene.

One should bear in mind that poly-pent-1-ene is not obtained directly in processes 2 and 3;³ its formation is preceded by the stage involving the conversion of *cis* and *trans*-pent-2-enes into pent-1-ene (processes 4 and 5). The $\Delta_r G^\circ$ for these processes are positive. This means that the reaction equilibrium is displaced to the left. However, since at elevated temperatures the Gibbs free energies $\Delta_r G^\circ$ of the processes are small, the equilibrium reaction mixtures contain a certain amount of pent-1-ene formed from *cis* and *trans*-pent-2-enes. For example, at 500 K the mole fractions of pent-1-ene in the reaction mixture are ~ 0.20 (process 4) and ~ 0.10 (process 5). These concentrations were calculated from the thermodynamic equilibrium constants for these processes K_r° , which were in their turn evaluated from the equation of the van't Hoff isotherm.

As the temperature decreases, the equilibrium concentrations of pent-1-ene in the above processes also decrease. This is the reason for the low rates of conversion of *cis* and *trans*-pent-2-enes into poly-pent-1-ene and the low yield of the polymer during the reaction time. This situation may be altered as a result of the search for more effective isomerisation catalysts, an increase in the concentration of the catalyst in the reaction mixture, or the discovery of physicochemical conditions leading to the displacement of the equilibria 4 and 5 to the right. However, one should bear in mind that the increase of, for example, the pressure does not shift the equilibrium because reactions 4 and 5 proceed without change in the number of moles of the reactants. Varia-

tion of the solvent is also apparently relatively ineffective, since the physicochemical properties of the isomers are similar and the nature of their interaction with the solvent is virtually the same.

An increase in temperature may be comparatively effective. Extrapolation of the $\Delta_r H^\circ = f(T)$ and $T\Delta_r S^\circ = f(T)$ relations for the process under consideration leads to temperatures of 2800 and 1700 K at which the $\Delta_r G^\circ$ for processes 4 and 5 changes sign (from plus to minus). However, the upper limiting temperature of the polymerisation of pent-1-ene is only 590 K, so that the limits within which the temperature can be varied are restricted.

The thermodynamic parameters of the polymerisation of 3-methylbut-1-ene have no singularities of any kind:^{78,111} $\Delta_{\text{pol}} H^\circ$ and $\Delta_{\text{pol}} S^\circ$ are negative throughout and their absolute values increase with increasing temperature; the Gibbs free energy of polymerisation is negative, diminishing with increase in temperature; the upper limiting polymerisation temperature is $T_{\text{ceil}}^\circ = 572$ K.

The enthalpy of the polymerisation of liquid hex-1-ene to highly elastic polyhex-1-ene at 298.15 K and 101.325 kPa is -101 kJ mol⁻¹. This value was obtained by the author of the present review from the enthalpies of formation of the liquid monomer $\Delta_f H^\circ(298.15 \text{ K}) = -72.38$ kJ mol⁻¹ (see Ref. 103) and the highly elastic polymer $\Delta_f H^\circ(298.15 \text{ K}) = 173.6$ kJ mol⁻¹, calculated from the equation quoted by Lebedev and Kiparisova.⁴⁶ The calculated enthalpy of the polymerisation of hex-1-ene, $\Delta_{\text{pol}} H^\circ = -82.8$ kJ mol⁻¹, published by Lebedev and Lebedev,⁹⁶ is significantly too low.

The thermodynamic functions of hex-1-ene in the range 0–300 K have been published by Lebedev and Lebedev.⁹⁶ All these data, together with the results presented in Table 4, have been used to calculate the thermodynamic parameters of the polymerisation of hex-1-ene in bulk in the range 0–300 K (Table 6). Evidently the change in the standard Gibbs free energy $\Delta_{\text{pol}} G^\circ(T)$ is negative throughout, while the numerical values are such that one may conclude that the equilibrium is almost fully displaced to the right. Extrapolation based on the $\Delta_{\text{pol}} H^\circ(T) = f(T)$ and $T(\Delta_{\text{pol}} G^\circ(T)) = f(T)$ relations for the liquid monomer \rightarrow highly elastic polymer process leads to an upper limiting polymerisation temperature of 865 K. The thermodynamic equilibrium concentration of the monomer in the reaction mixture $[M]_e^\circ = 2 \times 10^{-12}$ M was estimated from the equation of the van't Hoff isotherm and the value of $\Delta_{\text{pol}} G^\circ(300 \text{ K})$.

The reactions leading to the formation of isotactic poly-4-methylpent-1-ene may be represented by the Scheme 3:

Scheme 3

The reactions leading to the polymerisation of 4-methylpent-1-ene and *cis* and *trans*-4-methylpent-2-enes to poly-4-methylpent-1-ene in bulk and the reaction in which propene dimerises to 4-methylpent-1-ene have upper limiting polymerisation temperatures which are respectively 590, 540, 530, and 570 K. The numerical values of T_{ceil}° were found graphically from the intersection of the corresponding temperature variations of the enthalpies and the entropy factors: $\Delta_r H^\circ = f(T)$ and $T\Delta_r S^\circ(T) = f(T)$. The enthalpies and entropies were taken from Table 6. At $T < T_{\text{ceil}}^\circ$, the equilibria in processes 1–4 in Scheme 3 are displaced towards the formation of the reaction products ($\Delta_r G^\circ < 0$). The enthalpies and entropies of these processes are

Table 6. The enthalpies (kJ mol^{-1}), entropies ($\text{J mol}^{-1} \text{K}^{-1}$), and Gibbs free energies (kJ mol^{-1}) of the polymerisation of olefins in bulk with formation of polyolefins under standard pressure.

^a The following designations of the states of the polymers have been adopted: l — liquid, gas — gaseous, ov.l — supercooled liquid.

^b L Ya Tsvetkova's data. ^c N Smirnova's data.

negative throughout and their numerical values depend on the physical state of the reactants and increase with increasing temperature.

The isomerisation reactions of *cis* and *trans*-4-methylpent-2-enes (processes 5 and 6) have neither an upper nor a lower limiting temperature, which is characteristic of processes for which $\Delta_r H^\circ > 0$ and $\Delta_r S^\circ < 0$.¹¹ For this reason, the change in the Gibbs free energy is positive. In processes 5 and 6 under consideration, the free energies $\Delta_r G^\circ$ have small positive values: $\Delta_r G^\circ < 10 \text{ kJ mol}^{-1}$. This means that a small amount of 4-methylpent-1-ene is present in the equilibrium reaction mixture of the isomers. In this case, a shift of the equilibrium is possible provided that 4-methylpent-1-ene is continuously removed from the reaction mixture, for example when it is polymerised to poly-4-methylpent-1-ene, which does in fact occur in the isomeric polymerisation of *cis*- and *trans*-alk-2-enes to polyalk-1-enes.³

Owing to the similarity of the heat capacities of 4-methylpent-1-ene and the *cis*- and *trans*-isomers of 4-methylpent-2-enes, the influence of temperature on $\Delta_r H^\circ(T)$ and $\Delta_r S^\circ(T)$ is small. The enthalpies of the processes were calculated from the enthalpies of formation of 4-methylpent-1-ene,¹¹² *cis*- and *trans*-methylpent-2-enes,¹⁰³ propene,¹⁰³ and poly-4-methylpent-1-ene.⁸⁰ The entropies of the reactants required for the calculation of $\Delta_r S^\circ(T)$ were taken from Lebedev et al.⁸⁰ and Stull et al.¹⁰³

As for other olefins, the enthalpy and entropy of the polymerisation of dec-1-ene are negative throughout.⁸⁴ It follows from this that the polymerisation process has an upper limiting temperature. Indeed, $\Delta_{\text{pol}} G^\circ(T)$ decreases in absolute magnitude with increase in temperature and becomes zero at $T_{\text{ceil}}^\circ = 890 \text{ K}$, while at $T > T_{\text{ceil}}^\circ$ it is positive throughout. T_{ceil}° was estimated by Dainton's method.¹³ The T_{ceil}° obtained is apparently appreciably higher than the temperature of the onset of the thermal degradation of the polymer.

X. Principal regularities and characteristics of the thermodynamic properties of polyolefins and of the parameters of their formation reactions[†]

1. Thermodynamic functions

Since the C₂-C₆ and C₁₀ polyolefins with linear side substituents which have been investigated differ from one another by the number of methylene groups in these substituents, one may expect, for the same physical state of the polymers and under identical temperatures and pressures, a regular change in the thermodynamic properties as a function of the number of carbon atoms *n* in the repeat units of the polymers, as happens, for example, in the paraffins,¹¹³ polyalkenes,⁷ polyaldehydes,¹¹⁴ and polylactones.⁶⁴

The existence of such relations is due to the regular additive contribution of the methylene groups to the corresponding properties of the above polymers. It was found that this is fully valid also for polyolefins. As an example, Figs 9–11 present the isotherms (298.15 K) of the thermodynamic properties of polyolefins. Evidently, the dependences of the heat capacity *C_p*^o, the enthalpy *H*^o(*T*) – *H*^o(0), the entropy *S*^o(*T*), and the Gibbs free energy on *n* are represented by straight lines described satisfactorily by the equations

$$C_p^o(\text{cr}) = -8 + 25.5n, \quad (11)$$

$$C_p^o(\text{h.e.}) = 8 + 27.8n, \quad (12)$$

$$[H^o(T) - H^o(0)](\text{cr}) = -1.1 + 4.0n, \quad (13)$$

$$[H^o(T) - H^o(0)](\text{h.e.}) = -2.42 + 4.68n, \quad (14)$$

$$S^o(\text{cr}) = -21.2 + 30.2n, \quad (15)$$

$$S^o(\text{h.e.}) = -17.8 + 32.2n, \quad (16)$$

$$[G^o(T) - H^o(0)](\text{cr}) = 6.1 - 5.2n, \quad (17)$$

[†]Prepared jointly with the senior scientific member of the Institute of Chemistry at the Nizhni Novgorod State University, Candidate in Chemical Sciences N N Smirnova.

Figure 9. Isothermal dependences of the heat capacities of polyolefins with linear side substituents on the number of carbon atoms *n* in the monomer repeat unit.

State of the polymer: (I) crystalline; (2) highly elastic at *T* = 298.15 K; (3) crystalline and vitreous at *T* = 200 K; (I) experimental values; (II) extrapolated data.

Figure 10. Isothermal dependences of the enthalpies (1, 2) and Gibbs free energies (3, 4) of polyolefins with linear side substituents on the number of carbon atoms *n* in the monomer repeat unit at 298.15 K.

State of the polymer: (I) and (3) highly elastic; (2) and (4) crystalline; (I) experimental values; (II) extrapolated data.

$$[G^o(T) - H^o(0)](\text{h.e.}) = 3.5 - 5.1n. \quad (18)$$

The equations were obtained using experimental *C_p*^o data and data calculated from the temperature variations of the heat capacities, the temperatures and enthalpies of the physical transformations, and the enthalpies, entropies, and Gibbs free energies of the polyolefins investigated. The corresponding experimental values of *C_p*^o agree, subject to an error to within 2.5%, with the heat capacities calculated by Eqns (11) and (12); the enthalpies calculated by Eqns (13) and (14) and the entropies calculated by Eqns (15) and (16) agree with experimental values to within 2% and 3% respectively. This makes it possible in its turn to estimate the numerical values for a series of hitherto uninvestigated polyolefins in the same physical states and for the same physical conditions. The results of these estimates by Eqns (11)–(18) are presented in Table 7 for the closest analogues of the polyolefins investigated. We suggest that the errors of these estimates for *C_p*^o, *H*^o(*T*) – *H*^o(0), *S*^o, and *G*^o(*T*) – *H*^o(0) are within the limits of 3%.

Table 7. Thermodynamic functions of a series of higher polyolefins calculated by Eqns (11)–(18) for *T* = 298.15 K and *p* = 101.325 kPa.

Figure 11. Isothermal dependences of the entropies of polyolefins with linear side substituents on the number of carbon atoms n in the monomer repeat unit.

State of the polymer: (I) crystalline; (2) highly elastic at $T = 298.15$ K; (I) experimental values; (II) extrapolated data.

2. Thermochemical parameters of the formation reactions

The enthalpies of combustion $\Delta_c H^\circ$ and formation $\Delta_f H^\circ$ and the entropies of formation $\Delta_f S^\circ$ of the C_2 – C_6 polyolefins investigated as well as their thermodynamic functions are described satisfactorily by the relations between the thermochemical parameters and the number of carbon atoms in the monomer repeat unit in the macromolecule. At $T = 298.15$ K and the standard pressure, we have

$$\Delta_c H^\circ(\text{cr}) = -4.3 - 648.95 n, \quad (19)$$

$$\Delta_c H^\circ(\text{h.e.}) = -7.97 - 649.5 n, \quad (20)$$

$$\Delta_f H^\circ(\text{cr}) = 4.4 - 30.4 n, \quad (21)$$

$$\Delta_f H^\circ(\text{h.e.}) = 8.35 - 29.9 n. \quad (22)$$

The deviations of the experimental enthalpies of combustion from the corresponding straight lines [Eqns (19) and (20)] are within the limits of 2.3% and the deviations of the enthalpies of formation [Eqns (21) and (22)] are within the limits of 5%.

Under the same physical conditions, the entropies of formation of the polyolefins considered are described by the following equations

$$\Delta_f S^\circ(\text{cr}) = -6.1 - 108 n, \quad (23)$$

$$\Delta_f S^\circ(\text{h.e.}) = -3.8 - 105.4 n. \quad (24)$$

Table 8. The enthalpies of combustion and thermochemical parameters of the formation of a series of higher polyolefins calculated by Eqns (19)–(24) for $T = 298.15$ K and $p = 101.325$ kPa.

Substance	Physical state	$-\Delta_c H^\circ$ /kJ mol ⁻¹	$-\Delta_f H^\circ$	$\Delta_f G^\circ$	$-\Delta_f S^\circ$ /J mol ⁻¹ K ⁻¹
Polyhept-1-ene	cr	4547	208.4	18.8	762
	h.e.	4554	201.0	20.2	742
Polyoct-1-ene	cr	5196	238.8	20.6	870
	h.e.	5204	230.9	21.6	847
Polynon-1-ene	cr	5845	269.2	22.4	978
	h.e.	5853	260.8	23.0	952
Polyundec-1-ene	cr	7143	330.0	26.0	1194

Polydodec-1-ene	cr	7792	360.4	27.8	1302
	h.e.	7802	350.5	27.9	1269

The deviations of the experimental values of $\Delta_f S^\circ$ from the calculated entropies are within the limits of 2%.

The relations discovered also made it possible to estimate the corresponding thermodynamic characteristics for the hitherto uninvestigated polyolefins and to calculate $\Delta_f G^\circ$ from the values of $\Delta_f H^\circ$ and $\Delta_f S^\circ$ for these substances (Table 8).

3. Thermodynamic parameters of fusion

Polymorphism is characteristic of higher polyolefins.^{72, 90} Starting with polydecene,⁸⁶ two types of crystals appear on crystallisation: those formed by the main chains of the macromolecules and by the side substituents respectively. The thermodynamic parameters of the fusion of various crystalline modifications of the same polyolefin differ markedly. For example, the crystalline form III of polybut-1-ene melts at 374 K, while form I melts at 407 K; the enthalpies and entropies of the fusion of these forms are respectively 2.67 and 7.11 kJ mol⁻¹ and 7.14 and 17.5 J mol⁻¹ K⁻¹. The melting points of the polydec-1-ene crystals formed by the main chains and side substituents (276 and 301 K) differ by 25 K, whereas their enthalpies and entropies of fusion differ only slightly. For the majority of polyolefins, having several crystalline modifications the thermodynamic parameters of the fusion of one or two have been investigated. For example, poly-4-methylpent-1-ene is known to be capable of forming five different crystalline modifications.⁸⁰

The thermodynamic characteristics of only one of them have been investigated hitherto (Table 2).⁸⁰ Owing to the insufficient amount of experimental data, the search for quantitative regularities in the thermodynamic characteristics of the fusion of polyolefins is so far difficult. One may only note that, among the polyolefins investigated, polydecene has the lowest melting point (276 K). Crystals of form II, formed from the main chain, melt at this temperature. The highest melting point is that of poly-4-methylpent-1-ene (508 K). Polybut-1-ene (crystalline form III) has the lowest enthalpy of fusion (2.67 kJ mol⁻¹), whilst poly-4-methylpent-1-ene has the highest enthalpy of fusion (10.24 kJ mol⁻¹). The entropies of fusion of polyolefins are in the range from 7 to 20 J mol⁻¹ K⁻¹.

4. Parameters of the vitrification process and of the vitreous state

The glass transition temperatures of polyolefins with linear side chains decrease from 249 K for polybut-1-ene to 208 K for polydec-1-ene. For polyolefins with branched side substituents, T_g° is greater than for polyolefins with unbranched substituents. For example, the glass transition temperatures of poly-3-methylbut-1-ene and poly-4-methylpent-1-ene are respectively 327 and 300 K. T_g° for poly-3-methylbut-1-ene is higher by 100 K than for its structural isomer poly-4-methylpent-1-ene, while T_g° for poly-4-methylpent-1-ene is higher than that for polyhex-1-ene. This interesting fact requires additional analysis.

The increase in heat capacity on devitrification $\Delta C_p^\circ(T_g^\circ)$ is in the range from 21 to 34 J mol⁻¹ K⁻¹ for all the polyolefins investigated and corresponds, on according to Wunderlich,⁸³ to between 2.5 and 3 'beads' — kinetically independent atomic groups — in the monomer repeat unit of the polymer. However, $\Delta C_p^\circ(T_g^\circ) = 60$ J mol⁻¹ K⁻¹ for polydec-1-ene, which corresponds to virtually five 'beads'. Clearly this is due to the appearance of additional independently vibrating atomic groups in connection with the increase in the length of the side substituent.

In the vitreous state at $T = 0$ K, the entropies of the polymers $S_g^\circ(0)$ are small for the majority of higher polyolefins, varying from 0 for poly-3-methylbut-1-ene to 8 for poly-4-methylpent-1-ene. The fact that $S_g^\circ(0)$ is zero for poly-3-methylbut-1-ene is associated with the characteristic features of its structure in the crystalline and vitreous states, the same as for poly-4-methylpent-1-ene, which have been examined in detail.⁸⁰ The main reason is that in the crystalline polymer the packing density of the fragments of the macromolecules is smaller than in the vitreous

polymer. In particular, this leads to a decrease in T_g° as well as the density of such polymers with increase in the degree of crystallinity. Conversely, these parameters increase as the polymer passes from the partly crystalline to the amorphous glassy state.

The value $S_g^\circ(0) = 26 \text{ J mol}^{-1} \text{ K}^{-1}$, usual for amorphous polymers, has been observed for polydec-1-ene. For understandable reasons, the polymers in the vitreous state have an excess enthalpy compared with the crystalline state. In polyolefins, this excess $H_g^\circ(T) - H_{cr}^\circ(0)$ varies from 2 J mol^{-1} for poly-3-methylbut-1-ene to 8.4 J mol^{-1} for polydec-1-ene.

5. Thermodynamic characteristics of polymerisation reactions

In the temperature range investigated, the formation reactions of the higher polyolefins by the polymerisation of the corresponding monomers in bulk under standard pressure are thermodynamically allowed. The standard Gibbs free energy $\Delta_{pol}G^\circ$ is negative throughout. At 298.15 K and the standard pressure, $\Delta_{pol}G^\circ$ is in the range from 80 kJ mol^{-1} for the polymerisation reaction of but-1-ene to 116 kJ mol^{-1} for the polymerisation of dec-1-ene (the monomers and the polymers are in the liquid and highly elastic states respectively). Clearly the monomer \rightleftharpoons polymer reaction equilibrium is almost fully displaced towards the formation of the polymer. The enthalpies $\Delta_{pol}H^\circ$ and entropies $\Delta_{pol}S^\circ$ are also negative, so that all the processes considered have the corresponding upper limiting polymerisation temperatures. It is noteworthy that they are all comparatively high and are in the range from 390 K for polyisobutylene to 890 K for polydec-1-ene.

Figure 12 presents the dependences of the enthalpies, entropies, and Gibbs free energies for the polymerisation of olefins in bulk with formation of the corresponding higher polyolefins at 298.15 K and 101.325 kPa on the number of carbon atoms n in the molecules of the initial olefins and the corresponding monomer repeat units in the polymer macromolecules produced (the monomers and polymers were in the liquid and highly elastic states respectively). Evidently, the enthalpies (heats) of the polymerisation reactions increase smoothly from ethene ($n = 2$) to dec-1-ene ($n = 10$), curve 1 tending to a constant value of $\Delta_{pol}H^\circ$ with increase in n .

Lebedev and Rabinovich¹¹⁸ showed that the enthalpy of the polymerisation of a monomer via a C=C bond may be represented by the following sum:

$$\Delta_{pol}H^\circ(T) = \Delta E_{at} + \Delta E_{conj} + \Delta E_{s.s.} + \Delta E_{mol} + \Delta[H^\circ(T) - H^\circ(0)], \quad (25)$$

Figure 12. The enthalpies (I), entropies (2), and Gibbs free energies (3) of the polymerisation of olefins in bulk at $T = 298.15 \text{ K}$ and the standard pressure. Monomers and polymers in the liquid and highly elastic states respectively; (I) experimental values; (II) extrapolated data.

where ΔE_{at} is the difference between the average energies of the atomic C=C bond being ruptured and the two atomic C—C bonds being formed, ΔE_{conj} is the difference between the conjugation energies of the atomic bonds in the monomer and the polymer, $\Delta E_{s.s.}$ is the difference between the energies of the steric strain in the polymer and the monomer, ΔE_{mol} the difference between the energies of the intermolecular interaction in the monomer and the polymer at 0 K, and $\Delta[H^\circ(T) - H^\circ(0)]$ the difference between the energies associated with the heating of the polymer and the monomer. It is known that $\Delta E_{at} = 88 \text{ kJ mol}^{-1}$, $\Delta E_{conj} = 9 \text{ kJ mol}^{-1}$ (the hyperconjugation energy in the monomer), $\Delta E_{s.s.} < 4 \text{ kJ mol}^{-1}$ for the polymerisation reactions of monosubstituted vinyl monomers, and $\Delta E_{mol} = 34 \text{ kJ mol}^{-1}$ for the monomers having the same structure. It is found that the change of $\Delta_{pol}H^\circ$ is caused solely by the contribution of $\Delta[H^\circ(T) - H^\circ(0)]$. In fact, the experimental values of $\Delta[H^\circ(T) - H^\circ(0)]$ increase with increase in n and agree, within the limits of the error of the calculations and the assumptions made, with the values obtained by converse calculation from Eqn (25). For example, the experimental and calculated values of $\Delta[H^\circ(T) - H^\circ(0)]$ are 34 and 32 kJ mol^{-1} respectively for the polymerisation of but-1-ene; for polypent-1-ene, the respective values are 40 and 41 kJ mol^{-1} . In both cases, the monomer and the polymer are in the gaseous and highly elastic states respectively at 298.15 K; under these conditions, Eqn (25) yields the best results.

The entropy of polymerisation $\Delta_{pol}S^\circ$ (the monomer and polymer are in the liquid and highly elastic states respectively) at 298.15 K is approximately constant. The decrease in the entropy of the reaction is caused mainly by the formation of chains and corresponds to the rule established by Dainton and Ivin.¹³ According to this rule, the polymerisation of liquid monomers via the C=C bond to amorphous polymers leads to a decrease in entropy by $105\text{--}125 \text{ J mol}^{-1} \text{ K}^{-1}$ (usually by $125 \text{ J mol}^{-1} \text{ K}^{-1}$). In the polymerisation of the above olefins, the entropy diminishes by $120 \text{ J mol}^{-1} \text{ K}^{-1}$.

The Gibbs free energy of polymerisation, like the enthalpy of polymerisation, also gradually increases with increase in n and the form of the dependence of $\Delta_{pol}G^\circ$ on n (Fig. 12, curve 3) resembles the corresponding dependence of $\Delta_{pol}H^\circ$ on n (curve 1). This is of course associated with the fact that $\Delta_{pol}H^\circ$ varies with increase in n , while the entropy factor $T\Delta_{pol}S^\circ$ ($T = 298.15 \text{ K}$) is constant and independent of n . It therefore follows from the equation

$$\Delta_{pol}G^\circ = \Delta_{pol}H^\circ - 298.15 \Delta_{pol}S^\circ$$

that the forms of the curves representing the $\Delta_{pol}H^\circ$ and $\Delta_{pol}G^\circ$ isotherms as a function of n should be identical.

The existence of smooth dependences of the enthalpies, entropies, and Gibbs free energies of the polymerisation of olefins on n made it possible to estimate the thermodynamic characteristics of the polymerisation reactions of olefins (at 298.15 K and 101.325 kPa) for which experimental determinations have not yet been made. The results of the estimates are as follows (kJ mol^{-1}):

	Hept-1-ene	Oct-1-ene	Non-1-ene
$-\Delta_{pol}H^\circ$	107	111	114
$-\Delta_{pol}G^\circ$	72	76	79

In all cases, the monomer and polymer were in the liquid and highly elastic states and the entropy of polymerisation was $120 \text{ J mol}^{-1} \text{ K}^{-1}$.

In conclusion we may note that, in the analysis and generalisation of the thermodynamic characteristics of polyolefins and the parameters of the polymerisation reactions of the corresponding olefins published in the literature, the most reliable values were selected (Tables 2–6). These parameters are recommended for practical use. The quantitative dependences of the thermodynamic properties and parameters of the reactions on the composition and structure of the monomer repeat units in the macromolecules of the polyolefins, on the physical state of the

reactants, and on temperature at the standard pressure have been discovered. They have been used to estimate the numerical values for the corresponding polyolefins in the series polyethylene to polydecene which have not yet been investigated experimentally.

Abstract. The thermodynamic properties of polylactones and the thermodynamic parameters of their formation reactions involving the polymerisation of lactones in the range 0–400 K are examined on the basis of the results of calorimetric studies. The selected thermodynamic quantities which have been recommended for use are presented. The regularities and characteristics of the thermodynamic properties and parameters of the lactone polymerisation reaction and their dependence on the composition, structure and physical state of the reactants and on temperature at the standard pressure are described. The bibliography includes 99 references.

I. Introduction

Polylactones are obtained by the polymerisation of the corresponding lactones in accordance with the scheme

The interest in the thermodynamic properties of polylactones and the thermodynamic parameters of the reactions involving their synthesis is due to the wide variety of theoretical and applied studies on reactants and reactions^{1–5} in connection with the good prospects for the practical employment of polylactones as complex aliphatic polyesters with a chain structure.^{6–8} A series of polylactones and their copolymers are being manufactured industrially and are used in practice. As an example, one may point to polyglycolide and its copolymers with lactide, which are used in medicine as biocompatible surgical materials,^{7,9} and to polypivalolactone^{10,11} and poly-β-butyrolactone,^{3,8} which are used as biodegradable materials. The thermodynamic character-

istics of polylactones and their formation reactions are needed in the planning and implementation of theoretical and applied developments designed to obtain and process these materials and in the development of industrial technologies for their manufacture and conversion into articles.¹² The thermodynamic parameters of the polymerisation reactions of lactones are used in the search for the optimum physical conditions in their implementation, ensuring the maximum yield of products, for the determination of the temperature ranges of thermodynamic stability of polylactones relative to their depolymerisation to the initial monomers, and also for the determination of the temperature ranges corresponding to the existence of the polymers in particular physical states, which in many respects determine their specific applications.^{13,14}

Spontaneous polymerisation of the monomers takes place when the Gibbs free energy $\Delta_{\text{pol}}G(T, p)$ decreases.¹⁵ The standard Gibbs free energy $\Delta_{\text{pol}}G^\circ(T)$, characterising the state of thermodynamic equilibrium in the reaction, indicates directly the possibility or impossibility in principle, from the thermodynamic standpoint, of the conversion of the lactone into the corresponding polylactone under specific physicochemical conditions.^{13,15,16} For $\Delta_{\text{pol}}G^\circ(T) < 0$, the process equilibrium is displaced to the right — towards the formation of the polymer, while for $\Delta_{\text{pol}}G^\circ(T) > 0$ it is actually displaced to the left and the monomer predominates in the equilibrium reaction mixture. If the positive standard Gibbs free energy is less than 40 kJ mol^{–1}, then change of the physicochemical conditions in carrying out the reaction may lead to a change in the sign of $\Delta_{\text{pol}}G(T)$ and to a shift of the equilibrium to the right.¹⁶ For $\Delta_{\text{pol}}G^\circ(T) > 40$ kJ mol^{–1}, the spontaneous reaction is thermodynamically prohibited. In this case, the conversion of the monomer into the polymer is possible only with expenditure of energy from outside.

If the positive value of $\Delta_{\text{pol}}G^\circ(T)$ is small, then a low equilibrium polymer concentration corresponds to it in the equilibrium reaction mixture. If it is possible to create conditions such that the polymer formed is removed continuously from the equilibrium reaction mixture, then the conversion of the monomer into the polymer can be continued until the complete exhaustion of the monomer. Realistically this is possible, for example, in cases where the polylactone formed is insoluble in the reaction mixture and precipitates.¹⁷ Calculations have shown that the standard Gibbs free energy for δ-valerolactone and ε-caprolactone are

negative, whilst those for γ -butyrolactone are positive.¹³ Accordingly, δ -valerolactone and ϵ -caprolactone are readily converted into the corresponding polymers under the influence of catalysts; γ -butyrolactone cannot be polymerised under the same physico-chemical conditions. However, an increase in pressure from 10^5 to 2×10^9 Pa alters the sign of $\Delta_{\text{pol}}G(T)$ and leads to the virtually complete conversion of the monomer into poly- γ -butyrolactone.

The yield of the polymer corresponding to thermodynamic equilibrium and the content of the residual monomer in the polymer at any temperature for which the standard Gibbs free energy is known may be readily calculated from the values of $\Delta_{\text{pol}}G^\circ(T)$.¹⁴ $\Delta_{\text{pol}}G^\circ(T)$ may be calculated if the enthalpies $\Delta_{\text{pol}}H^\circ(T)$ and entropies $\Delta_{\text{pol}}S^\circ(T)$ of polymerisation are known. The latter are usually found from the results of calorimetric measurements. The calculation of these quantities from the equilibrium concentrations of the monomer $[M]_e$ in the reaction mixture as a function of temperature, as averages for a certain temperature range in which $\Delta_{\text{pol}}H^\circ(T)$ and $\Delta_{\text{pol}}S^\circ(T)$ are independent of temperature or depend little on the latter, is possible in principle.¹⁸ When this method is used, it is necessary to monitor rigorously the onset of the polymerisation-depolymerisation equilibrium in the reaction mixture at a specified temperature and pressure.^{18–20} One must bear in mind that the approach to equilibrium is frequently slow, usually owing to the high viscosity of the reaction mixture.

For several of the lactone polymerisation reactions investigated, the quantities $\Delta_{\text{pol}}H^\circ$ have been obtained from the enthalpies of combustion Δ_cH° of the monomers and the corresponding polymers or from their enthalpies of formation Δ_fH° at 298.15 K and the standard pressure. For other reactions, $\Delta_{\text{pol}}H^\circ$ has been measured directly during polymerisation in calorimeters. We may note that the quantity $\Delta_{\text{pol}}H^\circ(T)$ is independently important as the initial parameter for the calculation of the energy balances in the development of industrial technologies for the synthesis of polymers.

The entropies of polymerisation of lactones $\Delta_{\text{pol}}S^\circ(T)$ are calculated from the absolute entropies of the reactants, which are evaluated in their turn from the experimental temperature variations of the heat capacities and the temperatures, and enthalpies of the physical transformations of the polymers and monomers using the Third Law of Thermodynamics.²¹ For these calculations, it is necessary that the heat capacities of the test substances should be measured from as low temperatures as possible. The absolute entropies of the monomers are calculated in the usual way,²¹ whilst their calculation for the polymers is complicated by the fact that in any physical state the entropies of the polymers at $T = 0$ K are not zero,^{22,23} since polymers have a zero-point (residual) entropy $S^\circ(0)$.^{22–24} This is associated with the fact that polymers, particularly polylactones, are partly crystalline or amorphous and constitute a mixture of macromolecules having different masses.^{23,24} Furthermore, when polymers are cooled the conformations of the macromolecules are frozen at the glass transition temperature T_g° . On further cooling, such macromolecules do not pass to the state corresponding to thermodynamic equilibrium owing to the enormous activation energy for the rearrangement of their constituent segments and give rise to the so called conformational contribution S_{conf}° to the zero-point entropy of the polymer.^{25–27} There are also other causes of the existence of $S^\circ(0)$.²³

The problem of the zero-point entropy remained for a long time a serious obstacle to the calculation of the absolute entropies of polymers and hence to the employment of calorimetric methods for the determination of the thermodynamic parameters of polymerisation reactions.^{24,28} A consequence of the neglect of the values of $S^\circ(0)$ for polymers was serious errors in the calculations of $\Delta_{\text{pol}}G^\circ(T)$, $[M]_e$, and the polymerisation-depolymerisation equilibrium constants, K_{pol}° .

Lebedev and Rabinovich²⁹ found a way of estimating the zero-point entropies of polymers in the amorphous state from experimental temperature variations of the heat capacities and the

temperatures and enthalpies of the physical transformations of partly crystalline polymers. An approximate method for the determination of the configurational entropies S_{conf}° of amorphous polymers from the increments in their heat capacities on devitrification $\Delta C_p^\circ(T_g^\circ)$ at T_g° and from the ratio $T_g^\circ/T_2^\circ \approx 1.29$, where T_2° is the Kauzmann temperature,³⁰ has been proposed.^{25,26} It was shown that the configurational entropy constitutes the main contribution to the zero-point entropies of polymers and in many cases S_{conf}° is close or even equal to $S^\circ(0)$.^{25–27} Thus the problem of the calculation of the absolute entropies of polymers from calorimetric data has been virtually solved. The values of $\Delta_{\text{pol}}S(T)$ for more than 150 polymerisation reactions of monomers, including many lactones, have now been found from the absolute entropies of the reactants.

The physical transformations occurring on heating or cooling the test substances are manifested clearly in the temperature variations of the heat capacity, and the temperatures and enthalpies of these transformations may be measured accurately. By employing the heat capacities and the temperatures and enthalpies of the physical transformations, the enthalpies $H^\circ(T) - H^\circ(0)$, the entropies $S^\circ(T)$, and the Gibbs free energies $G^\circ(T) - H^\circ(0)$ may be found. These thermodynamic functions are used in their turn to calculate the enthalpies, entropies, and Gibbs free energies of the polymerisation processes. The thermochemical parameters Δ_fH° , Δ_fG° , Δ_fH° , and K_f° of the formation of the monomers and polymers are calculated from the standard enthalpies of combustion and $S^\circ(298.15 \text{ K})$. The degrees of crystallinity α of partly crystalline polymers are also estimated from calorimetric data.^{31,32}

$$\alpha = 100 \left[1 - \frac{\Delta C_p^\circ(\alpha)}{\Delta C_p^\circ(\alpha = 0)} \right], \quad (1)$$

$$\alpha = 100 \frac{\Delta_{\text{fus}}H^\circ(\alpha)}{\Delta_{\text{fus}}H^\circ(\alpha = 100\%)}, \quad (2)$$

where $\Delta C_p^\circ(\alpha)$ and $\Delta C_p^\circ(\alpha = 0)$ are respectively the increments in heat capacity on devitrification of the polymers at T_g° for the polymer with a degree of crystallinity α and for the fully amorphous polymer and $\Delta_{\text{fus}}H^\circ(\alpha)$ and $\Delta_{\text{fus}}H^\circ(\alpha = 100\%)$ are the enthalpies of fusion of the polymer with a degree of crystallinity α and the fully crystalline polymer.

The properties of polymers in the amorphous and crystalline states are estimated with the aid of the thermodynamic properties of the partly crystalline polymers. The method used for such estimations has been described.^{29,33} The results permit, apart from the calculation of $S^\circ(0)$ for amorphous polymers, also the calculation of the difference between the zero-point enthalpies of the polymer in the vitreous and crystalline states $H_g^\circ(0) - H_{\text{cr}}^\circ(0)$ at $T = 0 \text{ K}$.^{33,34} Using the values of $S^\circ(0)$ and $H_g^\circ(0) - H_{\text{cr}}^\circ(0)$ as well as the temperature variations of the heat capacities of the monomers in the amorphous and crystalline states, it is possible to find the thermodynamic parameters of the conversion of the amorphous polymer into the crystalline form: $\Delta H^\circ(a;cr)$, $\Delta S^\circ(a;cr)$, and $\Delta G^\circ(a;cr)$ in the range $0 - T_{\text{fus}}^\circ$. The values of $\Delta G^\circ(a;cr)$ represent a kind of estimate of the absolute thermodynamic stability of the amorphous polymer in relation to its crystalline state.^{35,36}

Polylactones are convenient objects for the determination of the dependences of the changes in the properties and thermodynamic parameters of the polymerisation reactions on the compositions and structures of the reactants — the monomer repeat units in the polymer macromolecules. In a series of polylactones, the composition changes by a CH_2 group on passing from one polylactone to another. This gives rise to a regular variation of the melting points and glass transition temperatures, heat capacities, thermodynamic functions, thermochemical parameters of formation, thermodynamic parameters of the polymerisation reactions, and other characteristics. If the above variations can be found, it is possible to estimate the properties of hitherto

uninvestigated polymers, as has been done for the alkanes,³⁵ polyalkenes,³⁶ and polyalkynynes.³⁷

In the present review, partly crystalline high-molecular-mass polylactones are examined (Table 1). For the polymers the degree of crystallinity of which has been determined, the latter proved to be somewhat greater than 60%. The masses of the monomer repeat units in the macromolecules of the polylactones were taken from Domalsky.³⁸

II. Calorimetric research methods

1. Combustion calorimetry

Combustion calorimetry is used in direct measurements of the combustion energies $\Delta_c U$. The enthalpies of combustion $\Delta_c H^\circ$ and formation $\Delta_f H^\circ$ of compounds at 298.15 K and the standard pressure are calculated from the values of $\Delta_c U$. They are in turn necessary for the calculation of the enthalpies of polymerisation $\Delta_{pol} H^\circ$ under the same physical conditions. For this very purpose, Sunner and coworkers,³⁹ Hall,⁴⁰ Andruzzi,⁴¹ and Kiparisova and the author of the present review³⁶ carried out experiments designed to determine $\Delta_c H^\circ$ and $\Delta_f H^\circ$ for lactones and the corresponding polylactones. The calorimetric apparatus and the methods used to measure $\Delta_c U$ by the above investigators did not differ fundamentally and in general were similar to those described by Skuratov et al.⁴² However, Sunner and coworkers³⁹ used a rotating bomb calorimeter[†].

Lebedev and Kiparisova³⁶ used a calorimeter with an isothermal jacket and a static bomb of the inverted type. In the calculation of the combustion energies $\Delta_c U$ under the conditions in the bomb calorimeter, the usual thermochemical corrections were taken into account.⁴² The values of $\Delta_c U$, adjusted to the standard pressure, were then used to calculate $\Delta_c H^\circ$ and $\Delta_f H^\circ$.

The majority of the values of $\Delta_c H^\circ$ were determined with an error of $\sim 0.02\%$.

2. Adiabatic vacuum calorimetry

Adiabatic vacuum calorimetry has been used to measure the temperature variation of the heat capacity C_p° and the temperatures and enthalpies of the physical transformations of polylactones in the range from 13.8 to 320 K. The thermodynamic parameters of fusion T_{fus}° , $\Delta_{fus} H^\circ$, and $\Delta_{fus} S^\circ$, the parameters of vitrification and the vitreous state T_g° , the increase in heat capacity on devitrification of the polymer $\Delta C_p^\circ(T_g^\circ)$, the zero-point $[S^\circ(0)]$ and configurational (S_{conf}°) entropies, the Kauzmann temperature T_2° , and the difference $H_g^\circ(0) - H_{cr}^\circ(0)$ were obtained from the above measurements. Hitherto virtually all the measurements of C_p° for polylactones in the range 13.8–370 K have been carried out on a thermophysical apparatus, the design of which and also the methods of measurement have been published.^{13,43} Overall, the analysis of the calibrations and checks of the calorimeter employed and of the experimental method permitted the conclusion that the error in the measurements of C_p° for the polymer was to within 1% in the range 13.8–20 K, 0.5% in the range 30–90 K, and 0.25% in the range 90–370 K; the error in the measurement of the temperature was 0.01 K in conformity with the International Practical Temperature Scale (IPTS-68) and that in the enthalpies of the transformations was 0.25%.

An adiabatic calorimeter of the Gal'chenko–Popov type was used in the measurements of the heat capacity in the range 300–550 K. The design of the calorimeter and the method of measurement have been described.^{44,45}

3. Differential scanning calorimetry

Differential scanning calorimetry (DSC) has been used in the study of polylactones mainly to obtain the melting points, the crystallisation temperatures, and the enthalpies of fusion.^{46–50}

Wunderlich and coworkers⁵⁰ used this method to investigate the temperature variation of the heat capacity, the glass transition temperature, the crystallisation temperature, and the melting point of polypivalolactone. The principles underlying the design of the differential scanning calorimeters and of the methods for their employment have been examined in a series of studies^{51–55} and on the whole are well known. The results obtained are consistent throughout with the data of the U S National Bureau of Standards⁵⁶ to within approximately $\pm 0.1\%$. The details of the methods of measurement are described by Jin and Wunderlich.⁵⁷

4. Isothermal calorimeter of the Mathews type

An isothermal calorimeter of the Mathews type has been used for the direct measurements of the enthalpies of polymerisation of a series of lactones with formation of the corresponding polylactones. The enthalpy of polymerisation was determined from the mass of carbon tetrachloride vaporised at its normal boiling point (349.66 ± 0.05 K) by the energy evolved on polymerisation of the monomer. The design of the calorimeter and the experimental method have been described.⁵⁸ The reliability of the operation of the calorimeter has been confirmed by the exact reproduction of Joshi's precision experiments⁵⁹ on the polymerisation of methyl methacrylate and styrene.⁶⁰ The values of $\Delta_{pol} H^\circ$ obtained for these monomers did not differ from those quoted by Joshi⁵⁹ by more than 0.3%.

III. Heat capacity

Polyglycolide. The polymerisation of glycolide with ring opening leads to the formation of polyglycolide. According to the formula of its smallest repeat unit (Table 1), it can be formally regarded as a polylactone which might have been obtained from a three-membered lactone, the latter apparently not existing owing to the high ring strain energy. The results of calorimetric measurements of the heat capacity of a partly crystalline ($\alpha = 67\%$) polyglycolide with a molecular mass (found from the viscosity) of 3.8×10^4 have been published by Lebedev et al.⁶¹ The heat capacity was determined in adiabatic calorimeters with an error of $\sim 0.3\%$ in the range 13.8–335 K⁴³ and $\sim 0.7\%$ in the range 335–550 K.⁴⁴ In the ranges 13.8–250, 340–450, and 501–550 K, the heat capacity of the polyglycolide increases smoothly with increasing temperature (Fig. 1). The rapid increase in C_p° in the range 250–345 K is associated with the devitrification of the amorphous component of the specimen, while the sharp increase in heat capacity and the break in the $C_p^\circ - T$ plot in the range 440–501 K are caused by the fusion of the crystalline component of the test specimen. Overall, the temperature variation of the heat capacity of polyglycolide is typical of that for partly crystalline polymers.¹⁴ in the range from 60–80 K up to the temperature of the onset of

Figure 1. The heat capacity of polyglycolide:⁶¹ ABRPM — with 67% crystallinity, AKC — crystalline, AK — vitreous, GD — highly elastic, DE — liquid; PLND — apparent heat capacity in the melting range.

[†] All the characteristics of the calorimeter employed by the above workers may be found in the paper of Lebedev and Kiparisova.³⁶

Table 1. The polylactones considered in the review.

Polylactones	Monomer repeat unit		Polylactones	Monomer repeat unit	
	formula	mass /g mol ⁻¹ ^a		formula	mass /g mol ⁻¹ ^a

^a Values taken from Domalsky.³⁸

the devitrification of the amorphous component of the polymer, the heat capacity is a linear function of temperature; the heat capacity of liquid polyglycolide is also a linear function of temperature, as for many other polymers.^{50,62}

Poly- β -propiolactone. The results of calorimetric measurements of the heat capacity of poly- β -propiolactone have been published.⁶³ The specimen was obtained by the polymerisation of β -propiolactone. The mass-average (\bar{M}_w) and number-average (\bar{M}_n) molecular masses of the polymer were respectively 3×10^4 and 8.3×10^3 , the polydispersity coefficient was $\bar{M}_w/\bar{M}_n = 3.8$, and the degree of crystallinity was $\alpha = 79\%$. The heat capacity of poly- β -propiolactone was measured in an adiabatic vacuum calorimeter⁴³ in the temperature range 13.8–330 K with an error of $\sim 0.3\%$ and in an adiabatic calorimeter⁴⁴ in the range 330–400 K with an error of $\sim 1\%$. The devitrification of the amorphous component of the specimen began at 240 K (Fig. 2), its completion being masked by the onset of the fusion of the crystalline component; the break in the C_p° – T relation in the melting range is also associated with this factor. In the range 100–210 K, the heat capacity is a linear function of temperature and is described by the following equations subject to an error of $\pm 0.3\%$:

$$C_p^\circ = 14.7 + \frac{T}{4},$$

where C_p° is the molar heat capacity of the polymer expressed in $\text{J mol}^{-1} \text{K}^{-1}$. The heat capacity of the poly- β -propiolactone melt is also a linear function of temperature. The temperature variations of the heat capacity of poly- β -propiolactone in the amorphous and crystalline states have been plotted on the basis of the experimental data by the method proposed in the study of Lebedev and Rabinovich²⁹ (Fig. 2).

Poly- β -methyl- β -propiolactone (poly- β -butyrolactone) is obtained by the polymerisation of β -butyrolactone with ring opening^{64,65} or from (*R*)-3-hydroxybutyric acid under the influence of microorganisms in the course of enzymic reactions.^{8,66} Lebedev et al.⁶⁷ investigated the temperature variation of the heat capacity of a poly- β -methyl- β -propiolactone specimen obtained from (*R*)-3-hydroxybutyric acid by a biotechnological method.⁶⁸ The number-average molecular mass of the polymer was 10^5 and its degree of crystallinity was 66%. The specimen was highly isotactic. The heat capacity was measured in the temperature range 10–490 K: in an adiabatic vacuum calorimeter (AVC)⁶⁸ in

Figure 2. Temperature dependence of the heat capacity of poly- β -propiolactone.⁶³

State of the polymer: *ABC* — crystalline; *AB* — vitreous; *DE* — highly elastic; *EF* — liquid; *APR* — partly crystalline, $\alpha = 79\%$; *RMNE* — apparent heat capacity in the melting range.

Figure 3. Temperature dependence of the heat capacity of poly- β -methyl- β -propiolactone.⁶⁷

State of the polymer: *ABC* — crystalline; *MHN* — liquid; *ABF* — partly crystalline, $\alpha = 66\%$; *FLDH* — apparent heat capacity in the melting range.

the temperature range 10–340 K with an error of $\sim 0.2\%$ and in a dynamic calorimeter (DC)⁶⁹ in the range 340–490 K with an error of 0.5%–1.5%. The results are presented in Fig. 3.

A characteristic feature of the temperature variation of the heat capacity of poly- β -methyl- β -propiolactone obtained is the absence of the devitrification of the amorphous component of the specimen — only the fusion of the crystalline component is manifested. Such relations are usually characteristic of polymers with a degree of crystallinity close to 100% (more than 90%). In the given instance, it was only 66%. For virtually the same degree of crystallinity, the devitrification of polyglycolide (Fig. 1) is manifested very clearly. The reason for this is probably the degree of interaction of the crystalline and amorphous components in partly crystalline polymer specimens — microheterogeneous systems.⁷⁰ It appears that the greater the uniformity in the distribution of the microheterogeneous crystalline and amorphous components in the bulk of the specimen, the greater the uniformity in their mutual influence and, in particular, in the reinforcement of the amorphous component of the polymer by crystals, which prevents the excitation of segmental motions in the polymer molecules on devitrification.^{71,72}

Poly- α,α -dimethyl- β -propiolactone (polypivalolactone). The heat capacity of poly- α,α -dimethyl- β -propiolactone has been determined by Wunderlich and coworkers⁵⁰ in a DSC-7 differential scanning calorimeter in the range 140–550 K at a rate of heating of the calorimeter with the test substance of $1.7 \times 10^{-1} \text{ K s}^{-1}$. A specimen with a molecular mass of 2.5×10^5 was investigated; the degree of crystallinity of the initial specimen was 51%. The devitrification of the amorphous component of the polymer in the range 260–280 K (section *BC*) and two transitions were manifested on the temperature variation of the heat capacity (Fig. 4, curve *J*): the first transition in the form of a diffuse hump (*DGN*) and the second in the form of the typical temperature variation of the apparent heat capacity of the polymer in the melting range (*NRSU*).

The first transition begins at 380 K, the maximum apparent heat capacity (point *G*) corresponds to 421.5 K, and the end of the transformation is masked by the onset of the fusion process. The nature of the transition is not altogether clear. However, one may postulate that it is due to the transformation of one crystalline modification of poly- α,α -dimethyl- β -propiolactone into another.

Poly- α,α -dimethyl- β -propiolactone is known to be capable of forming three crystalline modifications — α , β , and γ .^{73,74} The crystals melt in the range 497–530 K. The maximum apparent heat capacity corresponds to 511 K. The temperature variation of

Figure 4. Temperature dependence of the heat capacity of poly- α,α -dimethyl- β -propiolactone.⁵⁰

(1) Initial specimen; (2) specimen obtained by natural cooling of the melt in air; (3) specimen obtained by cooling the melt with liquid nitrogen (cooling rate 5.3 K s⁻¹); for the significance of the letter designations, see text.

C_p° of the polymer melt cooled naturally from 540 K in air is described by curve 2 in Fig. 4. It was found that the degree of crystallinity in the specimen obtained in this way is 68%. Only fusion, which begins at 502 K and ends at 530 K, is manifested on the curves describing the $C_p^\circ = f(T)$ relation; the maximum in the apparent heat capacity corresponds to 513 K.

The third series of measurements was carried out for a specimen of poly- α,α -dimethyl- β -propiolactone obtained by rapid cooling of the polymer melt with liquid nitrogen (rate of cooling ~ 5.3 K s⁻¹). Vitrification was again manifested on the $C_p^\circ = f(T)$ relation (Fig. 4, curve 3) together with an exothermic transformation (ELN section) and fusion. Even on such rapid cooling, the polymer was obtained in a highly crystalline form, its degree of crystallinity being close to that of the initial specimen. Repeated measurements of C_p° in the range 150–260 K and averaging of the latter yielded the following equation which makes it possible to determine the heat capacity of the polymer with an error of $\sim 0.3\%$:

$$C_p^\circ = \exp[-48.06197 + 27.29137 \ln T - 4.791726(\ln T)^2 + 0.28686(\ln T)^3], \quad (3)$$

where C_p° is expressed in J mol⁻¹ K⁻¹.

For the liquid polymer, the following equation was obtained also as a result of several experimental measurements:

$$C_p^\circ = 112.4 + 0.221T,$$

which reproduces satisfactorily (with an error of $\pm 0.13\%$) the heat capacities in the range 510–550 K.

Using the results of experimental determinations of the heat capacity and the vibration frequency of the atoms and atomic groups in poly- α,α -dimethyl- β -propiolactone, Wunderlich and coworkers⁵⁰ calculated the heat capacity of the polymer in the range 0.1–1000 K. The isochoric heat capacity, C_v , as well as the contributions to this quantity by skeletal and atomic vibrations calculated per monomer repeat unit in the polylactone macromolecules were estimated for the same range.

Poly- γ -butyrolactone. The results of the study of the temperature variation of the heat capacity of poly- γ -butyrolactone in an adiabatic vacuum calorimeter⁴³ at temperatures in the range 13.8–340 K have been published by Evstropov et al.⁷⁵ The error of the measurements was 0.3%. The test specimen was obtained

by the bulk polymerisation of γ -butyrolactone under a pressure of 2×10^6 kPa, because at the usual pressure the monomer does not polymerise. The number-average molecular mass of the polymer was $\bar{M}_n = 3 \times 10^3$ and its degree of crystallinity was $\alpha = 67\%$. The amorphous component of the specimen devitrified in the range 200–235 K and the crystalline component melted in the range 245–335 K. In the course of slow stepwise cooling of poly- γ -butyrolactone melt, Evstropov et al.⁷⁵ were able to measure the C_p° of the polymer in the supercooled liquid (highly elastic) state up to a temperature 12 K below its melting point. Overall, the plot of the temperature variation of the heat capacity of poly- γ -butyrolactone has a form similar to that of the plot of the same relation for poly- β -propiolactone (Fig. 2).

Poly- δ -valerolactone. Evstropov et al.⁷⁶ Published the results of a study of the temperature variation of the heat capacity of poly- δ -valerolactone in an adiabatic vacuum calorimeter⁴³ in the range 13.8–340 K. The error of the measurements of C_p° was $\sim 0.3\%$. The test specimen was obtained by the polymerisation of δ -valerolactone. The viscosity-average and number-average molecular masses of poly- δ -valerolactone were respectively 3.6×10^3 and 1.4×10^3 , the polydispersity coefficient was ~ 2.5 , and the degree of crystallinity of the specimen was 70%. The $C_p^\circ - T$ plot was similar to that presented in Fig. 2 for poly- β -propiolactone. The amorphous component of the polymer devitrified in the range 190–215 K and fusion, accompanied by a break in the $C_p^\circ = f(T)$ function, occurred in the range 250–330 K. On slow stepwise cooling of the polymer melt, it was possible to measure its heat capacity in the supercooled liquid state — from the melting point corresponding to thermodynamic equilibrium down to a temperature 10 K below it.

Poly- ϵ -caprolactone. The results of calorimetric studies of the heat capacity of poly- ϵ -caprolactone have been published by Lebedev and coworkers.^{77,78} The measurements in an adiabatic vacuum calorimeter⁴³ in the range 13.8–340 K were carried out with an error of $\sim 0.3\%$,⁷⁷ while those in a differential scanning calorimeter in the range 77–360 K were subject to an error of $\sim 1.5\%$.⁷⁸

Since all the subsequent calculations and conclusions are based on the treatment of the results of Lebedev et al.⁷⁷, we shall note the most important characteristics of the polymer which they investigated. The poly- ϵ -caprolactone specimen was obtained by the polymerisation of ϵ -caprolactone ($\bar{M}_w = 2.9 \times 10^4$, $\alpha = 63\%$). The temperature variation of the heat capacity of the polymer had no singularities: it increased smoothly with increase in temperature, a more rapid rise in C_p° being observed, as for other polylactones, in the devitrification range for the amorphous part of the specimen (200–245 K); the sharp rise in C_p° and the break in the $C_p^\circ - T$ plot in the range 298–336 K are due to the fusion of the crystalline component of the polymer. The differences between the heat capacities quoted in the above two studies^{77,78} do not exceed 1.5% in the range 90–130 K, 0.5% in the range 130–200 K, and 1% in the range 200–250 K.

Polyundecanolactone. The temperature variation of the heat capacity of polyundecanolactone in the temperature range 0–370 K has been published by Evstropov.⁷⁹ The measurements of C_p° were carried out in an adiabatic vacuum calorimeter⁴³ in the range 14–366 K subject to an error of $\sim 0.3\%$. The test specimen was obtained by the polymerisation of undecanolactone. The viscosity-average and number-average molecular masses of the polymer were 3.4×10^4 and 1.0×10^4 respectively. The degree of crystallinity of the specimen was 73%. The $C_p^\circ - T$ plot was similar to that presented in Fig. 2 for poly- β -propiolactone. The amorphous component of the specimen devitrified in the range 190–270 K and fusion, accompanied by a break in the $C_p^\circ = f(T)$ relation, occurred in the range 270–365 K. On slow stepwise cooling of the polyundecanolactone melt, it was possible to measure its heat capacity in the supercooled liquid (highly elastic) state in the temperature range from T_{fus}° to 350 K, which is 15 K below the melting point of polyundecanolactone.

Polytridecanolactone. The results of the study of the temperature variation of the heat capacity of polytridecanolactone in the range 0–370 K have been published by Lebedev et al.⁸⁰ The polymer specimen investigated was obtained by the polymerisation of tridecanolactone. The intrinsic viscosity of polytridecanolactone, measured in chloroform at 298 K, was 0.82 dl g⁻¹ and its degree of crystallinity was 75%. The heat capacity was determined in an adiabatic vacuum calorimeter⁴³ in the range 14–370 K. The error of the values of C_p° obtained was ~0.3%. The devitrification of the amorphous component began at 200 K and its end was masked by the incipient fusion of the crystalline component in the range 280–365 K. The polytridecanolactone melt hardly supercooled. Overall, the $C_p^\circ - T$ plot is similar to that presented in Fig. 2 for poly- β -propiolactone.

Polypentadecanolactone.⁸¹ The heat capacity of polypentadecanolactone was determined in an adiabatic vacuum calorimeter⁴³ in the range 13.8–372 K with an error of ~0.3%. The test specimen was obtained by the polymerisation of pentadecanolactone. The intrinsic viscosity of a solution of the polymer in chloroform at 298 K was 0.93 dl g⁻¹ and the degree of crystallinity of the polymer was 77%. The $C_p^\circ - T$ plot for polypentadecanolactone is similar to the plot presented in Fig. 3 for poly- β -methyl- β -propiolactone. The amorphous component devitrified in the range 200–270 K. In the range 140–200 K, the heat capacity of polypentadecanolactone is described by the equation

$$C_p^\circ = 51.34 + 1.0659T,$$

The deviation of the experimental C_p° points from those calculated by the equation is throughout within the limits of 0.2%. The heat capacity of the fused specimen, like that of other polylactones, is a linear function of temperature. In contrast to some of the preceding polylactones, polypentadecanolactone does not supercool in the liquid state.

IV. Thermodynamics of fusion

The fusion of all partly crystalline polylactones takes place over a wide temperature range. The $C_p^\circ - T$ plots in the melting range have left-hand branches, which ascend comparatively rapidly with increase in temperature, and rapidly descending right-hand branches (Figs. 1–4). Fig. 5 presents typical integral and differential fusion curves for polylactones in relation to poly- ϵ -caprolactone as an example.⁷⁷ They reflect the distribution of the crystals with respect to the melting points. Evidently poly- ϵ -caprolactone melts in the range 210–337 K, approximately 70% of the mass of the crystals melting over a comparatively narrow temperature range (328–337 K), and most of them melt at 336 K.

Figure 5. Temperature dependence of the fraction of the melt in the crystalline component of a poly- ϵ -caprolactone specimen ($\alpha = 75\%$).⁷⁷ Integral (1) and differential (2) curves.

The nonisothermal nature of fusion is known to be caused by the polycrystallinity of polymers — the presence of a set of different metastable and crystalline formations with ultramicroscopic and microscopic dimensions and with different chemical potentials. For ultramicroscopic dimensions of the crystals, the Gibbs free energy of the surface constitutes a significant proportion of the total Gibbs free energy G . Below the melting point corresponding to thermodynamic equilibrium, $G(\text{cr}) < G(\text{l})$ and at this temperature $\Delta G = 0$. This condition is attained at different temperatures for small crystals of different size: the smaller the crystal, the lower its melting point. This is in fact the reason for the nonisothermal nature of fusion.¹⁴ The fact that the crystallisation of the polymer does not entail the formation of microscopically ideal crystals of one definite type, the chemical potential of which depends only on the temperature and pressure, can also be accounted for by mainly kinetic causes.

Table 2 presents the thermodynamic parameters of the fusion of polylactones found from the results of calorimetric measurements. The greatest number of data have been obtained by adiabatic vacuum calorimetry. The melting points, corresponding to thermodynamic equilibrium, of defect-free ideal polymer crystals are presented for polylactones investigated by this method. For their calorimetric determination, measurements were made of the melting points T_F° , corresponding to thermodynamic equilibrium, for fractions F of the polymer melt. It was found that, for the polylactones investigated, the $T_F^\circ - F^{-1}$ plots are straight lines described satisfactorily by the equation

$$T_F^\circ = T_0^\circ - F^{-1}(T_0^\circ - T_1^\circ), \quad (4)$$

where T_1° and T_0° are the melting points, corresponding to thermodynamic equilibrium, of the crystals of the polymer specimen employed and a hypothetical defect-free crystal of the same polymer respectively. The above equation is used mainly for low-molecular-mass substances.⁸³ For example, the following results have been obtained for poly- ϵ -caprolactone:⁷⁷

F^{-1}	4.456	2.610	1.305	1.071
T_F° / K	314.584	325.586	334.408	335.420.

$T_1^\circ = 336$ K was obtained from the $T_F^\circ - F^{-1}$ plot for $F^{-1} = 1$ and $T_1^\circ = 342$ K was found by extrapolation for $F^{-1} = 0$.

The enthalpies of fusion of the test specimens of the polymers were measured by the method involving the continuous injection of energy⁸² and were calculated by the equation

$$\Delta_{\text{fus}} H^\circ(\alpha) = \left\{ \Delta H_i^\circ - \int_{T_i^\circ}^{T_{\text{fus}}^\circ} C_p^\circ(\text{s}) dT - \int_{T_{\text{fus}}^\circ}^{T_f^\circ} C_p^\circ(\text{l}) dT - \int_{T_i^\circ}^{T_f^\circ} C_{\text{cal}} dT \right\} \frac{M}{m}, \quad (5)$$

where ΔH_i° is the amount of energy consumed in the heating of the calorimeter with the test substance from the initial experimental temperature T_i° to the final temperature T_f° , $C_p^\circ(\text{s})$ and $C_p^\circ(\text{l})$ are the temperature variations of the heat capacities of a polymer specimen (placed in the calorimeter) with a mass m in the solid (s) and liquid (l) states, C_{cal} is the heat capacity of the empty calorimeter, and M is the molecular mass of the specimen.

The average value of $\Delta_{\text{fus}} H^\circ(\alpha)$ was calculated from the results of 3–4 experiments and was then used to calculate the molar enthalpy of fusion of the crystalline polymer $\Delta_{\text{fus}} H^\circ(\alpha = 100\%)$ from the formula

$$\Delta_{\text{fus}} H^\circ(\alpha = 100\%) = \frac{\Delta_{\text{fus}} H^\circ(\alpha)}{\alpha}, \quad (6)$$

where α is the degree of crystallinity.

In the study of the fusion process by differential scanning and dynamic calorimetry, the temperatures corresponding to the maximum apparent heat capacity in the melting range or the

maximum temperature of the melting range were adopted as T_{fus}° .⁶⁹ This is in fact the usual explanation of the discrepancies between the melting points quoted in different publications for the same polylactone. Unfortunately the temperatures T_{fus}° obtained by differential scanning calorimetry at specific rates of heating of the calorimeter with the test substance have not been adjusted to the zero heating rate. The enthalpies of fusion $\Delta_{\text{fus}}H^{\circ}(\alpha)$ were also determined in several experiments. The method has been described, for example, by Lebedev et al.⁸⁴ The average value of $\Delta_{\text{fus}}H^{\circ}(\alpha)$ obtained was then recalculated as $\Delta_{\text{fus}}H^{\circ}(\alpha = 100\%)$ by Eqn (6).

The entropies of fusion $\Delta_{\text{fus}}S^{\circ}(\alpha = 100\%)$ for all the polylactones (Table 2) were found from the enthalpies $\Delta_{\text{fus}}H^{\circ}(\alpha = 100\%)$ and the melting points T_{fus}° by the equation

$$\Delta_{\text{fus}}S^{\circ}(\alpha = 100\%) = \frac{\Delta_{\text{fus}}H^{\circ}(\alpha = 100\%) }{T_{\text{fus}}^{\circ}} \quad (7)$$

The heat capacity change $\Delta C_p^{\circ}(\alpha = 100\%)$ on passing from the crystalline to the liquid polymer at the melting point was found graphically. For example, $\Delta C_p^{\circ}(\alpha = 100\%)$ for polyglycolide is represented by section CD in Fig. 1.

In conclusion we may note that the results of measurements of the melting point and enthalpy of fusion of poly-β-propiolactone by differential scanning calorimetry have been published by Crescenzi et al.⁴⁶ $T_{\text{fus}}^{\circ} = 357 \text{ K}$ and $\Delta_{\text{fus}}H^{\circ}(\alpha = 100\%) = 9.6 \text{ kJ mol}^{-1}$. The enthalpy of fusion agrees satisfactorily with the value published by Lebedev et al.⁶¹ (Table 2), while the melting point is significantly lower, which is natural since Lebedev et al.⁶¹ calculated the melting point for an ideal defect-free poly-β-propiolactone crystal. Kort and Glet⁸⁵ gave the melting point and the specific enthalpy of fusion for poly-α-methyl-α-n-propyl-β-propiolactone as 370 K and 8 J g^{-1} , but there are no data on the degree of crystallinity of the test specimen. For this reason, it is impossible to calculate $\Delta_{\text{fus}}H^{\circ}(\alpha = 100\%)$ for this polymer.

Kort and Glet⁸⁵ found that the melting point of poly-γ-butyrolactone is 334–335 K. This also differs slightly from the temperature quoted in Table 2. The reason for the difference is the same as in the case of poly-β-propiolactone. Tadokoro et al.⁸⁶

determined $T_{\text{fus}}^{\circ} = 326 \text{ K}$ for poly-δ-valerolactone, which is 5 K lower than the corresponding temperature in Table 2. The values $\Delta_{\text{fus}}H^{\circ}(\alpha = 100\%) = 19 \pm 2 \text{ kJ mol}^{-1}$ and $T_{\text{fus}}^{\circ} = 336 \text{ K}$ have been obtained⁷⁸ for poly-ε-caprolactone in adiabatic vacuum calorimetry. The same quantities found by differential scanning calorimetry⁴⁶ proved to be $\Delta_{\text{fus}}H^{\circ}(\alpha = 100\%) = 15.9 \text{ kJ mol}^{-1}$ and $T_{\text{fus}}^{\circ} = 336 \text{ K}$. The enthalpies of fusion found from the results of Lebedev et al.⁷⁷ and Beraty⁷⁸ agree, while the value measured by Crescenzi et al.⁴⁶ is apparently too low.

We may note that, according to our observations,¹⁴ the decrease in the melting points of polymers ($\Delta T_{\text{fus}}^{\circ} = T_0^{\circ} - T_1^{\circ}$) is usually between 4 and 10 K, which is much larger than for the corresponding monomers with approximately the same content of impurities in the usual sense. In the case of polymers, the end groups of the macromolecules and crystal defects are also regarded as impurities.

In conclusion, we shall give a list of the melting points of di- and tri-alkyl-substituted poly-β-propiolactones published by Cornibert et al.⁸⁷ and Thielaut et al.⁸⁸

Poly lactone	$T_{\text{fus}}^{\circ} / \text{K}$
Poly-β-propiolactone	357
Polyα,α-dimethyl-β-propiolactone	513
Poly-α-ethyl-α-methyl-β-propiolactone	398
Poly-α-methyl-α-n-propyl-β-propiolactone	370
Poly-α-isopropyl-α-methyl-β-propiolactone	298
Poly-α-methyl-α-pentyl-β-propiolactone	327
Poly-α,α-diethyl-β-propiolactone	531
Poly-α-ethyl-α-n-propyl-β-propiolactone	478
Poly-α-n-butyl-α-thyl-β-propiolactone	453
Poly-α,α-di-n-propyl-β-propiolactone	530
Poly-α-n-butyl-α-n-propyl-β-propiolactone	500
Poly-α,α-di-n-butyl-β-propiolactone	518
Poly-α,α-dimethyl-β-methyl-β-propiolactone	458
Poly-β-ethyl-α,α-dimethyl-β-propiolactone	423

V. Parameters of vitrification and the vitreous state

Table 3 presents the parameters of the vitrification and the vitreous state of polylactones obtained from the results of calorimetric measurements by adiabatic vacuum and differential scanning calorimetry; the glass transition temperatures of a series of polylactones have been found by the torsional pendulum (TP) method.⁹¹ The temperature of the onset of the devitrification of polylactones in partly crystalline states is distinctly manifested on the temperature variations of C_p° (see, for example, Figs 1 and 2). However, the end of the devitrification process is in most cases masked by the incipient partial fusion of polylactones and it is therefore difficult to determine the temperature at which devitrification comes to an end. Nevertheless, one may conclude that polylactones are devitrified in the range from 20 K (for example, in the case of poly- α,α -dimethyl- β -propiolactone⁵⁰) to 60 K (for polyundecanolactone⁷⁹). The glass transition temperature T_g° is usually close to the average temperature of the vitrification range, but can be determined more accurately from the point of inflection in the $C_p^\circ - T$ and $S^\circ(T) - T$ plots.⁹²

We may note that, since vitrification is a relaxation process,¹⁴ it follows that in the vitrification temperature range the relaxation time of the conformational motions of the segments is of the same order of magnitude as the duration of the experiment (the time required to supply energy to the system). The results of the determination of T_g° therefore depend on the rate at which measurements are made and on the method of the preliminary heat treatment of the polymers (for example, quenching and annealing). The glass transition temperature of poly- β -propiolactone has been found as 245 ± 2 K by the torsional pendulum method,⁹⁰ which is slightly below the value obtained by the AVC method (Table 3). For a rapidly cooled specimen of poly- α,α -dimethyl- β -propiolactone, $T_g^\circ = 259.8$ K,⁵⁰ while for a specimen with a degree of crystallinity of 79% it amounts to 267.8 K. The following values of T_g° have been found for poly- ϵ -caprolactone by different investigators using the torsional pendulum method: 202 K,⁸⁹ 209 K,⁹² and 218 K.⁹³ The lowest value of T_g° corresponds to the fully amorphous polymer specimen and the highest to the specimen with the highest degree of crystallinity.

Thus an increase in the degree of crystallinity leads to an increase in T_g° . This can apparently be explained by the effect of

the reinforcement of the amorphous component of the polymer by crystals, which hinder the excitation of the motion of the segments of the macromolecules on devitrification.⁷¹ As a result of this, the devitrification of partially crystalline polymers occurs at higher temperatures, in contrast to amorphous polymers in which there is no reinforcement effect.

The increase in heat capacity on devitrification of the fully amorphous polymer at the glass transition temperature has been found graphically (Table 3). For example, $C_p^\circ(T_g^\circ)$ for poly- β -propiolactone is represented by section *DB* in Fig. 2. The justification of the validity of the extrapolation of the heat capacity, presented, for example, in Fig. 2, has been described in detail.²⁹ The difference between the enthalpies of the polymer in the vitreous and crystalline states and the zero-point (residual) entropies of the polymers in the vitreous state at 0 K have been calculated by the equations^{24, 29, 34}

$$H_g^\circ - H_{cr}^\circ(0) = \int_0^{T_{fus}} [C_p^\circ(cr) - C_p^\circ(a)]dT + \Delta_{fus}H^\circ(\alpha = 100\%), \quad (8)$$

$$S_g^\circ(0) = \int_0^{T_{fus}} [C_p^\circ(cr) - C_p^\circ(a)]d\ln T + \Delta_{fus}S^\circ(\alpha = 100\%), \quad (9)$$

where $C_p^\circ(a)$ and $C_p^\circ(cr)$ are respectively the temperature functions of the heat capacity of the polymer in the vitreous or highly elastic amorphous ($\alpha = 0$) and crystalline ($\alpha = 100\%$) states (see sections *ABDE* and *ABC* respectively in Fig. 2); $\Delta_{fus}H^\circ(\alpha = 100\%)$ and $\Delta_{fus}S^\circ(\alpha = 100\%)$ are the enthalpy and entropy of fusion of the crystalline polymer.

The enthalpies, entropies, and Gibbs free energies of polyglycolide, poly- β -propiolactone, and poly- ϵ -caprolactone in the amorphous and crystalline states have been calculated for the range $0 - T_{fus}$.^{13, 14, 77} It was postulated that the difference between the Gibbs free energies is an absolute measure of the metastability of the polymer in the amorphous state in relation to its crystalline state. As an example, Fig. 6 presents typical temperature dependences of the above quantities in the range $0 - T_{fus}$ for poly- ϵ -caprolactone.⁷⁷ Evidently the absolute enthalpy and entropy increase with increasing temperature, while the Gibbs free energy diminishes and becomes zero at T_{fus} .

VI. Thermodynamic functions

The thermodynamic functions of polylactones were calculated for the range from 10–14 to 350–550 K (largely with an error of 0.2%–0.3%) from the results of the study of their heat capacities in adiabatic vacuum calorimeters: the enthalpy $H^\circ(T) - H^\circ(0)$, the entropy $S^\circ(T)$, and the Gibbs free energy $G^\circ(T) - H^\circ(0)$; the smoothed heat capacities $C_p^\circ(T)$ were found (Table 4). For the range 0–14 K, the C_p° were obtained by extrapolating the experimental data in terms of the Debye heat capacity formula

$$C_p^\circ(T) = nD\left(\frac{\theta_D}{T}\right), \quad (10)$$

where D is the symbol of the Debye heat capacity and n and θ_D are special parameters chosen so that Eqn (10) describes the values of C_p° in the range from 14 to 20–25 K with an error not exceeding 0.5%–1.0%. It was assumed that at $T < 14$ K it reproduces C_p° with approximately the same error. For example, $n = 3$ and $\theta_D = 93.1$ in Eqn (10) for poly-ε-caprolactone.⁷⁷ For the same parameters, the equation describes the experimental C_p° for the polymer in the range 14–20 K with an error within the limits of 1%.

The thermodynamic functions were calculated from the equations

$$H^\circ(T) - H^\circ(0) = \int_0^T C_p^\circ(T) dT + \Delta_{\text{fus}} H^\circ(\alpha = 100\%), \quad (11)$$

$$S^\circ(T) = S_g^\circ(0) + \int_0^T C_p^\circ(T) d \ln T + \Delta_{\text{fus}} S^\circ(\alpha = 100\%), \quad (12)$$

$$G^\circ(T) - H^\circ(0) = [H^\circ(T) - H^\circ(0)] - TS^\circ(T), \quad (13)$$

where $C_p^\circ(T)$ is the temperature dependence of the heat capacity of polylactones in the given physical state: vitreous, crystalline, highly elastic, and liquid. The values of $C_p^\circ(T)$ were determined from the experimental measurements of the heat capacity of partly crystalline polylactones. The corresponding method has already been published.²⁹ In the calculation of the absolute entropies of the polymers, account was taken of the zero-point entropies $S_g^\circ(0)$ (Table 3).

The heat capacities and thermodynamic functions of polylactones with any degree of crystallinity α can be readily calculated from the numerical values of such functions for the polylactones in the crystalline and amorphous states. This calculation is correct because all the properties listed can be regarded as additive functions of the degree of crystallinity at the specified temperature and pressure. Having designated the property by X , we obtain

$$X(\alpha) = X(\alpha = 1) + [X(\alpha = 0) - X(\alpha = 1)](1 - \alpha), \quad (14)$$

where α is expressed as a fraction.

VII. Thermochemical characteristics

Table 5 presents the enthalpies of combustion ($\Delta_c H^\circ$) and formation ($\Delta_f H^\circ$), the entropies $\Delta_f S^\circ$ and the Gibbs free energies $\Delta_f G^\circ$ of formation of polylactones in the crystalline and amorphous states at 298.15 K and standard pressure, as well as the logarithms of the thermodynamic equilibrium constants of the formation reactions of these compounds from the simple substances in their standard states. For all the compounds listed in Table 5, except poly-β-propiolactone and poly-ε-caprolactone, the combustion energies $\Delta_c U^\circ(\alpha)$ were measured. The values of $\Delta_c U^\circ(\alpha)$, adjusted to the standard pressure [$\Delta_c U^\circ(\alpha)$], were used to calculate the enthalpies of combustion at the standard pressure $\Delta_c H^\circ(\alpha)$. The enthalpies of combustion of the polymers in the crystalline and amorphous (vitreous or highly elastic) states were calculated by the equations

$$\Delta_c H^\circ(\text{cr}) = \Delta_c H^\circ(\alpha) + (1 - \alpha)\Delta_{\text{fus}} H^\circ(298.15 \text{ K}), \quad (15)$$

$$\Delta_c H^\circ(\text{a}) = \Delta_c H^\circ(\alpha) - \alpha\Delta_{\text{fus}} H^\circ(298.15 \text{ K}), \quad (16)$$

where $\Delta_c H^\circ(\alpha)$ is the enthalpy of combustion of the polymer with a degree of crystallinity α and $\Delta_{\text{fus}} H^\circ(298.15 \text{ K})$ is the molar enthalpy of fusion of the fully crystalline polymer at 298.15 K. The latter quantity is hypothetical and it was calculated, using the molar enthalpy of fusion of the crystalline polymer at T_{fus}° and the temperature variations of the heat capacities for the polymer in the crystalline and amorphous states, by the Kirchhoff equation¹⁵

$$\Delta_{\text{fus}} H^\circ(298.15 \text{ K}) = \quad (17)$$

$$= \Delta_{\text{fus}} H^\circ(T_{\text{fus}}^\circ) + \int_{T_{\text{fus}}^\circ}^{298.15 \text{ K}} [C_p^\circ(\text{a}) - C_p^\circ(\text{cr})] dT.$$

This equation may be employed because the calculations relate to a constant (standard) pressure.

The quantities $\Delta_c H^\circ(\text{cr})$ and $\Delta_c H^\circ(\text{a})$ for poly-β-propiolactone and poly-ε-caprolactone were calculated from their enthalpies of formation, which were in their turn evaluated from the enthalpies of the polymerisation of the corresponding monomers to the crystalline and amorphous polymers and the enthalpies of formation of the monomers.

The enthalpies and entropies of formation of the polylactones were calculated from $\Delta_c H^\circ(\text{cr})$, $\Delta_c H^\circ(\text{a})$, the enthalpies of formation of liquid water and gaseous carbon dioxide, the absolute entropies of the polymers in crystalline and amorphous states (Table 4), and the entropies of carbon in the form of graphite and gaseous hydrogen and oxygen at $T = 298.15 \text{ K}$ and $p = 101.325 \text{ kPa}$. The Gibbs free energies of formation of the polymers were found from the formula

$$\Delta_f G^\circ = \Delta_f H^\circ - 298.15 \Delta_f S^\circ. \quad (18)$$

The logarithms of the thermodynamic equilibrium constants of the formation reactions of the polylactones from the simple substances were calculated from the $\Delta_f G^\circ$:

$$\lg K_f^\circ = \frac{-\Delta_f G^\circ}{2.303R \cdot 298.15}. \quad (19)$$

Any thermochemical parameter of a polylactone with any degree of crystallinity may be determined by Eqn (14) using the thermochemical characteristics (Table 5). The additivity of the properties of partly crystalline polymers is a consequence of the fact that they are heterogeneous (microheterogeneous) systems.

We may note in conclusion that Hall⁴⁰ measured in three experiments the energy of combustion of partly crystalline poly-α,α-dimethyl-β-propiolactone (polypivalolactone) and calculated

^a The following designations for the states of the polymers have been adopted: cr — crystalline, g — vitreous (glassy), h.e. — highly elastic.

from the results its enthalpy of combustion as $\Delta_c H^\circ(\alpha) = -2631.7 \text{ kJ mol}^{-1}$. The degree of crystallinity was unknown.

Andruzzi⁴¹ measured the combustion energies of five specimens of polyoxacarbonyl-1,4-cyclohexylene with different molecular masses — from 2.1×10^3 to 1×10^6 . All the specimens investigated were partly crystalline. The number of combustion experiments was 15. Calculation of the enthalpy of combustion showed that $\Delta_c H^\circ(\alpha)$ at $T = 298.15 \text{ K}$ varies from -3686.9 ± 7.6 to $-3700.3 \pm 9.0 \text{ kJ mol}^{-1}$. The authors believe that the reason for the differences is different degrees of crystallinity of the test specimens and also the different contents of the *cis*- and *trans*-units in the polymer. The results of the determination of $\Delta_c H^\circ(\alpha)$ obtained by Hall⁴⁰ and Andruzzi⁴¹ can be regarded only as estimates.

VIII. Thermodynamic parameters of the polymerisation reactions of lactones

The enthalpies of the polymerisation of β -propiolactone,³⁹ δ -valerolactone,⁷⁶ and ϵ -caprolactone⁷⁷ were measured directly in calorimeters;^{58, 94} those of glycolide,^{61, 95} α, α -dimethyl- β -propiolactone,⁴⁰ γ -butyrolactone,⁷⁵ 2-oxabicyclo[2.2.2]octan-3-one,⁴¹ undecanolactone,⁷⁹ tridecanolactone,⁸⁰ and pentadecanolactone⁸¹ were calculated from the experimental enthalpies of combustion of the monomers and polymers. In all cases, the polylactones were partly crystalline, so that the enthalpies of polymerisation were obtained from experimental data for the

processes liquid monomer \rightarrow partly crystalline polymer, i.e. $\Delta_{\text{pol}} H^\circ(l; \text{p.cr})$. The values obtained were used to calculate the enthalpies of polymerisation for the processes liquid monomer \rightarrow crystalline or amorphous (vitreous or highly elastic) polymer. The calculations were performed using the equations¹³

$$\Delta_{\text{pol}} H^\circ(l; \text{cr}) = \Delta_{\text{pol}} H^\circ(l; \text{p.cr}) + \int_T^{T_{\text{fus}}} [C_p^\circ(\text{p.cr}) - C_p^\circ(\text{cr})] dT - (20)$$

$$- (1 - \alpha) \Delta_{\text{fus}} H^\circ(T),$$

$$\Delta_{\text{pol}} H^\circ(l; \text{a}) = \Delta_{\text{pol}} H^\circ(l; \text{p.cr}) + \int_T^{T_{\text{fus}}} [C_p^\circ(\text{p.cr}) - C_p^\circ(\text{a})] dT - (21)$$

$$- \alpha \Delta_{\text{fus}} H^\circ(T),$$

where T is the temperature at which the enthalpy of polymerisation was determined experimentally and the calculation was performed; in those cases where the enthalpies of polymerisation were determined from the enthalpies of combustion the temperature was $T = 298.15 \text{ K}$, whereas in the direct measurements in the calorimeter $T \approx 350 \text{ K}$. The enthalpy of fusion of the polylactone $\Delta_{\text{fus}} H^\circ(T)$ at the temperature of the determination of the enthalpy of polymerisation was calculated by Eqn (17).

For other temperatures, the $\Delta_{\text{pol}} H^\circ$ were calculated from the Kirchhoff formula (Table 6):

Table 6. The enthalpies (kJ mol⁻¹), entropies (J mol⁻¹ K⁻¹), and Gibbs free energies (kJ mol⁻¹), of the polymerisation of lactones in bulk with formation of polylactones ($p = 101.325$ kPa).

^a The following designations of the states of the reactants have been adopted: cr — crystalline, g — vitreous (glassy), h.e. — highly elastic, l — liquid, gas — gaseous, crI, crII, crIV — different crystalline modifications, p.cr — partly crystalline.

$$\Delta_{\text{pol}}H^\circ(T) = \Delta_{\text{pol}}H^\circ(298.15 \text{ or } 350 \text{ K}) + \Delta[H^\circ(T) - H^\circ(0)], \quad (22)$$

where $\Delta[H^\circ(T) - H^\circ(0)]$ is the difference between the enthalpies of heating the monomer and the polymer, which may be calculated from the data in Table 4.

We may note the characteristic features of the experimental determinations of the enthalpies of the polymerisation of β -propiolactone, α, α -dimethyl- β -propiolactone, and 2-oxabicyclo[2.2.2]octan-3-one. The enthalpy of the bulk polymerisation of β -propiolactone was measured by Sunner and coworkers³⁹ in a Calvet calorimeter⁹⁴ in seven experiments at $T = 298.15 \text{ K}$. $\Delta_{\text{pol}}H^\circ(\alpha) = -80 \pm 3.8 \text{ kJ mol}^{-1}$ was found. The degree of crystallinity was not determined, but it was possible to measure the enthalpy of fusion of the crystalline component of the polymer as $\Delta_{\text{fus}}H^\circ(\alpha) = 7.5 \text{ kJ mol}^{-1}$. Using the value of $\Delta_{\text{fus}}H^\circ$ ($\alpha = 100\%$) (Table 2), Evstropov et al.⁶³ estimated the degree of crystallinity as 75%. This made it possible in its turn to calculate the enthalpy of the polymerisation of β -propiolactone to crystalline and amorphous poly- β -propiolactone⁶³ (Table 6).

The enthalpy of the polymerisation of α, α -dimethyl- β -propiolactone to poly- α, α -dimethyl- β -propiolactone at $T = 298.15 \text{ K}$ was found by Hall:⁴⁰ $\Delta_{\text{pol}}H^\circ(\text{l.p.cr}) = -84 \text{ kJ mol}^{-1}$. It was calculated using the results of the determinations of the enthalpies of combustion of the monomer and the polymer. In order to determine Δ_cH° for the monomer, four experiments were performed, while in the case of the polymer three experiments were carried out. The purity of the monomer specimen was 99%; the polymer was not characterised and it is only known that it was partly crystalline. From this it follows that the value of $\Delta_{\text{pol}}H^\circ$ obtained must be regarded only as an estimate.

Andruzzi⁴¹ gives $\Delta_{\text{pol}}H^\circ(\text{cr;cr}) = -20.9 \pm 2.3 \text{ kJ mol}^{-1}$ for the polymerisation of 2-oxabicyclo[2.2.2]octan-3-one to poly-2-oxabicyclo-1,4-cyclohexylene at $T = 298.15 \text{ K}$. It was obtained from the enthalpies of combustion of the monomer and the polymer. The enthalpy of combustion of the monomer was measured in five experiments and that of the polymer in fifteen experiments. A polymer with \bar{M}_n from 2.1×10^3 to 1×10^6 was used. Analysis of the products of the combustion of the monomer and the polymer showed that the CO_2 content was 99.50 mass%–99.72 mass% relative to the theoretical amount. For the monomer in the crystalline state, $\Delta_cH^\circ = -3717.5 \pm 1.3 \text{ kJ mol}^{-1}$ while for the polymer $\Delta_cH^\circ(\alpha) = -3686.9 \pm 7.6$ to $-3700 \pm 9.8 \text{ kJ mol}^{-1}$. The reasons for the differences between the enthalpies of combustion of the polymer are probably different degrees of crystallinity and also different contents of the *cis*- and *trans*-units in the macromolecules. Andruzzi⁴¹ attempted to measure $\Delta_{\text{pol}}H^\circ$ directly in the calorimeter, but did not succeed because of the unduly low rate of the polymerisation process. Furthermore, he estimated $\Delta_cH^\circ(\text{l;cr})$ as $-76 \pm 10 \text{ kJ mol}^{-1}$. Clearly the value of $\Delta_{\text{pol}}H^\circ$ quoted must be regarded as an approximate estimate.

The entropies of the polymerisation reactions of the lactones (Table 6) were calculated from the entropies of the reactants (Table 4):

$$\Delta_{\text{pol}}S^\circ(T) = S^\circ(\text{M}) - S^\circ(\text{P}), \quad (23)$$

where $S^\circ(\text{M})$ and $S^\circ(\text{P})$ are the absolute entropies of the monomer and the polymer respectively at a temperature T .

The Gibbs free energies of the processes were calculated from a $\Delta_{\text{pol}}H^\circ(T)$ and $\Delta_{\text{pol}}S^\circ(T)$ by the formula

$$\Delta_{\text{pol}}G^\circ(T) = \Delta_{\text{pol}}H^\circ(T) - T\Delta_{\text{pol}}S^\circ(T). \quad (24)$$

The equilibrium concentration of the monomer $[M]_e^\circ$ in the reaction mixture at thermodynamic equilibrium may be determined from the standard Gibbs free energy:

$$[M]_e^\circ = \exp \frac{\Delta G_{\text{pol}}^\circ(T)}{RT}, \quad (25)$$

while the equilibrium concentration of the polymer in the same mixture may be found from the formula

$$[P]_e^\circ = 1 - \exp \frac{\Delta_{\text{pol}}G^\circ(T)}{RT}. \quad (26)$$

Table 7 presents the limiting polymerisation temperatures of lactones, mainly for the liquid monomer \rightarrow liquid polymer processes. They were estimated graphically from the point of intersection of the $\Delta_{\text{pol}}H^\circ = f(T)$ and $T\Delta_{\text{pol}}S^\circ = f(T)$ relations^{14, 18} or by Dainton's method.¹⁸

Table 7. The upper limiting polymerisation temperatures of lactones in bulk under standard pressure.

Lactone	$T_{\text{cel}}^\circ / \text{K}$	Method of determination ^a	Ref.
Glycolide	1800	D	61

ϵ -Caprolactone	900	G	77

^a The following designations have been adopted: D — Dainton's method, G — graphical method.

IX. The regularities and characteristics of the thermodynamic properties of polylactones and of the parameters of the polymerisation reactions of lactones

1. Thermodynamic parameters of fusion

Figure 7 presents the dependences of the melting points and the enthalpies and entropies of fusion of polylactones on the composition of the monomer repeat units, each of which has one methylene group more than the preceding one.⁹⁶ Evidently T_{fus}°

Figure 7. Dependence of the thermodynamic parameters of fusion of polylactones on the number of atoms and atomic groups in the monomer repeat unit of the polymer.⁹⁶

(1) Melting point; (2) enthalpy of fusion; (3) entropy of fusion.

initially decreases rapidly from 501 K for polyglycolide to 331 K for poly- δ -valerolactone and then slowly increases to 371 K for polypentadecanolactone. On further increase in the number of CH₂ groups in the monomer repeat unit in polylactone, T_{fus}° would apparently increase, tending in the limit to T_{fus}° for polyethylene (405 K).⁹⁷

Thielaut et al.⁸⁸ investigated the influence of the composition and structure of the alkyl substituents on the melting points of di- and tri-alkyl-substituted poly- β -propiolactones. Qualitative examination of the results showed that polymers having a more symmetrical structure also have higher melting points; polyesters with the same substituents at the α -carbon atom have the highest T_{fus}° . The dependences of $\Delta_{fus}H^{\circ}$ and $\Delta_{fus}S^{\circ}$ on n are linear and are described by the following equation subject to an error of several percent:

$$\Delta_{fus}H^{\circ} = -5.5 + 3.74n, \quad (27)$$

$$\Delta_{fus}S^{\circ} = -9.0 + 9.75n. \quad (28)$$

The existence of these simple relations made it possible to estimate the corresponding parameters of fusion for polylactones which have not yet been investigated (Table 2).

Comparison of the melting points of polylactones and the corresponding lactones showed¹³ that T_{fus}° for the polymers is higher than for the monomers. The maximum difference between the T_{fus}° is 126 ° for poly- β -propiolactone and β -propiolactone. With increase in the ring size in lactones, ΔT_{fus}° gradually decreases to 62 ° for polypentadecanolactone and pentadecanolactone. The enthalpies of fusion of polylactones are also higher than for the lactones, usually by a factor of 1.2–1.5, while in the case of the polymers obtained from macrocyclic monomers ($n > 10$) the increase is severalfold. It is of interest that the entropies of fusion of (4–6)-membered lactones are equal to or somewhat greater than the $\Delta_{fus}S^{\circ}$ for the corresponding polylactones; $\Delta_{fus}S^{\circ}$ for (7–16)-membered monomers is smaller than for the corresponding polymers — several times smaller for lactones with $n > 12$.

2. Parameters of vitrification and of the vitreous state

The dependence of T_g° for polylactones on the number of atomic groups in the monomer repeat unit⁸² has a form similar to the dependence of T_{fus}° presented in Fig. 7. In the series from four-membered to seven-membered polylactones, T_g° decreases from 318 to 209 K and then increases comparatively slowly to 251 K for polypentadecanolactone. The influence of substitution by methyl groups on T_g° for poly- ϵ -caprolactone has been discovered.⁹³ $T_g^{\circ} = 213$ K for poly- ϵ -caprolactone, 233 K for poly- ϵ -methyl- ϵ -caprolactone, and 220 K for poly- γ -methyl- ϵ -caprolactone and poly- α , ϵ -dimethyl- ϵ -caprolactone. Koleske and Lundberg⁹⁰ compared the glass transition temperatures of polylactones obtained by the polymerisation of (4–16)-membered lactones. It was found that the difference between the glass transition temperatures of the corresponding polymers and monomers is $\Delta T_g^{\circ} = 70 \pm 3$ K. β -Propiolactone and poly- β -propiolactone and also ϵ -caprolactone and poly- ϵ -caprolactone, for which the corresponding differences are 103 and 33 K, are exceptions in the above series.

The $\Delta C_p^{\circ}(T_g^{\circ})$ data obtained for polylactones conform to the familiar Wunderlich rule⁹⁸ that the heat capacity increases on devitrification of amorphous polymers by 11.5 ± 1.7 J K⁻¹ per mole of beads: for polylactones, the increment is 12.5 ± 2.5 J K⁻¹ per mole of beads. The values of $H_g^{\circ}(T) - H_{cr}^{\circ}(0)$ and $S_g^{\circ}(0)$ (Table 3) increase linearly with increase in n , the deviations from the corresponding straight line not exceeding 10%. The accuracy of the calculation of the above quantities is the same.

3. Thermodynamic functions

The dependences of C_p° , $H^{\circ}(T) - H^{\circ}(0)$, $S^{\circ}(T)$, and $G^{\circ}(T) - H^{\circ}(0)$ on n for polylactones at a specified temperature and the standard pressure are straight lines, provided that all the polylactones are in the same physical state.^{13,82} For example, at $T = 298.15$ K and

$p = 101.325$ kPa, the thermodynamic functions for crystalline polylactones are described (subject to an error within the limits of 1%) by the linear equations

$$C_p^{\circ} = -2.2 + 23.42n, \quad (29)$$

$$H^{\circ}(T) - H^{\circ}(0) = 0.46 + 3.732n, \quad (30)$$

$$S^{\circ}(T) = 7.85 + 24.46n, \quad (31)$$

$$-[G^{\circ}(T) - H^{\circ}(0)] = 1.87 + 3.559n. \quad (32)$$

The dependences of the heat capacities of polylactones on n at different temperatures are presented in Fig. 8. The linear relations between the thermodynamic functions and n are undoubtedly associated with the additivity of the corresponding contributions of the methylene groups to particular properties of polylactones. The existence of these relations makes it possible to estimate reliably the thermodynamic functions of polylactones in the series from four-membered to 20-membered polylactones which have not yet been studied experimentally (Table 4).

Figure 8. Heat capacity isotherms for polylactones as a function of the number of atoms and atomic groups in the monomer repeat unit of the polymer.⁸² T/K : (1) 20; (2) 50; (3) 100; (4) 200; (5) 300.

4. Thermochemical characteristics

Using the data in Table 5, Kiparisova and Lebedev⁹⁹ fitted by the method of least squares the linear dependences of the thermochemical characteristics of polylactones on the number of carbon atoms ($n' = 3, 4, 6, 11, 13$, and 15) in the monomer repeat units of the macromolecules for $T = 298.15$ K and the standard pressure.

The following relations were found for the enthalpies of combustion and formation of polylactones in the crystalline and vitreous or highly elastic states per mole of the repeat units:

$$\Delta_c H^{\circ}(\text{cr}) = -598.2 + 650.0n', \quad (33)$$

$$\Delta_c H^{\circ}(\text{g}) = -591.8 + 652.8n', \quad (34)$$

$$\Delta_f H^{\circ}(\text{cr}) = -316.8 - 29.0n', \quad (35)$$

$$\Delta_f H^{\circ}(\text{g}) = -318.4 - 25.7n'. \quad (36)$$

The deviations of the experimental values of $\Delta_c H^{\circ}(\text{cr})$ and $\Delta_c H^{\circ}(\text{g})$ from the corresponding straight lines [Eqns (33) and (34)] do not exceed 0.2%, while the deviations of the $\Delta_f H^{\circ}(\text{cr})$ and $\Delta_f H^{\circ}(\text{g})$ do not exceed 2%.

The following relations were established for the entropies of formation:

$$\Delta_f S^{\circ}(\text{cr}) = -4.7 - 111.6n', \quad (37)$$

$$\Delta_f S^\circ(\text{g}) = -5.7 - 103.0n' \quad (38)$$

The deviations of the experimental points from the calculated $\Delta_f S^\circ(\text{cr})$ and $\Delta_f S^\circ(\text{g})$ are within the limits of 10%.

The equations found for the Gibbs free energies are as follows:

$$\Delta_f G^\circ(\text{cr}) = -315.9 + 4.3n', \quad (39)$$

$$\Delta_f G^\circ(\text{g}) = -316.6 + 5.0n'. \quad (40)$$

The deviations of the experimental data from the calculated values of $\Delta_f G^\circ(\text{cr})$ and $\Delta_f G^\circ(\text{g})$ are within the limits of 15%. It has been suggested⁹⁹ that the above equations will prove useful for the estimation of the corresponding thermochemical characteristics of the hitherto uninvestigated polylactones of the series considered. The chemical characteristics found for such polylactones by Eqns (33)–(40) will apparently be subject to approximately the same error as the values found experimentally.

In conclusion, we may note that poly- β -methyl- β -propiolactone and poly- γ -butyrolactone are structural isomers (according to the data of Holmers,⁸ poly- β -methyl- β -propiolactone is an isotactic polymer). Their thermochemical characteristics are fairly close (Table 5) and their enthalpies of combustion and formation in the crystalline state are simply identical. In this connection, the obvious conclusion arises that the $\Delta_c H^\circ$ and $\Delta_f H^\circ$ can also be estimated for other methylsubstituted crystalline polylactones — structural isomers of the polymers investigated.

5. Thermodynamic parameters of polymerisation

Figure 9 presents the Gibbs free energies of polymerisation of lactones in the range from 0 to 400 K at $p = 101.325$ kPa.^{13,96} Evidently the values of $\Delta_{\text{pol}} G^\circ$ for each lactone vary within a fully defined range as a function of temperature (the sections enclosed between curves 1 and 2). This range depends on the compositions, structures, and physical states of the reactants. $\Delta_{\text{pol}} G^\circ < 0$ for four- and (6–13)-membered lactones, while $\Delta_{\text{pol}} G^\circ$ for (14–18)-membered lactones assumes both positive and negative values; for the five-membered lactone, $\Delta_{\text{pol}} G^\circ > 0$. With increase in ring size, the limits of the variation of $\Delta_{\text{pol}} G^\circ$ increase from -54 – -68 kJ mol⁻¹ for β -propiolactone ($n = 4$) to -31 – -29 kJ mol⁻¹ for pentadecanolactone ($n = 16$). All the lactones can be arranged in a series in terms of the values of $\Delta_{\text{pol}} G^\circ$ for liquid monomer \rightarrow liquid polymer processes: β -propiolactone > undecanolactone > decanolactone > dodecanolactone > nonadecanolactone > nonanolactone > η -caprylactone > tridecanolactone > ϵ -caprolactone > ϕ -oenantholactone > pentadecanolactone > δ -valerolactone > lactones with

Figure 9. The Gibbs free energies of polymerisation of lactones in the range 0–400 K.^{13,96}
Process: (1) $\text{M}(\text{cr}) \rightarrow \text{P}(\text{cr})$ at 200 K; (2) $\text{M}(\text{cr}) \rightarrow \text{P}(\text{g})$ at 0 K.

Figure 10. The enthalpies of polymerisation of lactones in the range 0–400 K.^{13,96}
Process: (1) $\text{M}(\text{l}) \rightarrow \text{P}(\text{cr})$ at 300 K; (2) $\text{M}(\text{cr}) \rightarrow \text{P}(\text{cr})$ at 0 K; (3) $\text{M}(\text{l}) \rightarrow \text{P}(\text{l})$ at 370 K; (4) $\text{M}(\text{cr}) \rightarrow \text{P}(\text{g})$ at 0 K.

$n > 20 > \gamma$ -butyrolactone. The sequence thus obtained represents the thermodynamic series for the polymerisabilities of the lactones.

For the same lactone, the $\Delta_{\text{pol}} H^\circ$ for the polymerisation reactions with reactants in different physical states can be arranged in the following sequence: $\text{M}(\text{l}) \rightarrow \text{P}(\text{cr}) > \text{M}(\text{cr}) \rightarrow \text{P}(\text{cr}) > \text{M}(\text{l}) \rightarrow \text{P}(\text{l}) > \text{M}(\text{cr}) \rightarrow \text{P}(\text{g})$, where M is the monomer and P the polymer. The consecutive arrangement of curves 1–4 corresponds to this series in Fig. 10. The $\Delta_{\text{pol}} H^\circ(\text{l}; \text{l})$ increase in the direction from the four-membered to the five-membered lactone, after which they diminish towards the 12-membered lactone, and then again increase. This type of variation of $\Delta_{\text{pol}} H^\circ$ on passing from the four-membered to the 16-membered lactone is caused by the variation of the ring strain energy E . The ring strain energy is evolved on polymerisation of lactones with ring opening, making the main contribution to $\Delta_{\text{pol}} H^\circ(\text{l}; \text{l})$. For example $\Delta_{\text{pol}} H^\circ(\text{l}; \text{l}) = -6$ kJ mol⁻¹ for tridecanolactone, while $E = 8$ kJ mol⁻¹.

As the temperature varies from 0 to 400 K, the entropies of polymerisation of lactones assume both positive and negative values (Fig. 11). As was to be expected, $\Delta_{\text{pol}} S^\circ$ has minimum

Figure 11. The entropies of polymerisation of lactones in the range 0–400 K.^{13,96}
Process: (1) $\text{M}(\text{l}) \rightarrow \text{P}(\text{cr})$ at 330 K; (2) $\text{M}(\text{l}) \rightarrow \text{P}(\text{l})$ at 370 K; (3) $\text{M}(\text{cr}) \rightarrow \text{P}(\text{g})$ at 200 K.

values for the $M(l) \rightarrow P(cr)$ processes and maximum values for the $M(cr) \rightarrow P(g)$ processes. For the $M(l) \rightarrow P(cr)$ process, the entropy of polymerisation varies from -76 for the four-membered ring to $-116 \text{ J mol}^{-1} \text{ K}^{-1}$ for the 16-membered ring, while for the process $M(cr) \rightarrow P(g)$ the variation is from 14 to $108 \text{ J mol}^{-1} \text{ K}^{-1}$ respectively. The increase in $\Delta_{pol}S^\circ$ for the process $M(cr) \rightarrow P(g)$ is due to the contribution from the zero-point entropy of the polymer $S_g^\circ(0)$, which increases with n . The gradual expansion of the range of variation of $\Delta_{pol}S^\circ$ on passing from the four-membered to the 16-membered ring is associated with the influence of the entropies of the phase transitions of the reactants. The variation of $\Delta_{pol}S^\circ$ for the processes $M(l) \rightarrow P(l)$ is interesting (Fig. 11, curve 2). With increase in n , the quantity $\Delta_{pol}S^\circ(l;l)$ initially increases from $53 \text{ J mol}^{-1} \text{ K}^{-1}$ for β -propiolactone to $26 \text{ J mol}^{-1} \text{ K}^{-1}$ for tridecanolactone and then decreases. If curve 2 is imagined to be prolonged into the range of values $n > 16$, then $\Delta_{pol}S^\circ(l;l) = 0$ at $n \approx 22-25$. This means that rings of this size and larger ones as well as the corresponding repeat units in the polyester macromolecules are entropically indistinguishable. Since rings of this size are of course unstrained, it follows naturally that $\Delta_{pol}G^\circ = 0$ for such structures.

None of the lactones examined in this review has a lower limiting polymerisation temperature. A series of processes have an upper limiting temperature T_{ceil}° . The numerical values of T_{ceil}° are determined by the ratio of a $\Delta_{pol}H^\circ$ and $\Delta_{pol}S^\circ$ at T_{ceil}° . Thus $T_{ceil}^\circ = 1450 \text{ K}$ for β -propiolactone, which is due to the high value of $\Delta_{pol}H^\circ(l;l) = -74 \text{ kJ mol}^{-1}$ and the relatively low value of $\Delta_{pol}S^\circ = -51 \text{ J mol}^{-1} \text{ K}^{-1}$. On passing to δ -valerolactone, $\Delta_{pol}H^\circ$ diminishes sharply and there is only a slight decrease in $\Delta_{pol}S^\circ$. Both these factors lead to $T_{ceil}^\circ = 760 \text{ K}$ for δ -valerolactone. Lactones in which the number of ring members is between 9 and 16 have neither a lower nor an upper limiting temperature because $\Delta_{pol}H^\circ(l;l) < 0$, and $\Delta_{pol}S^\circ > 0$ for these substances.

Abstract. Published data dealing with the synthesis of esters of β -amino acids by nucleophilic addition of amines and metal amides to esters of α,β -unsaturated carboxylic acids are considered. Information on the influence of various factors on the chemical yield and diastereoselectivity of the Michael reaction is discussed systematically. The bibliography includes 70 references.

I. Introduction

During recent years, extensive studies on the synthesis and stereochemistry of β -lactams, which are fragments of numerous natural biomolecules, have been carried out. Since the biological activity of β -lactams is associated with only one of all possible diastereomers,^{1,2} the attention of researchers is focused on the problem of asymmetric synthesis of homochiral β -lactams.^{3–5} Chiral β -amino acids⁶ or their esters, which are difficult to obtain, are precursors of these compounds.

The simplest method for the synthesis of β -amino esters is the conjugate addition of primary or secondary amines (reaction 1) or the corresponding metal amides (reaction 2) to esters of α,β -unsaturated carboxylic acids.

These reactions (if R^1 and/or $\text{R}^2 \neq \text{H}$) result in the formation of a chiral centre at the C_β (and/or C_α) atom and, in some cases, if certain conditions are satisfied, asymmetric synthesis of esters of β -amino acids becomes possible.

II. Nucleophilic addition of amines to esters of α,β -unsaturated acids

The conditions of the syntheses of β -amino esters from primary amines and α,β -unsaturated carboxylates are presented in Table 1. Polar solvents such as alcohols or carboxylic acids are usually employed as the reaction medium. Aprotic solvents, in particular THF, are also used; in some cases, the addition occurs only in a polar medium.⁷

Primary amines do not react with esters of α,β -unsaturated carboxylic acids under ordinary conditions, except for some individual cases (Table 1, entries 1, 2, 6, and 41); therefore, to prepare β -amino esters, the process of addition must be activated.¹⁷

Thermal activation of this reaction leads to satisfactory results; primary amines react most readily with methyl hydroxybenzylacrylate (yields 92%–95%, see entries 3 and 4 in Table 1). With crotonates (entries 12–15, 17, and 18) and cinnamates (entries 38 and 39), the yields of β -amino esters are as low as 14%–47%. It can be seen that an increase in the size of the substituent at the β -carbon atom decreases the chemical yields of the resulting β -amino esters from 26%–47% to 14%–16%. Similar results were also obtained for the addition of (*S*)- α -phenylethylhydroxylamine to methyl esters of α,β -unsaturated carboxylic acids.¹⁸

Received 17 April 1996

Uspekhi Khimii 65 (12) 1170–1180 (1996); translated by Z P Bobkova

The yields of isoxazolidinones, which are formed in this reaction and can be readily reduced to β -amino acids, decrease from 91% (in the case of 4-methylpentenoic acid) to 54% (in the case of cinnamic acid).

The Michael reaction can also be activated by high pressure.¹⁹ This can be illustrated by the addition of benzylamine and α -methylbenzylamine to substituted menthyl crotonates (cf.

Table 1. Conditions of reactions of primary amines with esters of α,β -unsaturated carboxylic acids.

^a In Tables 1–4, d.e. stands for diastereomeric excess;

entries 17–19 and 20–26 in Table 1). The chemical yields vary between 50% and 90% and depend on the nature of the substituent in the substrate.

The use of titanium tetrachloride (Table 1, entry 33) or of ytterbium chloride (entry 34) as catalysts of the conjugate addition does not favour an increase in the yield of β -amino esters (yield ~28%); in addition, the amide of the initial α,β -unsaturated carboxylic acid is formed in these reactions as a side product in approximately the same yield (26%).

When various 2-chloro-2-cyclopropylideneacetates react with (4*S*,5*R*)-4,5-diphenyloxazolidin-2-one in THF in the presence of 10 mol.% of sodium hydride and a small amount of DB-18-C-6 crown ether, the corresponding 1,4-addition products are formed in chemical yields of 57%–88%.²⁰

Recently it has been shown¹⁵ that highly oxophilic lanthanide triflates, which are currently widely used in organic catalysis,²¹ accelerate the Michael reaction, in particular the addition of benzylamine to ethyl crotonate (Table 1, entries 27–32). The yields of the target products in these reactions are 92%–97%, and no side products are formed. In the presence of ytterbium triflate, pyrrolidine easily adds to ethyl crotonate giving the corresponding product in 95% yield; however, α -phenylethylamine, which is sterically more hindered, does not react so readily: the yield of the corresponding product is only 26% (see Table 1, entry 35).

The catalytic addition of amines to esters of α,β -unsaturated acids occurs at room temperature over a period of several hours. Both polar (ethanol) and non-polar (toluene) solvents have been used as the reaction media. The best results were achieved with THF as the solvent and ytterbium triflate as the catalyst. Variation of the polarity of the reaction medium or the use of triflates of other lanthanides do not lead to any substantial changes in the yield of the reaction product (Table 1, entries 30–32, 27–29).

More recent studies^{10, 22, 23} have confirmed that lanthanide triflates are preferred as catalysts in the Michael conjugate addition over other Lewis acids, since the latter are more prone to form complexes with amines thus decreasing their reactivity. The use of acetonitrile as the solvent increases the chemical yield of β -amino esters to 100% (Table 1, entries 36 and 37). In the case of sterically more hindered *tert*-butylamine, a considerable increase in the chemical yield can be achieved by using a combination of activating factors, such as high pressure and a catalyst (ytterbium triflate). Under these conditions, even secondary amines (for example, diisopropylamine and diisobutylamine) enter into the reaction with esters of α,β -unsaturated carboxylic acids. The main contribution to the increase in the chemical yields of the reaction products is made by pressure (Table 1, entries 8–11).

The addition of primary amines and cyclic secondary amines to esters of α,β -unsaturated carboxylic acids also led to satisfactory yields of products (39%–72%), when baker yeast was used as the catalyst.²⁴

Acyclic secondary amines do not usually react with esters of α,β -unsaturated carboxylic acids,^{14, 15} whereas cyclic secondary amines, for example, piperidine:^{15, 22, 23, 25} react to give products in very high chemical yields (up to 100%). For example, 2,7-dihydro-1*H*-dinaphtho[2,1-*c*:1',2'-*e*]azepine **2** adds to methyl crotonate to afford the corresponding product in 68% yield.²⁶

The reaction is carried out with excess methyl crotonate, with boiling, and without a solvent.

Analysis of the data presented in Table 1 indicates that when sterically less hindered reactants are used and when the optimal reaction conditions (solvent, temperature, pressure, and catalyst) are chosen, esters of β -amino acids can be synthesised in high yields.

III. Nucleophilic addition of metal amides to esters of α,β -unsaturated carboxylic acids

In recent years, metal amides, which have found wide application in asymmetric synthesis, have been used with increasing frequency for the nucleophilic addition to esters of α,β -unsaturated carboxylic acids.²⁷

Primary and some secondary lithium amides react with esters of α,β -unsaturated carboxylic acids as strong bases. Therefore, apart from the target esters of β -amino acids **3**, which are formed in relatively low yields, these reactions afford the corresponding amides **4** or esters of β,γ -unsaturated carboxylic acids **5** (Table 2), these compounds being the main reaction products. In some cases, β -aminoamides have also been detected among the products.³⁴

Side products **5** are also formed when sterically hindered secondary lithium amides react with esters of α,β -unsaturated carboxylic acids (Table 2, entries 9 and 10). For example, the formation of esters **5** in this reaction has been explained³³ by the fact that in the six-membered transition state, the amide attacks

Table 2. Products of the interaction of lithium amides with esters of α,β -unsaturated carboxylic acids.

^a The configuration of the initial ester is given in parentheses.

the protons of the methylene group, located in the γ -position with respect to the carbonyl group in the substrate, and thus induces the rearrangement of the double bond to the β,γ -position. This process is markedly facilitated if the initial ester has the *cis*-configuration.

The nucleophilic properties of secondary lithium amides, which are more bulky, dominate over their basic properties. Therefore, they preferentially add to the β -position with respect to the carbonyl group, which results in the formation of β -amino esters as the main (and practically the only) reaction products (Table 3). The reaction is usually carried out at a low temperature for 15–30 min. Varying the temperature conditions (from -78 to $+20^\circ\text{C}$) exerts no substantial influence on the chemical yield of β -amino esters.^{13, 29, 45} The best results have been achieved by using a 1.5-fold excess of the amide.⁴⁴ Lithium benzyl(α -phenylethyl)amide **7** is used most often in these conjugate addition reactions.

Good results have also been obtained when the lithium derivative of the above-mentioned dihydro-4*H*-dinaphthoazepine and lithium benzyl(trimethylsilyl)amide have been used as nucleophiles (chemical yields of up to 88% and of 77%–99%, respectively). When symmetrical lithium bis(α -phenylethyl)amide is used, the yield of the corresponding β -amino esters decreases to 23% due to the steric hindrance arising in the amide itself during the nucleophilic attack.⁴⁸ The introduction of substituents in one of the benzene rings in lithium benzyl(α -phenylethyl)amide exerts no influence on the final result of the reaction (Table 3, entries 60–62).

The introduction of a methyl group in the α -position with respect to the carbonyl group of the ester also decreases the yields of the corresponding β -amino esters from 77%–92% to 21%–61% (cf. entries 1, 2 and 7, 8 as well as entries 17, 18 and 21, 22, etc. in Table 3). The nature of the radical located in the β -position with respect to the carboxyl group of the substrate and the nature of the ester group exert as a rule no substantial influence on the chemical yield in the nucleophilic addition of metal amides to the double bond. The yield of β -amino ester increases somewhat if the initial ester contains a silyl group^{46, 49} (Table 3, entries 51–53 and 54).

The conjugate addition of lithium amides occurs more successfully with the *trans*-isomers of α,β -unsaturated esters. In those cases where the corresponding *cis*-isomers are used, the chemical yield decreases from 80% to 39% (see Table 3, entries 42 and 43). However the *cis*-configuration of cyclic esters does not influence the yield of the final β -amino ester (Table 3, entries 14, 15, and 26, 30–32).

The solvent exerts substantial influence on the addition. The reaction is usually carried out in polar aprotic solvents such as THF or 1,2-dimethoxyethane (DME). Less polar solvents, for example, toluene or its mixtures with THF, are also used sometimes. The addition of an excess of a crown ether (12-crown-4) increases the chemical yield of β -amino esters by a factor of 1.5–2 (cf. entries 36 and 41 as well as 47 and 48 in Table 3), whereas the addition of polar solvents (in particular, HMPTA) considerably decreases the yield (from 44% to 18%–28%) (Table 3, entries 36, 38, and 39).^{44, 50} Since the basic properties of amides are enhanced in a polar medium, the interaction of ethyl crotonate with lithium diisopropylamide in THF containing some HMPTA affords the isomeric β,γ -unsaturated ester **5** as the only product (see Table 2, entry 4), whereas in the absence of HMPTA, the reaction occurs as a 1,4-addition in nearly quantitative yield (90%).²⁹

Various protonating agents have been used to decompose the β -aminoenolates **A** formed upon 1,4-addition (see reaction 2); a saturated aqueous solution of ammonium chloride, alcohols, or a buffer solution with pH 7 are employed most frequently. The best result has been achieved by using sterically hindered 2,6-di-*tert*-butylphenol. The use of acetic acid as the protonating agent leads to a decrease in the chemical yield of β -amino ester from 40% to 21% (cf. entries 6 and 8 in Table 3), and when aqueous acetic acid is used, the final product may polymerise.⁵¹

If an alkyl halide is added to the reaction mixture instead of a protonating agent, the β -aminoenolate **A** is alkylated at the α -carbon atom (the so-called tandem reaction) resulting in the formation of α -alkyl- β -amino ester **8** (Table 4). An increase in the size of the radical R^5 in the alkylating agent usually deteriorates the chemical yield of the product **8** (see entries 10 and 11; 12 and 13; and 15 and 16 in Table 4). The nature of the substituents in the amide and in the ester is not crucial for the occurrence of the tandem reaction.

When (+)-(camphorsulfonyl)oxaziridine **9**

is used as a hydroxylating agent, α -hydroxy- β -amino esters **10** can be prepared (Table 5). If a phenyl substituent occurs in the β -position with respect to the carbonyl group, the yield of the final product is higher than those obtained with compounds containing aliphatic substituents (entries 2, 3, and 5–8 in Table 5). However, replacement of the phenyl group by a benzyl group leads to a sharp decrease in the product yields (entries 2 and 9; 3 and 10). It is of interest that when lithium (*S*)-benzyl(α -phenylethyl)amide is used, the yield of the product **10** is higher than with the (*R*)-isomer (Table 5, entries 7–10). The nature of the alkyl radical in the ester group exerts an ambiguous influence on the yield of the α -hydroxy- β -amino esters.

The conjugate addition of amides of other metals to esters of α,β -unsaturated carboxylic acids has not been studied in detail. It has been found that titanium amides like $\text{Ti}(\text{NR}_2)_4$, $\text{ClTi}(\text{NR}_2)_3$, and $\text{Cl}_2\text{Ti}(\text{NR}_2)_2$ ($R = \text{Me}, \text{Et}$) add to acrylates, crotonates, and cinnamates to give the corresponding β -amino esters in good chemical yields (34%–97%); however, amides of β,γ -unsaturated acids (21%–39%) are often formed as side products. The formation of the latter can be completely eliminated by using esters with bulky ester groups.⁵⁹

Lithium amidocuprates $(\text{R}_2\text{N})_2\text{CuLi}$ add to esters of α,β -unsaturated carboxylic acids yielding β -amino esters as the main reaction products,^{33, 60, 61} although in this case, too, small amounts of β,γ -unsaturated carboxamides are formed.³³

Magnesium benzyl(α -phenylethyl)amide has been used successfully in the conjugate addition to *tert*-butyl cinnamate,⁶² as well as in an addition reaction followed by α -alkylation.

The chemical yields of products in the latter reactions are comparable with the yields of the same products in the similar reactions involving the corresponding lithium amides (Table 3, entry 18; Table 4, entry 15).

^a The (S)-isomer of the amine was used.

IV. Stereochemistry of nucleophilic addition of amines and metal amides to esters of α,β -unsaturated carboxylic acids

The reactions of chiral amines, in particular, of α -phenylethylamine, with esters of α,β -unsaturated carboxylic acids are characterised by relatively low stereoselectivities (d.e. = 0%–19%, d.e. is diastereomeric excess), irrespective of the type of activation used: high temperature, high pressure, or a catalyst. The interaction of azepine **2** with methyl crotonate without a solvent is an exception; in this case, diastereomeric excess is 61%.²⁶

When the conjugate addition of amines to esters of α,β -unsaturated carboxylic acids is carried out with the catalytic activation by lanthanide triflates, the diastereomeric excess is only 12%–31%.^{15, 22, 23} However, in the case where the substrate molecule can be fixed due to the coordination of the catalyst to the oxygen atoms of the carbonyl groups in the substituted amide of α,β -unsaturated acid, presented below, the steric restrictions thus arising cause the nucleophile to attack the substrate from the side that is sterically less hindered. Consequently, 1,4-addition occurs stereoselectively (d.e. up to 80%).^{63, 64}

Reactions of benzylamine with acrylic acid derivatives having a chiral substituent in the α -position with respect to the carbonyl group are fairly stereoselective: d.e. is 49%–91% (Table 1, entries 1–6). The presence of a bulky substituent in the β -position with respect to the carbonyl group of the ester is probably the main factor responsible for the stereospecific character of the addition (Table 1, entry 41), although the fact that this reaction was carried out at a negative temperature and without a solvent should apparently also be taken into account. The presence of a bulky ester group also increases the stereoselectivity of the reaction (entries 21–24) and, in some cases (entries 25 and 26), it even makes the reaction stereospecific.

However, the stereoselectivity of the conjugate 1,4-addition of amines to esters of α,β -unsaturated carboxylic acids is influenced

most strongly by the geometric isomerism in the initial esters. It has been shown that, despite the fact that isomeric ethyl esters are characterised by the same (R)-configuration at the C γ atoms, the *trans*-isomer reacts with benzylamine non-stereoselectively (reaction 3), whereas the reaction of the *cis*-isomer is highly stereoselective (reaction 4); the absolute configuration at the β -carbon atom in diastereomer **C**, formed as the major product, is opposite to that in diastereomer **B**.¹⁵

A similar picture has been observed when 1,4-addition has been carried out with lithium amides: the β -amino esters formed are characterised by the opposite configuration at the β -carbon atom.^{44, 52, 53, 65} In this case, the stereoselectivity of the process depends to a lesser degree on the geometry of the initial ester (see Table 3, entries 42 and 43).

It should be specially noted that the intramolecular addition of the ω -amino-group, incorporated in the substituent at the asymmetric C γ atom, to a double bond (reaction 5) is stereospecific.^{66, 67}

Apparently, the high degree of diastereoselectivity observed in reactions (4) and (5) is due to the appearance of steric restrictions hampering the attack of the nucleophile from one of the sides of the substrate.

Unlike amines, lithium amides react with α,β -unsaturated esters with high degrees of diastereoselectivity (see Table 3); only one of all the possible diastereomers is often formed. The stereoselectivity of these reactions can be accounted for by the fact that, due to the high ability of lithium cation to participate in coordination, the formation of a six-membered transition state is favourable and, consequently, the nucleophile adds predominantly from one side of the substrate.

Bulky chiral substituents located in the γ -position with respect to the carbonyl group of the ester also increase the stereoselectivity of the addition. For example, it has been suggested⁴⁶ that the addition of lithium benzyl(trimethylsilyl)amide to butyl esters of silyl-substituted acrylic acids (entries 51–54 in Table 3) from the sterically hindered side is impossible.

However, neither the size of the group located in the β -position, nor the nature of the substituent in the α -position, nor the size of the ester group has a noticeable influence on the stereoselectivity of the addition of lithium amides to esters of α,β -unsaturated carboxylic acids.

In solvents such as THF and DME, which are capable of forming chelates with the β -aminoenolate produced during the reaction, the selectivity of conjugate addition is higher (d.e. = 90%–91%) than that in toluene (d.e. = 50%) (Table 3, entries 36, 37, and 40).⁴⁴

Unlike the products of simple addition of metal amides to a double bond, α -alkyl- β -amino esters resulting from the tandem 1,4-addition and simultaneous α -alkylation contain two asymmetrical centres at the α - and β -carbon atoms of the ester and are formed as mixtures of diastereomers with relatively low d.e. values. Only in some cases has stereospecific reaction been accomplished (Table 4, entries 2 and 3).

The reaction of lithium piperidide with *tert*-butyl α -naphthoate in the presence of methyl iodide as an alkylating agent occurs non-stereoselectively yielding a fairly large amount (32%) of a side product, α -naphthamide, whereas the similar reaction involving α - and β -naphthyloxazolines is stereospecific and affords no side products.⁶⁸ It is noteworthy that lithium benzyl(α -phenylethyl)amide does not react with *tert*-butyl α -naphthoate under these conditions.

High stereoselectivity in the tandem reaction can be achieved by using magnesium benzyl(α -phenylethyl)amide as the nucleophile. This leads not only to an increase in the diastereomeric excess (from 15% to 90%) compared to that attained with the corresponding lithium amide (see Table 4, entry 15), but also to the change in the absolute configuration of the asymmetric centre arising at the α -carbon atom in the ester.⁶²

If the substituent R^1 at the β -carbon atom in the initial *tert*-butyl ester is an aliphatic group, the diastereomeric excesses obtained in the reactions of these esters with (*S*)-(-)-2-methoxymethyl-1-trimethylsilylamino pyrrolidine are 63%–96%. In the case where R^1 is an aromatic substituent, the interaction is stereospecific (d.e. > 96%).⁶⁹

The reactions of tandem addition with simultaneous α -hydroxylation occur with high diastereoselectivity (d.e. = 75%–99%), except for the interaction of (*R*)-benzyl(α -phenylethyl)amine with *tert*-butyl γ -phenylcrotonate (Table 5, entry 9). Apparently, this is due to the presence of steric restrictions hampering the interaction of the (*R*)-isomer with the above substrate.³³

Thus, it follows from the analysis of the published data that the nature of the substituent in the substrate molecule is the main factor influencing the chemical yield in the conjugate addition of amines to esters of α,β -unsaturated carboxylic acids, whereas the geometry of the initial ester is the main factor determining the stereoselectivity of the process. The diastereomeric excess obtained in these reactions does not usually exceed 60% (Table 1). In the case where the reactions involve lithium amides, both the chemical yield and the stereoselectivity depend mostly on the geometry of the ester as well as on the solvent and the character of the protonating agent used.

In conclusion, it should be noted that at present, the addition of metal amides to esters of α,β -unsaturated carboxylic acids is the method of choice for the asymmetric synthesis of esters of β -amino acids. The most significant progress in this field of research has been achieved by a group of English scientists headed by S. Davies (Oxford).^{13, 35–41, 43, 48, 49, 54–58, 62}

V. Mathematical modelling of structures of the transition states in the Michael nucleophilic addition

The stereochemical outcome of the conjugate addition of amines or lithium amides to esters of α,β -unsaturated carboxylic acids can be reliably predicted in some cases by virtue of molecular mechanics modelling of the structure of the transition state of the process.^{48, 70} In the modelling, the tetrahedral angle of the attack and the N–C β bond length in the transition state are taken fixed (it should be noted that variation of the angle of the attack by a nucleophile has no substantial influence on the final stereochemical outcome of the process⁴⁸). It is believed that the H–N...C β –C α torsional angle is the main factor determining the stereochemistry of the reaction (if lithium amide is used, the position of the proton is occupied by the unshared electron pair at the nitrogen atom). The depths of the minima in the plot of the transition state energy versus the magnitude of the torsional angle are mostly determined by the spatial arrangement of the alkyl radicals in the nucleophile and by their structures. The natures of the substituents in the ester group and in the β -position with respect to the carbonyl group in the substrate and their mutual arrangement are also significant. In addition, in the reactions involving lithium amide, the possibility of chelate formation (the lithium atom can fix the structure of the transition state) should also be taken into account. A lower energy of the transition state corresponding to a particular minimum means that the probability of the formation of this transition state is greater.

The use of the energies of the transition states corresponding to minima in the calculation of Boltzmann distribution makes it possible to predict with high accuracy the ratio between the diastereomers of β -amino esters formed in the reaction; however, this is true only for kinetically controlled processes.⁷⁰ An increase in the difference between the energies of the transition states for the minima results in an increase in the stereoselectivity of conjugate addition. The absolute configuration of the reaction product depends on the structure of the most probable transition state.

The efficiency of this method has been demonstrated in relation to the reactions of azepine 2 and its lithium derivative with methyl crotonate⁷⁰ and the reaction of lithium benzyl(α -phenylethyl)amide with *tert*-butyl cinnamate.⁴⁸

Thus, despite the fact that the systems in question are very complex and, therefore, the number of assumptions (based on analysis of empirical features) is large, mathematical modelling of transition states can be used to predict the stereochemical outcome of the conjugate addition of amines or lithium amides to esters of α,β -unsaturated carboxylic acids.

The work was supported by the Russian Foundation for Basic Research (Project No. 96-03-32157) and the State Commission of

the Russian Federation on Higher Education (Science and Engineering Programme 'Fine Organic Synthesis', grant FT-28).
