Abstract. The published data on phase equilibria in the $M-X-X'$ and $M-Al-X$ ternary systems (M is a Group III–VIII transition metal, X, X' are B, C, N, Si) are surveyed. These systems provide a basis for the directed search for oxygen-free ceramic materials for various purposes. The phase diagrams for the ternary systems are presented; more than two hundred ternary phases formed in these systems are systematised and described for the first time. The typical crystal structures of the ternary compounds and of the phases are considered, the general and distinguishing features of these structures are analysed. It is shown that ternary compounds containing the XM_6 octahedral groups possess homogeneity regions. The bibliography includes 240 references.

I. Introduction

Ceramics are materials which have been in use for a very long time. Products of fired clay, faience, and porcelain have been traditionally referred to as ceramics. However, the range of ceramic materials has now considerably widened, and the term 'ceramics' is used in relation to polycrystalline materials based on compounds of Group III–VI nonmetals with one another and/or with metals, obtained by various methods such as sintering, pressing, precipitation from the gas phase or from the liquid colloidal state, etc. Borides, carbides, nitrides, oxides, and silicides are the initial compounds for the preparation of ceramics.

The interest in ceramic materials has substantially grown in the last few decades. In the developed countries, the amount of the manufactured ceramic products is rapidly increasing, new technologies appear, and the ceramic products have found wide application in industry, transport, energetics, electronics, and medicine. The new ceramics have revolutionised materials science. At present, ceramics are the third industrial material, regarding the tonnage of use, after metals and polymers, and it occupies a key position in the field of high technologies.

An evaluation of the dynamics of the increase in the manufacture of ceramics over the period between 1990 and 1995 and up to 2000 indicates that the output volume is doubling every five years (Table 1). This is caused by the demand for the materials meant for performing new functions (for example, in force lasers, memory cells, superconducting devices, catalysts, electrodes, and heat- or radiation-resistant devices). Actually, the new ceramics often prove to be stronger than metals, though they are lighter; they may be elastic enough to be suitable for the manufacture of elastic units; ceramics withstand high temperatures and thermal shocks; they are highly resistant to corrosion and to wear.

The perfection of the existing ceramic materials and the development of new materials involves both the synthesis of complex compounds and heterogeneous compositions and the preparation of finely dispersed materials (with a particle size of $\sim 1-10$ nm) from these compounds and compositions, which ensures the stability and the high level of performance.

The new ceramic materials and the relevant technologies are extremely science-dependent. This accounts for the intense fundamental research in the field of physical chemistry, physics and chemistry of solids, and physical material technology. All the studies on physical chemistry and material technology dealing with the search for new solid-phase compounds and compositions for ceramics are based on phase equilibria and phase diagrams presented in many publications.

The aim of the present review is to generalise and systematise the data on the phase equilibria in the oxygen-free $M-X-X'$ and $M-Al-X$ ternary systems (where M is a Group III–VIII

transition metal, X and X' are B, C, N, Si) and on the crystal structure of the ternary compounds formed in these systems. These ternary systems serve as the constituents of more complex 4- and 5-component systems and cover largely the systems that are used or can be used for preparing new ceramic materials.

Before we discuss ternary systems, let us consider briefly some characteristic features of the structures of the binary compounds that are permanently involved in the phase equilibria in the M–X–X' systems, namely, transition metal carbides, nitrides, borides, and silicides, and of binary high-melting compounds of nonmetals.

The cubic (with the *B1* structure) and hexagonal (with the *L'3* structure) carbides and nitrides of Group IV and V transition metals MC_y , M_2C_y , MN_y , and M_2N_y ($0.4 \leq y \leq 1.0$) belong to the group of nonstoichiometric interstitial compounds^{1,2} and possess (in contrast to other compounds considered here) metallic electrical conductivity. The atomic radius of carbon is fairly small and is equal to ~ 0.077 nm, therefore, in compounds with transition metals carbon always acts as the interstitial element and is located in the interstices of the metal sublattice. The interstitial nonmetal atoms (carbon or nitrogen) in the cubic carbides and nitrides MC_y and MN_y occupy the octahedral interstices of the face-centred cubic (Fcc) metal sublattice and can populate either all of the interstices or only some of them. The octahedral interstices free from these atoms are referred to as structural vacancies. In hexagonal lower carbides and nitrides M_2C_y and M_2N_y , the interstitial atoms occupy half the octahedral interstices of the hexagonal close-packed metal sublattice. The interstitial atoms and the structural vacancies may be arranged in a crystal lattice either statistically (irregularly) or regularly.

The nonstoichiometric carbides and nitrides with the *B1* and *L'3* structures belong to the class of the so-called octahedral structures, that is to the structures in which each six transition metal atoms constitute the octahedral environment of an interstitial atom X or of a vacancy. These structures are built of the XM_6 octahedra joined with one another in various ways. For example, in the NaCl type structure (*B1*) the octahedra are joined through their edges (Fig. 1). Many of the ternary compounds considered below also incorporate regular or distorted XM_6 octahedra as the main structural motif.

Carbides and nitrides of Group VI–VIII transition metals have virtually no homogeneity regions and can have various crystal structures with a relatively high symmetry, namely, orthorhombic, tetragonal, hexagonal, or cubic.

A detailed description of the structures and properties of binary carbides and nitrides of transition metals with allowance for the short-range and long-range effects of nonstoichiometry has been published.^{1–6}

Transition metal compounds with boron are built in a different manner. The boron atoms are larger than the carbon or

nitrogen atoms; therefore, B–B bonds can arise in the crystal lattice of borides. In the borides M_2B , the boron atoms are separated from one another, and the M–B interactions are the most significant. With the increase in the boron content, changes occur from the structure with the separated boron atoms in M_2B to the ...–B–B–... zigzag-like chains in MB and to hexagonal chains in M_3B_4 , and then to a two-dimensional hexagonal network of boron atoms bound to one another in the diborides MB_2 and to cage structures built of boron atoms in the borides MB_4 , MB_6 , and MB_{12} , which contain interpenetrating lattices of the metal and boron atoms.⁷

The atom radius of silicon, an analogue of carbon, is much larger, being equal to ~ 0.117 nm. In compounds with Group IV and V transition metals, whose atoms are sufficiently large, silicon still acts as an interstitial element; the silicides of other transition metals occupy an intermediate position between interstitial compounds and intermetallics. Thus, silicon can be incorporated in a metallic lattice as an interstitial element or as a substituting element. In lower silicides (for example, in M_3Si), the silicon atoms are separated from one another, and only M–Si bonds exist. As the content of silicon atoms increases, isolated Si–Si pairs are formed initially; the further increase in the silicon content results in one-dimensional zigzag-shaped chains of the silicon atoms (in compounds of the M_5Si_3 type), two-dimensional close-packed networks (in MSi_2), and, finally, three-dimensional spatial frameworks of silicon atoms (for example, in lanthanide disilicides⁸). The crystal structures of borides and silicides are quite diverse.

Aluminium forms numerous intermetallic compounds with transition metals, many of which have homogeneity regions.

The great difference between the crystal structures of carbides and nitrides, on the one hand, and borides, silicides, and aluminides, on the other hand, result in their low mutual solubility.

Boron, carbon, nitrogen, silicon, and aluminium form solid solutions not only with metals, but also with one another, for example, in the X–X' binary systems (B–C, B–N, Si–B, Al–B, C–N, Si–C, Al–C, Si–N, and Al–N). Let us discuss briefly the characteristic features of the crystal chemistry of these high-melting carbides, nitrides, and borides of nonmetals. The structural characteristics of the high-melting compounds are listed in Table 2.

The B–C system. The main phase in the B–C system is boron carbide B_4C ($B_{12}C_3$); the carbide $B_{13}C_2$ is also formed (see Table 2).

The twelve boron atoms in $B_{12}C_3$ are located at the vertices of an icosahedron. The B_{12} icosahedra constitute an Fcc-lattice, the three carbon atoms being located as the C–C–C chain in the large octahedral interstices. The terminal carbon atoms in this chain are linked to four boron atoms from the two nearest icosahedra (the B–C distance is 0.164 nm); and the central carbon atom of the carbon chain is bound only to the other carbon atoms of this chain, which are located at a distance of 0.139 nm from it.

The carbide $B_{13}C_2$ has a structure derived from that of B_4C ($B_{12}C_3$). This compound can be represented as $(B_{12})BC_2$, i.e., it may be regarded as $B_{12}C_3$ in which one of the C atoms has been substituted by boron. The boron atom and the two carbon atoms are located in the octahedral interstices of the B_{12} icosahedra as C–B–C chains.

The similarity of the crystal lattices of the carbides B_4C ($B_{12}C_3$) and $B_{13}C_2$ led some authors to suppose that there exists one phase with a broad homogeneity region. However, the dependence of the properties of boron carbide on the carbon content exhibits two extrema at the compositions $B_{12}C_3$ and $B_{13}C_2$, which attests to the existence of two different phases.

^a From here on, Z is the number of formula units in the unit cell.

The B–N system. In the B–N system only one compound is formed, namely, boron nitride BN, which exists in α , β , and γ modifications.

The nitride α -BN has a hexagonal graphite-like structure. The boron and nitrogen atoms in this ideal structure are regularly distributed in hexagonal networks; the networks are arranged one above the other in such a way that the boron and nitrogen atoms alternate along the *c* axis of the crystal. The distance between the layers in α -BN is larger than the interatomic distances in the networks by a factor of 2.5. This causes substantial anisotropy of the properties of α -BN. The α -BN modification can have various degrees of ordering ranging from an amorphous structure to a completely ordered structure. The resistance of α -BN to oxidation increases with an increase in the degree of ordering.

The cubic modification β -BN has a sphalerite-type structure (ZnS, *B3*), and γ -BN has a wurtzite-type structure (ZnS, *B4*). The structures of β - and γ -BN are very similar, and they may be regarded as polytypes. The cubic boron nitride β -BN is stable to attrition and possesses an extremely high hardness close to that of diamond. Only α - and β -BN are thermodynamically stable.¹³

The Si–B system. Three compounds, SiB₄, SiB₆, and SiB_{12+x} (SiB₁₄), are formed in this system (see Table 2).

The structure of the boride SiB₄ is similar to that of B₄C (B₁₂C₃): B₁₂ icosahedra form an Fcc-lattice, the silicon atoms being located in its octahedral interstices; some of the silicon atoms can substitute the boron atoms in the B₁₂ groups. The boride SiB₄ is stable at *T* ≤ 1640 K; at higher temperatures it decomposes peritectically to give the orthorhombic boride SiB₆ and silicon.

The compound SiB_{12+x} (SiB₁₄), which also exists in the Si–B system, is sometimes regarded as being a solid solution of silicon in β -B (the groups of boron atoms in the β -B structure constitute a rhombohedrally distorted cubic close packing, the interstices of

which may contain silicon and aluminium atoms, together with the boron atoms²⁵).

The Al–B system. In the Al–B system, the existence of borides AlB₂ and α - and γ -AlB₁₂ has been established reliably.

The boride AlB₂ has a hexagonal structure (space group *P*6/*mmm*) of the C32 type. In this structure, the aluminium atoms form trigonal prisms joined through all faces; the axes of the prisms are parallel to the *c* direction. The boron atoms are located at the centres of these prisms, therefore the structure of AlB₂ may be regarded as a filled structure of the WC type.

The borides α -AlB₁₂ and γ -AlB₁₂ have tetragonal and monoclinic structures of their own types (see Table 2). The orthorhombic boride β -AlB₁₂, which has been repeatedly described in the literature, is in fact the borocarbide Al₃B₄₈C₂.²⁵

The C–N system. Gaseous cyanogen C₂N₂ exists in this system under equilibrium conditions. On heating to 870 K cyanogen polymerises to give a dark-brown solid (amorphous) and insoluble paracyanogen. When paracyanogen is heated to 1130 K in the absence of air, it is again converted to cyanogen.

In the system under consideration, the existence of a solid phase resembling a diamond-like solid solution of nitrogen in carbon C(N) cannot be ruled out. Furthermore, in recent years, information on crystalline carbon nitride has been reported. Liu and Cohen^{26,27} who have used a model suggested previously²⁸ for the calculation of the crystal and electronic structures of solid phases, predicted the possible existence of crystalline β -C₃N₄. Later, this compound has been found as particles with a size of ~0.5 μ m in a ~1 mm thick C,N-containing film obtained on a silicon support by atomisation of graphite (*T* = 673–873 K) under a nitrogen atmosphere (*P*_{N₂} = 2.3 Pa).²⁰ The carbon nitride β -C₃N₄ has a hexagonal structure of the β -Si₃N₄ type (see Table 2).

The Si—C system. In this system only one phase exists, namely, silicon carbide SiC having α - and β -modifications.

The structure of α -SiC consists of close-packed layers of silicon atoms and close-packed layers of carbon atoms, which are arranged between the silicon layers at a height equal to $\frac{3}{4}$ of the distance between them; the carbon atoms occupy the same crystallographic positions as the silicon atoms. Consequently, all the atoms of one kind in the carbide α -SiC are located in the tetrahedral environment of atoms of the other kind (SiC₄ and CSi₄). The number of the layers in the structure of α -SiC may differ, which accounts for the polytypism of silicon carbide. The carbide α -SiC forms more than 100 hexagonal and rhombohedral polytypes. More than 70 polytypes of α -SiC differing in the number of the layers have been described in a review.²¹ The most commonly encountered structures are 4-, 6-, and 15-layered polytypes denoted as 4H, 6H, and 15R (the letters H and R correspond to hexagonal and rhombohedral polytypes and the digits correspond to the numbers of the layers in the polytypes; the cubic close-packed structure is designated as 3C).

The cubic modification β -SiC crystallises with the sphalerite ZnS (*B3*) structural type; its formation is probably promoted by a slight excess of silicon.

The temperature of the peritectic decomposition of silicon carbide is 3030–3100 K.

The Al—C system. Al₄C₃ is formed as the only hexagonal carbide in the Al—C system (see Table 2). In this compound, the aluminium atoms constitute close-packed planes, with $\frac{2}{3}$ and $\frac{1}{3}$ of all the carbon atoms being located between these planes in the tetrahedral and octahedral interstices, respectively. Consequently, the Al₂C₂ and Al₂C layers alternate along the *c* axis (a rhombohedral unit cell contains 12 close-packed planes of aluminium atoms).

The Si—N system. The silicon nitride Si₃N₄ is the only stable silicon compound with nitrogen. It exists in two modifications: α -Si₃N₄ (trigonal) and β -Si₃N₄ (hexagonal) (see Table 2).

The nitride α -Si₃N₄ has a layered structure in which each silicon atom is in the tetrahedral environment of four nitrogen atoms, and three silicon atoms constitute the nearest environment of each nitrogen atom.

The structure of β -Si₃N₄ also consists of SiN₄ tetrahedra in which each nitrogen atom is shared by three tetrahedra. The nitride β -Si₃N₄ is stable up to 1700 K in the absence of nitrogen. The intercalation of admixtures into the lattice of β -Si₃N₄ can lead to the formation of the α -modification (for example, the structure of α -Si₃N₄ is stabilised by elemental silicon).

The Al—N system. In the Al—N system, too, only one compound is known, namely, the nitride AlN with a hexagonal structure of the wurtzite ZnS (*B4*) type. The nitrogen atoms in AlN occupy tetrahedral vacancies between the hexagonal close-packed layers of aluminium atoms. The sintering of an aluminium nitride powder prepared by the plasmachemical method yields a multi-layer sphalerite polytype of AlN.¹³ In all probability, this modification arises due to the presence of an admixture of oxygen.

Aluminium nitride possesses high hardness, heat conductivity, and thermal stability and low thermal expansion coefficient; it is resistant to oxidation up to 1000 K.

The Al—Si system. In this system no compounds have been detected.

II. Phase equilibria in M—B—C borocarbide systems

The transition metal borocarbide systems are among the ternary systems of transition metals with boron, carbon, nitrogen, and silicon studied most thoroughly. Nevertheless, virtually no survey papers devoted to them have been published. Some of the M—B—C systems have been described in monographs.^{8, 29–31}

1. Borocarbides of Group III transition metals

Borocarbides of scandium, yttrium, and lanthanides have not been studied adequately, though it is in these systems that most of the known ternary compounds M_xB_yC_z (Table 3) have been found. In particular, scandium, yttrium, and all the lanthanides (except for Pm) form ternary borocarbides of the formula MB₂C₂.^{33, 34, 36, 37, 41, 44–46} For the lanthanide borocarbides LnB₂C₂, a small tetragonal unit cell containing one LnB₂C₂ formula unit and having similar *a*₀ and *c*₀ parameters was initially suggested.^{36, 41} The boron and carbon atoms in this structure are arranged randomly. Using YB₂C₂ as an example, Bauer and Nowotny have shown³⁴ that the crystal structure with disordered distribution of the B and C atoms is described by the *P4/mmm* space group, the small cell being regarded as only the first approximation to the structure of the borocarbides LnB₂C₂. Judging from the general views about bond lengths and directions, a tetragonal structure with a regular arrangement of B and C atoms (space group *P4/mbm* with *a* = *a*₀ $\sqrt{2}$ and *c* = *c*₀) has been suggested for the compounds MB₂C₂. Bauer and Nowotny³⁴ have suggested a more plausible model for the ordering of the boron and carbon atoms in the compounds MB₂C₂ under consideration in relation to yttrium borocarbide YB₂C₂. According to this model, the small tetragonal unit cell with a statistical distribution of the atoms is doubled along the *c* axis, i.e. *a* = *a*₀ and *c* = 2*c*₀. In the unit cell thus obtained (space group *P42c*), the metal atoms occupy the 2(*e*) sites, the four boron atoms occupy the 4(*i*) sites with *y* = 0.232, and the four carbon atoms are at the 4(*h*) sites with *x* = 0.168 (Fig. 2).

A study of the crystal structure of LaB₂C₂ carried out by Bauer and Bars³⁷ has confirmed the validity of the ordering model described above.³⁴ The diffraction pattern of LaB₂C₂ was interpreted³⁷ in terms of several models: a small tetragonal unit cell with a disordered distribution of boron and carbon atoms [space group *P422*, *Z* = 1, the B and C atoms occupy the 4(*m*) sites with *x* = 0.203]; a small unit cell with an ordered distribution of nonmetal atoms [space group *Pmmm*, *Z* = 1, the B and C atoms occupy the 2(*p*) and 2(*l*) sites, respectively]; an ordered tetragonal structure with *a* = *a*₀ $\sqrt{2}$ and *c* = *c*₀ (space group *P4/mbm*, *Z* = 2); and an ordered tetragonal structure (space group *P42c*, *Z* = 2). The latter model proved to be the most successful. This made it possible to conclude that all the borocarbides LnB₂C₂ crystallise with a tetragonal structure (space group *P42c*) with an ordered distribution of the carbon and boron atoms in the lattice. The unit cell parameters of the yttrium and lanthanide borocarbides MB₂C₂ with ordered and disordered distributions of the boron and carbon atoms are listed in Table 3.

Another common structure of scandium, yttrium, and heavy lanthanide borocarbides is MB₂C.^{32, 34, 35} In the case of disordered distribution of the B and C atoms in the borocarbide YB₂C (space group *P4/mbm*), four Y atoms occupy the 4(*g*) sites, and twelve boron and carbon atoms are distributed statistically

Figure 2. Projection along the [001] axis of the ordered crystal structure of the borocarbides MB₂C₂ of the YB₂C₂ type (space group *P42c*).³⁴ Only one half of the unit cell is shown; for *z* = $\frac{1}{4}$, the B—C network is rotated by 90°.

between the 8(*j*) and 4(*h*) sites. In the case of the borocarbides MB₂C with an ordered distribution of the B and C atoms (space group *P4₂/mbc*), the unit cell parameter *c* is twice as large as that for the disordered unit cell; the Y atoms occupy the 8(*g*) sites, sixteen boron atoms are arranged at the 8(*h*) sites of two types, and eight carbon atoms occupy the 8(*h*) sites.

Phase equilibria in the Y–B–C,³⁴ Eu–B–C,³¹ Gd–B–C,⁴¹ and Ho–B–C⁴⁴ systems have been studied; in these systems, four, two, five, and eight ternary compounds, respectively, have been found (Fig. 3). The state diagram for the Y–B–C system has been constructed using the data of an X-ray structural study of samples quenched from a melt. A phase

diagram for the Ce–B–C system has been suggested⁴⁷ based on thermodynamic estimates; however, only one ternary compound, which was known at that time, was taken into account in this study.

2. Borocarbides of Group IV transition metals

Due to their high stability borides of Group IV transition metals exist in equilibrium with carbon, boron carbide B_4C , and non-stoichiometric monocarbides $M^{IV}C_y$. The mutual solubility of borides and carbides is very low.

The Ti–B–C system. The first version of the state diagram for this system was suggested by Brewer and Haraldsen.⁴⁷ According to the thermodynamic calculations made by them, four titanium borides, namely, Ti_2B , TiB , TiB_2 , and Ti_2B_3 , are formed in this system. The existence of the Ti_2B and Ti_2B_3 phases has not been confirmed reliably in experimental studies. The phase diagram for the Ti–B–C system, commonly accepted at present, has been constructed using the results of a detailed study⁴⁸ and has been refined later in another study;⁴⁹ this variant has also been presented in a paper by Schouler et al.⁵⁰ (Fig. 4). The isothermal cross-section through the Ti–B–C system at 2273 K⁵¹ coincides almost exactly with that presented in Fig. 4a.

There is almost no mutual solubility of titanium carbide $TiC_{1.0}$ and titanium diboride TiB_2 at temperatures below 2273 K. When the stoichiometric composition of titanium carbide is disturbed, the solubility of TiB_2 in it increases. In fact, at 1873 K,

Figure 4. State diagram for the Ti–B–C ternary system and its pseudobinary cross-sections.^{49, 50}

(a) the isothermal cross-section through the Ti–B–C system at 1873 K (dark areas denote one-phase homogeneity regions); (b) polythermal pseudobinary TiB_2 –C cross-section; (c) polythermal pseudobinary TiB_2 – $B_{4.5}C$ cross-section.

~3 mol % of TiB_2 is dissolved in the carbide $TiC_{0.95}$, whereas $TiC_{0.68}$ dissolves ~7 mol % of TiB_2 . The increase in the solubility of TiB_2 is in good agreement with the conclusion made by Gusev² that an increase in the concentration of structural vacancies creates new interstitial positions and is favourable for the increase in the solubility. Note that the hardness of titanium carbide increases on the addition of TiB_2 .

In the TiC_y – TiB_2 , TiB_2 –C, and TiB_2 – B_4C pseudobinary cross-sections, ordinary eutectics at 2900, 2780, and 2600 K, respectively, are formed. The mutual solubility of titanium boride and titanium carbide along the TiC_y – TiB_2 pseudobinary cross-section should most likely be unlimited, if these compounds have identical structures of the $B1$ type, and their unit cells have similar sizes. In the TiC_y – TiB system, there is a possibility of the formation of solid solutions, but it is prevented by the decomposition of TiB at temperatures above 2200 K.⁵²

The Zr–B–C system. The state diagram of this system has been studied in a number of papers.^{47, 53, 54} The ZrC_y – ZrB_2 , ZrB_2 –C, and ZrB_2 – B_4C pseudobinary equilibria were found in the Zr–B–C ternary system; later, their existence has been confirmed experimentally. In addition, the ZrC_y – ZrB equilibrium exists at $T \leq 1523$ K and the ZrB_{12} – B_4C equilibrium exists at $T > 1923$ K.⁴⁷ ZrB has not been detected.⁵³ The solubility of ZrB_2 in the carbide ZrC_y increases with an increase in the concentration of structural vacancies in the carbon sublattice of the carbide.

The Hf–B–C system. The phase diagram for the Hf–B–C ternary system was constructed for the first time by Nowotny et al.⁵³ It proved to be fairly similar to the state diagram of the Ti–B–C system. The HfB – HfC_y , HfB_2 – HfC_y , HfB_2 –C, and ZrB_2 – B_4C pseudobinary equilibria exist in the Hf–B–C system. In the HfB_2 – HfC_y , HfB_2 –C, and ZrB_2 – B_4C pseudobinary cross-sections, ordinary eutectics at temperatures of 3410, 2790, and 2600 K, respectively, are formed. The solubility of HfB_2 in HfC_y increases with an increase in the defectiveness of the carbon sublattice of the carbide.

A general feature of the interaction of boron with titanium, zirconium, and hafnium carbides is the formation of limited MB_xC_{1-x} borocarbide solid solutions. The solubility of boron in carbides increases in the sequence $TiC_y \rightarrow ZrC_y \rightarrow HfC_y$ and with a decrease in the carbon content. Hafnium carbide dissolves up to 6 at.% of boron.

No ternary compounds are formed in the titanium, zirconium, and hafnium borocarbide systems.^{47–50, 53–55}

The Th–B–C system. Only binary carbides ThC , ThC_2 , and B_4C and borides ThB_4 and ThB_6 exist in this system. There are four pseudobinary phase equilibria in the Th–B–C ternary system, namely, ThC – ThB_4 , ThC_2 – ThB_6 , ThB_6 –C, and ThB_6 – B_4C .⁴⁷ It has been shown by experimental studies that in this system (in contrast to the titanium, zirconium, and hafnium borocarbide systems), four ternary compounds $Th_3B_2C_3$, $ThBC$, ThB_2C , and $ThBC_2$, are formed (Table 4). They all have homogeneity regions, the homogeneity region of $ThBC$ being fairly large. A state diagram for the Th–B–C system has been reported.⁵⁶ Five ternary compounds, namely, $ThBC$, ThB_2C , $ThBC_2$, Th_2BC , and Th_2BC_2 , were found in this diagram (the ternary monoclinic thorium borocarbide $Th_3B_2C_2$ reported in another paper⁵⁸ was not taken into account in this diagram). The compounds $ThBC$ and ThB_2C melt congruently at 2370 and 2310 K, respectively.

A characteristic feature of the Th–B–C system is that carbon is almost insoluble in borides, and boron is almost insoluble in carbides.

3. Borocarbides of Group V–VIII transition metals

The ternary systems of Group V transition metals with boron and carbon differ from the analogous systems containing Group IV transition metals in that new binary borides, M_3B_4 and M_3B_2 , arise in these systems. No ternary borocarbides of Group V transition metals were detected in the M^V –B–C systems.

Chromium, molybdenum, and uranium form borocarbides with boron and carbon, whereas in the W–B–C system no ternary compounds were detected.

The V–B–C system. The state diagram for the V–B–C system has been constructed by Markovsky et al.⁶⁹ In this system, all the carbides and borides are in equilibria with one another: V_2C_y – V_3B_2 , V_2C_y –VB, VC_y –VB, VC_y – V_3B_4 , VC_y – VB_2 , and VB_2 – B_4C . The VB_2 –C pseudobinary equilibrium also exists. The solubility of boron in vanadium carbides is low, but it is somewhat higher than the solubility of carbon in vanadium borides.

The Nb–B–C system. This system involves the same phase equilibria as the V–B–C system.⁶⁹ The NbC_y – NbB_2 pseudobinary cross-section is eutectic with an eutectic temperature of ~2900 K. The solubility of boron in the carbide NbC_y increases with a decrease in y and can reach 5 at.%. The hardness of the niobium carbide NbC_y increases noticeably on the dissolution of boron.

The Ta–B–C system. In this system, the existence of borides Ta_2B and Ta_3B , in addition to the borides TaB_2 , Ta_3B_4 , and TaB , which are also characteristic of the V–B–C and Nb–B–C systems, has been reported.⁴⁷ Later, the existence of Ta_2B has been confirmed, and the boride Ta_3B_2 has also been found. The existence of Ta_3B has not been confirmed. The Ta–B–C system, unlike the V–B–C and Nb–B–C systems, involves one more pseudobinary equilibrium, namely, Ta_2C_y – Ta_2B . The TaC_y – TaB_2 pseudobinary cross-section has a eutectic at a temperature of ~3000 K. The solubility of boron in TaC_y increases with an increase in the concentration of carbon vacancies and can reach 6 at.%. The solubility of carbon in TaB_2 is no more than 2 at.%. The dissolution of boron in TaC_y leads to a substantial increase in the microhardness.

The Cr–B–C system. Chromium carbides, in contrast to carbides of other transition metals, can dissolve substantial quantities of boron. This is caused by the significant differences between the crystal structures of chromium carbides and carbides

of other transition metals. For example, at 1723 K, about 30% of the carbon can be substituted by boron in the carbide $Cr_{23}C_6$, about 36% in Cr_7C_3 , and about 5% in Cr_3C_2 .²⁹ The state diagram for the Cr–B–C ternary system has been constructed;⁷⁰ however, the phase relationships in the region rich in carbon and boron have been studied inadequately. Chromium forms four ternary phases with boron and carbon, namely, the $Cr_3(B,C)_2$, $Cr_7(B,C)_3$, and $Cr_{23}(B,C)_6$ solid solutions and the compound Cr_7BC_4 (see Table 4).

The boron atoms and some of the carbon atoms in Cr_7BC_4 fill the trigonal prismatic interstices and the rest are arranged in the octahedral vacancies of the metal sublattice.⁶⁰ This compound is stable in the temperature range 1820 K–1980 K. A neutron-diffraction study has shown that the borocarbide Cr_7BC_4 has a filled structure of the Re_3B type (space group $Cmcm$) (Fig. 5), which is also peculiar to other ternary compounds (for example, zirconium and hafnium aluminidoborides).⁶¹ In the borocarbide

^a In the unit cell $\beta = 100.06^\circ$.

Cr_7BC_4 with the Re_3B type of structure, the carbon atoms at the 4(b) sites populate 85% of the octahedral interstices, and the rest of the carbon atoms together with the boron atoms share the 4(c) sites at the centres of trigonal prisms. Thus, the more exact structural formula of this compound should be written as $Cr_3(B_{0.44}C_{0.56})C_{0.85}$.

The Mo-B-C system. The possible phase equilibria in the Mo-B-C system were first estimated by a thermodynamic calculation.⁴⁷ According to this estimate, six pseudobinary phase interactions exist in this system, and ternary compounds are absent. More recently,⁶⁹ the Mo-B-C phase diagram has been made substantially more precise.

One ternary compound Mo_2BC with a small homogeneity region and an orthorhombic structure (space group $Cmcm$) of its own type (see Table 4), typical also of a number of other ternary compounds discussed in this review, is formed in this system. The structure of Mo_2BC is a combination of the boride and carbide sublattices (Fig. 6). The carbon atoms are located at the centres of the octahedra formed by the molybdenum atoms. The CMo_6 octahedra are connected to one another by eight edges and form double-stranded octahedral layers. The boron atoms in Mo_2BC linked in zigzag-shaped chains are arranged between the octahedral layers. Each boron atom is located at the centre of a trigonal prism, molybdenum atoms serving as the vertices of the prism. This distribution of boron atoms is specific and typical of transition metal monoborides. This gives grounds for regarding the borocarbide Mo_2BC as a derivative of β -MoB in which the octahedral interstices of the molybdenum sublattice are occupied by carbon atoms.

Figure 6. Crystal structure of Mo_2BC (space group $Cmcm$).

(a) projection along the [100] axis (the wholly visible atoms are located at height $x = 0$; the atoms that are partly seen are located at height $x = \frac{1}{2}$); (b) the layer of the CMo_6 octahedra joined through their edges, parallel to the (010) plane; in Mo_2BC , these layers are joined in pairs in such a way that each octahedron is linked to the neighbouring octahedra via its eight edges.

At 1573 K, three borides Mo_2B , MoB , and Mo_2B_5 , molybdenum carbide Mo_2C , boron carbide B_4C , and ternary compound Mo_2BC exist in the Mo-B-C system. The following equilibria are established between these compounds: Mo_2B-Mo_2C , $MoB-Mo_2C$, $MoB-Mo_2BC$, $MoB-C$, Mo_2BC-Mo_2C , Mo_2BC-C , $Mo_2B_5-B_4C$, and Mo_2B_5-C . At 2073 K, the Mo_2B_5-C equilibrium disappears, since the boride MoB_2 arises, and the MoB_2-C equilibrium is established; in addition, carbide Mo_3C_2 arises distinct from Mo_2C ; 1–2 at. % of boron dissolves in

both carbides. Boron stabilizes the high-temperature carbide phases of molybdenum. The MoB_2-C and $MoB-C$ pseudobinary cross-sections are eutectic systems.

The W-B-C system. This system contains only binary tungsten carbides W_2C and WC , tungsten borides W_2B , WB , and W_2B_5 , and boron carbide B_4C .⁴⁷ Tungsten borides WB_{12} ⁶⁹ and WB_4 ^{49,50} have also been detected. The existence of the boride WB_4 is more probable. Six pseudobinary cross-sections, namely, W_2B-W_2C , W_2B-WC , $WB-WC$, $WB-C$, W_2B_5-C , and $W_2B_5-B_4C$ contain ordinary eutectics with temperatures 2640, 2560, 2600, 2630, 2550, and 2500 K, respectively.⁴⁹ In all probability the WB_4-B_4C pseudobinary cross-section is also an eutectic system.

The U-B-C system. The phase equilibria in this system have been studied.^{63,64} It was originally believed that the U-B-C system contains one ternary compound UBC (see Table 4) with an extended homogeneity region, which exists at 1573 K in equilibrium with UC, UC_2 , C, UB_2 , and UB_4 . In addition, there are $UC-UB_2$, UB_4-C , UB_4-B_4C , and $UB_{12}-B_4C$ pseudobinary equilibria. The ternary borocarbide UBC lies at the UC_2-UB_2 pseudobinary cross-section. The distribution of the carbon and boron atoms in this orthorhombic phase is intermediate between those in the tetragonal carbide UC_2 and the hexagonal boride UB_2 .

In a more recent study of the U-B-C system, two other ternary compounds UB_2C and $U_5B_2C_7$ have been detected, apart from UBC (see Table 4). The isothermal cross-section through the U-B-C system at 1873 K at an argon pressure of 1×10^5 Pa has been constructed by Rogl et al.⁶⁴ The phase equilibria at 1273, 1673, 1873, and 2073 K are virtually identical. The high-temperature modification of UB_2C has a structure of the ThB_2C type and has a narrow homogeneity region; with an increase in carbon content the unit cell volume of U_2BC somewhat decreases. At temperatures below 1900 K, the low-temperature modification of UB_2C is formed; its structure is unknown. The compound $U_5B_2C_7$ probably has a tetragonal structure similar to that of $La_5B_2C_6$.⁴² The temperatures of the congruent melting of UBC and UB_2C are 2420 ± 25 K and 2550 ± 30 K, respectively. The borocarbide UB_2C exists in equilibrium with UBC, UB_4 , and C, and $U_5B_2C_7$ is in equilibrium with UBC, UC, and UC_2 .

The Mn-B-C system. Among the ternary systems formed by boron and carbon with manganese, technetium, and rhenium, only the Mn-B-C system has been studied fairly extensively. An isothermal cross-section through the manganese-rich part of the phase diagram of this system at 1073 K has been reported.⁶⁵ At 1073 K the borocarbide formed on the dissolution of boron in the cubic carbide $Mn_{23}C_6$ has the composition $Mn_{23}C_{4.6}B_{1.4}$ ($a = 1.064$ nm), and at 1273 K, its composition is $Mn_{23}C_3B_3$. The dissolution of boron in the carbide Mn_7C_3 at 1273 K yields the Mn_7BC_2 ternary phase (see Table 4).^{65,66} At 1273 K the boride Mn_4B exists in equilibrium with $Mn_{23}C_3B_3$ and Mn_7BC_2 , MnB is in equilibrium with Mn_7BC_2 and C; two other equilibria, namely, Mn_3B_4-C and $Mn_3B_4-B_4C$, also exist in the system.⁷¹

The borocarbide $Mn_{23}C_3B_3$ has a structure of the $Cr_{23}C_6$ type, which is also typical of the iron borocarbide $Fe_{23}B_3C_3$, the cobalt borocarbide $Co_{11}B_2C$, and some other ternary compounds.

The unit cell of the carbide $Cr_{23}C_6$ and the borocarbid $Mn_{23}C_3B_3$ and $Fe_{23}B_3C_3$ (space group $Fm\bar{3}m$) is a cube including 4 formula units, i.e. 92 metal atoms and 24 atoms of the nonmetals. Each metal atom occupies a cube vertex and is surrounded by 12 metal atoms constituting a cubooctahedron. Similar cubooctahedra formed by 12 metal atoms surround the centre of each face of the cube. Eight metal atoms occupy the 8(c) and equivalent sites and the remaining metal atoms are at the 32(f) sites and form simple cubes surrounding the middle of each unit cell edge. Each nonmetal atom in compounds with the $Cr_{23}C_6$ type of structure is surrounded by eight metal atoms located at the vertices of a tetragonal antiprism.

Among ternary systems of boron and carbon with Group VIII transition metal, only the Fe–B–C system has been studied in detail. In the Co–B–C system, a ternary compound $\text{Co}_{11}\text{B}_2\text{C}$ has been found (see Table 4).⁶⁹

The Fe–B–C system. Iron forms a carbide Fe_3C (cementite) and borides Fe_2B and FeB . Up to 80 at. % of the carbon in Fe_3C can be substituted by boron; carbon is markedly soluble in both borides. Two ternary compounds $\text{Fe}_{23}\text{C}_3\text{B}_3$ and $\text{Fe}_3(\text{B,C})$ have been found in this system (see Table 4). Boron introduced to the cementite Fe_3C can replace not only the carbon atoms, but also the iron atoms, the boron atoms being predominantly distributed over the crystallographic planes of cementite.⁶⁸ The borocarbide $\text{Fe}_{23}\text{C}_3\text{B}_3$ (the τ -phase) having fairly extended homogeneity regions both for boron and carbon has been studied most thoroughly. The borocarbide $\text{Fe}_{23}\text{C}_3\text{B}_3$ melts congruently. As the temperature increases, the homogeneity region of the τ -phase decreases, and at 1240 K, the τ -phase decomposes to give the γ -phase (austenite) and $\text{Fe}_3(\text{B,C})$.⁷³

III. M–B–N ternary boronitride systems

The properties of the boronitride systems of transition metals are largely similar to those of the borocarbide systems. For a long time, no ternary compounds were found in the M–B–N systems; however, since 1983, several boronitrides of lanthanides and also a ternary compound in the Nb–B–N system were detected (Table 5). The phase equilibria in the M–B–N ternary systems have been analysed in a number of studies.^{80–83}

Rogl et al.,⁷⁴ who have studied ternary systems containing lanthanides, boron, and nitrogen, have found a family of new ternary lanthanum, cerium, praseodymium, and neodymium boronitrides $\text{M}_3\text{B}_2\text{N}_4$ with the orthorhombic structure of the W_2CoB_2 type. In the M–B–N-systems ($\text{M} = \text{Sc}, \text{Y}, \text{Gd} \rightarrow \text{Lu}$), the $\text{M}_3\text{B}_2\text{N}_4$ ternary phases are not formed. The boronitride $\text{Nd}_3\text{B}_2\text{N}_4$ is unstable at temperatures above 1673 K. The structure of boronitrides $\text{M}_3\text{B}_2\text{N}_4$ can be regarded as a variant of the $(\text{W}_2\text{Co})\text{B}_2\Box_4$ filled structure. The boron atoms in this structure are located in trigonal prisms consisting of six metal atoms and form B–B pairs; in addition, each boron atom is bound to two nitrogen atoms (Fig. 7). In turn, the nitrogen atoms of $\text{M}_3\text{B}_2\text{N}_4$

Figure 7. Orthorhombic structure of the lanthanide boronitrides $\text{M}_3\text{B}_2\text{N}_4$ ($\text{M} = \text{La}, \text{Ce}, \text{Pr}, \text{Nd}$) of the $(\text{W}_2\text{Co})\text{B}_2\Box_4$ type (space group Immm).⁷⁴

occupy the 8(*l*) sites, which are vacant in $(\text{W}_2\text{Co})\text{B}_2\Box_4$. In other words, the nitrogen atoms are located in the distorted octahedral interstices and are surrounded by five metal atoms (the M atoms are in the vertices of a rectangular pyramid) and by one boron atom, i.e. NM_5B groups are formed. There are no direct N–N interactions in the structure of the boronitrides $\text{M}_3\text{B}_2\text{N}_4$.

Ternary compounds MBN_2 of the same type have been found in the M–B–N systems ($\text{M} = \text{Pr}, \text{Nd}, \text{Sm}, \text{Gd}$) (see Table 5). The boronitride GdBN_2 is stable only at $T > 1763 \text{ K}$.⁷⁶ The boronitride $\text{Ce}_{15}\text{B}_8\text{N}_{25}$ has been detected in the Ce–B–N system.⁷⁵ Scandium, yttrium, and lanthanides from Tb to Lu do not form compounds MBN_2 .⁸¹ In the M–B–N systems ($\text{M} = \text{Tb} \rightarrow \text{Lu}, \text{Y}$), the boron nitride BN exists in equilibrium with a metal nitride MN and with all the existing borides beginning with MB_4 and ending with MB_{66} , and MN coexists with borides MB_2 and MB_4 ; in the Sc–B–N system, there are only two borides, ScB_2 and ScB_{12} , existing in equilibrium with BN; and ScN is in equilibrium with ScB and BN.⁶³ The mutual solubilities of boron nitride and lanthanide borides and nitrides are extremely limited.⁸¹

Table 5. Some ternary compounds in boronitride systems of transition metals.

The Ti–B–N system. Studies of the phase equilibria in ternary systems containing Group IV transition metals, boron, and nitrogen have shown that no ternary compounds are formed in these systems. According to thermodynamic data,⁴⁷ six pseudobinary equilibria are possible in the Ti–B–N system, namely, TiN_y-Ti_2B , TiN_y-TiB , TiN_y-TiB_2 , TiB_2-N , TiB_2-BN , and Ti_2B_5-BN . There are no reliable experimental data supporting the existence of the borides Ti_2B and Ti_2B_5 . The phase diagram for the Ti–B–N system has been constructed by Nowotny et al.⁴⁸ Four binary compounds, namely, TiB , TiB_2 , TiN_y , and BN , exist in this system; ternary compounds are absent. The titanium nitride TiN_y exists in equilibrium with the borides TiB and TiB_2 and with BN . The lower boride TiB is in equilibrium with the solid solution of nitrogen in α -Ti and the higher boride TiB_2 is in equilibrium with BN . The solubility of boron in the titanium nitride is low, but it is higher than that in the carbide TiC_y . When the composition of nitride TiN_y deviates from the stoichiometric composition, the solubility of boron in it increases. The solubility of nitrogen in titanium borides is negligibly small. The TiN_y-BN equilibrium at a nitrogen pressure of 0.05 MPa exists only below 1900 K, and at $T > 1900$ K, the boride TiB_2 exists in equilibrium with nitrogen.⁴⁷

The Zr–B–N system. The phase equilibria in this system have been investigated in a number of studies.^{47, 54, 84} Brewer and Haraldsen⁴⁷ suggested the existence of three zirconium borides, ZrB , ZrB_2 , and ZrB_{12} , therefore, five possible pseudobinary equilibria, ZrN_y-ZrB , ZrN_y-ZrB_2 , ZrB_2-N , ZrB_2-BN , and $ZrB_{12}-BN$, were considered in the Zr–B–N system. ZrB_2 is the main boride phase of zirconium. In this system, four binary equilibria exist: zirconium diboride exists in equilibrium with the solid solution of nitrogen and boron in α -Zr and with the nitrides ZrN_y and BN ; and the nitride ZrN_y is in equilibrium with BN . The latter equilibrium can exist at a pressure of nitrogen of 0.05 MPa (0.5 atm) up to a temperature of 1820 K; at $T > 1820$ K, the zirconium diboride ZrB_2 exists in equilibrium with nitrogen.⁴⁷ The solubility of boron in zirconium nitride ZrN_y is much higher than that in TiN_y , and it increases from 8 at.% to 25 at.% as the composition of the zirconium nitride varies from $ZrN_{1.00}$ to $ZrN_{0.55}$.

The Hf–B–N system. In the state diagram of the Hf–B–N ternary system, the borides HfB and HfB_2 exist in an equilibrium with the solid solution of nitrogen and boron in α -Hf. The HfB_2-HfN_y , HfB_2-BN , and HfB_2-N equilibria exist in this system [the latter exists at a nitrogen pressure of more than 0.1 MPa (1 atm)].⁸⁴ The solubility of boron in the nitride HfN_y at the lower boundary of the homogeneity region reaches 40–50 at.%. The solubility of nitrogen in HfB and HfB_2 is low, but it is higher than that in the titanium and zirconium borides.

The V–B–N system. The phase equilibria in the V–B–N ternary system have been studied by Spear et al.⁸⁵ (Fig. 8a). No ternary compounds exist in this system, but there are eight binary compounds including five borides (V_3B_2 , VB , V_3B_4 , V_2B_3 , and VB_2), two vanadium nitrides (V_2N_y and VN_y), and one boron nitride (BN). At a pressure of nitrogen of 0.1 MPa (1 atm), eight pseudobinary equilibria are possible in the V–B–N system depending on the temperature, namely, $VB-BN$, $V_3B_2-V_2N_y$, $VB-V_2N_y$, $VB-VN_y$, V_3B_4-BN , V_2B_3-BN , VB_2-BN , and VN_y-BN . The central three-phase $VB + BN + VN_y$ field exists at $T < 2010$ K, the $VB + BN + V_3B_4$ field exists at $T < 2180$ K, and the $V_3B_4 + BN + V_2B_3$ and $V_2B_3 + BN + VB_2$ fields exist at $T < 2290$ K.⁸⁴ Boron is hardly soluble in vanadium nitrides, and nitrogen is almost insoluble in vanadium borides.

The Nb–B–N system. The phase equilibria in this system have been studied in a number of works.^{78, 79, 86} The Nb–B–N system is the only one among the boronitride systems of Group V–VIII transition metals in which ternary compounds have been found. Rogl et al.⁷⁹ have constructed an isothermal cross-section through the Nb–B–N system at 1473 K and a pressure of argon of 1×10^5 Pa (Fig. 8b). The phase equilibria in this system involve three ternary compounds, among which Nb_2BN is formed most

Figure 8. Isothermal cross-sections through the $M-B-N$ ($M = V, Nb$) ternary systems at 1473 K.

(a) the V–B–N system at a nitrogen pressure of 1×10^5 Pa (dark areas denote one-phase homogeneity regions);⁸⁵ (b) the Nb–B–N system at an argon pressure of 1×10^5 Pa [$T = Nb_2BN$, $\phi_{1,2}$ is the designation for two (or more) unknown ternary phases, observed in the $BN + Nb_2BN + NbB$ region].⁷⁹

easily (at 1473 K). The other two ternary compounds were observed in the $NbB-Nb_2BN-BN$ region. The boronitride Nb_2BN exists in equilibrium with ϵ -NbN, δ -NbN, γ -Nb₄N₃, BN , and NbB ; besides, the niobium nitride β -Nb₂N coexists with Nb_3B_2 and NbB ; γ -Nb₄N₃ coexists with the boride NbB , and boron nitride is in equilibrium with ϵ -NbN, Nb_3B_4 , and NbB_2 .

The crystal structure of only one of the ternary compounds, Nb_2BN_{1-x} , has been determined.^{78, 79} This compound has a very narrow homogeneity region and the orthorhombic structure of the Mo_2BC type (space group $Cmcm$).⁷⁸ The structure of the boronitride Nb_2BN is shown in Fig. 9. The boron atoms are located at the centres of trigonal prisms formed by six niobium atoms, and

Figure 9. Crystal structure of Nb_2BN (the Mo_2BC type, space group $Cmcm$).⁷⁸

the seventh niobium atom is located at the centre of one of the square faces of the prism. The nitrogen atoms in Nb_2BN occupy the octahedral interstices of the niobium sublattice. The boron atoms are joined in zigzag-shaped chains parallel to the c axis; the N–N and N–B bonds are missing. Similar compounds V_2BN and Ta_2BN could not be obtained even by the thermobaric treatment (pressure 65×10^8 Pa, temperature 1273 K). The boronitride Nb_2BN forms limited solid solutions with V and Ta, $\text{Nb}_{2-x}\text{V}_x\text{BN}$ ($x \approx 0.1$) and $\text{Nb}_{2-x}\text{Ta}_x\text{BN}$ ($x \approx 0.2$). The substitution of niobium by vanadium or tantalum is accompanied by a slight decrease in the unit cell volume.

The Ta–B–N system. In this system, boron is insoluble in nitrides and nitrogen is insoluble in borides.⁸⁶

The Cr–B–N system. The phase equilibria in ternary systems of Group VI–VIII transition metals with boron and nitrogen have not been adequately studied. The Cr–B–N system involves eight pseudobinary equilibria:⁴⁷ $\text{Cr}_4\text{B–N}$, $\text{Cr}_2\text{B–N}$, $\text{Cr}_5\text{B}_3\text{–N}$, CrB–N , $\text{Cr}_3\text{B}_4\text{–N}$, $\text{CrB}_2\text{–N}$, $\text{CrB}_2\text{–BN}$, and $\text{Cr}_2\text{B}_5\text{–BN}$. Three additional pseudobinary equilibria are possible at a nitrogen pressure of 0.05 MPa. The CrN–BN equilibrium can exist at temperatures below 1300 K, $\text{Cr}_2\text{N–BN}$ exists from 1300 K to 1500 K, and the Cr–BN equilibrium exists from 1500 K to 2000 K. An experimental study has confirmed the absence of ternary compounds in the Cr–B–N system and has shown the existence of one more chromium nitride, Cr_3N .⁸⁷ Later it was shown that at 1873 K and a nitrogen pressure of 0.1 MPa, the $\text{Cr}_2\text{B–Cr}_2\text{N}$, $\text{Cr}_2\text{B–N}$, $\text{Cr}_5\text{B}_3\text{–N}$, and $\text{Cr}_5\text{B}_3\text{–BN}$ pseudobinary equilibria are observed in the Cr–B–N system.²⁹

The W–B–N system. In this system, at a nitrogen pressure of 0.05 MPa, the tungsten borides W_2B (at $T > 1600$ K), WB , and W_2B_5 exist in equilibrium with nitrogen; a $\text{W}_2\text{B}_5\text{–BN}$ pseudobinary equilibrium also exists.⁴⁷ At the same nitrogen pressure, the $\text{W}_2\text{B–BN}$ and WB–BN equilibria as well as the W–BN equilibrium (at $T < 1600$ K) are also possible. Only binary compounds are formed in the W–B–N system.⁸⁷ Boron is virtually insoluble in tungsten nitrides, and nitrogen is virtually insoluble in tungsten borides.

The Fe–B–N system. Studies of the phase equilibria in the Fe–B–N system^{87,88} have shown the presence of binary compounds Fe_2B , FeB , Fe_2N (ζ), Fe_3N (ϵ), Fe_4N (γ'), and BN . Nitrogen is insoluble in iron borides, and boron is insoluble in iron nitrides.

IV. Phase relationships in the Si-containing M–B–Si, M–Si–C, and Me–Si–N systems

1. The common type of structures of ternary Si-containing compounds

The ternary systems of transition metals with boron and silicon are of interest as refractory materials resistant to the oxidation at high temperatures. The similarity of the structures of silicides and borides facilitates their mutual solubility and the formation of ternary compounds. The phase equilibria in the M–B–Si systems have been studied.^{89–100}

An investigation of doping of high-melting silicides with boron, carbon, nitrogen, and oxygen⁸⁹ and some more recent studies^{90–92} have shown that in all the M–Si–X systems (M is a transition metal, X = B, C, N, O) a number of ternary phases are formed on the basis of the silicides M_5Si_3 , namely, $\text{M}_5\text{Si}_3\text{X}$ or $\text{M}_5\text{Si}_3\text{X}_2$ with hexagonal structure of the Mn_5Si_3 type (D_{8h}) and/or M_5SiX_2 [the Cr_5B_3 type ($\alpha\text{-Nb}_5\text{Si}_3$) ($T_2 - D_{8h}$)], and $\text{M}_5\text{Si}_2\text{X}$ [the W_5Si_3 type ($\beta\text{-Nb}_5\text{Si}_3$) ($T_1 - D_{8h}$)].

The hexagonal filled structure of the Mn_5Si_3 type (the D_{8h} structural type, space group $P6_3/mcm$) (Fig. 10) is characteristic of many transition metal silicoborides, carbosilicides, and siliconitrides $\text{M}_5\text{Si}_3\text{X}$ as well as for aluminocarbides and aluminonitrides. It is likely to be the commonest structure of ternary compounds in the M–X–X' systems being considered. Its unit cell incorporates two $\text{M}_5\text{Si}_3\text{X}$ formula units. The transition atom metals M occupy the 4(d) and 6(g) sites in this structure.

Figure 10. Filled crystal structure of the Mn_5Si_3 (D_{8h}) type of the ternary compounds $\text{M}_5\text{Si}_3\text{X}$ (space group $P6_3/mcm$). Only the transition metal atoms M at the 6(g) sites and the interstitial nonmetal atoms X at the 2(b) sites forming the XM_6 octahedra are shown. The XM_6 octahedra are linked to one another through two faces and form columns directed along the $[001]$ axis.

The silicon atoms also occupy the 6(g) sites, but with other coordinates, and are located within distorted trigonal prisms constituted by two metal atoms at the (d) sites and four metal atoms at the (g) sites. The M atoms located at the 6(g) sites form octahedra; the nonmetal atoms X (C, N, O) can be arranged inside these octahedra at the 2(b) sites (see Fig. 10). Each XM_6 octahedron is joined with two neighbouring octahedra through its opposite faces; thus, parallel chains of octahedra are formed along the c axis. An important characteristic feature of the phases with the D_{8h} structure is the presence of a broad homogeneity region, since the interstitial atoms can occupy not all the octahedra, but only some of them.

The $\text{M}_5\text{Si}_2\text{X}$ tetragonal phases of the W_5Si_3 type [$\beta\text{-Nb}_5\text{Si}_3$, the D_{8h} (T_1) structural type] and M_5SiX_2 of the Cr_5B_3 type [$\alpha\text{-Nb}_5\text{Si}_3$, the D_{8h} (T_2) structural type] belong to the same space group $I4/mcm$ (D_{4h}^{18}) and have very similar structures. Their unit cells incorporate 4 formula units each, i.e. 20 metal atoms and 12 nonmetal atoms. A characteristic feature of the structure of these phases is that the silicon atoms at the 8(h) sites are isolated and form the localised Si–Si pairs. These phases may be regarded as resulting from the substitution of silicon in the silicides M_5Si_3 by the X atoms.

It is of interest that the tetragonal silicides M_5Si_3 are very sensitive to admixtures of the C, B, N, and O nonmetal atoms; their introduction leads to the transition to ternary phases with the Mn_5Si_3 (D_{8h}) type of structure. When this transformation takes place, the X nonmetal atoms occupy the octahedral interstices of the metal sublattice, whereas the displaced silicon atoms occupy the points in the metal sublattice. In the tetragonal silicoborides $\text{M}_5\text{Si}_2\text{B}$ (T_1), the boron atoms occupy the vacant positions in the silicon sublattice, whereas the silicon atoms replace some of the metal atoms in the metal sublattice.

Phases with the D_{8h} structure are stabilised most effectively by carbon and somewhat less effectively by boron, they are very slightly stabilised by nitrogen and not at all by oxygen.

2. The ternary M–B–Si silicoboride systems

The ternary phases formed in the M–B–Si systems are presented in Table 6. Typically, boron possesses substantial initial solubility in all the M_5Si_3 phases with the D_{8h} , D_{8h} , and D_{8h} structures. The addition of boron to pure silicides leads to an expansion of the D_{8h} lattice caused by the intercalation of boron to the vacant points of the silicon sublattice and to the compression of the T_1 and T_2 lattices due to the direct substitution of the silicon atoms by boron.

The Ti–B–Si system. This system involves four titanium borides Ti_2B , TiB , TiB_2 , and Ti_2B_5 and three titanium silicides Ti_5Si_3 , TiSi , and TiSi_2 .⁸ No reliable experimental data on the temperature-dependent concentration ranges for the existence of the borides Ti_2B and Ti_2B_5 have been reported. In all probability, the TiB–TiSi , $\text{TiB}_2\text{–TiSi}_2$, and $\text{TiB}_2\text{–Si}$ (or $\text{Ti}_2\text{B}_5\text{–Si}$)

Table 6. Some ternary compounds in silicoboride systems of Group IV–VIII transition metals.^{89–100}

^a *D*8₈ is a filled structure of the Mn₅Si₃ type (space group *P*6₃/*mcm*), *Z* = 2; *D*8₁(*T*₂) is a structure of the Cr₅B₃–α-Nb₅Si₃ type (space group *I*4/*mcm*), *Z* = 4; *D*0₁₁ is a structure of the Fe₃C type (space group *Pnma*), *Z* = 4; *D*8_m(*T*₁) is a structure of the W₅Si₃–β-Nb₅Si₃ type (space group *I*4/*mcm*), *Z* = 4; *C*22 is a structure of the Fe₂P type (space group *P*6̄2*m*), *Z* = 3.

pseudobinary equilibria exist in the Ti–B–Si system. The existence of the ternary hexagonal silicoboride Ti₅Si₃B formed from Ti₅Si₃ via the substitution of a minor portion (~1–2 at.%) of the silicon atoms by the boron atoms is also quite probable.

The Zr–B–Si system. The state diagram of the Zr–B–Si ternary system (Fig. 11) shows eight binary zirconium compounds.⁹³ They include three borides ZrB, ZrB₂, and ZrB₁₂ and five silicides Zr₂Si, Zr₅Si₃ (Zr₃Si₂), Zr₄Si₃, ZrSi, and ZrSi₂. The existence of the boride ZrB at 1623 K is doubtful, because it is stable only within a narrow temperature range and decomposes already at 1500 K. In addition, the silicon borides SiB₃, SiB₄, and SiB₆ are not shown in the diagram. In the zirconium diboride ZrB₂ up to 20 at.% of boron can be substituted by silicon, i.e. a limited solid solution of ZrSi₂ in ZrB₂, namely Zr(B,Si)₂, is formed. An important characteristic feature of the Zr–B–Si system is the presence of the ternary hexagonal compound Zr₅Si₃(B) containing from 5 to 8 at.% of boron. The phase diagram of this system (see Fig. 11) exhibits ten pseudobinary equilibria, namely, Zr(B,Si)₂–Zr, Zr(B,Si)₂–

**Figure 11.** Isothermal cross-section through the Zr–B–Si system at 1623 K (dark areas denote one-phase homogeneity regions).⁹³

ZrSi, Zr(B,Si)₂–Zr₅Si₃(B), Zr(B,Si)₂–ZrSi₂, Zr(B,Si)₂–Si, Zr₅Si₃(B)–Zr, Zr₅Si₃(B)–Zr₂Si, Zr₅Si₃(B)–Zr₃Si₂, Zr₅Si₃(B)–Zr₄Si₃, and Zr₅Si₃(B)–ZrSi. In all probability, three more pseudobinary equilibria of Z(B,Si)₂ with the silicon borides SiB₃, SiB₄, and SiB₆ also exist.

The Hf–B–Si system. This system includes the borides HfB and HfB₂, the silicides Hf₅Si₃, HfSi, and HfSi₂, and compound Hf₅Si₃(B) with a minor (2–3 at.%) content of boron, which substitutes silicon.⁸

The V–B–Si system. The V–B–Si ternary system has been studied.^{90,91} Kudielka et al.⁹⁰ suggested a scheme for the triangulation of the V angle (V–VB–VSi) of the state diagram of the V–B–Si system, which incorporates two ternary compounds, namely, V₅Si₃B_{0.45} with a hexagonal lattice and V₅SiB₂ (the *T*₂ type) with a tetragonal lattice (see Table 6). The former of these compounds crystallises with the *D*8₈ structural type and is formed via partial substitution of the silicon atoms in the silicide V₅Si₃ by boron atoms. Six pseudobinary equilibria exist in the system, namely, V₂B–V₅SiB₂, VB–V₅SiB₂, V₃Si–V₅SiB₂, V₅Si₃B_{0.45}–V₅SiB₂, V₃Si–V₅Si₃B_{0.45}, and V₅Si–V₅Si₃B_{0.45}. One may expect that six more pseudobinary equilibria, VB–V₅Si₃B_{0.45}, VSi₂–V₅Si₃B_{0.45}, VB–VSi₂, V₃B₄–VSi₂, VB₂–VSi₂, and VB₂–Si, will be found.

The Nb–B–Si system. The state diagram of the Nb–B–Si system has been studied rather comprehensively.⁹² This system incorporates ten binary compounds (the niobium borides Nb₃B₂, NbB, Nb₃B₄, and NbB₂, the niobium silicides Nb₄Si, Nb₅Si₃, and NbSi₂, and the silicon borides SiB₃, SiB₄, and SiB₆) and two ternary compounds based on Nb₅Si₃, namely, Nb₅Si₃B with the *D*8₈ structure and Nb₅SiB₂ with the *D*8₁ structure. Both ternary compounds have fairly extended homogeneity regions, and the nonmetal sublattice of these silicoborides can contain a substantial number of vacancies, apart from the boron and silicon atoms. The boride NbB₂ which has a homogeneity region can dissolve up to 2 at.% of silicon.

The Ta–B–Si system. The phase diagram of state of the Ta–B–Si ternary system has been studied.^{90,94} It is very similar to the state diagram of the Nb–B–Si system, but differs from it by the greater numbers of binary compounds (twelve) and ternary compounds (three). Two ternary phases (of the *D*8₈ and *T*₂ types) are based on the silicide Ta₅Si₃ and the third one is based on Ta₂Si.

The Cr–B–Si system. This system contains six chromium borides, four chromium silicides, and two ternary phases with the *D*8₈ and *T*₁ structures; the phase with the *T*₂ structure is a limited solid solution of silicon in the boride Cr₅B₃.⁹⁵ The Cr₅Si₃B ternary phase (the *D*8₈ type) (see Table 6) has virtually no homogeneity region.

The Mo–B–Si system. The phase equilibria in this system (Fig. 12a) have been studied in a number of works.^{91,96,97} The state diagram of the Mo–B–Si system is simpler than the analogous diagram for the system containing chromium, since it incorporates a smaller number of binary compounds. There are two ternary phases with structures of the *T*₁ and *T*₂ types, but the ternary phase with the *D*8₈ type of structure is missing. It has been shown that silicon is insoluble in the molybdenum borides Mo₂B, MoB, Mo₂B₅, and boron does not dissolve in MoSi₂.⁹⁷

The W–B–Si system. Two ternary phases exist in this system: W₁₀Si₃B₃ [W₅(Si₃B)₃] with the *T*₂ type of structure and W₅Si₂B with the *T*₁ type of structure (Fig. 12b).⁹¹

The Mn–B–Si system. In the Mn–B–Si system, the ternary compound Mn₅SiB₂ with the tetragonal structure of the *T*₂ type (see Table 6) existing in an equilibrium with the hexagonal silicide Mn₅Si₃ has been found.⁹⁹

The Fe–B–Si system. The phase equilibria in this system have been studied in detail in the Fe–angle of the state diagram.^{98,99} Four ternary phases were discovered, namely, Fe₅SiB₂ with the structure of the *T*₂ type and with a small homogeneity region formed on the B ↔ Si mutual substitution; Fe_{4.8}Si₂B with the *T*₁ type of structure; Fe₃(Si₃B) (with the composition Fe₃Si_{0.2}B_{0.8}) with the cementite Fe₃C structure and with a small homogeneity

Figure 12. Isothermal cross-sections through the Mo-B-Si system at 1873 K (a) and through the W-B-Si system at 2073 K (b); dark areas denote one-phase homogeneity regions.⁹¹

(a) a cross-section in the silicoboride region with iron contents ranging from 50 to 70 at.%; (b) the contours of the state diagram for the whole Fe-B-Si ternary system.

region; and $\text{Fe}_2(\text{Si,B})$ (with the composition $\text{Fe}_2\text{Si}_{0.4}\text{B}_{0.6}$), the structure of which is unknown (Fig. 13). It was found that a minor amount of boron can be dissolved in Fe_5Si_3 . The other binary iron borides and silicides are absolutely insoluble in one another.

The Co-B-Si system. Only one ternary phase $\text{Co}_{4.7}\text{Si}_2\text{B}$ with the T_1 type of structure and a small homogeneity region is formed in this system. It exists in an equilibrium with the cobalt borides CoB and Co_2B and with the cobalt silicides CoSi and Co_2Si ; in addition, there are the CoB-CoSi and $\text{Co}_2\text{B}-\text{Co}_2\text{Si}$ pseudobinary equilibria.⁹⁸

The Ni-B-Si system. The ternary compound $\text{Ni}_6\text{Si}_2\text{B}$ with a hexagonal structure of the C22 type, isomorphous to the phosphides Mn_2P , Fe_2P , and Ni_2P , has been found in this system (see Table 6).

3. The M-Si-C ternary carbosilicide systems

The atomic radius of carbon is small (~ 0.077 nm); therefore, carbon always acts as the interstitial element in compounds with transition metals and is located in the interstices of the metal sublattice. Silicon, which is an analogue of carbon in the Periodic System, has a substantially larger atomic radius, equal to ~ 0.117 nm. In compounds with Group IV and V transition metals, the atoms of which are fairly large, silicon can act as an interstitial element; silicides of other transition metals occupy an intermediate position between interstitial compounds and intermetallic compounds. Thus, silicon can enter into the metal lattice either as an interstitial element or as a substituting element. The same dual behaviour of silicon is exhibited in transition metal carbosilicides.

The ternary hexagonal phases of the $\text{M}_5\text{Si}_3(\text{C})$ type, similar to the $\text{M}_5\text{Si}_3(\text{B})$ silicoboride ternary phases with the filled structure of the Mn_5Si_3 type (D_{8h}) are characteristic of the majority of the M-Si-C systems. The main ternary carbosilicide phases are

Table 7. Some ternary compounds in carbosilicide systems of Group IV-VIII transition metals.

Note. All the ternary compounds listed in the Table, except for $\text{Mn}_8\text{Si}_2\text{C}$ and Mn_5SiC (the structures of which are unknown), Ti_3SiC_2 , and uranium ternary phases, have hexagonal filled structure of the Mn_5Si_3 (D_{8h}) type with space group $P6_3/mcm$, $Z = 2$. ^a This compound crystallises with a hexagonal structure and with space group $P6_3/mmc$, $Z = 2$. ^b $\text{R} = (\text{C,N,O})_{x+y}$. ^c $\text{U}_3\text{Si}_2\text{C}_3$ has the orthorhombic symmetry, $Z = 2$; $\text{U}_{20}\text{Si}_{16}\text{Si}_3$ crystallises with the hexagonal symmetry, $Z = 1$; $\text{U}_3\text{Si}_2\text{C}_x$ is a tetragonal (space group $P4/mbm$) solid solution of carbon in U_3Si_2 , $Z = 2$.

listed in Table 7. The phase diagrams for a number of M–Si–C ternary systems have been surveyed.^{101–103}

a. Carbonsilicides of Group IV–VI transition metals

The Ti–Si–C system. The kinetics and thermodynamics of the reactions of titanium silicides with carbon were studied for the first time by Kudielka et al.⁹⁰ They found that the titanium carbide TiC_y exists in equilibrium with the silicon carbide SiC and the titanium silicides Ti_5Si_3 , TiSi, and TiSi_2 , whereas SiC is in equilibrium with TiSi_2 . It has been shown⁸⁹ that the addition of carbon stabilizes the Ti_5Si_3 hexagonal phase and leads to the formation of a ternary phase $\text{Ti}_5\text{Si}_3\text{C}_x$, which contains¹⁰¹ up to 11 at.% of carbon. The $\text{Ti}_5\text{Si}_3\text{C}$ phase belongs to the group of ternary silicoborides and carbosilicides $\text{M}_5\text{Si}_3\text{X}$ with the hexagonal structure of the $D8_8$ type. The Ti–Si–C system includes one more ternary compound, Ti_3SiC_2 , with a hexagonal structure (space group $P6_3/mmc$) (Fig. 14).^{101–103} In this compound, the carbon atoms occupy the octahedral vacancies in the octahedra formed by the titanium atoms. Each CTi_6 octahedron is joined to the neighbouring octahedra through its nine edges in such a way that one octahedral layer is superimposed onto another (see Fig. 14b). A half of all the titanium atoms are located in the middle of the double octahedral layer and each of these atoms is shared by six octahedra. The remaining titanium atoms are located on the upper and lower surfaces of the double octahedral layer, and each of them is shared by three neighbouring octahedra. The chemical formula of the double octahedral layer is Ti_3C_2 . The octahedral layers contain open and closed tetragonal interstices, the open tetragonal vacancies of one double octahedral layer being located over the same vacancies of another double octahedral layer. The silicon atoms are arranged halfway between the centres of the tetrahedral vacancies of the neighbouring double octahedral layers and also constitute a layer.

Figure 14. Crystal structure of the titanium carbosilicide Ti_3SiC_2 . (a) unit cell (space group $P6_3/mmc$) with distinct CTi_6 octahedra; (b) the double layer of the CTi_6 octahedra joined via nine edges; the silicon atoms are arranged over the centres of the open tetrahedral vacancies.

The carbosilicide Ti_3SiC_2 exists in equilibrium with the carbides TiC_y and SiC, with the disilicide TiSi_2 , and with the $\text{Ti}_5\text{Si}_3\text{C}$ ternary phase. The phase equilibria in the Ti–Si–C system at 1373 K and 1523 K have been studied.^{118, 119} The ternary compounds and multiphase materials present in the Ti–Si–C system have been investigated by Auger spectroscopy.¹²⁰ The isothermal cross-sections through the Ti–Si–C system at 1473 K¹²¹ and 1523 K^{118, 119} are very similar. At a lower temperature of 1373 K, titanium silicide Ti_3Si appears. It exists

in equilibrium with $\text{Ti}_5\text{Si}_3\text{C}$ and with the solid solution of Si and C in $\beta\text{-Ti}$.

A schematic phase diagram for the Ti–Si–C system, which does not take into account the actual existing ternary phases has been reported.¹²²

The compatibility of phases in the Ti–Si–C system at 1473–1773 K has been studied under the conditions of confining compression at a pressure of $(1-2) \times 10^8$ Pa.¹²³ At high pressures, the titanium silicide Ti_3Si becomes stable and dissolves up to 9 at.% of carbon (without external pressure, Ti_3Si decomposes at the same temperatures to give TiC_y , Ti_5Si_3 , and a solid solution of silicon and carbon in titanium). It is of interest that at high pressures carbon is insoluble in the silicide Ti_5Si_3 , although under ambient conditions the solubility of carbon in this compound reaches 11 at.%.

The Zr–Si–C system. The first scheme for the triangulation of the phase diagram for the Zr–Si–C ternary system has been suggested by Brewer and Krikorian.¹⁰⁸ According to the data obtained by Nowotny et al.,⁸⁹ the silicide Zr_5Si_3 dissolves a substantial amount of carbon to give the $\text{Zr}_5\text{Si}_3\text{C}_x$ ternary phase. The Zr–Si–C system incorporates seven binary compounds (the carbides ZrC_y and SiC and the silicides Zr_2Si , Zr_5Si_3 (Zr_3Si_2), Zr_5Si_4 , ZrSi, and ZrSi_2) and one ternary phase $\text{Zr}_5\text{Si}_3\text{C}_x$. The silicon carbide exists in equilibrium with ZrC_y , ZrSi_2 , and ZrSi, whereas the zirconium carbide ZrC_y is in equilibrium with SiC, ZrSi, Zr_2Si , and $\text{Zr}_5\text{Si}_3\text{C}_x$.¹⁰¹ Pseudobinary equilibria connect the ternary phase also to the silicides Zr_2Si , Zr_5Si_3 (Zr_3Si_2), Zr_5Si_4 , and ZrSi. The isothermal cross-section at 1573 K through the Zr–Si–C ternary system has been studied.¹²⁴

The Hf–Si–C system. According to a number of studies,^{101–103} the phase diagrams for this system and for the system discussed above are similar. The existing differences are due to the fact that the hafnium carbide HfC_y is in equilibrium with HfSi_2 ; therefore, the SiC–HfSi pseudobinary equilibrium is missing. Taking into account the data on the stabilisation by carbon of hexagonal phases with the Mn_5Si_3 type of structure ($D8_8$) and also the similarity of the phase diagrams for Hf–Si–C and Zr–Si–C, one may assume that the Hf–Si–C system contains a $\text{Hf}_5\text{Si}_3\text{C}_x$ ternary phase.

The V–Si–C system. In the V–C, Nb–C, and Ta–C binary systems, rhombohedral ζ -phases of the composition M_4C_3 are formed in narrow concentration and temperature intervals ($1200 \text{ K} < T < 1800 \text{ K}$).^{125, 126} The carbides $\zeta\text{-M}_4\text{C}_3$ cannot be isolated as individual phases, therefore equilibria involving these compounds are not discussed in the ternary carbosilicide systems of vanadium, niobium, and tantalum. Vanadium forms three silicides, namely, V_3Si , V_5Si_3 , and VSi_2 . The dissolution of up to 10 at.% of carbon in V_5Si_3 leads to the formation of the $\text{V}_5\text{Si}_3\text{C}_x$ ternary phase.^{101, 107} It exists in an equilibrium with the carbides SiC and VC_y and with the silicides V_5Si_3 and VSi_2 . In addition, five pseudobinary equilibria, $\text{SiV} - \text{VS}_2$, $\text{SiV} - \text{VC}_y$, $\text{VC}_y - \text{V}_5\text{Si}_3$, $\text{V}_2\text{C}_y - \text{V}_5\text{Si}_3$, and $\text{V}_2\text{C}_y - \text{V}_3\text{Si}$, exist in the V–Si–C system. The phase diagrams for the V–Si–C ternary system have been reported.^{122, 127}

The Nb–Si–C system. In this system, the carbide NbC_y is in equilibrium with two silicides NbSi_2 and Nb_5Si_3 , with the silicon carbide SiC,^{101, 108} and with the $\text{Nb}_5\text{Si}_3\text{C}_x$ ternary phase.¹⁰⁷ The quantity of carbon dissolved in the $\text{Nb}_5\text{Si}_3\text{C}_x$ phase is likely to be less than that dissolved in the analogous $\text{V}_5\text{Si}_3\text{C}_x$ phase. The $\text{Nb}_5\text{Si}_3\text{C}_x$ ternary phase is in equilibrium with NbC_y and with the niobium silicides NbSi_2 and Nb_5Si_3 , whereas the carbides SiC and Nb_2C_y are in equilibrium with NbSi_2 and Nb_5Si_3 , respectively. The phase diagram for the Nb–Si–C ternary system has been reported by Brukl.¹²¹

The Ta–Si–C system. The phase equilibria in this system have been studied repeatedly.^{89, 101, 108, 127} The isothermal cross-sections through the phase diagram of the Ta–Si–C system at 1273 K,¹²⁷ 1823 K,⁸⁹ and 1873 K⁸⁹ are virtually identical. All the workers noted that the $\text{Ta}_5\text{Si}_3\text{C}_x$ ($\text{Ta}_{4.8}\text{Si}_3\text{C}_{0.5}$) ternary phase with the hexagonal structure of the Mn_5Si_3 type ($D8_8$) exists in this

system.¹⁰⁸ This phase is isomorphous to the hexagonal silicide Ta_5Si_3 stabilised by carbon (the pure silicide Ta_5Si_3 has a tetragonal structure) and forms a continuous series of solid solutions with it. The $Ta_5Si_3C_x$ phase is in an equilibrium with the carbides TaC_y and Ta_2C_y and with the silicides Ta_2Si , Ta_5Si_3 , and $TaSi_2$. The system also includes five pseudobinary equilibria: $SiC-TaSi_2$, $SiC-TaC_y$, TaC_y-TaSi_2 , $Ta_2C_y-Ta_2Si$, and $Ta_2C_y-Ta_3Si$.

The Cr-Si-C system. At 1673 K, eight binary compounds (SiC , Cr_3C_2 , Cr_7C_3 , $Cr_{23}C_6$, $CrSi_2$, $CrSi$, Cr_5Si_3 , and Cr_3Si),¹¹⁰ the $Cr_5Si_3C_x$ ternary phase having a homogeneity region,^{109,110} a solid solution of silicon in chromium $Cr(Si)$, and a substitution solid solution based on the silicide Cr_3Si exist in this system. The $Cr_5Si_3C_x$ ternary phase has the hexagonal structure of the $D8_8$ type and exists in an equilibrium with silicon carbide SiC , chromium carbides Cr_3C_2 and Cr_7C_3 , chromium silicides $CrSi$ and Cr_5Si_3 , and the substitution solid solution based on Cr_3Si . The solid solution based on Cr_3Si exists in equilibrium with the carbides Cr_7C_3 and $Cr_{23}C_6$ and with the solid solution of silicon in chromium $Cr(Si)$. In addition, there are four equilibria, namely, $SiC-CrSi_2$, $SiC-CrSi$, $SiC-Cr_3C_2$, and $Cr_{23}C_6-Cr(Si)$. The diagram of the phase equilibria in the Cr-Si-C system has been reported.¹²²

Parthe et al.¹⁰⁹ believed that the $Cr_5Si_3C_x$ ternary phase results from the substitution of chromium and silicon atoms by carbon. However, later it was shown¹¹⁰ that the unit cell parameters and the unit cell volume of the $Cr_{5\pm0.2}Si_{3\pm0.1}C_x$ ternary phase ($0.25 < x < 1.05$) increase with an increase in x . This means that the carbon atoms do not replace Cr or Si atoms, as was believed previously,¹⁰⁹ but are located in the vacant octahedral interstices of the structure of the $D8_8$ type of this compound. Evidence that the carbon atoms fill the octahedral interstices of the metallic sublattice of the $M_5Si_3C_x$ phases with the $D8_8$ type of structure has also been obtained in another study.¹¹¹

The Mo-Si-C system. The first variant of the phase diagram for the Mo-Si-C ternary system has been suggested by Brewer and Krikorian.¹⁰⁸ This diagram reflects fairly adequately all the characteristic features of this system including the existence of a stable ternary hexagonal compound with an extended homogeneity region and a temperature of congruent melting of ~ 2340 K. The composition Mo_4Si_3C has been suggested for this compound. This ternary compound exists in equilibrium with carbon, with the carbides SiC , MoC_y (Mo_3C_2), and Mo_2C , and with the silicides $MoSi_2$ and Mo_5Si_3 (Mo_3Si_2); SiC is in equilibrium with $MoSi_2$, and Mo_2C is in equilibrium with Mo_5Si_3 (Mo_3C_2) and Mo_3Si .¹²⁸

It has been shown¹¹² that the ternary molybdenum carbosilicide has the stoichiometric composition Mo_5Si_3C and belongs to the M_5Si_3X type of ternary hexagonal phases common for the M-Si-X systems ($X = B, C, N$); the homogeneity region of Mo_5Si_3C is much narrower than has been found by Nowotny et al.¹²⁸ The isothermal cross-section through the Mo-Si-C system at 1473 K has been reported.¹¹² According to this study, at 1473 K, the silicon carbide SiC exists in equilibrium with Mo_5Si_3 , and the $MoSi_2-Mo_5Si_3C_x$ pseudobinary equilibrium is absent.

The reason for the discrepancies between the results obtained by Van Loo et al.¹¹² and Nowotny et al.¹²⁸ concerning these pseudobinary equilibria can be elucidated by additional investigations of the phase relationships in the Mo-Si-C system. The isothermal cross-section through the Mo-Si-C system at 1873 K¹²⁸ virtually coincides with the cross-section at 1673 K reported by Spear et al.⁸⁵

It has been suggested¹⁰⁹ that the carbon atoms in the ternary molybdenum carbosilicide $Mo_{5-x}Si_{3-y}C_{x+y}$ substitute the molybdenum and silicon atoms; however, it has been shown in another study¹¹¹ that such a substitution does not occur, and the carbon atoms are located in the octahedral interstices formed by the molybdenum atoms.

The W-Si-C system. In this system, no ternary compounds exist,¹⁰⁸ however, when a minor amount of nitrogen or oxygen is present, a quasi-ternary hexagonal phase $W_{5-x}Si_{3-y}(C,N,O)_{x+y}$

arises.¹⁰⁹ In the absence of nitrogen or oxygen admixtures, the pseudobinary equilibria existing in the W-Si-C system at 2073 K involve only binary compounds: $SiC-WSi_2$, $SiC-W_5Si_3$, $SiC-WC$, $WC-W_5Si_3$, and $W_2C-W_5Si_3$.⁴⁹ The conclusion reached by Parthe et al.¹⁰⁹ that the tungsten and silicon atoms in the ternary phase have been substituted by interstitial atoms (C, N, O) was erroneous, since the carbon and nitrogen atoms in the compounds M_5Si_3X with the $D8_8$ structure behave as interstitial elements and are arranged in octahedral interstices formed by the metal atoms.^{110,111}

The U-Si-C system. The phase equilibria in this system at 1000–1773 K under an argon atmosphere have been investigated.¹¹³ Two ternary compounds $U_3Si_2C_3$ and $U_{20}Si_{16}C_3$ with orthorhombic and hexagonal crystal lattices, respectively, have been found in the U-Si-C system (see Table 7).^{114,115} It has also been shown^{113,116} that the silicide U_3Si_2 dissolves up to 4 at.% of carbon thus forming the $U_3Si_2C_x$ interstitial solid solution. At 1100 K (Fig. 15) the ternary compound $U_3Si_2C_3$ exists in the U-Si-C system in equilibrium with UC, SiC , and U_3Si_5 ; SiC is in equilibrium with U_2C_3 , UC, U_3Si_5 , USi_2 , and USi_3 ; UC coexists with U_3Si , $U_3Si_2C_x$, $U_{20}Si_{16}C_3$, and U_3Si_5 ; the carbosilicide $U_{20}Si_{16}C_3$ coexists with $U_3Si_2C_x$, USi , and U_3Si_5 ; and U_3Si exists in equilibrium with $U_3Si_2C_x$.

Figure 15. Isothermal cross-section through the U-Si-C system at 1100 K (the dark area denotes the homogeneity region of the $U_3Si_2C_x$ solid solution).¹¹³

$T_1 = U_3Si_2C_3$, $T_2 = U_{20}Si_{16}C_3$.

Later the phase equilibria in the alloys with large proportions of uranium have been studied at 1023–1223 K.¹¹⁶ At temperatures below 1090 K, the phase equilibria in the U-UC-USi region were the same as those in the diagram shown in Fig. 15. At 1100–1150 K, the UC- U_3Si pseudobinary equilibrium disappears and the U- $U_3Si_2C_x$ equilibrium appears instead and, at temperatures above 1200 K, the silicide U_3Si and the $U_3Si-U_3Si_2C_x$ equilibrium do not exist.^{116,129} According to the data obtained by Guinet et al.,¹¹⁶ the solubility of carbon in U_3Si_2 reaches 4 at.%. On the dissolution of carbon, the c parameter of the unit cell of U_3Si_2 increases by 0.0042 nm thus becoming equal to 0.3942 nm. The maximum solubility of carbon in the U_3Si silicide at 1083 K is 0.15 at.%.¹³⁰

b. Carbosilicides of Group VII and VIII transition metals

The Mn-Si-C system. The phase diagram for this system (Fig. 16a), in addition to eight binary compounds, contains the $Mn_5Si_3C_x$ ternary phase (a solid solution of carbon in Mn_5Si_3), Mn_8Si_2C , and Mn_5SiC .^{101–103} Silicon carbide exists in equilibrium with the silicides $Mn_{15}Si_{26}$ and $MnSi$, with the $Mn_5Si_3C_x$ and Mn_8Si_2C ternary phases, and perhaps with Mn_5SiC . The unit cell parameters of the $Mn_5Si_3C_x$ ternary phase are larger than the corresponding unit cell parameters of Mn_5Si_3 ;¹⁰⁷ this implies that

the carbon atoms are located in the octahedral interstices formed by the manganese atoms. The $\text{Mn}_5\text{Si}_3\text{C}_x$ hexagonal phase with a structure of the $D8_8$ type is in equilibrium with MnSi , Mn_3Si_3 , Mn_3Si , Mn_9Si_2 , and $\text{Mn}_8\text{Si}_2\text{C}$; and the $\text{Mn}_8\text{Si}_2\text{C}$ phase coexists with Mn_9Si_2 . The pseudobinary equilibria involving the Mn_5SiC ternary phase are given hypothetically. The scheme of phase equilibria in the Mn–Si–C system have been reported by Lyakishev et al.¹²²

The Re–Si–C system. This system contains no ternary phases.^{101–103, 131} The scheme of triangulation of the phase diagram of the Re–Si–C system at 1873 K suggested by Searcy and Finnie¹³¹ involves four pseudobinary equilibria of the silicon carbide SiC with rhenium and three rhenium silicides. Figure 16b presents the isothermal cross-section through this system at 1273 K constructed using published data;^{101–103} rhenium silicides are in equilibrium with carbon, and SiC coexists with ReSi_2 .

Jeitschko et al.,¹¹⁷ who have studied the phase equilibria in the M–Ga–C and M–Ge–C systems, also have paid attention to the M–Si–C systems (M = Mn, Re, Fe). In the Re–Si–C system they discovered a ternary phase containing 45 at.% Re, 40 at.% Si, and 15 at.% C; the structure of this phase was not determined. There is no other evidence in support of the existence of a ternary phase in this system.

The Fe–Si–C system. The phase relationships in the Fe–Si–C system have been considered in many studies, because they are related to the problems of the production of cast iron, steel, various iron-based alloys, and refractory materials. The equilibrium and nonequilibrium phase transformations in the Fe–C system become substantially more complicated on the addition of silicon, since the silicon atom is much larger than the carbon atom.

When silicon substitutes iron, the ferrite solid solution is stabilised and the γ -region (solid solution of C and Si in Fe) narrows. At the same time this substitution promotes decomposition and graphitisation of the cementite Fe_3C . In all probability, the Fe–Si–C system contains no stable ternary phase. The information concerning ternary iron carbosilicides (for example, a ternary phase of an unknown composition of the type of the Nowotny phase with the $D8_8$ structure has been observed in this system;¹¹⁷ and the carbosilicide $\text{Fe}_{10}\text{Si}_2\text{C}_3$ containing about 9 mass % of silicon has been mentioned in a monograph⁸) refers most probably to a metastable phase. It is even possible that there are several metastable phases in which silicon substitutes either iron $[(\text{Fe},\text{Si})_3\text{C}]$ or carbon $[\text{Fe}_3(\text{C},\text{Si})]$. The formation of a ternary metastable phase based on austenite also cannot be ruled out.

No stable ternary phases have also been found in the recent studies of the phase diagram of the Fe–Si–C ternary system at 1123 K¹³² and 1243 K.^{101–103} At temperatures below 1100 K (the temperature of the decomposition of the Fe_5Si_3 high-temperature phase) silicon carbide exists in equilibrium with the silicides FeSi_2 , FeSi , and Fe_3Si . Above this temperature the equilibrium silicide Fe_5Si_3 with a hexagonal structure of the $D8_8$ type appears in this system, and silicon carbide is in equilibrium with the disilicide FeSi_{2+x} having a homogeneity region and with the silicides FeSi and Fe_5Si_3 [according to a study by Schuster,¹⁰¹ instead of the SiC – FeSi_{2+x} equilibrium, two equilibria exist, SiC – Fe_2Si_5 and SiC – $\text{FeSi}_2(\text{h})$]. The silicides Fe_5Si_3 and Fe_3Si as well as α -Fe and γ -Fe are in equilibrium with carbon. The isothermal cross-section through the Fe–Si–C system at 1243 K is presented in Fig. 16c. The scheme of the main phase equilibria in this system have been reported by Lyakishev et al.¹²²

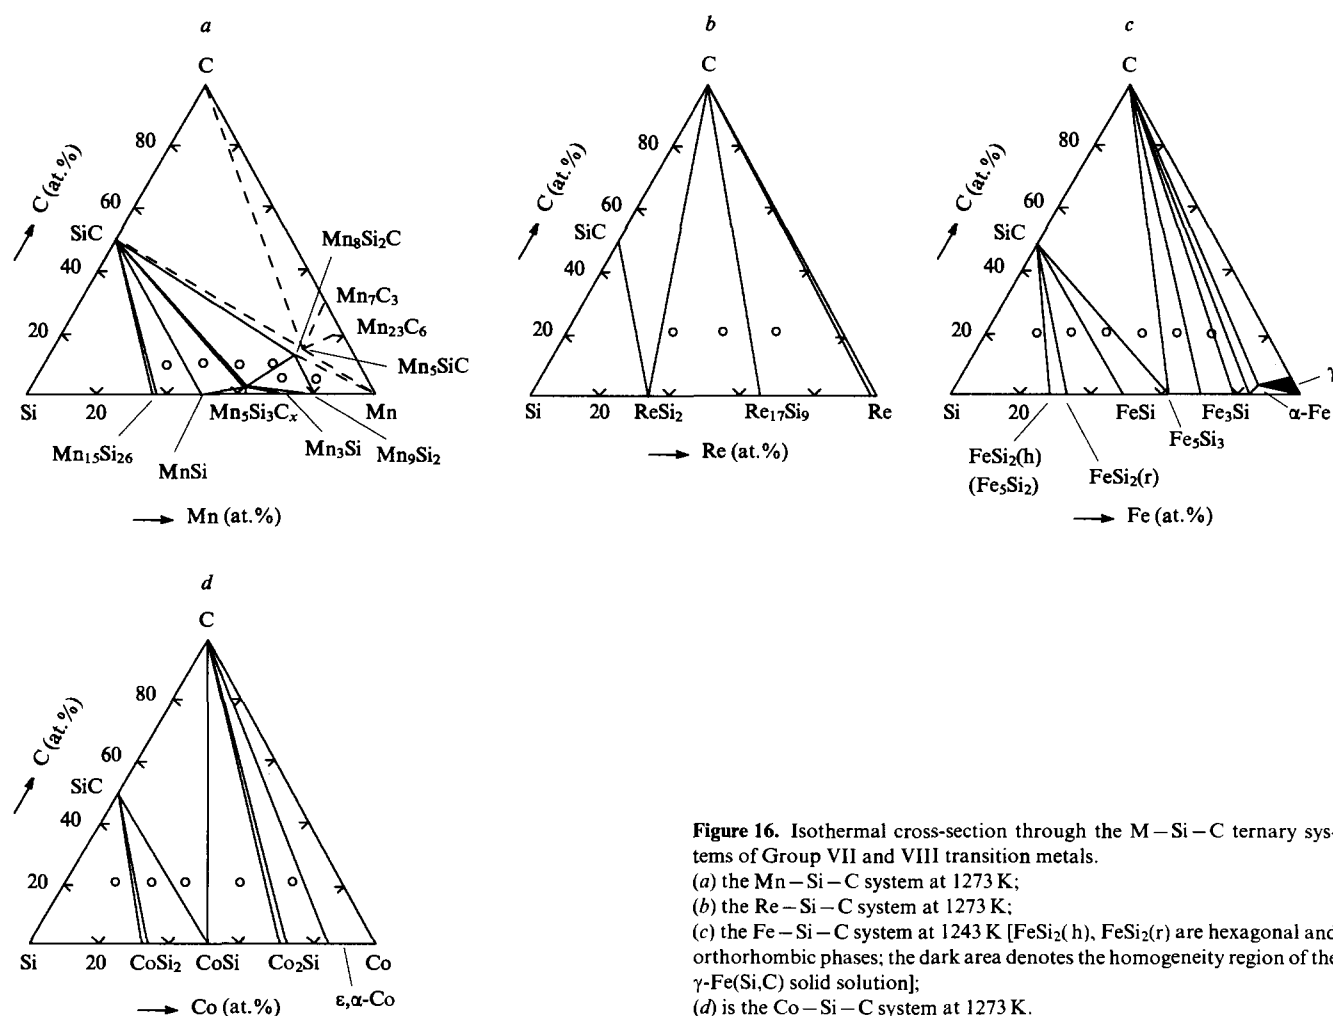

Figure 16. Isothermal cross-section through the M–Si–C ternary systems of Group VII and VIII transition metals.

(b) the Re–Si–C system at 1273 K;
(c) the Fe–Si–C system at 1243 K [$\text{FeSi}_2(\text{h})$, $\text{FeSi}_2(\text{r})$ are hexagonal and orthorhombic phases; the dark area denotes the homogeneity region of the γ -Fe(Si,C) solid solution];
(d) the Co–Si–C system at 1273 K.

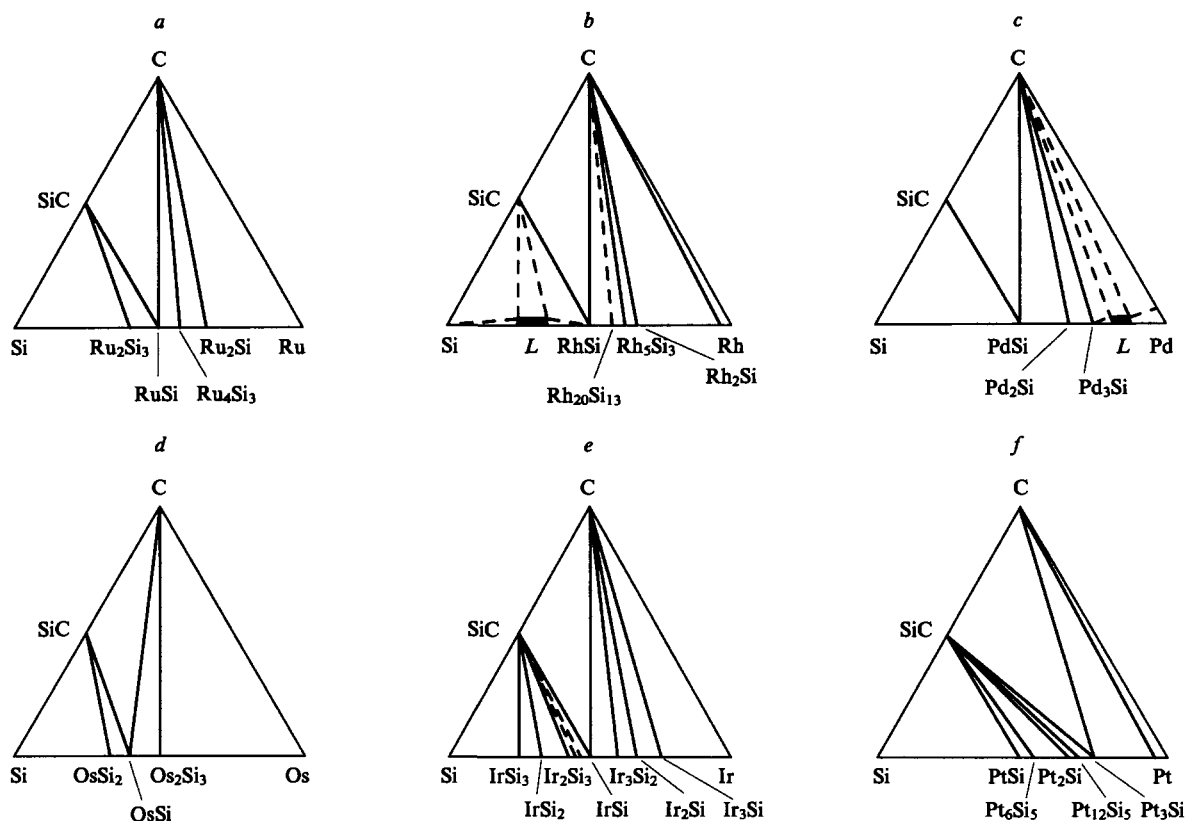

Figure 17. State diagrams for platinum group metal-silicon-carbon ternary systems, dark areas denote the regions of the existence of a liquid phase.^{103, 131}

Two metastable cubic phases of an unknown composition have been discovered in the Fe-Si-C system under the conditions of rapid cooling; the unit cell of one of these phases belongs to the $P4_132$ or $P4_332$ space group and has the period $a = 0.63$ nm, and the second metastable phase has a body-centred cubic (Bcc) lattice with the period $a = 0.89$ nm.¹³³

The Co-Si-C system. There are hardly any stable ternary phases in the Co-Si-C system. The silicon carbide SiC is in an equilibrium with the silicides CoSi₂ and CoSi, whereas carbon coexists with CoSi, Co₂Si, and with the extended solid solution of silicon in cobalt (Fig. 16d).¹⁰¹⁻¹⁰³

The Ni-Si-C system. The phase diagram for the Ni-Si-C system has been studied and constructed at 1123 K¹³² and 1423 K.¹³⁴ No ternary compounds were found. At 1123 K, the silicon carbide SiC is in equilibrium with four silicides: NiSi₂, NiSi, Ni₃Si₂, and Ni₂Si, whereas Ni₂Si, Ni₅Si₂ (Ni₃₁Si₁₂), Ni₃Si, and the solid solution of silicon and carbon in nickel Ni(Si,C) are in equilibrium with carbon. At 1423 K the SiC-Ni₂Si-C three-phase region is still retained. At higher temperatures the silicides Ni₅Si₂ and Ni₃Si no longer exist, and Ni₂Si coexists directly with the Ni(Si,C) solid solution and also with carbon and SiC.

On rapid cooling, the Ni_{67.5}Si_{17.5}C₁₅ nonequilibrium ordered Bcc phase with the period $a = 0.2744$ nm containing 4 at.% of carbon and 15-21 at.% of silicon is formed in the Ni-Si-C system.¹³⁵

(Ru,Rh,Pd,Os,Ir,Pt)-Si-C systems. The phase equilibria in the M-Si-C systems (M = Ru, Rh, Pd, Os, Ir, Pt) have been studied by Searcy and Finnie¹³¹ and have been refined later by Schuster¹⁰³ (Fig. 17). The platinum-group metals do not form carbides, and no stable ternary compounds of these metals with silicon and carbon exist; thus, only equilibria between carbon and silicon carbide on the one hand, and platinum metal silicides on the other hand, are possible in the (Ru, Rh, Pd, Os, Ir, Pt)-Si-C systems.

The SiC-MSi-C three-phase regions exist at 1613 K in the Ru-Si-C system, at 1443 K in the Rh-Si-C system, at 1100 K in the Pd-Si-C system, and at 1613 K in the Ir-Si-C system. The silicides with the highest proportions of silicon are in equilibrium with SiC, and the silicides with high proportions of metal coexist with carbon. In the Rh-Si-C system, the Rh₂SiC unstable ternary phase can be formed in the temperature range 1770-1870 K, whereas in the Pt-Si-C system, the formation of the Pt₃(Si_{2-x}C_x) phase is possible. In more recent papers these phases have not been mentioned. According to the data reported by Chou,¹³⁶ in the Pt-Si-C system at 1073 K silicon carbide SiC exists in an equilibrium with all the platinum silicides, and carbon coexists with Pt₃Si, i.e. the phase equilibria differ from those reported by Searcy and Finnie¹³¹ (see Fig. 17).

4. The M-Si-N ternary siliconitride systems

The ceramics based on silicon nitride Si₃N₄ preserve their high hardness, wear resistance, and strength up to high temperatures, which accounts for its wide industrial application. The composite ceramic materials based on silicon nitride usually also contain a metallic component. This has necessitated the investigation of the phase equilibria in the M-Si-N ternary systems formed by the transition metal M, silicon, and nitrogen. The studies on the M-Si-N ternary systems have been surveyed in a monograph.⁸⁰

The ternary phases formed in the M-Si-N systems are few in number, as in the M-Si-C carbosilicide systems. As a rule, these are M₅Si₃N₈ phases with a filled structure of the Mn₅Si₃ type (D_{8h}). Ternary phases with a different crystal structure are present in the siliconitride systems of some lanthanides and manganese. The structural characteristics of the ternary phases formed in the M-Si-N systems are presented in Table 8.

a. Siliconitrides of Group III transition metals

Based on the classification of the M-Si binary systems (M = Sc, Y, La → Lu) in terms of their composition and the crystal

Table 8. Some ternary phases in siliconitride systems of Group III–VII transition metals.

^a Hexagonal (space group *P6₃/mcm*) M₅Si₃N_x phases, among which there are ternary compounds (M = Zr, Hf, V, Nb, Ta) and solid solutions (M = Ho, Ti), have the filled structure of the Mn₅Si₃ (*D8₈*) type, Z = 2.

structure of the silicides formed, Weitzer et al.¹⁴⁰ have divided the M–Si–N ternary siliconitride systems into three groups: (1) (La,Ce,Pr,Nd)–Si–N; (2) (Sm,Gd,Tb,Dy,Ho,Er,Y)–Si–N; and (3) (Tm,Yb,Lu,Sc)–Si–N. They chose one M–Si–N ternary system from each group and studied the phase equilibria in it assuming that the phase equilibria in all the siliconitride systems of the same group are similar. This assumption is true only within certain limits: for example, no ternary compounds were found in the Ce–Si–N system (the first group) or in the Ho–Si–N system (the second group), but ternary compounds LaSi₃N₅ and Sm₃Si₆N₁₁ were discovered in the La–Si–N and Sm–Si–N systems, which belong to the same groups (see Table 8).¹³⁹ Thus, the phase equilibria in the M–Si–N ternary systems of the same group are not entirely similar.

The Sc–Si–N system. The isothermal cross-sections through this system at 1073 K and 1273 K have been reported¹⁴⁰ (Fig. 18a,b). No ternary compounds were found in this system. At 1073 K only two scandium silicides ScSi and Sc₅Si₃ are stable. The scandium silicides, silicon, and the silicon nitride Si₃N₄ exist in equilibrium with the scandium nitride ScN. At 1273 K one more stable silicide appears, namely, ScSi_{2–x} (Sc₃Si₅), which coexists with silicon nitride and scandium nitride; ScN is also in equilibrium with Si₃N₄, ScSi, and Sc₅Si₃.

The Ce–Si–N system. In the absence of external nitrogen pressure the Ce–Si–N system contains no ternary compounds at 1273 K.¹⁴⁰ The cerium nitride CeN exists in equilibrium with Si₃N₄ and six cerium silicides — CeSi₂, CeSi_{2–x}, CeSi, Ce₅Si₄, Ce₃Si₂, and Ce₅Si₃; the silicon nitride Si₃N₄ exists in equilibrium with CeSi₂ (Fig. 18c). The solubility of a third component in the binary phases is negligibly small.

The Ho–Si–N system. Based on an X-ray diffraction study and a metallographic study and on the determination of the melting points, Weitzer et al.¹⁴⁰ have constructed the phase diagram of the Ho–Si binary system. In this system, they detected all of the six known holmium silicides. The holmium disilicide HoSi₂ melts incongruently at 2153 K, whereas HoSi_{2–x} and HoSi melt congruently at temperatures above 2260 K. In the Ho–Si alloys containing less than 50 at.% Ho, HoSi has a structure of the FeB (*B27*) type; in the alloys containing more than 50 at.% Ho, the

HoSi modification with a structure of the CrB (*B_f*, *B33*) type predominates. The Ho₅Si₄ phase melts incongruently at *T* > 2120 K, and in the 1870 K > *T* > 1270 K range it decom-

**Figure 18.** Isothermal cross-section through the M–Si–N ternary systems of Group III transition metals.¹⁴⁰

(a) the Sc–Si–N system at 1073 K; (b) the Sc–Si–N system at 1273 K; (c) the Ce–Si–N system at 1273 K; (d) the Ho–Si–N system at 1273 K (dark areas denote the homogeneity regions of the Ho₅Si₃N_x solid solution and of the solid solution of silicon and nitrogen in holmium), *T* = Ho₅Si₃N_x.

poses to HoSi (the CrB structural type) and Ho₅Si₃. The temperature of the congruent melting of Ho₅Si₃ is 1983 K.

The Ho–Si–N system incorporates no ternary compounds at 1273 K (Fig. 18d); however, up to 4 at.% of nitrogen is dissolved in Ho₅Si₃ to form the Ho₅Si₃N_x limited solid solution having a filled structure of the Mn₅Si₃ (D8₈) type (see Table 8). The holmium nitride HoN is in equilibrium with Si₃N₄, HoSi_{2–x}, HoSi, and Ho₅Si₃N_x; in addition, there exist Si₃N₄–HoSi₂, HoSi–Ho₅Si₃N_x, and Ho–Ho₅Si₃N_x equilibria. Metallic holmium dissolves up to 2 at.% of nitrogen. The holmium silicide HoSi coexisting with HoN and Ho₅Si₃N_x has a structure of the CrB type.

b. Siliconitrides of Group IV and V transition metals

The Ti–Si–N system. According to thermodynamic estimates,^{146,147} the interaction of metallic titanium with silicon nitride Si₃N₄ in the 300 K < *T* ≤ 1800 K temperature range most probably yields the silicide Ti₅Si₃ and the nitride TiN_y. This type of interaction is retained up to 2300 K. Taking into account these data and also the results of a study^{148,149} of the interaction between silicon nitride and titanium nitride under an atmosphere of NH₃ and H₂ [at a total pressure in the gas phase of (1.33–10.7) × 10⁵ Pa] at 1323–1723 K, Schuster and Nowotny¹⁴¹ concluded that under these conditions, Si₃N₄ exists in equilibrium with TiN_y and with the silicide TiSi₂, whereas TiN_y coexists with all the titanium silicides. The study of the phase equilibria in the Ti–Si–N ternary system at 1273 K (in vacuo) and at 1573 K (under an argon atmosphere) has shown that the above phase equilibria are retained under these conditions (Fig. 19a). From the authors' viewpoint,¹⁴¹ the phase equilibria in the Ti–Si–N system are insensitive to the variations of the temperature or nitrogen pressure. No ternary compounds were found in the Ti–Si–N system; no solubility of nitrogen in the silicide Ti₅Si₃ with the structure of the Mn₅Si₃ type or in other binary phases was observed.

The isothermal cross-section through the Ti–Si–N system at 973–1273 K has been constructed by Beyers et al.,¹⁵⁰ who have studied phase equilibria in thin films. These researchers¹⁵⁰ (in contrast to Schuster and Nowotny¹⁴¹) did not note the equilibrium between Si₃N₄ and TiSi₂, because there exists an equilibrium between TiN_y and silicon. The other equilibria reported in these two papers^{141,150} are the same. Thermodynamic calculations^{119,151} have shown that the TiN_y–Si equilibrium exists most likely up to 1573 K; in particular, the variation in the Gibbs energy for the reaction 4TiSi₂ + Si₃N₄ → 4TiN + 11Si at 1373 K is –11.1 kJ (g-at)^{–1}.

The most recent studies^{119,151} of the phase equilibria in the Ti–Si–N system at 1373 K have been carried out in relation to the diffusion pairs of the Ti–Si₃N₄, Ti_{1–x}Si_x–Si₃N₄, and Ti_{1–x}Si_x–TiN types. A study involving the nitriding of Ti₃Si alloys proved to be impossible due to the formation of a thin film of titanium nitride on the surface of the samples, which prevents further diffusion of nitrogen. The isothermal cross-section through the Ti–Si–N system at 1373 K (Fig. 19b) largely coincides with the cross-section obtained by Beyers et al.¹⁵⁰ The titanium nitride TiN_y coexists with Si, Si₃N₄, TiSi₂, and the Ti₅Si₃N_x ternary phase, which is a solid solution of nitrogen in Ti₅Si₃. The solubility of nitrogen in Ti₅Si₃ reaches 11 at.%.^{119,151} The silicide Ti₃Si decomposes to β-Ti and Ti₅Si₃N_x at 1373 K on the addition of even small amounts of nitrogen. Similar effects (substantial solubility of carbon or oxygen in Ti₅Si₃ and decomposition of Ti₃Si on the addition of a third element) have also been observed in the Ti–Si–C and Ti–Si–O systems.^{118,119,151}

In all probability, the disagreement between the results of Schuster and Nowotny¹⁴¹ and those obtained by other workers^{119,150,151} is caused by the experimental procedure: Schuster and Nowotny¹⁴¹ studied the phase equilibria in the Ti–Si–N system using massive samples, Beyers et al.¹⁵⁰ used thin films, whereas in the other two studies^{119,151} diffusion pairs were employed. The phases formed in thin films due to diffusion are

Figure 19. Isothermal cross-sections through M–Si–N ternary systems of Group IV transition metals (dark areas denote one-phase homogeneity regions).

(a) the Ti–Si–N system at 1573 K; (b) the Ti–Si–N system at 1373 K, *T* = Ti₅Si₃N_x; (c) the Zr–Si–N system at 1573 K, *T* = Zr₅Si₃N_x; (d) the Hf–Si–N system at 1573 K.

The cross-sections *a*, *c*, and *d* were constructed using the results of a study of samples sintered under an argon atmosphere at 1573 K; the cross-section *b* was constructed by a layer-by-layer study of the samples obtained by sintering diffusion pairs at 1373 K.

not always reproduced in massive samples and are probably nonequilibrium phases. Also in massive samples the real equilibrium is not always reached due to the short durations of the annealing (sometimes, annealing requires hundreds or even thousands of hours).

The Zr–Si–N system. In the first investigation of this system,⁸⁹ a ternary zirconium siliconitride with a structure of the Mn₅Si₃ (D8₈) type has been detected. This compound contains up to 10 at.% of nitrogen and its chemical formula and crystal structure are similar to those of the zirconium carbosilicide Zr₅Si₃C_x. The distribution of phase fields in the Zr–Si–N system was reported⁸⁹ to be identical to that in the Zr–Si–C system at 1873 K. The experimental results obtained with the samples sintered at 1573 K under argon¹⁴¹ have confirmed the views⁸⁹ of the phase equilibria in the Zr–Si–N system.

The isothermal cross-section through the Zr–Si–N system at 1573 K is shown in Fig. 19c.¹⁴¹ The nitride ZrN_y is in equilibrium with Si₃N₄, with the ternary compound Zr₅Si₃N_x, with the silicides ZrSi₂, ZrSi, and Zr₂Si, and with the α-Zr(N) solid solution; Si₃N₄ is in equilibrium with ZrSi₂, and Zr₅Si₃N_x also coexists with ZrSi, Zr₅Si₄, Zr₃Si₂, Zr₂Si, and with the solid solution of nitrogen in α-Zr.

At a lower temperature, namely at 1273 K, all the phases existing in the Zr–Si–N system at 1573 K are retained, but the content of nitrogen in Zr₅Si₃N_x noticeably decreases (*x* ≤ 0.2), and the Si₃N₄–ZrSi, ZrN_y–Zr₅Si₄, and ZrN_y–Zr₃Si₂ equilibria arise instead of Zr₅Si₃N_x–Zr₅Si₄ and ZrN_y–ZrSi₂.

The Hf–Si–N system. The phase equilibria in this system at 1273 and 1573 K are virtually identical and are similar to those in the

Zr–Si–N system at these temperatures.¹⁴¹ The main distinction between the isothermal cross-section through the Hf–Si–N system at 1273 K and the corresponding cross-section through the Zr–Si–N system is the existence of the $\text{Si}_3\text{N}_4 + \text{HfSi}_2 + \text{HfN}$ three-phase field. The ternary compound $\text{Hf}_5\text{Si}_3\text{N}_x$ with a very low content of nitrogen ($x \leq 0.1$) is formed in the Hf–Si–N system. It has a structure of the Mn_5Si_3 (D_{8h}) type and exists in an equilibrium with HfN_y and Hf_2Si . The isothermal cross-section through the Hf–Si–N system at 1573 K is presented in Fig. 19d (the position of the ternary compound $\text{Hf}_5\text{Si}_3\text{N}_x$ is not shown).¹²⁴

The V–Si–N system. The heating of V_5Si_3 to 1673 K under an NH_3 atmosphere leads to the formation of the ternary compound $\text{V}_5\text{Si}_3\text{N}_x$ with a filled structure of the Mn_5Si_3 (D_{8h}) type and the nitride VN_y .⁸⁹ The phase equilibria in the V–Si–N system at 1273 K (in vacuo) and at 1773 K (under an argon atmosphere) (Fig. 20a,b) have been studied.¹⁴¹ At 1273 K the ternary compound is in equilibrium with Si_3N_4 , VSi_2 , V_6Si_5 , V_5Si_3 , V_3Si , and V_9N_4 ; the silicon nitride Si_3N_4 coexists with VSi_2 , VN_y , and V_9N_4 ; and the silicide V_3Si coexists with V_9N_4 and with the solid solution of nitrogen in vanadium.

As the temperature increases, the nitrogen content in $\text{V}_5\text{Si}_3\text{N}_x$ increases substantially, as indicated by the increase in the unit cell parameters from $a = 0.7121$ nm and $c = 0.4847$ nm at 1273 K to $a = 0.7155$ nm and $c = 0.4852$ nm at 1773 K. The nitrides Si_3N_4 and VN_y are unstable under an argon atmosphere at 1773 K. Thus, the ternary compound $\text{V}_5\text{Si}_3\text{N}_x$ and the silicide VSi_2 in the V–Si–N system coexist directly with nitrogen, whereas the other equilibria are retained (Fig. 20b). The solubility of a third component in the binary phases is negligibly small.¹⁴¹

The compound V_9N_4 crystallises with a hexagonal ordered structure with the periods $a = a_V \sqrt{3}$ and $c = c_V$ (a_V and c_V are the parameters of the hexagonal close-packed vanadium sublattice). According to the data obtained by Onozuka,¹⁵² the nitrides stable in the V–N binary system at temperatures above 900 K are VN_y and V_9N_4 (rather than V_2N_3 , as has been believed

previously), whereas at $T < 900$ K, the $\text{V}_{32}\text{N}_{26}$ (space group $P4_2/nmc$) and V_9N_4 (space group $P6_322$) ordered phases are stable. The VN_y ($y = 0.78$) $\rightarrow \text{V}_{32}\text{N}_{26}$ ordering occurs at 793 K as a first-order phase transition.

The Nb–Si–N system. A thermodynamic calculation¹⁴⁶ implies that the reaction between the silicon nitride Si_3N_4 and metallic niobium at 1300 K most probably yields the silicide Nb_5Si_3 and the nitride Nb_2N . This is in agreement with the experimental data.¹⁴¹ The isothermal cross-section through the Nb–Si–N system at 1273 K (in vacuo) is shown in Fig. 20c.¹⁴¹ There are no ternary phases in the Nb–Si–N system at this temperature, the nitride Si_3N_4 coexists with all the binary niobium silicides and nitrides, whereas the silicide Nb_5Si_3 exists in equilibrium with Nb_2N .

The annealing of the alloys existing in the Nb–Si–N system at 1773 K led to the appearance of the ternary compound $\text{Nb}_5\text{Si}_3\text{N}_x$ with a filled structure of the Mn_5Si_3 (D_{8h}) type.¹⁴¹ This compound exists in equilibrium with NbSi_2 , Nb_5Si_3 , Nb_2N , $\delta\text{-NbN}$, and probably with nitrogen. The equilibria of $\text{Nb}_5\text{Si}_3\text{N}_x$ ($\text{Nb}_{5-x}\text{Si}_{3-y}\text{N}_z$) with N_2 and NbSi_2 have been reported.¹⁰⁸ The assumption that in the ternary compound, nitrogen substitutes niobium and silicon¹⁰⁸ have not been confirmed: the interstitial atoms X in the compounds $\text{M}_5\text{M}'_3\text{X}$ with the Mn_5Si_3 (D_{8h}) type of structure fill the octahedral vacancies formed by the M atoms. The $\text{Nb}_5\text{Si}_3\text{N}_x$ ternary phase has been obtained by heating Nb_5Si_3 under an atmosphere of NH_3 at 1673 K.⁸⁹ The parameter c of the crystal lattice of $\text{Nb}_5\text{Si}_3\text{N}_x$ has been reported^{89,141} to increase from 0.5249 nm to 0.5310 nm with an increase in the nitrogen content, with the invariable parameter $a = 0.7517$ nm. The invariability of the parameters of the crystal lattices of the binary phases in the Nb–Si–N system indicates that the solubility of the third component in these phases is negligibly small.

The Ta–Si–N system. This system has been the most comprehensively studied among the siliconitride systems of group IV and V transition metals (except for titanium). The first investigation of the phase equilibria in this system was carried out by Kudielka et

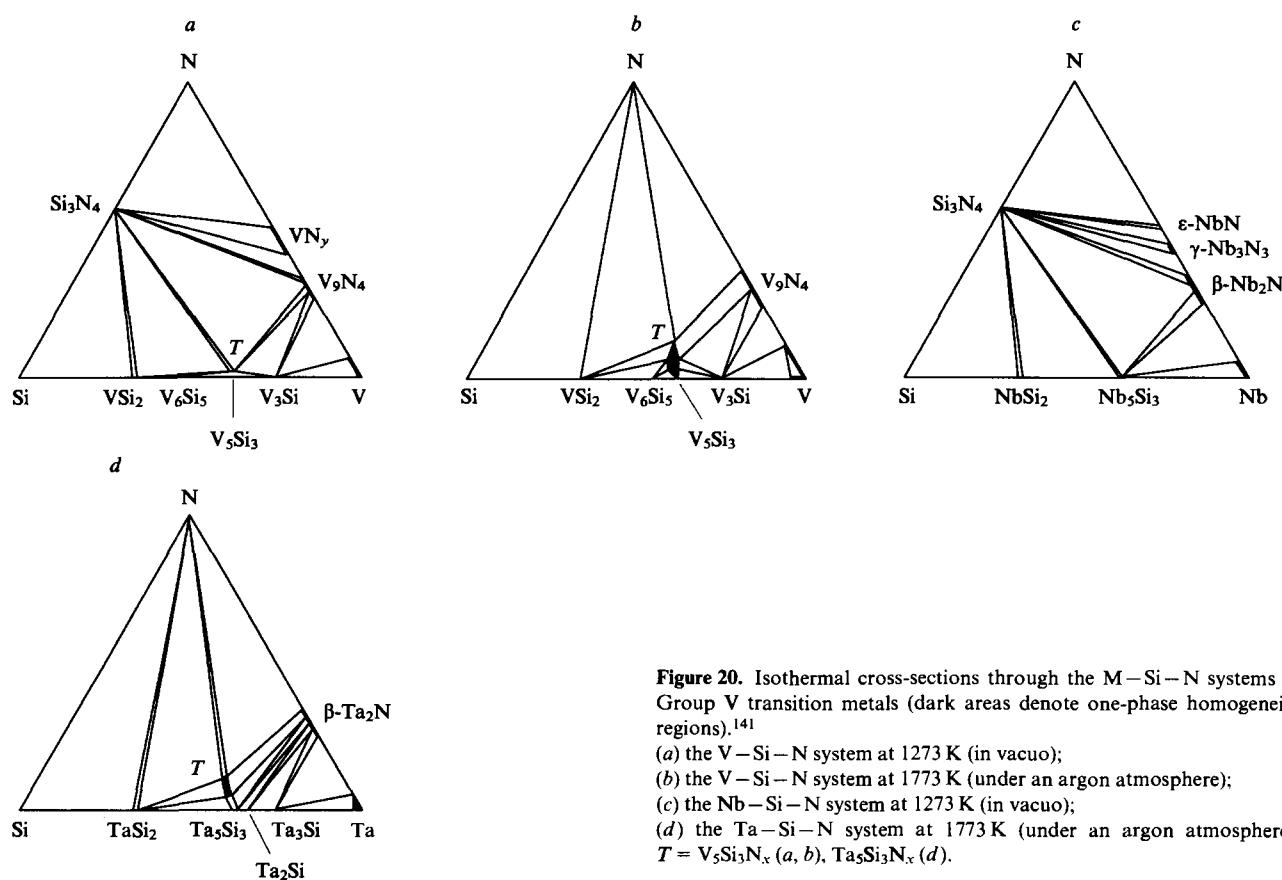

Figure 20. Isothermal cross-sections through the M–Si–N systems of Group V transition metals (dark areas denote one-phase homogeneity regions).¹⁴¹

al.⁹⁰ They constructed the isothermal cross-section through the Ta–Si–N system at 1600 K and a nitrogen pressure of 0.75×10^5 Pa. The ternary compound $Ta_{5-x}Si_{3-y}N_z$ with a broad homogeneity region exists in this system; it exists in equilibrium with nitrogen, the silicon nitride Si_3N_4 and with the tantalum nitrides and silicides TaN_y , Ta_2N , Ta_5Si_3 , and $TaSi_2$.¹⁰⁸ The formation of the $Ta_5Si_3N_x$ ternary phase on nitriding the silicide Ta_5Si_3 at 1673 K by various methods and on the interaction of Si_3N_4 with tantalum at 1873 K has also been observed in another study.⁸⁹ The ternary compound $Ta_5Si_3N_x$ has a filled structure of the Mn_5Si_3 ($D8_8$) type common to the $M_5Si_3N_x$ phases. The phase equilibria in the Ta–Si–N system have been studied at 1273 K (in vacuo) and at 1773 K (under an argon atmosphere).¹⁴¹ It was found that at 1273 K, no ternary phase exists, and the silicon nitride is in equilibrium with $TaSi_2$, Ta_5Si_3 , TaN_y , and Ta_2N , whereas the nitride Ta_2N coexists also with Ta_5Si_3 , Ta_2Si , and Ta_3Si . At 1773 K, the ternary compound $Ta_5Si_3N_x$ exists in the Ta–Si–N system. It is in equilibrium with nitrogen, Ta_2N , Ta_2Si , and Ta_5Si_3 (Fig. 20d). When the content of nitrogen in $Ta_5Si_3N_x$ increases, the parameter c of the crystal lattice increases from 0.5229 nm to 0.5246 nm with the parameter $a = 0.7501$ nm being constant. The solubility of the third component in the binary phases of the Ta–Si–N system is negligibly small.¹⁴¹

c. Siliconitrides of Group VI–VIII transition metals

The Cr–Si–N system. The interaction of the silicon nitride Si_3N_4 with chromium can yield Cr_3Si , Cr_5Si_3 , $CrSi$, $CrSi_2$, Cr_2N , Si, and gaseous nitrogen, depending on the amount of chromium.¹⁴⁶ Heating a mixture of Cr, Si, and Si_3N_4 to 1673 K in a moist atmosphere leads to the formation of Cr_5Si_3 (structure of the W_5Si_3 type), containing up to 10 at.% of nitrogen, and Cr_3Si , containing up to 20 at.% of nitrogen; chromium nitrides are not formed in the absence of an external nitrogen pressure.⁸⁹

A detailed study of the phase equilibria in the Cr–Si–N system¹⁵³ has shown that at 1273 K and under an argon atmosphere, the nitride Si_3N_4 coexists in this system with all the chromium silicides, namely, $CrSi_2$, $CrSi$, Cr_5Si_3 , and Cr_3Si , whereas Cr_3Si and the solid solution of silicon in chromium are in equilibrium directly with nitrogen. However, at 1273 K, even a low nitrogen pressure is sufficient to stabilise Cr_2N existing in equilibrium with Cr_3Si and with the solid solution of silicon in chromium; the other equilibria in the Cr–Si–N system under a low nitrogen pressure are the same as the equilibria under argon. At a higher temperature of 1673 K under an argon atmosphere, the silicides Cr_5Si_3 and Cr_3Si are in equilibrium with nitrogen, whereas Si_3N_4 coexists with Cr_5Si_3 . Nitrogen is insoluble in chromium silicides.¹⁵³

The isothermal cross-section through the Cr–Si–N system at 1873 K and at a nitrogen pressure of 1×10^5 Pa has been constructed¹⁵³ with the aid of the results obtained in another study.¹⁵⁴ The equilibria existing at 1673 K under argon are retained under these conditions; in addition, new equilibria arise, due to the stabilisation of the chromium nitride Cr_2N and the appearance of the liquid phase of chromium.

The Mo–Si–N system. The nitriding of Mo_5Si_3 at 1673 K gives Mo and Mo_3Si , whereas the nitriding of $MoSi_2$ under the same conditions is accompanied by the appearance of Mo_5Si_3 .⁸⁹ The annealing of a mixture of Mo, Si, and Si_3N_4 powders at 1973 K affords Mo_5Si_3 and nitrogen.⁸⁹ The reaction between Mo and Si_3N_4 at 1273 K proceeds very slowly; in the absence of an external pressure of nitrogen, Si_3N_4 coexists with $MoSi_2$ and Mo_5Si_3 , whereas the silicides Mo_5Si_3 and Mo_3Si exist in equilibrium with nitrogen.¹⁵³ The same phase equilibria are retained in the Mo–Si–N system at 1673 K under argon. At 1850 K, the silicon nitride Si_3N_4 is unstable, and all the molybdenum silicides are in equilibrium with nitrogen. No ternary compounds have been found in the Mo–Si–N system.

The phase equilibria in the Mo–Si–N system have been studied at 1573 K and at various nitrogen pressures (Fig. 21).¹³⁷

At $p_{N_2} < 18$ Pa, the Mo–Si–N system incorporates only the silicides $MoSi_2$, Mo_5Si_3 , and Mo_3Si existing in equilibrium with nitrogen. At $18 \text{ Pa} < p_{N_2} < 3000$ Pa all the molybdenum silicides are still in equilibrium with nitrogen, and $MoSi_2$ coexists with Si_3N_4 . The phase equilibria in the Mo–Si–N system at higher nitrogen pressures ($3 \times 10^3 \text{ Pa} \leq p_{N_2} < 7 \times 10^5 \text{ Pa}$) are the same as shown in Fig. 21c. At a nitrogen pressure of $7 \times 10^5 \text{ Pa} \leq p_{N_2} < 88 \times 10^5 \text{ Pa}$, the silicon nitride Si_3N_4 exists in equilibrium with all the molybdenum silicides, and Mo_3Si coexists with nitrogen. When the nitrogen pressure is $(88-98) \times 10^5 \text{ Pa}$, the nitride Mo_2N becomes stable, and one more equilibrium appears, namely, Mo_2N – Mo_3Si . At $p_{N_2} > 98 \times 10^5 \text{ Pa}$, the Mo_3Si –N equilibrium disappears, and the Si_3N_4 – Mo_2N equilibrium arises instead; silicon nitride coexists also with all the molybdenum silicides, and Mo_2N is in equilibrium with Mo_3Si (Fig. 21f).

The W–Si–N system. The nitriding of W_5Si_3 at 1673–2073 K under an NH_3 atmosphere does not lead to the formation of a phase with the structure of the Mn_5Si_3 ($D8_8$) type observed in the M–Si–N systems of Group V transition metals.⁸⁹ It has been shown¹⁵³ that silicon nitride does not react with tungsten or with the silicides WSi_2 and W_5Si_3 at 1273 K, but exists in equilibrium with them. The Si_3N_4 –W equilibrium is retained up to 1400 K. At higher temperatures, Si_3N_4 and tungsten interact to give W_5Si_3 and nitrogen that exist in equilibrium with each other. At 1773 K, the silicides WSi_2 and W_5Si_3 are in equilibrium with nitrogen.

The Re–Si–N system. The phase equilibria in this system have been studied at 1273 K and 1673 K under argon.¹⁵³ At 1273 K, the silicon nitride Si_3N_4 coexists with rhenium and with its silicides $ReSi_2$ and $Re_{17}Si_9$. At a higher temperature Si_3N_4 reacts with rhenium, and thus the $Re_{17}Si_9$ –N equilibrium arises instead of Si_3N_4 –Re. No ternary phases in the Re–Si–N system have been found.

The Mn–Si–N system. The interaction of liquid manganese with the silicon nitride Si_3N_4 in vacuo, under an inert gas, or under nitrogen is accompanied, in particular, by the formation of the ternary compound $MnSiN_2$.¹⁵⁶ The nitrogen atoms in the siliconitride $MnSiN_2$ are located at the centres of the distorted tetrahedra comprising two manganese atoms and two silicon atoms.^{143, 144} The decomposition of $MnSiN_2$ to the silicide $MnSi$ and gaseous nitrogen begins at 1570 K (at a nitrogen pressure of 1×10^5 Pa) or at 1070 K (under argon).

The study of the phase equilibria in the Mn–Si–N system carried out by Weitzer and Schuster¹⁴⁵ has confirmed the presence of only one ternary compound $MnSiN_2$ with an orthorhombic lattice (see Table 8). It has a narrow homogeneity region. In the absence of an external nitrogen pressure at 1273 K the siliconitride $MnSiN_2$ is in equilibrium with nitrogen, with the silicon nitride Si_3N_4 , with β -Mn (the solid solution of silicon in manganese), and with the silicide Mn_3Si ; Si_3N_4 also coexists with $MnSi_2$, $MnSi$, Mn_5Si_3 , and Mn_3Si . Nitrogen is insoluble in manganese silicides.

In the presence of an external nitrogen pressure, γ -Mn (the solid solution of nitrogen in manganese) arises in the system. This leads to the appearance of β -Mn– γ -Mn and $MnSiN_2$ – γ -Mn phase equilibria. With an increase in the external pressure of nitrogen, manganese nitrides (in particular, ϵ - Mn_4N) appear in the system and equilibria between them and $MnSiN_2$ are established.

The Fe–Si–N system. The combined influence of the nitrogen and silicon admixtures in iron and its alloys on the properties of the latter have been studied in connection with the development of siliceous sheet transformer steel. In steels with high silicon contents (up to 4 at.%), the nitride Si_3N_4 can segregate from the solid solution of silicon in iron. The silicon nitride is also formed in the nitriding of steels with low contents of silicon.

The phase equilibria in the Fe–Si–N system have been studied at 1173 K and 1423 K.¹⁴⁵ In the absence of an external nitrogen pressure at 1173 K, Si_3N_4 coexists with all the iron silicides stable at this temperature and with α -Fe (the solid

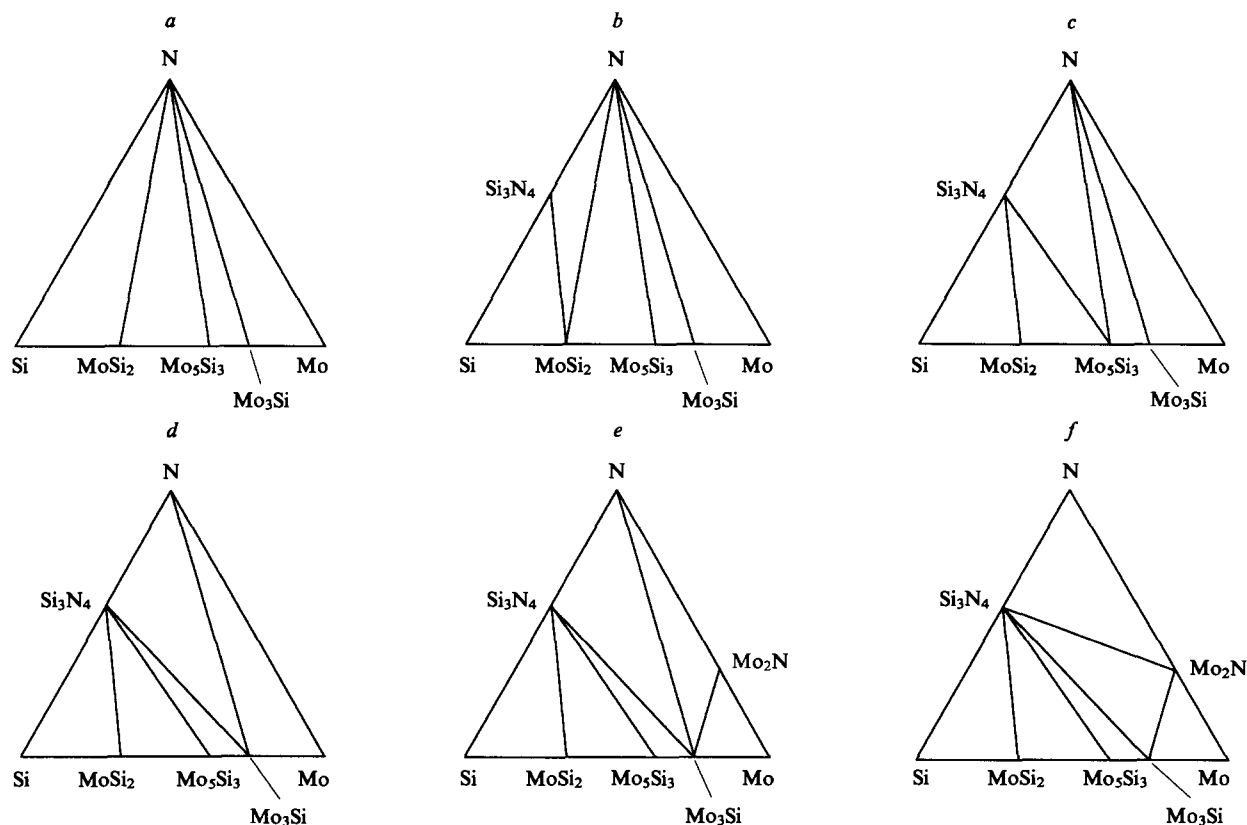

Figure 21. The influence of nitrogen pressure p_{N_2} on phase equilibria in the Mo–Si–N system at 1573 K.¹⁵⁵

(a) < 18 Pa, (b) $18 \leq p_{N_2} < 3 \times 10^3$ Pa, (c) $3 \times 10^3 \leq p_{N_2} < 7 \times 10^5$ Pa, (d) $7 \times 10^5 \leq p_{N_2} < 88 \times 10^5$ Pa, (e) $88 \times 10^5 \leq p_{N_2} < 98 \times 10^5$ Pa, (f) $p_{N_2} \geq 98 \times 10^5$ Pa.

solution of silicon in iron). In the presence of pure iron at 1390 ± 10 K Si_3N_4 starts to decompose yielding the solid solution of α -Fe containing 6–8 at.% of silicon.

At 1423 K the nitride Si_3N_4 coexists with silicides Fe_2Si_5 , $FeSi$, Fe_2Si , and Fe_3Si , and also with α -Fe (the solid solution of silicon in iron). No ternary phases have been detected in the Fe–Si–N system.

The Co–Si–N system. When Si_3N_4 reacts with liquid cobalt, it decomposes to give cobalt silicides and gaseous nitrogen. In the absence of an external nitrogen pressure at 1273 K, the silicon nitride is in an equilibrium with $CoSi_2$, $CoSi$, the low-temperature silicide Co_2Si , α -Co and ϵ -Co (the solid solutions of silicon in cobalt), and cobalt.¹⁴⁵ The reaction between Co and Si_3N_4 with the decomposition of the latter starts at 1440 K. Nitrogen is insoluble in cobalt silicides. No ternary compounds have been found in the Co–Si–N system.

The Ni–Si–N system. The interaction of molten nickel with the silicon nitride Si_3N_4 is accompanied by the decomposition of the latter. At temperatures above 1440 K, the decomposition occurs very rapidly. Without an external nitrogen pressure at 1173 K, the silicon nitride Si_3N_4 coexists with nickel and with all the nickel silicides stable at this temperature. Nickel silicides do not dissolve nitrogen. No ternary compounds have been detected in this system.

The phase equilibria in the Ni–Si–N system have been studied at 1373 K and at a nitrogen pressure of 1×10^5 Pa.¹⁵⁵ Under these conditions, the silicides Ni_2Si , Ni_5Si_2 ($Ni_{31}Si_{12}$), and Ni_3Si and the solid solution of silicon in nickel exist in equilibrium with the silicon nitride Si_3N_4 . Nickel dissolves up to 15 at.% of silicon.

The Ru–Si–N system. There are no ternary phases in the Ru–Si–N system at temperatures from 1270 K to 1520 K and at an argon pressure of 1×10^5 Pa.¹⁵⁷ At 1273 K the nitride Si_3N_4 coexists with ruthenium and with its silicides Ru_2Si_3 , $RuSi$, and Ru_4Si_3 (Fig. 22a). At 1480 K, decomposition of Si_3N_4 begins

and the appearance of the phase diagram changes. At 1520 K, the nitride Si_3N_4 exists in equilibrium with Ru_2Si_3 and $RuSi$, and the silicides $RuSi$, Ru_4Si_3 , and Ru_2Si are in equilibrium with nitrogen (Fig. 22b).

Figure 22. Isothermal cross-sections through the Ru–Si–N system at 1273 K (a) and 1520 K (b) under an argon atmosphere.¹⁵⁷

V. Phase equilibria in M–Al–X ternary systems (X = C, N, Si)

1. The common types of the crystal structures of ternary compounds in the M–Al–X systems

Aluminidocarbides and aluminidonitrides of transition metals have, as a rule, one of several specific crystal structures peculiar to these compounds.

The cubic structure [space group $Pm\bar{3}m(O_h^h)$] of the perovskite CaTiO_3 ($E2_1$) type, which is usually found in double oxides, for example, in barium titanate BaTiO_3 , is the most common among these structures. The M and Al atoms in the aluminidocarbides and aluminidonitrides M_3AlX with the perovskite type of structure form an ordered metallic Fcc-sublattice: the aluminium atoms occupy the vertices of a cube, whilst the transition metal atoms M are located at the centres of the faces of the cube; the M atoms constitute octahedra in the centres of which the interstitial atoms X are located (Fig. 23). The interstitial atoms X (C, N) occupy all or some of the octahedral interstices formed by the transition metal atoms M; this accounts for the fact that most of aluminidocarbides and aluminidonitrides with the perovskite type of structure have fairly extensive homogeneity regions. The presence of the metallic Fcc-lattice, with interstitial atoms located in its octahedral interstices, and the existence of the homogeneity regions make these compounds very similar to the classical nonstoichiometric interstitial compounds, namely, carbides and nitrides MX_y with the structure of the B1 (NaCl) type. In addition, in some cases the X atoms in the aluminidocarbides and aluminidonitrides M_3AlX with the perovskite type of structure can not only fill the octahedral interstices, but can also substitute aluminium.

Figure 23. Unit cell of the ternary compounds $\text{M}_3\text{M}'\text{X}$ with the ideal cubic structure (space group $Pm\bar{3}m$) of the perovskite CaTiO_3 type.

Another group of transition metal aluminidocarbides and aluminidonitrides $\text{M}_2\text{M}'\text{X}$ (H -phases) have the hexagonal structure (space group $P6_3/mmc$) of the Cr_2AlC type (Fig. 24). A significant element of this structure, as well as of the previous one, is the octahedron XM_6 formed by six transition metal atoms M with the nonmetal atom X located at the centre of it. In the $\text{M}_2\text{M}'\text{X}$ H -phases, each XM_6 octahedron is joined with the adjacent octahedra via its six edges; thus layers with tetrahedral vacancies between the octahedra are formed (Fig. 24b). The nontransition metal atoms M' are located over these tetrahedral vacancies in the trigonal prisms formed by six M atoms. The octahedral layers separated by the layer of the M' atoms are packed in such a way that the tetrahedral interstices are located above one another. The unit cell of the H -phases incorporates two $\text{M}_2\text{M}'\text{X}$ formula units.

The frequently occurring aluminidocarbides and aluminidonitrides of the composition $\text{M}_3\text{M}_2'\text{X}$ have a cubic structure [space group $P4_132(O_h^7)$] of the $\beta\text{-Mn}$ type ($A13$) in which twenty atoms of the transition and nontransition metals occupy the 12(d) and 8(c) sites, respectively. The transition metal atoms M constitute slightly distorted octahedra that are connected to one another via their vertices; the octahedral interstices correspond to the 4(a) sites in the structures of the $\beta\text{-Mn}$ type, and in the compounds $\text{M}_3\text{M}_2'\text{X}$

Figure 24. Crystal structure of the Nowotny phase (H -phase) of the Cr_2AlC type ($\text{M}_2\text{M}'\text{X}$).

(a) unit cell (space group $P6_3/mmc$); (b) the layer of the XM_6 octahedra joined via six edges; nontransition metal atoms in compounds with the Cr_2AlC type of structure are arranged over tetrahedral vacancies.

Figure 25. Filled crystal structure of the $\beta\text{-Mn}(A13)$ type of the ternary cubic (space group $P4_132$) compounds $\text{M}_3\text{M}'_2\text{X}$.

Only the transition metal atoms M at the 12(d) sites and interstitial nonmetal atoms X (C, N) at the 4(a) sites are shown; these atoms form distorted XM_6 octahedra joined via all the vertices.

of the stoichiometric composition they are occupied by the nonmetallic interstitial atoms X, that is, carbon or nitrogen atoms (Fig. 25). In the case where the composition of a ternary carbide or nitride with the structure of the $\beta\text{-Mn}$ type deviates from the stoichiometry, some of the octahedral interstices remain vacant.

A filled structure of the Mn_5Si_3 type ($D8_8$) (see Fig. 10), which is common for the transition metal silicoborides, carbosilicides, and siliconitrides $\text{M}_5\text{Si}_3\text{B}_x$, $\text{M}_5\text{Si}_3\text{C}_x$, and $\text{M}_5\text{Si}_3\text{N}_x$ considered above, is also a frequently encountered type of the structure of the ternary compounds in the M–Al–C and M–Al–N systems. It is of interest that this structure is hardly found among the transition metal aluminosilicides.

2. The M–Al–C ternary aluminidocarbide systems

The structural characteristics of the ternary phases formed in the M–Al–C aluminidocarbide systems are presented in Table 9.

Some lanthanides form aluminium and carbon cubic ternary compounds Ln_3AlC ($\text{Ln} = \text{Tb}, \text{Er}, \text{Tm}$) with the perovskite type of structure.¹⁵⁸

The Ti–Al–C system. In a study of the phase equilibria in the Ti–Al–C system,¹⁷⁹ the existence of the ternary cubic compound Ti_3AlC with the perovskite structure¹⁵⁹ and of the ternary hexagonal compound Ti_2AlC (the H -phase) with the Cr_2AlC type of structure^{169–172} has been confirmed (Table 9). The following pseudobinary equilibria occur in the Ti–Al–C system under equilibrium conditions at 1273 K (Fig. 26): $\text{Al}_4\text{C}_3\text{–TiC}_y$, $\text{TiAl}_3\text{–TiC}_y$, $\text{Ti}_2\text{AlC–TiAl}_3$, $\text{Ti}_2\text{AlC–TiAl}$, $\text{Ti}_2\text{AlC–Ti}_3\text{Al}$, $\text{Ti}_2\text{AlC–Ti}_3\text{AlC}$, $\text{Ti}_2\text{AlC–TiC}_y$, $\text{Ti}_3\text{AlC–TiC}_y$, $\text{Ti}_3\text{AlC–Ti}_3\text{Al}$, $\text{Al}(\text{liq})\text{–TiC}_y$, $\text{Ti}_3\text{AlC–}\alpha\text{-Ti}(\text{sol})$ and $\text{Ti}_3\text{AlC–}\beta\text{-Ti}(\text{sol})$ [$\text{Al}(\text{liq})$ is molten aluminium, and $\alpha\text{-Ti}(\text{sol})$ and $\beta\text{-Ti}(\text{sol})$ are solid solutions of aluminium in $\alpha\text{-Ti}$ and $\beta\text{-Ti}$, respectively]. Titanium is

**Figure 26.** Isothermal cross-section through the Ti–Al–C system at 1273 K (the dark areas denote one-phase regions).¹⁷⁹ (1) Ti₂AlC; (2) Ti₃AlC.

insoluble in Al₄C₃, carbon is insoluble in titanium aluminides, and aluminium is insoluble in TiC_γ. α-Ti dissolves up to 10 at.% of aluminium. The Ti₂AlC *H*-phase annealed at 973 K has no homogeneity region. The variation of the unit cell parameters on the substitution of titanium by aluminium in the ternary phases is relatively greater than the variation caused by a similar change in the carbon content.¹⁷⁹ Thus, the lattice period of the Ti₃AlC annealed at 1273 K decreases on the substitution of titanium by aluminium and increases with an increase in the concentration of carbon. The unit cell parameters of the Ti₂AlC *H*-phase annealed at 1273 K vary in the ranges *a* = 0.3045 to 0.3065 nm and *c* = 1.3636 to 1.3671 nm. The variation of the unit cell parameters points to the existence of small homogeneity regions of the ternary phases annealed at 1273 K.

While considering the phase equilibria in the Ti–Al–C system, one should mention a study¹⁸⁰ published in 1988, when the ternary compounds Ti₂AlC and Ti₃AlC were already known, in which a wrong variant of the phase diagram with no allowance for the existence of the ternary phases was suggested for the Ti–Al–C system.

The Zr–Al–C system. All the known zirconium aluminides except for Zr₂Al, Zr₅Al₄, and Zr₅Al₃, have been found in the Zr–Al–C system.¹⁷⁷ The Zr₂Al phase may be stabilised only in the presence of silicon.¹⁸¹ The aluminide Zr₅Al₄ decomposes at a

Figure 27. Isothermal cross-sections through the Zr–Al–C (a) and Hf–Al–C (b) systems at 973 K (dark sections denote single-phase homogeneity regions of carbides and of solid solutions of aluminium in transition metals).¹⁷⁷

$T_1 = M_2Al_3C_{5-x}$, $T_2 = MAlC_{2-x}$, $N = M_5Al_3C$ ($M = Zr, Hf$).

temperature of ~ 1250 K, and Zr_5Al_3 almost coincides in its composition with Zr_3Al_2 .

Three ternary phases have been found in the Zr–Al–C system: $Zr_2Al_3C_{5-x}$, $ZrAlC_{2-x}$, and Zr_5Al_3C (see Table 9). The new ternary compound with the ideal formula $Zr_2Al_3C_5$ has a hexagonal structure [space group $P31c$ (C_{3v}^4)] with the unit cell parameters $a = 0.3345$ nm and $c = 2.2230$ nm; carbon atoms are located in the octahedral interstices. The $ZrAlC_2$ phase also crystallises with a hexagonal structure [space group $P6_3/mmc$ (D_{6h}^4)], carbon being located in the octahedral interstices. The Zr_5Al_3C phase has a structure of the Mn_5Si_3 type the octahedral interstices of which are filled with carbon.

The greatest number of pseudobinary equilibria in the Zr–Al–C system are formed by the very stable zirconium carbide ZrC_γ (Fig. 27a). However, in contrast to the Ti–Al–C system, ZrC_γ does not form pseudobinary equilibria with aluminium at temperatures below ~ 1300 K. Carbon is soluble only in the aluminide Zr_3Al_2 (Zr_5Al_3), thus stabilising its structure (Mn_5Si_3 type); aluminium is insoluble in ZrC_γ . The distribution of the phase fields near the ternary compound Zr_5Al_3C at 1273 K differs from that at 973 K, namely, the ZrC_γ – Zr_3Al_2 and ZrC_γ – Zr_3Al equilibria disappear, the Zr_5Al_3C – Zr_3Al and Zr_5Al_3C – β -Zr(sol) appearing instead [β -Zr(sol) is the solid solution of aluminium in β -Zr].

The Hf–Al–C system. Three ternary compounds exist in the Hf–Al–C system, their structures and compositions (see Table 9) being similar to those of the corresponding ternary compounds formed in the Zr–Al–C system.¹⁷⁷ However, in

contrast to the zirconium-containing system, there is no Al_4C_3 – $HfAl_3$ equilibrium in the system under consideration, and aluminium coexists with $Hf_2Al_3C_5$, $HfAlC_2$, and HfC_γ (Fig. 27b). Carbon is insoluble in the hafnium aluminides and aluminium is insoluble in hafnium carbide. The phase equilibria in the Hf–Al–C system at 973 K and 1273 K are virtually identical, differing only in that the solubility of aluminium in α -Hf increases (up to 12 at.% of Al at 1273 K) and some solubility of carbon in α -Hf appears.

The V–Al–C system. One ternary compound, namely V_2AlC with a hexagonal structure of the Cr_2AlC type, is formed in the V–Al–C system (see Table 9).^{169–172} At 1273 K this compound coexists with molten aluminium, the carbides Al_4C_3 , VC_γ , ζ - V_4C_3 , and V_2C , and with V(sol) [V(sol) is the solid solution of aluminium in vanadium]; Al_4C_3 exists in an equilibrium with VC_γ (V_8C_7), and V_2C is in an equilibrium with V(sol).¹⁷⁹ The solid solution V(sol) coexisting with V_2AlC and V_2C contains up to 23 at.% of Al. Note that both the disordered carbide VC_γ and the ordered phase V_8C_7 have been observed in this system at 1273 K.¹⁷⁹ The V_2AlC ternary phase has no homogeneity region, binary phases do not dissolve the third component.¹⁷⁹

The Nb–Al–C system. The data^{169–172} concerning the existence of the Nb_2AlC ternary *H*-phase in this system (see Table 9) have been confirmed by Schuster et al.¹⁷⁷ At 973 K this phase exists in equilibrium with $NbAl_3$, Nb_2Al , Nb_3Al , NbC_γ , and Nb_2C ; NbC_γ coexists with Al_4C_3 and $NbAl_3$, and Al_4C_3 coexists with $NbAl_3$ (Fig. 28a). The carbide Nb_3Al_2C with the β -Mn type of structure (see Table 9) is unstable at 973 K and is not shown in Fig. 28a.

Figure 28. Isothermal cross-sections through the Nb–Al–C system at 973–1273 K (a) and through the Ta–Al–C system at 1273 K (b) and 973 K (c).¹⁷⁷

$H = Nb_2AlC$ (a), Ta_2AlC (b, c), $N = Ta_5Al_3C$.

At a higher temperature of 1273 K the Al_4C_3 – NbAl_3 equilibrium disappears, and the carbide NbC_y coexists directly with liquid aluminium (similarly to the Ti–Al–C system in which the carbide TiC_y is in an equilibrium with liquid aluminium). In all other aspects, the isothermal cross-sections through the Nb–Al–C system at 973 K and 1273 K are similar.

The variation of the parameters of the *H*-phase (*a* varies from 0.3105 nm to 0.3115 nm and *c* varies from 1.3860 nm to 1.3921 nm) indicates the existence of a small homogeneity region corresponding to the formula $\text{Nb}_{2-x}\text{Al}_{1+x}\text{C}_{1-x/2}$, which was suggested in a previous study.¹⁶⁹ Carbon is insoluble in the niobium aluminides, and aluminium is insoluble in the niobium carbides.

The Ta–Al–C system. The isothermal cross-sections through the Ta–Al–C system at 973 K and 1273 K are shown in Fig. 28*b,c*. At 973 K one ternary compound with the formula Ta_2AlC exists in this system, and at 1273 K the second ternary compound appears, namely, $\text{Ta}_5\text{Al}_3\text{C}_x$ with a filled structure of the Mn_5Si_3 type (see Table 9). The ternary compound $\text{Ta}_3\text{Al}_2\text{C}$ is unstable at these temperatures and is not shown in Fig. 28*b,c*. At 1273 K carbon populates only some of the octahedral interstices of the tantalum sublattice in $\text{Ta}_5\text{Al}_3\text{C}_x$ ($x < 1.0$), and the occupation of all the interstices can be achieved at a higher temperature.

As the temperature increases, carbon stabilises the $\text{Ta}_5\text{Al}_3\text{C}$ phase with the $D8_8$ type of structure; as this takes place an equilibrium arises between the carbide TaC_y and liquid aluminium, and the Al_4C_3 – TaAl_3 equilibrium disappears (see Fig. 28*b,c*).

The Cr–Al–C system. There is one ternary compound in this system: Cr_2AlC (see Table 9), which is more stable at 1073 K than the carbides Al_4C_3 and Cr_3C_2 and exists in an equilibrium directly with carbon (graphite); with an increase in the temperature, the *H*-phase becomes less stable than Al_4C_3 and Cr_3C_2 , and the Cr_2AlC –C equilibrium disappears (Fig. 29). According to the data obtained by Schuster et al.,¹⁷⁹ the compound Cr_2AlC has no homogeneity region. There is no solubility of the third component in the binary phases of the Cr–Al–C system. The existence of the Cr_3AlC carbide phase with an unknown structure has been reported;¹⁶⁰ however, these data have not been confirmed subsequently.

The Mo–Al–C system. One ternary compound has been detected in this system, namely, the compound $\text{Mo}_3\text{Al}_2\text{C}$ with a cubic structure of the β -Mn type, similar to the analogous compounds formed in the Nb–Al–C and Ta–Al–C systems. The aluminidocarbide $\text{Mo}_3\text{Al}_2\text{C}$ exists in equilibrium with the carbides Al_4C_3 and Mo_2C and with the aluminides Mo_3Al_8 and Mo_3Al ; Al_4C_3 coexists with Mo_2C , MoAl_3 , and Mo_3Al_8 ; the carbide Mo_2C is in equilibrium with Mo_3Al and with the solid solution of aluminium and carbon in molybdenum $\text{Mo}(\text{Al,C})$.¹⁷⁶ The ternary compound $\text{Mo}_3\text{Al}_2\text{C}$ has a small homogeneity region and is formed via a peritectic reaction between the carbide Mo_2C and the aluminium melt. A ternary eutectic ($\text{Mo}_3\text{Al}_2\text{C} + \text{Mo}_3\text{Al} + \text{Mo}_3\text{Al}_8$) with a melting point of ~ 1823 K exists in the system. The compound $\text{Mo}_3\text{Al}_2\text{C}$ has a small homogeneity region: as the content of molybdenum increases from 47 to 51 at.%, the content of carbon being constant and equal to 16.7 at.%, the cubic lattice period increases from 0.6860 nm to 0.6866 nm.^{171,172} A small amount of carbon can be dissolved in all the molybdenum aluminides, whereas molybdenum (up to 3 at.%) is soluble in Al_4C_3 . In all probability, the Al_4C_3 – MoC_y (Mo_3C_2) pseudo-binary equilibrium should exist in the Mo–Al–C system at $T > 1750$ K.

The W–Al–C system. There are no ternary compounds in the W–Al–C system at 1173 K.¹⁷⁶ The intermetallide WAl_2 exists in equilibrium with the carbides Al_4C_3 , WC, and W_3C , whereas Al_4C_3 is in equilibrium with the hexagonal carbide WC (the WC_y high-temperature cubic phase was not taken into account). It should be kept in mind that the designation of the intermetallide WAl_2 , which is formed from tungsten and aluminium melt via the

Figure 29. Isothermal cross-sections through the Cr–Al–C system at 1073 K (a) and 1273 K (b) (dark sections denote single-phase regions).¹⁷⁹

peritectic reaction and is stable in the narrow temperature range from 1600 K to 1830 K, is somewhat arbitrary.¹⁸²

The Mn–Al–C system. A study of the phase equilibria in the Mn–Al–C system has provided evidence for the existence of the ternary compound Mn_3AlC with the perovskite type of structure¹⁸³ (see Table 9). At 973 K this compound is in equilibrium with Al_4C_3 and with solid solutions of aluminium in α -Mn(sol) and β -Mn(sol) as well as with the carbides Mn_7C_3 , Mn_5C_2 , and Mn_{23}C_6 and with carbon, whereas Al_4C_3 is in equilibrium with all the manganese aluminides (Fig. 30a). The period of the lattice of Mn_3AlC annealed at 973 K varies from 0.3856 nm to 0.3873 nm. This apparently reflects the variation of the carbon content in the compound rather than the alteration of the ratio between the manganese and aluminium. A similar conclusion can be drawn from the results of another study.¹⁶³

At 1273 K γ -Mn dissolves ~ 5 at.% of carbon and 25 at.% of aluminium thus forming a broad one-phase region; the high-temperature ϵ -MnAl phase dissolves up to 5 at.% of carbon (Fig. 30b). The parameters of the cubic lattice in the compounds Mn_3AlC thus formed differ from each other and are equal to 0.3840 nm and 0.3874 nm. It should be noted that two phases (apart from the γ -Mn Fcc structure) with the perovskite structure and different parameters, $a = 0.384$ nm and $a = 0.387$ nm, have been also observed in the $\text{Mn}_7\text{Al}_2\text{C}$ alloy.

The temperature of the congruent melting of Mn_3AlC is 2000 K.

The Fe–Al–C system. Figure 31 presents a fragment of the Fe–Al–C ternary system at 1273 K.¹⁸⁴ The carbide Fe_3AlC_x with the perovskite type of structure is formed in this system (see Table 9); the metal atoms in this compound form an ordered Fcc-lattice. The corresponding aluminide Fe_3Al has a cubic structure (space group $Fm\bar{3}m$) of the BiLi_3 or BiF_3 ($D0_3$) type. This structure consists of four interpenetrating Fcc sublattices.

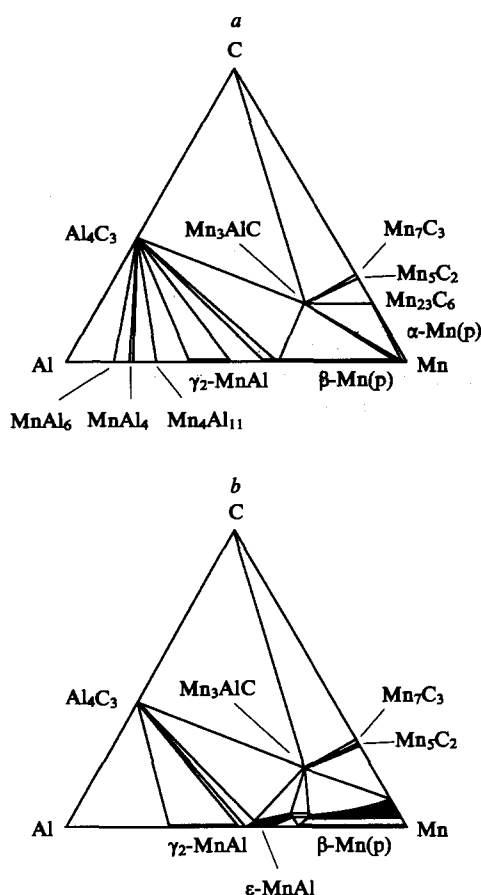

Figure 30. Isothermal cross-sections through the Mn-Al-C system at 973 K (a) and 1273 K (b) (dark sections denote single-phase regions).¹⁸³

The aluminium atoms are located at the unit cell vertices and at the centres of faces, whereas iron atoms occupy the centres of octahedral and tetrahedral interstices of the aluminium fcc-sublattice. As a whole, the atoms in Fe_3Al populate the same positions as do the atoms in the eight cells of a body-centred cubic (Bcc) lattice of the $\text{CsCl}(B2)$ type. This permits Fe_3Al to be regarded as a superstructure based on a Bcc lattice. The

Figure 31. Fragment of the isothermal cross-section through the Fe-Al-C system at 1273 K.¹⁸⁴ K is the ternary compound Fe_3AlC_x with the perovskite type of structure; dark area indicates the region of austenite $\gamma\text{-Fe}(\text{C})$.

introduction of carbon into Fe_3Al leads to the formation of the ternary carbide Fe_3AlC with the perovskite type of structure. The carbide Fe_3AlC has an extended homogeneity region that is connected to the homogeneity region of austenite $\gamma\text{-Fe}(\text{C})$ via a two-phase region. The ternary compound Fe_3AlC_x exists in equilibrium with Fe_3Al , FeAl , the solid solution of aluminium in $\alpha\text{-Fe}$, $\gamma\text{-Fe}(\text{C})$, carbon, and possibly with the cementite Fe_3C .

The Co-Al-C system. One ternary compound Co_3AlC_x with the perovskite type of structure is formed in the Co-Al-C system.^{163, 164, 166} The proportions of carbon in Co_3AlC_x and Fe_3AlC_x are approximately equal ($x \approx 0.6$).^{163, 164} The carbide Co_3AlC_x is formed via a peritectic reaction of CoAl with carbon and aluminium melt. The ternary compound Co_3AlC_x forms pseudobinary equilibria with $\alpha\text{-Co}$ (more precisely, with the limited solid solution of aluminium and carbon in cobalt), CoAl , C, and probably with Al_4C_3 .

The Ni-Al-C system. In the Ni-Al-C system, the nickel aluminide Ni_3Al [Cu_3Au ($L1_2$) structural type, space group $Pm\bar{3}m(O_h^1)$] has an ordered cubic lattice and dissolves up to 7 at.% of carbon, the symmetry of the metallic lattice being retained and the period of the lattice increasing from 0.3587 nm to 0.3617 nm.^{163, 164} Thus, the Ni_3AlC_x phase is an interstitial solid solution of carbon in Ni_3Al . The structure of this solid solution is characterised by the same distribution of atoms as in the carbides M_3AlC_x with the perovskite structure, which has been confirmed in a special study.¹⁶⁸ The method of forming the Ni_3AlC_x solid solution and its crystal structure (the $L1_2$ type with some of the octahedral interstices being filled with carbon atoms) indicate that the compounds M_3AlC_x with the perovskite structure are interstitial compounds, like the cubic [with the structure of the $\text{NaCl}(B1)$ type] carbides and nitrides MX_y ($y \leq 1.00$).

It has been found¹⁶⁸ that carbon is markedly soluble not only in Ni_3Al , but also in NiAl . According to this study, on passing from Ni_3Al to $\text{Ni}_3\text{Al}(\text{C}_{1.0})$, the period of the metallic lattice increases from 0.3557 nm to 0.3583 nm.

3. The ternary M-Al-N aluminidonitride systems

The interest in the use of the compounds and heterophase compositions formed in the M-Al-N systems as abrasives is due to their high chemical stability and hardness. In addition, the ability of the aluminium nitride AlN to retain its high mechanical properties at elevated temperatures $T > 1000$ K makes the development of construction materials based on it particularly attractive, since these materials can be used under drastic conditions, for example, in aggressive media, at high temperatures, and under great loads.

The structural characteristics of the ternary phases formed in the M-Al-N systems are listed in Table 10.

The Sc-Al-N system. All the alloys formed in the Sc-Al-N systems in which the concentration of scandium is more than 50 at.% contain the Sc_3AlN_x ternary cubic phase with the perovskite structure.¹⁸⁵ The ternary compound Sc_3AlN_x is in equilibrium with ScAl , Sc_2Al , ScN , and $\text{Sc}(\text{sol})$ (the solid solution of Al and N in scandium). In addition, the following pseudobinary equilibria exist in the Sc-Al-N system: $\text{AlN}-\text{ScAl}_3$, $\text{AlN}-\text{ScAl}_2$, $\text{AlN}-\text{ScN}$, $\text{ScN}-\text{ScAl}_2$, $\text{ScN}-\text{ScAl}$, $\text{ScN}-\text{Sc}(\text{sol})$, and $\text{Sc}_2\text{Al}-\text{Sc}(\text{sol})$ (Fig. 32a). The lattice period of Sc_3AlN_x is 0.4396 nm (in equilibrium with ScAl and Sc_2Al), 0.4405 nm [in equilibrium with $\text{Sc}(\text{sol})$ and ScN], and 0.4435 nm (in equilibrium with ScN and ScAl). Scandium dissolves up to 15 at.% of nitrogen and more than 5 at.% of aluminium.

The Yl-Al-N system. According to Schuster and Bauer,¹⁸⁵ there are no ternary phases in this system at temperatures from 1073 K to 1573 K. At 1273 K the yttrium nitride YN coexists with AlN , YAl_2 , YAl , and Y_3Al_2 , whereas the aluminium nitride AlN coexists with YAl_2 (Fig. 32b). At 1573 K the aluminides YAl and Y_3Al_2 disappear from the Y-Al-N system, the $\text{AlN} + \text{YN} + \text{YAl}_2$ region being retained as the only solid three-phase region.

^a In the unit cell $\beta = 106.39^\circ$. ^b In the unit cell $\beta = 106.33^\circ$.

The Ln–Al–N systems. A study has shown¹⁸⁶ that there are no ternary phases in the Ln–Al–N systems with Ln = Gd, Tb, Dy, Ho, Er, Tm, Yb, and Lu. In the La–Al–N, Nd–Al–N, and Sm–Al–N systems, the Ln₃AlN_x ternary phases with the perovskite type of structure are formed, whereas in the Ce–Al–N and Pr–Al–N systems, the Ce₃AlN_x and Pr₃AlN_x ternary phases based on the aluminides Ce₃Al and Pr₃Al with

structures of the Cu₃Al (*L1₂*) type are formed. The latter result from filling of the octahedral interstices of the lanthanide sublattice with nitrogen atoms.

Figure 33 presents the isothermal cross-section through the Pr–Al–N system at 873 K.¹⁸⁶ The ternary compound Pr₃AlN coexists with PrAl₂, PrAl₃, PrN, and Pr, the aluminium nitride

**Figure 32.** Isothermal cross-sections through the Sc–Al–N (a) and Y–Al–N (b) systems at 1273 K (dark areas indicate single-phase regions).¹⁸⁵**Figure 33.** Isothermal cross-section through the Pr–Al–N system at 873 K (pseudobinary equilibria marked by dashed lines are shown conventionally).¹⁸⁶

AlN coexists with PrAl_4 , PrAl_3 , PrAl_2 , and PrN , and PrAl_2 is in an equilibrium with PrN . The $\text{Pr}_3\text{Al}-\text{Pr}_3\text{AlN}_x$ pseudobinary equilibrium is shown with a dashed line, because the ternary phase is actually a solid solution of nitrogen in the aluminide Pr_3Al . The equilibria in the $\text{PrAl}_4-\text{AlN}-\text{PrAl}_3$ and $\text{PrAl}_2-\text{Pr}_3\text{AlN}_x-\text{Pr}_3\text{Al}$ regions are shown arbitrarily and require additional investigation.

The Ti–Al–N system. Numerous studies of the phase relationships in the Ti–Al–N ternary system have shown that depending on the temperature, two or three ternary compounds can exist in it under equilibrium conditions. At 1273 K there are two ternary phases Ti_3AlN and Ti_2AlN .¹⁸⁸ The cubic phase Ti_3AlN with the perovskite structure (see Table 10) is iso-structural to the carbide Ti_3AlC ¹⁵⁹ and has a negligibly small homogeneity region. The hexagonal Ti_2AlN *H*-phase has been detected for the first time by Jeitschklo et al.¹⁹⁰ Its existence has been confirmed in other studies.^{188,191,192} This phase is isostructural to the analogous Ti_2AlC phase^{169–172} crystallising with the Cr_2AlC type of structure and, judging from the difference in the lattice parameters determined in a number of studies,^{188,190,191} it possesses a certain homogeneity region, which is defective with respect to nitrogen. At 1273 K, the ternary cubic Ti_3AlN phase coexists with Ti_3Al , TiN_y , and Ti_2AlN , whereas the Ti_2AlN *H*-phase is in an equilibrium with TiAl , Ti_3Al , Ti_3AlN , TiN_y , and AlN . In addition, the $\text{AlN}-\text{TiAl}$, $\text{AlN}-\text{TiN}_y$, and $\text{TiN}_y-\text{Ti}_3\text{Al}$ pseudobinary equilibria exist in the Ti–Al–N system. The solubility of aluminium in TiN_y is less than 2 at.%. The lower hexagonal titanium nitride $\epsilon\text{-Ti}_2\text{N}$ does not form any equilibria with ternary compounds or titanium aluminides; it coexists only with TiN_y and with the solid solution of aluminium and nitrogen in $\alpha\text{-Ti}$.

Apart from Ti_2AlN and Ti_3AlN , the $\text{Ti}_3\text{Al}_2\text{N}_2$ ternary phase with a layered trigonal structure (see Table 10) arises in the Ti–Al–N system at 1573 K. It coexists with AlN , TiN_y , TiAl , TiAl_3 , and Ti_2AlN (Fig. 34) and exists in the narrow temperature range 1473–1573 K.

The Zr–Al–N system. The phase equilibria in this system have been studied.^{193,195} The ternary compound Zr_3AlN exists in the Zr–Al–N system at 1273 K (see Table 10). Initially this compound was believed to crystallise with a monoclinic symmetry,¹⁹³ however, an X-ray diffraction structural study of its single crystal¹⁹⁵ has shown that Zr_3AlN has an orthorhombic structure of the Re_3B type. The aluminium atoms in the compound Zr_3AlN are located at the centres of trigonal prisms formed by six

zirconium atoms, whereas the nitrogen atoms are arranged in the weakly distorted octahedral interstices of the zirconium sublattice. The formation of the second ternary phase $\text{Zr}_5\text{Al}_3\text{N}_x$ is associated with the stabilisation of the hexagonal structure of the Mn_5Si_3 type with nitrogen; at 1273 K the nitrogen content in $\text{Zr}_5\text{Al}_3\text{N}_x$ is low ($x < 0.2$).

At a temperature of 1273 K the compound Zr_3AlN exists in equilibrium with AlN , Zr_2Al_3 , ZrAl , $\text{Zr}_5\text{Al}_3\text{N}_x$ ($x < 0.2$), ZrN_y , and $\alpha\text{-Zr(sol)}$ (the solid solution of aluminium and nitrogen in $\alpha\text{-Zr}$); the aluminium nitride coexists with ZrAl_3 , ZrAl_2 , Zr_2Al_3 , and ZrN_y ; the $\text{Zr}_5\text{Al}_3\text{N}_x$ phase exists in equilibrium with ZrAl , Zr_5Al_4 , Zr_3Al_2 , Zr_5Al_3 , Zr_2Al , and $\alpha\text{-Zr(sol)}$; and ZrN_y is in equilibrium with $\alpha\text{-Zr(sol)}$ (Fig. 35a). Note that in a study of the Zr–Al–C system, Schuster and Nowotny¹⁷⁷ did not find such zirconium aluminides as Zr_2Al , Zr_5Al_4 , and Zr_5Al_3 , which have been observed in the related Zr–Al–N ternary system.¹⁹³

An increase in the temperature to 1573 K leads to a substantial extension of the homogeneity region of the $\text{Zr}_5\text{Al}_3\text{N}$ ternary phase, which contains up to 10 at.% of nitrogen under these conditions. At 1573 K the appearance of the phase diagram of the Zr–Al–N system (Fig. 35b) changes somewhat, since the $\text{ZrN}_y-\text{ZrAl}_2$, $\text{ZrN}_y-\text{Zr}_2\text{Al}_3$, $\text{ZrN}_y-\text{Zr}_5\text{Al}_3\text{N}$, $\text{Zr}_2\text{Al}_3-\text{Zr}_5\text{Al}_3\text{N}$, $\text{ZrAl}-\text{Zr}_5\text{Al}_3\text{N}$, and $\text{Zr}_5\text{Al}_3\text{N}-\beta\text{-Zr(sol)}$ pseudobinary equilibria arise [$\beta\text{-Zr(sol)}$ is the solid solution of aluminium in $\beta\text{-Zr}$].

The Hf–Al–N system. Only one stable ternary phase exists in this system at 1273 K, namely, the Hf_3AlN phase with a monoclinic structure determined using a powder.¹⁹⁴ A single-crystal X-ray diffraction study¹⁹⁵ has shown that Hf_3AlN has an orthorhombic structure of the Re_3B type. The Hf_3AlN phase coexists with HfN_y , AlN , Hf_2Al_3 , HfAl , Hf_4Al_3 , Hf_3Al_2 , and $\alpha\text{-Hf(sol)}$ (the solid solution of aluminium and nitrogen in hafnium, Fig. 35c). The line connecting HfN_y and $\alpha\text{-Hf(sol)}$ confines the possible area of the existence of the nitrides $\text{Hf}_4\text{N}_{3-x}$ and $\text{Hf}_3\text{N}_{2-x}$, which are unstable at 1273 K.

The X-ray diffraction patterns of the samples, the compositions of which corresponded to the $\text{Hf}_2\text{Al}_3-\text{Hf}_3\text{AlN}-\text{HfAl}$ region, exhibited an additional set of reflections due to a fourth phase.¹⁹⁴ In all probability, this phase exists in the equilibrium state only at lower temperatures or is stabilised by admixtures.

Two ternary phases Hf_3AlN and $\text{Hf}_5\text{Al}_3\text{N}$ exist in the Hf–Al–N system at 1673 K (Fig. 35d). The $\text{Hf}_5\text{Al}_3\text{N}$ phase has a structure of the Mn_5Si_3 type; its unit cell parameters ($a = 0.8062$ nm, $c = 0.5603$ nm) are smaller than those of the analogous carbide phase $\text{Hf}_5\text{Al}_3\text{C}$ ($a = 0.8120$ nm, $c = 0.5679$ nm). It follows from the comparison of the unit cell dimensions of $\text{Zr}_5\text{Al}_3\text{C}$ and $\text{Zr}_5\text{Al}_3\text{N}$, $\text{Hf}_5\text{Al}_3\text{C}$ and $\text{Hf}_5\text{Al}_3\text{N}$ that nitrogen occupies only some of the octahedral interstices of the transition metal sublattice. It should be noted that the $\text{Hf}_5\text{Al}_3\text{N}$ and Hf_3AlN ternary phases have no homogeneity regions.

The V–Al–N system. In the temperature range from 1273 to 1773 K no ternary compounds exist in this system, although the attempts to synthesise the nitride V_2AlN with a structure of the *H*-phase have resulted in some cases in multiphase samples, the X-ray diffraction patterns of which contained lines due to the *H*-phase.¹⁹⁸ However, the observed lattice parameters were close to those of the carbide V_2AlC *H*-phase. In addition, the sample containing the *H*-phase was nonequilibrium and incorporated more than three phases. The $\text{V}_{0.50}\text{Al}_{0.25}\text{N}_{0.25}$ alloy corresponding to the ideal stoichiometric composition of the *H*-phase contained only the nitrides VN_y and AlN even at a nitrogen pressure of 3×10^6 Pa. Thus, no ternary phases were detected in the V–Al–N system in the experiment described above.¹⁹⁸

At $T = 1273$ K the aluminium nitride AlN is in equilibrium with VAl_3 , V_5Al_8 , VN_y , and V(sol) [V(sol) is the solid solution of aluminium and nitrogen in vanadium]; VN_y and V_9N_4 exist in equilibrium with V(sol) . At 1573 K the cubic nitride VN_y does not exist, therefore the $\text{AlN}-\text{V}_9\text{N}_4$ equilibrium arises. The V(sol) solid solution existing in equilibrium with AlN and V_9N_4 has the

Figure 34. Isothermal cross-section through the Ti–Al–N system at 1573 K (dark areas denote single-phase regions).¹⁸⁸
(1) Ti_3AlN , (2) Ti_2AlN , (3) $\text{Ti}_3\text{Al}_2\text{N}_2$.

Figure 35. Isothermal cross-sections of the Zr–Al–N system at 1273 K (a) and 1573 K (b) and of the Hf–Al–N system at 1273 K (c) and 1673 K (d).^{193, 194} Dark areas denote single-phase regions; pseudobinary

equilibria marked by dashed lines are shown conventionally; $T_1 = M_3AlN$, $T_2 = M_5Al_3N$ ($M = Zr, Hf$).

composition $V_{0.67}Al_{0.33}$. At 1773 K the $AlN + V_9N_4 + V(sol)$ field is the main region where ternary phase equilibria exist. The solubility of nitrogen in the $V(sol)$ solid solution with high aluminium proportions is low, but it increases markedly with the decrease in the amount of aluminium. The homogeneity region of the $V(sol)$ solid solution expands with an increase in the temperature.

The Nb–Al–N system. The phase equilibria in the Nb–Al–N system have been studied by Schuster and Nowotny.¹⁹⁷ The samples for the investigation were prepared by sintering Nb–Al alloys with the nitrides AlN and NbN under an argon atmosphere. Previously the ternary compound Nb_3Al_2N with a structure of the β -Mn type has been found in this system.^{174, 196} According to Schuster and Nowotny,¹⁹⁷ this compound is stable in the temperature range from 1273 to 1773 K studied and melts congruently. The compound Nb_3Al_2N exists in equilibrium with AlN , Nb_2N , $NbAl_3$, and Nb_2Al ; the nitride AlN is in equilibrium with $NbAl_3$ and with the niobium nitrides Nb_4N_3 and Nb_2N ; and Nb_2N also coexists with Nb_2Al , Nb_3Al , and the solid solution of aluminium and nitrogen in niobium (Fig. 36a). The solubility of Nb or Nb-containing compounds in AlN is negligibly small. The compound Nb_3Al_2N has apparently a narrow homogeneity region, since the period of its lattice varies from 0.70314 nm (in equilibrium with Nb_2Al and Nb_2N) to 0.70387 nm (in equilibrium with $NbAl_3$ and Nb_2Al).

The nitride NbN_y becomes stable at 1273 K, and the $AlN-NbN_y$ equilibrium arises instead of $AlN-Nb_4N_3$. In all other aspects, the phase diagram for the Nb–Al–N system at 1273 K is identical to that at 1773 K.

The Ta–Al–N system. The ternary compound $Ta_5Al_3N_x$ with a structure of the Cr_5B_3 type having vacancies in the nitrogen sublattice has been found in the Ta–Al–N system.¹⁹⁶ However, in another study¹⁹⁷ no ternary compounds have been observed in this system at temperatures from 1273 to 1773 K. The following pseudobinary phase equilibria occur in this system at 1273 K and 1523 K: $AlN-TaAl_3$, $AlN-Ta_2Al_3$ (as the low-temperature modification at 1273 K and as the high-temperature modification at 1573 K), $AlN-Ta_2Al$, $AlN-Ta_2N$, and $AlN-\epsilon-TaN$ (Fig. 36b).

At low temperatures AlN coexists with tantalum, but the reaction between AlN and Ta slowly yields Ta_2N and Ta_2Al . At 1773 K the major part of the ternary system is liquid, and the melt is in an equilibrium with all the binary solid phases.

The Cr–Al–N system. This system contains no ternary phases under the equilibrium conditions in the temperature range 1273–1773 K.¹⁹⁸ The X-ray diffraction patterns of the samples, the composition of which was close to Cr_2AlN , exhibited reflections corresponding to a ternary compound of this composition with a structure of the H -phase. Nevertheless, an equilibrium H -phase could not be detected in the Cr–Al–N system even at a nitrogen pressure of 3×10^6 Pa. Four solid-phase equilibria exist in this system at 1273 K, namely, $AlN-CrAl_4$, $AlN-Cr_4Al_9$, $AlN-Cr_5Al_8$, and $AlN-\alpha-Cr$ ($\alpha-Cr$ is the solid solution of aluminium in chromium having the composition $Cr_{0.58}Al_{0.42}-Cr_{0.98}Al_{0.02}$). Chromium is insoluble in AlN .

The Mo–Al–N system. Two solid three-phase fields ($Mo_3Al_8 + AlN + Mo_3Al$) and ($Mo_3Al + AlN + Mo$) exist in the Mo–Al–N system in the temperature range 1273–1773 K.¹⁹⁸ Molybdenum is insoluble in AlN , and nitrogen

Figure 36. Isothermal cross-sections of the Nb–Al–N system (a) at 1773 K and the Ta–Al–N system (b) at 1523 K (dark areas denote homogeneity regions of binary phases and of solid solutions).¹⁹⁷

is insoluble in the molybdenum aluminides. The molybdenum nitride Mo_2N becomes stable at low temperatures or at high partial pressures of nitrogen (for example, at 1273 K and 1×10^6 Pa). The molybdenum nitride Mo_2N apparently exists in equilibrium with AlN. No ternary phases have been found in the Mo–Al–N system.

The W–Al–N system. There are two pseudobinary solid-phase equilibria, namely, $\text{AlN} - \text{WAl}_4$ and $\text{AlN} - \text{W(sol)}$ [W(sol) is the solid solution of aluminium in tungsten], and no ternary compounds in the W–Al–N system at temperatures from 1273 K to 1773 K. The solubility of tungsten in AlN and the solubility of nitrogen in WAl_4 and W(sol) are negligibly small.

The Mn–Al–N system. No ternary phases exist in the Mn–Al–N system at 873 K; the $\text{Mn}_{88.4}\text{Al}_{9.8}\text{N}_{1.8}$ and $\text{Mn}_{68.1}\text{Al}_{29.2}\text{N}_{2.7}$ alloys studied have a cubic structure of the β -Mn type with the periods a equal to 0.637 nm and 0.643 nm, respectively, and the $\text{Mn}_{75.9}\text{Al}_{8.3}\text{N}_{15.8}$ alloy incorporates two cubic phases, one of which has $a = 0.900$ nm and a structure of the β -Mn type, and the other is characterised by $a = 0.637$ nm and the α -Mn type of structure (the $A12$ structural type, space group $I\bar{4}3m$).¹⁸⁹

Schuster and Nowotny¹⁹⁸ also have not found any ternary phases in the Mn–Al–N system at temperatures of up to 1273 K. At 1073 K the nitride AlN coexists with MnAl_4 , $\text{Mn}_4\text{Al}_{11}$, MnAl, β -Mn (the solid solution of aluminium in manganese), γ -Mn (the solid solution of aluminium and nitrogen in manganese), and with the hexagonal nitride ζ - Mn_2N . Neither solubility of manganese in AlN or solubility of nitrogen in manganese aluminides was observed, while γ -Mn dissolves up to 10 at.% of aluminium and 8 at.% of nitrogen. The only solid-phase equilibrium existing at 1273 K is the equilibrium between AlN and β -Mn.

The Re–Al–N system. There are no ternary phases in the Re–Al–N system in the temperature range from 1273 to 1773 K at a nitrogen pressure of 2×10^7 Pa.¹⁹⁸ At 1273 K aluminium nitride exists in an equilibrium with ReAl_4 , ReAl_3 , ReAl, Re_2Al , and Re. Only two aluminides ReAl_3 and Re_2Al coexisting with AlN are stable at 1773 K.

The Fe–Al–N system. No ternary compounds were found in this system after nitriding the metal alloys at 873 K.¹⁸⁹ The $\text{Fe}_{57}\text{Al}_{19}\text{N}_{24}$ ($\text{Fe}_3\text{AlN}_{1+x}$) alloy contains only the hexagonal iron nitride ϵ - Fe_3N with the parameters $a = 0.276$ nm and $c = 0.442$ nm and contains no aluminium nitride AlN. The alloy of the composition $\text{Fe}_{63.9}\text{Al}_{21.3}\text{N}_{14.8}$ ($\text{Fe}_3\text{AlN}_{1-x}$), apart from ϵ - Fe_3N ($a = 0.273$ nm, $c = 0.438$ nm), incorporates also the cubic austenite γ -Fe (the $A1$ structural type, space group $Fm\bar{3}m$) with $a = 0.356$ nm. The main phases in the $\text{Fe}_{35.8}\text{Al}_{35.8}\text{N}_{28.4}$ (FeAlN_{1-x}) alloy are the hexagonal nitrides ϵ - Fe_3N ($a = 0.273$ nm, $c = 0.439$ nm) and AlN. Finally, the cubic iron nitride γ' - Fe_4N (the $L'1$ structural type) with the unit cell period $a = 0.380$ nm and the hexagonal aluminium nitride AlN [the wurtzite ZnS ($B4$) structural type, space group $P6_3mc$] are present in the alloy of composition $\text{Fe}_{43.1}\text{Al}_{43.1}\text{N}_{13.8}$ ($\text{FeAlN}_{0.32}$). The results obtained by Stadelmaier and Yun¹⁸⁹ indicate that γ' - Fe_4N dissolves substantial amounts of aluminium, and the homogeneity region is extended forming a ternary system.

The Co–Al–N system. There are no ternary compounds in this system.¹⁸⁹ The aluminium nitride is in an equilibrium with α -Co and with the only stable cobalt aluminide β -CoAl.

The Ni–Al–N system. In this system, the dissolution of up to 8 at.% of nitrogen in the cubic nickel aluminide Ni_3Al (the $L1_2$ structural type, $a = 0.358$ nm) leads to the formation of the ternary cubic phase Ni_3AlN_x (the $L'1_2$ structural type) with the lattice period $a = 0.380$ nm.¹⁸⁹

4. The ternary M–Al–Si aluminidosilicide systems

The ternary systems of transition metals with silicon and aluminium have been studied with regard to their resistance to oxidation at high temperatures and the possibility of using them for protective coatings. A characteristic feature of M–Al–Si systems is the ability of aluminium and silicon atoms to substitute each other, which leads to continued solid solutions (or limited solid solutions with high mutual solubilities) of silicides and aluminides. In particular, continued or limited solid solutions arise in those systems where the silicides MSi_2 and M_5Si_3 are formed. Virtually no ternary phases with filled structures of the Mn_5Si_3 type, which are highly typical of the M–B–Si, M–Si–C, M–Si–N, M–Al–C, and M–Al–N systems, are produced in the M–Al–Si systems. Nevertheless, ternary phases with the Mn_5Si_3 type of structure and with vacant octahedral interstices appear in the Zr–Si and Hf–Si systems in the presence of aluminium.

The structural characteristics of the ternary phases formed in the M–Al–Si systems are listed in Table 11.

The Ti–Al–Si system. The phase equilibria and the crystal structures of the compounds formed in this system have been studied in a number of works.^{199–201} The alloys were prepared by sintering the powders and were annealed at 1473 K. The $(\text{Ti},\text{Si})_{2-3}\text{Al}$ ternary phase with a structure of the Mg_3Gd (BiF_3) type was found in the Ti–Al–Si system. The homogeneity region of this phase is located from Ti_2Al to Ti_3Al , and it dissolves up to 5 at.% of silicon. A slight amount of silicon (no more than 2 at.%) is also dissolved in the γ -TiAl solid solution [the $\text{CuAu}(L1_0)$ structural type, space group $P4/mmm$]. A limited substitution solid solution containing up to 12 at.% of silicon is also formed based on the tetragonal aluminide TiAl_3 (the $D0_{22}$ structural type, space group $I4/mmm$). The orthorhombic disilicide TiSi_2 (the $C54$ structural type, space group $Fddd$) dissolves up to 5 at.% of aluminium. The hexagonal disilicide Ti_5Si_3 with the Mn_5Si_3 type of structure also dissolves up to 5 at.% of aluminium, some of the aluminium atoms substituting the silicon atoms and the rest filling the octahedral interstices. The ternary

^a The following designations are used: CSSS is a continuous series of solid solutions; LSS is a limited solid solution. ^b In the unit cell $\alpha = 91^\circ$. ^c The unit cell of the aluminosilicide Fe₅Al₂₀Si₂ incorporates 138 atoms (100 aluminium atoms, 24 iron atoms and 14 silicon atoms). ^d In the unit cell $\alpha = 132^\circ$.

pseudotetragonal (orthorhombic) TiAl_{0.3–0.6}Si_{1.7–1.4} phase [Ti(Si,Al)₂] has a structure of the ZrSi₂ type and possesses a significant homogeneity region.

A titanium silicide containing ~45 at.% of silicon and dissolving considerable amounts of aluminium has also been found. This compound has been reported to be a solution of aluminium in Ti₅Si₄.²⁰¹ The same authors²⁰¹ also showed that the orthorhombic silicide TiSi [the FeB (B27) structural type, space group *Pnma*] dissolves up to 8 at.% of aluminium. One more unknown ternary compound has been detected near the Ti(Si,Al)₂ ternary phase;²⁰⁰ its composition has been determined as Ti₇Al₅Si₁₂.²⁰¹ This compound is stable at least up to 1173 K; with allowance for the data of Schob et al.,²⁰⁰ it is stable up to 1473 K.

The Zr–Al–Si system. The phase equilibria in the Zr–Al–Si system have been studied at 973 K²⁰¹ and at 1273–1473 K.^{200, 202} Two ternary phases exist in this system at 1473 K, namely, the orthorhombic Zr(Si,Al) phase and the tetragonal Zr(Al,Si)₃ phase. The ideal composition of the ternary tetragonal phase was determined²⁰¹ to be Zr₂Al₃Si. One more ternary compound

Zr₃Al₄Si₅ with a narrow homogeneity region was found in this system at 973 K.

Continued solid solutions are formed in this system over the Zr₂Al–Zr₂Si pseudobinary cross-section. It has been reported²⁰⁰ that the mutual solubility of the components over the Zr₅Al₃–Zr₅Si₃ cross-section is absent only in a narrow region near Zr₅Si₃; according to another study,²⁰¹ the mutual solubility is infinite. Limited solid solutions of silicon in ZrAl₃ (up to 5 at.%) and of aluminium in ZrSi₂ (up to 8 at.%²⁰⁰ or up to 24 at.%²⁰¹) are also formed in the Zr–Al–Si system.

At 973 K aluminium is highly soluble in the silicide ZrSi substituting both zirconium and silicon up to the composition Zr_{0.33}Al_{0.33}Si_{0.34}. The high-temperature modification of this solution has the CrB type of structure, whereas the low-temperature modification crystallises with the FeB type of structure.

The Hf–Al–Si system. The isothermal cross-section through the Hf–Al–Si system at 1473 K has been constructed.²⁰⁰ The ternary compound Hf(Si,Al) (HfAl_{0.35}Si_{0.65}) with the orthorhombic structure of the CrB type was found in this system. A continuous series of solid solutions is formed over the Hf₂Al–Hf₂Si pseudobinary cross-section. The Hf₅(Al,Si)₃

ternary phase with a structure of the Mn_5Si_3 ($D8_8$) type possesses an extended homogeneity region, although there are no compounds M_5X_3 with the Mn_5Si_3 type of structure in the $Hf-Al$ and $Hf-Si$ binary systems. Thus, in the presence of aluminium, there is no need for boron, carbon, or nitrogen admixtures to stabilise the $D8_8$ structural type. The silicide Hf_3Si_2 dissolves aluminium yielding a solid solution of the composition $Hf_3Al_{0.5}Si_{1.5}$. Limited solid solutions of silicon (up to 10 at.%) in $HfAl_3$ and of aluminium (up to 10 at.%) in $HfSi_2$ are also formed. The $Hf(Si,Al)$ ternary phase with a structure of the CrB type is in an equilibrium with $HfAl_3$ (the $ZrAl_3$ type) and with the silicides Hf_3Si_2 and $HfSi$.

The V-Al-Si system. No ternary compounds have been found in the $V-Al-Si$ system.^{203,204} Vanadium disilicide VSi_2 dissolves substantial amounts of aluminium, which substitutes silicon thus yielding a limited solid solution with the $CrSi_2$ ($C40$) type of structure. The composition of the solid solution with the highest aluminium content can be written as $V(Si_{0.67}Al_{0.33})_2$. The unit cell parameters of the solid solution increase with an increase in the content of aluminium.

The Nb-Al-Si system. There are two ternary phases in the $Nb-Al-Si$ system at 1673 K, namely, $Nb_5(Al,Si)_3$ with a tetragonal structure of the W_5Si_3 ($D8_m$) type and $Nb(Si,Al)_2$ with an orthorhombic structure of the $TiSi_2$ ($C54$) type.^{204,205} These phases are in equilibrium with each other and have homogeneity regions in which silicon is substituted by aluminium. The tetragonal silicide Nb_5Si_3 with the Cr_5B_3 ($D8_7$) type of structure dissolves up to 18 at.% of aluminium; further increase in the aluminium content leads to the transition from the $Nb_5(Si,Al)_3$ substitution solid solution with the Cr_5B_3 type of structure to the $Nb_5(Al,Si)_3$ ternary phase with the W_5Si_3 structure. A substitution solid solution containing up to 10 at.% of aluminium is also formed based on the silicide $NbSi_2$ with the $CrSi_2$ ($C40$) structure. The aluminide Nb_3Al [the W_3O ($A15$) structural type, space group $Pm\bar{3}n$] dissolves up to 7 at.% of silicon thus yielding a substitution solid solution. The ternary σ -phase containing up to 2 at.% of silicon may be regarded as a solid solution of silicon in niobium aluminide in the region between Nb_2Al and Nb_3Al .

The Ta-Al-Si system. The isothermal cross-section through the $Ta-Al-Si$ system at 1673 K has been constructed.²⁰⁶ No ternary compounds were found in this system. On the basis of tantalum silicides, limited solid solutions are formed in which silicon is substituted by aluminium: Ta_2Si dissolves 9 at.% of Al; Ta_5Si_3 with the W_5Si_3 structure dissolves up to 20 at.% of Al (as a consequence, the unit cell parameters of Ta_5Si_3 increase somewhat); and $TaSi_2$ with a structure of the $CrSi_2$ ($C40$) type dissolves more than 20 at.% of aluminium. A solid solution with a low silicon content (up to 2 at.%) is formed on the basis of the σ -phase having the homogeneity region from Ta_2Al to Ta_3Al .

The Cr-Al-Si system. The phase equilibria in the $Cr-Al-Si$ system have been studied at 1573 K.²⁰⁴ There are no ternary compounds in this system, but the silicides Cr_3Si [the W_3O ($A15$) structural type], Cr_5Si_3 [the W_5Si_3 ($D8_m$) structural type], and $CrSi_2$ dissolve 12, 7, and 22 at.% of aluminium, respectively. The solid solutions resulting from the substitution of silicon by aluminium retain the crystal structures of the chromium silicides. The extended solid solution of aluminium in chromium also dissolves up to 4 at.% of Si. It has been reported²⁰⁷ that the ternary cubic compound $Cr_4Al_3Si_4$ having a homogeneity region is formed from the $Cr-Al-Si$ melt (see Table 11). This compound is stable at temperatures below 870 K, and at 870 K it melts incongruently.

The Mo-Al-Si system. The phase equilibria and the ternary phases existing in the $Mo-Al-Si$ system have been studied by a number of authors.^{199,204,208-210} Two ternary compounds were found: $Mo(Si,Al)_2$ with the hexagonal structure of the $CrSi_2$ ($C40$) type, having a broad homogeneity region from $MoAl_{0.3}Si_{1.7}$ to $MoAlSi$, and $Mo(Si,Al)_2$ with a rhombic structure of the $TiSi_2$ ($C54$) type and a narrow homogeneity region (see Table 11). A continuous series of cubic solid solutions with the $A15$ type of

structure are formed over the Mo_3Al-Mo_3Si pseudobinary cross-section. The silicide Mo_5Si_3 dissolves up to 12 at.% of aluminium, which substitutes silicon. The limited solid solution of aluminium in Mo_5Si_3 with the highest content of aluminium (Mo_5Si_2Al) exists in equilibrium with a solid solution of the composition $Mo_3Al_{0.77}Si_{0.23}$ from the Mo_3Al-Mo_3Si continuous series of solid solutions.

The W-Al-Si system. The isothermal cross-section through the $W-Al-Si$ system at 1773 K has been reported.²⁰⁶ The tetragonal silicides W_5Si_3 and WSi_2 dissolve 4 at.% and 15 at.% of aluminium, respectively, thus forming the $W_5(Si,Al)_3$ and $W(Si,Al)_2$ limited solid solutions; a limited solid solution of aluminium and silicon in tungsten also exists in the $W-Al-Si$ system. In addition, there exists the $W(Al,Si)_2$ hexagonal ternary phase with the $CrSi_2$ ($C40$) structure. It possesses a broad homogeneity region from $WAl_{0.6}Si_{1.4}$ to $WAl_{1.4}Si_{0.6}$, the unit cell parameters increasing as the content of silicon decreases (see Table 11). The $W(Al,Si)_2$ hexagonal ternary phase is in equilibrium with aluminium and silicon, with the $W_5(Si,Al)_3$ and $W(Si,Al)_2$ limited tetragonal solid solutions [the α - $MoSi_2$ ($C11_b$) structural type], and also with WAl_2 and with tungsten [more precisely, with the limited solid solution of aluminium (~ 2 at.%) and silicon (~ 8 at.%) in tungsten].

The Mn-Al-Si system. Six ternary phases exist in this system at 1073 K,²¹¹ namely, γ - Mn_2Al_2Si , $MnAl_{1.3}Si_{0.7}$ (near γ - Mn_2Al_2Si), $MnAl_{0.75}Si_{1.25}$ ($Mn_3Al_2Si_4$) with the $CrSi_2$ ($C40$) type of structure, α - $Mn_3Al_{21}Si_5$, δ - $Mn(Si,Al)_4$, and Mn_3Al_9Si with a hexagonal structure (see Table 11). The Mn_3Al_9Si ternary phase results from the dissolution of silicon in Mn_3Al_{10} and is apparently an ordered solid solution of silicon in this compound [silicon atoms replace only those aluminium atoms, which occupy the $2(a)$ sites]. It has been shown²¹¹ that $MnSi$ dissolves up to 3 at.% of aluminium; however, in another study,²⁰¹ the solubility of aluminium in $MnSi$ has been found to reach 20 at.%. The silicide Mn_3Al_9Si exists in an equilibrium with γ - Mn_2Al_2Si , $Mn_3Al_2Si_4$, and δ - $Mn(Si,Al)_4$. The $Mn_3Al_2Si_4$ ternary phase forms pseudobinary equilibria with γ - Mn_2Al_2Si and δ - $Mn(Si,Al)_4$, whereas δ - $Mn(Si,Al)_4$ is in an equilibrium with α - $Mn_3Al_{21}Si_5$.

The Fe-Al-Si system. The $Fe-Al-Si$ system has been studied repeatedly. The superstructure $Fe_3(Al,Si)$ has been discovered in the homogeneity region of the solid solution of aluminium and silicon in iron.²¹⁶ The solid solution of iron and silicon in aluminium is in equilibrium with two ternary phases: $Fe_5Al_{20}Si_2$ (which has also been written as $Fe_5Al_{19}Si_2$, $Fe_3Al_{12}Si$, and α - $AlFeSi$) with a cubic^{213,214} or hexagonal²¹⁵ structure and the monoclinic²¹³ $Fe_2Al_9Si_2$. Other ternary phases are also known (see Table 11).

The compounds $FeAl_4Si_2$ and $FeAl_3Si_2$ ought to be identical, in view of the similarity of their unit cell dimensions. However, it has been found²¹⁷ that the lattice of $FeAl_3Si_2$ is a superstructure with respect to the tetragonal disordered phase of the same composition isostructural to $PdGa_5$.

The great number of ternary compounds with similar compositions and close unit cell dimensions indicates that the majority of the ternary phases in the $Fe-Al-Si$ system possess homogeneity regions. It is of interest that most of the ternary phases contain from 14 at.% to 25 at.% of iron.

The Co-Al-Si system. Two ternary phases have been found in this system:²¹⁸ $Co_3Al_3Si_4$ with a cubic structure of the Ir_3Ge_7 ($D8_7$) type and Co_2AlSi_2 with a hexagonal structure (see Table 11). In all probability, the Co_2AlSi_2 ternary phase exists in equilibrium with $CoSi$ and $Co_3Al_3Si_4$. Judging by the substantial alteration of unit cell parameters, Co_2AlSi_2 possesses a noticeable homogeneity region. The cobalt atoms in the $Co_3Al_3Si_4$ cubic ternary phase occupy the $12(e)$ sites, while the aluminium and silicon atoms are likely to be statistically distributed among the $12(d)$ and $16(f)$ sites; the predominant location of the aluminium atoms at the $12(d)$ sites, with the silicon atoms filling predominantly the $16(f)$ sites, should lead to a superstructure based on the Ir_3Ge_7 structural type.

The Ni–Al–Si system. Three ternary phases exist in this system at 1000 K:^{219, 220} Ni_4AlSi (there is no information concerning its structure), $\text{NiAl}_{0.5}\text{Si}_{0.5}$, and $\text{Ni}_3(\text{Al},\text{Si})_7$ with a high content of aluminium (see Table 11). The $\text{NiAl}_{0.5}\text{Si}_{0.5}$ ternary phase is in equilibrium with all the nickel silicides, with the aluminide NiAl , and with the $\text{Ni}_3(\text{Al},\text{Si})_7$ and Ni_4AlSi ternary phases; Ni_4AlSi is in equilibrium with the aluminides NiAl and Ni_3Al and with the silicide Ni_3Si , and $\text{Ni}_3(\text{Al},\text{Si})_7$ coexists with silicon, aluminium, NiAl_3 , Ni_2Al_3 , and NiSi_2 . At temperatures above 1370 K all the alloys in the Ni–Al–Si system containing less than 50 at. % of Ni are in the molten state.

VI. Phase equilibria in $X-X'-X''$ ternary systems ($X, X', X'' = \text{B, C, N, Si, Al}$)

The overwhelming majority of the currently existing oxygen-free ceramic materials are multicomponent systems and, apart from metals, they contain such elements as B, C, N, Si, or Al. Therefore, for understanding the equilibria in complex multicomponent systems, it is important to know what compounds and phase equilibria exist in simpler ternary systems formed by boron, carbon, nitrogen, silicon, and aluminium. The $X-X'-X''$ ternary systems ($X, X', X'' = \text{B, C, N, Si, Al}$) are constituents of $M-X-X'-X''$ four-component systems containing transition metals M . The $X-X'-X''$ ternary systems have not been adequately studied so far, and phase diagrams have not been constructed for all of them. The crystal-chemical characteristics of the ternary compounds found in these systems are listed in Table 12.

The Si–B–C system. The phase equilibria in the Si–B–C system have been studied at temperatures of 1973 K and 2173 K.²²⁹ At these temperatures, the silicon carbide SiC exists in an equilibrium with the silicon melt, with the boride SiB_6 , and with the carbides B_4C and B_{13}C_2 ; and the boron carbides coexist with SiB_6 and SiB_{12+x} (Fig. 37a). The $\text{SiC}-\text{B}_4\text{C}$ pseudobinary cross-section is an eutectic system. The composition of the eutectics is close to SiB_5C_2 and its melting point is ~ 2530 K. These data are in good agreement with the results obtained by Dokukina et al.²³⁰ As the temperature increases to 2273 K, the $\text{SiC}-\text{SiB}_6$ equilibrium disappears, and the carbide B_{13}C_2 coexists with the silicon and boron melt (Fig. 37b).

The authors of a number of studies^{51, 229, 230} of the Si–B–C system have not found the ternary compounds SiB_5C_2 and $\text{Si}_2\text{B}_3\text{C}_2$, which have been reported by Portnoi et al.²³¹

The Si–C–N system. The phase equilibria in the Si–C–N system have been studied at 1900 K and 2000 K at a nitrogen pressure of 1×10^5 Pa.^{232, 233} At 1900 K the silicon nitride Si_3N_4 exists in equilibrium with the silicon carbide SiC , cyanogen C_2N_2 , and carbon (Fig. 37c). As the temperature increases, the nitride Si_3N_4 reacts with carbon yielding the carbide SiC ; therefore, the $\text{SiC}-\text{C}_2\text{N}_2$ equilibrium arises instead of $\text{Si}_3\text{N}_4-\text{C}$ (Fig. 37d). The carbide $\beta\text{-SiC}$ forms the nitride Si_3N_4 on heating in nitrogen [$T = 2273$ K, $p_{\text{N}_2} = (1-30) \times 10^5$ Pa].²³²

The possible phase equilibria involving the carbon nitride $\beta\text{-C}_3\text{N}_4$ are shown by the dashed lines in the isothermal cross-sections through the Si–C–N system (Fig. 37c,d). This compound, the existence of which had been predicted,^{26-28, 234} has been recently discovered experimentally.²⁰

Data concerning the existence of the ternary compounds $\text{Si}_2\text{C}_2\text{N}$ and $\text{Si}_3\text{C}_3\text{N}$ have found no support. A number of researchers, who have studied this system, have not found any silicon carbonitrides.^{232, 233, 235}

The Al–Si–C system. Several ternary compounds have been found in this system (see Table 12). However, these data are very contradictory. For example, the existence of two modifications α - and $\beta\text{-Al}_4\text{SiC}_4$ has been reported.²³⁶ Later the existence of $\alpha\text{-Al}_4\text{SiC}_4$ has been confirmed;^{225, 228, 237} however, the β -modification was not found. The ternary compound $\text{Al}_4\text{Si}_2\text{C}_5$ has been reported by Inoue et al.,^{225, 226} however, it was not detected in another study.²²⁸ The hexagonal carborosilicide Al_8SiC_7 has been observed.^{227, 228} The aluminium carborosilicides Al_4SiC_4 and Al_8SiC_7 were found to decompose incongruently at 2353 and at 2358 K, respectively.²²⁸ Both ternary compounds are formed with great difficulty at relatively low temperatures (below 1800 K).

The isothermal cross-sections through the Al–Si–C system at 900 and 2273 K are presented in Fig. 37e,f. At 900 K (below the melting point of aluminium), silicon carbide exists in equilibrium with Al_4SiC_4 and Al, Al_4C_3 coexists with Al_8SiC_7 , and the ternary compounds are in equilibrium with each other, and also with carbon and aluminium (see Fig. 37e). When the liquid phase appears, silicon carbide and aluminium carborosilicides coexist with the aluminium melt (Fig. 37f).

Table 12. Some ternary compounds in the Al–B–C, Al–C–N, and Al–Si–C systems.

^a The carbonitrides $\text{Al}_9\text{C}_3\text{N}_5$ and $\text{Al}_{10}\text{C}_3\text{N}_6$ have not been observed experimentally, their hypothetical structural characteristics have been reported.²⁵

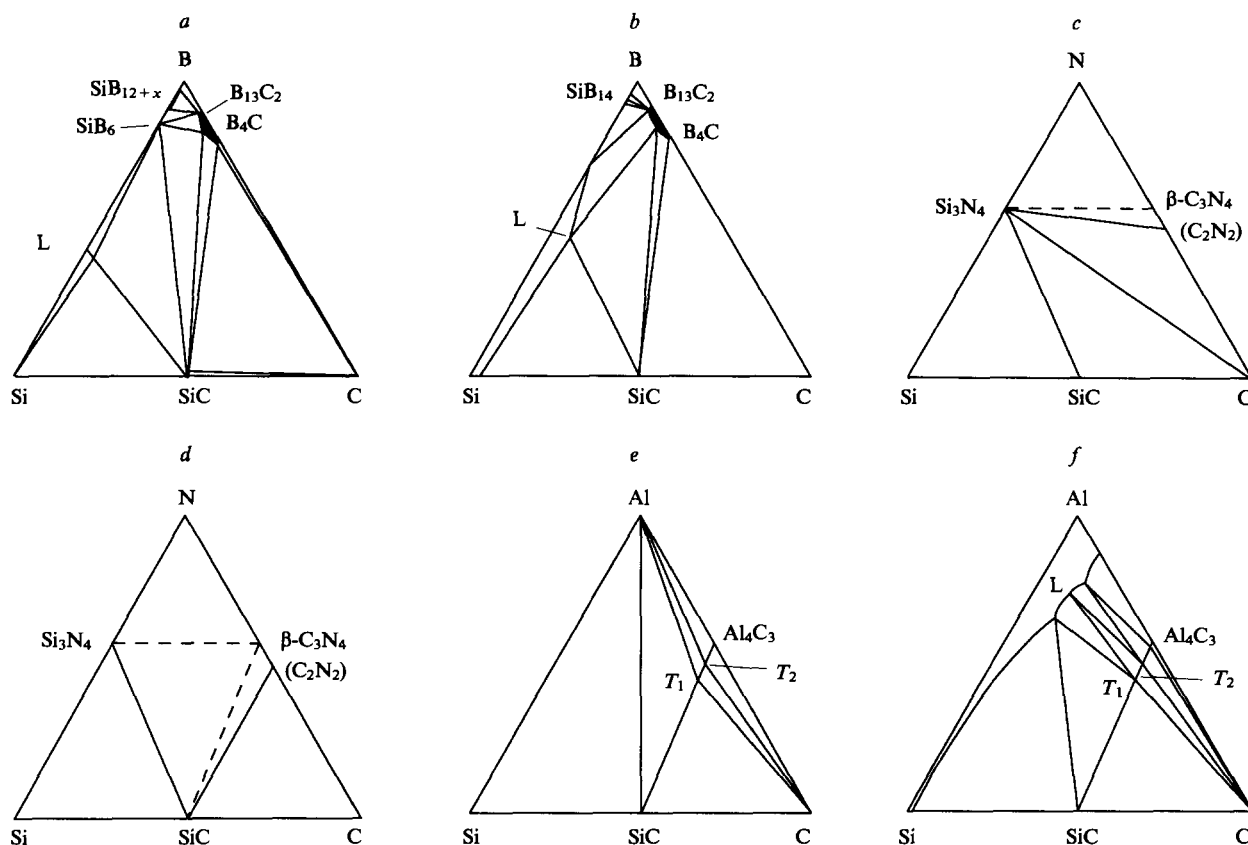

Figure 37. Isothermal cross-sections of ternary systems of silicon with boron, carbon, nitrogen, and aluminium (dark areas denote single-phase homogeneity regions). (a) the Si–B–C system at 1973 K; (b) the Si–B–C system at 2273 K; (c) the Si–C–N system at 1900 K;

$p_{N_2} = 1 \times 10^5$ Pa; (d) the Si–C–N system at 2000 K, $p_{N_2} = 1 \times 10^5$ Pa; (e) the Al–Si–C system at 900 K; (f) the Al–Si–C system at 2273 K; $T_1 = Al_4SiC_4$, $T_2 = Al_8SiC_7$.

The Si–B–N system. The silicon nitride Si_3N_4 in the Si–B–N system at temperatures below 1700 K coexists with the boron nitride BN and the boride SiB_6 ; the BN– SiB_{12+x} (SiB_{14}) pseudobinary equilibrium also exists (Fig. 38a).

The Al–Si–N system. The isothermal cross-section through the Al–Si–N system at 873 K is presented in Fig. 38b.²³⁸ The aluminium nitride AlN exists in equilibrium with Si and Si_3N_4 ; however, the Si_3N_4 –Al metastable equilibrium should also be taken into account. Its existence is caused by the following: the interaction of Si_3N_4 with aluminium leads to the appearance on the surface of aluminium grains of an AlN film, which acts as a diffusion barrier and prevents further occurrence of the reaction

even during prolonged annealing. No ternary compounds have been found in the Al–Si–N system.

The Al–B–C system. Several aluminium borocarbides have been found in this system (see Table 12). In all probability, the ternary compound $Al_8B_4C_7$ exists in equilibrium with the carbide Al_4C_3 and also with aluminium and carbon. The $AlB_{24}C_4$ phase observed by Will,²²¹ has the composition $Al_{2.1}B_{51}C_8$, according to Perotta et al.²²² The $Al_3B_{48}C_2$ phase exists at high temperatures as a tetragonal modification, which decomposes to two related orthorhombic phases of the same composition at $T < 800$ K (see Table 12).

The Al–C–N system. The carbide Al_4C_3 and the aluminium nitride AlN in the Al–C–N system form several ternary compounds, namely, aluminium carbonitrides $(Al_4C_3)(AlN)_n$, where $n = 1-4$ (see Table 12). The structures of aluminium carbonitrides have been studied.²⁵ The aluminium atoms in these ternary compounds form close-packed planes, the carbon and nitrogen atoms being arranged between these planes (the carbon atoms occupy the tetrahedral or octahedral interstices, while the nitrogen atoms populate only tetrahedral interstices). Thus, the Al_2C_2 , Al_2C , and AlN layers can be distinguished in the structure of aluminium carbonitrides. It has been suggested²⁵ that two other ternary compounds $Al_9C_3N_5$ and $Al_{10}C_3N_6$ also exist (see Table 12).

Aluminium carbonitrides are in equilibrium with aluminium and carbon as well as with the carbonitrides closest to them; Al_5C_3N is also in equilibrium with Al_4C_3 , and $Al_8C_3N_4$ coexists with AlN.

Figure 38. Isothermal cross-sections through the Si–B–N system (a) at 1700 K (the dark area denotes the single-phase homogeneity region of SiB_{12+x}) and through the Al–Si–N system at 873 K (b) (the dashed line marks a metastable equilibrium).

VII. Conclusion

The thermodynamic state of a multicomponent system containing several phases is described by a set of equations of state $\varphi(c, p, T)$ characterising each of the phases. The numerical values of the c , p , and T parameters unambiguously determine the state of the system, which is represented graphically as a point in the three-dimensional c , p , T system of coordinates. If two of these parameters are known, the third one can be found from the equation of state. This means that to determine the state of the system, it is sufficient to find the position of the figurative point in a two-dimensional system of coordinates, usually in the c, T -coordinates. This graphical representation of the equation of state of a system is its state diagram.

The real equations of state of multicomponent systems are unknown; therefore, the state diagrams are of great importance. By virtue of these diagrams, the actual relationship between the physical and chemical parameters determining the state of the system can be clearly represented on the basis of experimental data. Each characteristic of the system varies continuously as a function of one or several parameters within the limits of a particular phase region. The boundaries of phase regions are represented by singular points (inflection, break, or discontinuity points, cusps, etc.). Hence it is obvious, how important it is to know the positions of phase boundaries, which are the main information provided by state diagrams.

The problem of constructing state diagrams has been solved at present to a very small extent. In particular, no more than 5% of the state diagrams of ternary systems are known. In the present review, the author has attempted to generalise and to make available the results of experimental studies of the phase equilibria in the $M-X-X'$ and $M-Al-X$ ternary oxygen-free systems (M is a transition metal, X, X' are B, C, N, Si), which provide a basis for the development of new ceramic materials.

The greatest contribution to the systematic studies of phase diagrams of the ternary systems considered was made by scientists of the Austrian school: H Nowotny, W Jeitschko, F Benesovsky, E Rudy, P Rogl, J Schuster, and their colleagues.

It follows from the analysis performed that the interaction of a transition metal with the two other components of a $M-X-X'$ or $M-Al-X$ ternary system is often accompanied by the formation

of one or several ternary phases. This leads to a substantial complication of the phase equilibria, to the appearance of a large number of phase boundaries, and to the splitting of the state diagram into many phase fields. The allowance for these data will permit researchers to carry out the target-directed synthesis of compounds and heterogeneous compositions with specified properties.

The analysis of the crystal structures of the ternary compounds formed in the $M-X-X'$ or $M-Al-X$ systems considered has shown that an ideal or a distorted octahedron built of six transition metal atoms M is the main structural unit of the majority of these compounds. The octahedral interstice can be either occupied by an interstitial nonmetal atom X (B, C, N) or vacant. The possibility of the complete or partial population of the octahedral interstices causes the existence of the homogeneity regions (fairly broad or narrow) for many ternary compounds. Those of the considered ternary compounds, which incorporate the XM_6 octahedral units and possess homogeneity regions, constitute an extensive group of ternary nonstoichiometric interstitial compounds, which are related to the binary nonstoichiometric interstitial compounds MX_y and M_2X_y ($X = C, N$) with structures of the NaCl ($B1$) and W_2C ($L'3$) types. The ternary nonstoichiometric interstitial compounds have looser structures than the binary compounds, due to the presence of the third element, i.e. the V/n volume, which corresponds to one atom in the ternary compounds, is greater than in the binary compounds (V is the unit cell volume and n is the number of atoms in the unit cell).

In this connection, it is of interest to compare various carbide and nitride phases of the same transition metal differing in the X/M ratio of the atomic concentrations of the interstitial element and the metal. The titanium compounds, namely, the cubic Ti_3AlC and Ti_3AlN with the perovskite type of structure; the hexagonal Ti_2AlC and Ti_2AlN with a structure of the Cr_2AlC type; the hexagonal carbosilicide Ti_3SiC_2 and the trigonal aluminonitride $Ti_3Al_2N_2$; the cubic carbide $TiC_{1.0}$ and the cubic nitride $TiN_{1.0}$ with the NaCl ($B1$) type of structure (Table 13) can be considered as typical examples. Each pair of these compounds (except for Ti_3SiC_2 and $Ti_3Al_2N_2$) have the same structure. The structure of $Ti_3Al_2N_2$ differs from that of Ti_3SiC_2 in that in the former case, the double-stranded layers of the XTi_6 octahedra are separated by two layers of nontransition metal

Table 13. Interatomic distances in carbide and nitride phases of titanium with different degrees of filling of the titanium sublattice with interstitial atoms.

Stoichiometric composition	Symmetry and type of structure, space group	Unit cell parameters / nm		Interatomic distances / nm			V / nm^3	$V n^{-1} / \text{nm}^3$ (see ^a)
		a	c	Ti-C	Ti-Ti	Ti-N		
Ti_3AlC	Cubic, perovskite $CaTiO_3$ type, space group $Pm\bar{3}m$	0.4156	—	0.208	0.294	—	0.0718	0.0144
Ti_2AlC	Hexagonal H -phase, the Cr_2AlC type, space group $P6_3/mmc$	0.304	1.360	0.212	0.292	—	0.1088	0.0136
Ti_3SiC_2	Hexagonal, space group $P6_3/mmc$	0.3068	1.7669	0.215	0.297	—	0.1440	0.0120
$TiC_{1.0}$	Cubic, the NaCl ($B1$), type, space group $Fm\bar{3}m$	0.4328	—	0.216	0.306	—	0.0811	0.0101
Ti_3AlN	Cubic, the perovskite $CaTiO_3$ type ($E2_1$), space group $Pm\bar{3}m$	0.4120	—	—	0.291	0.206	0.0699	0.0140
Ti_2AlN	Hexagonal H -phase, the Cr_2AlC type, space group $P6_3/mmc$	0.2991	1.3621	—	0.290	0.208	0.1055	0.0132
$Ti_3Al_2N_2$	Trigonal, space group $P31c$	0.2988	2.3350	—	0.297	0.209	0.1805	0.0129
$TiN_{1.0}$	Cubic, the NaCl ($B1$), type, space group $Fm\bar{3}m$	0.4244	—	—	0.300	0.213	0.0764	0.0096

^a V is the unit cell volume, n is the number of atoms in the unit cell.

atoms, whereas in Ti_3SiC_2 , they are separated by one layer of nontransition element atoms.

A general feature of the structures of all these compounds is that the interstitial atoms (carbon or nitrogen) are located at the octahedral interstices formed by six transition metal atoms. In the compounds with an ideal stoichiometric composition, all the octahedral vacancies are filled with the interstitial atoms. The structures of the compounds under consideration differ in the manner in which the XM_6 octahedra are linked to one another. In the compounds $\text{M}_3\text{M}'\text{X}$ the octahedra are joined via all their six vertices (see Fig. 23); in the $\text{M}_2\text{M}'\text{X}$ *H*-phases, each octahedron is linked to the adjacent octahedra via six edges thus forming an octahedral layer of the composition M_2X (see Fig. 24); in the next pair of compounds, namely, Ti_3SiC_2 and $\text{Ti}_3\text{Al}_2\text{N}_2$, the XM_6 octahedra are joined with one another via nine edges thus forming a double octahedral layer of the composition M_3X_2 (see Fig. 14); finally, the XM_6 octahedra in the cubic carbides and nitrides $\text{MX}_{1.0}$ are joined via all their twelve edges and form the closest packing (see Fig. 1).

In the sequence $\text{M}_3\text{M}'\text{X} \rightarrow \text{M}_2\text{M}'\text{X} \rightarrow \text{M}_3\text{M}'\text{X}_2$ ($\text{M}_3\text{M}'_2\text{X}_2$) $\rightarrow \text{MX}$ the X/M ratio increases in the following way: $\frac{1}{3} \rightarrow \frac{1}{2} \rightarrow \frac{2}{3} \rightarrow 1$, which indicates an increase of the degree of filling of the transition metal sublattice with the interstitial atoms. For the cubic carbides and nitrides MX_y , the increase in the degree of filling of the octahedral vacancies of the metallic sublattice (i.e. the increase in the content of interstitial atoms) is accompanied by an increase in the period of the crystal lattice and by an increase in the interatomic distances. By analogy with the cubic carbides and nitrides MX_y , one may expect a similar variation of the interatomic distances and a similar decrease in the V/n volume corresponding to one atom in the sequence $\text{M}_3\text{M}'\text{X} \rightarrow \text{M}_2\text{M}'\text{X} \rightarrow \text{M}_3\text{M}'_2\text{X}_2$ ($\text{M}_3\text{M}'_2\text{X}_2$) $\rightarrow \text{MX}$.

Table 13 presents the Ti–X and Ti–Ti interatomic distances and the V/n volume for the binary and ternary titanium compounds considered as examples. With an increase in the X/M ratio the Ti–C interatomic distances in the series of carbide phases and the Ti–N distances in the series of nitride phases increase monotonically, whereas the V/n volume decreases. A similar increase is observed for the Ti–Ti interatomic distances, except for those in the *H*-phases.

Thus, the majority of the compounds of transition metals with B, C, N, Si, and Al retain the octahedral fragment consisting of six transition metal atoms M as the main structural unit; this fragment is either vacant or filled with interstitial nonmetal atoms. The atoms of the third element make the structure of the ternary compound more complex and more loose than the structure of the corresponding binary compound of the transition metal.

The ternary compounds with the homogeneity regions discussed in this review can exist in two structural states, namely, the disordered and the ordered state. In the former case, the interstitial atoms are randomly distributed among the octahedral interstices, and in the latter case, they are regularly distributed. The ordering phenomenon in the binary nonstoichiometric interstitial compounds has been studied fairly extensively^{1,2,6,239,240} however, ordering in the ternary nonstoichiometric compounds and its influence on the properties of these compounds are scarcely known. It may be expected that the investigation of the ordering effects will become one of the major directions in the research on ternary nonstoichiometric compounds of transition metals with boron, carbon, nitrogen, silicon, and aluminium.

The work was supported by the Russian Foundation for Basic Research (project 95-02-03549a) and the State scientific and technical programme 'New materials' (project 07.02.0103m).

Abstract. The results of studies on the use of sulfenamides in organic synthesis are systematised and generalised. The fields of industrial application of sulfenamides are considered. The bibliography includes 220 references.

I. Introduction

The wide application of sulfenamides in fine organic synthesis is due to the specific features of their structure and reactivity, namely, to the existence of two active reaction centres (S and N), one of them having variable valence, and to the instability of the S–N bond which can rather readily be cleaved by both nucleophiles and electrophiles. High lability of this bond allows one to remove the sulfenyl moiety of the sulfenamide function, which is frequently used as a protective group in peptide synthesis,^{1,2} and in natural product syntheses,^{3,4} at a certain stage of synthesis. Elimination of the sulfenyl moiety occurs under sufficiently mild conditions by hydrochlorolysis or thiolysis of the S–N bond.

On the other hand, the high lability of the S–N bond enables the sulfenamide function to be used for the introduction of a sulfenyl fragment into organic compounds under relatively mild conditions in multistep organic syntheses. Thus, the sulfenylation of 4-*tert*-butylcyclohexanone with chiral *N*-phenylthio- α -naphthylethylamine gives 62% of a diastereomeric mixture of the corresponding sulfides.⁵ The reduction of this mixture with NaBH₄, subsequent tosylation and elimination of toluene-*p*-sulfonic acid gives a mixture of unsaturated sulfides with an isomer of *S*-configuration being predominant.

Yet another specific feature of sulfenamides is their tendency to generate both relatively stable and highly reactive intermediates (aminyl and sulfenyl radicals, radical cations, nitrenes, etc.) that participate in the transfer of sulfenyl and aminyl groups and in some other processes. The ability of the sulfur atom in sulfenamides to pass relatively readily from one valence state to another, as well as to increase its electron density at the expense of its shift from the adjacent *N*-anionic centre, is often used for the synthesis of compounds possessing four- and six-valent sulfur, for example, sulfur-containing imino compounds.

Bifunctional sulfenamides, i.e., sulfenamides containing both sulfenamide and other functional groups (Cl, Br, CCl₃, CF₂Cl, etc.) are synthetically very important. Based on such

Received 15 August 1995

Uspekhi Khimii 65 (5) 452–473 (1996); translated by A V Geiderikh

sulfenamides, many preparative methods for the synthesis of various sulfur and nitrogen-containing heterocyclic compounds have been developed.

The primary products of sulfenamide transformations, such as aminosulfonium, thioammonium and sodium salts, are also widely used in organic synthesis, and numerous synthetic routes involve the conversion of sulfenamides to these products with their subsequent transformation without isolation from the reaction mixture.

In addition to fine organic synthesis, some sulfenamides are widely used in polymer chemistry, in agriculture, in the rubber industry, etc. These aspects are also considered in the present review.

II. Methods of sulfenylamide synthesis

1. Syntheses based on elemental sulfur

Elemental sulfur is not often used directly in the synthesis of sulfenamides because it has to be preactivated,⁶ or highly reactive reagents have to be used. Probably only one example of the direct use of sulfur in sulfenamide synthesis, involving the interaction of elemental sulfur with various nitrobenzenes in liquid ammonia, has been described.⁷ The reaction is accompanied by formation of the corresponding disulfides and sulfides, which is a drawback of the method.

2. Syntheses based on sulfenyl chlorides

The use of sulfenyl chlorides in the synthesis of sulfenamides is based on three main reactions:

(a) the sulfenylation of compounds containing N—H or N—X bonds (X = Li, Na, K, Ag, Me₃Si);

(b) the sulfenylation of inorganic isocyanates and the subsequent interaction of sulfenyl isocyanates with amines and alcohols;

(c) the addition of sulfenyl chlorides to the C=N or C≡N bond.

Based on these reactions, various preparative methods of sulfenamide synthesis have been developed. They are described in the published reviews,^{8,9} and in the references cited in them. Later publications^{10–21} are mostly devoted to the perfection of these methods and to the expansion of the scope of their application.

3. Syntheses based on thiols

Amination of thiols with *N*-halo compounds, amines in the presence of oxidising reagents, sodium hydroxylaminosulfonate, and with other iminating reagents is the basis for a series of preparative methods of synthesis of unsubstituted and *N*-substituted sulfenamides (see review²² and the references cited therein). The amination of thiols can also be performed using azides²³ in the presence of cuprous salts. The formation of disulfides and amines as side products is a drawback of the method.

$R^1 = \text{Bu, Bz}; R^2 = \text{BuCO, HCO}$

A two-step synthesis of sulfenamides from thiols, *p*-aminophenol, and nitrogen dioxide has been described.²⁴ The first step involves the interaction of thiols with N₂O₄ to yield alkylsulfenyl nitrenes which then react with *p*-aminophenol (the second step).

4. Syntheses based on disulfides

There are several methods of sulfenamide synthesis based on disulfides. One of them involves the interaction of disulfides with ammonia or amines in the presence of silver acetate or nitrate, or mercuric chloride in alkaline medium.^{25, 26}

$R^1 = \text{Alk, Ar, Het}; R^2 = \text{H, Alk, Ar};$

$MX = \text{AgNO}_3, \text{AgOAc, HgCl}_2$

It is supposed²⁶ that a complex of disulfide with a metal is formed initially, which then undergoes nucleophilic attack by ammonia or amines to produce the sulfenamide and other products. The reaction is performed in methanol or ethyl acetate by treating equimolar amounts of disulfide and a metal salt with an excess of ammonia or the amine. The best yields of sulfenamides (60%–80%) were obtained with aromatic disulfides.

The second method of sulfenamide synthesis from disulfides is based on their reaction with *N*-halo compounds.

$R = \text{Alk, Ar}; X = \text{Cl, Br}$

The reaction occurs by a radical mechanism, which involves the homolysis of the N—X bond and the interaction of the N·-radical formed with the disulfide.

$X = \text{Cl, Br}$

To bind sulfenyl halides, pyridine, triethylamine, and other reagents are used. *N*-Chloro- and *N*-bromosuccinimide,²⁷ *N*-chlorophthalimide,²⁷ *N*-chloroformamidoyl chloride,²⁷ alkyl *N*-chlorobenzenecarboximidates,²⁸ *N*-chloroimino-carbonates,²⁸ *N*-chlorobenzamide,²⁹ and *N*-chlorodialkylamines³⁰ react with disulfides according to this scheme. Sodium *N*-chlorosulfonamides react with disulfides in non-aqueous media to give sulfenamides of the general formula RSN(SO₂Ar)X [$X = \text{S(R)}=\text{NSO}_2\text{Ar}$]³¹ which can also be obtained by the reaction of sodium thiolates with dichlorosulfon-

$\text{Ar} = \text{Ph, 4-MeC}_6\text{H}_4$

amides.³²

The third method of sulfenamide synthesis from disulfides is their decomposition in the presence of lithium amides,³³ the yield of sulfenamides being as high as 62%–96%. As side products, Li thiolates are formed, which sometimes hinder the isolation of the target sulfenamides.

$R^1 = Pr^n, Ph; R^2 = H, Et, Pr^n, Pr^i, Bu^i;$
 $R^3 = Et, Pr^n, Pr^i, Bu$

5. Syntheses based on arylsulfenates, sulfonyl thiocyanates, and thiosulfonates

Sulfenamides are obtained in high yields by the sulfonylation of primary and secondary amines with esters of sulfenic acids.^{23, 34}

$R^1 = Pr, Ph; R^2 = H, Me, Et, Pr, Bu, Ph$

The use of sulfenates instead of sulfonyl chlorides as sulfonylation agents is sometimes preferable, in particular, if a substrate contains other highly reactive functional groups which are unstable toward sulfonyl chlorides. For example, trimethylsilyl derivatives of amines preserve the trimethylsilyl group upon interaction with sulfenates.³⁴

The possibility of using thiosulfonates for sulfenamide synthesis was first demonstrated by the sulfonylation of aromatic amines with *S*-(2-nitrophenyl) benzenethiosulfonate.^{23, 34} In this case the corresponding *N*-aryl-2-nitrobenzenesulfenamides were obtained in relatively good yields.

The reaction of *S*-(2-nitrophenyl) benzenethiosulfonate with sodium *N*-chlorobenzenesulfonamide to give *N*-(2-nitrophenylthio)benzenesulfonamide has been described.³⁵

A series of *N,N*-dialkylsulfenamides have been obtained by the interaction of sulfonyl thiocyanates with a twofold excess of dialkylamine in ether.³⁶

$R^1 = Ph, Et, Pr, Bu; R^2 = Et, Bu^i$

The possibility of using inorganic thiocyanates for the synthesis of sulfenamides has been demonstrated.³⁷ In particular, ammonium thiocyanate gives the corresponding sulfenamides on treatment with alkyl- and dialkylchloroamines.

6. Syntheses based on *N*-chlorothio-compounds

Two main routes of sulfenamide synthesis based on *N*-chlorothio-compounds have been developed. The first one involves the addition of *N*-chlorothio-compounds to C=C and C≡C multiple bonds. For example, *N*-(chlorothio)dichloroketimine adds to the C=C bond of cyclohexene to give 80% of the corresponding sulfenamide.³⁸

The addition of *N*-(chlorothio)dimethylamine to unsymmetrical alkenes in the presence of iodine was shown³⁹ to be anti-Markovnikov with subsequent isomerisation of the adducts formed to more stable sulfenamides.

A series of *N,N*-disubstituted vinylsulfenamides was obtained by the addition of *N*-(chlorothio)dialkylamines⁴⁰ and *N*-(chlorothio)phthalimide^{41–43} at the C≡C bond of alkynes.

$R^1 = Me, Et, Bu^i, Ph; R^2 = H, Me, Ph; R^3 = Me, Et$

The second method of sulfenamide synthesis based on *N*-chlorothio-compounds is the treatment of CH-acids or their salts with *N*-chlorothio-compounds. For example, a series of *N,N*-(dialkyl)phenylacetylenesulfenamides has been synthesised by the interaction of *N*-(chlorothio)dialkylamines with lithium phenylacetylide.⁴⁰

$R = Me, Et$

In the reaction of *N*-(chlorothio)phthalimide with dicarbonyl compounds containing activated C–H bonds sulfenamides are formed relatively readily and in high yields.^{44, 45}

The synthesis of *N*-methyl-*N*-tosylchloromethanesulfenamide from *N*-(chlorothio)methyltosylamine and diazomethane has been reported.³⁸

7. Syntheses based on sulfur imino compounds

a. Syntheses based on sulfinimines

The ability of the S^{IV} atom in sulfinimines to undergo rather easy conversion to the bivalent state can be used in the syntheses of sulfenamides. Several synthetic routes have been developed depending on the structure of the initial sulfinimines. One of them is based on the [2,3]-sigmatropic rearrangement of *S*-allylsulfinimines, which involves migration of the allyl group from the sulfur to the nitrogen atom to produce the *N*-substituted sulfenamides.^{32, 46}

The tendency of *S*-allylsulfinimines to rearrange into more stable *N*-substituted sulfenamides is so pronounced that sometimes they cannot be isolated. For example, the reaction of nitrenes, obtained on treatment of *N*-amino-compounds with lead tetraacetate, with allyl aryl sulfides gave not *S*-allyl-*S*-arylsulfinimines, but the corresponding *N*-substituted sulfenamides.⁴⁷⁻⁵⁰

The second route for the synthesis of sulfenamides based on sulfinimines is the thermal rearrangement of *S*-alkylsulfinimines which contain a β -H-atom^{46, 51} (a thermal cycloelimination of alkenes from sulfinimines).

$R^1 = \text{Ar, Alk}; R^2 = \text{H, Me}; R^3 = \text{Ar, MeCO}$

The reaction occurs under relatively mild conditions and leads to sulfenamides in good yields. One shortcoming of this method is the possible formation of a mixture of two sulfenamides from sulfinimines containing two different alkyl groups at the sulfur atom, as, for example, in the thermolysis of *N*-tosyl-*S*-*tert*-butyl-*S*-isopropylsulfinimines.⁵² *N*-Unsubstituted alkane- and arene-sulfenamides,⁵² as well as a series of *N*-substituted sulfenamides with aryl,^{53, 54} tosyl,⁵¹ ethoxycarbonyl,⁴⁶ and carbamoyl⁴⁶ substituents were obtained by thermal cycloelimination of alkenes from sulfinimines.

The third method of sulfenamide synthesis from sulfinimines is their reductive decomposition in the presence of thiolate anions. This reaction occurs on heating in DMF.⁵⁵

One drawback of this method is the formation of sulfides as side products, which complicates the isolation of the sulfenamides.

On the other hand, an excess of thiolate can favour the decomposition of the sulfenamide formed.

b. Syntheses based on derivatives of sulfinimide acids

Some amides of sulfinimide acids undergo reductive cleavage in the presence of thiophenols to give sulfenamides. For example, the reductive cleavage of *p*-nitrobenzenesulfinimido amide in the presence of *p*-chlorothiophenol gives a mixture of two sulfenamides.⁵⁶

The reductive cleavage of imidodihydrothiazine, which can be considered as a cyclic amide of sulfinimide acid, leads to amino-butenesulfenamides in 65%–95% yields.⁵⁷

$\text{Ar} = 4\text{-ClC}_6\text{H}_4, 4\text{-MeC}_6\text{H}_4$

Sulfinimido chlorides react in a similar manner in the presence of thiophenols.⁵⁷

$R^1 = \text{NO}_2; R^2 = \text{PhSO}_2, \text{PhCO}$

The reductive cleavage of sulfinimido chlorides to yield sulfenamides occurs also on treatment with some CH-acids.⁵⁸

$R^1 = \text{Me, NO}_2; R^2 = \text{PhSO}_2, \text{PhCO, EtOCO}$

8. Electrochemical methods of synthesis of sulfenamides

N,N-Disubstituted benzothiazolesulfenamides were obtained by electrolysis of a 2-mercaptobenzothiazole-amine or bisbenzothiazol-2-yl disulfide-amine system in 70%–98% yield.⁵⁹

The electrolysis was performed with platinum electrodes in DMF in the presence of triethylammonium perchlorate. Under similar conditions, sulfenamides are formed from tetraalkylthiuramdisulfide, diphenyldisulfide, di-*tert*-butyl-disulfide, and dibenzyl-disulfide.⁶⁰ The electrolysis of a disulfide-phthalimide and disulfide-succinimide system in the presence of NaBr in acetonitrile⁶⁰ gives the corresponding sulfenamides

The mechanism of formation of these sulfenamides is believed⁶⁰ to involve a nucleophilic attack of the disulfide on the intermediate *N*-bromoisimide.

9. Modification of sulfenamides

The change of sulfenamide structures by chemical modification of substituents at the sulfur and nitrogen atoms, as well as by the complete replacement of the amide or sulfonyl moieties, is the basis of methods for synthesising new types of sulfenamides. Chemical modification of the amide group of *N*-unsubstituted sulfenamides is the most common. The relatively high nucleophilicity of the nitrogen atom of the NH₂ group, as well as the availability of two active H atoms permit various chemical transformations. They are based on condensation with carbonyl compounds,⁶¹⁻⁶³ acylation,^{23,64,65} sulfonylation,⁸ phosphorylation,^{23,66} etc.³⁴ Some examples of such reactions are given below.

The modification of substituents at the nitrogen atom of sulfenamides,^{34,67-70} or their complete substitution by other substituents^{34,71-74} are also often used in the synthesis of new sulfenamides.

The chemical modification of radicals at the sulfur atom is not so frequently used for the synthesis of new sulfenamides. The substitution of one or two chlorine atoms by fluorine in *N,N*-(diethyl)trichloromethanesulfenamide using antimony trifluoride is an example of such modification.⁸

The thermolytic modification of the dichlorofluoromethyl group in *N*-(benzothiazole-2-yl)dichlorofluoromethanesulfenamide has been described.³⁸

The complete substitution of the amide moiety can be performed on transamidation of sulfenamides in their interaction with *N*-nucleophiles whose nucleophilicity is higher than that of the amide moiety.^{23, 32, 34}

$\text{R}^1 = \text{Me, Et, Ph}; \text{R}^2 = \text{Me, Et}; \text{R}^3 = \text{Et, Pr}^i$

$\text{R}^1 = \text{CCl}_3, \text{Ph}; \text{R}^2 = \text{R}^3 = \text{Me}; \text{R}^4 = \text{H, Ph};$
 $\text{R}^5 = \text{PhCH}_2; \text{R}^4 + \text{R}^5 = -(\text{CH}_2)_3-$

$\text{Ar} = \text{Ph, 4-MeC}_6\text{H}_4$

The replacement of the sulfenyl fragment in sulfenamides can result from the so called 'transsulfenylation', which involves the mutual exchange of sulfenyl groups between sulfenamides and other compounds containing these groups. For example, transsulfenylation of sulfenamides by esters of thiosulfonic acids has been described.⁷⁵

The mutual exchange of sulfenyl groups was observed upon photolysis of a mixture of two sulfenamides.⁷⁶ The photolysis is a radical process and involves the following transformations:

10. Other methods

a. The sigmatropic rearrangement of the products of the reaction of 3-hydroxy-2-phenyl-4-thioxo-3,4-dihydroquinazoline with diarylimidoyl chlorides.⁷⁷

b. The reaction of carbon disulfide with amines and *N*-chloroamines.⁷⁸

c. The addition of the products of sulfur trioxide insertion at the S-N bond of diaminosulfides to alkenes.⁷⁹

d. The interaction of alkylthiirane-S-oxides with lithium hexamethyldisilazide [Li(HMDSA)] and trimethylsilyl chloride.⁸⁰

III. The application of sulfenamides in organic synthesis

1. Synthesis of sulfides

Several basic methods of synthesis of sulfides from sulfenamides have been developed. One of them is based on the sulfonylation of CH-acids or their salts with both substituted and *N*-unsubstituted sulfenamides. The sulfenamides are milder sulfonylating agents than sulfonyl halides; this fact allows their use in reactions with CH-acids which contain multiple bonds or functional groups which are vulnerable to sulfonyl halides. For example, the reaction of *p*-nitrobenzenesulfenamide with a 2,4,6-trimethylpyrylium salt produces the corresponding sulfide.⁸¹

Sulfides are also obtained relatively smoothly and in good yields in the reaction of *N,N*-(dialkyl)arenesulfenamides with disubstituted methanes containing strong electron-withdrawing groups, such as CN, PhCO, MeCO, EtOCO, etc.⁸²

X	Y
CN	CN
PhCO	PhCO
MeCO	MeCO
MeCO	EtOCO
EtOCO	EtOCO

Excess of the sulfenamide can induce substitution of the second hydrogen atom of the CH-acid by the arylthio group.²³

The synthesis of unsaturated sulfides by the sulfonylation of chlorosulfonium salts containing activated CH-bonds with sulfenamides has been described.⁸³

The second method of sulfide synthesis from sulfenamides involves the addition of sulfenamides at the C=C bond of unsaturated compounds. This method is widely used for the synthesis of functionally substituted sulfides; several modifications of the method are known. The first one is the interaction of sulfenamides with alkenes in the presence of activating agents (Me₃O⁺BF₄⁻, Et₂O·BF₃, CF₃SO₃H, etc.). The role of the activating agents is to increase the electrophilic properties of the sulfur atom in the initial sulfenamide, and to stabilise the intermediates formed. For example, the aminosulfonylation of cyclopentene and 3,4-dihydro-2*H*-pyran with *N,N*-(dimethyl)methanesulfenamide occurs rather smoothly in nitromethane in the presence of trimethyloxonium tetrafluoroborate.^{84, 85}

The addition of *N*-substituted benzenesulfenamides at the C=C bond of cyclohexene in the presence of trifluoromethanesulfonic acid has been described.⁸⁶

R¹ = H, R² = Bu^t; R¹ + R² = -(CH₂)₅-, -(CH₂)₂O(CH₂)₂-

Under analogous conditions, these sulfenamides add at the C=C bond of octene and indene.⁸⁶ *N*-(Aryl)benzenesulfenamides readily react with cyclohexene in the presence of boron trifluoride etherate to give the corresponding aminosulfides in 50%–90% yields.⁸⁷

Ar = 4-NO₂C₆H₄, 4-ClC₆H₄, 4-MeC₆H₄, 4-MeOC₆H₄, 3-MeOC₆H₄

The sulfenamides PhSN(X)Ts [X = S(Ph)=NTs] add at the C=C bond of cyclohexene under acidic activation conditions to yield *N*-disubstituted aminosulfides.⁸⁸

X = S(Ph)=NTs

According to the second route, the participation of an external nucleophile in the reaction is envisaged, which provides a fragment substituting the amino group in the adduct. This route was first realised in the reaction of *N,N*-diacetyl-*p*-nitrobenzenesulfenamide with cyclohexene in the presence of trifluoroacetic acid.⁸⁸

Apparently, in this case, an episulfonium intermediate is formed initially⁸⁴ in which ring-opening by trifluoroacetate anion leads to a *trans*-adduct. Thus, trifluoroacetic acid acts as both the activator and the external nucleophile. Likewise, boron trifluoride etherate has a double function in reactions of arene-sulfenamides with norbornene⁸⁹ and norbornadiene.⁹⁰ The addition is accompanied by the rearrangement of the carbon skeleton resulting in a mixture of several products.

Ar = 2-O₂NC₆H₄; 2,4-(O₂N)₂C₆H₃; X = O, CH₂

Ar = 2,4-(O₂N)₂C₆H₃

Two reagents are generally used to accomplish the addition of sulfenamides to unsaturated compounds, one of them being an activator, and the other an external nucleophile. For example, the addition of *N*-substituted benzenesulfenamides to cyclohexene in the presence of trifluoromethanesulfonic acid and nitriles has been reported^{91,92} to give sulfides with the amidine fragments. In this case, nitriles act as external nucleophiles.

R¹ = R² = cyclo-C₆H₁₁; R¹ + R² = -(CH₂)₂O(CH₂)₂-;
R¹ = H, R² = Bu; R³ = Me, Et; R⁴ = Ph

The synthesis of sulfides of general formula R¹HN.C(Me)=NC(R²)=C(R³)SPh with an acetamidine fragment (R¹ = Ph, 4-O₂NC₆H₄, 4-ClC₆H₄, 4-MeC₆H₄, 4-MeOC₆H₄; R² = H, Me, Et; R³ = Me, Et, Pr, Bu) using the addition of *N*-(aryl)benzenesulfenamides to the corresponding alkynes in acetonitrile in the presence of boron trifluoride etherate has been described.⁹³

The addition of *N*-(*p*-nitrophenyl)benzenesulfenamide to alkynes R¹C≡CR² (R¹ = H, R² = Me; R¹ = H, R² = Bu^t; R¹ = H, R² = Pr; R¹ = H, R² = Bu; R¹ = Me, R² = Pr; R¹ = R² = Me;

R¹ = R² = Et; R¹ = R² = Pr; R¹ = H, R² = Ph; R¹ = Me, R² = Ph; R¹ = Et, R² = Ph; R¹ = R² = Ph) in acetic acid in the presence of boron trifluoride etherate is a stereospecific reaction, which results in a mixture of two products, (*E*)-R²C(OAc)=C(R¹)SPh and (*E*)-R¹C(OAc)=C(R²)SPh, in total yields of 30%–80%.^{94,95}

The third route to sulfides by the addition of sulfenamides at multiple bonds involves enhancement of the sulfur atom electrophilicity by insertion of sulfur trioxide into the S–N bond of sulfenamides with the subsequent addition of the insertion product to the C=C bond of alkenes (that is, sulfamatosulfonylation of alkenes).⁹⁶ For example, the addition of *N,N*-(diethyl)benzenesulfenamide to cyclohexene in the presence of sulfur trioxide in chloroform yields a *trans*-1,2-adduct, which is converted to the corresponding functionally substituted sulfide upon treatment with acid.⁹⁷

X = Br, MeCOO, CF₃COO, HCOO

The sulfamatosulfonylation of norbornene and norbornadiene⁹⁸ is accompanied by rearrangement of the carbon skeleton and results in a mixture of different sulfides that are difficult to separate. The use of pyridine–sulfur trioxide as a donor of SO₃ allows one to perform the sulfamatosulfonylation of alkenes at ambient temperature.⁹⁹ The addition of sulfenamides to alkenes in the presence of sulfamic acid^{100,101} and potassium persulfate¹⁰² has also been studied.

Yet another method of sulfide synthesis from sulfenamides which should be mentioned involves thermal decomposition of arylthioazo compounds.¹⁰³

R¹ = 4-NCC₆H₄, 4-O₂NC₆H₄; R² = Bu^t, Ph

The thermolysis is believed¹⁰³ to occur by aromatic nucleophilic substitution (*S_{NR}1*) through the intermediate radical anion [R¹N=NSR²]^{·-}. The formation of sulfides, together with other products, was observed¹⁰⁴ in the reaction of sulfenamides with alcohols in the presence of trialkylphosphites.

2. Synthesis of sulfonyl halides

The treatment of sulfenamides with hydrogen halides in anhydrous organic solvents yields the corresponding sulfonyl halides.

The reaction has preparative value, but it is not often used for the synthesis of sulfonyl halides, because the starting sulfenamides are usually synthesised from the same sulfonyl halides, to which they are then converted. The transformation of a sulfonyl halide function to sulfenamide followed by cleavage of the S–N bond with gaseous hydrogen halide is used as a synthetic method in the modification of a sulfonyl halide aimed at protecting the sulfonyl

halide function,⁸ as well as in peptide synthesis, in which the sulfenyl fragment acts as a protective group. 2-Nitrobenzenesulfenyl chloride forms crystalline sulfenamide derivatives with amino acids, which can rather readily be cleaved in the presence of hydrogen chloride; this appeared to be of particular value in peptide synthesis.¹⁰⁵ The triphenylmethanesulfenyl group is also successfully used as a protective group in the synthesis of alkaloids.³⁴

3. Synthesis of disulfides

Thermolysis, thiolysis, and hydrolysis of sulfenamides are the most common processes for the practical synthesis of disulfides among a wide range of reactions of sulfenamides that give disulfides. The homolytic cleavage of the S–N bond upon the heating of sulfenamides gives thiyl radicals which recombine to disulfides. The choice of thermolysis conditions depends both on the basicity and the structure of the initial sulfenamides. For example, the thermolysis of tri(phenylsulfenyl)amine occurs under rather mild conditions at ~50 °C to yield diphenyldisulfide.¹⁰⁶

The thermolysis of *N*-(aryl)benzenesulfenamides requires more severe conditions, the products being diaryldisulfides and azobenzene.¹⁰⁷

The homolytic cleavage of the S–N bond with the subsequent recombination of the thiyl radicals formed was observed during the anodic oxidation of *N*-(2-nitrophenylthio)morpholine in acetonitrile in the presence of NaClO.¹⁰⁸

The thiolysis of sulfenamides is used in the synthesis of both symmetrical and unsymmetrical disulfides. Nucleophilic substitution of the amide group at the sulfur atom of sulfenamides by an alkyl- or arylthio group occurs upon their interaction with thiols^{34, 109} or thiolates,¹¹⁰ thioacids,¹¹¹ alkyl- or arylthiosilanes.¹¹²

However, the synthesis of unsymmetrical disulfides is accompanied by the formation of a small amount of symmetrical ones,¹⁰⁹ this being the drawback of the method.

The hydrolysis of sulfenamides in acid-alcoholic media results in the formation of symmetrical disulfides.²³ They are, apparently, disproportionation products of sulfenic acids that are formed at the first stage of the hydrolysis.

Symmetrical disulfides are also formed upon decomposition of thioammonium salts resulting from the alkylation of sulfenamides with alkyl halides or trialkyloxonium salts.¹¹³

4. Synthesis of sulfenic esters

N,N-Disubstituted sulfenamides having strong electron withdrawing substituents relatively readily undergo alcoholysis in the presence of alkoxides. Alkyl sulfenates are produced in this way. For this purpose, *N*-(alkylthio)phthalimides^{114, 115} are most frequently used. They react with alkoxides in alcoholic media to form the corresponding sulfenates.

N-Arylsulfenyl-*N,N'*-bis(arylsulfonyl)arenesulfonamides undergo even easier alcoholysis.^{32, 116, 117}

The use of sulfenamides for the synthesis of sulfenates is preferable to that of sulfonyl chlorides, because the latter often induces undesirable side processes.¹⁰⁴

5. Synthesis of compounds with a P—S bond

The use of sulfenamides for the synthesis of various phosphor-sulfur-containing compounds is based on phosphorolysis of the S—N bond with phosphorylating reagents. The synthesis of thiolphosphates using the interaction of *N,N*-disubstituted sulfenamides with dialkyl phosphites has been described.^{118, 119}

The syntheses of thiolphosphonates and thiolphosphinates were performed in a similar manner.¹¹⁹

The reaction of sulfenamides with alkyl phosphodichloridites yields alkyl (amido)thiophosphochloridates.¹¹⁹

The reaction of sulfenamides with methyldichlorophosphine gives phosphoranes, which may be converted to *S*-alkyl dialkylamidothiophosphonates upon treatment with sulfur trioxide.²³

Similar compounds are formed when sulfenamides react with methylphosphonous anhydride.²³

Sulfenamides react with *S,S*-dialkyl-*O*-trimethylsilyl dithiophosphites to yield trithiophosphates.¹²⁰ In this case, a part of the initial *O*-trimethylsilyl dithiophosphite is transformed to *S*-alkyl-*O*-trimethylsilyl dithiophosphonate.

6. Synthesis of nitrogen-containing compounds

Sulfenamides are good amidating reagents with respect to *S*-esters of thiocarboxylic acids, carboxylic anhydrides, and acyl chlorides. This feature is often used in syntheses of various *N*-substituted carboxamides. The corresponding reactions occur in the presence of trivalent phosphorus compounds under rather mild conditions to give the target products in high yields.^{23, 121-123}

The role of the catalyst is to form the intermediate phosphonium salts with sulfenamides having a highly polarised S—N bond.¹²⁴

Different rearrangements of sulfenamides are often used in the syntheses of functionally substituted aromatic amines. For example, the heating of *N*-(phenyl)arenesulfenamides in aniline in the presence of hydrochloric acid results in a mixture of ortho- and para-substituted aniline derivatives.¹²⁵

Under similar conditions, *N*-phenyl-2-nitrobenzenesulfenamide gives a mixture of 2- and 4-aminodiphenyldisulfides, phenothiazine, and 2-aminobenzenesulfenamide.¹²⁶

When heated in CCl_4 , *N*-methyl-*N*-phenylmethanesulfenamide rearranges into 4-methylthio-*N*-methylaniline.¹²⁷

When 4-nitrobenzenesulfenamide reacts with liquid ammonia in an autoclave, a mixture of 4-nitroaniline, 4,4'-dinitrodiphenyl-disulfide, and 4-nitrothiophenol is formed.¹²⁸ In addition to various rearrangements, other transformations of sulfenamides are used in the syntheses of functionally substituted aromatic amines. For example, the treatment of *N*-(4-nitrophenyl)-benzenesulfenamide with di-*tert*-butyl hyponitrite at 40 °C in *tert*-butyl alcohol has been reported¹²⁹ to yield a radical

$4\text{-O}_2\text{NC}_6\text{H}_4\text{NSPh}$, which transforms to the *N*-nitroaniline under the action of Bu_3SnH . Vicarious nucleophilic substitution of the hydrogen atom in the aromatic nucleus of nitroarenes using *N*-unsubstituted sulfenamides has been described.¹³⁰ For example, the amination of nitrobenzene with 1-pyrrolidino-carbonylsulfenamide in DMF in the presence of potassium *tert*-butoxide produces a mixture of 2-nitro- and 4-nitroanilines in yields of 34% and 41.5%, respectively. The amination of 1-nitronaphthalene with benzothiazole-2-sulfenamide in DMSO in the presence of potassium *tert*-butoxide gives a mixture of 2-amino-1-nitro- and 4-amino-1-nitronaphthalenes in 11% and 75% yield, respectively.

Among other nitrogen containing compounds that have been synthesised from sulfenamides, tetrasubstituted hydrazines should be noted; they are formed by dimerisation of thioaminy radicals generated from sulfenamides.^{131, 132}

7. Synthesis of heterocyclic compounds

The use of sulfenamides in the synthesis of heterocyclic compounds is mainly based on the following transformations: a) generation of highly reactive intermediates and their reactions with unsaturated compounds; b) thermal rearrangements of sulfenamides; and c) various cyclisation reactions of sulfenamides.

a. Generation of highly reactive intermediates and their reactions with unsaturated compounds

Generation of nitrenes. The generation of nitrenes from *N*-unsubstituted sulfenamides followed by their reactions with alkenes is one method for the synthesis of *N*-aryltioaziridines.^{133–135} Nitrenes are generated in situ by the action of lead tetraacetate on *N*-unsubstituted sulfenamides that contain strong electron-acceptor groups at the sulfur atom, such as 2,4-dinitrophenyl.

$\text{R}^1 = \text{H, Me, Ph, H}_2\text{C}=\text{CH}_2$; $\text{R}^2 = \text{H, Me, Ph}$; $\text{R}^3 = \text{H, Me}$

It is noted^{133, 135} that 2,4-dinitrobenzenesulfenamide is oxidised by lead tetraacetate in the presence of (*Z*)-phenylpropene to give a mixture of *trans*- and *cis*-1-(2,4-dinitrophenylsulfenyl)-2-methyl-3-phenylaziridines, their ratio being dependent on the nature of solvent, on the ratio of the reactants, and on the order of mixing the reagents.^{133, 135} For example, in benzene, the ratio of

trans- and *cis*-isomers is 1 : 1, while in chloroform and dichloromethane it is 3 : 1. In more polar solvents (MeCN, MeOH), the overall yield of both isomers decreases. If lead tetraacetate is added to a mixture of 2,4-dinitrobenzenesulfenamide and (*Z*)-phenylpropene, *N*-(2,4-dinitrophenyl)-2,4-dinitrobenzenesulfenamide is formed together with aziridines, and partial isomerization of (*Z*)-phenylpropene to (*E*)-phenylpropene is observed. However, the addition of a mixture of 2,4-dinitrobenzenesulfenamide and lead tetraacetate in chloroform to (*Z*)-phenylpropene results only in high yields of aziridines. The oxidation of 2,4-dinitrophenylsulfenamides is assumed¹³³ to produce initially a triplet nitrene in equilibrium with the singlet one, both of which react with (*Z*)-phenylpropene. This concept is supported by the fact that the introduction of $4\text{-ClC}_6\text{H}_4\text{SCH}_2\text{CH}=\text{CH}_2$, which is an efficient trap for singlet nitrenes, into the reaction mixture changes both the overall yield of aziridines and the ratio of isomers, while in the presence of efficient traps for triplet nitrenes, e.g. alkenes, $\text{PhC(R)}=\text{CH}_2$ ($\text{R} = \text{Ph, Me}$), the ratio of *cis*- and *trans*-isomers does not change, while the overall yield of aziridines decreases.

Generation of iminyl radicals. The generation of iminyl radicals from sulfenamides containing $\text{C}=\text{N}$ and $\text{C}=\text{C}$ bonds, and their subsequent addition to alkenes, is the basis for the synthesis of various pyrrolines. For example, a preparative method of synthesis of the pyrroline system is described¹³⁶ which involves the interaction of sulfenamide $\text{Me}_2\text{C}=\text{CHCH}_2-\text{CH}_2\text{C(Me)}=\text{NSPh}$ with the alkenes $\text{H}_2\text{C}=\text{CR}^1\text{R}^2$ ($\text{R}^1 = \text{H, COOBu}^t$; $\text{R}^2 = \text{COOMe, COOBu}^t, \text{CN}$) in the presence of Bu_3SnH –azobis(isobutyronitrile) (AIBN).

It is supposed¹³⁶ that the iminyl radical generated from the sulfenamide is transformed, via cyclisation, to the carbon-centred pyrrolinyl radical whose addition to the alkenes gives the final product.

In this case, inconsiderable amounts of the products of the double addition of the primary pyrroline system to alkenes are formed, as well as the products of its stabilisation without subsequent addition.

Similarly, when the sulfenamide $\text{H}_2\text{C}=\text{CHCH}_2-\text{CH}(\text{CH}_2)_4\text{C}=\text{NSPh}$ reacted with $\text{H}_2\text{C}=\text{C}(\text{COOBu}^t)_2$ in the

presence of $\text{Bu}_3\text{SnH} - \text{AIBN}$,¹³⁶ the heterocyclic ester was isolated as the main product.

The transformation of 4-substituted *N*-(aryl)benzenesulfenamides into phenazine derivatives in the presence of lead tetraacetate or upon electrolysis is also assumed to occur via iminyl radicals.³⁴

$\text{X} = \text{Me}, \text{Cl}, \text{OMe}$

Generation of thionitroso compounds. A method for the synthesis of *N*-substituted derivatives of 1,2-thiazine has been described,¹³⁷ which involves the cycloaddition of dienes, (*E,E*)- and (*E,Z*)- $\text{MeCH}=\text{CH}-\text{CH}=\text{CHMe}$, to arylthionitroso compounds $\text{ArN}=\text{S}$ ($\text{Ar} = 4\text{-MeOC}_6\text{H}_4$, $4\text{-BrC}_6\text{H}_4$, $4\text{-MeC}_6\text{H}_4$, $4\text{-ClC}_6\text{H}_4$), obtained upon the action of triethylamine in acetone on sulfenamides

The cycloaddition occurs with retention of configuration of the initial dienes, and the following products are obtained, respectively:

Generation of thiones. In the presence of organic bases, sulfenamides with β,β' -dicarbonyl fragments at the sulfur atom relatively readily transform into α,α' -dioxothiones. The latter undergo Diels-Alder type reactions with unsaturated compounds to yield various cyclic products.¹³⁸ A convenient preparative method for the synthesis of some 5,6-dihydro-1,4-oxathiine derivatives has been developed taking into account these features.^{44, 138}

$\text{R}^1 = \text{Me}, \text{R}^2 = \text{MeO}$ (70%); $\text{R}^1 = 4\text{-MeOC}_6\text{H}_4, \text{R}^2 = \text{SPh}$ (87%)

b. Thermal rearrangements of sulfenamides

Sulfenamides containing ethenyl and ethynyl fragments at the sulfur atom are usually prone to thermal rearrangement resulting in heterocyclic systems. For example, heating of the sulfenamide $\text{Ph(Me)C}=\text{NSCH}=\text{CH}_2$ for 40 h in 1,2-diethoxyethane under nitrogen flow gives a 40% yield of 2-phenyl-pyrrole.¹² Under similar conditions, the sulfenamide $\text{cyclo-C}_6\text{H}_{10}=\text{NSCH}=\text{CH}_2$ gives 4,5,6,7-tetrahydroindole in 60% yield.¹² Upon heating in toluene, *N*-(1-naphthyl)-ethenesulfenamides undergo a [3,3]-sigmatropic rearrangement with subsequent elimination of hydrogen sulfide and formation of 1-*R*-1*H*-benz[g]indoles ($\text{R} = \text{H}, \text{Me}$).¹³⁹ Similar rearrangement with subsequent cyclisation occurs upon heating *N*-aryl-1-alkynesulfenamides in anhydrous benzene in an argon atmosphere.¹⁴⁰

$\text{R}^1 = \text{H}, \text{Me}; \text{R}^2 = \text{Me}; \text{R}^3 = \text{Me}, \text{Me}_3\text{Si}$

c. Cyclisation reactions of sulfenamides

The possibility of cyclisation of sulfenamides to heterocyclic systems depends on several factors, and mainly on the nature and the structure of substituents at the sulfur and nitrogen atoms, their mutual arrangement, as well as the lability of the S-N and of other bonds in the molecule. Taking into account these factors, preparative synthetic methods for various heterocyclic systems have been developed. For example, *N*-monosubstituted arenesulfenamides containing the alkoxycarbonyl group in the ortho position have successfully been used for the synthesis of 1,2-benzothiazole derivatives. Intramolecular cyclisation of such sulfenamides occurs relatively readily in alcoholic media in the presence of alkoxides.¹⁴¹

$\text{R} = \text{Me}, \text{Et}, \text{Pr}, \text{PhCH}_2, 4\text{-MeOC}_6\text{H}_4$

Intramolecular cyclisation of *N*-unsubstituted arenesulfenamides containing the nitro group in the ortho-position occurs in the presence of phosphorus acid chlorides [POCl_3 , PhOP(O)Cl_2 , $(\text{PhO})_2\text{P(O)Cl}$] and organic bases to give benzo-1,2,3-thiadiazole 3-oxide hydrochlorides.¹⁴²

$\text{R} = \text{H}, \text{NO}_2$

A simple and efficient method for the synthesis of 1,3,4-oxathiazolium perchlorates has been described¹⁴³ that involves the

cyclisation of *N*-(acyl)arenecarbonylsulfenamides in acetic anhydride in the presence of 70% HClO_4 .

$\text{R}^1 = 4\text{-MeOC}_6\text{H}_4$; $\text{R}^2 = \text{Me}, \text{Ph}, 4\text{-MeOC}_6\text{H}_4$

Sulfenamides

($\text{R}^1 = \text{H}, \text{Me}, \text{Et}, \text{R}^2 = \text{Me}, \text{Et}, \text{Bu}^t$) form ¹⁴⁴ a diastereomeric mixture (93:7) of thiirane derivatives when treated with 2 equiv. of LiEt_3BH , NaBH_4 , or LiAlH_4 in THF at -78°C .

$\text{R} = \text{Me}, \text{Et}$

Owing to the high reactivity of the trichloromethyl group a rather wide range of methods for the synthesis of various heterocycles has been developed based on *N*-substituted trichloromethanesulfenamides. For example, *N*-(aryl)trichloromethanesulfenamides cyclise in the presence of alcoholic alkali to give 2,5-diaryl-3,3,6,6-tetrachloro-2,3,5,6-tetrahydro-1,4,2,5-dithiadiazines.^{8, 38}

$\text{Ar} = \text{Ph}, 4\text{-MeC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4$

Under the action of bases (NaOH , EtONa , Et_3N , Py), *N*-(acyl)trichloromethanesulfenamides cyclise to form 5-*R*-1,3,4-oxathiazol-2-ones.^{145, 146}

$\text{R} = \text{Ph}, 4\text{-MeC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4, 3\text{-MeOC}_6\text{H}_4, 3,5\text{-Me}_2\text{C}_6\text{H}_3$

In the presence of triethylamine, *N*-(trichloromethylthio)arenesulfenamides are converted into 2,4-dichloro-2,4-bis(chlorothio)-1,3-bis(arylsulfonyl)-1,3-diazetidines.⁸

A series of 1,2,4-thiadiazole derivatives have been synthesised by the reaction of *N*-(pyrid-2-yl)- and *N*-(tetrahydropyrid-2-yl)trichloromethanesulfenamides with 2-aminopyridine^{147, 148} or benzoylacetic acid.¹⁴⁹

A considerable number of sulfur-nitrogen-containing heterocyclic compounds were obtained by reactions of trichloromethanesulfenyl chloride with various nitrogen-containing compounds, without isolating the intermediate *N*-substituted trichloromethanesulfenamides. Methods for the synthesis of these heterocycles are described in detail in a review⁸ and in the literature cited therein.

8. Synthesis of iminosulfur compounds

a. Synthesis of amides of sulfinimidic acid

Several methods for the synthesis of amides of sulfinimidic acids based on sulfenamides have been developed. One of the most common methods is based on oxidative imination of sulfenamides with *N*-halo compounds. The main advantage of this method is its one-step character, as well as the possibility of synthesising amides of sulfinimidic acids of varying structure by altering the nature of both the sulfenamide and the iminating reagent. For example, the amides of arenesulfinimidic acids containing acyl and carboximidoyl groups at the nitrogen atoms can be obtained by oxidative imination of *N*-(acyl)arenesulfenamides with *N*-bromoamidines, or by oxidative imination of *N*-(carboximidoyl)arenesulfenamides with *N*-chlorocarboxamides.¹⁵⁰

$\text{Ar} = 4\text{-O}_2\text{NC}_6\text{H}_4$; $\text{R} = \text{Me}, \text{Ph}$

N-Bromoamidines also react relatively readily with *N*-(carboximidoyl)sulfenamides to give salts of *N,N'*-bis-(carboximidoyl)amides of sulfinimidic acids which form triazines upon heating.^{151, 152}

R = Alk, Ar

A series of amides of sulfinimidic acids containing the same or different acyl groups at the nitrogen atoms was obtained by the oxidative imination of *N*-(acyl)sulfenamides with *N*-chlorocarbonylamides in the presence of organic bases (RONa, Py, Et₃N).^{153, 154}

R¹ = 4-O₂NC₆H₄, CCl₃;

R² = Me, Et, Ph, 4-MeC₆H₄, PhCH₂, NH₂, PhNH;

R³ = Me, Ph

Several amides of sulfinimidic acids containing arylsulfonyl groups were synthesised from sulfenamides and sodium *N*-chlorosulfonamides.^{19, 20, 35, 65, 146, 155-163}

R¹ = Ar, Me, CH₂Cl, EtOCCl₂, CCl₃, CCl₂F, CF₂Cl;

R² = H, Alk, Ar, Ac, ArSO₂, CN; R³ = H, Alk, Ar

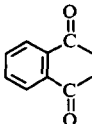

R = Ar; X = S(O)Ph₂, C(OMe)NH₂, C(OEt)NH₂, C(SeEt)NH₂, C(NH₂)NH₂

Yet another method of synthesis of amides of sulfinimidic acids from sulfenamides involves chlorination of sodium *N*-(arylthio)arenesulfonamides with chlorine in the presence of *N*-nucleophiles.¹⁶⁴⁻¹⁶⁶

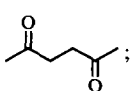

R¹ = 2-O₂NC₆H₄, 2,4-(O₂N)₂C₆H₃;

R², R³ = Et, C₅H₁₁, iso-C₅H₁₁; R² + R³ = 

The reaction of sodium *N*-(arylthio)arenesulfonamides with *N*-haloimides is one of the modifications of this method.^{166, 167}

R = 2-O₂NC₆H₄, 4-O₂NC₆H₄; X = Cl, Br;

Y = ; 

The reaction of *N,N*-dialkylsulfenamides with *N*-chlorosuccinimide gives sulfonium salts which form amides of sulfinimidic acids in the presence of amines.¹⁶⁸

R¹ = Alk, Ar; R² = R³ = R⁴ = Alk

b. Synthesis of sulfinimidoyl chlorides

Sulfinimidoyl chlorides are obtained by oxidative chlorination of sulfenamides containing N-H, N=C, N-Si, and N-Na groups, usually in anhydrous aprotic organic solvents.¹⁶⁹⁻¹⁷⁴

R¹ = Ar, CF₃; R² = ArSO₂, ArCO, CF₃S, Me₃Si, Bu^t;

X = H, Na, Me₃Si

c. Synthesis of alkyl sulfinimidoates

A simple and efficient method of synthesis of alkyl *N*-(arylsulfonyl)sulfinimidoates has been developed, which involves the chlorination of sodium *N*-(arylthio)arenesulfonamides with *tert*-butyl hypochlorite or chlorine in alcoholic media.¹⁷⁵⁻¹⁷⁷

65% - 90%

R = Me, Et, Pr, Prⁱ, Bu, Buⁱ

d. Synthesis of sulfurdiimines

N-Unsubstituted arenesulfenamides react with sulfur dichloride in anhydrous benzene to yield *N,N'*-bis(arylsulfonyl)sulfurdiimines.¹⁷⁸

Ar = 4-O₂NC₆H₄

Sulfurdiimines are obtained in the reaction of *N,N*-bis(trimethylsilyl)sulfenamides with *N*-substituted *S,S*-dichlorosulfonimides.¹⁷⁹

R¹ = Et, Ph; R² = Ts, 4-O₂NC₆H₄, 2,4,6-Cl₃C₆H₂, 2,4,6-Br₃C₆H₂

N,N'-Bis(2,4,6-*tert*-butylphenyl)sulfurdiimine resulted from the reaction of 2,4,6-tri-*tert*-butylbenzenesulfenamide with lead tetraacetate.¹⁸⁰

9. Synthesis of sulfin- and sulfonamides

The oxidation of sulfenamides can yield either sulfin- or sulfonamides, depending on the nature of the sulfenamide and the oxidant, on their ratio, and on the oxidation conditions. Manganese dioxide,¹⁸¹ *m*-chloroperbenzoic acid (MCPBA),^{182–184} *N*-chlorosuccinimide,¹⁸⁵ *N*-chlorobenzotriazole,¹⁸⁶ and other reagents¹⁸⁴ are generally used as the oxidants. MCPBA is the most common oxidising reagent for the synthesis of sulfin- and sulfonamides from sulfenamides. The use of 1 equiv. of MCPBA yields sulfinamides, while three or more equivalents of the oxidising reagent are required for the preparation of sulfonamides, as exemplified by the oxidation of *N,N*-disubstituted trichloromethanesulfenamides.

R¹ = Alk; R² = Alk, Ar

The oxidation of *N*-arylsulfinamides with 1 equiv. of MCPBA results in *N*-sulfinylimines, while a large excess of MCPBA leads to *N*-alkylsulfonylaziridines of (*E*)-configuration.³⁴

R = Me, Bu, PhCH₂

The oxidation of 6-ethoxybenzothiazole-2-sulfenamide to the corresponding sulfonamide has been shown¹⁸⁴ to occur smoothly in the presence of MCPBA, while the use of hydrogen peroxide or *tert*-butyl hypochlorite is accompanied by oxidation of the heterocycle. The reaction of sulfenamides with *N*-chlorosuccinimide proceeds via the intermediate succinimidiosulfonium salt.¹⁸⁵

Optically active sulfinamides are obtained by oxidation of the corresponding sulfenamides with *N*-chlorobenzotriazole in the presence of L-menthol or D-tartrate.¹⁸⁶

IV. Practical application of sulfenamides

1. Biological activity of sulfenamides

After the first reports on the biological activity of sulfenamides,¹⁸⁷ investigations in this area began to develop intensely. Many patents and scientific papers devoted to this problem have been

published. An analysis of the results obtained has been partially reviewed.^{8, 23, 24, 188, 189} The main achievements involve: the discovery of the fungicidal activity of some sulfenamides, the development of technology for the manufacture of highly effective sulfenamide-based fungicides, and their application in agriculture. The *N*-(trichloromethyl)thiophthalimide, Phthalan, is one of the most valuable fungicides of this series.^{190, 191}

This sulfenamide is widely used as a standard fungicide, against the diseases of apples and pears (tetter), stone-fruits (leaf spots), grapes (mould, anthracnose, red-rot, black, white, and grey rot), gooseberries and currants (anthracnose), tomatoes and potatoes (phytophthora infection).

N-Trichloromethylthio-1,2,5,6-tetrahydrophthalimide (commercial name Kaptan) is also a very valuable fungicide.^{190, 191} It is widely used against diseases of apples, pears, stone-fruits, strawberries, berry bushes, grapes, tomatoes and potatoes. Mesulfan¹⁹⁰ and Difolathan¹⁹⁰ are characterised by the same fungicidal properties.

The sulfenamides FCl₂CSN(Ph)SO₂NMe₂ (Euparen) and FCl₂CSN(SO₂NMe₂)C₆H₄Me-4 (Euparen-M) are also effective fungicides.^{191, 192} They are used against the diseases of apples, currants, and grapes. The sulfenamides

appear to have similar fungicidal properties.^{34, 193, 194}

Some phosphorus-containing sulfenamides also exhibit rather high fungicidal activity.^{34, 195–197}

as well as some derivatives of sulfonylurea^{198, 199} which in addition display insecticidal activity.²⁰⁰

Some *N*-substituted 4-pyridinesulfenamides²⁰¹ and 2-nitrobenzenesulfenamides²⁰² exhibit herbicidal, insecticidal, and nematocidal activity.

$R^1 = R^2 = \text{H, Me, Et, etc.};$
 $R^3 = \text{F, Cl}$

$R = \text{H, 2-O}_2\text{NC}_6\text{H}_4\text{S, PhCO, PhSO}_2$

The sulfenamides of the general formula

$R^1 = \text{H, Cl, NO}_2; \quad R^2 = \text{Me, EtO, Ph.}$

are plant growth regulators.²⁰³

2. Sulfenamides in the rubber industry

In the rubber industry, sulfenamides are mainly used to accelerate the process of rubber vulcanisation^{34, 204, 205} owing to the high lability of the S—N bond and to its relatively easy homolysis to yield sulfenyl radicals that participate in the vulcanisation processes. Sulfenamides meet all the main requirements for industrial vulcanisation accelerators. In addition to intensification of the process, sulfenamides affect the structure of the resulting cross-linked structures, thus largely predetermining the mechanical properties of the rubber.

2-Benzothiazolesulfenamides are efficient accelerators of rubber vulcanisation;^{204, 205} they have found wide industrial application.

For example, *N,N*-(diethyl)benzothiazole-2-sulfenamide ($R^1 = R^2 = \text{Et}$) is an efficient delayed action accelerator at the beginning of vulcanisation. It provides the rubber with strong resistance to ageing and good elasticity. In particular, it is very efficient for rubber working under hard, dynamic conditions.

N-(*tert*-Butyl)benzothiazole-2-sulfenamide ($R^1 = \text{H, } R^2 = \text{Bu}^t$) is also an efficient delayed action accelerator. It results in rubber with strong resistance to ageing, and is used for the production of protectors and carcass rubber.

N,N-(Diisopropyl)benzothiazole-2-sulfenamide ($R^1 = R^2 = \text{Pr}^i$) is used as markedly delayed action accelerator which

increases the resistance of rubber mixtures to prevulcanisation as well as to ageing.

N-(*tert*-Octyl)benzothiazole-2-sulfenamide ($R^1 = \text{H, } R^2 = \text{Me}_3\text{CCH}_2\text{CMe}_2$) is characterised by distinct delayed action at the beginning of vulcanisation. It prevents rubber mixtures undergoing premature vulcanisation.

N-(Cyclohexyl)benzothiazole-2-sulfenamide ($R^1 = \text{H, } R^2 = \text{cyclo-C}_6\text{H}_{11}$) is a very efficient delayed action accelerator at the beginning of vulcanisation. It provides rubber of high elasticity and increased tensile strength as well as good durability. This accelerator is used for the manufacture of protectors and tyre carcasses.

N-(Hexamethylene)benzothiazole-2-sulfenamide [$R^1 + R^2 = -(\text{CH}_2)_6-$], as well as benzothiazole-2-sulfenomorpholide and -(2,6-dimethylmorpholide) [$R^1 + R^2 = (\text{CH}_2\text{CH}_2)_2\text{O}$ and $(\text{CH}_2\text{CHMe})_2\text{O}$, respectively], display analogous functional activity.

N,N-(Dicyclohexyl)benzothiazole-2-sulfenamide ($R^1 = R^2 = \text{cyclo-C}_6\text{H}_{11}$) is also a pronounced delayed action accelerator at the initial stage of vulcanisation and provides rubber mixtures of high elasticity and strong resistance to ageing. This accelerator is used in the manufacture of tyres, transporters, shock absorbers, etc.

The thiocarbonylsulfenamides of the general formula

$X = \text{O, CH}_2.$

are even more efficient vulcanisation accelerators than the benzothiazole-2-sulfenamides.^{206, 207}

The sulfenamides $\text{RSN}(X)\text{SO}_2\text{Ph}$ [$X = \text{S(R)} = \text{NSO}_2\text{Ph}$; $R = \text{Ph, 4-MeC}_6\text{H}_4, \text{benzoxazolyl}$] have proved to be efficient accelerators of vulcanisation of butadiene–nitrile rubber 'SKN-26'.^{208, 209}

Sulfenamides are also used, but not so often, as vulcanisation inhibitors to prolong the prevulcanisation period.^{210–213} Usually, *N*-substituted sulfenamides with acyl, arylsulfonyl, and other substituents display these properties.

3. Sulfenamides in the chemistry of polymers

To protect polymers from oxidative degradation specific anti-oxidants are introduced into polymers. They not only prevent oxidation, but often suppress other undesirable processes favoured by oxygen or peroxides. According to the generally accepted mechanism of oxidant activity,²¹⁴ their main role is to bind the active radicals $R^\cdot, \text{RO}^\cdot, \text{ROO}^\cdot, \text{HO}^\cdot$ formed under the action of oxygen. This results in stable substances or stabilised radicals, X^\cdot , that cannot attack a new polymeric chain.

If we take these criteria into account, sulfenamides can be considered as potential polymer antioxidants. Similar to the secondary amines used as industrial antioxidants,²¹⁴ *N*-mono-substituted sulfenamides are prone to eliminate a hydrogen atom from the nitrogen atom to produce aminyl radicals; this process can occur in the presence of peroxide radicals.

On the other hand, the presence of bivalent sulfur in the sulfenamide molecule, which is able to pass to a higher valence state in the presence of oxidants, should favour the antioxidative properties. Hence, *N*-(cyclohexyl)pentachlorobenzene sulfenamide has been proposed as an antioxidant for polyolefins.²¹⁵

One serious problem hindering the processing of poly(vinyl chloride) is its thermal instability. Thermal destruction of poly(vinyl chloride) occurs in a temperature range of 130–170°C, while the plastic state which is necessary for processing is reached at a temperature higher than 200°C.²¹⁶ The processing of poly(vinyl chloride) is therefore performed after it has been stabilised. The destruction process of this polymer is rather complicated and has not yet been entirely studied. However, radicals are assumed to play the main role in this process.^{214, 215} The destruction is initiated by the R· radical, which is formed from admixtures or from the polymer itself upon heating.

During degradation, the initially colourless poly(vinyl chloride) first turns yellow, then orange, brown, and black depending on the concentration of conjugated double bonds, which, in turn, depends on the extent of the degradation. It is supposed²¹⁴ that HCl liberated is a catalyst of this process, and the role of thermostabilisers is to bind it. However, another mechanism of action of thermostabilisers involving a capture of R· radicals and their transformation into inactive products at the beginning of the initiation, should not be excluded. Apparently, the thermostabilisation of poly(vinyl chloride) in the presence of some *N*-substituted sulfenamides occurs according to this scheme. Thus, high thermostabilising activity of *N*-(cyclohexyl)thiazole-2- and benzothiazole-2-sulfenamides towards poly(vinyl chloride) has been reported.²¹⁵

The following sulfenamides have been proposed to thermostabilise halogenated butyl rubber.²¹⁵

4. Sulfenamides as pharmaceuticals

Some sulfenamides are potential pharmaceuticals. Thus, sulfenamides of the pyrimidine series have proved to be antihemorrhagic inhibitors of lipoxygenase and hinder leukocyte migration.^{217, 218} The oxazolidinone sulfenamide has been described²¹⁹ which, in addition to the above mentioned properties, also displays antiasthmatic activity.

3-Nitropyridine-2-sulfenamide and its analogues display anti-tumour activity.

5. Sulfenamides as electrolytic additives

The application of *N*-phenylthio-*N,N'*-bis(phenylsulfonyl)benzenesulfenamide as an additive to the electrolyte for silver plating of metals was shown to improve the coating quality.²²⁰ The use of this electrolyte provides coatings with fine crystal structure, lustre, and good adhesion to a support.

* * *

Thus, application of sulfenamides in fine organic synthesis is based on the specific features of their structure and reactivity, namely the presence of two active centres (S and N) and the high lability of the S–N bond. The capability of this bond to be relatively easily cleaved in the presence of both nucleophilic and electrophilic reagents, as well as to be homolysed, enables sulfenamides to be used as carriers of the sulfonyl group in syntheses of sulfides, disulfides, esters of sulfenic acids, and other sulfur-containing compounds, and to be used as a protective function in syntheses of peptides and alkaloids. The ability of sulfenamides to generate various highly reactive intermediates is a property of synthetic importance, which is widely used in syntheses of heterocyclic compounds and various sulfur-imino compounds. The practical application of sulfenamides in the rubber industry, macromolecular chemistry, agriculture, and other areas is of no less importance.

The search for, and development of, unusual methods of sulfenamide synthesis, such as the chlorosulfonylamidation of alkenes and alkynes, sulfonylamidation of CH-acids, etc., seem in the immediate future to be the main directions of research in this field of organic synthesis. The study of the reactions of sulfenamides involving the generation of various highly reactive intermediates should progress considerably. Their employment in organic synthesis will prompt the emergence of new polyfunctional compounds, including potentially valuable ones.

Natural aliphatic oxygenated unsaturated acids. Synthesis and biological activity

A G Tolstikov, G A Tolstikov

Contents

I. Introduction	441
II. Linear unsaturated hydroxy and epoxy acids and their derivatives	441
III. Branched-chain unsaturated acids	446
IV. Unsaturated di- and tricarboxylic acids and their derivatives	448
V. Acids with oxygen-containing heterocyclic fragments	449
VI. Total synthesis of natural unsaturated acids with oxygen-containing functions	451

Abstract. The review is devoted to natural unsaturated acyclic acids containing oxygen functions. Compounds of the aceto-genin and propiogenin types containing hydroxy, oxo, and epoxy groups as well as ether, hydrofuran, and hydropyran fragments are considered. Data are given on the biological activities of the acids themselves or of natural compounds whose structural elements are unsaturated acids. The methodology and strategy of the synthesis of both linear unsaturated hydroxy and alkoxy acids and those containing a heterocyclic fragment are discussed. The bibliography includes 172 references.

I. Introduction

The unique biological role of oxygen-containing unsaturated acids is generally acknowledged. By now, a unified theory for the arachidonic acid cascade has been elaborated, which provides, together with offering a deeper insight into the mechanism of oxidative metabolism, a means to important discoveries in bio-organic chemistry and medicine. More and more attention is being given to hydroxy unsaturated acids as promising tools in the self-defence of plants against fungal diseases. The development in the foreseeable future of radically new fungicides, which are active even when used at nanogram concentrations, is becoming ever more realistic. Of significant interest are unsaturated acids that possess the ability to control the biosynthesis of cholesterol. A striking diversity of biological activities has been found among the unsaturated acids and compounds containing their fragments, isolated from marine organisms.

Thus, the importance of biological screening, however modest are the means it employs, is in no doubt. At present, biotesting is becoming a more and more sophisticated procedure, which reflects the increasing interest in naturally occurring acids shown by numerous laboratories and firms engaged in the design of medicinal drugs and means for raising agricultural yields.

Uspekhi Khimii 65(5) 474–495 (1996); translated by R L Birnova

Nevertheless, the chemistry and biochemistry of oxygen-containing unsaturated acids discussed herein needs further extensive research. It can be said with confidence that this class of natural compounds is of interest both to synthetic chemists and specialists dealing with the development of technological methods for the synthesis of natural compounds and their analogues with predetermined biological activity.

While preparing the present review, the authors were faced with the necessity to restrict its remit and exclude from the consideration:

lactones of hydroxy unsaturated acids meriting special attention;

macrolide antibiotics that are regularly covered in reviews and monographs;

compounds of the arachidonic acid cascade with the exception of certain metabolites;

polyester toxins of the ocaidaic acid type.

The review is concerned with the acids and their derivatives, in the structure of which a continuous carbon chain can be traced providing for the formation of oxygen-containing heterocycles of the hydrogenated furan and pyran type. In some cases, metabolites of unsaturated acids are considered that have an ether group, which interrupts the continuous carbon chain, as well as halogen-containing acids. Special attention is given to the biological activities and physiological functions of the compounds under discussion.

II. Linear unsaturated hydroxy and epoxy acids and their derivatives

Many unsaturated monohydroxy acids are related to the group of widely occurring natural compounds. Thus, in 1985 the worldwide production of castor oil containing ricinoleic acid **1** as the major acid component, amounted to 400 000 tons.¹ The technical significance of castor oil is great. This includes polymeric compounds and the production of sebacic and undecenoic acids, as well as enanthal. Of great practical utility is the microbial degradation of ricinoleic acid into the optically active decanolate **2**.

Scheme 1

The isolation of several monohydroxy monoenoic acids has been described. Thus, 3-hydroxy-(5*Z*)-dodecenoic acid **3** has been obtained from the lipids of the plant *Serratia marcescens*.² (2*R*)-Hydroxy-(15*Z*)-tetracosenoic acid is a constituent of the galactosphingolipid **4** isolated from marine organisms.³ Lesquerolic acid **5**⁴ and the acid **6**⁵ have been isolated from plants of the *Lesquerella* genus. Internodes of the timothy (*Phleum*) infested with the fungus *Epichloe typhii* have been found to contain the acids **7** and **8**; the enhanced resistance of the infested plants against some pathogenic fungi has been noted.⁶ The plant *Acanthopanax sessilifloria* contains the acids **9** and **10** with an unestablished configuration of the asymmetric centre.⁷ The physiologically active 12-hydroxy-(9*Z*)-dodecenoic acid **11** has been isolated from homogenates of pea leaves;⁸ the synthesis of this acid has been described.⁹ The sphingolipid **12** containing (2*R*)-hydroxy-(3*E*)-octadecenoic acid possesses antileukemic activity.¹⁰ The structure of the antibiotic malingamide A isolated from the marine alga *Lyngbya majuscula* involves (7*R*)-hydroxy-(4*E*)-tetradecenoic acid **13**¹¹ (Scheme 1).

An important role in the vital activity of plants is played by monohydroxy dienoic acids. Thus, dimorphecolic acid **14** isolated from rice stems,¹² from seed oils of *Dimorphotheca* and *Osteospermum*,¹³ as well as from sea buckthorn oil,¹⁴ belongs to the class of acids that provide defence against diseases in some rice varieties known for their high productivity and resistance against pathogenic fungi. Esters of the acid **14** also exhibit insecticidal activity.¹⁵ The synthesis of four geometric isomers of dimorphecolic acid **16** has been performed. Densipolic acid **15** has been isolated from the lipids of *Lesquerella densipila*.¹⁷

Much attention in the current literature is being given to coriolic acid **16** detected as a component of sea buckthorn lipids¹⁴ and isolated as the (13*S*) isomer from the roots of the rice plant.¹⁸ This compound can influence Ca^{2+} transport in the cell system of some pathogens of rice diseases, which accounts for its role in self-defence of the plant. Its (13*R*)-isomer **17** and the geometric isomers **18** and **19** exhibit similar fungicidal activity. The synthetic dehydrocoriolic acids **20** and **21** display potent antifungal activity.¹⁸

The natural enynic acids **22**¹⁹ and **23**²⁰ possessing antibacterial and antifungal properties are also worth noting in this context (Scheme 2).

Of particular interest is the detection of coriolic acid in heart tissue mitochondria of patients with Mediterranean fever. Highlighted is the role of (*R*)-coriolic acid in the control of thrombosis, which is associated with its ability to block Ca^{2+} transport.²¹ The synthesis of coriolic acid has been described in Refs 22 and 23.

Hydroxydienoic acids **24**–**27** of unknown configuration have been isolated from the seeds of the plant *Galeopsis bifida*.²⁴ The configuration of the asymmetric centres of the acids **28** and **29** detected in some plants of the *Acanthopanax* genus is

also unknown.⁷ The fungistatic activity of the fungus *Epichloe*, which infests the timothy, is ascribed to the presence of the acids **30** and **31**; the latter has been obtained synthetically.²⁵

The seed oil of *Securidaca longipedunculata* contains (9*R*)-hydroxy-(5*Z*,7*E*)-tetradecadienoic acid **32**.²⁶ The acid **33** is the structural component of the nucleoside antibiotic produced by *Streptomyces griseosporus*.²⁷ The optically active allenic acid **34** isolated from the plant *Sapium japonicum* has a potent antifungal action.²⁸

High biological activity has been detected in some monohydroxy tri- and monohydroxy polyenoic acids. The disease-resistant rice variety Fukuyuki contains the C₁₈-trienoic acids **35** and **36** endowed with strong fungicidal activity.²⁹ Their structures have been confirmed by total synthesis.³⁰

The acid **37** isolated from wheat epithelium turned out to be a strong vasodilator that stimulates the protein inflow into the ocular fluid. Noteworthy, its enantiomer **38** is fully devoid of activity, while the (8*E*)-isomer **39** displays only 10% of the activity of the natural acid (Scheme 3).³¹ The lipids of the Indian Ocean

Scheme 3

black coral *Leiopathes* contain leiopathic acid **40** as well as the acids **41** and **42**.³² The sponge *Echinochalina mollis* inhabiting the Coral Sea produces three hydroxypolyenoic acids, **43–45**.³³ The eicosanoid **46** has been isolated from the starfish *Patiria miniata*.³⁴ Biologically active acids have been detected in red algae. Thus, *Litotamnion corallioides* and *Litotamnion calcareum* produce the acids **47** and **48**;³⁵ pentaenoic acid **49** exhibiting antimicrobial activity has been isolated from the alga *Laurensia hybrida*.³⁶ The high content of the acid **50** which inhibits platelet aggregation has been found in the alga *Murrayella pericladus*.^{36,37} The acid **51** isolated from the lipids of the alga *Liagora farinosa* is ichthiotoxic.³⁸

Only a few unsaturated dihydroxy acids have been described, and among them there are *threo*-12,13-dihydroxyoleic **52**,³⁹ 6,7-dihydroxy-(2*Z*,4*E*)-octadienoic, and 8,9-dihydroxy-(2*E*,4*E*,6*E*)-decatrienoic acids.

Dihydroxyoctadienoic acids are structural components of the trichotecenoid toxins produced by the fungi *Fusarium*, *Myrothecium*, *Trichoderma*, and *Cylindrocarpon*. Trichotecenes are strong poisons inhibiting such vital processes as protein and DNA biosynthesis. Also known are mycotoxins, e.g., the vomiting factor of *Fusarium* and toxic aleukia of pigs and cattle fed on a pathogenic fungi-infested forage. Two types of toxins, **53** and **54**, exist that contain dihydroxyoctadienoic acids. The antibiotic dioxamycin **55** comprises a fragment of decatrienoic acid.⁴⁰

The extensive literature on trichotecenoid toxins has been generalised in various monographs.^{41–43}

The dihydroxytetra- and pentaenoic acids **56** and **57** have been isolated from the lipids of the red alga *Farlowia mollis*.⁴⁴

$R^1 = H, R^2 = OH; R^1 = OH, R^2 = H$

A group of trihydroxy acids **58–62** has been isolated from the stems of some rice varieties resistant to fungal diseases.^{45,46} It has been demonstrated that wetting of rice seedlings in aqueous solutions of these acids increases the resistance of the plant against fungal diseases throughout the whole vegetation period.⁴⁷ The pharmacologically promising trihydroxy acids **63–66** are contained in the lipids of the medicinal plant *Brionia alba*.^{48–50} Like prostaglandins, the complex of these lipids increases smooth muscle tonicity, lowers the glucose level in the blood, normalises the lipid composition in liver and brain of experimental animals, and produces stimulating and tonic effects. These acids are formed by lipoxygenase oxidation of α -linolenic acid.

The sea alga *Lyngbya majusculus* contains malyngic acid **67**,⁵¹ whereas the cyanobacteria (blue-green algae) produce its stereoisomer **68**.⁵²

	R ¹	R ²	R ³	R ⁴
58	OH	H	H	OH
59	OH	H	OH	H
67	H	OH	H	OH
68	H	OH	OH	H

	R ¹	R ²	R ³	R ⁴	R ⁵	R ⁶
60	H	OH	OH	H	H	OH
61	OH	H	H	OH	OH	H
62	OH	H	H	OH	OH	H

Syntheses of some of these acids have been described in Refs 47, 51–55.

Natural unsaturated acids are known that contain alkoxy, oxo, and epoxy groups. The structural element of the malyngamides isolated from the alga *Lyngbya majuscula* is (7*R*)-methoxy-(4*E*)-tetradecenoic acid.⁵⁶ Nontoxic stylocheiamides have been isolated from the tissues of the ugrug *Stylocheilus longicanela*, which feeds on this alga.⁵⁷

Malyngamide G contains (7*R*)-methoxy-(4*E*)-tridecenoic acid.⁵⁸ (2*S*)-Methoxy-(5*Z*)-hexadecenoic acid **69**, a tentative structural component of sphingolipids, has been isolated from the sea sponge *Amphimedon compressa*.⁵⁹ The lipids of the green sea alga *Higginsia tethyoides* contain the unique C₂₈-acid **70**.⁶⁰

The aldehydo acid **71** with antimicrobial action is present in the lipids of the red alga *Laurensia hybrida*.³⁶ The C₁₈-oxo acid **72** has been found in the seed oil of *Gardenia lucida*.⁶¹ The acids **73** isolated from the lipid fraction of *Cuspidaria pterocarpa* seeds have a longer chain.^{62,63} The hydroxyoxo acid **74** is formed in the potato plant as a result of lipoxygenase oxidation of linolenic acid.⁶³

$n = 13, 15, 17$

The red alga *Ptilota filicina* produces the oxo acid **75** manifesting antimicrobial activity and the ability to inhibit 5-lipoxygenase and Na⁺/K⁺-ATPase.⁶⁴ The oxo acid **76** has been isolated from the alga *Lithotomnion corallioides*.⁶⁵ Gram-positive bacteria of the deep-sea sediment core produce macrolides and open-chain acids exhibiting antiviral activity. Among them, macrolactinic **77** and isomacrolactinic **78** acids have been identified; however, their absolute configurations have not been established.⁶⁶

The *Cantharellus cibarius* (chanterelle) is one of the most widespread edible mushrooms. Its resistance against parasites, insects, and snails is due to the high content of cibacic acid **79**.⁶⁷ The dioxoacid **80**, which has been named ostopanonic acid, has been isolated from the stems and fruits of the plant *Ostodes paniculata*. Its ability to inhibit the growth of lymphocytic leukemia cells has been reported.⁶⁸

The antibiotic MG 398HF9A **81** with a unique structure isolated from the culture of *Pseudomonas azurea*, has been recommended for the treatment of fungal diseases⁶⁹ (Scheme 4).

Vernolic acid **82**, which has an epoxy group in its structure, has been detected in the seeds of *Euphorbia lagascea*.^{1,21} The epoxy acid **83**, whose structure was confirmed by total synthesis, had been isolated from rice.⁷⁰ Like coriolic and vernolic acids, this compound has been attributed to the factors that ensure self-defence of the rice plant against pathogenic fungi. The fungus *Cephalosporium caerulens* produces cerulenin **84**, which inhibits the biosynthesis of steroids and lipids. Its inhibition index for fatty acid synthetase is very high ($JC = 1 \mu\text{g ml}^{-1}$).⁷¹ As stated in Ref. 13, sea buckthorn oil contains more than twenty epoxy acids which have been identified by chromatomass spectrometry; their major component is the 15,16-epoxy-octadeca-9,12-dienoic acid of an unestablished stereochemistry.

Incubation of (8*R*)-hydroperoxyeicosatetraenoic acid with homogenates of the coral *Plexaura nomomalea* affords the allenic epoxide **85**, an intermediate in the biosynthesis of the cyclopropane eicosanoid **86** isolated from the coral.⁷²

Scheme 4

Colnelic **87** and colnelenic **88** acids from potato have a unique structure.⁷³⁻⁷⁵ It is assumed that these acids are formed due to enzymatic rearrangements of the hydroperoxides produced by lipoxygenase oxidation of linoleic and linolenic acids. It is remarkable that the above compounds have a strong inhibiting action on potato lipoxygenase.

III. Branched-chain unsaturated acids

Several α -branched mono- and dioenoic acids have been isolated from the lipids produced by mycobacteria and actinomycetes. They involve corinomycolenic **89**,⁷⁶ nocardenoic **90**,⁷⁷ nocardienoic **91**, α' -smegmamycolic **92**, and α -smegmamycolic **93** acids.⁷⁸

Hydroxysterculic acid **94** is contained in the roots of the plant *Hibiscus rosa*.^{79,80} The fungus *Nocardia* produces the acid **95** possessing antiulcerous activity.⁸¹ The green alga *Bifurcaria bifurcata* contains isoprenoid acid **96**.⁸² The acid **97** has been isolated from the fruits of *Cydonia oblonga*.⁸³ Some hydroxy acids containing methyl substituents are structural fragments of the molecules of natural compounds. Thus, dendriphiellin **98** isolated from the sea sponge *Dendriphiella salina* contains a fragment of 8-hydroxy-(6*R*)-methylocta-(2*E*,4*E*)-dienoic acid⁸⁴ and variotin **99**, a potent inhibitor of fatty acid synthetase, is an amide of 6-methyltrienoic acid.⁷¹ The fungus *Papularia sphaerosperma* produces the glycolipids, xanthicandin **100a** and papulacandins, e.g., papulacandin B **100b** possessing strong fungicidal activity.⁸⁵⁻⁸⁷ Structurally related fungicides have been isolated from cell cultures of the fungi *Pialophora cyclaminis*⁸⁸ and *Dictyochaeta simplex*⁸⁹ (Scheme 5).

The pathogenic fungus *Alternaria kikuchiana*, the agent of the black spot disease in strawberry, produces the toxins AF-II a, b, c **101-103**, AK-I, and AK-II **104**,^{90,91} whose structures have been confirmed by total synthesis.^{92,93} The ester of the oxotetraenoic acid **105** isolated from the culture of *Aspergillus versicolor* has been patented as a means for reducing the cholesterol level in the blood.⁹⁴ The sea sponges of *Choristid* sp.⁹⁵ and *Jaspidae*⁹⁶ contain the antibiotics bengamides A-F **106** and isobengamide **107**, which are highly active against the parasites *Nippostrongyls brasiliensis*, streptococci, and fungi^{97,98} (Scheme 6).

The isolation of amides of the polyenoic acid with a more complex structure has been described. Thus, *Myxococcus xanthus* produces the antibiotics myxalamides **108**, which demonstrate high activity against gram-positive bacteria and yeasts.⁹⁹ The fungus *Myxococcus stipitatus* is a source of phenalamides **109** and

Scheme 5

110, which have been patented as a basis for medicinal drugs designed for the treatment of fungal and parasitic diseases.¹⁰⁰⁻¹⁰³ Phenalamide **C 111** has been noticed to inhibit strongly the reproduction of the human immunodeficiency virus. Malingamide **E** isolated from algae is the amide of 7-methoxy-9-methyl-hexa-(4*E*)-decenoic acid **112**.¹⁰⁴ The sea sponge *Clathria* contains clathrinamides **113** capable of inhibiting cell division, as has been established in experiments with starfish eggs.¹⁰⁵ The molecule of the antitumour antibiotic **AJL** produced by *Streptomyces* contains the acid **114** linked via an amide bond

with the fragment of a complex structure.¹⁰⁶ The structurally simple hydroxy acid **115** is a constituent of the molecule of oxazole macrolides (virginiamycins), which have found wide use as antibiotic drugs.¹⁰⁷ The antibiotic enacyloxin **116**, which is active against gram-positive bacteria and influences protein synthesis, has a unique structure.¹⁰⁸

The antibiotic conocandin **117**¹⁰⁹ and the compound **118**¹¹⁰ are free acids. The fungus *Xylaria cubensis* produces the antibiotic, cubenic acid **119**¹¹¹ (Scheme 7).

Scheme 7 (continued)

IV. Unsaturated di- and tricarboxylic acids and their derivatives

The group of unsaturated dicarboxylic acids is not too numerous but diverse as regards their structural elements. The ability to control plant growth is characteristic of radiclonic acid **120** isolated from *Penicillium* sp.¹¹² The antibiotic 123313 **121** has been obtained from *Cephalosporium*.¹¹³ Bongkreic acid **122** produced by the fungus *Pseudomonas cocoreneaus* causes severe (sometimes, lethal) food poisoning. 'Bongkreik' coconuts, commonly used as a dietary product in Indonesia, are infested with a culture of *Pseudomonas*. The high toxicity of the acid **122** produced by this culture is due to its effect on ATP/ADP translocation in mitochondrial membranes and blocking of oxidative phosphorylation.¹¹⁴ Isobongkreic acid **123** isolated from an unidentified strain of *Eubacterium* strongly inhibits the activity of phytopathogenic fungi when used at concentrations of

7–125 $\mu\text{g ml}^{-1}$. The antibiotic activity of compound **123** is lower than that of bongkreic acid. Both compounds are characterised by high toxicity: LD_{50} is 4.5 mg kg^{-1} . Tetraenedioic acid is a structural element of the molecule of the calbistrin antibiotic **124** produced by *Penicillium restrictum*.¹¹⁵

Baccharinoids related to toxins of the trichotecenoid series and produced by the fungus *Baccharis megapota mica* are cyclic esters of the dicarboxylic acids **125–127**.^{116,117} The alkaloids of the groundsel *Senecio* possessing valuable biological properties contain dicarboxylic acids, of which intergerrineic acid **128** as well as the acids **129** and **130**, are especially widespread.^{118,119} Platyphilline **131** has found use in medicine as a cholinolytic agent.

The oxotricarboxylic acid peptide derivatives, viridifungins A and C **132**, produced by *Trichoderma viride*, exert a strong antifungal action against *Candida*, *Aspergillus*, and *Cryptococcus*. Their ability to inhibit squalene synthetase has also been reported¹²⁰ (Scheme 8).

Scheme 8

Scheme 8 (continued)

V. Acids with oxygen-containing heterocyclic fragments

The formation of tetrahydrofuran or tetrahydropyran cycles is rather typical of linear polyhydroxy compounds. Polyhydroxy-unsaturated acids are not exceptional in this respect. If their molecules contain oxo groups, appropriate arrangement of the hydroxyl groups gives rise to heterocyclic systems containing two oxygen atoms which represent internal ketals.

Among the variety of acids containing the tetrahydrofuran fragment, we shall note the antibiotic ionomycin **133** possessing the properties of an ionophore selective towards calcium ions.¹²¹ The cycloecosanoids **134** and **135** isolated from ram seminal fluid are the metabolites of arachidonic acid.^{122, 123}

Of practical significance is pseudomonic acid **136** and its structural analogues containing the tetrahydropyran fragment **137**.^{124–126}

The antibiotic zincoforin **138** produced by *Streptomyces griseus* selectively binds Mg^{2+} and Zn^{2+} ions which accounts for its ability to stimulate the growth and development of ruminant animals.^{127, 128} Some strains of *Streptomyces* produce the antibiotic gerboxydiene **139**, which has a strong antimicrobial action.¹²⁹ The 8,12-epoxy-9,11,15-trihydroxy-(5*Z*,13*E*)-eicosadienoic acid with an unestablished configuration of the asymmetric centres is the product of enzymatic conversion of arachidonic acid in humans.¹³⁰ The synthesis of its (8*R*,9*R*,11*S*,12*R*)-diastereoisomer **140** has been carried out¹³¹ (Scheme 9).

Scheme 9

Scheme 10

R = OH, NH₂, NHMe, NMe₂, ONMe₂, NMe₃⁺

R = trisaccharide

	R ¹	R ²	R ³	R ⁴	R ⁵
145	OH	Et	H	H	H
146	H	Me	OH	Me	

The acids of this series, which contain two heterocyclic fragments, possess valuable biological activity. For example, ambruticin¹³² **141** (R = OH) and its amino derivatives¹³³ are active against many pathogenic fungi. A potent cytostatic action is exerted by swincholide D **142** isolated from the sea sponge *Theonella*.¹³⁴ The alga *Polycavernosa tsudai* contains the antibiotic polycavernoside A **143**.¹³⁵ Hydrangenoside A **144** detected in the plant *Hydrangea macrophylla* is a glycoside.¹³⁶ Some strains of *Streptomyces* produce antibiotics L 681.217 **145**¹³⁷ and SB 22.484 **146**¹³⁸ (Scheme 10).

The di- and tricarboxylic acids of this type are structurally very diverse. Some trichotenes comprise dicarboxylic acids carrying the tetrahydropyran fragment,¹³⁹ e.g., the acids **147–150** are present in satratoxin H, roritoxin A, mitoxin B, and vertisporin, respectively. The epoxy acids **151–155** are the structural components of myratoxin, satratoxin F, roritoxins D and C, and of mitoxin C (Scheme 11).

Some acids are of the ketal type. For example, the potent antibiotics, reversomycins F, C, D **156**, and B **157**, have been

Scheme 11

147: R¹ = $\text{CH}_2\text{CH}=\text{CHCO}_2\text{H}$; R² + R³ = O

153: R¹ = H, R² = OH; 154: R¹ + R² = O

isolated from some strains of *Streptomyces*.¹⁴⁰ The ionophore antibiotics, didemnoketals A and B **158**, possess high antimicrobial activity.¹⁴¹

R = Bu, C₅H₁₁, (CH₂)₂CHMe₂

R = COMe, —CH₂—C(CH₃)=CH—CH₂—CH₂—CO₂H

Considerable attention has recently been focussed on the tricarboxylic acids of the ketal type, which can effectively reduce the cholesterol level. These extremely active farnesyl transferase inhibitors produced by the cultures of *Sporomielia intermedia*, and *Leptodontium elatius*¹⁴² as well as by the fungi of *Phoma* species,^{143, 144} have been named zaragozic acids A, B, C, D₁, and D₂, and squalostatins S₁, S₂, and H₁. The identity of the zaragozic acid A with squalostatin S₁ has been established. These metabolites are of particular importance for cardiology, since it has been

reported that they have a number of advantages over clinically widespread hypocholesterolinemic drugs, such as lovastatin mevinoids.^{145, 146} The structures **159–162** are considered to be correct for the zaragozic acids A, B, D₁, and D₂, and structures **163** and **164**, for squalostatins S₂ and H₂.^{147–150}

VI. Total synthesis of natural unsaturated acids with oxygen-containing functions

Total synthesis of natural acids of the above type has received much attention. Its significance is growing with increasing frequency far beyond the scope of the laboratory studies aimed at confirming a structure or elaborating a methodology. Many synthetic schemes are of technological value and suitable for obtaining the target products in amounts having practical significance.

An exhaustive discussion of papers dealing with the complete synthesis of unsaturated acids with oxygen-containing functions is not the specific goal of the present review. It seemed more reasonable to trace the strategy and methodology of the synthesis; therefore, our attention was focussed not only on enantiospecific approaches but on the syntheses of achiral compounds as well.

The first stage in the synthesis of a 12-hydroxy-dodec-(9Z)-enoic acid metabolite **11**⁹ is particularly remarkable, for it makes use of a novel procedure of hydroalumination with AlHCl₂.¹⁵¹ Hydroalumination of octa-2,7-dien-1-ol **165** followed by oxidation of the organoaluminium compound **166** affords oct-2-en-1,8-

Scheme 12

THP = tetrahydropyran-2-yl; (a) AlHCl₂; (b) O₂, H₃⁺O; (c) HC≡CNa, H₃⁺O, H₂CrO₄; (d) LiN(Pr)₂, CH₂=CH₂-O; (e) H₂, Pd-BaSO₄

diol **167**; its further conversions are depicted in Scheme 12.

The racemic 10-hydroxy-octadec-(8E)-enoic acid **170** isolated from rice stems, which provides self-defence in the plant against fungal diseases, has been synthesised from undecene **168**

Scheme 13

(a) Bu^tO₂H—SeO₂; (b) PhCOCl—Py; (c) OsO₄, NaIO₄; (d) HO₂C(CH₂)₆CH=PPh₃

(Scheme 13).¹⁵² Allylic oxidation, benzylation, and periodate cleavage of the double bond results in 2-benzoyl oxydecanal **169** which, after Wittig olefination and hydrolysis, gives the target product.

The preparation of the C₁₂-synthon **172** used in the synthesis of the optically inactive 9-hydroxy-(10*E*,12*Z*,15*Z*)-octadecatrienoic acid **36** is based on the allylic oxidation of methyl undec-10-enoate **171** (Scheme 14).¹⁵²

- (a) Bu^tO₂H – SeO₂; (b) PhCOCl – Py; (c) O₃; (d) Ph₃P=CHC(=O)H;
(e) $\text{CH}_2=\text{CH}-\text{PPh}_3\text{Br}$, Bu^tOK

The syntheses of biologically active C₁₈-acids employ a wide variety of approaches, from metal complex catalysis to enantio-specific methods based on the use of the initial chiral compounds.

The palladium phosphine complex-catalysed coupling of vinyl halides with alkynes has been used in the synthesis of (13*R*)-coriolic acid **16**. One of the key synthons, 1-bromo-oct-1-en-(3*R*)-ol **175**, has been obtained from hept-1-ene **173** as shown in Scheme 15, which involves the asymmetric reduction of 1-bromo-oct-1-en-3-one **174** in the presence of baker's yeast (Scheme 15).¹⁵³

- (a) CHBr₃; (b) AcOK, 18-crown-6;
(c) NaOH, PCC (pyridinium chlorochromate); (d) baker's yeast;
(e) HC≡C(CH₂)₇CO₂Me, Pd(PPh₃)₄, CuI; (f) H₂, Pd – CaCO₃

This approach, in a slightly modified form, has been used in the synthesis of the *S*-enantiomer of coriolic acid **16** (Scheme 16).¹⁵⁴

- (a) Pd(PPh₃)₄, CuI; (b) LiAlH₄

Interesting procedures have been employed in the synthesis of (9*R*)-hydroxytetradeca-(5*Z*,7*E*)-dienoic acid **32**.¹⁵⁵ The stages of stereospecific reduction of methyl 6-iodo-hept-5-ynoate **176** in the presence of dipotassium azodicarboxylate and the Pd(OAc)₂-catalysed oxidative coupling of methyl-6-iodohex-5-enoate **177** with oct-1-en-(3*R*)-ol **178** (Scheme 17) have attracted our attention.

Scheme 17

- (a) KO₂CN=NCO₂K, BuNH₂;
(b) $\text{C}_5\text{H}_{11}\text{CH}(\text{OH})\text{CH}_2\text{C}\equiv\text{CH}$ (**178**); 5 Pd(OAc)₂ – AgOAc

The formation of the carbon – carbon bond at the key stage of the synthesis of dimorphecolic acid **14** is effected by cross-coupling of the *Z*-vinylzinc intermediate **179** with the vinylic iodide **180** catalysed by Pd(PPh₃)₄ (Scheme 18).¹⁵⁶

Scheme 18

- (a) Bu^tLi, ZnBr₂; (b) I-CH=CH-(CH₂)₇CO₂Me (**180**), Pd(PPh₃)₄

An interesting procedure involved in the synthesis of coriolic acid **16** which has been developed by Indian investigators¹⁵⁷ is the preparation of the acetylenic precursor **184**. Tetrahydroxyfurfuryl chloride **181** gives dec-4-yn-1-ol **182** under the action of lithium bromide and bromopentane; this is further isomerised into dec-9-yn-1-ol **183** in the presence of sodium amide and propane-1,3-diamine. Further synthesis is depicted in Scheme 19.

Scheme 19

(a) LiNH_2 , $\text{C}_5\text{H}_{11}\text{Br}$; (b) NaNH_2 , $(\text{CH}_2)_3(\text{NH}_2)_2$; DHP (dihydropyran);

(e) MnO_2 ; (f) $\text{C}_5\text{H}_{11}\text{MgBr}$, $\text{PhCOCl}-\text{Py}$

The Sharpless asymmetric epoxidation has been widely used to obtain optically active hydroxy- and epoxyunsaturated acids. For example, the first stage in the enantioselective synthesis of malingic acid **67** is the epoxidation of the initial oct-(2*E*)-en-5-yn-1-ol **185** (Scheme 20).¹⁵⁸

(a) $\text{Bu}^t\text{O}_2\text{H}$, $\text{Ti}(\text{OPr}^i)_4$, (+)DIPT (diisopropyl tartrate); (b) PhNCO ;

(e) NaBH_4 , NaOH

The asymmetric epoxidation of the compound **186** containing the fragment of allylic alcohol, has been used in the synthesis of (12*S*,13*S*)-epoxy-(11*R*)-hydroxyoctadeca-(9*Z*,15*Z*)-dienoic acid **83** possessing antifungal activity.¹⁵⁹ The two-step oxidation of the

primary hydroxyl group into the carboxyl group (Scheme 21) is noteworthy. It is based on the use of pyridinium chlorochromate and then of NaClO_2 in the presence of 2-methylbut-2-ene.

(a) $\text{Bu}^t\text{O}_2\text{H}$, $\text{Ti}(\text{OPr}^i)_4$, (+)DIPT; (b) Ac_2O , Py, H^+O ;

(c) PCC; (d) NaClO_2 , NaHPO_4 , $\text{Me}_2\text{C}=\text{CHMe}$;

(e) H_2 , Pd - CaCO_3

Monosaccharides have been widely employed in the past decade for enantiospecific syntheses of low molecular weight bioregulators, including hydroxyunsaturated acids as the starting chiral compounds. Thus, the scheme of synthesis of vernolic **82** and coriolic **16** acids is based on the transformations of 2-deoxy-D-glucose **187**. A noteworthy step in this chain of conversions is the allyl isomerisation of the epoxy group in the acid **82** under the action of cyclohexyl(isopropyl)methylmagnesium amide **188** (Scheme 22).¹⁶⁰

The synthesis of colnelic acid **87** having in its structure a rather rare fragment of divinyl ether also presents certain interest.¹⁶³ The key step in the synthesis of this compound is the acylation of non-3-ynal **193** with 8-pivaloyloxyoctanoyl chloride **194** in the

(a) $(\text{Me}_3\text{Si})_2\text{NNa}$; (b) H_2 , Pd – CaCO_3 ; (c) LDA, $(\text{EtO})_2\text{POBr}$;

(d) Et_3Al , $\text{Pd}(\text{PPh}_3)_4$

presence of bis(trimethylsilyl)sodium amide to form the enynyl ester **195**. The creation of the divinyl ether fragment has required the phosphorylation of the diene ester **196** in the presence of lithium diisopropylamide (LDA) and triethylaluminum-mediated hydrogenolysis of phosphate **197** in the presence of $\text{Pd}(\text{PPh}_3)_4$ (Scheme 25).

The synthesis of bongkreic acid **122** is related to syntheses of higher complexity.¹⁶⁴ Hydroxysylans **198** were the starting compounds for the preparation of bongkreic acid. Thus, in the synthesis of the synthon **201**, hydroxysylane **198** ($n = 2$) was converted into propionate **199**, which after silylation was subjected to Klaisen–Ireland rearrangement. The necessary (*S*)-enantiomer was isolated from the racemic mixture of 2-methyl-non-4-nonen-8-ynoic acid **201**, using HPLC on a column with a chiral adsorbent. The latter was transformed into the key synthon **202** in several steps (Scheme 26).

(a) Me_3SiCl , LDA; (b) HF

A parallel scheme for the conversion of C_6 -hydroxysylane **198** ($n = 1$) involves its asymmetric epoxidation to form the optically active epoxide **203**. An important step in these transformations is the preparation of cyanodiyne **205** from α -cyanoketone **204** with elimination of trifluoromethanesulfonic acid by NaH. Further conversions resulting in the block **206** are shown in Scheme 27.

The final step in the synthesis of the acid **122** involved interaction of the dilithium derivative of methyl 3-methylglutamate **207** with the aldehyde **202**. This was followed by hydroboration of acetylene **208** with diisoamylborane, preparation of the cuprate reagent **209**, and its stereoselective coupling with the bromide **206**. Hydrogenation of the triple bond in the precursor **210** and alkaline hydrolysis gave bongkreic acid **122**, whose characteristics were identical with those of the natural toxin (Scheme 28).

The high reactivity of vinylsilanes has been employed in the synthesis of ostopanoic acid **80**.¹⁶⁵ The interaction of 1,4-bis(trimethylsilyl)buta-1,3-diene **211** first with heptanoyl chloride and then with pimeloyl chloride made it possible to obtain the target dioxocarboxylic acid.

The synthesis of unsaturated acids carrying a heterocyclic fragment is acknowledged to be rather difficult to realise. This is the reason for the appearance of a large number of publications dealing with the problems of stepwise synthesis of these structures. For example, the synthesis of the C_{22} -fragment of ionomycin **133** has been carried out on the basis of (*S*)-malic acid **212** via compound **215** (Scheme 29).¹⁶⁶

In this sequence of conversions, the formation of the tetrahydrofuran derivative **213** and the heterocycle ring-opening in the product **214** by dimethylbromoborane are of interest.

Triacetyl-D-glucal has been used as the starting compound in the enantioselective synthesis of the arachidonic acid metabolite **140**.¹³¹ Its interaction with trimethylallylsilane accompanied by Ferrier rearrangement gives the diol **216**, the subsequent conversions of which are shown in Scheme 30.

(a) MeI , LDA ; (b) $\text{BH}_3 \cdot \text{Me}_2\text{S}$; (c) $\text{Et}_2\text{C}(\text{OMe})_2$; (d) H^+O ; (e) I_2 , NaHCO_3 ; (f) $\text{Ac}_2\text{O}-\text{Py}$; (g) Bu_3SnH ; (h) Me_2BBr , Et_3N .

In the scheme of synthesis of the zaragozic acid **A 159** (squalstatin **S₁**) published recently, the synthesis of the key synthon **228** merits attention.^{167, 168} This synthesis begins with coupling of the vinylstannane **217** with the iodide **218** catalysed by a palladium complex. This is followed by chiral Sharpless hydroxylation of the diene ester **219** with the $\text{K}_3\text{Fe}(\text{CN})_6\text{-K}_2\text{OsO}_2(\text{OH})_4$ complex in the presence of the bidentate ligand, $(\text{DHQD})_2\text{PHAL}$ responsible for the stereodifferentiating effect (Scheme 31).¹⁶⁹

The thus formed optically active ester **221** is lactonised by 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) to give the lactone **222**, which is further converted into the diol **223**. The latter undergoes a series of conversions aimed at differentiated

protection of the hydroxyl groups and is further oxidised with the Dess–Martin reagent.¹⁷⁰ The resulting aldehyde **224** is oxidised with NaClO_2 to the corresponding acid, which was benzylated with N,N' -dicyclohexyl-*O*-benzylisourea (DCBI) into the ester **225** (Scheme 31).

After removal of the protecting silyl group, the benzyl ester **225** is converted into the ester **226** in three steps. Its hydrolysis with trifluoroacetic acid and treatment of the reaction product with $\text{CF}_3\text{CON}(\text{CH}_3)\text{SiMe}_3$ in the presence of toluene-*n*-sulfonic acid in pyridine results in the bisilyl ether **227**. The oxidation of compound **227** with the Dess–Martin reagent is regiospecific and does not involve the tertiary Me_3SiO group, giving the key aldehyde **228**.

$R = \text{COC}_6\text{H}_4\text{OMe}$; $\text{SEM} = \text{Me}_3\text{Si}(\text{CH}_2)\text{OCH}_2$

(a) $\text{PdCl}_2(\text{MeCN})_2$; (b) $(\text{DHQD})_2\text{PHAL}$ (**220**), $\text{K}_3\text{Fe}(\text{CN})_6$, $\text{K}_2\text{OsO}_2(\text{OH})_4$;

Similar conversions of bissilyl ethers under the action of a $(\text{COCl})_2$ –DMSO system has been used to obtain synthons for prostaglandins.¹⁷¹ The aldehyde **228** reacts with the lithium derivative of the dithiane **229**, giving the compound **230**, and is then converted into zaragozic acid A in two steps **159** (Scheme 32).

The total synthesis of zincoforin **138** is marked by multiple application of organosilicon reagents.¹⁷² For example, the role of the Me_3Si group in the reaction of the aldehyde **231** consists in stereodifferentiation of the attachment of the Grignard reagent **232**; the aldehyde-acetal **233** obtained upon desilylation and

ozonolysis reacts with siloxy-1,3-diene **234** to form dihydropyran **235**. The latter undergoes a series of conversions to give the aldehyde **236** which, after an analogous reaction with siloxy-1,3-diene **237**, affords the ketone **238**; the latter is further converted into the acetate **239**. This is followed by $\text{BF}_3 \cdot \text{Et}_2\text{O}$ -catalysed cross-coupling with trimethylcrotylsilane, eventually resulting in the compound **240**. The conventional procedures gave the methylformylcarboxylate **241**, which was then introduced in the reaction with the sulfone anion **242**. The obvious conversions of the hydroxysulfone **243** afforded zincoforin **138** (Scheme 33).

The authors of the present review would like to call the reader's attention to the prospects that emerge from synthetic studies in the area of unsaturated acids. For example, polyhydroxy acids present interest as potential immunizing agents capable of protecting plants from pathogenic fungi even when used in nanogram quantities. Metabolites of the zaragozic acid type are of prime interest for large pharmaceutical firms involved in the solution of vital problems of cardiology, such as regulation of cholesterol biosynthesis. Bengamides, the technological synthesis of which is quite feasible, are also of substantial interest.

The authors express the hope that synthetic chemists will not only further advance the problems discussed in this review but will also proceed along interesting and promising paths.

This review has been written with the financial support of the Russian Fundamental Research Fund (Grant Nos 94-03-08009 and 95-03-08517).

Abstract. Data obtained in theoretical and experimental studies on the electronic structures, the nature of chemical bonding, and certain physicochemical properties of ternary carbides and nitrides involving transition metals and subgroup IIIB and IVB elements are surveyed. The possibilities and prospects for the application of computational quantum-chemical methods for the modelling of new complex solid solutions based on metal-like carbides and nitrides and also for the description of their fundamental properties are discussed. The bibliography includes 168 references.

I. Introduction

The high-temperature refractory transition metal (TM) carbides and nitrides and their reciprocal solid solutions (SS) constitute an extensive class of compounds which are interstitial phases.^{1–3} By virtue of a unique combination of a series of physicochemical properties, these compounds are exceptionally important.^{3–6} Studies on the electronic properties and on the nature of the chemistry bonding in such compounds have made a significant contribution to the development of the quantum chemistry of the solid state. They are being continued vigorously also at the present time. The results obtained in the course of these investigations have been described in numerous publications.^{7–12}

The current state of the chemistry and materials science of refractory transition metal carbides and nitrides involves vigorous investigations directed to the improvement of their properties. The properties can be altered by introducing into the composition 'non-traditional' interstitial elements, mainly subgroup IIIB and IVB elements (Al, Si, etc.). The compounds of these elements with carbon and nitrogen are nonisostructural with *d* metal carbides and nitrides, involving predominantly covalent bonding. Such compounds have found a wide variety of application as chemically stable, ultrahard, semiconducting materials^{13–15} and they are also convenient objects for the investigation of the electronic structures of solids by computational quantum-chemical methods.^{16–21}

The interest in the study of ternary systems of the type $M-M'-(C,N)$, where *M* is a transition metal and *M'* a non-

transition subgroup IIIB or IVB element, is associated primarily with the search for new ceramic materials, which are likely to be useful in the development of protective coatings, materials for the manufacture of instruments, and constructional materials and with the creation of new composites and the determination of the possibilities for their employment in microelectronics, and optics, as catalysts, and as elements in reinforced composite materials for space technology.

Studies on the equilibrium phase relations in the $M-M'-(C,N)$ systems have demonstrated^{1–5} the existence of an extremely large set of ternary phases. The thin-film technologies,^{22–29} which make it possible to produce equilibrium metastable or crystalline and amorphous phases and to vary their microstructure and the content of atomic components over a wide range of concentrations, have therefore assumed a special importance in the creation of new materials. The combination of thin-film technologies with various procedures for the activation of processes involving the preparation of the compositions has led to the possibility of a flexible modification of their physicochemical properties. The problem of the description of the electronic properties of the above multicomponent systems (both mono- and hetero-phase) has become of current interest in this connection. An important place has also been assigned to the determination of specific features of the electronic structure (ES) and the chemical bonding in the individual ternary phases formed in the $M-M'-(C,N)$ systems. The groups of carbides and nitrides having the composition $M_3M'(C,N)$ are of considerable interest in this respect.

The magnetic properties of these carbides and nitrides, in particular the magnetic (and structural) phase transitions, which are of technological importance, have attracted the greatest attention of investigators.^{29–32}

In the present review, an attempt has been made to survey available data on the electronic structures and the chemical bonding in the solid solutions and in the ternary carbide and nitride phases based on transition metals and subgroup IIIB and IVB elements, obtained within the framework of computational approaches to solid state quantum chemistry and also with the aid of X-ray emission and X-ray photoelectron spectroscopy.

II. Chemical bonding and electronic structures of *d*-metal aluminonitrides and aluminocarbides

The aluminium-containing phases formed in the $M-Al-C$, $M-Al-N$, $M-Al-C-N$, etc. systems have been most thoroughly investigated among complex carbides and nitrides. A representative group of solid compounds of the type $M_3Al(C,N)$ and $M_2Al(C,N)$, having individual crystal structures^{1–4} and

A L Ivanovskii Institute of Solid State Chemistry, The Ural Division of the Russian Academy of Sciences, Pervomaiskaya ul. 91, 620219 Ekaterinburg, Russian Federation. Fax (7-343) 244 44 95.

between the octahedra. According to estimates,^{1,60} the compositions of Ti_2AlC_x and Ti_3AlC_x may vary in the range $0.2 \leq x \leq 1.2$.

The initial ideas about the possible types of interatomic interactions in the Ti_2AlC_x and Ti_3AlC_x phases were based on the analysis of their crystal-chemical parameters. Thus the Ti–C distance in Ti_3AlC is close to the sum of the covalent radii of titanium and carbon, which makes it possible to postulate⁶¹ the existence of a strong covalent Ti–C bond. On the other hand, the Al–Al distance is much greater than the sum of the covalent radii of aluminium, which discounts the occurrence of direct Al–Al interactions. Similar comparisons of the atomic radii and the interatomic distances for the Ti–Ti, Al–Ti, and Al–C pairs of atoms lead to the conclusion that there is a possibility of the formation of bonds between titanium and aluminium atoms (Ti–Ti, Al–Ti) and that there are no bonds between aluminium and carbon atoms.⁶¹

A more detailed analysis of the nature of the interatomic interactions in the aluminocarbides Ti_2AlC_x and Ti_3AlC_x has become possible by virtue of the results of studies of their X-ray emission and absorption spectra.⁶² It was found that the Ti L_α band in the emission spectrum, reflecting the energy distribution of the d states of the metal, becomes appreciably broadened in the sequence $\text{TiC}_x \rightarrow \text{Ti}_2\text{AlC}_x \rightarrow \text{Ti}_3\text{AlC}_x$, the main maximum shifting towards the long-wavelength region of the spectrum with simultaneous increase in the intensity of the short-wavelength maximum, which has the same energy as the Al $L_{2,3}$ peak, i.e. the $d(t_{2g})$ states of titanium are filled as a result of the partial transfer of electron density in the Al \rightarrow Ti direction. This may indicate the hybridisation of the near-Fermi Ti $3d, 4s$ –Al $3s, 3d$ states. The identity of the energies of the long-wavelength Ti L_α and Al $L_{2,3}$ maxima in the emission spectra indicates the appearance of covalent Ti–Al bonds.⁶²

With increase in the number of carbon vacancies, the intensity of the low-energy maximum of the Ti L_α band also increases, which is due to the transfer of part of the electron density to the near-Fermi region. Overall, the variable-composition transition metal aluminocarbides may be regarded as phases involving the insertion of carbon into the hypothetical titanium aluminides Ti_2Al and Ti_3Al , the system of interatomic interactions which results in the formation of the Ti–C, Ti–Ti, and Ti–Al bonds.⁶² The ionic components of the Ti–C and Ti–Al bonds are due to partial charge transfer in the Ti \rightarrow C and Al \rightarrow Ti directions.

More detailed information about the nature of the interatomic structure and the chemical bonding in aluminium-containing carbides and nitrides has been provided by the results of quantum-chemical calculations.^{10, 12, 63–65}

The initial ideas about the specific features of the rearrangement of the electronic state in MC and MN ($M = \text{Ti, V, Zr, Nb}$), associated with the insertion of isolated aluminium atoms in the sublattices of these binary phases (similar systems evidently occur in the initial stage of the syntheses of aluminocarbide and aluminonitride solid solutions and compounds) have been considered,⁶³ resorting to band and cluster approaches.

The linearised muffin-tin-orbital Green's functions method (LMTO GF) has been used^{63, 65} to calculate the electronic structures of the MC:Al and MN:Al systems in which single aluminium impurities are inserted at sites within the metallic or nonmetallic sublattices of the matrix with formation of 'micro-clusters' of the type AlC_6 , AlN_6 or AlM_6 (when account is taken of the size factor, this appears most likely) in the bulk of the initial crystal.

In particular, it has been found for the TiC:Al system in the case of Al \rightarrow Ti substitution that there is now an admixture of the Al $3s$ states at the bottom of the valence band of the monocarbide. The Al $3p$ states form an intense peak near the Fermi energy (E_F) in the region of the minimum of the density of states (DOS) of titanium carbide, i.e. in this instance the impurity–crystal interaction takes place mainly with participation of the Al $3s$ –C $2p$ functions with an additional contribution by the hybrid Al $3p$ –C $2p$ orbitals.

The pattern in the distribution of the local density of states (LDOS) of the impurity inserted at a C-sublattice site, whereupon the Al $3s$ states are localised near the lower edge of the p – d band of the carbide and their overlap with the valence states of the latter is significant, becomes markedly different. In their turn, the Al $3p$ functions give rise to distinct atom-like resonances in the region of the local DOS minima of the carbide.

A similar pattern in the distribution of impurity states occurs in the TiN:Al system.⁶⁵

Thus an appreciable difference in the energy distributions of the impurity states of the aluminium and the states of the component atoms of the matrix is observed in the MC:Al and MN:Al systems, which indicates significant differences in the nature of the bonds formed by Al with the matrix component atoms and the M–C (or M–N) bonds.^{7–12} This is one of the causes of the limited solubility of aluminium in TiC and TiN (in contrast to transition metals).^{1, 60}

Evidently the presence of local impurity peaks near the edge of the TiC and TiN energy bands, reflecting the states of the aluminium atoms not participating in the formation of the Al–carbide (Al–nitride) bonds, promotes an increase in the number of direct Al–Al interactions with increase in the concentration of aluminium in the bulk of the crystals. Such interactions compete with the system of bonds in carbides and nitrides. As a result, the structural type of the initial matrix changes because of the formation of phases with an individual type of crystal structure, which has in fact been observed experimentally.⁶⁰

The partial interatomic interactions in the TiN:Al system have been analysed⁶⁶ within the framework of the nonempirical discrete variation method.^{67, 68} The parameters of the photoelectron spectrum and the populations of the interatomic bonds of the $\text{TiN}_6\text{Ti}_{12}\text{N}_8$ and $\text{AlN}_6\text{Ti}_{12}\text{N}_8$ fragments, modelling $\text{TiN}_{1.0}$ and TiN:Al respectively, have been compared. The overlap integrals (OI) of the atomic wave functions obtained for the above fragments indicate that the interatomic bonds are based on the Ti $d(e_g, t_{2g})$ –N $2p_{x,y,z}$ interactions (of the σ and π types). The introduction of aluminium atoms diminishes somewhat the maximum values of the Ti–N overlap integrals (c ranges from approximately 0.300e to 0.296e for the $\text{TiN}_6\text{Ti}_{12}\text{N}_8$ and $\text{AlN}_6\text{Ti}_{12}\text{N}_8$ groups respectively), the Al–N interaction occurring as a result of the overlap of the Al $3s, 3p$ –N $2p$ functions.

The electronic properties of a series of hypothetical ordered $\text{Ti}_x\text{Al}_{1-x}\text{N}$ ($x = 0.75, 0.50$) cubic solid solutions have been investigated by the self-consistent linearised augmented plane waves (LAPW) method.^{69, 70} The unit cell of the model structure of the $\text{Ti}_{0.75}\text{Al}_{0.25}\text{N}$ ($\text{Ti}_3\text{AlN}_3^{[4]}\text{N}^{[6]}$) phase contained a nitrogen atom ($\text{N}^{[6]}$) involved in a regular Ti_6 octahedral coordination and $\text{N}^{[4]}$ type atoms with a Ti_4Al_2 in closest proximity. The cell used for the description of the $\text{Ti}_{0.5}\text{Al}_{0.5}\text{N}$ ($\text{TiAlN}^{[2]}\text{N}^{[4]}$) composition is formed on the basis of the cubic cell by the displacement of the titanium atoms in its upper and lower planes by aluminium atoms.

The principal characteristics of the electron spectra of both phases are presented in Fig. 3 and Table 3. Comparison with the data obtained with the $\text{TiN}_{1.0}$ electron spectrum^{71–74} shows that the aluminonitride alloys on the whole retain the principal features of the spectrum characteristic of titanium mononitride: the $\text{Ti}_x\text{Al}_y\text{N}$ valence band contains an isolated low-energy band made up predominantly of the nitrogen $2s$ states (the s band) and separated by the forbidden gap (FG) from the main valence-bonding band (the p – d band). Partial Ti \rightarrow Al replacement leads to a narrowing of the s band (by 0.08 Ry for $\text{Ti}_{0.5}\text{Al}_{0.5}\text{N}$ compared with $\text{TiN}_{1.0}$) and of FG (by 0.18 Ry); on the other hand, the p – d band, partially overlapping the bands of the near-Fermi Ti d states, is broadened (as a consequence of the admixture of the aluminium s, p valence states).

Compared with $\text{TiN}_{1.0}$,^{71–74} the DOS distribution for aluminonitrides^{60, 70} does not exhibit significant differences in the region of the s and d subbands. The most notable DOS rearrangement, arising due to the appearance of new DOS peaks near the

Table 3. The results of LMPW calculations for the $\text{Ti}_{0.75}\text{Al}_{0.25}\text{N}$ and $\text{Ti}_{0.50}\text{Al}_{0.50}\text{N}$ ordered cubic phases.

upper and lower edges of the given subband, is observed in the region of the $p-d$ band of the nitride.

The densities of states of the $\text{N}^{[6]}$ atoms, having the Ti_6 environment, are similar to those for nitrogen in $\text{TiN}_{1.0}$ ⁷⁴ and are determined by the σ -bonds ($p-d_{z^2}$ overlap) and π -bonds (overlap of $p-d_{xz}$, d_{yz} orbitals). The $\text{N}^{[4]}$ p_z orbitals are oriented towards the aluminium atoms and form DOS peaks in the region of the localisation of the energies of the Al 3s,3p states, which indicates the occurrence of the $\text{N}^{[4]}-\text{Al}(p_z-s,p)$ interactions. The highest-energy peak of the $\text{N}^{[4]}$ p_z states is due to the partial

Table 4. The effective atomic charges (e) for $\text{TiN}_{1.0}$, $\text{Ti}_{0.75}\text{Al}_{0.25}\text{N}$, and $\text{Ti}_{0.50}\text{Al}_{0.50}\text{N}$.

Phase	Ti	$\text{N}^{[6]*}$	$\text{N}^{[4]}$	$\text{N}^{[2]}$	Al
$\text{TiN}_{1.0}$	-0.33	0.38	—	—	—
$\text{Ti}_{0.75}\text{Al}_{0.25}\text{N}$	-0.27	0.36	0.38	—	-0.43
$\text{Ti}_{0.50}\text{Al}_{0.50}\text{N}$	-0.24	—	0.39	0.41	-0.39

Note. The effective atomic charges were determined as the differences between the charges in the atomic spheres according to the LAPW calculations and the superposition of the charge densities of the atoms in the crystal.

transfer of electron density from the nearest surrounding nitrogen atoms to the atomic sphere of the aluminium.

The distribution of the local density of states of $\text{Ti}_{0.50}\text{Al}_{0.50}\text{N}$ repeats overall the situation examined above with the exception of certain features⁷⁰ associated with the decrease in the symmetry of the system as a consequence of the increase in the Al:Ti ratio.

Analysis of the partial charges in the atomic spheres presented in Table 4 shows that the charge polarisation in aluminonitrides leads to a partial shift of electron density (ED) in the (Ti,Al) \rightarrow N direction, which agrees with the XPES data and the results of cluster calculations by the discrete variation method.^{35, 54, 66}

The features noted above in the distribution of the charge densities and interatomic interactions are clearly illustrated by the maps of the electron density distribution (Fig. 4). Comparison of Figs 4a and 4b shows that the $\sigma(\text{Ti}-\text{N})$ -bond in the $\text{Ti}_{0.50}\text{Al}_{0.50}\text{N}$ phase is somewhat stronger than in the $\text{Ti}_{0.75}\text{Al}_{0.25}\text{N}$ phase. This is also true of the π -type Ti-Ti bonds. Furthermore, the distribution

**Figure 3.** The energy bands of the hypothetical ordered aluminonitrides $\text{Ti}_{0.75}\text{Al}_{0.25}\text{N}$ (a) and $\text{Ti}_{0.50}\text{Al}_{0.50}\text{N}$ (b); calculation by the LAPW method.

of the maxima in the contours of the $d(e_g)$ orbitals indicates the possibility of Ti–Al bond formation and the appreciable density of the lines around the atomic nuclei of aluminium indicates the presence of an ionic component of the bond.

It was noted previously that the cubic aluminonitride alloys synthesised are characterised by configurational disorder in the metallic sublattice. An attempt has been made^{69,75} to take this factor into account. The calculation was performed within the framework of the Korringa–Kohn–Rostocker coherent potential approximation (KKR CPA) method; the concept of an effective medium, simulating the average configuration of the system, has been introduced for the description of disordered systems.⁷⁶ Since the calculations^{69,75} were nonself-consistent, the potentials of the atoms of the disordered $\text{Ti}_x\text{Al}_{1-x}\text{N}$ ($x = 0.75, 0.50$) alloys were taken from calculations of regular structures by the LAPW method⁷⁰ and were averaged for atoms of one kind.

Fig. 5 presents as an example the local densities of states for aluminium in the ordered and disordered aluminonitrides. Evidently, allowance for disorder in the metallic sublattice is manifested mainly (with retention of the overall sequence in the energy distributions of the s, p, d functions of aluminium in the spectrum) by the ‘spreading’ of a series of peaks in the LDOS spectrum of the regular structure. Furthermore, the noncoincidence of the maxima of the Al 3s subband, calculated by the KKR CPA and LAPW methods, has been noted,⁷⁵ while the bottom of the band for the ordered alloy is ~ 1 eV deeper than for the disordered alloy with a statistical distribution of the Ti and Al atoms at the corresponding sublattice sites.

The specific features of the fitting of the coherent potential approximation are known⁷⁷ to preclude a detailed consideration of the mechanism of chemical bonding. The LDOS obtained were therefore used⁷⁵ for the theoretical calculation of the form of the X-ray emission, photoelectron, and Auger electron spectra. The Al $K\alpha$ emission lines plotted (within the framework of the formalism of the dipolar approximation^{77,78}) for $\text{Ti}_{0.75}\text{Al}_{0.25}\text{N}$ and

$\text{Ti}_{0.50}\text{Al}_{0.50}\text{N}$ are presented in Fig. 5. Estimates⁶⁹ of the transition matrix elements make it possible to interpret the form of the L spectrum of aluminium as a superposition of its s and d states. The L band in the aluminium spectrum (as for the wurtzite-like AlN)⁷⁹ contains three maxima, but the ratios of their intensities are markedly different, while the energy gaps between the maxima for $\text{Ti}_{0.75}\text{Al}_{0.25}\text{N}$ are greater than those for AlN by ~ 0.9 eV. Furthermore, in contrast to aluminium nitride,⁷⁹ the Al N and Al K line maxima do not have the same energies. The aluminium K bands undergo the greatest changes (with a relative stability of Al L line) associated with the variation of the Al/Ti ratio.

The photoelectron spectra of $\text{Ti}_x\text{Al}_y\text{N}$ have been calculated^{77,80,81} by a standard method for the photon energies $E = 1487$ and 150 eV. The theoretical integral Auger spectra were also plotted (Fig. 5) as convolutions of the corresponding partial states of the aluminonitrides.^{82,83} In particular, it was noted that the form of the Ti $L_2M_{23}V$ line is determined by the distribution of the p and d states of titanium.

Comparative analysis of the stability of the cubic titanium aluminocarbides and aluminonitrides as a function of the site of substitution (Al \rightarrow Ti or Al \rightarrow C, N) and also of the aluminium content in the initial TiC and TiN has been carried out^{84–86} within the framework of the LMTO method in terms of the atomic sphere approximation (ASA).⁸⁷

Using the Ti_4X_4 ($X = \text{C}, \text{N}$) supercell, the Ti–Al–N and Ti–Al–C solid solutions having the following compositions have been modelled with the aid of the successive substitution of titanium or nonmetal atoms by aluminium atoms: TiN, $\text{Ti}_{0.75}\text{Al}_{0.25}\text{N}$, $\text{Ti}_{0.50}\text{Al}_{0.50}\text{N}$, $\text{TiAl}_{0.25}\text{N}_{0.75}$; TiC, $\text{Ti}_{0.75}\text{Al}_{0.25}\text{C}$, $\text{Ti}_{0.50}\text{Al}_{0.50}\text{C}$, $\text{TiAl}_{0.25}\text{C}_{0.75}$.

The results of the calculations of the electronic structure of $\text{Ti}_x\text{Al}_{1-x}\text{N}$ by the LMTO^{84–86} and LAPW⁷⁰ methods agree satisfactorily. A significantly different type of DOS and LDOS has been obtained^{84,86} for the $\text{TiAl}_{0.25}\text{N}_{0.75}$ solid solution, where

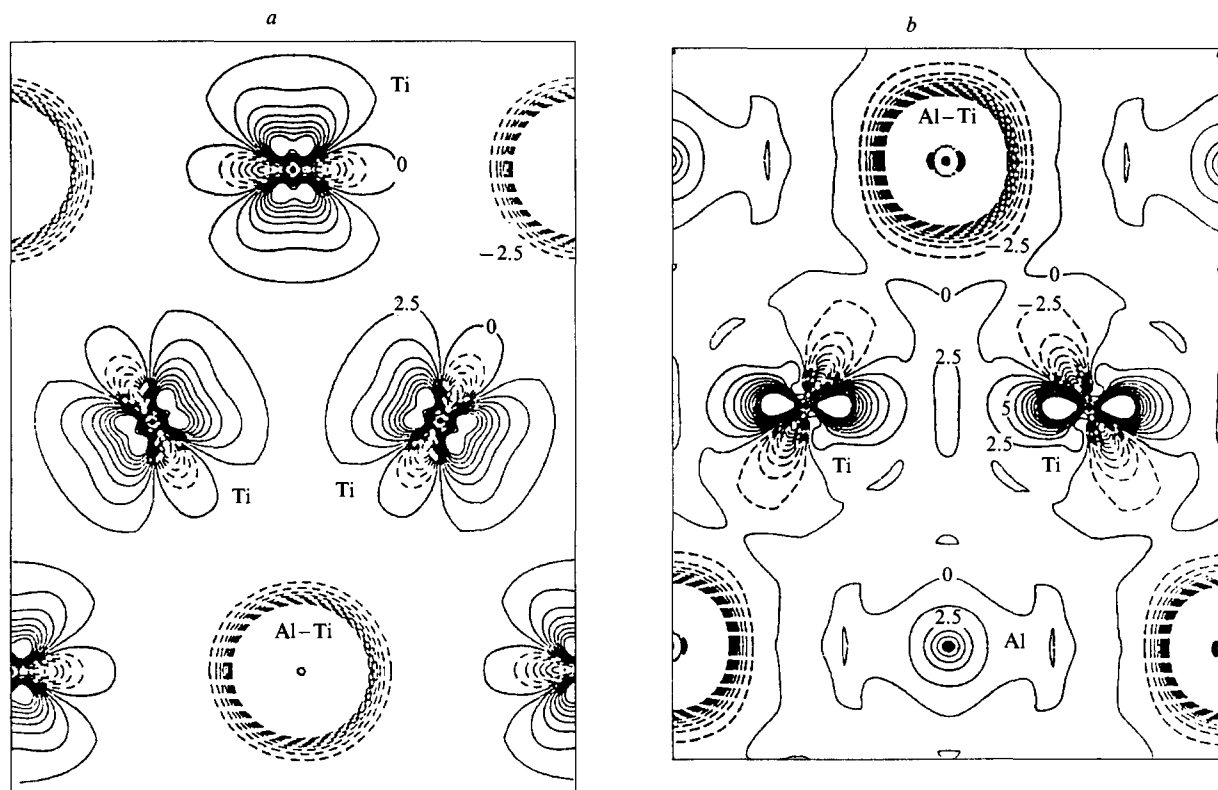

Figure 4. Maps of the differential electron density in the (111) plane of the $\text{Ti}_{0.75}\text{Al}_{0.25}\text{N}$ and $\text{TiN}_{1.0}$ phases (a) and of the $\text{Ti}_{0.50}\text{Al}_{0.50}\text{N}$ and $\text{Ti}_{0.75}\text{Al}_{0.25}\text{N}$ phases (b). The numerals on the curves denote the electron densities; the electron density between the contours is $0.01 \text{ e } \text{\AA}^{-3}$; calculation by the LAPW method.

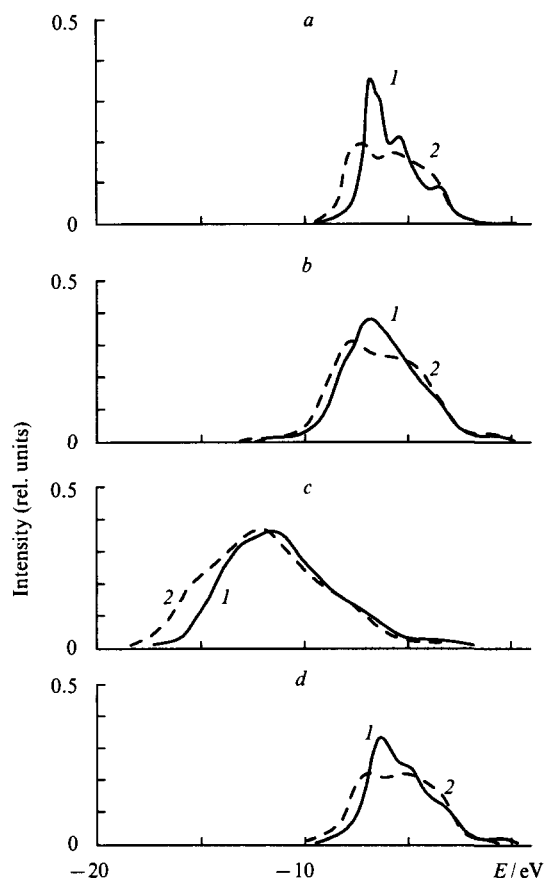

Figure 5. The distribution of the Al 3p states (a), the theoretical forms of the Al $KL_{2,3}V$ (b) and Al KVV (c) Auger electron spectra, and the form of the Al $K\alpha$ line (d) in the X-ray emission spectra for the $Ti_{0.75}Al_{0.25}N$ (1) and $Ti_{0.50}Al_{0.50}N$ (2) phases. Calculation by the KKR CPA method.

the insertion of the aluminium atoms at the N-sublattice sites was postulated (Fig. 6).

The most characteristic difference between the $TiAl_{0.25}N_{0.75}$ and $Ti_xAl_{1-x}N$ spectra is the sharp increase in the energies of the Al 3s and Al 3p states: the energies of the Al 3s state range from -0.55 to -0.52 Ry (peak A in Fig. 6; the lower edge of the $p-d$ band), giving rise to an intense atom-like resonance, while the energies of the Al 3p states (peak B in Fig. 6) correspond to the region of the DOS minimum for the nitride between the $p-d$ and d bands. The forms of the N 2s and N 2p local densities of states remain similar to those in the nitride under these conditions (the immediate environment of aluminium in the given solid solution is $AlTi_6$), which may be attributed to the local character of the interatomic interactions occurring in the solid solutions under discussion.

The dissociation of some of the Ti–N bonds in $TiAl_{0.25}N_{0.75}$ (on replacement of N atoms by Al) results in the transition of a series of titanium states to a higher-energy region [between the $p-d$ and d bands, the LDOS peak of titanium (Fig. 6) has the same energy as peak B of the density of states of $TiAl_{0.25}N_{0.75}$] where the Al 3p,3d states are also located. As a result, in contrast to the solid solutions $Ti_xAl_{1-x}N$, in which the bonding of the aluminium atoms is achieved via the Al 3s,3p–N 2p hybridisation, in the hypothetical solid solution $TiAl_yN_{1-y}$ the bonding of aluminium takes place primarily as a result of the mixing of the Al 3p,3d–Ti 3d,4s functions.

The LMTO calculations^{84,86} for the electronic states of the cubic (B1) solid solutions $Ti_xAl_{1-x}C$ and $TiAl_xC_{1-x}$ show that, as for the aluminonitride alloys, the LDOS distributions for the component atoms in these solutions differ markedly depending on the sites occupied by the aluminium atoms. Thus, for the

Figure 6. The total (a) and partial (b–d) DOS for the cubic $TiAl_{0.25}N_{0.75}$. Calculation by the LMTO method.

substitution of the Ti → Al type, the impurity states are located in the region of the C 2s and $p-d$ bands of the carbide; the occurrence of impurity resonances in the region of the local minima in the density of states in the $p-d$ band of $TiC_{1.0}$ and between the $p-d$ and d bands is characteristic of the $AlTi_6$ coordination.

Furthermore, with increase in the aluminium content (with decrease in the concentration of the valence electrons), E_F for $Ti_xAl_{1-x}C$ shifts, as for $Ti_xAl_{1-x}N$, to the region of low energies. However, the nature of the change in the filling of the valence band for these two groups of solid solutions is fundamentally different: in the case of $Ti_xAl_{1-x}N$ the band of the antibonding delocalised Ti d,s,p states is 'emptied', whereas in the case of $Ti_xAl_{1-x}C$ the filling of the band of the bonding $p-d$ states diminishes.

The above effect as well as the energy required to 'dissociate' the Ti–(N,C) bonds (for the Ti → Al substitution mechanism) can be attributed⁶⁵ to the relative stability of the cubic titanium aluminonitrides and aluminocarbides. Numerous calculations have shown^{8–11} that the Ti–C bond energy is much higher than the Ti–N bond energy. Taking into account the nature of the variation of the filling of bands of different nature noted above for the carbide and nitride phases and also the smaller energy expenditure required for the dissociation of the Ti–N bonds, it was concluded qualitatively^{64,65} that the probability of the formation of single-phase cubic alloys is higher in the Ti–Al–N system than in the Ti–Al–C system.

In order to confirm this hypothesis, calculations of the cohesion energy (E_{coh}) (i.e. the atomisation energy), of the energy of the substitution (E_{sub}) of titanium (or C, N) by aluminium, and the partial pressures of the electronic-nuclear system of the crystals (p_i) were carried out by the LMTO method.^{64,66} The energies E_{coh} and E_{sub} are presented in Table 5. Evidently the absolute value of the cohesion energy for the $Ti_xAl_{1-x}N$ solid solutions diminishes with increasing aluminium content; in the presence of identical aluminium concentrations, $|E_{coh}|$ for

$\text{Ti}_{0.75}\text{Al}_{0.25}\text{N}$ is greater than that for $\text{TiAl}_{0.25}\text{N}_{0.75}$. Similar relations have been obtained also for substitution energies. From the foregoing, one may conclude that, firstly, the synthesis of homogeneous cubic aluminium-containing solid solutions under equilibrium conditions is difficult (the solutions have been obtained mainly in a metastable state — in the form of films^{35–48}); secondly, the probability of the formation of solid solutions diminishes with increasing aluminium content; thirdly, for equal concentrations of aluminium, the substitution by the latter of Ti sublattice sites is energetically more favourable.

Table 5. The cohesion and substitution energies for the aluminium-containing solid solutions based on TiC and TiN.

Compound	$-E_{\text{coh}}/\text{Ry}$	E_{sub}/Ry
TiC	1.588	—
$\text{Ti}_{0.75}\text{Al}_{0.25}\text{C}$	1.452	0.136
$\text{Ti}_{0.50}\text{Al}_{0.50}\text{C}$	1.316	0.272
$\text{TiAl}_{0.25}\text{C}_{0.75}$	1.379	0.209
TiN	1.327	—
$\text{Ti}_{0.75}\text{Al}_{0.25}\text{N}$	1.224	0.103
$\text{Ti}_{0.50}\text{Al}_{0.50}\text{N}$	1.062	0.265
$\text{TiAl}_{0.25}\text{N}_{0.75}$	1.185	0.142

Similar conclusions^{65,66} follow also from the analysis of the energies E_{coh} and E_{sub} for the Ti–Al–C system (Table 5). By comparing the above quantities for the aluminocarbides and aluminonitrides having the same compositions and structures, one may claim that, since $|E_{\text{coh}}|$ for Ti–Al–C is greater than that for Ti–Al–N whereas E_{sub} for Ti–Al–N is greater than that for Ti–Al–C, the formation of stable cubic titanium aluminonitrides is more probable.

These conclusions have been confirmed⁶⁴ also by the comparison of the pressures p_1 . The highest values of $|p_1|$ for TiC and TiN correspond to the (C,N) 2*p* and Ti 3*d* states, the hybridisation of which determines the nature of the chemical bonding in the binary phases.^{8–11} When aluminium atoms are inserted at the Ti sites the Ti–(C,N) bonds are somewhat weakened [the quantities $|p_1(\text{Ti})|$ diminish], but some new bonds of the type (N,C)–Al arise as a result of the interaction of the (C,N) 2*p*–Al *s,p,d* states. Such bonds proved to be much stronger than the Ti–Al bonds formed when aluminium is inserted at nonmetallic sublattice sites. Finally the bonding (negative) pressure of the aluminium states is higher for the nitride alloys than for the carbide-based solid solutions, which again indicates a greater stability of the cubic aluminonitride solid solutions.

The synthesis of aluminium-containing solid solutions involving IVA–VIA subgroup *d* metals, for example, $(\text{TiAlZr})\text{N}_x$, $(\text{ZrAl})\text{N}_x$, and $(\text{TiAlV})\text{N}_x$, has been reported.^{23,36,37} However, there is at present no information about their electronic-energy spectra.

In conclusion of this section, we shall mention again those studies^{64,65} in which the cluster semiempirical LCAO method was used to analyse the energies of the molecular orbitals (MO) of the clusters, simulating the nonstoichiometric (with respect to the nonmetallic sublattice) *H*- and perovskite-like titanium aluminocarbides and aluminonitrides. In conformity with the available X-ray emission data (see above), it has been established, in particular, that, in the overall system of the Ti_2AlC_x molecular orbitals, it is possible to distinguish four groups, consisting predominantly of the contributions of the C 2*s*, Al 3*s*, C 2*p*–Ti 3*d*–Al 1*s,p*, and Al *s,p*–Ti 3*d* states. The differences between the formula compositions and the crystal structures of the aluminocarbide phases determine the relative change in the line widths and energies of the individual subbands of the Ti_3AlC and Ti_2AlC valence spectra.

The formation of carbon vacancies leads⁶⁵ to the progressive filling of the delocalised near-Fermi Ti 3*d* and Al 1*s,p* states and

also to some decrease in the contribution of the C 2*p* orbitals to the hybrid band of the Ti 3*d*–C 2*p*–Al 3*s,3p* type and to a narrowing of the quasi-core C 2*s* band. Similar relations are observed also in the transition $\text{Ti}_2\text{AlN} \rightarrow \text{Ti}_2\text{AlN}_x$ ($x < 1$).

Narrowing and low-energy shifts of the metalloid *s,p* sub-bands are characteristic of aluminonitrides (compared with aluminocarbides). The energy separation of the Ti *d*–N *p* states leads to the virtually complete absence of contributions by the latter to the subband of the Ti–Al states, the population of which increases (as a consequence of the increase in the electron concentration per unit cell of the compound).

The overlap populations (OP) of the atomic orbitals and the bond indices [bond populations (BP)] in the case of the fragments for which calculations have been made indicate that the chemical bonding in the *H*-phases is based on Ti–(C,N), Ti–Al, Ti–Ti-type interactions, comparable in terms of BP, and on the interactions of nontransition metals with one another, whereas the bonds between the atoms of nontransition metals and metalloids are virtually absent (Table 6). The Ti–C and Ti–N bond populations in Ti_2AlC and Ti_2AlN are much smaller than in titanium carbides and nitrides, which is evidently the main reason for the reduced hardness and thermal stability of the aluminocarbides compared with titanium carbides.^{1,61,62}

The relative bond populations depend on the number of vacancies: when nonmetal defects are introduced, the interlayer interactions are weakened and the bonds in the aluminium layer are strengthened. Individual Ti–(C,N) bonds are weakened (in contrast to the bonds in the cubic TiC_x and TiN_x ,^{9,10} where the formation of vacancies strengthens some of the remaining metal–nonmetal bonds). An appreciable anisotropy of the individual interactions in the layers near the defect arises; the occurrence of a weak direct Ti–Ti interaction through the carbon or nitrogen layer is observed.

Table 6. Results of calculations by the LCAO MO method of the overlap populations of the valence atomic orbitals (e) for the clusters in the structures of titanium aluminocarbides and aluminonitrides.

^a The symbol \Box denotes vacancies in the C or N sublattices.

On passing from the carbon-containing to the nitrogen-containing phases, the Ti–nontransition metal bonds and the bonds in the aluminium layers are strengthened, primarily as a result of the weakening of the Ti–nonmetal bonds.

It follows from the data^{64,65} that the transition metal atoms have an effective positive charge in all the phases considered, which increases on passing from the carbide to the nitride phases. Finally analysis of the overlap integrals between the atomic orbitals shows⁶⁵ that the Ti–(C,N) interaction in the *H*-phases takes place, as in the binary carbides and nitrides mainly as a result of the hybridisation of the Ti *3d*–(C,N) *p* states. The Ti–Al bonds are of a mixed character, involving predominantly the Al *s, p* states hybridised with all the valence orbitals of titanium.

III. Electronic properties of transition metal siliconitrides and silicocarbides

Yet another class of objects, for which quantum-chemical studies of the electronic-energy spectra and of the nature of the chemical bonds have been initiated and are developing vigorously, comprises transition metal siliconitrides and silicocarbides. Together with aluminium-containing compounds, these substances are of great interest for the manufacture of new ceramic materials, including constructional ceramics. Preliminary investigations^{88–94} of ceramics based on transition metal and silicon carbides and nitrides have demonstrated particularly their potential suitability in manufacturing technology at high temperatures.

The first information about the electronic states of the atomic components in phases based on the M–Si–C systems was obtained⁹⁵ by the LMTO GF method. This method has been used to calculate the LDOS for isolated atoms of aluminium and

the entire series of *3d* metals which are incorporated at the Si sublattice sites of cubic silicon carbide. These objects were regarded as models and the process involving the incorporation of the atoms M was considered to be a stage leading to the formation of hypothetical solid solutions in the M–Si–C systems, which retain the initial sphalerite-like structure of silicon carbides. In addition, they can simulate one of the probable mechanisms of the formation of intermediate layers in complex silicon-containing ceramics at the contact boundary between a solid grain (SiC) and the elements of the plasticiser, which consist as a rule of *d, p* metals or their alloys.

The results obtained are presented in Fig. 7. Taking into account the data obtained by band calculations for the ideal 3C–SiC carbide,^{96–101} it was found that the form of the LDOS for the transition metals at the beginning of the *3d* series is determined by the nature of the overlap of their outer states with the valence band of the matrix. As the orbital energies of the impurity decrease (Sc → Cu), the filled part of the LDOS undergoes a low-energy shift. For M = Mn, the impurity states are concentrated in the region of the local minimum in the density of states in the *pp* band of SiC, whereas for M = Fe, Co or Ni atom-like (nonbonding) LDOS resonances arise in the forbidden gap between the *ss* and *pp* bands of silicon carbide.

The distributions of the lowest free states of the doping *d* atoms are also found to be significantly different. Their concentration near the upper boundary of the forbidden gap of the carbide increases sharply with increase in the atomic number of the impurity. The nickel impurity exerts the most 'dramatic' effect on the conducting properties of SiC, its presence being responsible for the appearance of resonance peaks in the forbidden gap of silicon carbide.⁹⁵

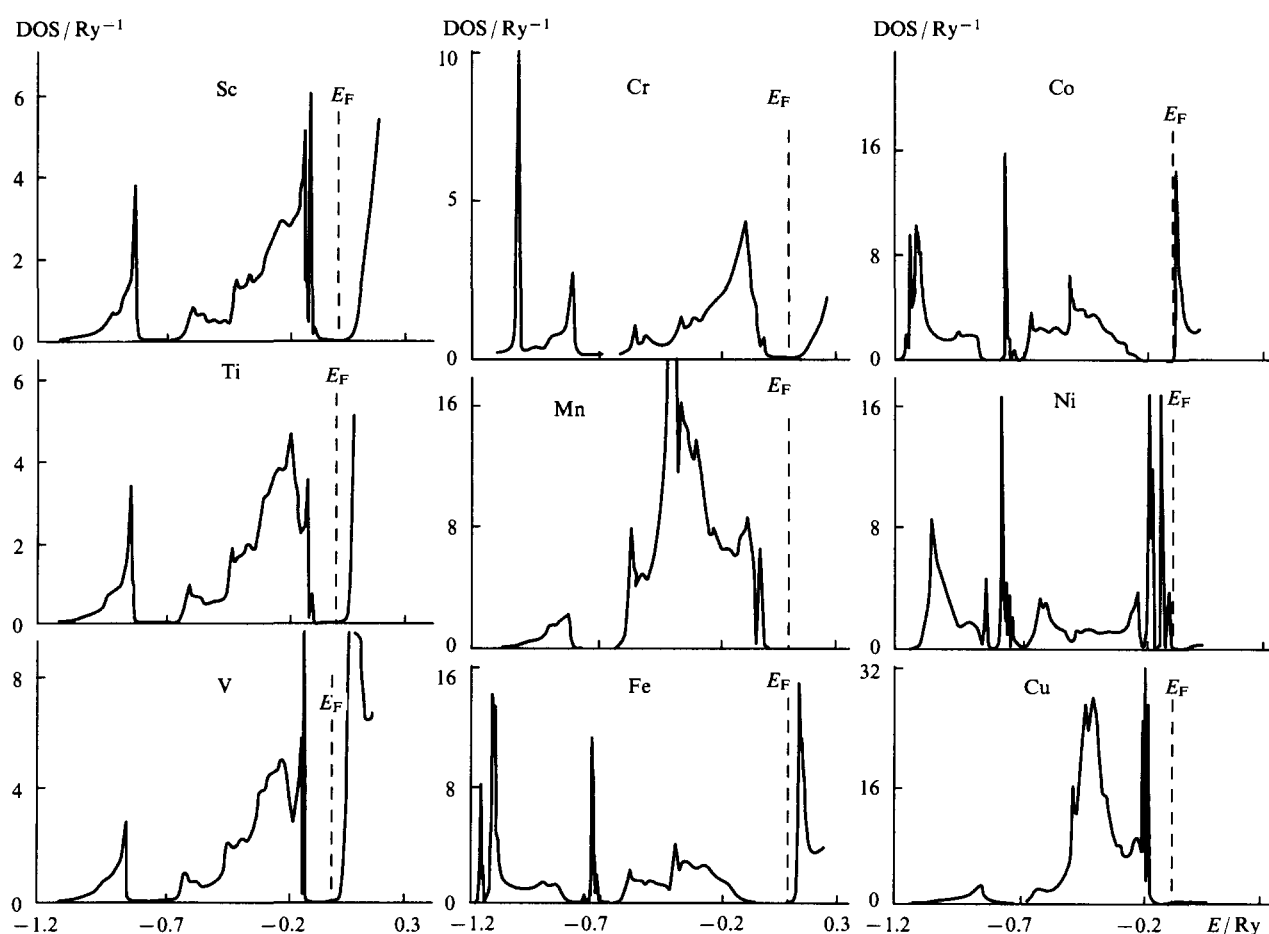

Figure 7. Local DOS of the *3d* metal impurities in cubic 3C–SiC. Calculation by the LMTO GF method.

Estimation of the energy characteristics of the rearrangement of the interatomic interactions under the influence of the impurity (by the method proposed in the study of Anisimov et al.¹⁰²) indicates that in all cases the change in the total energy of the initial crystal is positive ($\Delta E > 0$), i.e. the 'rupture' of the stronger Si–C bonds is not compensated by the newly formed M–C bonds and in this respect the systems under consideration proved to be unstable. Minimal destabilisation occurs when the atoms of aluminium and of the 3d metals at the beginning and end of the series are introduced into the bulk of silicon carbide. It follows from the foregoing that the formation of the modelled homogeneous solid solutions, retaining the SiC structure, is more difficult⁹⁵ than, for example, the formation of reciprocal solid solutions of transition metal carbides and nitrides.^{1–7}

The study of M → Si substitution for a 25% concentration of titanium and vanadium impurities in 3C-SiC, which exert the least destabilising effect on the energetics of the system under consideration, has been continued^{103,104} by the LMTO method. The initial carbide was described using the Si₄C₄ supercell in which the silicon atoms were replaced by titanium or vanadium atoms. This made it possible to calculate the electronic properties of the Si_{0.75}Ti_{0.25}C and Si_{0.75}V_{0.25}C ternary systems. It has been noted that the titanium and vanadium impurities lead to the appearance of sharp DOS peaks in the region of the top of the valence band and alter significantly the form of the DOS of the conductivity band of silicon carbide. These changes are caused by the 3d orbitals of the metal, to which corresponds a large negative pressure of the electronic-nuclear system (p_1), i.e. they are bonding in character. For Si_{0.75}Ti_{0.25}C, the energy of the substitution of 25% of the silicon atoms by titanium (E_{sub}) is negative, which indicates the possibility of the formation of a stable structure in the Si–Ti–C system, where the titanium atoms occupy silicon sites.

For Si_{0.75}V_{0.25}C, the substitution energy is positive. This may be associated both with the differences in the energetics of the formation of bonds by vanadium and titanium with the environment [$|p_1|(\text{Ti}) > |p_1|(\text{V})$] and with the overall decrease in the cohesion energy of the carbide crystal with the vanadium impurity as a result of the increase in the overall electron concentration.

The possibility of the partial substitution by titanium atoms of the silicon carbide C-sublattice sites has been considered.¹⁰⁴ It was established that the doping of the nonstoichiometric (with respect to carbon) SiC_x with titanium has a negative effect on the overall stability of the system.

The nitrogen impurity has a significantly different effect in this respect. LMTO calculations for the silicon carbonitride SiC_{0.75}N_{0.25} have shown¹⁰⁴ that, on partial C → N substitution, the substitution energy is 0.09 Ry, whereas after application of corrections for dissociation (0.10 Ry) the substitution energy becomes negative.^{105,106} Consequently such substitution may be energetically favourable. We may note that a similar small deviation from the linear variation of E_{sub} has been found also for titanium carbonitride.¹⁰⁶

The results obtained in the syntheses and in the study of the electronic states of yet another group of silicon-containing solid solutions with a different (cubic, of the NaCl type) structure of titanium siliconitrides and silicocarbides have been published in a series of communications.^{85,107–109} Films of Ti_xSi_yN_z solid solutions were deposited on a molybdenum foil substrate and on the (100) surface of a NaCl crystal.¹⁰⁹ The composition of the solid solution and the structure and chemical state of the component atoms were investigated as a function of the pressure of the working gas (N₂), temperature, and the potential of the substrate and the cathodic current. With increase in p_{N_2} the nitrogen content in the film increases up to saturation, while the oxygen concentration actually diminishes. The observed type of variation of the N:Ti and O:Ti ratios with nitrogen pressure (Fig. 8) is typical for MN films (M is a transition d metal). At lower nitrogen pressures, the variation of the Si:Ti ratio is

Figure 8. Dependence of the composition of the Ti_xSi_yN_z(O) films on the nitrogen pressure. X: (1) Si; (2) O; (3) N; (4) O + N; (5) O + N + Si.

unexpected — it increases in parallel with increase in the oxygen content up to 0.3, which is much greater than the Si:Ti ratio in the target employed (~0.1).

It was established that, within the narrow range of nitrogen pressures $p_{\text{N}_2} = 6 \times 10^{-2} - 1 \times 10^{-1}$ Pa (region II in Fig. 8), the Ti_xSi_yN_zO₂ films have a single-phase cubic structure. X-Ray photoelectron spectra indicate¹¹⁰ identical energetics of the core states (Ti 2p, N 1s, O 1s) of these films and cubic titanium nitride and oxide nitride films.^{53,54} The Si 2p silicon line is recorded distinctly in the region of the 99.1 eV binding energy. An estimate of the Si:Ti ratio based on XPES yielded ~0.04–0.12 depending on the film deposition conditions.^{109,110} X-Ray probe microanalysis confirmed the presence of silicon and its uniform distribution in the cubic phase.

An increase in the lattice parameter of the siliconitride (from 4.16 to 4.28 Å) with increase in the silicon content was observed, which has been attributed to the differences between the atomic radii of silicon and nitrogen (1.71 and 0.71 Å respectively).¹⁰⁹

The question of the sites occupied by the silicon atoms in the single-phase (of the NaCl type) Ti_xSi_yN_z solid solutions, which was investigated by XPES, is of independent interest.¹¹⁰ The binding energies of the Si 2p, Ti 2p_{3/2} N 1s, and O 1s core levels for a TiSi_{0.1}N_{0.9}(O) film with a cubic structure and certain chemical compounds containing silicon and titanium are presented in Table 7. Evidently, in the specimens where silicon is the electron donor, oxygen or nitrogen atoms are disposed in its immediate environment and the maximum of the Si 2p level is displaced towards higher binding energies relative to the 'pure' silicon. On the other hand, if the first coordination sphere of silicon contains titanium atoms, the Si 2p line shifts towards lower binding energies.

Table 7. The binding energies (eV) for certain core levels in Ti_xSi_yN_z(O) cubic (B1) films and certain titanium- and silicon-containing compounds according to X-ray photoelectron spectroscopy studies.

Compound	Ti 2p _{3/2}	Si 2p	N 1s	O 1s
Ti ₅ Si ₃ (O)	454.1	98.8	—	530.9
Ti _{0.7} Si _{0.25} O _{0.02} (target)	454.1	99.0	—	531.6
Ti _x Si _y N _z (O)	455.0	99.1	397.3	531.4
TiN(O)	455.1	—	397.3	531.5
Si	—	99.5	—	—
Si ₃ N ₄ (O)	—	101.7	397.5	531.3
SiO ₂	—	103.1	—	532.4

The energy of the Si 2*p* level in the Ti–Si–N(O) film (99.1 eV) indicates the existence of a negative charge on the silicon atom and hence the disposition of these atoms in the nonmetallic sublattice of titanium oxynitrides.

A correlation between the content of silicon, nitrogen, and oxygen atoms and the degree of defectiveness has been observed^{109, 110} for all the Ti_xSi_yN_z films investigated: in the region of the existence of the single-phase structure, the silicon content in the films increases simultaneously with increase in the oxygen concentration with retention of a virtually constant overall concentration of oxygen and nitrogen [(N + O)/Ti ≈ 1.0]. The decrease in the quantity (N + O)/Ti leads to an increase in the silicon concentration in the cubic B1 phase and one can therefore postulate that, as the degree of defectiveness of the nonmetallic sublattice and its oxygen content increase, the incorporation of silicon atoms into the TiN(TiN_xO_y) structure becomes more favourable.

A synthesis of metastable cubic single-phase SS (as a coating) of the composition Ti_{0.5}Si_{0.5}C by the magnetron sputtering method using a hot-pressed two-phase TiC/SiC target has been reported.⁹⁴ The preparation of single-phase SS based on TiC and including silicon was noted to be substantially more energy consuming (ion bombardment, heating of the substrate) than the preparation of aluminium-containing alloys like Ti_{0.5}Al_{0.5}N. This was attributed⁹⁴ to the lower mobility of atoms in the near-surface layer of TiC/SiC, which is due to the presence of strong covalent bonds. The localisation of the silicon atoms in the cubic structure of the Ti_xSi_yC_z films has not been specially studied (it has been assumed implicitly that the silicon atoms substitute the metal atoms in TiC by analogy with the Al→Ti substitution). In our opinion, this problem needs to be further considered.

Simultaneously with the synthesis and the study of the structure and properties of films of the cubic TiSi_xN_y phase, the computer simulation of the electronic characteristics of a series of cubic (of the NaCl type) alloys with a variable content of component atoms in the unit cell of the crystals was undertaken.^{107, 108} The relative stabilities of the hypothetical cubic solid solutions were investigated as a function of their composition and the possible mechanism of the substitution by silicon of different kinds of sites in the initial TiC and TiN matrices.

The following series of solid solutions were examined:

I. TiC–TiSi_{0.25}C_{0.75}–TiSi_{0.50}C_{0.50}; TiN–TiSi_{0.25}N_{0.75}–TiSi_{0.50}N_{0.50}–TiSi_{0.75}N_{0.25}.

II. TiC–Ti_{0.75}Si_{0.25}C–Ti_{0.50}Si_{0.50}C; TiN–Ti_{0.75}Si_{0.25}N–Ti_{0.50}Si_{0.50}N.

The process involving the formation of a solid solution on Si→(C,N) substitution was simulated for the series I solid solutions (by the LMTO method adopting TiC and TiN as the bases), whereas the substitution of silicon atoms by titanium atoms was simulated for the series II solutions.

Certain results of such simulation^{107, 108} are presented in Table 8 and in Fig. 9. Evidently, when silicon atoms are introduced into the bulk of the initial TiN, its spectrum is significantly transformed. On Si→N substitution, two intense DOS peaks arise near the upper and lower edges of the *p*–*d* band and broaden markedly with increase in the silicon concentration, which diminishes the forbidden gap between the *s* and *p*–*d* bands of TiN. A decrease in the intensity of the peak of the density of the N 2*s* states, as well as the partial emptying (as a consequence of the decrease in the concentration of valence electrons) of the antibonding (relative to the *p*–*d* band) subband of the delocalised metallic states, a decrease in the density of states at the Fermi level *N*(*E*_F), are observed at the same time.

On the other hand, on Ti→Si substitution the concentration of valence electrons in the cell does not change (9 e) and the Fermi energy does not actually shift; however, the perturbation of the TiN spectrum as a result of the introduction of the impurity is accompanied by an appreciable increase in *N*(*E*_F).

A series of significant differences in the distribution of the LDOS of the elements comprising the solid solution have also

Table 8. The cohesion and substitution energies for solid solutions in the Ti–Si–C–N–O system.

TiSi _{0.50} C _{0.50}	1.28	0.31

been noted as a function of the type of sites occupied by silicon. These are caused primarily by the fundamentally different nature of the hybridisation of the valence states of silicon and the atoms coordinating it (SiN₆ or SiTi₆).¹⁰⁷ One may assume that fairly simple X-ray emission experiments (for example the study of the nitrogen and silicon *K* lines and the titanium *L*_α lines) may provide unambiguous evidence in support of one of the possible mechanisms of the incorporation of silicon in the crystal.

The incorporation of silicon in TiC exerts an even greater influence on the electronic structure of the matrix (Fig. 9). In the completed state, the carbide may be classified as a semimetal.^{1–4} Thus, whereas on substitution of silicon by carbon the Si 3*p* states are concentrated in the region of the *p*–*d* subband and peak *A* corresponds to the atom-like nonbonding Si 3*s* resonance in the region of the forbidden gap between the C 2*s* and *p* subbands of the carbide (i.e. the bonding in TiSi_xC_{1–x} is of the Ti 3*d*–Si 3*p* hybrid type), in the Ti_{1–x}Si_xC spectrum one can trace distinctly, apart from the additional Si 3*s*-like maximum (in the vicinity of the lower edge of the C 2*s*-type band) and the DOS peak (in the region of the forbidden gap of TiC of the mixed Si 3*s*, 3*p* type), a progressive increase in the Si 3*s*, 3*p* and C 2*p* local density of states (giving rise to the *p*–*p* bonding) in the near-Fermi region of the crystal characterised by a deep DOS maximum for the ideal TiC_{1.0}.

The introduction of silicon at both N and Ti sites of the TiN lattice reduces appreciably the cohesion energy of the crystal, while the substitution energy is positive (Table 8). This should hinder the synthesis of homogeneous silicon-containing cubic solid solutions under equilibrium conditions, i.e. these solutions may be obtained predominantly in a metastable state.

On Si→N substitution (for solid solutions with identical silicon concentrations) |*E*_{coh}| is greater and *E*_{sub} is smaller than the corresponding values calculated for the alloys where silicon is inserted at Ti sublattice sites (solid solutions containing identical silicon concentrations are compared), which indicates unambiguously that the substitution of nitrogen by silicon is preferable. With increase in the silicon concentration, |*E*_{coh}| diminishes and there is a corresponding sharp increase in the positive *E*_{sub}, which indicates that the preparation of cubic solid solutions with a high silicon content becomes more difficult.

Comparison of the energy parameters of the silicon-containing nitride and carbide alloys shows^{107, 108} that the trends in the variation of *E*_{coh} and *E*_{sub} for the Ti_xSi_yC_z solid solutions are the same as for titanium siliconitrides.

(1) The insertion of silicon at both Ti and C sites is an energetically unfavourable process, the Si→C substitution occurring more readily than Si→Ti.

(2) With increase in the silicon concentration, there is an appreciable decrease in |*E*_{coh}| and an increase in *E*_{sub}, which is the

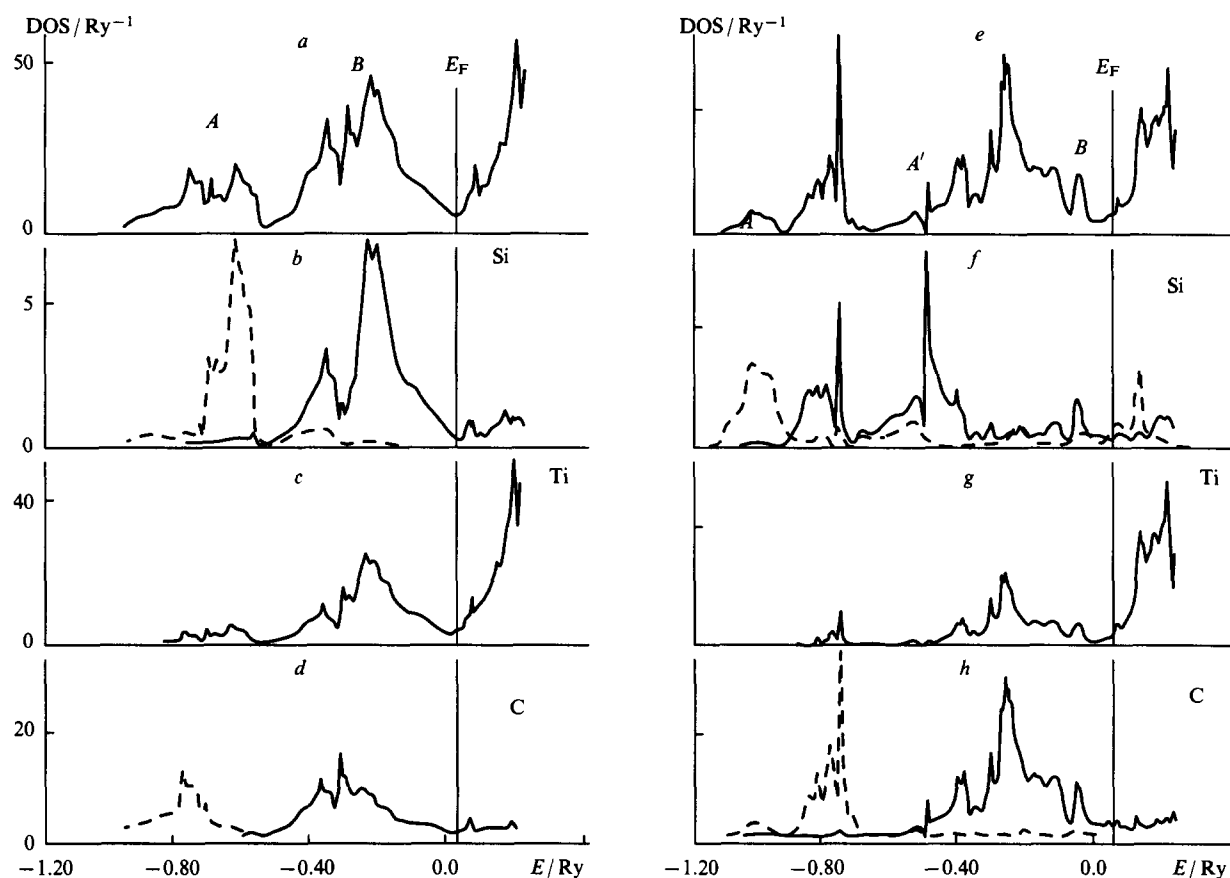

Figure 9. The total (a, e) and partial (b–d, f–h) DOS for the $\text{TiSi}_{0.25}\text{C}_{0.75}$ (a–d) and $\text{Ti}_{0.75}\text{Si}_{0.25}\text{C}$ (e–h) solid solutions.

reason for the instability of the silicon-enriched cubic solid solutions.

(3) In the $\text{Si} \rightarrow \text{C}$ substitution, silicon becomes involved in a p – d hybrid bond with the metal, whereas in the $\text{Si} \rightarrow \text{Ti}$ substitution the type of bond is determined by the mixing of the p – p functions.

The influence of impurities and N vacancies on the electron spectra and the stability of the cubic TiSi_xN_y solid solution have been investigated within the framework of the LMTO method. The following compositions were examined:¹⁰⁸ $\text{TiN}_{1.0}$, $\text{TiSi}_{0.25}\text{N}_{0.75}$, $\text{TiSi}_{0.25}\text{N}_{0.50}$, and $\text{TiSi}_{0.25}\text{N}_{0.50}\text{O}_{0.25}$. In addition, the dependence of the equilibrium lattice parameter R of the TiSi_xN_y alloys on the composition of the metalloid sublattice was determined.¹⁰⁸ Fig. 10 presents the dependence of the total energy of the alloys E_{tot} on R . Evidently, for the completed nitride $\text{TiN}_{1.0}$, the calculated parameter $R = 4.22 \text{ \AA}$ agrees with the experimental value.^{4,5} The incorporation of silicon atoms in the N sublattice leads to an appreciable increase in R (from 4.22 \AA in $\text{TiN}_{1.0}$ to 4.32 \AA in $\text{TiSi}_{0.25}\text{N}_{0.75}$). The presence of oxygen impurities or vacancies promotes a further increase in R ($\sim 4.34 \text{ \AA}$ for $\text{TiSi}_{0.25}\text{N}_{0.50}$ and $\text{TiSi}_{0.25}\text{N}_{0.50}\text{O}_{0.25}$), which agrees with experiment.^{109, 110}

Comparison of the DOS and LDOS distributions for the $\text{TiN}_{1.0}$, $\text{TiSi}_{0.25}\text{N}_{0.75}$, $\text{TiSi}_{0.25}\text{N}_{0.50}$, and $\text{TiSi}_{0.25}\text{N}_{0.50}\text{O}_{0.25}$ phases, obtained for equilibrium values of R , shows that the introduction of N defects is accompanied by a steady decrease in the contributions of the N $2s, 2p$ states to the region of the occupied states of the spectrum and also by a significant redistribution of the valence states of titanium with the appearance of distinct d resonances, one of which is in the immediate vicinity and the other has the same energy as E_F (Fig. 11). The distribution of the ‘vacancy’ states is similar. The above features are due to the reorganisation of the states of the metallic centres coordinating the vacancy and reflect the partial ‘elimination’ of the splitting of the Ti states into bonding and antibonding. (This occurs for the completed TiX_6

immediate environment.) The Ti states pass to the region of nonbonding states (in the vicinity of E_F), giving rise to the ‘vacancy’ peaks in the DOS for titanium noted above. Some of the latter are ‘trapped’ by the sphere of the defect, giving rise to DOS vacancies.^{9, 10, 102, 108, 111–114}

A different type of DOS distribution is observed for the $\text{TiSi}_{0.25}\text{N}_{0.50}\text{O}_{0.25}$ alloy (Fig. 11). The most notable changes in the electronic structures of the solid solutions, associated with the incorporation of oxygen atoms in their sublattices, consist^{86, 108} in the appearance of additional ‘impurity’ subbands of the O $2s$ and O $2p$ types, the former being of the quasi-core type and being located in the energy gap below the bottom of the valence band of

Figure 10. Dependence of the total energy of the crystal (E_{tot}) on the lattice constant for the $\text{TiN}_{1.0}$ (a), $\text{TiSi}_{0.25}\text{N}_{0.75}$ (b), $\text{TiSi}_{0.25}\text{N}_{0.50}$ (c), and $\text{TiSi}_{0.25}\text{N}_{0.50}\text{O}_{0.25}$ (d) cubic phases. Calculations by the LMTO method.

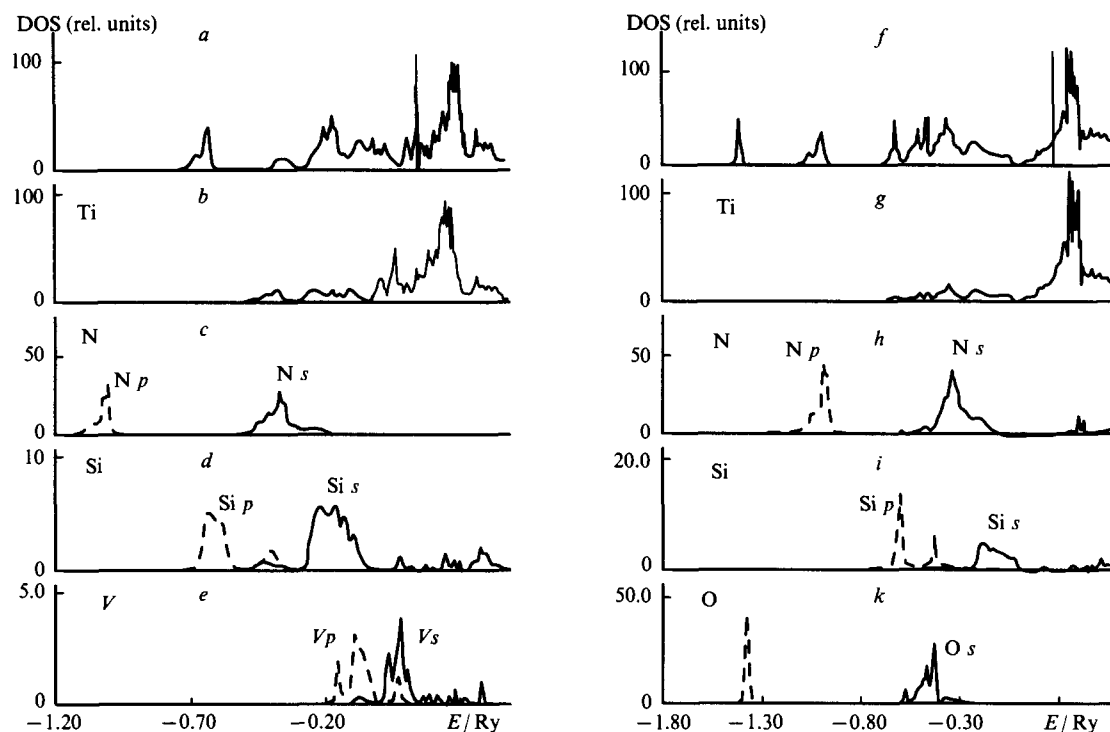

Figure 11. The energy distributions of the total (*a, f*) and partial (*b–d, g–k*) DOS for the nonstoichiometric (with respect to the N sublattice) $\text{TiSi}_{0.25}\text{N}_{0.50}$ (*a–c*) and $\text{TiSi}_{0.25}\text{N}_{0.50}\text{O}_{0.25}$ (*f–k*) cubic solid solutions. the siliconitride. The latter subband (of the O 2*p* type) is localised near the DOS minimum between Si 3*s* band and the hybrid *p–d* band of the matrix.

The influence of the defects considered on the energy state of the Ti–Si–N system has been discussed^{86, 108} using the cohesion energies of the crystals and the substitution energies. It was established that the presence of the oxygen impurity or of lattice vacancies in the structure of the TiSi_xN_y phase leads to a decrease in $|E_{\text{coh}}|$ and an increase in $|E_{\text{sub}}|$, indicating a progressive destabilisation of the system in the series $\text{TiSi}_{0.25}\text{N}_{0.75} \rightarrow \text{TiSi}_{0.25}\text{N}_{0.50}\text{O}_{0.25} \rightarrow \text{TiSi}_{0.25}\text{N}_{0.50}$. These data indicate a greater energy stability of the siliconitride with an oxygen impurity compared with the solid solution containing N vacancies.^{109, 110}

The results of studies on the electronic properties of silicon-containing solid solutions retaining the basic structure of the initial binary phases — sphalerite (SiC) or rock salt (TiC, TiN) — have been considered hitherto.

The study of the phase equilibria in the Ti–Si–C system made it possible to establish the existence of at least two ordered silicocarbide phases — $\text{Ti}_5\text{Si}_3\text{C}_x$ and Ti_3SiC_2 .^{1–3, 88, 92, 115–117} Among these phases, the Ti_3SiC_2 phase with a hexagonal structure (P6₃/mmc space group, unit cell parameters $a = 3.066 \text{ \AA}$, and $c = 17.646 \text{ \AA}$), in which the metal atoms occupy two structurally nonequivalent sites with and without silicon atoms in their immediate environment (Fig. 12), has attracted the greatest attention recently.^{93, 94, 116, 117} It plays a significant role in the formation of the microstructure of the contact band of ceramics of the type TiC/SiC and Ti/SiC.^{92–94} The development of ceramic polycrystalline materials based on titanium silicocarbide has been reported.^{88–93}

The band structure of Ti_3SiC_2 has been calculated by the full-potential self-consistent LMTO method.¹¹⁸

In contrast to the electron structure of the binary titanium carbide,^{7–10} E_F for the electronic structure of the silicocarbide coincides with the peak of the density of the *d* states of titanium (Fig. 13), which should give rise to the metal-like properties of this phase. The contributions to $N(E_F)$ by the states of the structurally

nonequivalent titanium atoms are significantly different, the Ti(1) states playing a decisive role [$N(E_F)_{\text{Ti}(1)} : N(E_F)_{\text{Ti}(2)} \approx 3.76$].

The form and energy distribution of the DOS for the Ti(1) and Ti(2) atoms are also different (Fig. 13). Thus, whereas the DOS for the Ti(1) atoms, having both Si and C centres in its environment, contains two maxima with energies identical with those of the DOS peaks for carbon and silicon, the valence states of the Ti(2) atoms, containing only carbon atoms in the first coordination sphere, are displaced downwards on the energy scale [relative to the density of states of the Ti(1) type], whereas the form of the density of states for the Ti(2) centres repeats in many respects the form of the C 2*p* states.

An estimate of the effective charges on the atoms [$+0.614 e$ for Ti(1); $+0.641 e$ for Ti(2); $-0.304 e$ for Si; $-0.384 e$ for C] indicates partial charge transfers in the Ti(1,2) → Si direction, which ensures the existence of an ionic component in the overall chemical bonding system in Ti_3SiC_2 . Consequently a combined ionic-covalent-metallic type of chemical bonding arises in Ti_3SiC_2 . It is determined by the charge polarisation between the

Figure 12. A fragment of the Ti_3SiC_2 crystal structure.

Figure 13. The total (a) and partial (b–e) DOS for Ti_3SiC_2 . For the significance of Ti(1) and Ti(2), see text.

atoms of the metal and the metalloids, the hybridisation of the valence states [of the Ti(1) $3d$ –Si $3p$, Ti(1) $3d$ –C $2p$, Ti(2) $3d$ –C $2p$, and Si $3p$ –Si $3p$ types], and the delocalisation of the near-Fermi d states of titanium [mainly of the Ti(1) atoms].¹¹⁸

The next stage in the study of the electronic properties of titanium silicocarbides (as well as the silicocarbides of other transition metals) should include a more detailed description of the chemical bonding, its anisotropy, and its influence on the properties of the silicon-containing phases.

IV. Chemical bonding in ternary carbides and nitrides based on subgroup VIIA and VIIIA transition metals

The compounds based on subgroup VIIA and VIIIA transition metals constitute a representative class of ternary carbides and nitrides.^{1–3, 29–32} The carbides $\text{M}_3\text{M}'\text{C}$ (M is a transition metal and M' are subgroup IIIB and IVB nontransition elements) have been most thoroughly investigated. The magnetic characteristics of these compounds as well as the magnetic and structural phase transitions, observed in the temperature range 200–500 K, have attracted the greatest attention of investigators.^{29–32} In the high-temperature region, these compounds have a cubic structure of the antiperovskite type^{1–3, 119–128} and are paramagnetic materials of the Pauli type; at lower temperatures, tetragonal lattice distortions as well as second-order magnetic phase transitions with formation of several possible types of ordered magnetic structures have been discovered for the series of carbides.^{29–32, 129–142}

The first model of the interatomic interactions and the electronic states in the $\text{M}_3\text{M}'\text{C}$ phases was proposed by Jardin and Labbe.^{143–145} According to this model, the carbides have an extended conductivity band, which overlaps with a narrow band of hybrid states made up of contributions by the M d and C $2p$ orbitals. The distribution of the DOS for this band has been estimated with the aid of the approximate tight-binding scheme.¹⁴⁵ A logarithmic singularity has been observed in the DDS near its energy centre. Postulating that the Fermi level E_F is located near the peak of the antibonding p – d subband, Jardin and

Labbe^{143–145} explained the instability of the crystal and magnetic structures of $\text{M}_3\text{M}'\text{C}$ on the basis of the characteristics of the electronic structure which they postulated.

We may note that this model was not confirmed in subsequent numerical calculations for the series of perovskite-like carbides.

The first self-consistent LAPW calculations for $\text{Mn}_3\text{M}'\text{C}$ ($\text{M}' = \text{Zn, Ga, In, Sn}$) in a nonmagnetic high-temperature state (cubic structure) established^{146, 147} that the near-Fermi region of the carbide is made up mainly of the d states of the transition metal, whereas the valence bonding (antibonding) subbands for the other component atoms are located somewhat below (above) the Fermi level. Estimates of the local magnetic moments (LMM), carried out with the aid of spin-polarised calculations for the ferromagnetic states of Mn_3GaC , showed¹⁴⁶ that the Mn $3d$ states undergo the maximum spin splitting; the LMM on the atoms are $1.35 \mu_B$ (Mn), $-0.12 \mu_B$ (C), and $-0.008 \mu_B$ (Ga), the estimates being quite reasonably correlated with experiment (the LMM on Mn is $1.3 \pm 0.1 \mu_B$ at 193 K).³²

Systematic LMTO calculations for the cubic carbides $\text{M}_3\text{M}'\text{C}$ ($\text{M} = \text{Mn, Fe}$; $\text{M}' = \text{Zn, Al, Sn, Ga}$) made it possible to discover^{148, 149} the rules governing the variation of the electronic structures of the compounds as a function of the composition of the M and M' lattices. Fig. 14 presents as an example the electronic states of Mn_3ZnC . Evidently the valence band contains four distinct subbands. The lower subband is of the quasi-core type and is made up mainly of the contributions of the C $2s$ states with slight additional contributions of the Zn $3d$, Mn $3d$, and Zn $4s$ states. The next bonding band includes the hybrid C $2p$ –Mn $3d$ functions as well as the pseudoatomic resonances of the Zn $3d$ and Zn $4s$ states. The nonbonding, partly filled near-Fermi subband is determined by the dispersion of the Mn $3d$

Figure 14. The total (a) and partial (b–e) DOS for the nonmagnetic Mn_3ZnC . Calculations by the LMTO method.

Table 9. The partial charges in the atomic spheres (q/e) and the differences between the charges in the atomic spheres in the crystal and in the free state ($\Delta q/e$) in manganese and iron carbides.

^a $\text{M}' = \text{Zn, Al, Sn, or Ga}$.

states, with a lower vacant antibonding band including the C 2*p* and Mn 3*d* states. The above four-band structure is characteristic of all the carbides examined^{146–149} and the changes in the composition of the M' sublattice influence only the energetics of the 'centre of gravity' of the M' subband and the degree of their splitting (into bonding and antibonding components). Furthermore, the change in the concentration of valence electrons on replacement of the nontransition metal by elements of a different kind determines the position of E_F relative to the near-Fermi resonance of the M 3*d* type. Thus the Fermi level for Mn₃SnC coincides with the DOS peak, as a result of which $N(E_F)$ is a maximum in the above series of compounds. This can be treated as the factor responsible for the minimal stability of the cubic structure of the given carbide, which undergoes lattice distortions or variations in composition.^{1, 2, 119–122}

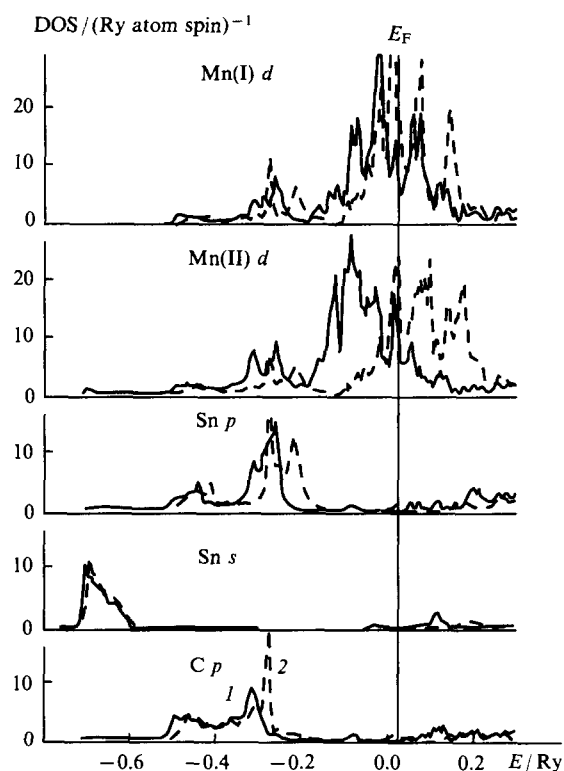

The Mn → Fe replacement in the above phase leads (as a consequence of the decrease in the lattice parameter) to a somewhat greater splitting of the bonding and antibonding sub-bands^{148, 149} and also to the filling of the nonbonding states, whereupon $N(E_F)$ reaches a maximum value for Fe₃AlC.

As regards the nature of the interatomic interactions, analysis shows^{148, 149} that, apart from the direct bonds linking transition and nontransition metals to one another and covalent M–C interactions of the *p*–*d* type, the chemical bonding system in crystals is supplemented by interactions of the *s*–*s*, *s*–*p*, and *p*–*p* types between nontransition metals and carbon. In addition, it follows from Table 9 that partial transfer of charge density from metals (transition and nontransition) to the sphere of the carbon atom is observed, but in the case of compounds with the same M' sublattice [for example, Mn₃M'C and Fe₃M'C (Table 9)] the effective positive charges are found to be higher for manganese than for iron. We may note that in this respect the situation repeats the familiar tendency in binary carbides, where the ionic component of the bond diminishes with increase in the atomic number of the carbide-forming metal.^{7–12}

The band structures and magnetic properties of individual representatives of the carbides $\text{M}_3\text{M}'\text{C}$, in the first place the relative stabilities of the possible types of ordering of the spin subsystem, have been investigated.^{150–153}

The total energy has been estimated by the LAPW method for the nonmagnetic, ferromagnetic, and antiferromagnetic states of Mn₃GaC as a function of the volume of the unit cell.¹⁵⁰ It was established that the ferromagnetic spin ordering is energetically most preferred for the equilibrium volume, since with increase in the lattice constant a transition from the ferromagnetic to the antiferromagnetic state (FM → AFM) should be observed. This finding conflicts with experiments^{153, 154} according to which the AFM state is established at $T < 165$ K. The authors¹⁵⁰ attribute this discrepancy to the use of the spherically-symmetrical approximation to the potential.

An attempt to take into account the influence of the tetragonal lattice distortion on the photoelectron spectra of the Mn₃M'C ($\text{M}' = \text{In, Sn}$) has been undertaken¹⁵¹ within the framework of the LMTO ASA method wherein the manganese atoms are at two structurally nonequivalent sites [Mn(I) and Mn(II)], which is significantly reflected both in the distribution of their DOS (Fig. 15) and in the local magnetic moments localised on the given atoms, the difference between which amounts to $\sim 1.59 \mu_B$ for Mn₃SnC (in the ferromagnetic state) and to $\sim 1.17 \mu_B$ for Mn₃InC. Together with the ferromagnetic spin ordering, ferromagnetic spin ordering as well as the possibility of their coexistence were investigated. An estimate of the total energy for the above cases made it possible to claim¹⁵¹ that a 'mixed' state of the spin subsystem is most probable.

**Figure 15.** The partial DOS for the Mn₃SnC ferromagnetic phase with a tetragonal structure. The DOS for the structurally nonequivalent manganese atoms [Mn(I) and Mn(II)] with 'upward' (1) and 'downward' (2) spin directions. Calculation by the LMTO method.

The type of transition (FM \rightleftharpoons AFM) has been determined¹⁵¹ in relation to Mn_3GaX ($X = \text{C}, \text{N}$) as a function of the composition of the metalloid sublattice and the lattice constant (the LMTO ASA method). In contrast to the preceding data,¹⁵¹ it was established that, for the equilibrium value of the lattice constant, the AFM state is the most stable for Mn_3GaC , the maximum local magnetic moment corresponding to it (the local magnetic moment on the manganese atom is $1.63 \mu_B$ for AFM and $1.39 \mu_B$ for FM); the local magnetic moment increases with increase in the lattice constant. The local magnetic moment on the manganese atom in Mn_3GaN is $1.52 \mu_B$,¹⁵² which exceeds somewhat the experimental value of $1.17 \mu_B$.³²

In contrast to carbides, the available information about the electronic properties of the ternary nitrides belonging to the class under discussion is extremely limited. With the exception of the study already mentioned,¹⁵² we are aware only of calculations for the nitride Fe_3SnN ¹⁵⁵ and also for Fe_3MnN and Fe_3PdN ,¹⁵⁶ carried out by the LMTO method. The main task of the above investigations^{155, 156} was to determine the influence of partial substitution of the iron atoms in the face-centred cubic crystal structure of $\gamma\text{-Fe}_4\text{N}$ by elements of a different kind on the parameters of the band structure and on the stability and magnetic properties of the latter.

The magnetic characteristics of the cubic Fe_4N have now been investigated in fair detail both experimentally^{157–159} and theoretically (by the quantum-chemical computational method).^{160–162}

In the series of ternary nitrides listed above, the electronic structure of the Fe_3SnN alloy is of greatest interest in the context of this review.¹⁵⁵ According to Mössbauer spectroscopic data,^{158, 163} the tin atoms are inserted predominantly at the sites occupied by the Fe(1) atoms located at the vertices of the $\gamma\text{-Fe}_4\text{N}$ unit cell [in contrast to the Fe(2) atoms, which are at the centres of its lateral faces].

In order to take into account the influence of the size factor [in the $\text{Sn} \rightarrow \text{Fe}(1)$ substitution], calculations were made of the DOS with the lattice constant varied in the range $\sim 7.17\text{--}7.46$ a.u. It was established¹⁵⁵ that the energy bands close to E_F are made up mainly of the Fe d states, which make the maximum contribution to $N(E_F)$, with only slight additional contributions by the Sn d and N p states. The introduction of the tin impurity into the perovskite-like $\gamma\text{-Fe}_4\text{N}$ diminishes appreciably the overall magnetisation of the system from 9.40 to $6.00 \mu_B$ (per formula unit) respectively. The contributions of iron to $N(E_F)$ and the local magnetic moments on the given centres in Fe_3SnN exceed in their turn the corresponding values for Fe(2) in $\gamma\text{-Fe}_4\text{N}$.

The dependence of the local magnetic moments on the Fe(1) and Fe(2) atoms in $\gamma\text{-Fe}_4\text{N}$ and on the iron atoms in Fe_3SnN on the lattice parameter is extremely interesting (Fig. 16). It shows that the 'contraction' of the crystals (by 10% of the volume) has the most 'dramatic' effect on the local magnetic moments on the Fe(2) and Fe centres: as a result of the contraction, they diminish sharply up to the disappearance of the local magnetism on the Fe(2) atoms of the γ -nitride. A similar phenomenon had been observed earlier for iron^{164–167} in a series of Fe–Pd and Fe–Ni invar alloys with a face-centred cubic structure.¹⁶⁸ The above 'magnetic collapse' effect on decrease in volume can be accounted for by the appearance of several magnetic phases. The wide scale employment of this model for the interpretation of the nature of the variation of the local magnetic moments on the Fe centres of the nitrides requires correct calculations of the total energies of these objects for different types of spin ordering.

Finally, the results of Kuhn and dos Santos¹⁵⁵ make it possible to describe the charge transport and the nature of the interatomic bonds in Fe_3SnN . The effective atomic charges [$-1.415 e$ (Sn), $+0.658 e$ (Fe), and $-0.560 e$ (N)] indicate the transfer of charge density into the sphere of the iron atoms. As regards the nature of the chemical bonding, analysis of the form of the LDOS for the component atoms permits the conclusion that the nitrogen atoms are mainly involved in covalent $p\text{--}d$ bonds with the iron atoms to which they are coordinated, the outer states

Figure 16. Dependence of the local magnetic moments of iron [Fe(1) and Fe(2), see text] for $\gamma\text{-Fe}_4\text{N}$ and of the iron atoms in Fe_3SnN on the lattice parameter: (1) Fe; (2) Fe(2); (3) Fe(1).

of the latter becoming mixed with the s, p functions of the Sn centres and the s, p, d states of the neighbouring (in the Fe_6N octahedron) iron atoms, whereas the Sn–N interaction is assumed¹⁵⁵ to be negligible. Finally, the determination of the types of interatomic interactions, predominating in the organisation of the overall chemical bonding system in the crystal and responsible for its structural and physicochemical properties, requires more detailed calculations, including the estimation of pair (and multicentre) bonds of different nature as regards energy.

* * *

In conclusion we may note that, despite the fact that the studies on the electronic properties of complex carbides and nitrides of transition metals and subgroup IIIB and IVB elements began fairly recently, the results obtained hitherto constitute a fairly promising basis for a correct interpretation of the fundamental features of the electronic structure, the nature of the chemical bonding, the charge distributions, and certain properties (in the first place spectroscopic and magnetic) of the groups of the above substances which are of greatest interest and practical significance.

Priorities in further research are formulated taking into account the results obtained. Among such priorities, one may include the determination of the characteristics of the transformation of the properties of ideal three-component systems under the influence of impurities, defects (in the ordered and disordered states), and crystal distortions as well as under the influence of their combined action. The mechanical, thermal, strength, and catalytic properties, which determine the technological aspects of the employment of the phases under discussion, have been virtually uninvestigated (from the theoretical standpoint). The development of models and numerical calculations of the above properties (which may also be predictive in nature) should constitute the next stage in the study of such phases. Investigations designed to achieve a theoretical description and modelling of the heterophase (in the structural and magnetic respects) materials based on the substances considered will be of undoubted importance.

Stabilisation of metal ions in unusual oxidation states and electron dynamics in oxide glasses

A I Aleksandrov, A I Prokof'ev, N N Bubnov

Contents

I. Introduction	479
II. Ions in unusual oxidation states in oxide glasses	479
III. Electron dynamics in oxide glasses	489
IV. Conclusion	

Abstract. The results of studies on the stabilisation of metal ions in unusual oxidation states in oxide glasses are surveyed. Attention is concentrated on the relation between the stabilisation of these ions and redistribution of the electron density, and on the disproportionation reactions accompanying it. The effect of reversible low-temperature disproportionation on niobium, titanium, vanadium, molybdenum, tungsten, and other ions is considered. The formation of metal clusters in oxide glasses is shown also to be associated with disproportionation. The bibliography includes 108 references.

I. Introduction

Current developmental chemistry is addressing the problems of producing new compounds and materials possessing valuable practical properties.

Metal ions in unusual oxidation states (UOS) arise in intermediate stages of redox processes including radiation-induced, catalytic, biochemical, mechanochemical, and other processes. Ions of this type have short lifetimes, and their steady-state concentrations are low. The fact that these ions are formed and their role in physicochemical processes have long remained obscure and their existence has been supported only by indirect data. Therefore, the physicochemical properties of these species could be inferred only from theoretical considerations. The appearance of matrix isolation methods in combination with various spectroscopic methods and techniques for the investigation of fast chemical processes have made it possible to begin an investigation of the properties of ions of various elements in UOS.

By the early 70s, studies devoted to the preparation of compounds containing metal ions in UOS in liquid or glassy aqueous media were published.^{1,2} The UOS of metals were generated by radiation. Glassy media have been studied at 77 K by stationary methods, namely, EPR and optical spectroscopy.^{3–6} The aqueous solutions at room temperature have been studied by

pulse radiolysis using fast optical recording.^{7,8} The information obtained made it possible to identify the regular variation of the physicochemical properties of metal ions in UOS as a function of their position in the Periodic Table and to embark upon solving the problem of their long-term stabilisation in inorganic glasses at 300 K.

It turned out that the solution of this problem is primarily associated with the elucidation of the role of the ligand environment of the metal ion, namely, the influence of the nature of ligands on the distribution of the electron density in the atomic orbital (AO) containing the electron that imparts to the ion the properties typical of ions in UOS. In the second place, solution of this problem is associated with the study of the physical properties of the solid glassy matrix itself, which contains modifying ions passing into UOS under various physical influences. Despite the great structural diversity of inorganic glasses, the problem actually reduces to the solution of a single fundamental problem, namely, to the study of localisation and delocalisation of electrons in the outer orbitals of atoms or ions as a function of the structure and properties of the solid matrix. Our review is devoted to this problem in relation to low-temperature glasses and inorganic oxide glasses (silicate, germanate, borate, and phosphate).

II. Ions in unusual oxidation states in oxide glasses

1. Frozen (glassy) solutions

In the late 1970s and the early 1980s, a series of studies was carried out at the Institute of Physical Chemistry of the RAS dealing with UOS of Period 4–6 metals obtained by low-temperature radiolysis in aqueous solutions of acids (HClO₄, HCl, H₂SO₄) or bases (NaOH, KOH) containing salts of these metals.^{3–6,9–14} The choice of metals was determined by the fact that ions with the electron configuration $d^{10}s^1$, i.e. ions existing in a $^2S_{1/2}$ electronic state, are conveniently studied by the highly sensitive EPR method. These ions contain an unpaired electron in the outer ns -AO and arise upon single-electron reduction or oxidation of the central metal atom of an aqua, chloride, or other complex induced by γ -irradiation of frozen glassy solutions. The ions in UOS can be stabilised in glassy matrices at 77 K for an infinitely long period.

It has been shown^{3–6,9–14} that the reactions of the initial ions with thermalised electrons (e^-) and HO \cdot radicals in low-temperature glasses make it possible to obtain Zn¹⁺, Cd¹⁺, Hg¹⁺, Ga²⁺, In²⁺, Tl²⁺, Ge³⁺, Sn³⁺, Pb³⁺, Sb⁴⁺, and Bi⁴⁺ ions in the $^2S_{1/2}$ electronic state as well as Sn¹⁺ and Pb¹⁺ ions, which contain an unpaired electron in the outer p -orbital. The ions in a $^2S_{1/2}$ electronic state were shown to arise in the competing reactions of e^- with metal ions or with the hydroxonium ion. The Sn¹⁺ and Pb¹⁺ ions are also formed via the reduction of Sn²⁺ and Pb²⁺

with thermalised electrons. The relative rate constants for the reactions of e^- with Group IB–VB metal ions were determined.

For the ions in a $^2S_{1/2}$ electronic state and for the Sn^{1+} and Pb^{1+} ions, g -factors, constants A_i of the isotropic hyperfine coupling (HFC), optical absorption bands, and the extinction coefficients were determined from EPR data and optical spectroscopy at 77 K (Table 1).

To study metal ions in a $^2S_{1/2}$ electronic state by EPR, it is important to know the isotropic HFC constants for these species in the free state, $A_i^{(0)}$. Ershov and Aleksandrov¹⁵ have suggested a semiempirical method for the calculation of the $A_i^{(0)}$ HFC constants for series of isoelectronic ions of Periods 4–6 of the Periodic Table existing in the $^2S_{1/2}$ electronic state. Comparison of these $A_i^{(0)}$ values obtained with the HFC constants A_i of these ions in a real medium permits determination of the character of their interaction with ligands. In fact, for a 'free' ion, $A_i^{(0)} = |\Psi_{ns}(0)|^2$, where $|\Psi_{ns}(0)|^2$ is the electron density at the nucleus caused by the electron in the outer ns -AO, while for the M^{Z+} ion in a real medium, $A_i \sim \Psi_{ns}$, where Ψ_{ns} is the electron density in the presence of a certain ligand environment. Thus, the $A_i/A_i^{(0)}$ ratio is the electron occupancy of the outer ns -AO that forms the chemical bond with the ligands of the complex.

It has been shown that the density of the unpaired electron at IIB–IVB Group metal ions, existing in the $^2S_{1/2}$ electronic state, in aqua and chloride complexes decreases with an increase in the charge of the metal ion within the same period.^{9, 12, 14}

In a study of optical characteristics of these ions, it has been found that the energy of optical transitions at the maxima of absorption bands ($E_{\lambda_{\text{max}}}$) for the aqua complexes of IIB–IVB Group metal ions existing in UOS and in the $^2S_{1/2}$ electronic state increases regularly with an increase in the charge of the metal ion within the same period, while for the chloride complexes, this energy decreases. Semiempirical calculations of the energies of the a_{1g}^* and t_{1u}^* molecular orbitals for aqua complexes have shown that experimental $E_{\lambda_{\text{max}}}$ values are in agreement with $\Delta E = E(t_{1u}^*) - E(a_{1g}^*)$; this confirms the fact that the optical absorption bands are due to the $a_{1g}^* \longrightarrow t_{1u}^*$ transition.

It has been shown that in the case of chloride complexes, optical absorption bands are due to the $1t_{1u} \longrightarrow a_{1g}^*$, $2t_{1u} \longrightarrow a_{1g}^*$, and $3t_{1u} \longrightarrow a_{1g}^*$ electron transitions. The energies of these transitions decrease with increase in the charge on the central metal ion in isoelectronic series.¹² The antiparallel courses of the variation of the energies of optical transitions in aqua and chloride complexes of metal ions in an isoelectronic series are accounted for by the crucial role of the ligand environment. Unlike the optical transition in aqua complexes, which is caused by the transfer of an electron from the central ion to the ligands (H_2O molecules), the optical transition in the chloride complexes

is due to the electron transfer from the ligand (Cl^- ion) to the central ion.

A regular variation of the $E^0[\text{M}^{(Z+1)+}/\text{M}^{Z+}]$ redox potentials as a function of the charge on the cation existing in an unusual oxidation state has been found:^{14, 16} the $E^0[\text{M}^{(Z+1)+}/\text{M}^{Z+}]$ values increase as the charge on the cation increases within one Period, whereas within one Group, i.e. for ions having the same charge, they increase with increase in the number of the Period. The theoretical grounds for these regularities have been reported.¹⁷

The above results reflect a fundamental feature of metals (in particular, of metals in UOS having the $d^{10}s^1$ electron configuration), namely, that their physicochemical properties vary monotonically with the atomic number.

These conclusions refer also to the ions in UOS arising at room temperature. At 300 K in aqueous solutions, these species disappear over periods of 10^{-6} – 10^{-4} s, the time for their destruction being determined by the diffusion mobility. Their properties can be conveniently studied by pulse radiolysis with fast optical recording,^{18–22} which makes it possible to determine the positions of optical absorption bands and the extinction coefficients and to measure the rate constants for the reactions of these ions with short-lived species such as hydrated electron (e^-), the CO_2^- radical anion, the HO^\cdot radical, and the $\text{O}^{\cdot-}$ radical anion in aqueous solutions. Based on the characteristics of the optical spectra recorded in the initial stages of chemical transformations over various time intervals (up to 10^{-4} s), the formation of monosubstituted hydroxo- and chloride complexes of IB–IVB Group metals in UOS and in a $^2\text{S}_{1/2}$ electronic state was established, and the instability constants for these complexes were determined; these constants were found to vary monotonically in the series of isoelectronic ions in UOS as a function of the position of the metal in the Periodic Table.

When low-temperature glasses are defrosted, the ions in UOS disappear irreversibly due to the intensification of the diffusion of cations and anions in the matrix. This is why the authors cited above did not answer the question of how hydrogen-like ions with the $d^{10}s^1$ electron configuration form stable chemical compounds. However, the results of studies on the influence of the ligand environment on the properties of metal ions in UOS suggest the possibility of preparing solid glasses in which metal ions in UOS will be stable over periods of time from microseconds to months and even longer. The physicochemical parameters of these glasses should vary as functions of the properties of the stabilised ion.

2. Stabilisation of metals in unusual oxidation states in oxide glasses

As noted above, ions in UOS can exist over extended periods in low-temperature glasses at 77 K. However, it is obvious that these frozen aqueous solutions containing ions in UOS are of no practical interest, since the unusual properties imparted to them by metals in UOS disappear irreversibly when the temperature is slightly raised. Therefore, the logical pathway to the development of new materials with new unusual properties caused by the presence of ions in UOS is the preparation of solid-state materials based on 'true' molten glasses, which are capable of stabilising these species in their matrices.

In fact, the absence of symmetry in their structure and their isotropic properties make glasses identical to liquids, whereas the elasticity of shape makes glasses similar to solids. A glass is considered to be a true solution in which a relationship exists between the composition, the structure, and the properties. At present, articles of glass and glassy materials are used in virtually all branches of industry.²³ Therefore, to confer on these objects new properties specified beforehand is a significant and urgent problem.

In recent years, investigations of glassy media have been vigorously pursued, although the background for these studies was laid long ago by D I Mendeleev,²⁴ who suggested the polymeric concept of the structure of glass, and by Lebedev and

Zakhariasen,^{25, 26} who developed the ideas of microheterogeneity and network structure of glass. Even now these works stimulate studies aimed at controlling the properties of glasses both by varying the structure of glass with a particular elemental composition²⁷ and by introducing ions to modify its properties.²⁸ The modifying ions can alter the properties of a glass both during its synthesis (glass melting) and when a finished (solid) glass is exposed to a certain influence (heat, light, radiation).^{29, 30} Oxide glasses have found the widest practical application.

Oxide glasses can be divided conventionally into four main classes (according to the main glass-forming compound), namely, borate, silicate, germanate, and phosphate glasses. These groups of glasses differ in microstructure and, consequently, their physicochemical properties are also dissimilar. The introduction of modifying ions into these glasses extends considerably the range of existing properties.³¹ Stabilisation of these ions in a glass matrix is associated with redistribution of the electron density of the ligands surrounding the ions and with local variations of the glass structure.

Since the 1970s, studies have been carried out dealing with chemically active species generated by various kinds of treatment and stabilised in glassy matrices as colour centres (CC), paramagnetic centres (PMC), and luminescence centres.^{27–31} The physicochemical properties of these centres have been studied by stationary and pulse methods.^{27–31} However, all the information obtained at that time referred to the matrix centres of the main classes of glasses. The studies were concerned with the optical and kinetic properties of these centres, i.e., they reduced to utilitarian investigation of the radiation sensitivity of glasses by a trial-and-error method. This approach did not conform completely to the modern state of development of the physical chemistry of the glassy state. Therefore, systematic studies are needed that would take into account the properties of elements incorporated in glasses, depending on their position in the Periodic Table.

Apparently, glasses capable of stabilising the modifying ions as well as ions in UOS should contain a wide range of valence states of atoms and ions, which would permit the glassy system to reach an equilibrium after the introduction of ions in metastable states. Borate, silicate, germanate, and phosphate glasses have been studied.^{32–47} Particular attention was focused on three-component alkali glasses: lithium, sodium, and potassium borate, germanate, phosphate, and silicate glasses as well as on the barium aluminophosphate glasses (BAPG). The content of metal oxide in these glasses varied from 3 to 30 mol %. Other glass-forming systems have also been studied; they are mentioned below.

As a rule, after irradiation at 77 and at 300 K, the systems under study containing admixtures of metal oxides exhibited EPR signals and optical absorption bands (AB) differing from those typical of the known electron and hole sites in borate, silicate, and germanate glasses and also from those exhibited by PO_4^{2-} and PO_3^{2-} radical anions in the phosphate glasses.^{32–43} The intensity of these additional EPR signals and of the absorption bands depends on the amount of the oxide introduced, on the ratio of all the glass components, and on the method used for the synthesis of the glass.

For glasses containing cadmium, mercury, gallium, thallium, and lead oxides, it has been found that the increase in the intensity of the additional EPR signals in the magnetic field region corresponding to the g -factor for the free electron (g_e) is accompanied by an increase in the intensity of the high-field (450–700 mT) EPR signals. The latter signals are due to the hyperfine coupling of the electron spins in the outer ns -AO with the $J \neq 0$ nuclear spins of the odd isotopes of the metals added.³⁶ The ratio of the normalised surface of the high-field signals to the surface of the signals in the g_e region corresponds to the ratio of the percentage of metal isotopes with $J = \frac{1}{2}$ or $\frac{3}{2}$ to the percentage of isotopes with $J = 0$. This indicates that the additional EPR signals in question are associated with the metals introduced and proves unambiguously that these signals refer to UOS of metals in

the $^2S_{1/2}$ electronic state, namely, Cd^{1+} , Hg^{1+} , Ga^{2+} , Tl^{2+} , Sn^{3+} , and Pb^{3+} . The spectral parameters for these species are listed in Table 2.

In the case of glasses containing zinc, antimony, and germanium oxides (for odd isotopes of these metals, $J = \frac{5}{2}$, $\frac{7}{2}$ and $\frac{9}{2}$, respectively), additional signals typical of Zn^{1+} , Ge^{3+} , and Sb^{4+} , have also been detected in the EPR spectra after γ -irradiation. The parameters of these signals are also presented in Table 2. All the above metals in UOS in a phosphate matrix exhibit symmetrical EPR lines, the difference between the widths of the high-field and low-field signals being smaller than that in the case of borate, germanate, and silicate glasses.^{37,38} This suggests that in phosphate glasses the ligand environment of the metal ions in UOS is more symmetrical than in other glasses.

Studies³²⁻³⁶ of the optical characteristics of glasses irradiated at 77 and 300 K have shown that, in addition to the well known AB corresponding to the 'matrix' colour centres, additional AB are observed due to the introduction of various metal oxides. For example, it has been shown that on γ -irradiation of sodium borate glasses, the intensity of the absorption bands that appear after the introduction of metal oxides increases in parallel with the concentration of the oxides, whereas the intensities of the absorption bands with $\lambda = 350$ and 500 nm associated with BO_4^{4-} decrease correspondingly, until these bands disappear completely.³³ The spectra of borate glasses containing Zn, Cd, Ga, and Pb oxides and irradiated at 300 K, apart from the AB caused by BO_4^{4-} , contain broad absorption bands possessing a

^a The value of the nuclear spin of the odd isotope is given in parentheses. ^b Notation: LBG, SBG, and PBG — lithium, sodium, and potassium borate glasses, respectively; LSG, SSG, and PSG — lithium, sodium, and potassium silicate glasses; LGG, SGG, and PGG — lithium, sodium, and potassium germanate glasses; LPG, SPG, and PPG — lithium, sodium and potassium phosphate glasses; BAPG — barium aluminophosphate glasses.

low-intensity 'satellite' peak. These AB can be assigned to the Zn^{1+} , Cd^{1+} , Ga^{2+} , and Pb^{3+} ions as follows:

Ion	Zn^{1+}	Cd^{1+}	Ga^{2+}	Pb^{3+}
$\lambda_{\text{max}}/\text{nm}$	310	330	380	325
	550	440	470	500

The presence of the 'satellite' line indicates that the energy levels responsible for the optical transition are split due to the asymmetrical environment of the ions in sodium borate glasses. This is consistent with the EPR spectroscopic data, namely, with the anisotropy observed for the g -factor of the EPR signals corresponding to the ions in UOS in the region $g_e = 2.0023$.

The absorption spectra recorded at 77 K for ions in UOS in sodium borate glasses irradiated at 77 K are shifted to the long-wavelength region with respect to the spectra recorded at 300 K. For example, the following AB are observed for the Cd^{1+} , Pd^{3+} , Ge^{3+} , and Sb^{4+} ions at 77 K:

Ion	Cd^{1+}	Pb^{3+}	Ge^{3+}	Sb^{4+}
$\lambda_{\text{max}}/\text{nm}$	375	340	310	380
	480	530	—	520

The EPR spectra exhibit additional signals due to these ions, the signals corresponding to BO_4^{4-} being virtually absent.^{33, 34}

The absorption spectra of sodium borate glasses containing thallium oxide, measured after γ -irradiation at 300 K, exhibit AB with maxima at 420, 500, 640, and 740 nm. The intensity of the AB with a maximum at 420 nm varies in parallel with that of the 20 mT-wide EPR signal observed in the region of 580 mT and corresponding to Ti^{2+} ions.^{33, 34} In addition, this is the only band that undergoes temperature displacement (at 77 K, the maximum absorption is observed at 430 nm); therefore it is assigned to the Ti^{2+} ion.

Of special note is the observation³⁶ that, in the $\text{Ti}_2\text{O}-\text{Na}_2\text{O}-\text{SiO}_2$ ($\text{Ti}_2\text{O}-\text{Na}_2\text{O}-\text{B}_2\text{O}_3-\text{SiO}_2$) and $\text{PbO}-\text{Na}_2\text{O}-\text{SiO}_2$ ($\text{PbO}-\text{Na}_2\text{O}-\text{B}_2\text{O}_3-\text{SiO}_2$) systems, there is no correlation between the increase in the intensity of some additional AB and the increase in the intensity of the EPR signals corresponding to Ti^{2+} and Pb^{3+} ions. This may be due to the fact that during the synthesis of these glasses under specific redox conditions, metallic clusters of the Pb_m^{n+} and Ti_m^{n+} type (where $n, m = 1, 2, 3 \dots$) are formed. These clusters capture the electrons knocked out by γ -irradiation and thus give additional AB. Clusters of this type are also formed during the post-radiation annealing of glasses, when the following processes occur: $\text{Ti}^{1+} + \text{Ti}^{2+} \rightarrow \text{Ti}_2^{3+}$; $\text{Ti}_2^{3+} + \text{Ti}^0 \rightarrow \text{Ti}_3^{3+}$, etc. In place of thallium ions, these reactions can involve cadmium, lead, bismuth, and other ions. The cluster formation is induced by metal ions in UOS.

In the case of other kinds of glasses, it has also been found that the additional AB arise in parallel with the EPR signals corresponding to the UOS of metals. One intense bell-shaped AB is typical of glasses containing zinc, gallium, germanium, indium, tin, and antimony oxides, whereas in the case of glasses with cadmium, mercury, thallium, lead, and bismuth oxides, two or more optical absorption bands are recorded. The parameters of these bands are presented in Table 2.

It should be noted that for identical matrices with equal contents of oxides of Group IB–VB metals, the energy of the optical transitions $E_{\lambda_{\text{max}}}$ (the energy of the optical transition at the maximum λ_{max} of the optical absorption band corresponding to the metal in UOS was taken as $E_{\lambda_{\text{max}}}$) and the electron density in the ns -AO (which is characterised by the $A_i/A_i^{(0)}$ ratio) in the isoelectronic series $\text{Cd}^{1+} - \text{In}^{2+} - \text{Sn}^{3+} - \text{Sb}^{4+}$ and $\text{Hg}^{1+} - \text{Ti}^{2+} - \text{Pb}^{3+} - \text{Bi}^{4+}$ have been found to decrease with an increase in the formal oxidation number Z . An exception is provided by the $\text{Zn}^{1+} - \text{Ga}^{2+} - \text{Ge}^{3+}$ series, for which the reverse correlation has been established in lithium, sodium, and potassium phosphate glasses, i.e. the $E_{\lambda_{\text{max}}}$ and $A_i/A_i^{(0)}$ values increase with an increase in

(1) Hg^{1+} , (2) Cd^{1+} , (3) Ga^{2+} , (4) Ti^{2+} , (5) Ge^{3+} , (6) Sn^{3+} , (7) Pb^{3+} , (8) Sb^{4+} .

Z (Fig. 1). These results indicate both that the physicochemical properties of metals in UOS vary regularly as a function of their positions in the Periodic Table and that there is a possibility of controlling the course of the above dependences by changing the glass matrix, for example, by replacing one glass-forming oxide by another (SiO_2 by P_2O_5).^{32–36}

The spectral characteristics of metal ions in UOS also depend on the alkali metal cation incorporated in the glass. In other words, for glasses of the same class with equal percentages of oxides, the parameters of metal ions in UOS change when the alkali metal oxide present is replaced by another one. It is seen from Table 2 that the $A_i/A_i^{(0)}$ ratios and other parameters for the same ions in UOS incorporated in glasses, containing equal proportions of oxides but different cations (Li^+ , Na^+ , K^+), are distinct. However, there is no general well-defined rule for the variation of the properties of metals in UOS in the series of alkali metal cations (Li^+ , Na^+ , and K^+).

When the temperature of the irradiation changes from 77 to 300 K, the absorption bands corresponding to metal ions in UOS in all matrices undergo a hypsochromic shift, the magnitude of which depends on the alkali metal cation introduced into the glass. It has been found that the more stable the metal ion in UOS, the greater this shift. Thus, the framework of alkali metal cations participates in the stabilisation of UOS. It can be suggested that the alkali metal cations participate in the rearrangement of the ligand environment of the metal during stabilisation of its UOS. This conclusion has also been confirmed by EPR data. The magnitude of the shift of the high-field component of the EPR spectrum, occurring when the irradiation temperature changes from 77 to 300 K, depends on the nature of the alkali metal cation. The nature of the alkali metal cation also influences the magnitude of the g -factor and the width of lines in high and low fields (the corresponding g_e).

It has been noted^{32–38} that by choosing appropriately the composition of glasses, one can achieve stabilisation of metal ions in UOS at 300 K for a period of a month or even longer; in other words, stable compounds of metals in UOS can be obtained in glasses. By varying the elemental composition of a glass or by creating particular redox conditions during its synthesis, one can enhance or reduce the ability of the glass to stabilise or destabilise UOS of metals, colour centres (CC), and paramagnetic centres (PMC).

The kinetic curves for the thermal annealing of ions in UOS have a stepped shape for all types of glasses and are linearised in the coordinates n/n_0 against $\lg(t/t_0)$ at a fixed temperature [here n and n_0 are the concentrations of ions in UOS at current (t) and

initial (t_0) instants of time, respectively]. The kinetic curves for photoannealing can also be linearised in the coordinates n/n_0 against $\lg(t/t_0)$ and depend both on the intensity and on the spectral composition of the incident light.^{37, 38} The above characteristic features imply that there is a discrete set of activation energy values for these processes and that there exist sites for the stabilisation of metals in UOS, which are nonequivalent in their energy and structural parameters.

For glasses of the same composition synthesised under identical conditions but containing various metal oxides, the rates of the thermal annealing or photoannealing of PMC and CC (carried out at the same temperature or with light of the same spectral composition) are different. This refers both to the matrix PMC and CC (PO_4^{4-} , PO_3^{3-} , BO_4^{4-} , $>\text{SiO}^*$, $>\text{GeO}^*$, SiO_3^{3-}) and to metals in UOS in all the glasses considered above. If we assume that the rate (the efficiency) of the photodestruction of metals in UOS is proportional to the tangent of the slope ξ of the curve describing the kinetics of the destruction in the coordinates mentioned above, then the following rule is fulfilled: in the isoelectronic series of ions Cd^{1+} – Sn^{3+} – Sb^{4+} and Hg^{1+} – Tl^{2+} – Pb^{3+} – Bi^{4+} , the efficiency of the thermo- (ξ_t) and photo- (ξ_{ph}) destruction decreases as the oxidation number of ions increases (Figs 2 and 3). In the case of the Zn^{1+} – Ga^{2+} series of ions, the order of this correlation differs depending of the type of glass. For example, the efficiency of photodestruction of these ions in phosphate glasses varies in the reverse order.

Figure 2. Dependence of ξ_t on Z in lithium borate glasses for ions in UOS (light circles) and for BO_4^{4-} ions (dark circles). All the glasses contain 10 mol % of the metal oxide, which gives rise to the ions in UOS.

The efficiency of the destruction of matrix PMC and CC in glasses with various oxides in the presence of various metals in UOS also depends linearly on Z . However, the course of these dependences can be opposite to the analogous dependence for the UOS. It is seen from Fig. 2 that in the Zn^{1+} – Ga^{2+} – Ge^{3+} series, the ξ_t value for the cations in UOS increases with an increase in Z , while this value for the matrix BO_4^{4-} centre decreases. Thus, the ξ_t and ξ_{ph} values for the matrix centres PO_4^{4-} , PO_3^{3-} , BO_4^{4-} , $>\text{SiO}^*$, and $>\text{GeO}^*$ are influenced by the nature of the modifying metal introduced into the glass. The strength of this influence depends both on the position of this metal in the periodic system of elements and on its state in the glass, namely, whether the metal exists as a modifying cation or is incorporated into the glass-forming network.

Certainly, the structural features of the glass matrix have an influence on the course of the A_i – Z and $E_{i_{\max}}$ – Z dependences and determine the photo and thermal stability of ion ensembles.

Figure 3. Dependence of ξ_{ph} on Z for ions in UOS (light circles) and for PO_4^{3-} ions (dark circles) in barium aluminophosphate glasses, containing 10 mol % of the metal oxide, which gives rise to the ions in UOS.

In fact, ions in UOS can be formed both in reactions with thermalised electrons (2) or in reactions with hole sites (3)

The Zn^{1+} , Cd^{1+} , Hg^{1+} , Ga^{2+} , In^{2+} , Tl^{2+} , Ge^{3+} , Sn^{3+} , Pb^{3+} , Sb^{4+} , and Bi^{4+} ions are formed via reaction (2), and only the Tl^{2+} , Sn^{3+} , Pb^{3+} , Sb^{4+} , and Bi^{4+} ions are formed via reaction (3). Both reactions can occur simultaneously in the same glass if it contains pairs of ions, for example, Sn^{2+} – Sn^{4+} , Tl^{1+} – Tl^{3+} , Pb^{2+} – Pb^{4+} , Sb^{3+} – Sb^{5+} , or Bi^{3+} – Bi^{5+} .

These suggestions have been confirmed in a study of the kinetic behaviour of ions in UOS at various stages of formation and destruction, carried out by pulse radiolysis with optical recording. Such studies were reported for the first time by Aleksandrov et al.^{45–47} The measurements were carried out using a setup with optical recording, designed based on a 'U-12F' accelerator and operating on the microsecond time scale ($t = 2.3 \mu\text{s}$, $E = 5 \text{ MeV}$, $I = 0.2 \text{ A}$).^{7, 8} The radiation colour centres (RCC) arising due to a pulse of accelerated electrons were annealed in the light beam of a DKSSH-150 xenon lamp focused to a diameter of 3 mm. The absorption spectra were recorded within intervals from 2 μs to several minutes. The amount of metal oxides added ranged from 1 to 10 mol %. Simultaneously, optical characteristics of glasses of the same composition exposed to γ -irradiation at 77 and 300 K were measured.

In the case of pulse irradiation of sodium borate glasses with various metal oxides added, rapidly diminishing absorption was detected, the λ_{\max} of which lay at 360 and 520 nm (without metal oxides), 350 nm (with ZnO added), 380 and 440 nm (CdO), 390 and 440 nm (Ga_2O_3), 430, 500, 550, 620, and 750 nm (Tl_2O_3), 360 and 430 nm (PbO), and 460 and 500 nm (Sb_2O_3). The λ_{\max} values of the absorption bands corresponding to ions in a $^2\text{S}_{1/2}$ electronic state observed immediately after a pulse of fast electrons differ only slightly from those obtained in the case of γ -radiolysis at 77 K (see Table 2 and the data given in the text). However, 140–200 μs after the pulse, the absorption maxima start to shift toward the position at which they are observed in the case where the irradiation is carried out at 300 K. Since the EPR parameters (g -factors, A_i , intensities of EPR lines) of ions in a $^2\text{S}_{1/2}$ electronic state at 77 K and at 300 K are different,^{33, 34} it is obvious that the changes in the optical spectra following the temperature rise or the photoannealing are due not only to the variation of the geometry of the nearest atom environment but also to the disappearance of some of the least photo- and thermostable ions in UOS. In fact, at

77 K the overall spectrum is recorded, whereas the spectrum obtained at 300 K corresponds only to those ions which are stable at this temperature.

The diminution of the absorption in glasses of the same composition corresponds to a linear dependence of D/D_0 on $\lg(t/t_0)$ (D and D_0 are optical densities at times t and t_0 , respectively, $t_0 = 1 \mu\text{s}$). The kinetics of the destruction of an individual ion in a glass of a particular composition depend on the intensity of the light acting on the sample. When ions in a $^2S_{1/2}$ electronic state are photoannealed with unfiltered light within a broad time interval (from microseconds to minutes), the slope of the straight lines depends on the nature of the metal ion. The tangent of the slope ξ_{ph} characterises the efficiency of the photoannealing of a particular ion in an UOS. The higher the intensity of light, the more efficient the photoannealing. This follows from the dependences obtained with the light beam attenuated by 55% with a reticulated filter. Experiments on the photoannealing also confirm the fact that only ions in a $^2S_{1/2}$ electronic state, rather than cluster groups incorporating these ions, are formed in the glasses under consideration containing zinc, cadmium, gallium, germanium, and antimony oxides, because under various conditions of light treatment, all the optical absorption bands assigned to these ions disappear in parallel.

In glasses containing lead oxide, two types of species with dissimilar kinetic parameters exist, which account for the AB with $\lambda_{max} = 360$ and 430 nm, whereas glasses with thallium oxide contain at least three types of species, which absorb light at 430, 500 and 550, and 620 and 750 nm, respectively. Evidently, all the CC in these glasses belong to ions and clusters of thallium and are destroyed in parallel by the influence of light.

The energies of optical transitions at the maxima of the AB ($E_{\lambda_{max}}$) for the ions in a $^2S_{1/2}$ electronic state (Ag^0 , Cd^{1+} , Ga^{2+} , Tl^{2+} , Ge^{3+} , Pb^{3+} , and Sb^{4+}), obtained on exposure to pulse radiation, depend on both the oxidation number Z of the metal and its position in the Periodic Table. In the isoelectronic series $\text{Zn}^{1+} - \text{Ga}^{2+}$, $\text{Cd}^{1+} - \text{Sb}^{4+}$, and $\text{Tl}^{2+} - \text{Pb}^{3+}$, the $E_{\lambda_{max}}$ values decrease as Z increases. A similar correlation has also been observed for the efficiency of the photoannealing of the above ions with unfiltered light. This is in agreement with the dependences found previously for the optical parameters and for the density of the unpaired electron in the outer ns -AO for ions in UOS in isoelectronic series.^{33, 34}

The method of pulse radiolysis has also been used to study the fast processes occurring in sodium silicate glasses (SSG), containing 10 mol % of Zn, Cd, In, Ga, Ge, Sn, Pb, and Sb oxides, exposed to ionising radiation.⁴⁷ It was found that in these glasses, apart from the known AB (with maxima at 460, 580, and 620 nm) typical of glasses containing no metal oxides,⁴⁸ additional AB corresponding to the long-lived products of radiolysis arise after irradiation. Simultaneously, the absorption bands associated with the sodium silicate matrix disappear. For example, for glasses with zinc, cadmium, gallium, germanium, tin, indium, and antimony oxides irradiated with a pulse of accelerated electrons at 300 K, the following absorption bands were observed:

Oxides	Zn	Cd	Ga	Ge	In	Sn	Sb
λ_{max}/nm	370	390	375	430	360	470	480
	—	460	435	—	490	—	—

The intensity of these bands depends on the concentration of the metal oxide added. The positions of the AB maxima corresponding to the products of the pulse radiolysis are in good agreement with the λ_{max} values of the AB obtained by γ -radiolysis at 77 K of the SSG containing the same compounds.³⁶ The absorption spectra of glasses containing cadmium, gallium, indium, and lead oxides recorded immediately after a pulse of accelerated

electrons are broad AB accompanied by satellite lines of low intensity. Since no other AB arise upon irradiation of glasses with the above metal oxides, and the intensities of the main and the satellite lines vary in parallel, these AB can be attributed to the Zn^{1+} , Cd^{1+} , Ga^{2+} , In^{2+} , Pb^{3+} , Sn^{3+} , and Sb^{4+} ions in the $^2S_{1/2}$ electronic state. The presence of the satellite line indicates that the energy levels responsible for the optical transition are split due to the asymmetrical environment of the ions in UOS.

The kinetic curves for the photodestruction of the Zn^{1+} , Cd^{1+} , and Pb^{3+} ions are similar in appearance: they have no inflection points. The kinetic curves for the SSG with gallium, germanium, tin, and antimony oxides contain two sections, namely, a section where the absorption falls quickly (up to 100 μs) and a section where it diminishes slowly (up to several minutes). This implies that there are two pathways to the disappearance of the Ga^{2+} , Ge^{3+} , Sn^{3+} , and Sb^{4+} ions. In the case of indium, the kinetic curve for the diminution of the absorption in the coordinates mentioned above has a flat section (up to 0.1 s), which is followed by a steeper section. Thus, in terms of destruction kinetics, metal ions can be divided into three main groups: the first group includes Cd^{1+} , Zn^{1+} , and Pb^{3+} ions, the second group consists of Ga^{2+} , Ge^{3+} , Sn^{3+} , and Sb^{4+} ions, and In^{2+} belongs to the third group. Evidently, the difference between the kinetic behaviour of the ions is due to the specific structural features of the glass matrix that arise during the synthesis of glasses containing the corresponding metal oxides.

In fact, cadmium, zinc, and lead oxides are capable of being incorporated into the glass network formed by the main oxide, which constitutes the glass structure. Gallium, germanium, tin, and antimony oxides exhibit dual properties: they can act both as modifying compounds and as glass-forming compounds. A part of the ensemble corresponding to the modifying ions is responsible for the fast-diminution section on the kinetic curves. Indium oxides act as modifying ions existing both as free ions and as ions linked to bridging and nonbridging oxygen atoms. Under certain conditions the modifiers of the former type are fairly free to move in the matrix and react with the electrons knocked out of the glass matrix, similarly to ions in solution. This accounts for the fact that the kinetic curve for the photodestruction of In^{2+} ions consists of two components, one of which (for the free modifying ions) obeys formally second-order kinetics, i.e. it is linearised in the $1/D - t$ coordinates, and is most clear-cut for periods of time of the order of seconds. The other component follows the normal disappearance kinetics typical of solids, which has been observed for other ions (the initial more gently sloping section of the curve). Thus it is obvious that in the initial stage, the In^{2+} ions connected to the glass network through oxygen atoms predominantly disappear, and then the free modifying In^{2+} ions are destroyed. These ions vanish completely, i.e. the glass is completely 'photobleached' over a period of several seconds. This has also been observed for Zn^{1+} and Tl^{2+} ions in sodium borate glasses.⁴⁶

The pulse radiolysis studies also permitted the following characteristic features to be elucidated. The course of the dependences of $E_{\lambda_{max}}$ and ξ_{ph} on Z coincides with the course of the kinetic curves for the destruction of the Zn^{1+} , Cd^{1+} , Ga^{2+} , In^{2+} , Ge^{3+} , Sn^{3+} , Pb^{3+} , and Sb^{4+} ions, plotted as $D/D_0 - \lg(t/t_0)$ coordinates and obtained for the 'steady-state' variant in the analysis of the gently sloping sections. In contrast, the initial (steep) sections of the curves for the destruction of the Ga^{2+} , Ge^{3+} , Sn^{3+} , and Sb^{4+} ions show an inverted profile (Fig. 4). This fact is of fundamental importance, since it thus becomes obvious that there are several structurally different sites for the stabilisation of the same ion in an unusual oxidation state. However, despite the above distinctions, the general rule of the regular variation of physicochemical properties of ions in UOS as functions of the positions of these elements in the Periodic Table is retained.

Figure 4. Dependence of $E_{\lambda_{\max}}$ (continuous line) and of ζ_{ph} on the steep (dashed line) and gently sloping (dot-and-dash line) sections of the kinetic curves for the destruction of metal ions in UOS on the oxidation number Z in sodium silicate glasses.

3. Formation of unusual oxidation states of transition metals Ti, Ni, Mo, W, and Nb

When glasses containing transition metal oxides are exposed to radiation, ions in UOS are also formed. For example, Ni^{1+} ions have been detected in BAPG with nickel oxide. The EPR parameters of these ions depend substantially on the composition of the glass. When 10 mol % of nickel oxide is added, an EPR signal with triaxial anisotropy is observed, $g_1 = 2.355$, $g_2 = 2.229$, and $g_3 = 2.074$, and when the oxide concentration is increased to 30 mol %, a broad singlet with $g_{\text{aver}} = 2.327$ arises.

In alkali glasses and in BAPG, Ti^{3+} , Nb^{4+} , Mo^{5+} , and W^{5+} ions exhibiting characteristic EPR spectra have been detected following γ -irradiation at 77 K. For example, the Ti^{3+} ion in SPG is characterised by a line with biaxial anisotropy with $g_{\perp} = 1.876$ and $g_{\parallel} = 1.991$. In alkali phosphate glasses with high concentrations of tungsten oxide (more than 35 mol %), an EPR signal with $g_{\text{aver}} = 2.018$ and a line width ΔH of 2.25 mT arises. This signal differs from the known signals typical of W^{5+} ($g_{\perp} = 1.81$ and $g_{\parallel} = 1.66$).

In the case of LPG, SPG, and PPG (lithium, sodium, and potassium phosphate glasses) containing niobium oxide (Nb_2O_5 concentration not exceeding 20 mol %), the formation of niobium ions in UOS has been observed after γ -irradiation at 77 and 300 K. In fact, in addition to the doublet signals corresponding to the $PO_4^{\cdot-}$ radical anion, the EPR spectrum exhibited ten main lines extending by 252 mT, the distance between them being 28 mT. Since only Nb possesses a nuclear spin of $\frac{9}{2}$, this spectrum consisting of ten lines is unambiguously associated with the Nb^{4+} ion, for which $g_{\perp} = 1.91$, $g_{\parallel} = 1.88$, $A_{\perp} = 28.0$, $A_{\parallel} = 13.0$ mT, and $A_{\parallel}/A_{\perp}^{(0)} = 0.12$. Apart from the signal due to Nb^{4+} , a 19.0 mT-wide singlet with $g_{\text{aver}} = 2.017$ arises in these glasses, when the concentration of Nb_2O_5 exceeds 20 mol %. As this signal appears, the signal due to Nb^{4+} disappears. The new signal has been attributed to a hole site.³²

In view of the fact that the spectra of glasses with large amounts of WO_3 , MoO_3 , and Nb_2O_5 contain broad singlets, one may assume that an increase in the concentration of the oxides and, consequently, in the intensity of the EPR signals associated with the corresponding ions leads to the appearance of isotropic exchange interaction. Blurring of the HFS resulting in the appearance of broad lines (100.0 and 140.0 mT, respectively) has also been observed in glasses containing manganese oxides with an increase in the oxide concentration. In the EPR spectra of glasses with iron oxide a set of lines is recorded, the intensities of which depend on the redox conditions of the synthesis.

Short-lived radiation-induced defects have been studied by pulse radiolysis in the $M_2O-P_2O_5-Nb_2O_5$ glass systems ($M = Na, K, Li$) that exhibited no initial ('glass melting') absorption bands.³⁹ At low concentrations of Nb_2O_5 , an AB with $\lambda_{\max} = 500$ nm, typical of $PO_4^{\cdot-}$, was observed. With an increase in the concentration of Nb_2O_5 the intensity of the absorption band corresponding to the $PO_4^{\cdot-}$ ion decreased, and an AB with $\lambda_{\max} = 650$ nm appeared instead, its intensity increasing with increase in the concentration of Nb_2O_5 . The lifetime of this AB, which was assigned to Nb^{4+} , is tens of microseconds at 300 K.

The $Na_2O-SiO_2-CeO_2$ (Eu_2O_3) glasses have been studied.⁴⁰ The spectra of these glasses exhibit at least two broad AB in the region of 500–700 nm. The kinetic parameters of the species responsible for these AB are influenced by the Na_2O/SiO_2 ratio and by the amount of the oxides CeO_2 and Eu_2O_3 added.

* * *

Thus, the studies of alkali glasses of four main classes described above permit the following conclusions to be made:

- the properties of ions in UOS vary regularly with the position of the element in the Periodic Table;
- the order of these dependences can be controlled by varying the ligand environment;
- formation of metal clusters in glasses is possible and is initiated by metal ions in UOS;
- the UOS of metals influence regularly the photo- and thermal stability of the matrix CC and PMC in glasses, the kinetic curves for the photoannealing and thermoannealing being linearised in the $n/n_0 - \lg(t/t_0)$ coordinates;
- the possibility of the long-term stabilisation of UOS of metals in alkali glasses was established, and the influence on it of the cationic framework was found.

All the above properties depend on the elemental composition of glasses and on the redox conditions of their synthesis. Evidently, it is these factors that are favourable for the stabilisation of the UOS and for the appearance of certain integral properties against the background of the topological disordering of the spatial structure of glass. Thus, the following causal relationship arises: composition–synthesis–structure–stabilisation or destabilisation of the UOS of a metal. From this it follows that by choosing the composition of a glass and the method for its synthesis under appropriate redox conditions one may impart desired properties to the glass by means of ions in UOS or by means of other species that arise with their participation.

4. Oxide glasses containing no alkali metals

We have considered above the processes of stabilisation of ions in UOS in glasses of four main classes (borate, silicate, germanate, and phosphate glasses) containing alkali metal cations. The role of alkali metal cations in the stabilisation of transition metal ions in UOS has been repeatedly emphasised. However, the role of the ligand environment, i.e. of the oxygen-containing network formed in the glass during its synthesis, has not been considered separately. The structure of the glass network is known to depend on the redox conditions under which it has been formed. These conditions account for a wide range of various matrix defects in a glass and ensure the formation of various types of coordination of ions in the glass network. These effects are most clear-cut in borate glasses in which boron can exist both in tricoordinated and tetracoordinated states.²³

Studies carried out with $CdO-B_2O_3$, $CdO-SiO_2$, and $CdO-B_2O_3-SiO_2$ glasses^{42, 49, 50} have shown that, if the synthesis is carried out under reducing conditions, the proportion of tricoordinated boron increases. This was found by comparison of the intensities of IR absorption bands at $1500-1150\text{ cm}^{-1}$ and at $1100-800\text{ cm}^{-1}$ corresponding to $BO_3^{\cdot-}$ and $BO_4^{\cdot-}$, respectively.

In addition, glasses obtained under these conditions exhibit a photochromic effect, which becomes more pronounced as the proportion of tricoordinated boron atoms increases.^{49, 50}

It has been shown by EPR⁴² that following the photo- and γ -irradiation of cadmium-containing glasses, Cd^{1+} ions are formed, and it is these ions that account for the colour of the glasses. The maximum optical absorption of the Cd^{1+} ion is observed at 400–420 nm for both types of treatment, but the concentration of the Cd^{1+} ions arising upon γ -irradiation is higher than that arising upon UV irradiation by 1–2 orders of magnitude.⁴² It is therefore obvious that any ion in an UOS can also be stabilised in the absence of alkali metal cations. Fig. 5 shows the plots for the accumulation of the hole ($\text{BO}_4^{\cdot-}$) and electron (Cd^{1+}) sites in glasses exposed to equal doses of γ -radiation but synthesised under different conditions, namely, under normal and reducing conditions. The accumulation of hole sites in these glasses occurs similarly, whereas the accumulation of the electron sites depends essentially on the conditions of the synthesis. The amount of Cd^{1+} formed in the glasses synthesised under reducing conditions is several times greater than that formed in glasses synthesised under normal conditions. Apparently, the synthesis of glasses under oxygen-deficient conditions leads to greater instability of the system, to the rupture of chemical bonds, and to the displacement of the Cd^{1+} ions to the cationic part of the glass network.

Figure 5. Accumulation of paramagnetic centres in cadmium borate glasses synthesised under normal (1, 2) and reducing (1', 2') conditions: (1, 1') Cd^{1+} ; (2, 2') $\text{BO}_4^{\cdot-}$.

Bismuth-containing glasses are also fairly sensitive to the conditions of the synthesis and are readily reduced as far as the liberation of metallic bismuth. By introducing transition metal oxides into these glasses, one may influence the occurrence of redox processes even during glass melting. This effect of added compounds is due to their influence on the glass structure. Data on the structure of bismuth borate glasses as well as on the influence of transition metal oxides on their structure are scarce, whereas data on the stabilisation of ions in UOS in these glasses are totally lacking. This problem has been investigated in relation to glasses melted on the basis of the $\text{ZnO}-\text{Bi}_2\text{O}_3-\text{B}_2\text{O}_3$ system and to the same glasses containing added tungsten oxide.⁵¹

An IR-spectroscopic study of bismuth-containing glasses showed that the initial glass exhibits AB in the region of 1300–1400 cm^{-1} and a band at 1250 cm^{-1} corresponding to the stretching vibrations in the $\text{B}^{3+}-\text{O}-\text{B}^{3+}$ and $\text{B}^{3+}-\text{O}-\text{B}^{4+}$ groups, respectively, and a weak band in the range

900–1000 cm^{-1} associated with the vibrations in the $\text{B}^{4+}-\text{O}-\text{B}^{4+}$ group. The EPR spectrum of the initial glass, containing no additives, recorded after γ -irradiation is a broad singlet with a g -factor of 2.022 ($\Delta H = 3.3$ mT) due to Bi^{4+} ions, which can result both from localisation of electrons by Bi^{5+} ions and from capture of holes by Bi^{3+} ions. The strong broadening of the signal and the absence of a hyperfine structure in Bi (the nuclear spin J of Bi is $\frac{9}{2}$) suggest that bismuth exists in the glass as clusters, because under oxygen deficiency, a Bi–Bi bond is formed.

The introduction of tungsten oxide into bismuth-containing glasses leads to the appearance of an AB at 870 cm^{-1} in its IR spectrum, corresponding to the stretching vibrations of tungsten in the WO_6 octahedra. The intensity of this band increases with an increase in the content of tungsten oxide in the glass. The EPR spectra of these glasses contain an additional anisotropic line with $g_{\text{aver}} = 1.607$ ($\Delta H = 46$ mT) corresponding to the W^{5+} ions and caused by the localisation of electrons at W^{6+} ions. The intensity of the signal due to Bi^{4+} simultaneously decreases. The relationship between the intensities of lines of Bi^{4+} and W^{5+} suggests that the tungsten ions are incorporated into the bismuth network of the glass. When bismuth and tungsten ions are located close to each other, the localisation of the free electrons during γ -irradiation occurs mainly at the W^{6+} ions, which possess stronger acceptor properties.⁷ This conclusion has been supported by the results of X-ray phase analysis of thermally treated glasses: bismuth tungstates were detected as one of the phases in the products of crystallisation.⁵¹ Thus, in bismuth-containing glasses modified by tungsten oxides, bismuth tungstate complexes are formed; they bind the bismuth ions strongly and prevent them from liberation as metallic macroparticles during the glass melting. This change in the glass structure favours the occurrence of single-electron processes accompanied by the formation of W^{5+} and Bi^{4+} ions under the influence of ionising radiation.

* * *

Thus, ions in UOS can also arise under the action of radiation in glasses containing no alkali metal cations. The fact that these ions are stabilised in the matrices of the glasses considered above implies that the set of various oxidation states of ions forming the glass network (for borate glasses, these are B^{3+} and B^{4+} ions) permit the processes of stabilisation to be accomplished also in the absence of alkali metal cations.

5. Sulfate-containing glasses

The studies described above have shown unambiguously that the stabilisation of UOS of metal ions is related to the structure of a glass. Since the stabilisation of UOS of metals is caused in some cases by mobile cations, the stabilisation of these cations, in its turn, can be due to the formation of ions in UOS. The latter, being present in the glass as modifying ions or being incorporated into the glass-forming network, can stabilise the cationic framework to different extents, since the Na^+ , K^+ , Li^+ , and Cs^+ cations are incorporated into the 'ligand' environment of ions in UOS in different ways.

These considerations are related directly to the problem of neutralisation of radioactive wastes with medium activity level.⁵² In fact, a glass matrix consisting of a continuous irregular network of coordination polyhedra of glass-forming units accumulates various radionuclides, which can either enter into the composition of the crystalline framework (Na_2O , Cs_2O , SrO , etc.) or be accumulated in the cavities of the structural network as discrete species (RuO_2 , UO_2 , PuO_2 , etc.); a glass matrix can also accumulate inactive salts often containing sulfur. Therefore, the solution of the problem of stabilisation of radionuclide ions and sulfur-containing ions accompanying them can be linked to the stabilisation of ion metals in UOS, for example, Pb^{3+} and VO^{2+} , in sulfate-containing glasses of three main classes, namely, borate, phosphate, and silicate glasses.

Any information on the structure and the nature of radiation-induced defects, on the mechanism of damage arising under the action of radionuclide radiation, and on the radiation resistance of glasses during prolonged storage is of scientific and practical interest. For example, the possibility of stabilising ions of different natures in glasses of various compositions in the $\text{Na}_2\text{O}(\text{PbO}, \text{V}_2\text{O}_5) - \text{EO}_x(\text{SiO}_2, \text{B}_2\text{O}_3, \text{P}_2\text{O}_5) - \text{SO}_3$ systems has been studied by EPR.⁵³⁻⁶⁰ It was found^{53, 56-59} that the regions of glass formation in the $\text{Na}_2\text{O}(\text{PbO}) - \text{EO}_x(\text{SiO}_2, \text{B}_2\text{O}_3, \text{P}_2\text{O}_5) - \text{SO}_3$ systems are broadened on passing from silicate glasses to borate and phosphate glasses and also on passing from sodium to lead glasses (Fig. 6 *a, b*). The largest region of glass formation was observed in the $\text{PbO} - \text{P}_2\text{O}_5 - \text{SO}_3$ system (the maximum content of SO_3 being 33 mol %).

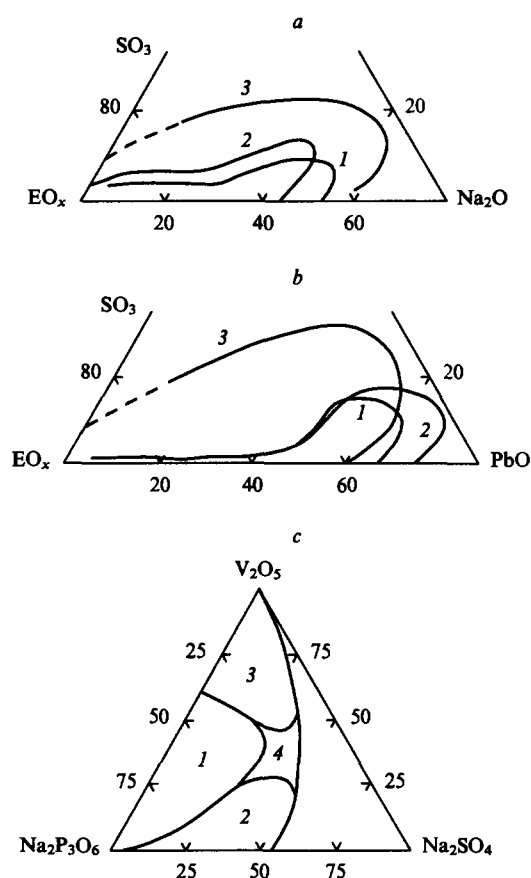

Figure 6. Regions of glass formation in the $\text{Na}_2\text{O} - \text{EO}_x - \text{SO}_3$ (*a*), $\text{PbO} - \text{EO}_x - \text{SO}_3$ (*b*), and $\text{Na}_2\text{P}_2\text{O}_7 - \text{V}_2\text{O}_5 - \text{Na}_2\text{SO}_4$ (*c*) systems. $\text{EO}_x = \text{SiO}_2$ (1), B_2O_3 (2), and P_2O_5 (3).

In order to study the structure in each system, two series of glasses were chosen, with the following concentrations of the initial components: $[\text{SO}_3]/([\text{SO}_3] + [\text{EO}_x]) = \text{const.}$ in the first series and $[\text{M}_y\text{O}]/([\text{SO}_3] + [\text{EO}_x]) = \text{const.}$ in the second series, where EO_x and M_yO are glass-forming oxides and modifying oxides, respectively.

Glasses based on the $\text{Na}_2\text{O} - \text{SiO}_2 - \text{SO}_3$ system, in which the region of glass formation is the smallest among the glasses studied and the content of SO_3 does not exceed 7 mol %, give no EPR signals due to sulfur-and-oxygen-containing PMC; only signals corresponding to the silicon-and-oxygen PMC are observed.⁵⁸ The EPR spectra of sulfate-containing borate and sulfate-containing phosphate glasses, in addition to the signals corresponding to boron-and-oxygen and phosphorus-and-oxygen PMC, exhibit signals due to the sulfate constituent of the anionic character of the glass.^{54, 55, 58}

The EPR spectra of binary alkali borate and sulfate-containing alkali borate glasses,⁵⁵ the compositions of which fall in the centre of the glass-formation region, exhibit signals characteristic of irradiated alkali borate glasses: BO_3^{2-} ($g_1 = 2.002$; $g_2 = 2.011$; $g_3 = 2.034$) and BO_4^{3-} ($g_{\text{aver}} = 2.012$ for glasses containing more than 20 mol % of Na_2O). In the spectra of sulfate-containing borate glasses (the compositions of which are at the boundary of the glass-formation region), in addition to the signals mentioned above, a signal due to the (SO_4^-) PMC has also been detected (a similar signal has been observed in irradiated solutions of H_2SO_4).³ The formation of the (SO_4^-) PMC in this composition region can be associated with the processes of chemical differentiation leading to the formation of microregions enriched in sodium sulfate. This inference has been confirmed in a study of thermally treated glasses by electron microscopy.⁵⁵

In the magnetic field region corresponding to $g < g_e$, for sulfate-containing borate glasses⁵⁷ with compositions lying at the centre of the glass-formation region, an electron site signal has been detected, the thermal behaviour of which differs from that of (BO_4^{3-}) or (SO_4^{2-}) PMC. This PMC was assigned to a sulfur-containing ion in UOS, namely, to the S^{5+} ion. This may arise when an electron is trapped by an SO_4 tetrahedron incorporated into the glass-forming chains (trapping of an electron is not typical of isolated SO_4^{2-} ions). Apparently, in this case, redistribution of the electron density occurs among mixed boron-sulfur-and-oxygen chains between the boron- and sulfur-and-oxygen fragments in the following way:

This process accounts for the increase in the concentration of the S^{5+} ion. This assumption is supported by the fact that the (SO_4^{3-}) PMC is not found in the irradiated glasses, the compositions of which lie near the boundary of the glass-formation region, because chemical differentiation in these glasses leads to the destruction of the chains containing SO_4 polyhedra.

The EPR spectra of sulfate-containing borate glasses with compositions corresponding to the metaphosphate region, together with the known signals due to the (PO_4^{3-}) and (PO_3^{2-}) PMC, also exhibit a signal associated with SO_4^- .⁵⁵ As the proportion of the sulfur-and-oxygen-containing constituent in the anionic character of the glass increases, the concentration of phosphorus-and-oxygen PMC decreases, while that of SO_4^- increases. The irradiation of glasses with compositions lying in the ultraphosphate region⁵⁴ also results in the formation of PMC associated with branched units and ring structures like $\text{P}_4\text{O}_{12}^{3-}$. Simultaneously, the (SO_3^-) PMC with $g = 2.004$ are formed upon rupture of phosphorus-sulfur-oxygen chains under the action of γ -radiation ($-\text{O}-\text{PO}_2-\text{O}-\text{SO}_2-\text{O} \longrightarrow -\text{O}-\text{PO}_2-\text{O} + -\text{SO}_2-\text{O}$). On passing from the ultraphosphate region to the metaphosphate region of composition, the concentrations of SO_3^- and $\text{P}_4\text{O}_{12}^{3-}$ decrease, whereas those of SO_4^- and PO_4^{3-} increase. This is associated with the depolymerisation of the sulfate-phosphate network. Evidently, ultraphosphate glasses incorporate a common phosphorus-sulfur-oxygen network, while metaphosphate glasses contain phosphorus-oxygen chains and isolated sulfate ions. This interpretation of the EPR spectra is not inconsistent with the van Wazer rearrangement theory.⁶¹

The EPR spectra of irradiated sulfate-containing lead silicate, borate, and phosphate glasses with a PbO concentration of more than 30 mol % exhibit only one well-known singlet due to Pb^{3+} in the g_e region and at high fields.^{53, 56, 58, 59} Glasses containing ≤ 30 mol % of PbO can be synthesised only in the sulfate-phosphate system. The EPR spectra of glasses containing not less than 20 mol % of SO_3 or Na_2SO_4 are complex in appearance, being a superposition of the singlets corresponding to Pb^{3+} and SO_4^- .

For glasses based on the $\text{PbO} - \text{SiO}_2(\text{B}_2\text{O}_3) - \text{SO}_3(\text{Na}_2\text{SO}_4)$ systems, no signals corresponding to sulfur-oxygen PMC have been recorded. However, with an increase in the content of sulfate

ions, the shape of the Pb^{3+} line changes; in particular, anisotropy of the g -factor increases ($g_{\perp} = 2.004$, $g_{\parallel} = 1.955$), which is associated with a change in the glass structure. This is also indicated by the presence of maxima in the curves of the dependence of the concentration (the width of the EPR line) of the Pb^{3+} ion on the composition of the glass (Fig. 7). However, the fact that only the signal for SO_4^- ions is recorded in the EPR spectra indicates that sulfate ions, responsible for their formation in the networks of lead glasses, are mainly isolated.

Figure 7. Dependences of the concentration of Pb^{3+} (curves 1–3) and of the line width $\Delta H(\text{Pb}^{3+})$ (curves 1'–3') on the composition of the glass $\text{PbO}-\text{P}_2\text{O}_5-\text{SO}_3$ $\{R = [\text{PbO}]/([\text{P}_2\text{O}_5] + [\text{SO}_3])$, mol % $\}$. Content of SO_3 , mol %: 0 (1), 10 (2), 20 (3).

The influence of sulfate ions on the radiation resistance of vanadate glasses has been studied in relation to the pseudoternary $\text{Na}_2\text{P}_2\text{O}_6-\text{V}_2\text{O}_5-\text{Na}_2\text{SO}_4$ system.⁶⁰ Fig. 6,c shows the region of glass formation in this system. It was found⁶⁰ that this region can be divided into four areas, according to the character and behaviour of the PMC formed in them. In the first area the HFS, due to VO^{2+} with $g_{\perp} = 1.994$, $g_{\parallel} = 1.932$; $A_{\perp} = 9.0$ and $A_{\parallel} = 21.2$ mT, is observed at 77 and 300 K. In the second area, the HFS due to VO^{2+} is also observed at 77 K; however, at 300 K in nonirradiated glasses and at 77 and 300 K in the case of γ -irradiated glasses, a symmetrical singlet with $g_{\text{aver}} = 1.957$ and $\Delta H = 2.5$ mT is recorded. The EPR spectra recorded for the third area at 77 K are characterised by poorly resolved HFS, while at 300 K, they exhibit a broad line with $\Delta H = 28$ mT and $g_{\text{aver}} = 1.970$, which narrows as the content of V_2O_5 increases from 50%–60% to 90%–100% and turns into a narrow asymmetrical line with $g_{\text{eff}} = 1.975$. For γ -irradiated glasses corresponding to this area, only an asymmetrical singlet is recorded at 77 and 300 K. In the fourth area, well resolved HFS corresponding to VO^{2+} is observed at 77 K, while at 300 K a low-intensity symmetrical singlet line with $g_{\text{aver}} = 1.960$ and $\Delta H = 2.0$ mT is recorded. The spectra of glasses γ -irradiated at 77 and 295 K contain no singlet with $g_{\text{aver}} = 1.960$; an anisotropic singlet with $g_{\text{eff}} = 1.975$ appears instead. All these changes were attributed to variations in the glass structure. The structure of the glass in the first area is based on the phosphorus–oxygen network, which may incorporate vanadium–oxygen tetrahedra, and the cavities in the network are occupied by Na^+ , SO_4^- , and VO^{2+} ions. The network consisting of vanadium–oxygen chains with tetrahedrally coordinated vanadium predominates in the third area. In the second area, the glass contains a fairly large amount of VO^{2+} ions present in an octahedral coordination with tetragonal constriction as well as VO^{2+} ions arranged in the cavities of the structural network as modifying ions. In the fourth area glasses have an intermediate structure: they consist of phosphorus–oxygen, vanadium–oxygen, and mixed chains as well as of sulfate ions.

The studies considered in this Section reflect most clearly the principle of construction of a glassy matrix based on the composition–structure dependence and the possibility of investigating the glass structure by EPR. When various glasses are compared, one can note that the course of the composition–property dependence for sulfate-containing phosphate glasses varies more smoothly than that for silicate or borate glasses. This difference may be attributed to the higher homogeneity of sulfate-containing phosphate glasses. Sulfate ions increase the radiation resistance of glasses. Some chemically inert and radiation-resistant lead-containing glasses may incorporate up to 25 mol % of sulfate-containing wastes.

III. Electron dynamics in oxide glasses

1. Reactions of reversible electron transfer occurring under the action of light

We have described above the processes of destruction of ions in UOS on exposure to light. It was noted that photoannealing with boundary filters leads to partial destruction of both CC and PMC. As the region of transmission of the boundary filter used moves to the UV region, energetically more stable CC and PMC (i.e. centres for which the activation energies for the photodestruction are higher) are annealed, the photoannealing curves being linearised in the $n/n_0 - \lg(t/t_0)$ coordinates. By now it has been established that if CC with nonoverlapping AB arise in a γ -irradiated glass, reversible phototransfer of an electron between the species responsible for these AB is possible. From this standpoint, lithium, sodium, potassium, and barium aluminophosphate glasses proved most promising, since γ -irradiation of these glasses leads to the appearance of $\text{PO}_4^{2-}-\text{M}^{Z+}$ pairs of species ($Z+$ is an unusual oxidation number), which are responsible for nonoverlapping AB. In fact, an AB with $\lambda_{\text{max}} = 500$ nm corresponds to the PO_4^{2-} ion, while, for example, Ti^{2+} and Nb^{4+} ions account for AB with $\lambda_{\text{max}} = 420$ and 650 nm, respectively.

It has been shown that these ions arising on irradiation can be involved in reversible photoprocesses of the type

and the unpaired electron can thus be transferred from the ion in UOS to the PO_4^- ion by phototreatment (in the region of the AB corresponding to the ion in UOS). The reverse process is carried out by treating the PO_4^{2-} ion with light (in the region of the AB with $\lambda_{\text{max}} = 500$ nm). In this case, the kinetic curves are also linearised in the $n/n_0 - \lg(t/t_0)$ coordinates. The concentration of the PO_4^{2-} ions being destroyed decreases in parallel with an increase in the concentration of the ions in UOS being formed (for example, Ti^{2+} and Nb^{4+} ions); this can be written as $|\Delta[\text{PO}_4^{2-}]| = |\Delta[\text{Ti}^{2+}]| \{|\Delta[\text{Nb}^{4+}]]|\}$. The paramagnetic species PO_4^{2-} , Ti^{2+} , and Nb^{4+} are especially convenient, because the reversible processes involving these species can be monitored both by optical spectroscopy and by EPR.

The number of cycles in such reversible processes is influenced by the structure of the glass as well as by the degree of overlap of an edge of the AB corresponding to the ion in UOS with an edge of the AB due to the phosphorus-containing radical ion resulting from the light treatment. The formation in the glass of cluster species of the M_m^{n+} type (where m and n are 1, 2, 3, ...), together with the ions in UOS, prevents the realisation of a large number of cycles; the clusters also participate in the electron dynamics thus creating additional reaction pathways and blurring the pattern of 'ideal' photoreversible transitions between the radiation-induced CC and PMC. In the case of phosphate glasses with added Nb_2O_5 the pattern of reversible photoreactions is also blurred because niobium oxide forms its own niobium–oxygen network, along which the electron, knocked out from PO_4^{2-} by the phototreatment, can migrate. Apparently, this electron no longer participates in the reverse reactions. This may be why the number of cycles for the $\text{PO}_4^{2-}-\text{Nb}^{4+}$ pair is much smaller than for the $\text{PO}_4^{2-}-\text{Ti}^{2+}$ pair.

2. Temperature-dependent reactions of reversible electron transfer

An attempt has been made⁶² to obtain metal ions in UOS without the action of ionising radiation. For this purpose, lithium tungstate-, lithium niobate-, and lithium molybdate-phosphate glasses (LTPG, LNPG, and LMPG) with added tin, titanium, vanadium, molybdenum, tungsten, and nickel oxides have been synthesised under reducing conditions. The completed glasses were intensely coloured (the 'glass melting' colour). The following PMC were found in these glasses by EPR:⁶² Nb^{4+} , Mo^{5+} , W^{5+} , Ti^{3+} , VO^{2+} , and Ni^0 . The integral intensity of the EPR signals corresponding to the above PMC in these glasses increased by several orders of magnitude as the temperature decreased from 300 to 6 K. It was also found that as the temperature decreased, the EPR parameters of the PMC already present altered, which points to structural changes in the glass network, at least in the local environment of the ions in UOS. As the temperature decreased, the edge of the fundamental absorption for all the above glasses shifted to the UV region of the optical spectrum by 5–10 nm. For the matrix LNPG, the intensity of the AB with $\lambda_{\text{max}} = 800$ nm decreased, whereas the intensity of the AB with $\lambda_{\text{max}} = 600$ nm increased with a decrease in the temperature, i.e. a low-temperature thermochromic effect was observed. All the processes and parameters are temperature-reversible, i.e. the parameters return with time to the values corresponding to a given temperature.

Aleksandrov et al.⁶² believe that these variations are due to the stabilisation–destabilisation (localisation–delocalisation) of electron pairs caused by slight local variations of the structural network of the glass. A decrease or an increase in the temperature leads to the transfer of an electron pair and to disproportionation reactions of the type:

where Z is the oxidation number; M^{Z+} are Nb^{3+} , Sn^{2+} , Ti^{2+} , V^{3+} , Mo^{4+} , and W^{4+} ions at which a pair of electrons with opposite spins is localised due to structural features of the glasses obtained. The existence of $\text{M}^{(Z+2)+}$ ions in the glasses synthesised is indicated unambiguously by the fact that the γ -irradiation of these glasses at 300 K leads to reduction reactions of the following type

The continuous increase in the concentration of ions in UOS as the temperature decreases down to 6 K (Fig. 8) is evidence in favour of the disproportionation of electron pairs [according to reaction (6)].

Thus, Aleksandrov et al.⁶² showed for the first time the possibility of temperature-dependent reversible transfer and disproportionation of a pair of electrons in oxide glasses, i.e. the so-called P_e -processes and D^2 -disproportionation reactions, the existence of which in solids had already been suggested in theoretical papers.^{63–65}

Aleksandrov et al.⁶⁶ have also proved unambiguously the possibility that during the synthesis of glasses, D^+ and D^- sites arise on transition metal ions, i.e. pairs of negatively and positively charged defective sites existing in charge equilibrium. The quantum level of the D^- site is occupied by two electrons, while that of the D^+ site contains no electrons. The reason why these sites are defective was considered by Street and Mott in their model of glassy media.⁶⁵ The quantum levels of the D^+ and D^- sites are located near the conduction band and near the valence band, respectively. According to Street and Mott, the metastable D^0 site, which is a level singly occupied by an unpaired electron, is

Figure 8. Dependences of the concentration of (Nb^{4+}) PMC on temperature in the 'matrix' LNPG (1) and in LNPG with added tin (2), vanadium (3), or titanium (4) oxide. Curve 4 shows the overall concentration $\text{Nb}^{4+} + \text{Ti}^{3+}$.

located in the middle of the forbidden gap; this site results from an external action on the glassy medium during reduction or oxidation reactions involving D^+ and D^- sites. In the examples described above, ions in UOS act as D^0 sites. Aleksandrov et al.⁶² were the first to find experimentally the D^+ , D^- , and D^0 defects at transition metal ions in oxide glasses.

It is noteworthy that in the LNPG doped with tin oxide, additional PMC have been observed only on Nb^{4+} ; when the glass is doped with titanium oxide, PMC can be detected either on both Nb^{4+} and Ti^{3+} or only on Ti^{3+} , depending on the composition of the glass and on the glass melting conditions; in the case where vanadium, molybdenum, and tungsten oxides act as dopants, only PMC caused by VO^{2+} , Mo^{5+} , and W^{5+} are observed. In the LMPG system doped with tungsten oxide, (Mo^{5+}) and (W^{5+}) PMC have been observed, the ratio between the concentrations of Mo^{5+} and W^{5+} depending on the composition of the glass and on the glass melting conditions. The yields of all ions on decreasing the temperature are strongly dependent on these conditions. Thus, it is obvious that under certain conditions the D^2 -disproportionation reactions are preceded by the P_e -process involving the transfer of an electron pair from Nb^{3+} to V^{5+} , Mo^{6+} , W^{6+} , and Ti^{4+} yielding V^{3+} , Mo^{4+} , W^{4+} , and Ti^{2+} and then V^{4+} , Mo^{5+} , W^{5+} , and Ti^{3+} . The Nb^{4+} ion is not formed in these glasses, i.e. the separated electrons do not react with the dopant. Apparently, this is an example of accepting an electron pair and subsequent accepting of the separated electrons by a stronger acceptor.

If glasses contain dopants leading to the formation of metal ions with weaker accepting properties compared with those of the V^{5+} , Mo^{5+} , W^{5+} , and Ti^{4+} ions, only Nb^{4+} is formed. However, the influence of the compounds added on the trapping of the electrons resulting from the dissociation of electron pairs can be judged from the increase in the concentration of the Nb^{4+} ion with a decrease in the temperature. Fig. 9 shows the dependence of the concentration of the Nb^{4+} ions at 77 K in LNPG on the kind of dopant (silver, zinc, indium, tin, antimony, gallium, or germanium oxide), which can lead to the formation of ions in UOS with the corresponding oxidation number Z . The dopants were introduced during the glass melting in a concentration of 3 mol %. The pattern of the $\Delta[\text{Nb}^{4+}] - Z$ plot coincides with those

Figure 9. Dependence of the yield of Nb^{4+} ions at 77 K in LNPG containing metals, forming the corresponding ions in UOS, added as dopants (introduced as oxides in an amount of 3 mol %).

of the $A_i/A_i^{(0)} - Z$ and $E_{\lambda_{\text{max}}} - Z$ plots obtained for γ -irradiated alkali phosphate glasses. Evidently, after the decomposition of species with paired electrons to single-electron species, doping metals enter into redox reactions with them yielding ions in UOS, as with the action of γ -radiation.

Since niobium oxide acts in LNPG as the glass-forming compound, forming a glass network possessing microcavities, channels, and pores peculiar to it, one can assume that surface disproportionation reactions occur, which are accompanied by surface transport of electron pairs to stronger acceptors affording ions in UOS. Naturally, the disproportionation reactions proceeding within the structural units of the glass also contribute to this process.

To elucidate the mechanism of the reversible low-temperature disproportionation (RLD) and the reasons for stabilisation of particular concentrations of elements in UOS at a fixed temperature, the following experiments have been carried out. LNPG (this glass is subsequently referred to as the 'matrix LNPG') with added titanium, tin, and vanadium oxides, containing Nb, Li, P, and M (Sn, Ti, V) atoms in concentrations of $(1-4) \times 10^{21}$, $(4-8) \times 10^{21}$, $(1-3) \times 10^{22}$, and $2 \times 10^{20} \text{ cm}^{-3}$, respectively, were taken as model objects. These glasses had an intense ('glass melting') colour, resulting from the reducing conditions used in their synthesis. The number of PMC was determined from the EPR spectra recorded in the integration regime.⁶⁶ In this case, up to 10^{21} PMC per cm^3 arise.

It is seen from Fig. 8 that the activation energy for the increase in the concentration of elements in UOS depends on temperature, $E = f(T)$. The increase in the concentration of ions in UOS (Nb^{4+} , Ti^{3+} , etc.) is caused by several processes for which a spread in energy parameters is possible due to the statistical distribution of the initial transition metal ions in the glass matrix. These processes include: decomposition of species with electron pairs (denoted formally by Nb^{3+} , Ti^{2+} , Mo^{4+} , W^{4+} , etc); and stabilisation of 'separate' electrons (subsequently, this term refers to 'exchange' electrons participating in exchange processes and to the free electrons in the glass matrix). These processes end with the formation of ions in UOS: Nb^{4+} , Ti^{3+} , etc., which are stable at a given temperature.

In order to evaluate the contributions of the stabilisation of 'separate' electrons, and of those electrons resulting from the decomposition of species with electron pairs, to the RLD effect (to the formation of the Nb^{4+} , Ti^{3+} , etc. UOS), the temperature dependences of the electrical conductivity at direct current have been recorded (by the four-electron method) for the matrix LNPG and for the LNPG doped with vanadium, titanium, and tin oxides (Fig. 10). In fact, since the electrical conductivity varies down to

Figure 10. Temperature dependence of electrical conductivity in the $\sigma - 10^3/T$ coordinates (curves 1-4) and in the $\sigma - T^{-1/4}$ coordinates (curves 3'-4') in the 'matrix' LNPG (1) and in LNPG with added tin (2), vanadium (3, 3'), or titanium (4, 4') oxide.

low temperatures (200 K), the hopping mechanism of conductivity is valid, as well as the thermostimulated conductivity of electrons and holes, described by the dependence $\sigma = \sigma_0 \exp(\Delta E/kT)$, where $\Delta E = E_c - E_F$ for electrons and $\Delta E = E_F - E_v$ for holes (E_c , E_v , and E_F are the energies of the edge of the conduction band, the edge of the valence band, and the Fermi level, respectively). The hopping conductivity involves tunnelling of thermoactivated charge carriers from one trap to another over the energy levels at the edges of the bands (in the energy ranges $E_c - E_a$ and $E_b - E_v$), occurring in accordance with the geometrical and energy distances between the individual traps (see Fig. 11).

Apparently, one more charge transfer mechanism occurs. It involves 'jumps' of various distances over localised states near the Fermi level. For this type of conductivity, Mott⁶⁷ has found the relation $\sigma = \sigma_1 \exp[-(T_0/T)^{1/4}]$. It is the Mott's temperature dependence of the conductivity that is obeyed at low temperatures in the glasses under consideration (Fig. 10). Tentative values for the number of conduction electrons (numerically equal to the

Figure 11. Scheme for the density of the electron states on ions in LNPG at low temperatures (the dashed line shows the possible energy spectrum of niobium ions intercalated with Li^+ cations).

concentration of 'separate' electrons) in these glasses are 10^6 – 10^{12} cm $^{-3}$. This is less by many orders of magnitude than the number of Nb $^{4+}$ and Ti $^{3+}$ UOS arising by the RLD mechanism in the same glasses on decreasing the temperature. Thus, it is obvious that the contribution of the stabilisation processes of the exchange and free electrons to the formation of UOS is quite insignificant. The UOS observed arise largely via the type (6) disproportionation of species with paired electrons. In addition, the conductivity of the glasses increases by several orders of magnitude following the introduction of transition metal oxides (Fig. 10); and the conductivity determined for direct current is time-dependent. Hence, it can be claimed that there is a contribution of the cationic framework to the conductivity of this class of glasses; in other words, these glasses incorporate a mobile cationic framework.

It has been found⁶⁶ that the yields of Nb $^{4+}$ and Ti $^{3+}$ in LNPG with a constant Nb $_2$ O $_5$ /P $_2$ O $_5$ ratio depend on the number of lithium cations, since the concentrations of Nb $^{4+}$ and Ti $^{3+}$ pass through a maximum at a particular Li $^+$ concentration and fall to undetectable values as the latter decreases. This suggests that the mobile cation ensemble has an influence on the dissociation of the electron pairs at Nb $^{3+}$ and on the subsequent stabilisation of the UOS of niobium ion, Nb $^{4+}$. Evidently the cationic ensemble stimulates the reaction (6) and stabilises the resulting UOS by the following multistage mechanism.

In the first stage, the electron pair at Nb $^{3+}$ dissociates, and Nb $^{4+}$ is stabilised by a lithium cation.

The unpaired electron thus liberated reacts with Nb $^{5+}$

and the resulting Nb $^{4+}$, in its turn, is stabilised by a lithium cation

Thus, if we refer the designations Nb $^{3+}$, Nb $^{4+}$, Nb $^{5+}$, Ti $^{2+}$, etc. to oxygen-containing cluster species incorporating a particular ion in the corresponding oxidation state and consider that the lithium ions are located within the sphere of this cluster and are probably bound to the metal (titanium, niobium, etc.) ions via oxygen bridges, then formally Nb $^{4+}_{\text{st}} = (\text{Nb}^{4+} \cdots \text{Li}^+)$. The stable Nb $^{4+}_{\text{st}}$ ion is now detectable by the EPR method (strictly speaking, only Nb $^{4+}_{\text{st}}$ can be detected 'directly' by EPR). Thus, the temperature-dependent reversible liberation–capture of the cations from shallow to deep energy traps stabilises the forming UOS and promotes the disproportionation reaction (6). This is certainly accompanied by variations of the charge density in the local space in the vicinity of the ion in UOS.

Obviously, the cationic ensemble also influences the conductivity of glasses, since intercalation of a glass with lithium changes (splits, shifts, etc.; see Fig. 11) the energy levels of all the ions present. The transfer of electrons and holes at low temperatures occurs along the system of the lithium-intercalated glass, i.e. the glass in which energy levels and quantitative ratios of ions have changed.

Thus the RLD effect can be considered to be associated with the crucial role of the cationic framework in the stabilisation of UOS and, consequently, with the occurrence of the disproportionation processes (6). The cationic framework determines the Nb $^{3+}$ /Nb $^{4+}$ /Nb $^{5+}$ ratio of ion concentrations. However, at the concentrations found [Nb $^{4+}$] = $N = 10^{21}$ cm $^{-3}$, the value $NZ_B < 0.25$ (Z_B is the Bohr radius of Nb), i.e. according to the Mott criterion,⁶⁷ metallisation of this glassy system has still not been achieved.

3. Formation of ions in UOS as a result of mechanochemical treatment

It follows from the above that the unpaired electrons arising due to various kinds of treatment of a solid (γ -radiation, phototreatment, heat treatment) are characterised by similar chemical behaviour: they give rise to ions in UOS in the glass matrix. It should be expected that mechanical treatment of the glasses described above will also lead to the appearance of ions in UOS. It has been noted⁶⁸ that when a LiF crystal is cracked, F atoms are liberated. One of the hypotheses put forward for the explanation of the emission of F atoms states that the following electron transfer reactions occur during the cracking: $\text{F}_v^- \longrightarrow \text{F} + \text{e}^-$, $\text{Li}^+ + \text{e}^- \longrightarrow \text{Li}$, where F_v^- is a vibrating F $^-$ ion which has undergone vibrational excitation immediately after the cleavage of bonds in the mouth of the mechanical crack. If the amplitude of these vibrations reaches 0.75 of the magnitude of the lattice parameter, rupture of the chemical bond occurs according to the above scheme. The mechanisms of dislocation-induced excitation of the electron subsystem of a solid, according to which electron-hole pairs are formed upon collision of dislocations or upon their exposure at the surface of a pore (or a crack) in a solid, have also been reported.^{69,70} The collision or surface exposure of dislocations is accompanied by intense acoustic emission, i.e. vibrational excitation of atoms. If the amplitude of vibrations of the atoms exceeds the limit mentioned above, an electron-hole pair is formed. Obviously, the subsequent scheme of elementary chemical steps following the mechanical destruction of a solid should include reaction (2) (formation of ions in UOS).

We carried out experiments on mechanical treatment in a ball mill of sodium silicate (SSG) and sodium borate (SBG) glasses at 77 K. It was found by EPR that in the SSG doped with cadmium, tin, thallium, and lead oxides, Cd $^{1+}$, Sn $^{3+}$, Tl $^{2+}$, and Pb $^{3+}$ ions are formed. The $A_i/A_i^{(0)}$ ratios for these ions are 0.64, 0.35, 0.55, and 0.48, respectively. It is seen that the $A_i/A_i^{(0)} - Z$ dependences for the ions in UOS obtained by mechanical treatment and by γ -irradiation at 77 K are similar.

After the mechanical treatment of SBG in a ball mill at 77 K, only weak signals corresponding to BO $_4^{4-}$ PMC were observed. Apparently, the number of ions in UOS in these glasses is so small that they cannot be detected by EPR.

These data are in good agreement with the views on the structure of inorganic glasses presented above and with the model of the vibrational formation of electron-hole pairs in a glass after mechanical treatment. In fact, boron oxide usually forms linear chains in glasses with low resistance to deformation, whereas silicate glasses consist of highly rigid three-dimensional networks.⁷¹ Naturally, the stronger the glass, the higher is the mechanical stress needed for its destruction, and the more intense in amplitude and frequency are the vibrational processes arising in it. Hence, it is clear that the formation of electron-hole pairs and, consequently, of ions in UOS, should be more intense in silicate glasses. This is in good agreement with the above experimental results.

4. The role of metals in UOS in the nucleation in a glass

The formation of the crystalline phase from glasses and melts is an important problem in the theory and practice of the glassy state. This process plays a key role in the preparation of crystalline enamels and glazes, in the directed colloidal colouring of glasses, and in the production of glass ceramics, photo glass ceramics, and photochromic glasses existing in both the amorphous and crystalline states. The theoretical foundations for these processes have been formulated by Kolmogorov⁷² and developed further by other researchers.^{73–81} However, stage-by-stage molecular chemical investigation of the mechanism of the formation of the crystalline phase has hardly been developed. In all these studies, only the initial and final substances were examined. Nothing was said about the role of disproportionation reactions.

The formation of the colloidal and crystalline phases can be divided conventionally into three stages: (1) the formation of atomic centres; (2) the appearance of molecular aggregates; and (3) the formation of colloidal and crystalline inclusions. The first two stages are often combined into a single stage — nucleation, the growth of crystals and colloids being regarded as the second stage.

To obtain the nuclei, photosensitisers, thermosensitisers and photosensitive metals are introduced into photo glass ceramics and in photochromic glasses. Ce, Sm, and Pr compounds, i.e. compounds of elements that readily release electrons on exposure to light, for example, by the reaction

act as photosensitisers.

The wavelength of the active light depends on the nature and properties of both the photosensitiser and the matrix glass. The metals Sn, Sb, Pb, etc., small amounts of which (0.02%–1.5%) increase the capability of a photosensitive metal to form nuclei during heat treatment of the glass and thus decrease the irradiation time, are referred to as thermoreducing sensitizers.

Photosensitive metals are mainly Cu, Ag, Au, and Pt. Thermosensitisers can reduce the ions of photosensitive metals even during glass melting. In this case, the following reactions occur on exposure to light:

The atomic copper, gold, silver, etc. form colloidal and crystalline phases when heated to a certain temperature. Cerium added to the glass permits the yields of Cu^0 , Ag^0 , and Au^0 to be increased, due to the occurrence of reactions of the type

Photosensitive materials can act as self-sensitisers

where Δ is the excess energy liberated. Hard radiation exerts a similar influence on these glasses, i.e. γ -irradiation also creates prerequisites for the nucleation.

Spontaneous (homogeneous) crystallisation can proceed in a glass melt. The process of nucleation in this case has been rationalised at the microquantitative level by Weyl,^{77,78} who relates the nucleation to defects or asymmetric fragments. In his opinion, the 'asymmetry' is caused by disproportionation (not electronic) of the bonding forces, which lowers the energy barrier to the formation of crystallisation centres. Berezhnoi⁷⁹ believes that the 'appearance of the centres for spontaneous crystallisation in complex glasses is associated with the diffuse chemical differentiation of atoms and structural groups forming aggregates as zones, the composition of which is close to that of the segregating crystals.' Thermodynamic description of the homogeneous crystallisation has also been reported.⁷³

An important role in the theory of heterogeneous (or catalytic) crystallisation is played by metastable zones, the necessity of wetting the catalyst with the crystalline phase, and the similarity of crystal structures and interatomic distances in the catalyst and in the crystalline phase. This process is greatly influenced by stirring or vibration of the supercooled melt or by the action of ultrasound, electrical and magnetic fields, and γ -irradiation. The oxides TiO_2 , ZrO_2 , P_2O_5 , ZnO , Cr_2O_3 , V_2O_5 , NiO , Nb_2O_5 , WO_3 , and MoO_3 are used as catalysts. The choice of the catalyst in each particular case depends on the composition and properties of the glass melt.

Turnbull⁸⁰ has derived equations for calculating the rate of formation of crystallisation centres for heterogeneous crystallisation. After that, the rules for the selection of the catalyst have been established:⁸¹ the catalyst should be readily soluble in the glass blend at the temperature of glass melting (and manufacture) and

be sparingly soluble at low temperatures; the free activation energy for the formation of homogeneous crystallisation centres from the melt at low temperatures should be low, which is favoured by a low surface energy of the dissolved and crystalline phases and by a high degree of supersaturation on cooling; the free activation energy for the diffusion process should be low; the surface energy at the interface between the glass and the catalyst crystal should be low; the parameters of the crystal lattice of the catalyst should be close to those of the segregating crystalline phase. However, Weyl^{77,78} has noted that the distribution of chemical bonds within the system is also important.

It is clear from the foregoing that the processes of nucleation and segregation of the crystalline and colloidal phases from glasses have mainly been described at a macroscopic level. The role of transition metal ions and ions in UOS as well as concepts at the molecular level, similar to those considered above in relation to the formation of metal clusters M_m^{n+} ($\text{M} = \text{Pb}, \text{Tl}, \text{Bi}$), was not mentioned in any of these studies. In none of the papers surveyed in relevant monographs^{79,82,83} is mention made of the fact that only the presence of atoms capable of disproportionating, such as $\text{Bi}^{3+} - \text{Bi}^{5+}$, $\text{Tl}^{1+} - \text{Tl}^{3+}$, $\text{Cu}^{1+} - \text{Cu}^{3+}$, $\text{Pt}^{2+} - \text{Pt}^{4+}$, $\text{Ti}^{2+} - \text{Ti}^{4+}$, in combination with ions in UOS acting as sensitizers, is the crucial factor for the beginning of the nucleation process.

The above is confirmed by the reversible formation and decomposition of Cu_m^{n+} colloidal particles, induced by ions in UOS obtained by irradiation, such as Zn^{1+} , Cd^{1+} , Hg^{1+} , In^{2+} , Tl^{2+} , Sn^{3+} , Pb^{3+} , Sb^{4+} , and Bi^{4+} .⁸⁴ Let us consider a sodium aluminoborosilicate glass with added cadmium and copper oxides. It has been shown by EPR that irradiation of this glass leads to the formation of Cd^{1+} and BO_4^{4-} ions. On heating to 150–200 °C these ions virtually disappear. Further heating to 800 °C leads to the formation and destruction of particles of colloidal copper Cu_m^{n+} . This indicates that the Cd^{1+} and BO_4^{4-} ions are not merely annihilated, but enter into redox reactions with Cu^{2+}

which afford the D^- , D^+ defects, i.e. the Cu^{1+} and Cu^{3+} ions. It is pairs of these ions, identified based on the AB with $\lambda_{\text{max}} = 570$ nm, that act as the precursors of the nuclei of colloidal copper. In fact, the lattice around the D^+ defect should be substantially stressed, whereas the D^- defect interacts with the environment only weakly but possesses a higher mobility. This leads to the possible occurrence of the following reactions:

The species Cu_2^{5+} , Cu_2^{4+} , Cu_2^{3+} , and Cu_2^{2+} can also be regarded formally as D^- and D^+ defects. Some of them are more mobile than others. Reactions then proceed in which the number of copper atoms in one nucleus increases to give Cu_m^{n+} particles.

The decomposition of the colloidal particles Cu_m^{n+} following further increase in the temperature occurs stepwise. This is indicated by the decrease in the intensity of the AB with $\lambda_{\text{max}} = 570$ nm and by the appearance of an AB with $\lambda_{\text{max}} = 455$ nm, which also disappears as the temperature is further increased. The latter AB corresponds apparently to species with lower numbers of copper atoms or to small colloidal particles of copper incorporating cadmium atoms. It can be assumed that the decomposition of Cu_m^{n+} is related to the high-temperature disproportionation reactions. The diagram for this process is shown in Fig. 12. This process can be repeated many times, beginning with the radiation-induced generation of the Cd^{1+} and BO_4^{4-} ions at 300 K.

Thus, the following sequence of transformations occurs: low-temperature defects \longrightarrow disproportionation reactions \longrightarrow high-temperature products \longrightarrow disproportionation reactions \longrightarrow

Figure 12. Processes in the accumulation and disappearance of Cd^{1+} ions and Cu_m^{n+} clusters after γ -irradiation followed by thermoannealing.

return to the initial state. To control the formation of the nuclei of crystalline and colloidal phases in glasses, in glass-like materials, and, possibly, in ceramics, one should elucidate the relationships in this sequence. The problem of elucidating these relationships can be solved only by detailed investigation of the whole set of ions present in the glass and of the electron dynamics of their interactions,⁸⁵ which, in the presence of disproportionation reactions, may be complex and involve in oxide glasses both the metal and oxygen. For example, the following disproportionation reactions of the D^{2-} type may occur

Oxygen ions and clusters should promote the disproportionation reactions.^{86–90} Obviously, studies along these lines will be continued.

IV. Conclusion

The data presented in our review imply that the stabilisation and reversible stabilisation–destabilisation of metal ions in UOS with the localisation of one or two electrons are complex processes involving the whole glass or the glass-like solid. These processes are associated with the electron-vibrational and conformational rearrangements, electron density transfer, shifts of atoms, and with variations (reversible or irreversible) of the local structure of the glass. The processes of electron disproportionation are accompanied by redox chemical reactions. Specific features of these processes are determined by the structure of the glass (the network geometry and the characteristic features of the electronic structure).

Currently the most common view on the structure of glasses is that the borate, germanate, silicate, and phosphate glasses are built of the main structural units $\text{BO}_{3/2}$, $\text{BO}_{4/2}$, $\text{GeO}_{4/2}$, $\text{SiO}_{4/2}$, and $\text{PO}_{4/2}$ (the indices 3/2 and 4/2 point to the fact that the B, Ge, Si, and P atoms are linked to the glass network via three or four bridging oxygen atoms), which are transformed during the synthesis into progressively more complex structures,^{91–98} i.e. mono-, di-, and oligomeric anions. The latter are converted, in their turn, into diverse macroanions (MA) of linear $(\text{SiO}_3^{2-})_n$, layered (philo) $[\text{BO}_{3/2}(\text{O}^-)]_m^{2mn}$, or network (texto) $(\text{Si}_2\text{O}_5^{2-})_n$ type or into clusters with any number of atoms. Thus, glass can be treated as a solid, porous at the molecular level, with an immense inner surface, the channels and pores of which are occupied by modifying cations, and dangling bonds also emerge there.^{38, 84}

The dangling chemical bonds and modified structural groups give rise to a set of various defects of donor or acceptor character. The frequency of origination of these sites (defects) is determined by the free energy of formation of each of them. At the same time, if a glass contains no paramagnetic ions introduced during the synthesis, it is a diamagnetic material. If singly charged positive and negative defects could arise during the synthesis of glasses,

they would correspond to high concentrations of unpaired electrons. However, EPR studies indicate unambiguously that their concentration is lower than 10^{15} cm^{-3} and can be brought to $10^{17} - 10^{19} \text{ cm}^{-3}$ in amorphous Si and Ge only by various external factors.^{99, 100} The presence of singly charged positive and negative defective sites would also cause substantial conductivity at low temperatures, but no contribution of this conductivity has been found so far.⁸³

These contradictions have been resolved in terms of the theory of chemical bonding describing the characteristic features of the electronic structure of glass. A great contribution to the development of this theory has been made by Anderson.¹⁰¹ He noted that in amorphous semiconductors and glasses, electrons tend to be combined in pairs thus forming stable states. The stability of the states with paired electrons is due to the fact that the energy of the Coulomb repulsion is lower than the energy of the electron-phonon interaction; the polarisability of the solid lattice surrounding the electrons should also be taken into account. Later Street and Mott⁶⁵ and Kastner, Adler, and Fritzche¹⁰² developed (almost contemporaneously) the theory of localised states in a glass, which are positively and negatively charged defects (D^+ and D^- , respectively). These authors claim that a half of the defects remain unoccupied with electrons and acquire a positive charge (D^+ site), and the rest of the defects are occupied by electron pairs and have a negative charge (D^- site). These studies made it possible to explain the diamagnetism of glass and the linearity of the variation of the molecular heat capacity of glasses at low temperature.

Lucovsky¹⁰³ and Greaves¹⁰⁴ have developed these views in relation to glassy SiO_2 . They proved that the abstraction of an electron from a D^- site or the addition of an excited electron from the valence band to a D^+ site result in the formation of a paramagnetic neutral D^0 site. Within the framework of quantum chemistry, all these models are based on the fact that the heterolytic rupture of chemical bonds yielding D^+ and D^- sites is energetically more favourable than the homolytic rupture of bonds leading to the formation of sites with unpaired spins. The antibonding state has an electronic configuration that is described by the D^+ state located in the forbidden gap below the conduction band, while the D^- state has a completely filled valence electronic shell, forms no additional bonds, and is located in the forbidden gap above the valence band. The smaller the polarisation of the lattice caused by the D^- site, the stronger the polarisation effect caused by the D^+ site.

All the models considered above describe the same effect; they go under the general name of the model of charged defective sites, which is valid only for fairly simple structures in the glass.⁸³ A more adequate model, namely, the model of quasimolecular defects, has been suggested by Popov.¹⁰⁵ This model involves the realisation of multicentre multielectron bonds in glasses. This model shares a number of traits with the Dembovskii model, which develops the theory of 'soft' three-centre bonds (arising due to the fact that the bonds are formed by antibonding electrons).¹⁰⁶ It is clear that the extension of the above concepts to the description of the geometric and electronic structure of glass has not yet been completed.

If we suggest, from general chemical knowledge, that an analogy between the processes of structural disordering in glass and dissociation reactions like $2\text{H}_2\text{O} \rightleftharpoons \text{H}_3\text{O}^+ + \text{OH}^-$ in aqueous media can be drawn legitimately,^{55, 101–105} then the acid–base concept applied to oxide melts and glasses correlates quite well with views on the redox disproportionation yielding D^+ and D^- sites. According to this concept, the heterolytic rupture of bonds leads to the formation of a D^+ hole site on the oxygen atom bound to three silicon atoms [$^+\text{O}(\text{SiO}_{3/2})_3$] and of a D^- two-electron site on the oxygen atom bound to one silicon atom [$\text{SiO}_{3/2}\text{O}^-$]. In the presence of foreign metal oxides, the scheme by which the defective sites arise changes: metal cations act as the D^+ sites instead of $^+\text{O}(\text{SiO}_{3/2})_3$. This refers also to three other main types of oxide glasses: borate, germanate, and phosphate glasses.^{83, 107}

The modelling of the formation and stabilisation of ions in UOS at the level of local reactions, with allowance for the disproportionation of the electron density between the selected atomic centres, makes it possible to explain completely the processes of stabilisation of ions and switching of bonds both during the synthesis of glasses and following various kinds of physical treatment of them.¹⁰⁸ Moreover, it follows from the data presented in our review that a key role in the stabilisation of ions in UOS in low-temperature glasses is played by hydrogen bonds, due to which a glass-like network is formed. In this case, protons act as the mobile cationic framework; after the addition of an unpaired electron to a metal cation, protons occupy energetically favourable positions in its environment and lead to the redistribution of the electron density due to local disproportionation reactions.

Thus, allowance for the structural features of glass, the presence of dangling and multicentre bonds leading to the initial localisation of the electron pairs, and the presence of a mobile cationic ensemble determine the subsequent cooperative processes based on redox reactions, which are similar as regards the nature of the elementary step and lead to the formation and stabilisation of ions in UOS.

Abstract. The possibility of determining relative rates of oxidation of hydrocarbons and of their individual C–H bonds by competitive oxidation has been demonstrated. Data on the reactivities of C–H bonds of various hydrocarbons are discussed. Information about relative reactivities of the C=C double bonds of cyclic alkenes and of some styrene derivatives is presented. The bibliography includes 42 references.

I. Introduction

Competitive reactions have been widely used to obtain data concerning the relative rates of chlorination of various hydrocarbons.^{1–6} If these data and also the compositions of the isomeric chloro-derivatives formed from the individual hydrocarbons are known, it is possible to calculate the relative reactivities of individual C–H bonds with chlorine atoms.

In the chlorination of mixtures of hydrocarbons only one radical capable of attacking C–H bonds is present, namely the chlorine atom. In the liquid-phase oxidation of a mixture of two hydrocarbons, individual C–H bonds may be attacked by at least two different peroxy radicals, each derived from one of the starting hydrocarbons (Scheme 1). It has been assumed that

Scheme 1

$k_{11} : k_{12} = k_{21} : k_{22} = k_1 : k_2$. Here k_1 and k_2 are the rate constants for the oxidation of the hydrocarbons R^1H and R^2H , respectively. In competitive oxidation correct data for k_1/k_2 can be obtained only if the relative reaction rates of peroxy radicals with different

C–H bonds are independent of the nature of the attacking radical.⁷ If the cooxidation is accomplished in the presence of a large excess of an individual hydroperoxide then all peroxy radicals formed from the starting hydrocarbons will react with it (Scheme 2).⁸

Scheme 2

In this case the relative reactivities of hydrocarbons and their individual C–H bonds with respect to the peroxy radical derived from the added hydroperoxide can be calculated by the methods used in chlorination.^{8,9}

Table 1 presents the relative rates of oxidation of certain aromatic hydrocarbons in the presence of different individual

hydroperoxides. The data confirm the assumption that the relative rates do not depend strongly on the nature of the attacking peroxy radical.⁸

The ratios of oxidation rates of hydrocarbons R¹H and R²H (i.e. their relative reactivities with peroxy radicals) were calculated from the equation

$$\frac{k_1}{k_2} = \frac{\Sigma[R^1OH][R^2H]}{\Sigma[R^2OH][R^1H]}.$$

Binary mixtures of hydrocarbons were oxidised at molar ratios ranging from 25 : 75 to 60 : 40, temperatures of 90–110 °C, and oxygen absorptions up to 10 mmol per 100 mmol of the sum of both hydrocarbons. After oxidation was complete, the reaction mixture was reduced with lithium aluminium hydride, and the alcohols formed were analysed gas chromatographically. For all the mixtures investigated k_1/k_2 ratios identical within the limits of error were obtained (Table 2). This demonstrates the validity of the assumption that the relative rates of reaction of peroxy radicals with hydrocarbons are independent of the nature of the radical. One must take into account the fact that at high concentrations of R¹H the fraction of its peroxy radical R¹OO[•] in the reaction mixture must be higher than at low concentrations.

The independence of the relative rates of oxidation of a mixture of two hydrocarbons of a given initial ratio demonstrates that the relative rates of the individual C—H bonds with attacking peroxy radicals are independent of the nature of the latter. If this is the case, the rates of oxidation relative to any other partner can be calculated indirectly by employing the oxidation of two pairs of hydrocarbons (e.g. R¹H + R³H and R²H + R³H) in accordance with the equation

$$\frac{k_1}{k_2} = \frac{k_1/k_3}{k_2/k_3}.$$

The results of such calculations do agree with data obtained by direct cooxidations (of R¹H and R²H) (Table 3). This constitutes yet another confirmation of the independence of the relative rates of oxidation of various hydrocarbons (or different C—H bonds) of the nature of the attacking peroxy radicals.

Evidently, it is necessary to select a certain hydrocarbon as a standard and to refer to its oxidation rate the oxidation rates (reactivities) of all other compounds. In the present review, the highly reactive tertiary C—H bond of cumene was chosen as the standard. This means that in most cases cumene was used as the second component of the starting mixture in the cooxidation experiments. Cyclooctane can also be used as a convenient reference hydrocarbon; its reactivity is relatively high, and only

one alcohol (cyclooctanol) is formed from its oxidation products on reduction with lithium aluminium hydride.

Table 3. A test of the possibility of the indirect determination of the relative rates of oxidation of the R¹H + R²H pairs of hydrocarbons under the conditions of their cooxidation.

II. Reactivities of alkylbenzenes and their activated α -C—H bonds

The reactivities of activated (α -position to the benzene ring) and nonactivated C—H bonds of alkylbenzenes have been investigated in detail.^{7, 10–12} Table 4 presents data on the relative rates of oxidation of alkyl-substituted benzene and also on the relative reactivities of their individual C—H bonds. Evidently, the reactivities of both the primary and secondary C—H bonds at the α -position in most cases do not depend significantly on the presence of additional alkyl substituents in the benzene ring. A similar conclusion can also be reached concerning the reactivities of tertiary α -C—H bonds. Table 4 shows that the reactivities of the α -C—H bonds increase in the sequence primary (0.08) < secondary (0.29) < tertiary (0.82) in the ratio of approximately 1 : 3 : 10 (Table 5). The mean deviation of the reactivity data increases in the same sequence. The reason for this is obviously the steric hindrance caused by the alkyl groups linked to the α -carbon atoms.

^a The average reactivities of the C–H bonds are 0.083 ± 0.008 for the primary bond, 0.294 ± 0.051 for the secondary bond, and 0.82 ± 0.23 relative units for the tertiary bond.

Table 5. Relative reactivities of the C–H bonds^a nonactivated and activated by one phenyl group.

C–H bond	Nonactivated	Activated	Activation factor
Primary	0.00133	0.083	64
Secondary	0.011	0.29	26
Tertiary	0.10	0.82	8

^a With respect to the tertiary C–H bond of cumene.

It is known from the literature^{13–15} that *ortho*-substituted cumene derivatives are very difficult to oxidise; this is caused by steric hindrance of the coplanar arrangement of the methyl groups of the intermediate 2-arylisopropyl radical and the *ortho*-substituted benzene ring. Our data on the relative reactivities of the tertiary C–H bonds of two cumene derivatives containing *ortho*-methyl groups confirm this qualitative conclusion (the relative reactivities of the C–H bonds are indicated in brackets in the formulae presented).¹²

A similar decrease in reactivity is also observed in the case of α -isopropyl naphthalene,¹² which can be regarded as an *ortho*-substituted cumene derivative.

The tertiary C–H bonds in *ortho*-substituted cumenes and the inactivated tertiary C–H bonds have approximately the same reactivities in relation to the tertiary C–H bond of cumene (on average 0.10 ± 0.03):

Compound	Relative reactivity of the tertiary C–H bond
Isobutylbenzene	0.17
<i>p</i> -Isobutyltoluene	0.12
3-Methyl-1-phenylbutane	0.07
3-Methyl-1- <i>p</i> -tolylbutane	0.04

Only the question of the reactivities of the C–H bonds activated by a single benzene ring has been discussed hitherto, but Table 4 also contains data on diphenylmethane derivatives and 1,1-diphenylalkanes, i.e. hydrocarbons possessing C–H groups activated by two phenyl groups.

From the data presented in the formulae shown above, it follows that the second phenyl group induces only a small additional activation of the secondary C—H bonds and influences even less the reactivity of the tertiary C—H bonds. The cause of the influence of the phenyl groups on the reactivities of α -C—H groups is known to be the stabilisation of the corresponding carbon radicals and of the transition states during their formation. A prerequisite to such mesomeric stabilisation is the coplanar arrangement of the benzene rings with all the substituents at the α -carbon atom. Since two benzene rings at one radical (sp^2) carbon atom cannot be located in one plane, it follows that the second phenyl group is unable to induce a significant additional activation of the α -C—H bonds. On the other hand, if both benzene rings are forcibly accommodated in one plane, as in the case of fluorene, then the reactivity of α -C—H bonds is indeed increased (2.18).

III. Relative reactivities of aliphatic C—H bonds

Numerous studies of the cooxidation of n-alkanes with cumene carried out in our laboratory made it possible to determine their relative oxidation rates and also the reactivities of their individual C—H bonds (Table 6).¹⁶ The secondary C—H bonds of n-alkanes are appreciably more reactive than the primary bonds in oxidation as well as in other radical substitution reactions.⁵ The reactivity of the secondary C—H bond is lower the more remote its position from the end of the hydrocarbon chain. In the oxidation of normal paraffins a side reaction takes place, the intramolecular hydrogen transfer in the intermediate peroxy radicals, which results in the formation of up to 20% of bifunctional products.^{16–18} In the case of branched paraffins, the contribution of the intramolecular H-transfer is much higher, so that the determination of relative reactivities of such hydrocarbons and their C—H bonds is difficult. In the oxidation of aromatic compounds containing bulky alkyl groups, the non-

^a With respect to the tertiary C—H bond of cumene. ^b The average reactivities of one C—H bond are 0.00125±0.00014 for the primary bond, 0.011±0.001 for the secondary bond, and 0.10±0.03 relative units for the tertiary bond.

activated C—H bonds are also attacked by peroxy radicals. It follows from Table 7 that the ratios of the reactivities of the primary, secondary, and tertiary aliphatic C—H bonds in alkanes and alkylaromatic hydrocarbons are 0.0013:0.011:0.10 ≈ 1:8.5:80. This was in fact to be expected, since the reactivities of aliphatic C—H bonds increase in precisely this sequence in all radical substitution reactions.

The reactivities of activated and nonactivated C—H bonds are collated in Table 5. The ratio of these quantities constitutes the activation factor. The data presented in Table 5 show that the activating effect of the phenyl group at the α -position decreases in the sequence primary > secondary > tertiary C—H bond. The cause is probably steric hindrance of the coplanar arrangement of the alkyl groups linked to the α -carbon atom with the atoms of the benzene ring. The coplanar arrangement gives rise to strain which increases with the increase in the number and the size of the alkyl groups. In indane and tetralin the groups linked to the α -carbon atoms are located in approximately the same plane as the benzene ring, and this causes an increase in the reactivities of their α -C—H bonds.

IV. Ring strain effects in the oxidation of cycloalkanes and their derivatives

The change in the hybridisation of one carbon atom of a carbocyclic compound from sp^3 to sp^2 is always associated with a change of the ring strain, which depends on the size of the ring.¹⁹ Therefore the rates of the reactions in which cycloalkyl radicals are formed are determined to a large extent by the ring size.²⁰ A similar dependence is characteristic also for the radical bromination (but not for the chlorination) of cycloalkanes.⁴

The cooxidation of cycloalkanes and their methyl-, ethyl-, and phenyl-substituted derivatives with cumene made the determination of the relative reactivities of their individual C—H bonds possible (Table 8).^{21, 22} As is to be expected,^{4, 19, 20} the reactivities of the C—H bonds in six-membered rings are especially low, whilst those in five-, seven-, and eight-membered rings are much higher. In cyclododecane, the C—H bonds have about the same reactivity as the secondary C—H bonds in normal paraffins (Table 6).

Table 8. Dependence of the reactivities of the C—H bonds of cycloalkane derivatives on ring size.

Number of carbon atoms in the ring	Relative reactivity ^a of one C—H bond (rel. units)

^a With respect to the tertiary C—H bond of cumene.

It must be expected that ring strain effects observed in saturated carbocyclic compounds also occur in cycloalkenes and benzocycloalkenes and that the reactivity of the C—H bonds at the α -position to the double bond in cycloalkenes and benzocycloalkenes depends on the ring size. Such dependence has indeed been observed in the oxidation of cycloalkenes.²³ This also gives an explanation for the particularly high reactivity of indane and tetralin.⁷

Ring strain effects should also determine their reactivities in the oxidation of bicyclic and tricyclic compounds. The cooxidation of *cis*-pinane and cumene yields an unexpected result: the tertiary C—H bond in position 2 is 22 times more reactive than the analogous tertiary C—H bond of methylcyclohexane.²⁴ It is even more reactive than the tertiary C—H bond of cumene.

The tertiary C—H bonds at the bridgehead carbon atoms of *cis*-pinane do not react with peroxy radicals in accordance with Bredt's rule.^{24, 25} In adamantane both the secondary and the tertiary C—H bonds have approximately the same reactivities as the corresponding bonds in *n*-paraffins and in alkylaromatic hydrocarbons (Table 7).

V. Reactivities of the equatorial and axial C—H bonds in cyclohexane derivatives

The rates of oxidation of the *cis*- and *trans*-isomers of decalin²⁶ and dimethyl cyclohexanes²⁷ are substantially different. Obviously, tertiary C—H bonds in the equatorial position react more readily with peroxy radicals than similar C—H bonds in the axial position.²⁸ The cooxidation of the isomeric dimethyl cyclohexanes and of the decalins made it possible to determine the relative reactivities of the tertiary and secondary C—H bonds in these hydrocarbons (Table 9).²⁹ We were able to calculate separately the reactivities of the equatorial and axial C—H bonds from the overall reactivities of the tertiary C—H bonds (Table 10).

Table 9. Reactivities of the *cis*- and *trans*-isomers of dimethylcyclohexane and decalin and of their individual C—H bonds relative to cumene.

Compound	Relative reactivity (rel. units)		
	overall	tertiary C—H bond	secondary C—H bond ^a
<i>cis</i> -1,2-Dimethylcyclohexane	0.541	0.227	0.0087
<i>trans</i> -1,2-Dimethylcyclohexane	0.217	0.064	0.0113
<i>cis</i> -1,3-Dimethylcyclohexane	0.344	0.150	0.0059
<i>trans</i> -1,3-Dimethylcyclohexane	0.545	0.239	0.0085
<i>cis</i> -1,4-Dimethylcyclohexane	0.556	0.245	0.0082
<i>trans</i> -1,4-Dimethylcyclohexane	0.267	0.108	0.0065
<i>cis</i> -Decalin	0.671	0.262	0.0094
<i>trans</i> -Decalin	0.235	0.056	0.0078

^a The average reactivity is 0.0083 ± 0.0006 rel. units.

Table 10. Relative reactivities of axial and equatorial C—H bonds in cyclohexane derivatives.

Compound	Overall reactivity of tertiary C—H bond	Equation for the calculation of the reactivity of an individual C—H bond ^a	Reactivity of one tertiary C—H bond (rel. units) ^b	
			a	e
<i>cis</i> -1,2-Dimethylcyclohexane	0.227	$a + e = 0.454$	0.064	0.390
<i>trans</i> -1,2-Dimethylcyclohexane	0.064	$2a = 0.128$		
<i>cis</i> -1,3-Dimethylcyclohexane	0.150	$2a = 0.300$		
<i>trans</i> -1,3-Dimethylcyclohexane	0.239	$a + e = 0.478$	0.150	0.328
<i>cis</i> -1,4-Dimethylcyclohexane	0.245	$a + e = 0.490$	0.108	0.382
<i>trans</i> -1,4-Dimethylcyclohexane	0.108	$2a = 0.216$		
<i>cis</i> -Decalin	0.262	$a + e = 0.524$	0.056	0.468
<i>trans</i> -Decalin	0.056	$2a = 0.112$		

^a Designations: (a) reactivity of axial tertiary C—H bond; (e) reactivity of equatorial C—H bond. ^b The average reactivities are 0.095 ± 0.022 for the axial bond and 0.392 ± 0.029 relative units for the equatorial bond.

This was possible because one of the tertiary C—H bonds in *cis*-1,2- and *cis*-1,4-disubstituted cyclohexanes is in an equatorial whilst the other is in an axial position. In the corresponding *trans*-isomers, both tertiary C—H bonds are in axial positions. In *cis*-1,3-dimethylcyclohexane, both tertiary C—H bonds are axial, in *trans*-1,3-dimethylcyclohexane one of the tertiary C—H bonds is axial, the other is equatorial.

The reactivities of the secondary C—H bonds of disubstituted cyclohexane derivatives (Table 9) are similar to those of the secondary C—H bonds in acyclic hydrocarbons (Table 7). The equatorial tertiary C—H bond is approximately four times more reactive than the tertiary C—H bond in an axial position (Table 10). The reason for this difference is still not quite clear.²⁹ On the one hand, attack by peroxy radicals on the axial C—H bond is more hindered than on the equatorial bond. On the other hand, the internal strain in compounds with axial C—alkyl bonds is greater than in compounds with analogous equatorial bonds. It must be expected that the internal strain of cyclohexane derivatives diminishes if one H-atom is abstracted from a tertiary C—H bond and that the decrease of strain is higher if the geminal alkyl group is axial than if it is equatorial.

VI. Reactivities of cycloalkenes

In the oxidation of cycloalkenes, peroxy radicals do not only attack C—H bonds but also the C=C double bond.

We studied the cooxidation of certain cyclic alkenes with cumene and determined their relative reactivities (Table 11).²³ The reactivity of the allylic C—H bonds diminishes in the cyclopentene–cyclooctene sequence. The reactivity of these bonds is particularly high in the case of five- and six-membered rings. The reactivities of cyclopentene and cyclohexene are comparable with the reactivities of the corresponding indane and tetralin bonds. The reactivity of the C=C double bond also depends on the ring size and increases from cyclopentene to cyclooctene. The data presented in Table 11 make it possible to explain the results obtained previously in the oxidation of individual cycloalkenes.³⁰

Table 11. The reactivities of certain cycloalkenes and their individual bonds relative to cumene.

Alkene	Overall reactivity (rel. units)	Reactivity (rel. units)	
		of C=C bond	of allylic C—H bond
Cyclopentene	8.2	0.24	1.98
Cyclohexene	6.6	0.56	1.62
Cycloheptene	4.9	1.02	0.97
Cyclooctene	1.6	1.16	0.10
Norbornene	6.5	6.5	0.00

The bicyclic olefin norbornene has an unusually high reactivity³¹ and is attacked by peroxy radicals exclusively at the C=C double bond.^{32,33} It is noteworthy that in the cooxidation of cycloalkenes and norbornene with cumene, the only products from the interaction of the peroxy radicals with the C=C double bond are the corresponding epoxy compounds.

VII. Reactivities of styrene derivatives

The study of the cooxidation of certain styrene derivatives with cumene made the estimation of relative reactivities of their double bonds possible (Table 12). The C=C bond of styrene is much more reactive than the double bonds in monocyclic alkenes, and its reactivity is comparable to that of the C=C bond of norbornene. A methyl group at the α -position increases the reactivity of the double bond and the effect induced by it is only slightly weaker than the effect of the α -phenyl group. The introduction of a phenyl group at the α -position increases only insignificantly the reactivity of the double bond in comparison with α -methylstyrene because a coplanar arrangement of two phenyl groups linked with one radical carbon atom is not possible. A *tert*-butyl group at the α -position diminishes the reactivity of styrene since in this case it is not possible to achieve a planar structure of the intermediate carbon radical. Further studies showed that the reactivity of the double bond in styrene derivatives usually increases if an electron-donating substituent is introduced in the α - or *para*-position.^{34,35}

Table 12. The relative rates of oxidation of certain styrene derivatives.

Substituents in styrene molecule		Reactivity of the C=C bond (rel. units)
α -position	<i>para</i> -position	
H	H	6.98 \pm 0.40
Me	H	12.78 \pm 0.54
Bu ^t	H	0.75 \pm 0.05
Ph	H	15.6 \pm 0.9
Me	Bu ^t	14.0 \pm 0.2

In the cooxidation of styrene and its derivatives with cumene, not only the corresponding epoxides but also oligomeric peroxides and products of an oxidative degradation are formed.^{34–36} The proportion of the particular product depends on the nature of the substituent and on the reaction conditions.

VIII. Conclusion

Thus the oxidation of binary hydrocarbon–cumene mixtures makes it possible to determine both the relative overall rates of interaction of hydrocarbons with peroxy radicals and the relative reactivities of their individual C—H bonds without the addition of an individual hydroperoxide. For this purpose, the oxidation products are subjected to total quantitative analysis after preliminary reduction of the oxidation products by lithium aluminium hydride. Reproducible and mutually consistent

relative reactivities of hydrocarbons, which in most cases agree with the theoretical predictions, can be obtained in this way.

In the studies^{37–42} the absorption of oxygen was followed during liquid-phase cooxidations. Relative and absolute rate constants for the interaction of peroxy radicals with hydrocarbons were determined with the aid of the copolymerisation equation without taking into account the formation of various isomeric peroxy radicals from each hydrocarbon. For this reason, in all the studies it was assumed that the rates of reaction of isomeric peroxy radicals with various hydrocarbons are equal. It is noteworthy that in most cases the data obtained in the studies^{37–42} for the relative rates of interaction of hydrocarbons with peroxy radicals agree well with our results.⁷ It must be stressed, however, that relative reactivities of individual C—H bonds cannot be determined by the methods described in Refs 37–42.

Abstract. All the mechanisms known at present for cyclic (repeated) chain termination involving aromatic amines, quinones, nitroxyl radicals, and variable-valence metal complexes in the oxidation of hydrocarbons, polymers, alcohols, and aliphatic amines are surveyed. The mechanisms are classified and the factors needed for the realisation of a particular mechanism are analysed. The reasons for the limitation of the number of cycles in the cyclic chain termination mechanism are considered. The bibliography includes 84 references.

I. Introduction

Inhibitors of oxidation (antioxidants) play an important role in modern technology for the production of polymers,^{1–4} lubricants,⁵ hydrocarbon fuel,⁶ solvents, intermediate products in organic synthesis,⁷ and foodstuffs.⁸ They also perform the function of protecting living organisms from the harmful influence of oxygen, light, and radiation. Studies in the fields of synthesis and physicochemical and biochemical properties of antioxidants and intermediate products formed from them have been developed intensely during the last three decades. An important place among these studies is occupied by the studies of elementary reactions of inhibitors and of the radicals derived from them.^{9–11}

The oxidation of organic compounds with oxygen in the liquid phase proceeds as a rule by a chain mechanism involving participation of peroxy radicals in the chain propagation. Therefore, compounds that are able to react rapidly with peroxy radicals and thus cause chain termination occupy a prominent place among antioxidants. Phenols, thiophenols, and aromatic amines are effective oxidation inhibitors and are irreversibly consumed in reactions with peroxy radicals. When the oxidation is propagating rapidly at a sufficiently high temperature or under the action of very intense light, these inhibitors permit the process to be decelerated for only a short period.

In this connection, the inhibiting systems that ensure the possibility of regenerating the inhibitor consumed in the chain termination steps are of interest. This permits the oxidation to be retarded effectively by adding a relatively small amount of an inhibitor.

The cyclic mechanism of chain termination was discovered in a study of oxidation of alcohols^{12–14} in which aromatic amines have been used as inhibitors. A short time later, the ability of copper ions to terminate repeatedly the chains during oxidation of cyclohexanol was found.¹⁵ The cyclic mechanisms of chain termination are due to the dual reactivity of the hydroxyperoxy radicals formed in the oxidation of an alcohol. This has been confirmed in relation to *p*-benzoquinone,¹⁶ which terminates the chains in the oxidation of alcohols by the cyclic mechanism, but has virtually no influence on the oxidation of hydrocarbons.

The possibility of the repeated chain termination with stable nitroxyl radicals in the oxidation of polymers was discovered in 1972.¹⁷ Later, a fundamentally new three-component system ensuring the cyclic chain termination in the oxidation of hydrocarbons was suggested. Apart from nitroxyl radicals, an important role in this system is played by an alcohol (primary or secondary) and an organic (citric) acid, which are responsible for the acid catalysis.¹⁸ Certain aspects of the cyclic chain termination during oxidation have been considered in a number of reviews.^{19–23} However, in the present review all the currently known systems and mechanisms for the cyclic chain termination in the oxidation of organic compounds are considered comprehensively for the first time, and the reasons enabling the realisation of these mechanisms are also analysed.

II. Chain termination with phenols and aromatic amines in the oxidation of hydrocarbons

Oxidation of hydrocarbons⁹ and of many other organic compounds^{24,25} involves alkyl (R^\cdot) and peroxy (RO_2^\cdot) radicals and proceeds by a chain mechanism that includes the following elementary stages:

E T Denisov Laboratory of the Kinetics of Liquid-Phase Radical Reactions, Institute of Chemical Physics in Chernogolovka, Russian Academy of Sciences, 142432 Chernogolovka, Moscow Region, Russian Federation. Fax (7-096) 515 35 88.

Received 10 November 1995

Uspekhi Khimii 65 (6) 547–563 (1996); translated by Z P Bobkova

At a partial pressure of oxygen of 10–100 kPa and with sufficiently intense stirring of the liquid phase (which facilitates the diffusion of oxygen into the compound being oxidised) alkyl radicals are converted very rapidly (over a period of 10^{-6} – 10^{-4} s) into peroxy radicals. Chain termination occurs via reaction (6), which accounts for the limitation of the chain length.

$$v = \frac{k_2[RH]}{(2k_6v_i)^{0.5}},$$

where v_i is the rate of initiation and k_2 and k_6 are rate constants of the corresponding stages. The lower the rate of reaction (6), the longer the chain. The chain regime is realised when

$$k_2^2[RH]^2 > 2k_6v_i.$$

As the hydroperoxide is accumulated, the initiation rate increases and the oxidation accelerates.

The introduction of an inhibitor InH (phenol or amine) accelerates the chain termination due to the occurrence of the following reactions:^{9–11}

(Mol are molecular products).

If the concentration of the inhibitor is sufficiently high, so that

$$k_7[InH] > (2k_6v_i)^{0.5},$$

then the chain termination will proceed via reactions (7)–(9) and the chain length will be equal to

$$v = \frac{k_2[RH]}{fk_7[InH]},$$

where f is the stoichiometric coefficient of inhibition. The reactions (8) and (9) occur very rapidly (their rate constants are 10^8 – 10^9 dm³ mol⁻¹ s⁻¹), the rate of the chain termination being limited by the reaction (7). Within the framework of this scheme, which is typical of oxidation of hydrocarbons, $f \cong 2$ in the case where reaction (8) predominates or $f \cong 1$ if the reaction (9) predominates. The f values determined experimentally fall in this range.²⁶

The In^{\cdot} radicals can react with ROOH and RH to give the RO_2^{\cdot} and R^{\cdot} radicals,²³ which are then involved in the chain propagation:

When the temperature is fairly high (>400 K), the inhibitor starts to react with the hydroperoxide and with oxygen at a noticeable rate thus initiating chains:²³

The quinolide peroxides InOOR, resulting from the recombination of phenolic and peroxy radicals, redissociate into radicals, which initiate oxidation at fairly high temperatures:¹¹

The decomposition of *p*-alkoxy-substituted phenoxyl radicals affords alkyl radicals, which continue the oxidation chain.¹¹

The semiquinone radicals continue the chain by reacting with oxygen.²⁷

Thus, the kinetics of the inhibited oxidation depend, on the one hand, on a number of reactions involving ROOH, RO_2^{\cdot} , and O_2 and, on the other hand, on the reactions involving the inhibitor and the radicals derived from it.

The duration of the retarding action of an inhibitor is determined by its concentration and reactivity, and also by the conditions and the regime of the chain oxidation. At a constant initiation rate and with intense chain termination by the inhibitor [$fk_7[InH]_0 > (k_6v_i)^{0.5}$], the induction period τ is equal to $f[InH]_0v_i^{-1}$, i.e. it is directly proportional to the concentration of the added inhibitor and to the inhibition coefficient. Under the conditions of autooxidation, when the hydroperoxide formed acts as an initiator, a feedback appears between the efficiency of the chain termination with the inhibitor and the induction period τ . Problems of the mechanism and the efficiency of oxidation inhibitors have been considered in detail in a number of monographs and reviews.^{3,6,9–11} It is noteworthy that the induction period of the inhibited oxidation depends in all cases on the coefficient f and on the concentration of the inhibitor. The reactions (7)–(15) associated with the participation of the inhibitor may be divided into two groups: reactions having no influence on the coefficient f [reactions (7), (–7), and (10)], and reactions, the occurrence of which influences the f value [reactions (8), (9), (11)–(15)].

It seems that oxidation could be retarded if a large amount of an inhibitor is added. However, both theory and experience indicate that the use of high concentrations of an inhibitor reduces its efficiency and leads sometimes to a shortening rather than to an extension of the induction period. This is accounted for by the following reasons. An increase in the concentration of an inhibitor leads to an increase in the quasi-steady concentration of the In^{\cdot} radicals, and, consequently, the chain propagation reactions involving these radicals [reactions (10), (–7), (14), and (15)] proceed more intensely. The rate of the initiation reactions [(11) and (12)] involving the inhibitor is directly proportional to its concentration. Therefore, it is expedient to increase the concentration of the inhibitor only up to a value at which initiation involving it is insignificant.

There are also other reasons why high antioxidant concentrations are undesirable. First, the evaporation of the inhibitor from the polymer sample or its washing-out in the case where it is in contact with a liquid accelerates at high concentrations. Second, high concentrations of an antioxidant may be toxic for a human organism. Third, antioxidants deteriorate the mechanical properties of polymeric articles. Fourth, the introduction of large quantities of a fairly expensive antioxidant increases substantially the cost of an article or a product. In some cases, this contradictory situation can be resolved by using antioxidants that provide repeated chain termination per one initial molecule of the inhibitor, owing to the realisation of the cyclic chain termination mechanism. In these cases, prolonged retardation of the oxidation can be achieved with a small amount of an inhibitor.

An important role in the identification and investigation of cyclic mechanisms of chain termination has been played by experiments dealing with the measurement of the coefficient f . It should be noted that this coefficient is stoichiometric only when it is determined by the reactions (7)–(9). In the case where cyclic chain termination occurs, the coefficient f is influenced by the competition between the irreversible destruction of the In^{\cdot} radicals on the one hand, and the conversion of In^{\cdot} into the initial InH on the other hand. In these systems, f should be considered and said to be the inhibition coefficient.

The coefficient f has been measured by various methods. When aromatic amines were used as inhibitors, f was defined as the ratio v_i/v_{InH} , where v_{InH} is the rate of consumption of the amine in an experiment with a constant rate of initiation.

The concentration of the amine was determined by colorimetry after its conversion into a brightly coloured compound.^{12–14} When stable nitroxyl radicals were used as inhibitors, the variation of their concentration during the experiment has been monitored by EPR.^{17,18} The consumption of a quinone has been evaluated from the increase in the rate of the initiated oxidation during the experiment.¹⁶ In the case where variable-valence metals were used as inhibitors, the evaluation was based on the induction period.

III. Cyclic chain termination in the oxidation of alcohols, alkenes, and amines

A high value of the inhibition coefficient ($f = 28$) was detected for the first time in the oxidation of cyclohexanol in the presence of α -naphthylamine (393 K, *tert*-butyl peroxide as the initiator, $P_{O_2} = 10^5$ kPa).¹² For the oxidation of *n*-decane under the same conditions, $f = 2.5$. In the case of the oxidation of *n*-decane–cyclohexanol mixtures, the coefficient f increased with increase in the cyclohexanol concentration, from 2.5 (in pure *n*-decane) to 28 (in pure alcohol).¹² When the oxidation of cyclohexanol was carried out in the presence of tetraphenylhydrazine, the diphenylamino radicals produced from tetraphenylhydrazine were reduced to diphenylamine.¹⁴ This conclusion has been confirmed in another study.²⁸ Diphenylamine was formed only in the presence of the initiator, no matter whether the process was conducted under an oxygen atmosphere or under an inert atmosphere. In the former case, the amino radical was reduced by the hydroperoxyl radical derived from the alcohol, and in the latter case, it was reduced by the hydroxyalkyl radical:

On the basis of these results the following mechanism was suggested for the cyclic chain termination:¹⁴

The oxidation of primary and secondary alcohols in the presence of α -naphthylamine, β -naphthylamine, or phenyl- α -naphthylamine is characterised by high values of the inhibition coefficient ($f \gg 2$).^{12–14} Alkylperoxyl and α -ketoperoxyl radicals, like the peroxyl radicals derived from tertiary alcohols, are incapable of reducing the amino radicals. For example, when oxidation of *tert*-butanol is inhibited by α -naphthylamine, f is equal to 2, which coincides with the value found in the oxidation of alkanes.¹⁴ However, the addition of hydrogen peroxide to the *tert*-butanol being oxidised leads to the realisation of the cyclic chain termination mechanism (α -naphthylamine as the inhibitor, 393 K, cumyl peroxide as the initiator, $P_{O_2} = 100$ kPa).²⁹ This is due to the participation of the HO_2^\cdot radicals formed in the chain termination:

where AmH is an amine (in this particular case, it is α -naphthylamine).

Since the peroxyl radicals derived from the alcohol dissociate to a carbonyl compound and HO_2^\cdot

three reactions, in which the amino radicals formed from the amine are reduced, proceed in parallel under the conditions of the oxidation of the alcohol:

In the presence of dissolved oxygen, the hydroxyalkyl radicals are converted very rapidly into the hydroxyperoxyl radicals, therefore, only $>C(OH)OO^\cdot$ and HO_2^\cdot participate in the reduction of the amino radicals. The higher is the temperature, the more effectively the decomposition of the hydroxyperoxyl radicals proceeds and the higher is the proportion of the HO_2^\cdot radicals participating in the regeneration of the amine.

Our investigation has shown³⁰ that in the case of repeated chain termination with aromatic amines in the oxidation of alcohols, the situation is more complicated. In parallel with the reaction (23), the following reaction proceeds:

The nitroxyl radical, in its turn, gives rise to a new cyclic mechanism of chain termination according to reactions:

The intermediate formation of nitroxyl radical has been detected in the oxidation of isopropanol retarded by diphenylamine; chain termination occurs by cyclic mechanisms involving both Am^\cdot and AmO^\cdot .³⁰ In the case where the oxidation of isopropanol is decelerated by bis(*p*-methoxyphenyl)amine, only the cycle involving nitroxyl radicals is realised.³⁰

Organic acids retard the formation of nitroxyl radicals via reaction (25).³¹ Apparently, the formation of a hydrogen bond of the $N \cdots HOC(O)R$ type leads to shielding of nitrogen, which precludes the addition of oxygen to it, yielding the nitroxyl radical. Thus, the products of the oxidation of hydrocarbons (acids) have an influence on the mechanism of the cyclic chain termination.

As noted above, the duration of the retarding action of an inhibitor is directly proportional to the f value. In systems with a cyclic chain termination mechanism, the coefficient f depends on the ratio of the rate constants for the two reactions, in which the inhibitor is regenerated and irreversibly consumed. In the oxidation of alcohols, amino radicals are consumed irreversibly via reaction (25) and via the following reaction:

The formation of the nitroxyl radical [reaction (25)] and of quinone imine [reaction (28)] precludes the possibility of the recovery of amine and, hence, either of the above reactions interrupts the cycle at the amino radical

$$f = 1 + \frac{k_{23}}{k_{25} + k_{28}}.$$

Table 1 presents the inhibition coefficients and the termination rate constants in systems with a cyclic mechanism of chain termination with aromatic amines. Naturally, these are effective rate constants, which characterise primarily the rate-limiting stage of the chain termination process.

The question of why the amino radicals ensure cyclic chain termination in those systems in which the HO_2^\cdot and $>C(OH)OO^\cdot$ radicals are formed, but not in the oxidation of hydrocarbons where alkylperoxyl radicals RO_2^\cdot are the chain-propagating species, deserves special attention.⁴²

Disproportionation of the amino and peroxyl radicals that involves both the O–H and C–H bonds is, in principle, possible:

Table 1. Inhibition coefficients and rate constants for the reactions of peroxy radicals with aromatic amines in systems with a cyclic mechanism of chain termination.

We present below the heats (ΔH) of disproportionation of the diphenylamino radicals both with hydroxyl radicals and with alkyl-containing peroxy radicals:⁴²

Peroxy radical	$-\Delta H / \text{kJ mol}^{-1}$
HO_2^\cdot	161
$(\text{CH}_3)_2\text{C}(\text{OH})\text{O}_2^\cdot$	145
cyclo- $\text{C}_6\text{H}_{10}(\text{OH})\text{O}_2^\cdot$	135
$\text{C}_6\text{H}_5\text{C}(\text{CH}_3)_2\text{O}_2^\cdot$	95
cyclo- $\text{C}_6\text{H}_{11}\text{O}_2^\cdot$	84

It can be seen that all these reactions are exothermic, and the ΔH values are fairly close to one another. All these reactions should seemingly proceed equally rapidly. The question as to how easily the amino radicals react with the O—H and C—H bonds of the peroxy radicals can be answered by analysing these reactions in terms of the parabolic model of transition state.^{43–45} This model treats the transition state in a radical abstraction reaction as the point of intersection of two nonperturbed parabolic terms, one of which describes the potential energy of the bond being attacked, whereas the other describes the potential energy of the bond being formed. The model makes it possible to calculate, using experimental data (activation energy, rate constant), an important characteristic of the elementary step, namely the distance by which the hydrogen atom being attacked shifts. This permits, in turn, the calculation of the activation energy for a thermally neutral reaction of this class. By a class of reactions is meant a set of all structurally similar reactions, characterised by the same distance of the displacement of an atom in the elementary step. For example, all the $\text{RO}_2^\cdot + \text{RH}$ reactions, in which an aliphatic hydrogen atom is attacked, belong to the same class.

Each elementary reaction is characterised in this model by enthalpy ΔH_e , which incorporates the difference between the zero point energies of the reacting bonds, and also by activation energy E_a , which is the sum of the activation energy E measured experimentally and the zero point vibration energy of the bond being attacked (in the case of the O—H bond, the latter is 21 kJ mol^{−1}). The activation energies for all the thermally neutral reactions of radical abstraction ($E_{e,0}$) and the coefficients α of reactions of this class are identical.⁴⁵

Analysis of experimental data has shown that, when amino radicals react with hydrocarbons, phenols, and hydroperoxides, they are extremely reactive toward specifically the O—H bonds.⁴⁶ The $E_{e,0}$ values for the reactions of amino radicals with various compounds are presented below:⁴⁶

Compound	$E_{e,0} / \text{kJ mol}^{-1}$
ROOH	39.0
ArOH	41.8
AmOH	32.2
AlkH	69.7
AralkH	81.7

The reactions of amino radicals with the O—H bonds ($E_{e,0}$ varies from 32 kJ mol^{−1} to 42 kJ mol^{−1}) and their reactions with the C—H bonds ($E_{e,0}$ varies from 70 kJ mol^{−1} to 82 kJ mol^{−1}) are very different, which leads to the following significant fact.

The activation energies for reactions are known to decrease as ΔH decreases. According to the parabolic model,⁴⁵ for highly exothermic reactions with fairly high ΔH_e values the activation energy $E = 0.5 RT$. The transition from higher activation energies to $E = 0.5 RT$ occurs at a certain minimum value of ΔH_e ($\Delta H_{e,\min}$), which depends on $E_{e,0}$ for the class of reactions being considered. The higher $E_{e,0}$, the higher $\Delta H_{e,\min}$ and the broader the ΔH range, in which $E > 0.5 RT$.

For the reaction of amino radicals with the O—H bond in ROOH, $\Delta H_{e,\min} = -39.4 \text{ kJ mol}^{-1}$, which is substantially smaller in magnitude than $\Delta H_{e,\min}$ for the reactions of diphenylamino radicals with HO_2^\cdot and $(\text{CH}_3)_2\text{C}(\text{OH})\text{O}_2^\cdot$ (−161 to −135 kJ mol^{−1}, see above). Thus all these reactions require virtually no activation energy, i.e. proceed fairly rapidly. The $E_{e,0}$ value for the reactions of Am^\cdot with the C—H bond is markedly higher,⁴⁶ and the $\Delta H_{e,\min}$ value corresponding to it is −141.1 kJ mol^{−1}. In the case of the reactions of diphenylamino radicals with $\beta\text{-C-H}$ bonds in the alkylperoxy radicals, $\Delta H = 84\text{--}95 \text{ kJ mol}^{-1}$, which is smaller than $\Delta H_{e,\min}$. Hence, these reactions should proceed with activation energies $E > 0.5 RT$, i.e. their rates are much lower than the rate of interaction of Am^\cdot with the O—H bond in the corresponding peroxy radical.

To give the ultimate answer to the question of why the cyclic chain termination mechanism is realised in those systems where HO_2^\cdot and $\text{>C}(\text{OH})\text{OO}^\cdot$ radicals act as the chain-propagating species but is not realised during the oxidation of hydrocarbons, one should compare the rate constants for the disproportionation reactions in which Am^\cdot affords the starting AmH [reactions (23) and (27)] with the rate constant for the irreversible destruction of Am^\cdot [reaction (28)]. The diphenylamino radical reacts with RO_2^\cdot via two parallel routes (25) and (28) at approximately identical rates.³⁰ The rate constant for the overall reaction k is known to be $6 \times 10^8 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$.⁴⁷ This implies that the rate constant for the addition of the peroxy radical to the aromatic ring of the diphenylamino radical k_{28} is $3 \times 10^8 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$. The cyclic mechanism is realised if the inequality $k_{21} > k_{28}$ or $k_{23} > k_{28}$ inequality holds. Therefore, it is necessary to evaluate the rate constants for the disproportionation of Am^\cdot and RO_2^\cdot and for the regeneration of AmH . It should be noted that, according to the parabolic model, in the case of highly exothermic reactions the pre-exponential factor A is related to the enthalpy of the reaction at $\Delta H_e > \Delta H_{e,\min}$ by the following relationship:⁴⁸

$$\left(\frac{A}{A_0}\right)^{0.5} = 1 - \beta[|\Delta H_e|^{0.5} - |\Delta H_{e,\min}|^{0.5}]$$

For this class of reactions, $A_0 = A$ at $\Delta H_e < \Delta H_{e,\min}$, and the coefficient β for the reactions

is $1.6 \text{ kJ}^{-0.5} \text{ mol}^{-0.5}$.⁴² The activation energy, which is equal to $0.5 RT$ for exothermic reactions with $\Delta H_e > \Delta H_{e,\min}$ and is greater than $0.5 RT$ for reactions with $\Delta H_e < \Delta H_{e,\min}$, can be calculated from the equations of the parabolic model.⁴⁵

The activation energies and rate constants for the reactions (21), (23), and (29) of the diphenylamino radical with various RO_2^\cdot calculated in this way are presented below:⁴²

Peroxy radical	$E / \text{kJ mol}^{-1}$	$k / \text{dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$
$\text{C}_6\text{H}_5\text{C}(\text{CH}_3)_2\text{O}_2^\cdot$	16.6	1.5×10^7
cyclo- $\text{C}_6\text{H}_{11}\text{O}_2^\cdot$	19.8	3.1×10^6
HO_2^\cdot	1.4	8.4×10^9

One can see that the rate constants for the disproportionation of the amino and peroxy radicals (k_{29}) involving the C—H bond are substantially lower than the rate constants for the addition of RO_2^\cdot to the aromatic ring of the amino radical ($k_{28} = 3 \times 10^8 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$). Conversely, the reaction of Am^\cdot with HO_2^\cdot proceeds very rapidly and can compete successfully with the addition reaction. Thus, the result obtained in terms of the parabolic model is in good agreement with the experiment.

The reason for the different reactivities of Am^\cdot with respect to alkyl- and hydroxyl-containing peroxy radicals lies in the energy characteristics of the transition states of the C...H...N and O...H...N types. In the former case, the triplet repulsion makes a substantial contribution to the energy of the transition state, because the C—N bond is fairly strong, and the energy of its nonbonding orbital is high.⁴⁵ In the latter case, the hypothetical

compound ROOAm incorporates a weak N—O bond, and the contribution of the triplet repulsion to $E_{e,o}$ is slight. Apart from the triplet repulsion, the electronegativities of the atoms forming the reaction centre of the transition state are also significant:⁴⁵ the higher the difference between the electronegativities of the atoms, the lower the $E_{e,o}$ activation barrier. In this respect, too, the relationship between the C...H...N and O...H...N reaction centres counts in favour of the latter: the electron affinities of the C and N atoms are close to each other, whereas the electronegativities of the O and N atoms are substantially different.

An evaluation based on the equations of the parabolic model⁴⁵ indicates that a reaction of the type (18) involving phenoxyl radicals also requires no activation energy (in this case, $\Delta H_e > \Delta H_{e,min} = 57 \text{ kJ mol}^{-1}$). However, the addition of RO_2^\cdot to the aromatic ring of the phenoxyl radical occurs very rapidly, so that the rate constant for this reaction is determined by diffusion processes.¹¹ The data on the $E_{e,o}$ values are also consistent with this: for $\text{ArO}^\cdot + \text{HOOR}$ reactions (the O...H...O reaction centre and for $\text{Am}^\cdot + \text{HOOR}$ reactions (the N...H...O reaction centre), these values are 45.3 kJ mol^{-1} and 39.0 kJ mol^{-1} , respectively.⁴⁶ At the same time, calculation of the pre-exponential factor in terms of the parabolic model indicates that the rate constant k_{-7} for the reaction of ROOH with the participation of amino radical is several times higher than that for the reaction involving phenoxyl radical, the enthalpies of these reactions being identical. Thus, the irreversible destruction of ArO^\cdot in its reactions with HO_2^\cdot and $>\text{C}(\text{OH})\text{O}_2^\cdot$ occurs more rapidly than the conversion of ArO^\cdot into ArOH , and the cyclic mechanism of chain termination is not realised with phenols. An exception is provided by hydroquinones, which are considered below.

Aromatic amines also cause cyclic chain termination in the oxidation of primary and secondary aliphatic amines (Table 1). AmH is recovered from Am^\cdot via the reaction of Am^\cdot with the N—H bond of the $\text{RCH}(\text{NHR}')\text{O}_2^\cdot$ peroxy radical. Together with AmH , the reaction yields the imine $\text{RCH}=\text{NR}'$ and O_2 , i.e. a process similar to reaction (23) occurs. The rapid occurrence of this reaction involving primary and secondary amines is apparently due to the fact that the triplet repulsion in this case is weak, because a transition state of the N...H...N type is formed and the energy of the dissociation of the N—N bond is substantially lower than that for the N—C and C—C bonds. This can be seen from a comparison of the $D_{\text{C}-\text{C}}$, $D_{\text{N}-\text{N}}$ and $D_{\text{N}-\text{C}}$ dissociation energies (see handbooks^{26,49}):

Compound	$D/\text{kJ mol}^{-1}$
CH_3-CH_3	376
$\text{H}_2\text{N}-\text{NH}_2$	275
$\text{H}_2\text{N}-\text{NHC}_6\text{H}_5$	219
$\text{CH}_3-\text{NHC}_6\text{H}_5$	299
$(\text{C}_6\text{H}_5)_2\text{N}-\text{N}(\text{C}_6\text{H}_5)_2$	119

Cyclic chain termination with aromatic amines also occurs in the oxidation of tertiary aliphatic amines (see Table 1). To explain this fact, a mechanism of the conversion of Am^\cdot into AmH involving the $\beta\text{-C}-\text{H}$ bonds [reaction (29)] has been suggested;³⁹ however, its realisation is hampered by its high activation energy. Since tertiary amines have low ionisation potentials and readily participate in reactions with electron transfer, the cyclic mechanism in systems of this type is realised apparently as a sequence of such reactions, similar to what occurs in the systems containing complexes of variable-valence metals (see below).

IV. Cyclic chain termination with quinones in the oxidation of alcohols and polymers

Quinones (Q) are well known as inhibitors of radical polymerisation; they terminate chains by adding alkyl radicals via the following reactions⁵⁰

At the same time, quinones do not retard oxidation of hydrocarbons, since alkyl radicals react very rapidly with oxygen (see Section II) to give alkylperoxy radicals, which scarcely react with quinones. Quinones exhibit their inhibiting properties only in the oxidation of polymers; the chain termination results from their interaction with alkyl macroradicals,⁵¹ which is due to the specific features of the oxidation of polymers in the solid phase and also due to the fact that alkyl macroradicals react with O_2 in a polymeric matrix relatively slowly.³ Quinones decelerate the oxidation of alcohols very effectively and for long periods by ensuring cyclic chain termination via the following reactions¹⁶

The processes of oxidation of cyclohexadiene, 1,2-substituted ethenes, and aliphatic amines are decelerated by quinone or hydroquinone by a similar mechanism. The values of the stoichiometric inhibition coefficients and of the rate constants (f and k) for the corresponding reactions involving peroxy radicals [HO_2^\cdot , $>\text{C}(\text{OH})\text{OO}^\cdot$, and $>\text{C}(\text{NHR})\text{O}_2^\cdot$] are presented in Table 2. The f coefficients in these reactions are relatively high, varying from 8 to 70. Evidently, the irreversible consumption of quinone in these systems is due to the addition of RO_2^\cdot to the aromatic ring of the quinone followed by the decomposition of the resulting adduct.

The data on the deceleration of the oxidation of polymers (polyethylene, polypropylene) by quinones deserve particular attention.⁵¹ It has been noted above that benzoquinone, which retards the initiated oxidation of polymers, behaves as a typical acceptor of alkyl radicals. It decreases the rate of chain oxidation, which obeys the following dependence:

$$v \sim v_i P_{\text{O}_2} [\text{Q}]^{-1}$$

In this case, the chain termination occurs stoichiometrically: one quinone molecule terminates two chains.

However, when stilbenequinone is introduced into a preliminarily oxidised polymer containing hydroperoxy-groups, a totally different picture is observed.⁵² In this case, quinone acquires the ability to repeatedly terminate the chains ($f = 20$ in the oxidation of polypropylene with a concentration of the hydroperoxy-groups $[\text{POOH}] = 0.13 \text{ mol kg}^{-1}$, $T = 356 \text{ K}$). The chain termination at $P_{\text{O}_2} = 10^5 \text{ Pa}$ occurs predominantly via the reaction with peroxy radicals. The increase in the efficiency of the retarding action of the quinone is due to the fact that in the oxidised polypropylene containing associated $\beta\text{-OOH}$ groups, the latter decompose to give hydrogen peroxide, which serves as the source of the HO_2^\cdot radicals and these radicals ensure cyclic chain termination via interaction with quinones:⁵²

(PO_2^\cdot is the peroxy macroradical).

It is evident from Table 2 that quinones react rapidly with the hydroperoxy radicals. Calculation shows that the change in the enthalpy in the reaction (33) is relatively small. The calculation was based on the ΔH_f data for quinone and hydroquinone⁴⁹ and on the $D_{\text{O}-\text{H}}$ value for hydroquinone⁵³ ($350.3 \text{ kJ mol}^{-1}$). The dissociation energy of the O—H bond in the 4- $\text{HOC}_6\text{H}_4\text{O}^\cdot$ semiquinone radical is $228.1 \text{ kJ mol}^{-1}$. The dissociation energies

Table 2. Inhibition coefficients and rate constants for the reactions of quinones and hydroquinones with RO₂[•] in systems with a cyclic mechanism of chain termination.

of the O—H and C—H bonds in the corresponding peroxy radicals⁴² and enthalpies of the reaction (33) are presented in Table 3. It can be seen from this Table that the ΔH_f value for reaction (33) varies from -25 kJ mol⁻¹ in the case of HO₂[•] to 1.7 kJ mol⁻¹ in the case of hydroxycyclohexylperoxy radical. The activation energies for this reaction were calculated from the equations of the parabolic model;⁴⁵ parameters of a similar reaction of phenoxyl radicals with hydroperoxide ($E_{e,o} = 45.3$ kJ mol⁻¹, $\alpha = 1$) were used for the calculation. The activation energies of these reactions were found to be relatively low and equal to 14 – 26 kJ mol⁻¹. The low activation barriers to these reactions are accounted for by the fact that the transition state of the O...H...O type arising in the reaction (33) is characterised by the absence of the triplet repulsion, which makes a substantial contribution to the activation energy in other reactions. For the ArO[•] + ROOH reaction, the pre-exponential factor A is equal to 10^8 dm³ mol⁻¹ s⁻¹. Therefore, with allowance for the fact that benzoquinone incorporates two reaction centres, we may take $A = 2 \times 10^8$ dm³ mol⁻¹ s⁻¹ for the reaction (33).

Table 3 presents the results of the calculations of the rate constants for reactions (33) involving HO₂[•] and two hydroperoxy radicals. Comparison of the calculated and experimental values of k_{33} can be carried out using the reaction of benzoquinone with the peroxy radical derived from isopropanol as an example. According to the data of Denisov,¹⁶ the $k_{33}/2k_t$ ratio in this case at 344 K is 9.4 litre^{0.5} mol^{-0.5} s^{-0.5}, whereas the rate constant for the disproportionation of two RO₂[•] radicals is 1.1×10^9 dm³ mol⁻¹ s⁻¹.²⁶ Hence we obtain $k_{33} = 3.1 \times 10^5$ dm³ mol⁻¹ s⁻¹. The theoretical calculation from the equations of the parabolic model gives $k_{33} = 2 \times 10^8 \exp(-21.2/RT) = 1.2 \times 10^5$ dm³ mol⁻¹ s⁻¹ (344 K), i.e. a closely similar value. Thus, the calculation permits the rate constants for reaction (33) to be evaluated with sufficient accuracy.

The question arises as to why quinones terminate chains via reaction (33) and not via reaction with the β -C—H bond of the alkylperoxy radical:

The cleavage of the C—H and C—O bonds in the reaction (39) is compensated to a substantial degree by the formation of the π -C=C and O—H bonds of the semiquinone radical. Table 3 presents the ΔH values for the reaction (39) involving two hydrocarbon peroxy radicals C₆H₅(CH₃)₂CO₂[•] and cyclo-C₆H₁₁O₂[•]. The reaction is endothermic in both cases

($\Delta H = 40$ – 50 kJ mol⁻¹). However, the fact that such reactions proceeding via a transition state of the C...H...O type are characterised by high thermally neutral activation energies $E_{e,o}$ is more significant. The difference between the $E_{e,o}$ values for reactions involving an ArO[•]...H...R transition state [an analogue of reaction (39)] and an ArO[•]...H...OOR transition state [an analogue of reaction (33)] amounts to 69.8 – $45.3 = 24.5$ kJ mol⁻¹. This accounts for the high activation energy for reaction (39) involving the C₆H₅(CH₃)₂CO₂[•] and cyclo-C₆H₁₁O₂[•] radicals (~ 74 and ~ 79 kJ mol⁻¹, respectively). If we take the pre-exponential factor A to be equal to 2×10^9 dm³ mol⁻¹ s⁻¹, then the rate constants for the reaction (39) will assume the values given in Table 3. With the rate constants being so small, reaction (39) cannot influence the oxidative chain termination via the interaction of two RO₂[•] radicals {the rate constant for the latter is 10^5 – 10^7 dm³ mol⁻¹ s⁻¹;²⁶ in these cases, the inequality $(2k_{60})^{0.5} \ll 2k_{39}[Q]$ always holds}. What is the reason for such high $E_{e,o}$ values and, hence, for the high activation energies characteristic of the reactions involving transition states of the O...H...C type? Comparison of reactions of various types has shown that this is the strong triplet repulsion.⁴⁵ It is this repulsion that precludes rapid occurrence of reaction (39), as also in the reactions involving amino radicals. In the case of aminoperoxy radicals (primary and secondary amines), the high rate of the reaction

is due to the low activation barrier $E_{e,o}$, which is only 39 kJ mol⁻¹ for the N...H...O type transition state.⁴⁶ This is explained by weak triplet repulsion in compounds AmOOR and by an additional attraction between the N and O atoms owing to their different

Table 3. Some energy and kinetic parameters of the reactions of benzoquinone with the O—H [reaction (33)] and C—H bonds [reaction (39)] of peroxy radicals.

electron affinities (as also in the case of reactions of amino radicals with the O—H groups of the peroxy radicals). (Apparently, quinones react with the peroxy radicals derived from tertiary amines with transfer of an electron).

The selectivity of the reaction of benzoquinone with hydroxyperoxy radicals and its inertness with respect to alkylperoxy radicals has been used for the development of an original method for measuring the rate constants for the reactions of alkylperoxy radicals with alcohols.⁵⁴ For this purpose, the initiated oxidation of a mixture of a hydrocarbon and an alcohol is carried out in the presence of benzoquinone. The latter is added in a concentration that is high enough to ensure that all the hydroxyperoxy radicals derived from the alcohol react with it (are destroyed) and is low enough to cause no noticeable chain termination via the reaction of quinone with the alkyl radicals. This 'operating' range of the benzoquinone concentrations is $(1-10) \times 10^{-3}$ mol dm⁻³. The rate constants for the reactions of a number of alkylperoxy radicals with alcohols found by this method are presented in Table 4.

V. Cyclic chain termination mechanisms involving nitroxyl radicals

Nitroxyl radicals react rapidly with alkyl radicals⁵³ and efficiently retard the radical polymerisation of hydrocarbons. At the same time, only aromatic nitroxyls are capable of reacting with alkylperoxy radicals,⁵³ and in this case the chain termination in the oxidation of saturated hydrocarbons occurs stoichiometrically. However, in the processes of oxidation of alcohols, alkenes, and primary and secondary aliphatic amines in which the chain reaction involves the HO₂[•], >C(OH)O₂[•], and >C(NHR)O₂[•] radicals, respectively, nitroxyl radicals are capable of terminating the chains repeatedly by a cyclic mechanism.^{30,32,40} For example, chain termination in the oxidation of alcohols occurs via the following reactions

Reaction (41) is the rate-determining stage. During the oxidation a kinetic equilibrium is established between the two forms of the

inhibitor — AmO[•] and AmOH.³⁸ The kinetic characteristics of this mechanism are presented in Table 5.

Let us try to account for the rapidity of reactions (41) and (42). The disproportionation of radicals (41) is an exothermic reaction. For example, the enthalpies of disproportionation of 2,2,6,6-tetramethylpiperidinoxyl with HO₂[•], (CH₃)₂C(OH)O₂[•], and cyclo-C₆H₁₀(OH)O₂[•] are -109, -92, and -82 kJ mol⁻¹, respectively. The *E*_{e,o} value for the abstraction of an H atom from the O—H bond in ROOH by a nitroxyl radical is 45.6 kJ mol⁻¹ and is matched by the value Δ*H*_{e,min} = -58 kJ mol⁻¹. Since Δ*H* < Δ*H*_{e,min}, the activation energy *E* ≈ 0.5 *RT* for these reactions is low,⁴⁸ and the rate constant is correspondingly high. Therefore, in the systems in which hydroperoxy and hydroxyperoxy radicals participate in the chain propagation, the cyclic chain termination mechanism is realised.

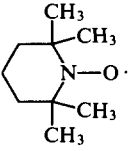

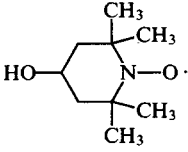

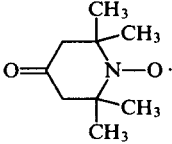

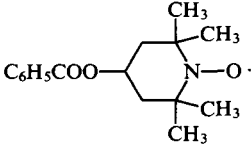

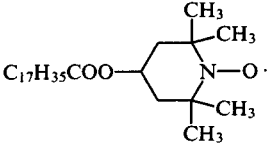

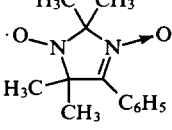

The reactions of disproportionation of nitroxyl and alkylperoxy radicals are also exothermic. For example, 2,2,6,6-tetramethylpiperidinoxyl abstracts an H atom from the β-C—H bond of cumylperoxy and cyclohexylperoxy radicals. The enthalpies of these reactions are -42 and -32 kJ mol⁻¹. The activation energy for the radical abstraction (*E*_{e,o}) for the AmO[•] + RH reaction is 58 kJ mol⁻¹, and the corresponding Δ*H*_{e,min} value is -125 kJ mol⁻¹,⁴² that is, Δ*H*_{e,min} substantially exceeds Δ*H* in magnitude. Thus, both reactions under consideration

should require appreciable activation energies. According to a calculation,⁴² for the reaction of AmO[•] with C₆H₅(CH₃)₂CO₂[•], *E* = 23.7 kJ mol⁻¹ and *k* = 1.1 × 10⁶ dm³ mol⁻¹ s⁻¹, and for the reaction of AmO[•] with cyclo-C₆H₁₁O₂[•], *E* = 27.4 kJ mol⁻¹ and *k* = 2.0 × 10⁵ dm³ mol⁻¹ s⁻¹. The recombination of nitroxyl radicals with alkyl radicals proceeds as a rule much more rapidly.⁵³

Why are the *E*_{e,o} values in the reactions of nitroxyl radicals with O—H bonds lower than those in their reactions with C—H bonds? As in the case of disproportionation of RO₂[•] with amino radicals, the low *E*_{e,o} values are accounted for by triplet repulsion.⁵⁷ When a transition state of the O...H...O type is formed (the AmO[•] + HO₂[•] reaction), the triplet repulsion is close to zero, because the O—O bond in the labile compound AmOOH is very weak. Conversely, the triplet repulsion in the reaction of AmO[•]

Table 5. Some kinetic characteristics of the cyclic mechanism of the chain termination on nitroxyl radicals in the oxidation of alcohols and amines.

with the C—H bond is fairly great, due to the high dissociation energy of the AmO—R bond. This accounts for the difference between the activation energies and between the rate constants for the reactions considered above. Thus, the possibility of the realisation of a cyclic chain termination mechanism in the reactions of Am \cdot and AmO \cdot with peroxy radicals, incorporating O—H groups, is caused by the weak triplet repulsion in the disproportionation reactions in which the corresponding inhibitor (AmH or AmOH) is recovered.

HO $_2\cdot$ radicals are also generated in the oxidation of polymers, in particular, in the oxidation of polypropylene,⁵⁸ when intramolecular chain transfer affords associated hydroperoxy-groups.³ The thermal decomposition of the latter yields H $_2$ O $_2$, which reacts with peroxy macroradicals and thus generates the HO $_2\cdot$ radicals, which are responsible for the cyclic chain termination via reactions (41) and (42).^{52,58}

The nitroxyl radicals also participate in other cyclic mechanisms of chain termination. One of these mechanisms involves alternation of reactions involving the R \cdot and RO $_2\cdot$ radicals. This mechanism has been discovered in a study of the retarding effect of 2,2,6,6-tetramethyl-4-benzoylpiperidin-*N*-oxyl on the initiated oxidation of polypropylene.¹⁷ It has been shown^{17,59,60} that the nitroxyl radical terminates the oxidation chain by reacting with the alkyl macroradical of polypropylene being oxidised. The resulting compound AmOR is fairly reactive with respect to the peroxy radicals AmO \cdot being regenerated in this reaction. Thus, the cycle includes the following two reactions (mechanism I):^{59–62}

where Y is a polypropylene macromolecule with a double bond formed by the abstraction of the H atom from the β -C—H bond and by the cleavage of the O—N bond in ROAm. This conclusion was confirmed later in a study of radiation-induced chemical oxidation of octane;⁶³ in this work, AmOR was identified as a reaction product.

The ether AmOR is thermally unstable. At elevated temperatures it dissociates with cleavage of the R—O bond, which leads to the appearance of an [Am \cdot + R \cdot] radical pair in the cage of the polymer or of the hydrocarbon being oxidised; disproportionation of this radical pair gives hydroxylamine and an alkene. The peroxy radical reacts rapidly with hydroxylamine thus regenerating the nitroxyl radical. This scheme was suggested and justified in a number of papers.^{64–68} The cyclic mechanism (II) includes the following stages:

The fact that hydroxylamine has been found among the products of the transformations of nitroxyl during the oxidation of hydrocarbons is evidence in support of this mechanism. Both mechanisms described above are realised in parallel and supplement each other. The result of the competition between them depends primarily on the temperature, since the thermal decomposition of the product ROAm requires a fairly high activation energy. The problem of the competition between the mechanisms I and II of cyclic chain termination has been considered by Denisov.²¹ In the case of the oxidation of polypropylene at the initiation rate $v_i = 10^{-7}$ mol kg $^{-1}$ s $^{-1}$ and for $[O_2] = [AmO\cdot] = 10^{-3}$ mol kg $^{-1}$, the ratio of the rates of chain termination via reactions (44) and (46) varies as a function of the temperature in the following way:⁶²

T/K	350	365	380	388	400	420
v_I/v_{II}	50.0	9.55	2.14	1.00	0.33	0.029

It is obvious that when the temperature is not very high and the ether AmOR is stable, the mechanism I predominates, that is, the regeneration of AmO \cdot from AmOR is ensured by the reaction of AmOH with the peroxy radical. At higher temperatures, when AmOR becomes unstable, the mechanism II predominates. It should be taken into account that only some of the radical pairs formed upon decomposition of ROAm disproportionate giving AmOH and an alkene. The remaining radical pairs pass into the bulk, and the radical R \cdot reacts with O $_2$ to give RO $_2\cdot$ and thus initiate a new oxidation chain. Hence, the regeneration of AmO \cdot from AmOH is inevitably accompanied by the initiation of the process, which certainly decreases the efficiency of the inhibition.

As the oxidation of the polymer proceeds and hydroperoxy groups which decompose to give H $_2$ O $_2$ accumulate, the cyclic chain termination mechanisms involving the HO $_2\cdot$ radical [reactions (41) and (42)] become more significant. Below we present the results illustrating the relative efficiency of the chain termination mechanisms involving the R \cdot and RO $_2\cdot$ radicals (mechanisms I and II), on the one hand, and the mechanism involving the HO $_2\cdot$ radicals, on the other hand, obtained for the oxidation of polypropylene.⁶² Polypropylene was oxidised at 388 K and $P_{O_2} = 10^5$ Pa in the presence of an initiator (cumyl peroxide) and with an inhibitor (2,2,6,6-tetramethyl-4-stearyl piperidin-*N*-oxyl),⁵⁶ the consumption of which was monitored by EPR. The inhibiting activity was characterised by the coefficient

$$f = \frac{v_i}{v_{AmO\cdot}},$$

where v_i and $v_{AmO\cdot}$ are the initiation rate and the rate of consumption of the nitroxyl radical, respectively, and by the parameter F :

$$F = \frac{v_i}{v} \left(1 - \frac{v^2}{v_0^2} \right) [AmO\cdot]^{-1},$$

where v_0 and v are the rates of oxidation of the polymer without an inhibitor and with the inhibitor AmO \cdot , respectively. The parameter F characterises the efficiency of AmO \cdot as an inhibitor terminating the chains. In experiments on the oxidation of polypropylene containing no hydroperoxy-groups the following values were found: $f = 4$ and $F = 7$ kg mol $^{-1}$, whereas for the oxidation of polypropylene that had been preliminarily oxidised and contained 4.12×10^{-2} mol kg $^{-1}$ of hydroperoxy-groups, these parameters were: $f = 40$ and $F = 1060$ kg mol $^{-1}$.

Thus, there is a clear dissimilarity between the cyclic chain termination mechanism involving only R \cdot and RO $_2\cdot$ radicals and the mechanism involving HO $_2\cdot$ radicals produced from H $_2$ O $_2$.

Recently, a new cyclic mechanism of chain termination by nitroxyl radicals, including the formation of amino radicals as intermediate species, has been found.^{69,70} It was shown that the addition of 4,4'-dioctyldiphenylnitroxyl radical to hexadecane being oxidised ($T = 433$ K) leads to the formation of the corresponding diphenylamine as an intermediate compound during its transformations. The following cyclic mechanism of chain termination was suggested:

A specific feature of this mechanism is the reaction (48), in which AmOR cleaves at the N—O bond rather than at the C—O bond as observed for the inhibition by alicyclic nitroxyl radicals. An alternative mechanism of the regeneration of the amino radical from the nitroxyl radical is also possible:

In this case, the cyclic chain termination mechanism can be realised only with participation of peroxy radicals.

Thus, nitroxyl radicals can participate in various cyclic mechanisms of chain termination. In the oxidation of alcohols, peroxides, and amines, when peroxy radicals possess both oxidising and reducing ability, the cyclic mechanism of chain termination includes reactions of peroxy radicals with AmO^\cdot and AmOH . The cyclic mechanism occurring under the conditions of polymer oxidation includes the $\text{R}^\cdot + \text{AmO}^\cdot$ and $\text{RO}_2^\cdot + \text{AmOR}$ reactions. At elevated temperatures AmOR becomes thermally unstable, and the mechanism that includes homolysis of AmOR at the C—O or N—O bonds with the generation of AmO^\cdot (AmOH) or Am^\cdot (AmH) radicals is realised.

VI. Cyclic chain termination mechanisms involving acid catalysis

We have by no means described all the cyclic mechanisms of chain termination involving nitroxyl radicals. A new interesting branch of modern antioxidant chemistry deals with cyclic mechanisms involving acid catalysis. The first inhibiting system of this type was discovered in 1988.¹⁸ It consisted of an alcohol (primary or secondary), a stable nitroxyl radical (2,2,6,6-tetramethylpiperidin-*N*-oxyl), and an organic (citric acid). This three-component system effectively retarded the initiated oxidation of ethylbenzene. Each component taken by itself and binary combinations of these components did not retard oxidation of ethylbenzene or retarded it only slightly. Intense chain termination was ensured only by the presence of all three components of this system.

The important role of the acid was established in experiments on the oxidation of ethylbenzene containing an alcohol and nitroxyl radicals, when air or air mixed with gaseous HCl was passed through the reactor. The concentration of the peroxy radicals in the hydrocarbon being oxidised was determined by the chemiluminescence method. The intensity of chemiluminescence was evaluated in terms of $I \sim [\text{RO}_2^\cdot]^2 \sim v_i^2/2k_t$, where k_t is the rate constant for the disproportionation of RO_2^\cdot . When a mixture of air with HCl was used, the intensity of the chemiluminescence decreased by approximately two orders of magnitude.¹⁸

The $\text{H}_2\text{O}_2 + \text{AmO}^\cdot$ (2,2,6,6-tetramethylpiperidin-*N*-oxyl) + HA (citric acid) system also exhibits an extremely high inhibiting effect. The data presented below demonstrate how the individual components of this system and the whole system influence the rate of the chain oxidation of ethylbenzene (343 K, $P_{\text{O}_2} = 10^5$ Pa, $v_i = 5.21 \times 10^{-7}$ mol dm⁻³ s⁻¹):⁷¹

$[\text{AmO}^\cdot]/10^{-4}$ mol dm ⁻³	$[\text{HA}]/10^{-4}$ mol dm ⁻³	$[\text{H}_2\text{O}_2]/10^{-3}$ mol dm ⁻³	$v/10^{-6}$ mol dm ⁻³ s ⁻¹
0	0	0	4.92
5	0	0	3.78
5	5	0	3.00
5	5	2.5	0.22

It can be seen that complete termination of the chain process is ensured only by the three-component system.

The very effective retardation of the oxidation of the hydrocarbon by this system can be explained in terms of the following mechanism:^{71,72}

According to this mechanism, H_2O_2 is consumed during oxidation of hydrocarbons at a rate of $\frac{1}{2}v_i$, whereas the rate at which nitroxyl radicals are consumed via the reaction (46) is much lower. Only a small portion of the R^\cdot radicals react with AmO^\cdot , since the latter react very rapidly with oxygen. The kinetic characteristics of the inhibited oxidation are fully consistent with the suggested scheme for the cyclic chain termination. When the concentration of H_2O_2 is relatively low, the chain termination rate is limited by the stage (54), and then the function F assumes the following form:⁷¹

$$F = 2 \frac{k_{36} + k_{54}K_{52}[\text{AmO}^\cdot][\text{HA}]}{(2k_1v_i)^{0.5}} [\text{H}_2\text{O}_2].$$

If the concentration of H_2O_2 is large, the stage (54) occurs rapidly and the reaction (53) becomes the rate-limiting stage of the cyclic chain termination. Under these conditions

$$F = 2 \frac{k_{53}K_{52}[\text{AmO}^\cdot][\text{HA}] + k_{36}[\text{H}_2\text{O}_2]}{(2k_6v_i)^{0.5}}.$$

The mechanism of chain termination consisting of the reactions (47), (52), (53), and (54) is notable because the acid protonates nitroxyl and thus converts it into a donor of hydrogen atom for the peroxy radical, while hydrogen peroxide reduces the AmO^+ cation to hydroxylamine, which reacts rapidly with RO_2^\cdot . Thus, the acid and hydrogen peroxide transform AmO^\cdot , which is unreactive with respect to RO_2^\cdot , into AmOH^+ and AmOH , and the latter inhibit effectively the oxidation of hydrocarbons.

Recently an analogous mechanism for cyclic chain termination has been proposed for quinones.⁷³ Quinones, which can act as acceptors of alkyl radicals, do not decelerate the oxidation of hydrocarbons at concentrations of up to 5×10^3 mol dm⁻³, because the R^\cdot radicals react very rapidly with oxygen. However, the ternary quinonemonoanilide (Q) + H_2O_2 + acid (HA) system effectively retards the initiated oxidation of methyl oleate and ethylbenzene.⁷³ This is indicated by the following results obtained for the oxidation of ethylbenzene (343 K, $P_{\text{O}_2} = 10^5$ Pa, $v_i = 5.21 \times 10^{-7}$ mol dm⁻³ s⁻¹).

$[\text{Q}]/10^{-4}$ mol dm ⁻³	$[\text{H}_2\text{O}_2]/10^{-3}$ mol dm ⁻³	$[\text{HA}]/10^4$ mol dm ⁻³	$v/10^{-7}$ mol dm ⁻³ s ⁻¹
0	0	0	4.92
5.0	0.0	0	3.01
0.0	1.25	0	3.27
0.0	0.0	5.0	3.93
5.0	1.25	5.0	2.39
5.0	12.5	5.0	0.69

The following mechanism, analogous to the mechanism involving nitroxyl radicals, has been suggested for the retarding influence of this system:

In conformity with this mechanism, the function F depends on the concentrations of the components of the inhibiting mixture in the following way:

$$F = \frac{2K_{55}k_{56}k_{57}[\text{Q}][\text{H}_2\text{O}_2][\text{HA}]}{(k_{57}[\text{H}_2\text{O}_2] + k_{59}[\text{RH}])(2k_6v_i)^{0.5}}.$$

Experimental data on the kinetics of oxidation of methyl oleate and ethylbenzene are in good agreement with the scheme consisting of the reactions (55)–(59).

The cyclic mechanism of chain termination with quinone imines involving acid catalysis is very important for an understanding of the retarding influence of aromatic amines on the oxidation of hydrocarbons and of other organic compounds via the reaction (28). Hydrogen peroxide arises during the oxidation of alcohols due to the decomposition of RO_2^\cdot to yield HO_2^\cdot and ketone and due to the decomposition of $>\text{C}(\text{OH})\text{OOH}$ giving ketone and H_2O_2 . In addition, H_2O_2 is formed in the hydrolysis of alkyl hydroperoxide through the action of water or acids, which also arise in the system during oxidation of hydrocarbons. Thus, two of the three components needed for the realisation of the cyclic chain termination mechanism involving acid catalysis result from the oxidation of the hydrocarbon, while the third component — quinone imine — results from the oxidation of the starting inhibitor (amine). It is possibly owing to this mechanism that aromatic amines exhibit high inhibiting capacity during oxidation at elevated temperatures ($>400\text{ K}$).

VII. Ions and complexes of variable-valence metals as catalysts for chain termination in the oxidation of alcohols, amines, and alkenes

Compounds of variable-valence metals (Mn, Fe, Co, Ce) are well known as catalysts for oxidation of hydrocarbons and aldehydes. They accelerate oxidation by destroying hydroperoxides and initiating the formation of free radicals.⁹ Salts and complexes containing transition metals in a lower valence state react rapidly with peroxy radicals and so when these compounds are added to a hydrocarbon prior to its oxidation an induction period arises.⁹ The chain termination occurs stoichiometrically ($f \approx 1$) and stops when the metal passes to a higher valence state due to oxidation. On the addition of an initiator or hydroperoxide the induction period disappears.

Another situation is observed when salts or complexes of metals with variable valence states are added to an alcohol (primary or secondary) subjected to oxidation: in this case, a prolonged deceleration of the initiated oxidation occurs, owing to repeated chain termination. This was discovered for the first time in relation to the oxidation of cyclohexanol in the presence of a copper salt.¹⁵ Copper and manganese ions also exert a decelerating influence on the initiated oxidation of cyclohexadiene,³²

aliphatic amines,⁴⁹ and 1,2-disubstituted ethenes.³³ This is accounted for by the dual redox nature of the peroxy radicals HO_2^\cdot , $>\text{C}(\text{OH})\text{O}_2^\cdot$, and $>\text{C}(\text{NHR})\text{O}_2^\cdot$, and by the ability of ions (complexes) of heavy metals to accept an electron when they are in a higher valence state, and to release an electron when they are in a lower valence state, for example:

Table 6 presents the results of a kinetic study of the reactions (60) and (61). Copper and manganese compounds exhibit the highest inhibiting activity. The chain termination on variable-valence metals in the systems in which hydroperoxyl and hydroxy-peroxyl radicals act as the chain-propagating species is characterised by very large coefficients: $f \approx 10^4 - 10^6$.

Both reactions (60) and (61) may include several stages. If an aqueous solution of a copper salt, for example sulfate, is used, the following mechanism involving the incorporation of RO_2^\cdot into the inner coordination sphere of the metal ion is possible for the reaction (60):

In the case of metal complexes with strongly bound ligands, the outer-sphere transfer of an electron from the radical to the ion and back is more probable.

When variable-valence metals are used as catalysts in the oxidation of hydrocarbons, the chain termination via reactions (60) and (61) manifests itself late in the process. This case has been specially studied in relation to the oxidation of paraffins to fatty acids in the presence of a K–Mn catalyst,⁸⁰ which ensures a high oxidation rate and a high selectivity of formation of the target product. As the reaction proceeds, alcohols are accumulated in the reaction mixture, their oxidation being accompanied by the formation of hydroxyperoxyl radicals. The more extensively has the oxidation proceeded, the higher is the concentration of alcohols in the oxidised paraffin, and, hence, the higher is the kinetically equilibrium concentration of these radicals. The latter enter into reactions resembling the reactions (60) and (61) with Mn^{2+} and Mn^{3+} ions and thus cause chain termination. When

^a Notation: AcacH — acetylacetone, StH — stearic acid, DMGH — dimethylglyoxime, SlmH — salicylaldehyde, 4-X-SlmH — 4-X-salicylanilide, ENSlm — o-salicylaldehydeneimine, ENH₂ — ethylene diamine, TlnH — toluidine, SalH — salicylic acid, Prf — porphyrin, DPGH — diphenylglyoxime.

the rate of chain termination with the hydroxyperoxyl radicals becomes equal to the rate of generation of the chain-propagating radicals, the oxidation virtually ceases.

The oxidation of alcohols is also retarded by bases,⁸¹⁻⁸³ which is apparently due to the decomposition of the hydroxyperoxyl radical giving ketone and superoxide ion $O_2^{\cdot-}$:

The superoxide ion cannot continue the chain and is destroyed via disproportionation with RO_2^{\cdot} .

VIII. Conclusion

Studies of the mechanisms of cyclic chain termination in oxidation processes carried out for three decades have demonstrated on the one hand that they are extremely diverse and, on the other hand, that they are highly structurally selective. The 19 currently known mechanisms, which are presented in Table 7, can be divided into three groups.

The first group includes mechanisms with the participation of such inhibitors as aromatic amines, nitroxyl radicals, quinones, and compounds of variable-valence metals (Mn, Fe, Co, Cu, Ce). These inhibitors or, more precisely, the inhibiting pairs (AmH and Am^{\cdot} , Q and QH^{\cdot} , AmO^{\cdot} and $AmOH$, and M^{n+} and M^{n+1})

retard oxidation only provided that the chain is continued by the HO_2^{\cdot} , $>C(OH)O_2^{\cdot}$, or $>CH(NHR)O_2^{\cdot}$ radicals. The latter disproportionate very rapidly with hydrogen atom acceptors such as Am^{\cdot} , AmO^{\cdot} , or Q . This leads to the recovery of the reduced form of the inhibitor, which again reacts rapidly with a peroxy radical; this ensures the effective chain termination. The number of cycles is determined by the ratio of the rate of the reaction of the peroxy radical, in which the inhibitor is recovered, to the rate of its irreversible consumption. The direction of the transformation of RO_2^{\cdot} is largely determined by the nature of the reaction centre of disproportionation. Analysis has shown that the triplet repulsion in the transition state of an elementary step of the regeneration of the inhibitor by the peroxy radical needs to be very weak. It is also essential that the atoms between which the electron transfer occurs (for example, N and O) should differ in electron affinity. Thus, the structure of the peroxy radical is the crucial factor for the mechanisms of the first group.

The second group of mechanisms, by which the inhibitors (nitroxyl radicals) are recovered, involves successive participation of the R^{\cdot} and RO_2^{\cdot} radicals in the reactions with AmO^{\cdot} and $AmOH$. The possibility of the realisation of these mechanisms depends on the conditions of the oxidation, which should ensure fairly rapid interaction of the alkyl radicals with AmO^{\cdot} , and this requires that the reaction of R^{\cdot} with oxygen does not occur very rapidly. This requirement is fulfilled in the oxidation of solid

B	>C(OH)O $_2\cdot$	$>\text{C}(\text{OH})\text{O}_2\cdot + \text{B}^- \longrightarrow >\text{C}=\text{O} + \text{O}_2^{2-} + \text{BH}$	81–83

polymers, since in this case, the solubility of O $_2$ and the rate of its reaction with R \cdot are lower than those in a liquid under similar conditions. Mechanism of this sort can also occur in the liquid phase, when the concentration of the dissolved oxygen is relatively low ([O $_2$] \ll [ArO \cdot]). For the dissociation of the intermediate product at the O–C or N–O bond, a sufficiently high temperature is needed.

The third group of mechanisms includes acid catalysis as a necessary stage of the cycle. An acid protonates an inhibitor in the oxidised form (AmO \cdot , Q) and thus transforms the corresponding species into a potential hydrogen donor. The cycle begins with attack by RO $_2\cdot$ on the protonated inhibitor. Of course, the reduction of the cationic form of the inhibitor with hydrogen peroxide also plays an important role. Mechanisms of this sort should be characteristic of the oxidation in the systems in which hydrogen peroxide and an acid are generated, and this refers to many organic compounds.

Evidently, catalysis with bases is characteristic of systems in which the HO $_2\cdot$ or >C(OH)O $_2\cdot$ radicals act as the chain-propagating species in the oxidation. Repeated chain termination has also been observed in the presence of sulfur-containing inhibitors,²³ but the exact mechanism of these processes is still unknown.

Abstract. The results of studies on the structural, conformational, and dynamic properties of organic conducting polymers by 2 mm EPR spectroscopy are treated systematically and surveyed. The structural and dynamic features of the paramagnetic centres as well as the mechanism of charge transfer in the conducting polymers are discussed. The bibliography includes 73 references.

I. Introduction

Various organic conducting compounds are known at the present time: charge-transfer complexes and radical-ion salts, platinum complexes with cyanide ligands, phthalocyanines, dyes, metal-filled polymers, etc.^{1–4} These compounds are of interest from the standpoint of a study of the fundamental principles of charge transfer. Among them, one should distinguish particularly organic conducting polymers such as polyparaphenylene (PPP), polythiophene (PT), polypyrrole (PP), the emeraldine base (EB) and emeraldine salt (ES) form of polyaniline (PANI), polytetra-thiafulvalene (PTTF), polyacetylene (PA), etc., which may prove promising in molecular electronics (the spin charge carriers stabilised in the polymers are shown below).^{5–7}

These compounds are characterised by an anisotropic quasi-one-dimensional (1D) π -conjugated structure and, in contrast to classical polymers, exhibit an electrical conductivity which varies by more than 10 orders of magnitude when the polymer is doped with various counterions.⁵ The introduction of BF_4^- , ClO_4^- , AsF_6^- , I_3^- , FeCl_4^- , MnO_4^- , etc. anions induces a positive charge on its chains, i.e. leads to a *p*-type conductivity, whereas *n*-type conductivity is achieved by doping the polymer with various alkali metals, for example Li^+ , K^+ , and Na^+ .

The electrodynamic properties of conducting polymers are significantly influenced by their structure, conformation, and the packing of their chains. The globular structure of the polymers is made up of fibrils with a typical diameter of 100 nm, the fibrils consisting in their turn of crystallites. The parameters of the corresponding unit cells of such crystallites are listed in Table 1. The dihedral angle θ between the planes of the monomer units in the polymer, for example in PPP, is $\sim 23^\circ$.¹² The value of this angle is a result of a compromise balance between the conjugation effect, tending to bring the system to a planar conformation, and the steric repulsion of the hydrogen atoms in the *ortho*-positions, which rules out a planar conformation. The electron density transfer integral I between the monomer units is given by $I \sim \cos \theta$,¹³ so that the probability of the 1D-charge transfer in the polymer increases with increase in the planarity of the chain.

Table 1. The unit cell parameters of conducting polymers.

Polymer	System	Parameter / nm			Ref.
		<i>a</i>	<i>b</i>	<i>c</i>	
PPP	Monoclinic	0.779	0.562	0.426	8
	Orthorhombic	0.781	0.553	0.420	8
PT	Hexagonal	0.950	0.620	1.220	9
PP	Monoclinic	—	0.341	0.718	10
PANI	Monoclinic	0.705	0.860	0.950	11

The overlap of the π orbitals of the monomer rings results in the formation of a band structure of the polymer with gap widths of 3.5 eV (PPP), 2.2 eV (PT), 3.0 eV (PP), 4.0 eV (undoped PANI), and 1.5 eV (ES form of PANI).^{10,14} The resonance interaction of the energetically nonequivalent benzenoid and quinonoid forms of the monomers is the cause of the nonlinear topological excitation — the formation of a polaron with a spin of $\frac{1}{2}$, delocalised over 4–5 monomer units of the polymer.⁸ The energy levels of such a polaron are located in the forbidden band at a distance Δ_1 below the conductivity band and at a distance Δ_2 above the valence band. $\Delta_1 = \Delta_2 = 0.7$ eV for PPP, $\Delta_1 = 0.9$ eV and $\Delta_2 = 0.45$ eV for PP, and $\Delta_1 = 0.7$ – 0.9 eV and $\Delta_2 = 0.5$ – 0.6 eV for the other conducting polymers.¹⁴ For sufficiently high levels of doping, pairs of polarons may recombine with formation of longer spin-less bipolarons.

Conducting polymers contain paramagnetic centres (PC) at a concentration $N = 10^{16}$ – 10^{21} spins g^{-1} ,^{15,16} so that one of the most promising methods for their investigation is EPR spectroscopy, which makes it possible to obtain varied and unique information about the structure of the polymer and about the nature and properties of the paramagnetic centres (their concentration, mobility, relaxation, etc.). Such studies are as a rule carried out at relatively low recording frequencies ($\nu_e \leq 10$ GHz). In these bands, conducting polymers, like other π -electron systems, usually give rise to a single symmetrical line with a width between the peaks $\Delta B_{\text{PP}} = 0.02$ – 1.70 mT and a g -factor close to that for a free electron ($g_e = 2.00232$).^{15,16} The deviation from g_e can occur on interaction of an unpaired electron with heteroatoms or the alkali metals of the dopants.^{17,18} For a sufficiently high level of doping, the so called Dyson line,^{15,19} leading to the asymmetry of the spectrum, is manifested as a consequence of the increase in the electrical conductivity of the sample. However, in the study of conducting polymers with $\nu_e \leq 10$ GHz, investigators have encountered fundamental difficulties associated mainly with the low spectral resolution and a strong spin–spin exchange in this EPR frequency range.

It was shown previously in relation to various organic radicals^{20–23} that the information content and the accuracy of the method increase significantly on passing to the 2 mm band for the recording of the EPR spectra. In this range, it is possible to achieve the separate detection of paramagnetic centres with similar magnetic parameters, which permits a more accurate determination of the components of their anisotropic g -factor and also makes it possible to investigate the anisotropic dynamics of the radicals and of their microenvironment. The method makes it possible to study in fair detail different properties of *cis*- and *trans*-polyacetylenes as well as the relaxation and dynamic features of nonlinear charge carriers (solitons) in *trans*-polyacetylene.²⁴

The present review is devoted to the consideration of the principal results of the study at the 2 mm EPR band of the structural and conformational properties of certain other conducting polymers as well as the charge carriers present in them, the dynamics of which is described by the universal nonlinear Korteweg-de Vries equations of motion.

II. Polyparaphenylene

The concentration of unpaired electrons in PPP depends significantly on the polymerisation methods and may vary within the range 10^{17} – 10^{19} spins g^{-1} .^{15,16} The line width increases on doping and such broadening may depend both on the degree of doping and on the atomic number of the alkali metal of the dopant. The latter finding indicates an appreciable spin–orbital interaction between the dopant molecule and the unpaired electron. As in other conducting polymers, the charge transfer is effected mainly by polarons in lightly doped PPP and by bipolarons in a quasi-metallic sample.^{8,12,14}

Various PPP samples (in the form of films), synthesised by the electrochemical oxidation of benzene in a $\text{C}_3\text{H}_7\text{C}_5\text{H}_4\text{NCl} - \text{AlCl}_3$ melt, have been investigated by the EPR method: the initial evacuated PPP sample doped with Cl^{3-} anions (PPP-1); the same sample after storage over four days (PPP-2); the initial sample brought into contact with atmospheric oxygen for several seconds (PPP-3); the initial dedoped sample (PPP-4); the sample redoped with BF_4^- anions (PPP-5).²⁵

In measurements at the 3 cm EPR band, the PPP-1, PPP-2, and PPP-3 samples give rise to a single asymmetric line with a distinct Dyson form and $g = 2.0029$ (Fig. 1a). The line asymmetry factor A/B (the ratio of the amplitudes of the positive and negative peaks) varies as a function of the conductivity of the sample. When the Cl_3^- dopant is removed, i.e. on passing from the PPP-1 to the PPP-4 sample, the above spectrum is transformed into an axially symmetrical spectrum with $g_{\perp} = 2.0034$ and $g_{\parallel} = 2.0020$ (Fig. 1b). This is accompanied by the broadening of the spectral lines and also by a sharp decrease in the concentrations of spins and charge carriers (Table 2). It is noteworthy that neither in the case of PPP nor in the case of other π -conjugated polymers, investigated previously at the 3 cm EPR band, were axially symmetrical spectra recorded.¹⁵ The above form of the spectrum remains unchanged on further doping of the neutral PP with BF_4^- anions (PPP-5), but in this case some decrease in the spin concentration and a change in the sign of its temperature dependence are observed (Table 2). The minimum excitation energy of the unpaired electron $\Delta E_{\sigma\pi^*} = 5.2$ eV, close to the energy of the first ionisation potential of polycyclic aromatic hydrocarbons,¹³

Figure 1. Typical 3 cm EPR absorption spectra of PPP-1–PPP-3 (a) and PPP-4 and PPP-5 (b) samples and the 2 mm in-phase dispersion spectrum of the PPP-4 and PPP-5 samples (c) recorded at room temperature. The narrow line on the right-hand spectrum belongs to the $(\text{DBTTF})_3\text{PtBr}_6$ reference standard with $g_s = 2.00411$. The measured magnetic parameters are presented.

Table 2. The concentration of the paramagnetic centres (N), the d.c. (σ_{dc}) and a.c. (σ_{ac}) conductivities ($\nu_e = 140$ GHz), the line asymmetry parameter (A/B), the line width (ΔB_{PP}), and the spin-lattice relaxation time (τ_1) for polyparaphenylene samples at $T = 300$ K.

Parameters	Sample				
	PPP-1	PPP-2	PPP-3	PPP-4	PPP-5
$10^{-17} N/\text{spin g}^{-1}$	120	320	210	4	0.6
$\sigma_{dc}/\text{S m}^{-1}$	$10^3\text{--}10^4$	—	—	10^{-6}	1
$10^{-5} \sigma_{ac}/\text{S m}^{-1}$	3	4	1.4	—	—
A/B	2.3	2.5	1.4	—	—
$\Delta B_{PP}/\text{mT}$	0.09	0.12	0.22	0.37 ^a	0.47 ^a
$10^6 \tau_1/\text{s}$	0.4	0.5	0.2	~ 100	~ 100

^a The width of the high-field spectral component is presented.

may be calculated, using the difference $\Delta g = g_{\perp} - g_{\parallel} = 1.4 \times 10^{-3}$, from the equation

$$\Delta E_{\sigma\pi'} = \frac{2\lambda_C \rho_C}{\Delta g}, \quad (1)$$

where λ_C is the constant for the spin-orbital interaction of the unpaired electron with a carbon nucleus and ρ_C the electron density on carbon.²⁶ Thus the paramagnetic centres in PPP-4 and PPP-5 can be localised in the vicinity of the polycyclic hydrocarbon cross-links, as predicted previously.¹⁵

At the 2 mm EPR band, the PPP-4 and PPP-5 samples give rise to a bell-shaped signal (Fig. 1c), which arises as a result of the manifestation of the effect due to the rapid adiabatic passage of a nonuniformly broadened line.²⁷ The spin-lattice relaxation time of the paramagnetic centres in these samples, estimated from their spectra, is $\tau_1 \approx 10^{-4}$ s. The rapid passage effects will be examined in greater detail below.

The rate of the spin-spin exchange of the paramagnetic centres in the neutral and redoped PPP has been determined as $\nu_{ex} = 4 \times 10^7 \text{ s}^{-1}$ by analysing the form of the 3 cm and 2 mm EPR spectra.²⁵ For PPP-1, this quantity is $1.8 \times 10^8 \text{ s}^{-1}$ owing to the greater concentration and mobility of the paramagnetic centres. The isotropic g -factor ($\langle g \rangle = \frac{1}{3}(g_{\parallel} + 2g_{\perp})$) for a neutral sample is close to the g -factor for the polymer doped with Cl_3^- anions. This finding indicates the averaging of the components of the g -tensor for the paramagnetic centres as a consequence of the spin 1D-diffusion along the polymer chain of the PPP-1 sample at a minimal rate:

$$\nu_{1D}^0 \geq \frac{(g_{\perp} - g_{\parallel})\mu_B B_0}{h}, \quad (2)$$

where μ_B is the Bohr magneton, B_0 the magnetic field strength, and h the Planck constant. For the PPP sample doped with Cl_3^- anions, this quantity is $\nu_{1D}^0 \geq 6.8 \times 10^6 \text{ s}^{-1}$. Indeed the effective rate of the spin 1D-diffusion, calculated from the equation

$$(\Delta B_{PP}^{\text{mob}})^3 = \frac{\gamma_e (\Delta B_{\perp}^{\text{loc}})^4}{\nu_{1D}}, \quad (3)$$

(here $\Delta B_{PP}^{\text{mob}}$ is the width of the line between the peaks of the PPP-1 samples, $\Delta B_{\perp}^{\text{loc}}$ the width of the perpendicular component of the spectrum of the PPP-4 and PPP-5 samples, and γ_e the gyromagnetic ratio for the electron) proved to be $\nu_{1D} \approx 9 \times 10^{10} \text{ s}^{-1}$ at room temperature. The temperature dependence of the electrical conductivity of the PPP-1 sample, determined using alternating current from the function $A/B(T)$, has the form $\sigma_{ac}(T) \sim T^{-1/3}$. This shows that several conduction mechanisms, including the interchain variable range hopping (VRH) charge transfer and isoenergetic tunnelling of the charge carriers, operate in the doped PPP. The sharp decrease in spin concentration and in the rates of the spin

exchange and relaxation processes on dedoping of the sample (transition from PPP-1 to PPP-4) indicates the annihilation of the majority of the polarons, the 1D-diffusion of which determines the effective electronic relaxation of the entire spin system.

Thus the data obtained make it possible to conclude that, in the highly doped PPP-1 sample, the charge is transferred mainly by the mobile polarons, whereas in PPP-5 charge transfer is effected by diamagnetic bipolarons. On electrochemical substitution of the Cl_3^- anion by the BF_4^- anion, the location of the latter may differ from that of the dopant in the initial sample. The morphology of the PPP redoped with BF_4^- anions may be close to that in the neutral film (PPP-4).

It has been established²⁵ that a film of PPP synthesised from the $\text{C}_3\text{H}_7\text{C}_5\text{H}_4\text{NCl}-\text{AlCl}_3$ melt is characterised by a decrease in the number of benzenoid monomers and an increase in that of the quinonoid ones. This leads to a more ordered structure and to a planar conformation of the polymer, which apparently prevents the collapse of the spin charge carriers to a bipolaron in the highly doped polymer. On dedoping, the anions are 'washed out', which results in an increase in the packing density of the polymer chains. This may prevent the intrafibrillar introduction of BF_4^- anions and may lead to localisation of the dopant molecules in the interfibrillar free volume of the polymer matrix. Such a conformational transition apparently alters the mechanism of charge transfer in the course of the redoping of PPP.

III. Polythiophene

The 3 cm EPR spectrum of neutral PT consists of a single symmetrical line with $g \approx 2.0026$ and a width $\Delta B_{PP} = 0.8 \text{ mT}$ ¹⁵ which indicates the localisation of the spin on the polymer chain and its weak interaction with the sulfur atoms. The low concentration of paramagnetic centres ($N \approx 7 \times 10^{-5}$ of a spin per monomer unit) is associated with the comparatively low degree of defectiveness of this compound. The EPR signal of lightly doped poly(3-methyl)thiophene represents a superposition of a Gaussian line due to the localised paramagnetic centres with $g_1 = 2.0035$ and $\Delta B_{PP} \approx 0.7 \text{ mT}$ and a Lorentzian line with $g_2 = 2.0029$ and $\Delta B_{PP} = 0.15 \text{ mT}$. The latter is characteristic of delocalised paramagnetic centres.²⁸ The overall concentration of paramagnetic centres in this sample is $\sim 3 \times 10^{19} \text{ spins cm}^{-3}$ or about one spin per 300 thiophene rings. After doping, a single Lorentzian component remains. It is symmetrical up to a doping level $z \leq 0.25$ (z is the number of dopant molecules per polymer monomer unit), but becomes asymmetric (Dyson line) for $z > 0.3$. The appearance of the Dyson-like line is accompanied by a significant decrease in the spin-spin and spin-lattice relaxation times,²⁹ which may be a consequence of the increase in the dimensionality of the system. Analysis of the variation of the paramagnetic susceptibility $\chi(z)$ showed that the number of paramagnetic polarons increases during the doping process in the polymer, the polarons recombining to diamagnetic bipolarons for high values of z .

Powder-like PT samples,³⁰ containing different counterions, were investigated at the 2 mm EPR band. The samples were obtained electrochemically from thiophene and bithiophene.

At the 3 cm EPR band, the PT samples synthesised from thiophene and doped with BF_4^- , ClO_4^- , and I_3^- ions give rise to symmetrical lines with $g \approx g_e$ and a width ΔB_{PP} , which varies slightly over a wide temperature range (Table 3), whereas in the spectrum of the PT synthesised from bithiophene and doped with I_3^- anions the lines are appreciably broadened as the temperature increases.

The PT spectra recorded at the 2 mm EPR band are distinguished by a greater variety (Fig. 2). Axially symmetrical spectra, indicating the localisation of the paramagnetic centres on the polymer chains, are characteristic of the polymers PT(BF_4^-) and PT(ClO_4^-). A similar pattern apparently occurs also in the case of PT(I_3^-), the EPR spectrum of which may be broadened owing to the strong spin-orbital interaction of the paramagnetic centres with the counterions.

Figure 2. Typical 2mm EPR absorption spectra of polythiophene synthesised electrochemically from thiophene and doped with I_3^- (a), BF_4^- (b), and ClO_4^- (c) anions. The spectra were recorded at $T = 300$ K (continuous line) and 200 K (dashed line).

Table 3 presents the magnetic resonance parameters calculated from the 2 mm EPR spectra, the d.c. and a.c. conductivities of the samples (σ_{dc} and σ_{ac}), and the energies of the excitation of an electron to the nearest level ($\Delta E_{\sigma\pi^*}$). Analysis of the data presented shows that, in the series of anions $I_3^- \rightarrow BF_4^- \rightarrow ClO_4^-$, the quantity $\Delta E_{\sigma\pi^*}$ increases by a factor greater than 4. This transition also leads to an increase in the conductivity of the film and to significant alteration of the concentration of paramagnetic centres. This may indicate charge transfer in PT both by polarons and by bipolarons, the ratio of the concentrations of which depends on the nature and number of the anions introduced into the polymer. The width of the PT spectral lines proved more sensitive to a change in the recording frequency, which indicates a less intense spin exchange in this polymer compared, for example, with PA^{24,31} and PPP.²³

Table 3. The concentration of the paramagnetic centres (N), the electrical conductivity (σ_{dc}), the line width (ΔB_{PP}), the components of the g -tensor, and the energies of the excited electronic state ($\Delta E_{\sigma\pi^*}$) for polythiophene samples at $T = 300$ K.

Parameter	Polythiophene samples doped with the anions			
	I_3^-	BF_4^-	ClO_4^-	$ClO_4^-^a$
$10^{-19} N/\text{spins g}^{-1}$	2	8	5	10
$10^3 \sigma_{dc}/\text{S m}^{-1}$	0.5	1.2	16	11
$\Delta B_{PP}/\text{mT}$				
3 cm band ^b	0.75(0.80)	0.23(0.34)	0.46(0.52)	0.70(0.25)
2 mm band	6.5	1.5	2.6	0.5
g_{\parallel}	2.00679 ^c	2.00412	2.00230	2.00232 ^c
g_{\perp}	2.00232 ^c	2.00266	2.00239	2.00364 ^c
$\Delta E_{\sigma\pi^*}/\text{eV}$	1.6	4.0	7.0	4.5

^a The sample was synthesised from bithiophene. ^b The values of ΔB_{PP} at 77 K are given in brackets. ^c Values calculated from the equation $\langle g \rangle = \frac{1}{3}(g_{\perp} + 2g_{\parallel})$.

On reducing the temperature of the $PT(BF_4^-)$ sample, a Dyson-like line is manifested in the perpendicular component of its EPR spectrum without an appreciable change in the signal intensity. The quantity A/B increases monotonically in the temperature range 100–300 K, which indicates an increase in the electrical conductivity of the sample σ_{ac} , as happens in classical low-dimensional semiconductors. Knowing the characteristic size of the polymer particles δ and using the relation $A/B(\delta)$, it is possible to estimate for amorphous low-dimensional semiconductors³² the electrical conductivity of the sample and also the mobility μ and the rate of the 1D-diffusion of the charge carriers from the formula

$$\sigma_{ac} = N\mu e = \frac{Ne^2 v_{1D} c_{1D}^2}{kT}, \quad (4)$$

where c_{1D} is the lattice constant. The quantities σ_{ac} , μ_{1D} , and v_{1D} calculated for $PT(BF_4^-)$ in this way were found to be respectively $3.6 \times 10^2 \text{ S m}^{-1}$, $1.1 \times 10^{-5} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$, and $3.2 \times 10^{12} \text{ s}^{-1}$ at room temperature.³⁰

Polythiophene, synthesised from bithiophene and doped with ClO_4^- anions, is characterised by a single symmetrical EPR line at the 3 cm band, the width of which decreases monotonically from 0.7 to 0.25 mT on reducing the temperature from 300 to 77 K. In the 2 mm EPR band, this sample also shows a single line over a broad temperature range, which indicates the occurrence of charge transfer in it mainly by delocalised paramagnetic centres. With increase in temperature from 100 to 200 K ($T_c \approx 200$ K), the paramagnetic susceptibility of this sample decreases significantly and, on further rise of temperature, rises sharply (Fig. 3). This is accompanied by a corresponding change in line width, and the inverse relation of the functions $\Delta B_{PP}(T)$ and $\chi(T)$ (Fig. 3). This effect can be accounted for by the annihilation of polaron pairs to bipolarons when the temperature is varied from 100 K to T_c and on subsequent decomposition of the bipolaron into polarons at $T > T_c$, apparently owing to the intensification of the librations of the polymer chains. If one adopts a linear dependence of the rate of decomposition of bipolarons on the frequency of the librations of the polymer chains, then it is possible to estimate the activation energy for the latter process from the $\chi(T)$ behaviour. It proved to be $E_a \approx 0.16 \text{ eV}$ at $T > T_c$. Such polaron–bipolaron transformation is apparently in fact the cause of the unusual broadening, indicated above, of the EPR line of this sample at the 3 cm band, observed on raising the temperature.

Figure 3. Temperature variations of the rate of diffusion of charge carriers v_{1D} along a polymer chain (1), of the relative paramagnetic susceptibility χ (2), and of the inverse of the line width ΔB_{PP} (3) for polythiophene synthesised electrochemically from bithiophene and doped with ClO_4^- counterions.

As in the spectrum of polythiophene, a Dyson-like line appears in the EPR spectrum of polybithiophene at low temperatures, which reflects the change in the electrical conductivity of the film. Bearing in mind that the concentrations of the polarons and bipolarons are unchanged and using the above procedure, it is possible to determine the rate of 1D-diffusion of the charge carriers in the sample (Fig. 3). At room temperature, this quantity proved to be $v_{1D} = 3 \times 10^{13} \text{ s}^{-1}$, which is similar in order of magnitude to v_{1D} determined for polarons in doped PANI,³³ in which the interchain charge transfer predominates. The weak temperature dependence of the rate of the 1D-diffusion of the charge carriers in bithiophene also indicates the predominance of the interchain charge transfer in this polymer and its increased dimensionality.

IV. Polypyrrole

Neutral PP is characterised by a complex spectrum at the 3 cm EPR band, consisting of a superposition of a narrow (0.04 mT) and a wider (0.28 mT) line with a g -factor ($g = 2.0026$) typical for π -conjugated and aromatic compounds.¹⁵ The concentration of paramagnetic centres in neutral PP corresponds to one spin for several hundreds of monomer rings. The width and intensity of the narrow spectral line are of the activated character, whereas the wider component follows the Curie law. This indicates the existence in neutral PP of two types of paramagnetic centres with different relaxation parameters.

At the same EPR band, doped PP is characterised by an intense single and narrow line ($\sim 0.03 \text{ mT}$) with $g = 2.0028$, which obeys the Curie law in the temperature range 30–300 K.¹⁵ The majority of the results obtained previously indicate that the charge carriers are not responsible for the EPR spectrum of this polymer because there are no correlations between the magnetic susceptibility and the concentration of charge carriers as well as between the line width and the mobility of the carriers. This may be interpreted as a result of the formation of spin-less bipolarons in PP during the doping of the latter. Thus the EPR signal of doped PP cannot yield adequate information about the conduction processes.

The spin probe method, based on the introduction of a stable nitroxyl radical into the test system, may prove more effective in this instance.³⁴ However, hitherto this method has been rarely used in the study of conducting polymers.^{34,35} The reason for this is primarily the fact that the low spectral resolution at $\nu_e \leq 10 \text{ GHz}$ precludes the separate recording of all components of the g - and A -tensors and hence hinders the separate determination of the magnetic parameters of the nitroxyl radicals and the paramagnetic centres localised on the polymer chains, as well as the establishment of the dipole–dipole interaction between different paramagnetic centres. Thus electrochemically synthesised PP, in which the nitroxyl radical was bound covalently to the pyrrole ring, has been investigated.³⁵ However, despite the appreciable concentration of the nitroxyl radicals introduced into the polymer, the 3 cm EPR spectrum of this sample showed no lines corresponding to the spin label.

The spin probe method proved to be more effective in the study of doped PP at the 2 mm EPR band.³⁶

Fig. 4 presents the EPR spectra of 4-carboxy-2,2,6,6-tetramethyl-1-piperidinyloxy (a nitroxyl radical), introduced as the probe and the counterion into a nonpolar model system and PP (electrochemically) simultaneously. The EPR spectrum of the spin-modified PP at the 3 cm band represents a superposition of the lines due to the probe, which is characterised by a rotational correlation time $\tau_c \geq 10^{-7} \text{ s}$, and a superimposed single line due to the paramagnetic centres (R) localised on the chain (Fig. 4a). This superposition of the individual spectra precludes the separate determination of the magnetic resonance parameters of the probe and the radical R in PP and also the analysis of the dipole–dipole broadening of their spectral components.

Figure 4. EPR absorption spectra of 4-carboxy-2,2,6,6-tetramethyl-1-piperidinyloxy (a nitroxyl radical) introduced as a spin probe into frozen (120 K) toluene (dashed line) and conducting polypyrrole (continuous line). Recording band: (a) 3 cm; (b) 2 mm. Fig. (a) illustrates the anisotropic spectrum of the localised paramagnetic centres R as well as the measured magnetic parameters of the probe and the radical R.

The EPR spectrum of the spin-modified polymer systems at the 2 mm band has a higher information content (Fig. 4b). All the canonical components of the nitroxyl probe are fully resolved in the spectrum, which permits the direct determination of the principal values of its g - and A -tensors. Furthermore, in the region of the Z -component of the probe spectrum in PP, the axially symmetrical spectrum of the radical R is recorded with the magnetic parameters $g_{\parallel}^R = 2.00380$, $g_{\perp}^R = 2.00235$, and $\Delta B_{PP} = 0.57 \text{ mT}$.

The form of the spectrum of this radical indicates its localisation on the polymer chain, i.e. charge transfer in PP by spin-less bipolarons, as happens in $\text{PPP}(\text{BF}_4^-)$ and $\text{PT}(\text{BF}_4^-)$. The difference $\Delta g = g_{\parallel}^R - g_{\perp}^R = 1.45 \times 10^{-3}$ corresponds to an excited electronic configuration in R with an excitation energy $\Delta E_{\sigma\pi^*} = 5.1 \text{ eV}$, which is close to the excitation energy of the electron in neutral PPP.

The nitroxyl probe in nonpolar toluene is characterised by the following magnetic parameters: $g_{XX} = 2.00987$, $g_{YY} = 2.00637$, $g_{ZZ} = 2.00233$, $A_{XX} = A_{YY} = 0.6$, and $A_{ZZ} = 3.31 \text{ mT}$. In the conducting PP, the quantity g_{XX} diminishes to 2.00906, whereas both the X - and Y -components of the probe spectrum are broadened by 4 mT (Fig. 4b). Analysis of the form of the probe spectrum permits the conclusion that there are no rapid movements of this radical in PP (correlation time $\tau_c \leq 10^{-7} \text{ s}$) even at comparatively high temperatures, which is apparently associated with the small size of the region of localisation of the probe, not exceeding 1 nm.

In neutral PP there are no fragments with an appreciable dipole moment. The dipole–dipole interactions between the radicals may be neglected, because the concentrations of the probe and the paramagnetic centres localised on the chain are small. The changes in the magnetic-resonance parameters of the probe on passing from the model nonpolar system to the conducting polymer matrix, indicated above, may occur as a consequence of the Coulombic interaction of the active fragment

of the probe and the spin-less charge carriers — bipolarons. The effective electric dipole moment of the bipolaron closest to the probe, calculated from the shift of the g_{XX} component, amounted to $\mu_v = 2.3$ D. The shift of the g_{XX} component of the probe g -factor may be calculated within the framework of the electrostatic interaction of the dipoles of the probe and the bipolaron by means of the following procedure. The potential of the electric field induced by the bipolaron at the location of the probe is defined by the expression³⁷

$$E_d = \frac{kT}{\mu_u} (x \coth x - 1), \quad (5)$$

$$x = \frac{2\mu_u \mu_v}{4\pi\epsilon\epsilon_0 kTr^3},$$

where μ_u is the electric dipole moment of the probe, ϵ and ϵ_0 are dielectric constants for the PP and the vacuum respectively, and r is the distance between the active fragment of the nitroxyl radical and the bipolaron. Using the variation of the increment in the isotropic hyperfine interaction constant for the probe due to the electrostatic field of the microenvironment $\Delta a = 7.3er_{NO}I^{-1}E_d$ (here r_{NO} is the distance between the N and O atoms of the active fragment of the probe and I is the resonance overlap integral for the C=C bond) as well as the relation $\partial g_{XX}/\partial A_{ZZ} = 2.3 \times 10^{-3}$ mT for 2,2,6,6-tetramethyl-1-piperidinyloxyl radicals,^{21–23} it is possible to formulate the following equation for Δg_{XX} :

$$\Delta g_{XX} = 6 \times 10^{-3} \frac{er_{NO}kT}{I\mu_u} (x \coth x - 1). \quad (6)$$

Adopting $\mu_u = 2.7$ D,³⁸ $\mu_v = 2.3$ D, and $r_{NO} = 0.13$ nm,²⁶ we obtain $r = 0.92$ nm.

The rate of spin–spin relaxation, which determines the width of the spectral line of the radical, can be formulated as $\tau_2^{-1} = \tau_{2(0)}^{-1} + \tau_{2(D)}^{-1}$ where $\tau_{2(0)}^{-1}$ is the rate of relaxation of a radical which does not interact with the environment and $\tau_{2(D)}^{-1}$ is the increment in the rate of relaxation due to the dipole–dipole interaction. The characteristic time of such interaction τ_c in a polycrystalline sample may be calculated from the broadening of the spectral lines $\delta(\Delta B_{X,Y})$.³⁹

$$\tau_{2(D)}^{-1} = \gamma_e \delta(\Delta B_{X,Y}) \quad (7)$$

$$= \frac{1}{2} \langle \omega^2 \rangle [3J(0) + 5J(\omega_e) + 2J(2\omega_e)],$$

where

$$\langle \omega^2 \rangle = \frac{1}{5} \left(\frac{\mu_0}{4\pi} \right)^2 \gamma_e^4 \hbar^2 S(S+1) N \sum_{r_0}^N \sum_r^N \frac{(3 \cos^2 \vartheta - 1)^2}{r_1^3 r_2^3},$$

$$J(\omega_e) = \frac{2\tau_c}{1 + \omega_e^2 \tau_c^2}.$$

Here μ_0 is the magnetic permeability of a vacuum, $\hbar = h/2\pi$, $\omega_e = 2\pi\nu_e$ is the recording frequency, and ϑ is the angle between the vectors r_1 and r_2 . The inequality $\omega_e \tau_c \gg 1$ holds for the majority of highly viscous condensed systems, so that, by averaging with respect to the angles $\Sigma \Sigma (3 \cos^2 \vartheta - 1)^2 (r_1^{-3} r_2^{-3}) = 6.8 r^{-6}$ and, using the value $\gamma_e \delta(\Delta B_{X,Y}) = 7 \times 10^8$ s⁻¹ and the value $r = 0.92$ calculated above, we obtain $\tau_{2(D)}^{-1} = \gamma_e \delta(\Delta B_{X,Y}) = 3 \langle \omega^2 \rangle \tau_c$ or $\tau_c = 8.1 \times 10^{-11}$ s. Bearing in mind that the average time between translational hops depends on the diffusion coefficient D and the average length of the hop, which is equal to the product of the lattice constant c_{1D} and the half-width of the spin delocalisation on the charge carrier $N_P/2$, i.e. $\tau_c = 1.5 \langle c_{1D}^2 N_P^2 \rangle D^{-1}$, and, taking into account the value $D \approx 5 \times 10^{-7}$ m² s⁻¹ typical for conducting polymers, we obtain $\langle c_{1D} N_P \rangle = 3$ nm, which corresponds approximately to four pyrrole rings. This quantity is close to the width of the bipolaron

in polypyrrole and polyaniline, but is appreciably smaller than N_P obtained for polybithiophene.⁴⁰

Thus the form of the EPR spectrum of the spin-modified PP, recorded at the 2 mm band, indicates extremely slow rotational motions of the probe, apparently as a consequence of the fairly dense packing of the polymer chains in PP. The interaction of the spin-less charge carriers with the active fragment of the spin probe leads to a redistribution of the spin density between the N and O atoms of the nitroxyl radical and hence to a change in its magnetic-resonance parameters. This makes it possible to determine the distance between the radical and the chain, along which the charge carrier moves, and also the effective length of the bipolaron in a randomly oriented polymeric semiconductor.

V. Polyaniline

A characteristic behaviour of polyaniline (PANI) is known⁴¹ to be the insulator/conductor transition, occurring on protonation or oxidation of the polymer, i.e. on transition from its emeraldine base form (EB form) to the emeraldine salt form (ES form). This compound differs from other conjugated polymers in a number of features. Thus, in contrast to PPP, PT, and PP, both the benzene rings and the nitrogen atoms are involved in conjugation in PANI. On protonation or oxidation, the conductivity of the polymer increases by more than 10 orders of magnitude, whilst the number of electrons on the polymer chain remains unchanged.⁴² Polyaniline in the EB form is an insulator. This form is amorphous and contains traces of the ES form, whereas the ES form of PANI contains highly conducting crystalline domains with a characteristic size of 5 nm¹¹ distributed in the amorphous EB phase.

The oxidation or protonation of the EB form of PANI is accompanied by a monotonic increase in the concentration of paramagnetic centres and a narrowing of the line from 0.2 to 0.05 mT in the 3 cm EPR spectrum.^{28,43} The paramagnetic susceptibility of the weakly conducting PANI follows the Curie law, which indicates the formation of single polarons in the polymer chain, whereas Pauli spins, characteristic of the polaron lattice of a highly conducting polymer, have been detected in the ES form of PANI.^{43,44}

The spin dynamics in PANI has been investigated by the complementary EPR and NMR spectroscopic methods.⁴⁵ The frequency dependences $\tau_{1p} \sim \omega_p^{1/2}$ (for nuclear spins) and $\Delta B_{pp}^{-1} \sim \omega_e^{-1/2}$ (for electron spins), obtained for isolated chains of the ES form of PANI, have been interpreted within the framework of the 1D-diffusion of polarons at a rate $\nu_{1D} > 10^{13}$ s⁻¹. The anisotropy of the spin diffusion ν_{1D}/ν_{3D} varies from 10⁴ in the EB form to 10 in the ES form of PANI at room temperature. The correlation found between the spin dynamics and the charge transfer process has been interpreted as evidence in support of the predominantly interchain electron transport. However, this conclusion conflicts with another concept,^{11,46} which predicts the 3D-transport of electrons in massive metal-like domains with a characteristic size 5 nm and 1D-transport of electrons between these domains. Investigations have shown that the charge transfer process in PANI is determined to a significant extent by structural parameters such as the crystallinity of the sample, the size of the crystalline domains, the conformation and degree of orientation of the chains, etc., which depend on the history of the sample and also on the amount of modifying agent introduced into it.

The results of studies on the magnetic and electrodynamic properties of PANI samples with different conductivities by 2 mm EPR spectroscopy are presented below.^{18,47}

Fig. 5 presents the 2 mm EPR spectra of the initial and oxidised PANI samples. Analysis of these spectra showed that at least two types of paramagnetic centres were stabilised in the initial sample, namely an immobilised paramagnetic centre (R¹) (Fig. 5a) with the anisotropic magnetic-resonance parameters $g_{XX} = 2.00535$, $g_{YY} = 2.00415$, $g_{ZZ} = 2.00238$, $A_{XX} = A_{YY} = 0.33$, and $A_{ZZ} = 2.3$ mT, and a more mobile paramagnetic centre (R²) with $g_{\perp} = 2.00351$ and $g_{\parallel} = 2.00212$. The relative

Figure 5. Typical 2 mm EPR absorption spectra (a, d) and the in-phase (b) and $\pi/2$ out-of-phase (c) components of the dispersion signal of neutral (a–c) and oxidised ($z = 0.53$) (d) polyaniline recorded at $T = 300$ K. The dashed lines represent the absorption spectrum of the radical R^1 (a) localised on the chain and the $\pi/2$ out-of-phase component of the dispersion signal of the neutral sample at $T = 200$ K (c).

concentrations of these radicals N_i depend both on the degree of oxidation and on the temperature of the sample (Fig. 6a). The concentrations of paramagnetic centres of both types increase with increasing z (Table 4), which can be accounted for by an increase in the number of spin charge carriers and by the formation of a polaron lattice in PANI for $z \geq 0.3$.

The paramagnetic centre R^1 with an anisotropic EPR spectrum can be attributed to the radical species $(-C_6H_4-NH-C_6H_4-)^{\cdot}$ localised on the polymer chain. Its magnetic parameters differ somewhat from those of the structurally similar radical $-C_6H_4-\dot{N}-C_6H_4-$.²⁶ This is apparently associated with a lower degree of localisation of the unpaired electron on the nitrogen atom ($\rho_N^{\pi} = 0.39$) and with a more planar conformation of the latter radical. The contribution of the CH groups of the radical to g_{XX} is small ($g_{XX} \approx 1.7 \times 10^{-5}$, see Buchachenko and Vasserman²⁶), so that it can be neglected. The energies of the excited electronic configurations of the radical R^1 are $\Delta E_{n\pi^*} = 3.8$ eV and $\Delta E_{\sigma\pi^*} = 6.5$ eV for $\rho_N^{\pi} = 0.61$.⁴⁸

The averaged g -factor of the radicals R^1 ($\langle g \rangle = \frac{1}{3}(g_{XX} + g_{YY} + g_{ZZ})$) is close to the isotropic g -factor R^2 ($\langle g \rangle = \frac{1}{3}(2g_{\perp} + g_{\parallel})$) for the paramagnetic centres R^2 . The polaron diffusing along the polymer chain at an effective rate $v_{1D}^0 \geq 10^9$ s⁻¹ [see Eqn (2)] may therefore be responsible for the EPR spectrum of the radical R^2 .

During the oxidation of the initial PANI sample, the perpendicular component of the EPR spectrum becomes monotonically narrower and the paramagnetic susceptibility increases (Table 4) before the attainment of the degree of oxidation $z = 0.53$, which constitutes additional evidence for the formation in the highly conducting PANI of regions with a high spin density and rapid spin–spin exchange. This fact as well as the decrease in the g -factor for the radical R^2 with increase in z may be associated with the decrease in the spin density on the nucleus of the nitrogen atom and the change in the conformation of the polymer chains. The C–N–C bond angle in PANI is known¹¹ to increase by 22° on passing from the EB to the ES form. Calculation shows that this may alter g_{\perp} only by several per cent. A more significant change in this magnetic parameter is induced by a change in the dihedral angle θ , i.e. the angle between the planes of neighbouring benzene rings. Taking into account the dependence of the overlap integral of the p_z orbitals of the nitrogen atoms and the carbon atom of the PANI benzene ring in the *para*-position relative to the

Figure 6. Temperature variations of the relative concentration N_1/N (a) and the g_{XX} -factor (b) of the paramagnetic centres R^1 localised in polyaniline with different degrees of oxidation z : (1) and (1') 0; (2) and (2') < 0.01 ; (3) and (3') 0.02; (4) and (4') 0.2.

Table 4. Dependence of the electrical conductivity (σ_{dc}), the critical temperature (T_0), the Pauli susceptibility (χ_p), the density of states at the Fermi level [$n(\epsilon_F)$], the distance between the polaron level and the Fermi level (A_3), the polaron localisation length (L), the concentration of

paramagnetic centres (N), the line width (ΔB_{PP}), and the spin-spin relaxation time (τ_2) for polyaniline samples at $T = 300$ K on their degree of oxidation z .

^a The values of A_3 were calculated by the formula $A_3 = 0.5 \hbar^2 (3\pi^2 N)^{2/3} m_e^{-1}$. ^b The times τ_2 were calculated by the formula $\tau_2^{-1} = 0.866 \gamma_e \Delta B_{PP}$.

nitrogen atom on the dihedral angle ($I \sim \cos \theta$)¹³ and assuming that $\theta = 56^\circ$ for the initial EB,⁴⁹ it is possible to calculate the effective dihedral angle and the spin density on the nitrogen atom in the ES form of PANI with $z = 0.2$, which are respectively $\theta = 33^\circ$ and $\rho_N^* = 0.42$. The decrease in the angle θ leads to an increase in the transfer integral and hence to a greater delocalisation of the unpaired electron over the benzene rings. Thus the change in the magnetic parameters on oxidation of PANI reflects the transition to a more planar chain conformation.

It is important to note that the shape of the EPR spectrum of the radical R^2 in the ES form of PANI with $z = 0.2$ undergoes major change at 300 K. Whereas the inequality $g_\perp > g_\parallel$ is valid for this sample when $z < 0.2$ and $T \leq 300$ K, the inequality $g_\parallel > g_\perp$ actually holds when $z = 0.2$ and $T \geq 300$ K (Fig. 5). The latter inequality remains unaltered for $z \geq 0.2$ in the temperature range $90 \leq T \leq 330$ K. We recorded a similar transformation of the spectrum previously⁵⁰ on saturation of a PANI sample with water vapour and explained it by a significant change in the conformation of the radical R^2 as a consequence of the formation of H_2O bridges between the polymer chains. On the other hand, in the case described the change in line shape can be accounted for by the transformation of the polymer chains.

The components of the hyperfine structure, arising as a consequence of the interaction of the unpaired electron with the protons of the neighbouring benzene rings, have also been recorded in the EPR spectra of PANI samples with $z \geq 0.3$. The isotropic hyperfine interaction constant a_H is correlated with z and varies in the range 5.0–9.6 μT for different samples, which corresponds to a spin density $\rho_H^* = (2.2-4.3) \times 10^{-3}$. The density of the unpaired electron delocalised over two benzene rings in a solution of the EB form of PANI in dioxane is $\rho_H^* = 1.5 \times 10^{-2}$.⁴⁸ The data obtained therefore indicate the delocalisation of the unpaired electron over a larger number of benzene rings owing to the more planar conformation of the ES samples investigated.

Bell-like components with a Gaussian distribution of the spin packets (Figs 5b and 5c), the intensity and shape of which depend on the amplitude B_m and the frequency ω_m of the high-frequency modulation, the amplitude of the magnetic component of the radiofrequency field B_1 , and also on the spin-spin (τ_1) and spin-lattice (τ_2) relaxation times of the paramagnetic centres, have been recorded in the 2 mm EPR spectra of PANI samples. The appearance of such signals is induced by the effect associated with the rapid adiabatic passage of an inhomogeneously broadened line,²⁷ which may be accounted for as follows.

The shape of an individual spin packet in PANI is determined by the time parameters τ_1 , τ_2 , $(\gamma_e \Delta B_{PP})^{-1}$, ω_m^{-1} , $(\gamma_e B_m)^{-1}$, $(\gamma_e B_1)^{-1}$, and $B_1(dB_0/dt)^{-1}$. The distance between the spin packets which have moved apart is $\Delta\omega_{ij}$ and varies linearly with the recording frequency. On transition to stronger magnetic fields, the frequency ν_{ex} of the spin exchange between the paramagnetic centres with $S = -\frac{1}{2}$ and $g \approx 2$, separated by a distance r , decreases in accordance with the law⁵¹

$$\nu_{ex} \sim \frac{4\mu_B^2}{r^3} \exp\left[\frac{-0.25B_0^2 r^6}{\mu_B^2}\right],$$

as a consequence of which the interaction between the spin packets diminishes and their width begins to depend on the recording frequency.⁵²

$$\Delta B_{PP} = \Delta B_{PP}^0 + \frac{\Delta\omega_{ij}^2}{8\nu_{ex}}. \quad (8)$$

In the adiabatic passage of a saturated signal [i.e. when $\gamma_e \omega_m B_m \ll \gamma_e^2 B_1^2$ and $s = \gamma_e B_1 (\tau_1 \tau_2)^{1/2} \geq 1$, where s is the EPR signal saturation factor], a stationary trajectory of the paramagnetic centre magnetisation vector is established and the succeeding signal projections, for example the dispersion U ,⁵³ with the shape function $g(\nu_e)$ are recorded on the Z , $-Z$, and $-X$ axes.

$$U = u_1 g'(\nu_e) \sin(\omega_m t) + u_2 g(\nu_e) \sin(\omega_m t - \pi) + u_3 g(\nu_e) \sin(\omega_m t \pm \frac{1}{2}\pi). \quad (9)$$

The inequality $\omega_m \tau_1 > 1$ is obtained for the EB form of PANI, so that the dispersion signal is determined mainly by the last two terms of Eqn (9). In this case the relaxation times may be determined from the central amplitude of these components by means of the following formulae:⁵⁴

$$\tau_1 = \frac{3\omega_m(1 + 6\Omega)}{\gamma_e^2 B_{10}^2 \Omega(1 + \Omega)}, \quad (10a)$$

$$\tau_2 = \frac{\Omega}{\omega_m}, \quad (10b)$$

where $\Omega = u_3 u_2^{-1}$ and B_{10} is the value of B_1 for $u_1 = -u_2$.

In the EPR spectra of the ES form of PANI, the passage effects are less appreciable and the relaxation times can therefore be calculated from the formulae⁵⁴

Figure 7. Temperature variations of the effective spin–lattice (τ_1) (curves 1–3) and spin–spin (τ_2) (curves 1'–4') relaxation times of the paramagnetic centres in polyaniline with different degrees of oxidation z : (1) 0; (2) < 0.01; (3) 0.02; (4) 0.2.

$$\tau_1 = \frac{\pi u_3}{2\omega_m u_1}, \quad (11a)$$

$$\tau_2 = \frac{\pi u_3}{2\omega_m(u_1 + 11u_2)}. \quad (11b)$$

Fig. 7 presents the temperature variations of the effective relaxation times of the paramagnetic centres in different PANI samples. Evidently the spin–lattice relaxation time diminishes with increase in z , which indicates an increase in the number and size of the quasi-metallic domains in the ES form of PANI. It also follows from the figure that a temperature dependence of the type $\tau_1^{-1} \sim NT^l$, where $l=3-4$ for $z \leq 0.02$ and $l=0.3$ for $0.02 < z \leq 0.20$, is characteristic of PANI, which is a consequence of the sharp change in the rate of energy transfer from the spin ensemble to the polymer lattice and a change in the mechanism of charge transport during the oxidation of PANI.

The times τ_1 and τ_2 are effective and are determined by the relaxation times of the localised and mobile paramagnetic centres — the radicals R^1 and R^2 at the concentrations N_1 and N_2 respectively — so that for the general case one can write

$$N\tau_{1,2}^{-1} = N_1(\tau_{1,2}^{-1})_{\text{loc}} + N_2(\tau_{1,2}^{-1})_{\text{mob}}, \quad (12)$$

where $N = N_1 + N_2$. This equation permits the separate determination of the relaxation parameters of the trapped and mobile paramagnetic centres in the polymer.

We shall now consider the possibility of using the 2 mm EPR spectroscopic method for the investigation of the dynamics of the polymer chains in PANI and other conducting polymers in which the paramagnetic centres exhibit an appreciable anisotropy of the magnetic parameters. It is seen from Fig. 6b that the quantity g_{XX} for the radical R^1 depends in a complex manner on the degree of oxidation z and the temperature of PANI. The decrease in this parameter with increase in z and/or temperature may be explained both by the increase in the polarity of the microenvironment of the radical R^1 and by the acceleration of the small-scale vibrations of the polymer chain and hence of the radical localised on the latter. The motions of the macromolecules in this and other similar polymers are anisotropic and are characterised by a correlation time $\tau_c \geq 10^{-7}$ s.^{34,55} The 'linear' EPR absorption spectra are usually insensitive to superslow motions and such molecular processes are therefore better investigated by the RF-saturation transfer method (ST-EPR).⁵⁶

Figure 8. Arrhenius plot for the correlation times τ_c of the anisotropic librations of the polymer chains in the EB form of polyaniline with the degree of oxidation $z = 0$.

The ST-EPR method is based on the introduction into the test system of a nitroxyl label or probe and the recording of the spectrum of this radical under the conditions of the rapid passage of the saturated signal. On rotation of the paramagnetic centres, the above conditions may not be fulfilled for spin packets oriented in a particular way relative to the direction of the external magnetic field, as a result of which the form of the overall spectrum changes. It had been shown earlier²³ that the parameter most sensitive to the anisotropy of the molecular dynamics is the ratio of the components of the derivative of the dispersion signal, $K_{\text{mov}} = u_3^X/u_3^Y$, $\frac{1}{2}\pi$ out-of-phase. The sensitivity of the ST-EPR method also depends on the anisotropy of the magnetic parameters of the paramagnetic centres and on the recording frequency.⁵⁶ Bearing in mind that the paramagnetic centres localised on the polymer chain are themselves paramagnetic labels and are characterised by an appreciable anisotropy of the magnetic parameters, one may expect an increase in the effectiveness of this method in the study of conducting compounds at the 2 mm EPR band.

As can be seen from Fig. 5c, the parameter K_{mov} increases with increase in the temperature of the sample. This is a result of the anisotropic librational reorientations of the pinned polarons around the specified X axis of the polymer chains. The correlation time for the librations of the chains, calculated from the ST-EPR spectra by the method described by the present author,²¹⁻²³ was found to be given by the following expression for the initial PANI sample:

$$\tau_c = 2.4 \times 10^{-7} \exp\left(\frac{0.046}{kT}\right) \text{ s},$$

in the temperature range $200 \leq T \leq 90$ K (Fig. 8). At higher temperatures, the correlation time varies in accordance with the law

$$\tau_c(T) = 61.1 \exp\left[-\left(\frac{T_0}{T}\right)^{1/4}\right] \text{ s},$$

where

$$T_0 = \frac{18.1}{kn(\epsilon_F)L^3} = 1.5 \times 10^7 \text{ K}.$$

Here T_0 is the percolation constant, which depends on the density of states $n(\epsilon_F)$ on the Fermi level ϵ_F and L is the charge carrier localisation length. Using $n(\epsilon_F) = 4.5 \times 10^{-2} \text{ eV}^{-1} \text{ mol}^{-1}$, it is possible to obtain the polaron localisation length in neutral PANI, which is 0.53 nm, and the most probable length of the 3D-hop of the polaron between the chains $R = 0.39L(T_0/T)^{1/4} = 3.1 \text{ nm}$ at

$T = 300$ K. The data obtained indicate a close relation between the molecular spin dynamics in the EB form of PANI. With increase in τ_c or with significant decrease in B_1 , the ST-EPR spectrum becomes insensitive to the molecular dynamics and in this case $K_{\text{mov}} \approx 0.07$. The maximum value of τ_c recorded at the 2 mm EPR band can be estimated from these data as $\sim 10^{-4}$ s at 90 K.

We shall now consider the dynamic parameters of the polaron in PANI. As in the case of a mobile soliton in *trans*-polyacetylene,²⁴ the diffusion of the polaron along the polymer chain is characterised by a translational propagator of motion $P_{\text{tr}}(r, r_0, \tau)$. This quantity determines the probability at a time $t = \tau$ that the i th spin is located in the region $r + dr$ relative to the new position of the j th spin, which was located in the initial instant at the point r_0 relative to the i th spin.

On solving the equation for Brownian diffusion

$$\frac{\partial P_{\text{tr}}(r, r_0, \tau)}{\partial \tau} = \mathbf{D}_{\text{tr}} \Delta P(r, r_0, \tau), \quad (13)$$

we find the propagator for a diffusing polaron subject to the initial condition $P_{\text{tr}}(r, r_0, \tau) = \delta(r_0 - r)$, where $\mathbf{D}_{\text{tr}} = [D_i]$ and i is the unit vector for the molecular coordinate system. For a 1D-system, the above propagator is defined explicitly by the relation³⁹

$$P(r, r_0, \tau)_{1D} = (4\pi v_{1D}\tau)^{1/2} \exp\left[-\frac{(r-r_0)^2}{4v_{1D}\tau}\right] \exp(-v_{3D}\tau). \quad (14)$$

The mobile polaron induces a local magnetic field $B_{\text{loc}}(t)$ at the location of other electron or nuclear spins, influencing thereby the relaxation times of the latter. The relaxation time can therefore be expressed in terms of the frequency function $\tau_{1,2} = f[J(\omega)]$, where

$$J(\omega) = \int_{-\infty}^{+\infty} G(\tau) \exp(-i\omega\tau) d\tau.$$

Here $J(\omega)$ is the spectral density function. The autocorrelation function of a local field $B_{\text{loc}}(t)$ fluctuating in a discrete system is

$$G(\tau) = c_{1D} \sum_{r_0} \sum_r A(r_0, t) P(r, r_0, \tau) F(r_0) F^*(r) dr_0 dr, \quad (15)$$

where $A(r, t)$ is the probability that the spin is at a distance r at time t and is equal to the spin concentration N , while $F(r)$ is the probability that two spins are at a distance r at time t . For frequencies $\omega \ll v_{1D} c_{1D}^2 (r - r_0)^{-2}$ the spectral density function assumes the form:⁵⁷

$$J(\omega) = N J_{1D}(\omega) \sum \sum F(r_0) F^*(r) f_{1D}(|r - r_0|), \quad (16)$$

where $N = N_1 + (1/\sqrt{2})N_2$ is the probability that in the initial instant the spin is in the position r_1 , $J_{1D}(\omega) = (2\pi v_{1D} v_e)^{-1/2}$ for $v_{3D} \ll v_e \ll v_{1D}$ and $J_{1D}(\omega) = (2\pi v_{1D} v_{3D})^{-1/2}$ for $v_{3D} \gg v_e$, $F(r_0) F^*(r) f_{1D}(|r - r_0|) = (3\cos^2 \vartheta - 1)^2 r_1^{-3} r_2^{-3}$, and ϑ is the angle between the vectors r_1 and r_2 .

The relaxation times of the paramagnetic centres in PANI are characterised by the relation $\tau_{1,2} \sim N\omega_e^{1/2}$,^{45,48} so that the experimental results presented in Fig. 7 may be interpreted within the framework of the modulation of the spin relaxation of the 1D-diffusion of a polaron and its interchain hopping 3D-transfer at rates v_{1D} and v_{3D} respectively. Since the electron relaxation is determined mainly by the dipole-dipole interaction between equivalent electron and nuclear spins, it follows subject to the condition $S = I = \frac{1}{2}$, that the equations for the rate of relaxation³⁹ in the polycrystalline sample can be more simply formulated:

$$\begin{aligned} \tau_1^{-1} &= \langle \Delta\omega^2 \rangle [J(\omega_e) + 4J(2\omega_e)] \\ &= 1.16 \times 10^{-43} N (v_{1D})^{-1/2} \sum \sum_i, \end{aligned} \quad (17a)$$

Figure 9. Temperature variations of the rates of diffusion of the polarons along the chain (v_{1D}) and between the chains (v_{3D}) in polyaniline with the degrees of oxidation $z = 0$ (1), < 0.01 (2), and 0.02 (3) and also of the electrical conductivity σ_{ac} calculated within the framework of the isoenergetic (continuous lines) and activated (dashed lines) interchain charge transfer. The horizontal line corresponds to the effective value v_{3D} calculated by Eqns (16) and (17) subject to the condition $\tau_1 \approx \tau_2$ for polyaniline with $z \geq 0.3$.

$$\tau_2^{-1} = \frac{1}{2} \langle \Delta\omega^2 \rangle [3J(0) + 5J(\omega_e) + 2J(2\omega_e)] \quad (17b)$$

$$= 4.13 \times 10^{-38} (v_{1D})^{-1/2} [(v_{3D})^{-1/2} + 2.28 \times 10^{-6}] \sum \sum_i,$$

where $\sum \sum_i$ is the lattice sum equal to $1.21 \times 10^{57} \text{ m}^{-6}$ for PANI.

Fig. 9 presents the temperature variations of the rates of diffusion v_{1D} and v_{3D} of the paramagnetic centres in certain PANI samples under the conditions of spin delocalisation over five monomer units. Evidently the anisotropy of the spin dynamics is a maximum in the initial sample (EB form) and diminishes with increase in the degree of oxidation z . For comparatively high degrees of oxidation ($z \geq 0.2$), the times τ_1 and τ_2 are approximately equal and depend only slightly on temperature in view of the intense spin-spin exchange in the metal-like domains and the increased dimensionality of the system. Bearing in mind that $\tau_2^{-1} \approx \tau_1^{-1}$ it is possible to calculate v_{3D} . It proved to be $1.6 \times 10^{12} \text{ s}^{-1}$ for PANI samples with $z \geq 0.2$ (Fig. 9). The calculated values of v_{1D} are significantly smaller than the rate of 1D-diffusion of the polaron, obtained for PANI by magnetic-resonance methods in weak recording fields.⁴⁵

It had been shown earlier⁴⁵ that the anisotropy of the spin diffusion in PANI at room temperature remains fairly high up to $z = 0.6$, but it follows from Fig. 9 that the ratio v_{1D}/v_{3D} remains fairly high only in neutral and weakly oxidised samples. The dimensionality of PANI increases on oxidation as a result of the intensification of the interaction between the polymer chains, so that the spin diffusion in this polymer becomes almost isotropic for $z \geq 0.2$, which is characteristic of classical 3D-semiconductors. This finding constitutes unambiguous evidence for the formation of massive quasi-metallic domains in the oxidised polymer and for the increase in its dimensionality and crystallinity, which we confirmed in an X-ray diffraction study of PANI.⁴⁷ During the oxidation of the polymer, the concentration of electron traps diminishes, which decreases the probability of the scattering of electrons by lattice phonons and hence leads to a weaker temperature dependence of the relaxation and dynamic parameters of the charge carriers in PANI, as happens in classical inorganic amorphous semiconductors.⁵⁹

If one assumes that the diffusion coefficients D of the spin and diamagnetic charge carriers are identical, it is possible to obtain from Eqn (4) the quantity σ_{1D} , which is 10 S m^{-1} for the sample with $0 \leq z \leq 0.02$ at room temperature whereas σ_{3D} increases in this range of z from 1.0×10^{-3} to 0.5 S m^{-1} . Subject to the condition $v_{1D} \approx v_{3D}$, these quantities are $\sigma_{1D} = (5-18) \times 10^3$ and $\sigma_{3D} = (3-10) \times 10^3 \text{ S m}^{-1}$. Thus the rate of the interchain charge transfer increases with increase in z , which constitutes additional confirmation of the increase in the number and size of the quasi-metallic 3D-domains in PANI.

As in other quasi-one-dimensional polymeric semiconductors, different charge transfer processes may occur in PANI, such as charge transfer along a π -conjugated chain as well as the inter-chain and interfibrillar charge transfer. Evidently the contribution of each of these processes to the bulk conductivity depends on the method of synthesis, structure, and degree of oxidation of the polymer and also on the dynamics of the nonlinear excitations.

The data obtained at the 2 mm EPR band permit a more correct and fuller determination of the mechanism of the charge transfer in PANI. As shown above, the EB form of PANI exhibits a strong temperature dependence of the spin-lattice relaxation time. This means that the hops of the unpaired electron in PANI are accompanied by the absorption or emission of a minimal number of polymer lattice phonons. Since the linkage between the spin and the lattice in the EB form of PANI is fairly strong, multiphonon charge transfer processes predominate in this system. The approach proposed for the description of the motion of solitons in lightly doped *trans*-PA may therefore be used in the study of the spin dynamics in the amorphous regions of PANI.⁶⁰

The essential feature of this approach consists in the phonon-linked interchain tunnelling of the charge between isoenergetic levels of the carriers under the conditions of Coulombic interaction of a soliton with a charge q_1 and an ion with the opposite charge q_2 . The excess charge $\Delta q = q_1 - q_2$ may undergo a phonon-linked transfer, with a finite probability, to a neutral carrier moving along a neighbouring polymer chain. If in the instant of such transfer the charge carrier is also in the vicinity of the ion, then its energy before and after charge transfer remains unchanged. In this case, the components of the electrical conductivity of the polymer, in which the charge is transferred between soliton levels, are determined by the probability that the soliton is located near a charged ion and also by the probability that the energies of the charge carriers are within the limits of kT ,

$$\sigma_{dc} = \frac{k_1 e^2 \dot{\gamma}(T) \xi N_0}{k T R_0} \exp\left(-\frac{2k_2 R_0}{\xi}\right) = \sigma_0 T^n, \quad (18a)$$

$$\begin{aligned} \sigma_{ac} &= \frac{e^2 N_i^2 N_0 \xi_{\parallel}^2 \xi_{\perp}^2 v_e}{384 k T} \left[\ln \frac{2v_e}{N_0 \gamma(T)} \right]^4 \\ &= \sigma_0 v_e T^{-1} \left[\ln \frac{k_3 v_e}{T^{n+1}} \right]^4, \end{aligned} \quad (18b)$$

where $k_1 = 0.45$, $k_2 = 1.39$, and k_3 are constants, $\gamma(T) = \gamma_0 (T/300)^{n+1}$ is the hopping frequency of the charge carrier, $\xi = (\xi_{\parallel} \xi_{\perp}^2)^{1/3}$, ξ_{\parallel} and ξ_{\perp} are the averaged parallel and perpendicular lengths of the charge carrier respectively, $N_0 = N_n N_{ch} (N_n + N_{ch})^{-2}$ (N_n and N_{ch} are the numbers of the neutral and charged carriers per monomer unit respectively), and $R_0 = [(4/3) \pi N_i]^{-1/3}$ is the typical distance between ions at a concentration N_i . The above temperature variations have been obtained experimentally for lightly doped *trans*-PA^{61,62} and other conducting polymers.^{63,64} It can be shown that, within the framework of the approach considered, the following relation is valid:

$$\frac{\sigma(v_e \rightarrow \infty)}{\sigma(v_e \rightarrow 0)} = \frac{\exp(1.9k_1)}{k_1^4}, \quad (19)$$

where $k_1 = (0.4\pi N_i \xi_{\parallel} \xi_{\perp}^2)^{-1/3}$ is a constant. Calculation showed that $\sigma_{ac}/\sigma_{dc} \approx 130$ for PANI at $v_e = 140 \text{ GHz}$.

It is essential to note that the approach described is valid in the case of charge transfers by carriers with a small radius such as solitons. This approach may also be used for the interpretation of the spin dynamics in other conjugated polymers,⁶⁴ for example in tetrathiafulvalene (see below), where charge transfer is effected by nonlinear excitations with a small radius.⁶⁵ Apparently it can also be used for the interpretation of the spin dynamics in PANI when there are N_n polarons with a charge q and N_{ch} bipolarons with a charge $2q$ in this polymer.

Fig. 9 presents the temperature dependence of the electrical conductivity σ_{ac} calculated from Eqn (18b) by using $n = 12.9$ and $\sigma_0 = 2.8 \times 10^{-12} \text{ S m}^{-1} \text{ s K}$ for the initial sample in the EB form and $n = 12.6$ and $\sigma_0 = 8.8 \times 10^{-14} \text{ S m}^{-1} \text{ s K}$ for the sample with $0.02 \geq z \geq 0$, as well as $k_3 = 1 \times 10^{24} \text{ s K}^{n+1}$. A satisfactory agreement of the experimental $v_{1D}(T)$ and theoretical $\sigma_{ac}(T)$ relations obtained for these samples follows from the figure. Bearing in mind that the conductivity of PANI obeys the law $\sigma_{dc}(T) \sim T^a$ ($a = 12-20$) for a low oxidation level,⁴⁷ one may conclude that the charge transfer mechanism considered operates in PANI with $z \leq 0.02$.

An appreciable temperature dependence of σ_{ac} may also be observed on thermal activation of the charge carriers with an energy E_a for activation from their energy level located in the gap to the conductivity band. In this case the conductivities σ_{dc} and σ_{ac} can be determined from the equations⁶¹

$$\sigma_{dc} = \sigma_0 \exp\left(-\frac{E_a}{kT}\right), \quad (20a)$$

$$\sigma_{ac} = \sigma_0 v_e^\gamma T \exp\left(-\frac{E_a}{kT}\right), \quad (20b)$$

where γ is a constant which varies in the range $0.3 < \gamma < 0.8$ depending on the dimensionality of the system. Indeed the $v_{3D}(T)$ relations can be fitted by the function $\sigma_{ac}(T)$ calculated from Eqn (20b) with $\gamma = 0.8$ and $\sigma_{ac}^0 = 3.2 \times 10^{-18} \text{ S m}^{-1} \text{ s}^{0.8} \text{ K}^{-1}$ and $E_a = 0.06 \text{ eV}$ at $T \leq 240 \text{ K}$ or $\sigma_{ac}^0 = 9.1 \text{ S m}^{-1} \text{ s}^{0.8} \text{ K}^{-1}$ and $E_a = 0.9 \text{ eV}$ at $T \geq 240 \text{ K}$ for the sample in which $z = 0$ and with $\sigma_{ac}^0 = 1.4 \times 10^{-11} \text{ S m}^{-1} \text{ s}^{0.8} \text{ K}^{-1}$ and $E_a = 0.13 \text{ eV}$ for samples in which $0.02 \geq z > 0$ (Fig. 9). However, the function $\sigma_{dc}(T)$ for the initial sample has a higher slope than should follow from Eqn (20b). Therefore the activation mechanism of charge transfer can apparently be realised in a polymer with an intermediate degree of oxidation.

The temperature dependence of the electrical conductivity of PANI with $z \geq 0.2$ obeys the law $\sigma_{dc} = \sigma_0 \exp[-(T_0/T)^{1/2}]$.⁴⁷ This is evidence for charge transfer in the oxidised PANI within the framework of the variable range hopping model.⁶⁶ In this case, one can write for the components of the electrical conductivity of a system with a dimensionality d

$$\sigma_{dc} = 0.39 v_0 e^2 \left[\frac{n(\epsilon_F) L}{k T} \right]^{1/2} \exp\left[-\left(\frac{T_0}{T}\right)^{1/(d+1)}\right], \quad (21a)$$

$$\sigma_{ac} = \frac{2}{3} \pi^2 e^2 k T n^2(\epsilon_F) L^5 v_e \left[\ln \frac{v_0}{v_e} \right]^4, \quad (21b)$$

where v_0 is the limiting hopping frequency approximately equal to the frequency of the optical lattice phonon ($v_{ph} \sim 10^{13} \text{ s}^{-1}$).

Using the experimental values of $n(\epsilon_F)$ and the $\sigma_{dc}(T)$ relations, it is possible to determine $v_0 = 3.2 \times 10^{13} \text{ s}^{-1}$. Table 4 presents the constants L , T_0 , and Δ_3 for different PANI samples. It follows from the data presented that the polaron localisation length is approximately equal to the coherence length for the crystalline domains in the ES form of PANI,¹¹ which indicates the 3D-delocalisation of electrons in these regions.

In PANI with $z = 0.53$, charge is transferred between crystalline quasi-metallic domains with a characteristic size 6.8 nm (Table 4), located at a distance $R = 0.25L(T_0/T)^{1/2} = 4.2 \text{ nm}$

($T = 300$ K). The domain consists of polymer chains rolled as a bundle in which the 3D-electron transfer predominates and intense spin-spin exchange takes place. The appearance of a Dyson-like line was recorded in the EPR spectrum of the sample as a consequence of the increase in its conductivity (Fig. 5). Assuming that the characteristic size of the particles is $r_0 \approx 2 \times 10^{-6}$ m, it is possible to calculate the alternating current electrical conductivity of the polymer at room temperature: $\sigma_{ac} = 2.5 \times 10^5 r_0^{-2} v_e^{-1} = 4.5 \times 10^5$ S m $^{-1}$. Next, the constants T_0 and L for an individual domain ($T_0 = 2100$ K and $L = 2.5$ nm) may be determined from Eqn (21b). 3D-Hopping of the polarons takes place within the limits of the domain at a rate $v_{3D} = 1.6 \times 10^{12}$ s $^{-1}$ over a distance $R = 0.39L(T_0/T)^{1/4} = 1.6$ nm at $T = 300$ K. The latter value exceeds significantly the interchain distance as a consequence of the structural disorder in the crystalline domains. The rate of the 1D-diffusion of the polaron at room temperature, determined from the line width of the 3 cm EPR spectrum, is $v_{1D} = 2.0 \times 10^{12}$ s $^{-1}$. The similarity of the rates of diffusion of the polaron along polymer chains and between the chains confirms the quasi-three-dimensional isotropic diffusion of the spin charge carrier in the oxidised polymer. The rate of charge transfer in the vicinity of the Fermi level proved to be $v_F = (2A_2 m_e^{-1})^{1/2} = 4.6 \times 10^5$ m s $^{-1}$.

Thus the 2 mm EPR spectroscopic data obtained confirm the existence in PANI of highly conducting domains dispersed in the amorphous EB phase. On oxidation of the polymer, the number and size of such domains increase and there is also an increase in the dimensionality of the system. This process is accompanied by an increase in the number of Pauli charge carriers and also by an increase in the concentration of polarons. The transition from the EB to the ES form of PANI leads to an increase in the rates of relaxation and electrodynamic processes and to a change in the mechanism of charge transport in the polymer. In the oxidised sample with $z \geq 0.3$, the concentration of paramagnetic centres is approximately equal to the concentration of charge carriers. This permits the conclusion that there is 1D-charge transfer between the quasi-metal domains and 3D-charge transfer in the polaron lattice of these domains by polarons with a small radius in the ES form of PANI.

VI. Polytetrathiafulvalene

The 3 cm EPR spectra of powder-like polytetrathiafulvalene samples, in which the monomer TTF units are linked by phenyl (PTTF-1) or tetrahydroanthracene (PTTF-2) bridges, represents a superposition of the strongly anisotropic spectrum of immobilised paramagnetic centres with $g_{xx} = 2.0147$, $g_{yy} = 2.0067$, and $g_{zz} = 2.0028$ and the almost symmetrical spectrum of mobile polarons with $g = 2.0071$.^{18, 67, 68} The relatively high value of the g -tensor of the radicals indicates an appreciable interaction of the unpaired electron with the sulfur atom nucleus. The spin-lattice relaxation time of the neutral PTTF-1 sample exhibits a temperature dependence of the type $\tau_1 \sim T^{-\alpha}$, where $\alpha \approx 2$ at $100 < T < 150$ K and $\alpha = 1$ at $150 < T < 300$ K.^{67, 68} Doping or heating of the matrix leads to the appearance of a large number of mobile paramagnetic centres and a change in their magnetic and relaxation parameters as a consequence of the conversion of the bipolarons into paramagnetic polarons. However, owing to the low spectral resolution, it proved impossible to analyse using the 3 cm EPR spectra the influence of the relaxation and dynamic parameters of the initial paramagnetic centres on the conducting properties of PTTF in greater detail.

The nature, composition, and dynamics of various paramagnetic centres in the initial and iodine-doped PTTF samples were investigated in greater detail at the 2 mm EPR band.^{18, 23, 69}

Figs 10a and 10c present the EPR absorption spectra of PTTF, from which it is possible to determine more accurately all the components of the g -tensor and also to identify the lines attributed to different paramagnetic centres. Computer simulation demonstrated the presence in PTTF of two types of

Figure 10. Typical 2 mm EPR absorption spectra (a, c) and also the spectra of the in-phase (b) and $\pi/2$ out-of-phase (d) components of the dispersion signals of the initial (a) and doped (c) polytetrathiafulvalene samples recorded at $T = 300$ K (1) and $T \leq 150$ K (2). The measured magnetic parameters are indicated.

paramagnetic centres with temperature-independent components of the g -tensors. The anisotropic spectrum of PTTF-1 is characterised by the magnetic parameters $g_{xx} = 2.01424$, $g_{yy} = 2.00651$, and $g_{zz} = 2.00235$, whereas the paramagnetic centres with an almost symmetrical spectrum are recorded with $g^p = 2.00706$. The principal values of the g -tensor of the paramagnetic centres localised in PTTF-2 are $g_{xx} = 2.01292$, $g_{yy} = 2.00620$, and $g_{zz} = 2.00251$, while the paramagnetic centres with a weakly asymmetric spectrum are characterised by the parameters $g_{||}^p = 2.00961$ and $g_{\perp}^p = 2.00585$. The ratio of the paramagnetic centres with different forms of the spectrum is 1 : 1.8 for PTTF-1 and 3 : 1 for the neutral PTTF-2.

Since the average g -factors (g) for both types of paramagnetic centres are approximately equal, one may conclude that, as in other conducting polymers, there are in PTTF paramagnetic centres with different mobilities, namely polarons diffusing along polymer chains at a rate $v_{1D}^0 \geq 5 \times 10^9$ s $^{-1}$ and polarons pinned on traps and/or on short polymer chains.

On doping, the comparatively large iodine ions are incorporated into the polymer matrix, increasing the mobility of its polymer chains. This is apparently the cause of the increase in the number of delocalised polarons (Fig. 10c). The components of the g -tensor of the mobile paramagnetic centres in PTTF-1 are fully averaged, whereas in the case of PTTF-2 such averaging takes place only partially. This finding can be accounted for by the different nature and conformations of the monomer units of the polymers.

The width of the spectral components ΔB_{pp}^{loc} of the paramagnetic centres trapped in PTTF-1 depends only slightly on temperature. However, ΔB_{pp}^{loc} for these paramagnetic centres depends on the recording frequency, increasing from 0.28 to 0.38 and then to 3.9 mT ($T = 270$ K) with increase in the recording frequency from 9.5 to 37 and then to 140 GHz respectively. The value ΔB_{pp}^{mob} for mobile polarons changes under these conditions from 1.0 to 1.12 and then to 17.5 mT. The fact that the mobile paramagnetic centres have a wider line than the pinned centres can be accounted for by their stronger interaction with the dopant molecules. This is typical for conducting polymers,^{23, 30} but conflicts with the 3 cm EPR data obtained previously for PTTF-1.^{67, 68}

Following a decrease in temperature by a factor of 2, the components of the spectrum of the mobile polaron in PTTF-1 are narrowed by 2.2 mT, which indicates an increase in the mobility of the polaron. Such a change in ΔB_{pp}^{mob} is analogous to the narrowing of the lines of the spin charge carriers in classical metals.

In the range of resonance frequencies $37 \leq \nu_e \leq 140$ GHz, the line width for the paramagnetic centres varies in accordance with Eqn (8), which indicates a weak interaction between the spin packets in this polymer. As a result of this, at the 2 mm EPR band the paramagnetic centres in PTF are saturated for relatively low values of B_1 , so that rapid passage effects are manifested in the in-phase and $\pi/2$ out-of-phase components of the dispersion signal (Figs 10b and 10d). Since the inequality $\omega_m \tau_1 \geq 1$ is valid for the neutral PTF-2 sample, its dispersion signal U is determined mainly by the last two terms of Eqn (9). Since the condition $\omega_m \tau_1 \leq 1$ holds for the doped samples, their dispersion signal is determined by the u_1 and u_3 terms of this equation.

Modelling of the dispersion spectra showed that they are a superposition of the dominant asymmetric spectrum of the localised polarons with $g_{XX} = 2.01356$, $g_{YY} = 2.00603$, and $g_{ZZ} = 2.00215$ for PTF-1 and $g_{XX} = 2.01188$, $g_{YY} = 2.00571$, and $g_{ZZ} = 2.00231$ for the neutral PTF-2 and of the spectrum of mobile polarons (Fig. 10b).

Figure 11. Temperature variations of the effective spin-lattice (τ_1) and spin-spin (τ_2) relaxation times of the paramagnetic centres in polytetrathiafulvalene-1 samples with the doping level $z = 0.4$ (2) and also of polytetrathiafulvalene-2 with the doping levels $z = 0$ (1) and 0.1 (3).

Fig. 11 presents the temperature variations of the effective relaxation times of the paramagnetic centres in both PTF samples calculated from the 2 mm EPR spectra by the equations presented above. The time τ_1 varies with temperature in accordance with the $T^{-\alpha}$ law, where $\alpha \geq 3$ for the trapped and mobile polarons. The exponent α exceeds the corresponding value obtained previously by the spin echo method in the 3 cm EPR band.⁶⁷ The slight difference between the time τ_1^{mob} and τ_1^{loc} may be induced, for example, by the strong interaction between the different paramagnetic centres.

It is seen from Fig. 10d that an increase in temperature leads to an increase in the parameter $K_{\text{mov}} = u_3^X / u_3^Y$. As in the case of PANI, this is a result of the anisotropic librational reorientations of the pinned polarons about a specified X axis of the polymer chains. The correlation time of such molecular motions, calculated by the method described by the present author,²³ was

$$\tau_c = 9.8 \times 10^{-6} \exp\left(\frac{0.02}{kT}\right) \text{ s}$$

for the PTF-1 sample with the maximum value $\tau_c \approx 10^{-4}$ s ($T = 75$ K). The activation energies for the librations and the interchain charge transfer in the doped PTF-1 are

comparable,^{67,69} which indicates interaction of the pinned and mobile polarons in this polymer matrix.

The degree of saturation transfer depends not only on the dynamics and anisotropy of the magnetic parameters of the paramagnetic centres but also on the level of doping of the polymer. Thus the correlation time for the chain librations of the PTF-2 samples, determined by the ST-EPR method, was

$$\tau_c = 5.2 \times 10^{-6} \exp\left(\frac{0.02}{kT}\right) \text{ s.}$$

On doping, the chains of this polymer become more rigid, which leads to a higher slope of the Arrhenius relation for this sample.²³

$$\tau_c = 2.4 \times 10^{-6} \exp\left(\frac{0.04}{kT}\right) \text{ s.}$$

As in the case of PANI, both 1D-diffusion and 3D-hopping of the polaron at rates ν_{1D} and ν_{3D} respectively take place in PTF. Figs 12 and 13 present the temperature variations of these rates for PTF-1 and PTF-2 respectively calculated by Eqns (16) and (17) using the data presented in Fig. 11. If one assumes a spin delocalisation on the polaron equal to five monomer units, then

Figure 12. Temperature variations of the rates of diffusion of the polarons along the chain (ν_{1D}) and between the chains (ν_{3D}) and of the electrical conductivity σ_{ac} calculated within the framework of the isoenergetic (continuous line) and activated (dashed line) interchain charge transfer in polytetrathiafulvalene-1 with the doping level $z = 0.4$.

Figure 13. Temperature variations of the rates of diffusion of the polarons along the chain (ν_{1D}) and between the chains (ν_{3D}) in polytetrathiafulvalene-2 samples with the doping levels $z = 0$ (1, 1') and 0.1 (2, 2') and also of the electrical conductivity σ_{ac} calculated within the framework of the isoenergetic (continuous line) and isoenergetic-activated (dashed line) interchain charge transfer.

ν_{1D} is $2 \times 10^{10} \text{ s}^{-1}$ for PTTF-1 and $2 \times 10^{12} \text{ s}^{-1}$ for the neutral PTTF-2 sample at room temperature. This quantity is smaller by at least two orders of magnitude than the frequency of the spin 1D-diffusion in PP⁷⁰ and PANI³³ obtained previously by magnetic-resonance methods at low recording frequencies, but exceeds the frequency ν_{1D}^0 calculated earlier. The anisotropy of the spin dynamics ν_{1D}/ν_{3D} in PTTF at room temperature exceeds 10 and increases as the temperature is reduced.

Evidently the spin dynamics play a significant role in the charge transfer process. When the diffusion coefficients of the spins and charge carriers are equal and for $N_2 = 6.9 \times 10^{-5}$ of an electron per monomer unit, the components of the conductivity of PTTF-1, calculated by Eqn (4), are $\sigma_{1D} \approx 0.1$ and $\sigma_{3D} \approx 4 \times 10^{-3} \text{ S m}^{-1}$ at room temperature. The value σ_{1D} obtained exceeds significantly the electrical conductivity of the sample measured using a direct current ($\sigma_{dc} \approx 10^{-3} \text{ S m}^{-1}$).⁶⁷ Indeed, the macroscopic parameter σ_{dc} which reflects the hopping charge transfer between polymer chains, should not exceed the microconductivity, because $\nu_{1D} \gg \nu_{3D}$. Taking into account the different temperature variations of the conductivities σ_{1D} and σ_{3D} and also the charge transfer in PTTF by polarons with a small radius,⁶⁵ one may postulate that isoenergetic charge transfer takes place in this sample.⁶⁰

As can be seen from Fig. 12, the function $\nu_{1D}(T)$ correlates satisfactorily with the function $\sigma_{1D}(T) = 2.4T^{-1}(81 - 13.6 \ln T)^4$ calculated from Eqn (18b) within the framework of the approach considered. According to Eqn (18a), the isoenergetic charge transport should also lead to the temperature dependence $\sigma_{dc}(T) \approx T^{12.6}$, but the experimental σ_{3D} has a temperature variation of the type⁶⁷

$$\sigma_{3D}(T) \sim \exp\left(-\frac{E_a}{kT}\right).$$

Thus the dynamic process considered must be analysed within the framework of thermally activated polaron hops to the edges of the conductivity band.

Indeed, the temperature variation of the rate of diffusion ν_{1D} for the PTTF-1 sample can be fitted satisfactorily by the function (20b) with $\sigma_0 = 8.3 \times 10^{-14} \text{ S s m}^{-1} \text{ K}^{-1}$, $\nu_e = 1.4 \times 10^{11} \text{ s}^{-1}$, $\gamma = 0.8$, and $E_a = 0.04 \text{ eV}$ (Fig. 13). The value of E_a obtained is close to the activation energy for the interchain charge transfer ($E_a = 0.03 \text{ eV}$) at low temperatures.^{67,68} Furthermore, this quantity corresponds to the activation energy for the librations of the chains in PTTF calculated above. This fact permits the conclusion that the conductivity of PTTF is determined predominantly by the interchain phonon-assisted polaron hopping.

The probability of charge transfer is determined by the strength of the interaction of the electron with the lattice, the interchain transfer of which is accompanied by the absorption of a minimal number m of lattice phonons. It follows from Fig. 12 that the rate of the interchain spin transfer in PTTF-1 varies with temperature in accordance with the law $\nu_{3D} \approx T^{4.7}$. On the other hand, the spin-lattice relaxation time of the paramagnetic centres has a temperature dependence of the type $\tau_1(T) \approx T^{3.6}$ (Fig. 11), which is a consequence of a multiphonon process. Adopting $E'_a = m\hbar\nu_{ph}$ and assuming that the averaged value $\langle m \rangle = 4.2$, one may calculate ν_{ph} for phonons in this sample as $\nu_{ph} = 2.5 \times 10^{13} \text{ s}^{-1}$, which is typical for conducting polymers. Thus, as a consequence of the strong electron-phonon interaction, the conductivity of the polymer is initiated by the librations of the polymer chains and is determined by multiphonon processes.

On passing from PTTF-1 to PTTF-2, the frequency ν_{1D} increases approximately by two orders of magnitude at room temperature (Figs 12 and 13), which is apparently associated with the more planar conformation of the monomer units in PTTF-2. Indeed, the g_{xx} parameter of the g -tensor changes by $\Delta g_{xx} = 1.32 \times 10^{-3}$ in this transition. Bearing in mind the dependence of the overlap integral I and the spin density on the

sulfur nucleus ρ_S on the dihedral angle θ in the form $I \sim \cos \theta$ and $\rho_S \sim \sin \theta$,¹³ it is possible to calculate by Eqn (1) the change $\Delta\theta$ in such a transition, which amounts to 22° . We may note that a similar conformational change occurs on passing from the benzenoid to the quinonoid form of PPP¹² and also on transition from the EB to the ES form of PANI.⁴⁹

If it is postulated that a certain number of bipolarons (concentration N_{BP}) with a charge $2e$ are present in PTTF, an attempt may be made to interpret the spin dynamics in PTTF-2 within the framework of isoenergetic electron transport.⁶⁰ The quantities n and N_{ch} may be determined from the $\nu_{1D}(T)$ relation presented in Fig. 13: $n = 12.2$ and $N_{ch} = N_{BP} = 7.5 \times 10^{-5}$. Using the values $N = 2 \times 10^{23} \text{ m}^{-3}$ and $c_{1D} = 1.2 \text{ nm}$, as well as the data presented in Fig. 13, it is possible to calculate by Eqn (4) the conductivity σ_{1D} , which amounts to 1.8 S m^{-1} at room temperature. Adopting $\xi_{\parallel} = 6 \text{ nm}$, $\xi_{\perp} = 0.6 \text{ nm}$, $N_n = N_p = 6.7 \times 10^{-4}$, $N_0 = 0.11$, and $\sigma_{dc} = 2 \times 10^{-6} \text{ S m}^{-1}$,⁶⁷ we obtain from Eqns (18) $R_0 = 4.1 \text{ nm}$, $\gamma(T) = 4.0 \times 10^{-23} T^{13.2} \text{ s}^{-1}$, and $N_i = 3.3 \times 10^{24} \text{ m}^{-3}$. Fig. 13 shows that the $\sigma_{1D}(T)$ relation, derived from Eqn (18a) for a neutral PTTF-2 sample, fits the function $\nu_{1D}(T)$ fairly satisfactorily.

The rate of diffusion of the polaron in doped PTTF-2 samples varies approximately linearly in the region of low temperatures and is characterised by a high slope at higher temperatures (Fig. 13). This justifies the assumption that the charge transfer in the PTTF polymers is effected within the framework of the variable range hopping model at low temperatures with a contribution by the activated charge transfer at higher temperatures. Putting $L = \xi$, $d = 3$, and $\nu_0 = \nu_{ph} = 3.6 \times 10^{13} \text{ s}^{-1}$, it is possible to determine by Eqn (21) $T_0 = 7.8 \times 10^7 \text{ K}$ and $n(\epsilon_F) = 7.9 \times 10^{-4} \text{ eV}^{-1} \text{ monomer}^{-1}$ for these polymers.

The high-temperature part of the $\nu_{3D}(T)$ relation is described satisfactorily by Eqn (20b) for $\gamma = 0.8$ and $E_a = 0.035 \text{ eV}$ (Fig. 13). The latter quantity is close to the activation energies for the superslow librations of the PTTF polymer chains and also for the interchain charge transfer in PTTF-1. This finding indicates a close relation between the molecular dynamics and the charge transfer process in PTTF and confirms the earlier hypothesis⁷¹ that the fluctuations of the lattice vibrations, including librations, may modulate the interchain electron transfer integral for conducting compounds. The polymer chains in PTTF-1 are less rigid than in PTTF-2, so that the above modulation in this polymer occurs at lower temperatures (Figs 12 and 13).

The intensification of the libron-exciton interactions at high temperatures indicates the formation in doped PTTF of complex quasi-particles — a molecular-lattice polaron.⁷² Within the framework of this phenomenological model, it is postulated that the molecular polaron, the mobility of which is characterised by the temperature variation $\mu_m \sim T$, is additionally coated by a lattice polarisation shell. Since the mobility of the lattice polaron μ_1 is expressed by an activation function, the resultant mobility of the molecular-lattice polaron is expressed by the sum

$$\mu(T) = \mu_m(T) + \mu_1(T) = aT + b \exp\left(-\frac{E_a}{kT}\right), \quad (22)$$

where a and b are constants. Since the formation energies of the molecular polaron in PTTF and polyacetylene crystals are similar, $E_{pm} = 0.15 \text{ eV}$,⁷³ it is possible to determine the formation energy of the molecular-lattice polaron in PTTF as $E_{pml} = E_{pm} + E_{pl} = 0.19 \text{ eV}$. The time necessary for the polarisation of the atomic and molecular orbitals of the polymer is then $\tau_e \approx \hbar E_{pml}^{-1} = 2.2 \times 10^{-14} \text{ s}$ at room temperature. This time is significantly shorter than the characteristic polaron diffusion time in PTTF, i.e. the minimum time of the 1D- and 3D-hops of the charge carriers exceeds significantly the polarisation time of the microenvironment of these carriers in the polymer: $\tau_h \gg \tau_e$. Consequently this inequality is a necessary and sufficient condition for the electronic polarisation of the polymer chains by the charge carriers.

The Fermi velocity v_F of the polarons in PTF is $1.9 \times 10^5 \text{ m s}^{-1}$ (see Ref. 23) and is close to the corresponding value for PANI. The length of the free path l^* of the charge carrier in different PTF specimen is $l^* = v_{1D} c_{1D}^2 v_F^{-1} = 10^{-2} - 10^{-4} \text{ nm}$. The latter quantity is too small to regard the PTF polymer as a quasi-one-dimensional metal.

Thus both 1D- and 3D-spin dynamics occur in PTF, influencing significantly the charge transfer processes. The conductivity of the polymer is determined mainly by the interchain transfer of the positive charge, but, in the analysis of the transport properties of PTF, account must also be taken of the 1D-diffusion of the spin and spin-free charge carriers.

VII. Conclusion

The data obtained demonstrate clearly the advantages of the EPR method in the study of conducting polymers at the 2 mm band. The high spectral resolution with respect to the g -factor achieved in this range makes it possible to record more accurately and separately the components of the g -tensor of organic radicals and hence makes it possible to analyse more fully and correctly the magnetic parameters of paramagnetic centres with different mobilities. The combination of a high resolving power with a low spin-spin cross-interaction permits a more effective employment of the paramagnetic centre steady-state saturation and saturation transfer methods as well as the spin label and probe method for the investigation in this frequency band of the detailed characteristics of the anisotropic molecular and spin dynamics in organic polymeric semiconductors.

The data presented demonstrate the great variety of the electronic processes occurring in organic conducting polymers. The fundamental properties of polymeric semiconductors are determined by the structure and conformation of the polymer chains, the nature and amount of the dopant introduced, and, in the first place, by the dynamics of the nonlinear excitations of the polarons and bipolarons participating in the charge transfer.

The polarons are formed on the chains of the polymer in the initial stage of its doping. With increase in the doping level, they may recombine into bipolarons. Incidentally, this process may be hindered by the structural or conformational characteristics of the polymer. The charge transfer mechanism changes on doping. Thus the conductivity of a neutral and lightly doped polymer are determined largely by the isoenergetic tunnelling of the charge between polymer chains, which is characterised by a fairly strong interaction of the spins with the lattice phonons. At an intermediate doping level, the charge is as a rule transferred by an activated mechanism and this process is initiated by the superslow anisotropic librations of the polymer chains. Finally, the variable range hopping interchain charge transfer, accompanied by comparatively weak scattering of electrons by the lattice phonons, predominates in the relatively highly conducting polymers.

Positively charged lipids: structure, methods of synthesis, and applications

I D Konstantinova, G A Serebrennikova

Contents

I. Introduction	537
II. The structure and synthesis of positively charged lipids	537
III. Applications of positively charged lipids	543

Abstract. Data on the structure, methods of synthesis, and applications of positively charged lipids are presented. Their likely usefulness as antitumour and antiviral agents and also as antagonists of the platelet activating factor and transfection mediators is demonstrated. The bibliography includes 80 references.

I. Introduction

There has been a considerable growth of interest in recent years in a new type of modified glycerolipids containing a positively charged group (cationic lipids). Such interest in compounds of this class is due to the possibility of their wide scale employment in the transportation of genetic material and other macromolecules into cells of animal origin and plant protoplasts and also in the creation of artificial membranes with an affinity for negatively charged cell surfaces. Their antitumour activity, partly associated with the inhibition of protein kinase C and diacylglycerol kinase, is also known. Many representatives of cationic lipids inhibit effectively the replication of the HIV-1 virus. In addition, promising antagonists of the lipid bioregulator — the platelet activating factor (PAF) have been discovered among them. All these features lead to the possibility of devising chemotherapeutic preparations of a new type on the basis of positively charged lipids.

II. The structure and synthesis of positively charged lipids

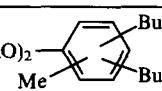

Among positively charged lipids, particular attention has been devoted to glycerol derivatives. Cationic glycerolipids have a wide variety of structures, but their common feature is the presence of a positively charged head, an intramolecularly uncompensated negatively charged group, and one or several long-chain substituents in the hydrophobic part of the molecule. It has been established that the length of the chains of the substituents at the C(1) and C(2) atoms of glycerol, the type of cationic head, and also

the presence of a spacer group, separating it from the glycerol fragment, exert a significant influence on the biological activity exhibited by a particular compound.

1. Tetraalkylammonium derivatives

The quaternary ammonium detergents 1–4 in liposomes have found applications in the transfection of genetic material into cells of animal origin.^{1–3}

Com- pound	Name ^a	R ¹	R ²	X
1	DEBDA	CH ₂ C ₆ H ₅	(C ₂ H ₄ O) ₂ 	OH
2	DTAB	Me	(CH ₂) ₁₁ Me	Br
3	TTAB	Me	(CH ₂) ₁₃ Me	Br
4	CTAB	Me	(CH ₂) ₁₅ Me	Br

^a DEBDA = diisobutylcresoxyethoxyethyltrimethylbenzylammonium hydroxide, DTAB = dodecyltrimethylammonium bromide, TTAB = tetradecyltrimethylammonium bromide, CTAB = cetyltrimethylammonium bromide.

These cationic lipids are fairly widely distributed and are cheap. They can be synthesised by simple chemical reactions and can be incorporated in liposomes having different compositions in order to stabilise the bilayer. The tetraalkylammonium derivatives 5 and 6, incorporating carbohydrates as the structural fragments (the so-called bolaamphiphiles) are regarded as promising amphiphiles for negatively charged polyelectrolytes such as nucleic acids. The presence of the electrically neutral carbohydrate fragment at one end of the long-chain residue and of an electro-positive group at the other ensures their amphiphilic properties.⁴

The mannose bolaamphiphiles 5 have been synthesised by alkylating thio- α -D-mannopyranose with the corresponding ω -iodo(or bromo)- α -trimethylalkylammonio-derivatives.

5a-d, 6

R = (CH₂)₁₁C(O)O(CH₂)₂N⁺Me₃ Cl⁻ (5a),
 (CH₂)₁₁C(O)NH(CH₂)₂N⁺Me₃ Cl⁻ (5b),
 (CH₂)₁₁C(O)O(CH₂)₁₁N⁺Me₃ Cl⁻ (5c),
 (CH₂)₉C(O)O(CH₂)₁₁C(O)NH(CH₂)₂N⁺Me₃ I⁻ (5d),

(6)

The bolaamphiphile 6, containing two hydrocarbon chains, has been obtained by adding thiomannose to the corresponding maleic acid diester.

In order to investigate the influence of a series of quaternary ammonium derivatives of types 7–10 on normal and neoplastic cells, a series of such derivatives have been synthesised.^{5–7}

7–10

Compound	R	X	Y	Z
7	(CH ₂) _n Me, n = 14, 16	OC(O)	N(Me) ₂ (CH ₂) ₂ OH	Br
8	H, Ph, (CH ₂) _n Me, n = 11, 13, 15, 17	O	N(Me) ₂ (CH ₂) _n OH, n = 2–4	I
9	(CH ₂) ₁₅ Me	S	N(Me) ₂ (CH ₂) ₂ OH, NC ₅ H ₅	Br
10	(CH ₂) ₆ Me	OC(O)	NMe ₃	I

The synthesis of these compounds is based on the quaternisation of tertiary amines or aromatic heterocyclic bases by β-haloethanolamine with subsequent alkylation or acylation of the free hydroxy-group.

Scheme 1

2. Synthetic amphiphiles — aminoacid derivatives

Lipophilic derivatives of aminoacids, peptides, and polyamines have proved fairly effective in the transfection of DNA into eukaryotic cells.

The new cationic amphiphiles 11 and 12 have been recently synthesised from glutamic acid.⁸

11

n = 2, 4, 6, 8

12

n = 1, X = Cl; n = 5, X = Br

Lipopoly-L-lysine 13 (LPLL) has been attained in accordance with Scheme 1 by the reaction of poly-L-lysine and N-glutarylphosphatidylethanolamine in the presence of N-hydroxysuccinimide and dicyclohexylcarbodiimide (DCCD).⁹

Compound 13 usually includes two molecules of the phospholipid per poly-L-lysine molecule.

Lipophilic polyamines — the lipospermines 14 and 15 — have proved to be effective mediators of the transfection of DNA.¹⁰

14

15

The lipospermines 14 and 15 have been synthesised by the reaction of protected L-5-carboxyspermine with the lipophilic glycine N,N-diheptadecylamide and dipalmitoylphosphatidylethanolamine (DPPE) respectively.

3. Cationic lipids — glycerol derivatives

The commonest type of cationic lipids may be represented by the general formula 16.^{11–15}

X = O, S, or OCONH; R¹ = alkyl, alkenyl, and acyl (C₁₀–C₂₀), alkyls with aromatic and heterocyclic residues, etc.; R² = long-chain (C₁₀–C₂₀) or short-chain (C₁–C₈) alkyl and acyl substituents; Z = spacer groups of different types (their absence is also possible); Y⁺ = ammonium and sulfonium groups or heterocyclic heads in which positively charged nitrogen or sulfur atoms are incorporated; Q = Hal, AcO, TsO, etc. counterions.

Depending on the nature of the substituents R¹ and R² in the hydrophobic part of the molecule, the cationic lipids of a given type can be subdivided into several varieties, which determine the methods of their synthesis and their applications:

- (a) positively charged lipids with long-chain alkyl substituents [R¹ = R² = Alkyl(C₁₀–C₂₀)];
- (b) lipids with long-chain and short-chain alkyl substituents [R¹ = Alkyl(C₁₀–C₂₀), R² = Alkyl(C₁–C₈)];
- (c) cationic glycerolipids with long-chain acyl substituents;
- (d) mixed type lipids containing alkyl, acyl, acylcarbamoyl, and other types of long-chain and short-chain substituents in various combinations.

a. Cationic lipids with long-chain alkyl substituents

The compounds having the general formula 17 are used for the transfection of various biologically active substances (nucleosides, polynucleotides, peptides, hormones, etc.), containing a negatively charged section, into cells of animal origin and plant protoplasts.^{11–15}

R¹ = R² = alkenyl or alkyl (C₁₀–C₂₀); R³ = R⁴ = R⁵ = Me or Et; n = 1–4 (predominantly n = 1); Q = Hal

These lipids are usually incorporated in liposomes produced from phosphatidylcholine (PC) or phosphatidylethanolamine (PE) in the molar proportions cationic lipid : phospholipid = 1 : 1. This ratio may vary depending on the type of the transfected substance and the target cells.^{11, 12, 14}

The scheme used in the synthesis of the lipids 17 is fairly simple and includes stages involving the alkylation of the aminodiols system with subsequent quaternisation of the amino-group.^{11, 12}

Racemic mixtures are usually obtained via this scheme with R¹ = R², while R³, R⁴, and R⁵ are different or the same but are not incorporated into aromatic systems. Optically active compounds of this type [(S)-isomers] are synthesised via Scheme 2 from 3,4-isopropylidene-D-mannitol.¹⁴

Scheme 2

Optically active compounds with various alkyl residues R¹ and R² are synthesised from 2,5-dibenzyl-D-mannitol.

Positively charged glycerolipids of the alkyl type with various substituents in the hydrophobic part of the molecule are then synthesised similarly to Scheme 2.

In order to obtain compounds containing a spacer group comprising 2–8 methylene groups, the derivative 19 is synthesised initially (Scheme 3) and is then converted into cationic lipids by the method described above.

Scheme 3

b. Positively charged lipids with long-chain and short-chain substituents of the alkyl type

This group of lipids has been investigated most vigorously because its representatives exhibit an inhibiting activity on the growth of neoplastic cells and are also effective antagonists of the lipid bioregulator of the platelet activating factor. Certain compounds are capable of suppressing the development of the HIV-1 virus. In a general form, the structure of such glycerolipids can be represented as follows:

X = O or S;

R¹ = alkenyl or alkyl (C₁₀–C₂₀), a branched alkyl, an alkyl with aromatic substituents, naphthylaryl, or aryl;

R² = alkyl (C₁–C₄), a cyclic alkyl, heterocycles (pyridine, triazoline, pyrazine, etc.), H, or CH₂CF₃;

Z = bond, O(CH₂)_n (n = 1–7), (OCH₂CH₂)_n (n = 1–3), S(CH₂)_n (n = 1, 2), a spacer group of the alkyl or arylalkyl type, etc.;

Y = NR¹R²R³, where R¹ = R² = R³ = Me or Et, R¹ = R² = Me and R³ = (CH₂)₂OH or (CH₂)₃OH, or R¹, R², and R³ may be combined into heterocycles; Q = Hal, MsO, TsO, etc.

The groups R¹ and R² may be combined into an acetal ring with a long-chain alkyl group (for example, R¹ = C₁₇H₃₅ and R² = H).^{16, 17}

The cationic glycerolipids **22**, containing a spacer group of the succinyl type, are synthesised in accordance with Scheme 4.^{18, 19}

The synthesis of compound **23**, containing a cationic group attached directly to the glycerol fragment, involves the preliminary preparation of disubstituted glycerols using a trityl protecting group.¹⁶

Scheme 4

Various approaches are used in the preparation of compounds containing a spacer group depending on the structure of the latter.

If the quaternary ammonium group is separated from the glycerol fragment by several methylene groups, compound **24** is synthesised and then converted into cationic lipids by traditional methods.¹⁶

The 3-(2-hydroxyethoxy)- and 3-[2-(2-hydroxyethoxy)-ethoxy]-residues are also used as spacer groups. They are introduced into the molecule by treating the corresponding tosyl derivatives of mono- or di-alkylglycerols with ethylene glycol or diethylene glycol.²⁰

A series of cationic lipids **26** with a spacer group have been obtained from 1-O-alkyl-2-O-benzyl-*rac*-glycerols **25** (Scheme 5).^{21, 22}

The synthesis of positively charged lipids **27**, having an ethylthio spacer group, has been reported.^{6, 23}

Scheme 5

Compounds of types **28** and **29**, containing heterocycles as the substituent R^2 and the $(OCH_2CH_2)_n$ group as the spacer, are synthesised in accordance with Scheme 6.²⁴

The scheme may be modified by employing the trityl protecting group.

The method involving the reductive cleavage of cyclic acetals has been used in the synthesis of the disubstituted thioglycerol derivative **30**, which is converted into cationic lipids by traditional methods.²⁵

Together with lipids containing alkylammonium groups as the polar head, compounds incorporating various heterocycles have been obtained.^{22, 26, 27}

c. Cationic lipids with long-chain acyl substituents

2,3-Dioleoyloxypropyltrimethylammonium chloride **31** (DOTAP) is one of the commonest glycerolipids of this series.

This lipid is used to investigate the processes involving the fusion of liposomes carrying opposite charges, the mixing of the biologically active substances incorporated in them, and their possible transport through a liposomal bilayer.

DOTAP is synthesised by acylating 3-bromopropane-1,2-diol with subsequent quaternisation of the resulting compound with trimethylamine.²⁸

The synthesis of the positively charged lipids **32a–c** containing various cationic groups and higher aliphatic acid residues has been described.⁷

The general scheme for the synthesis of compounds **32** can be represented as follows:

Compounds **32a–c** are inhibitors of the membrane-bound protein kinase C to the same extent as cationic lipids of the alkyl ether type having a short-chain substituent at the C(2) atom of the glycerol fragment.⁷

g. Cationic lipids of the mixed type

Among positively charged glycerolipids of the mixed acylalkyl ether, alkyl ether, or acylcarbamoyl types, a series of effective antagonists of the platelet activating factor as well as compounds with antitumour activity have been discovered. This stimulated the study of the structure–function relations in this class of lipids and led to the synthesis of a large group of compounds having the general formula 33.

X = O, S, OCONH or SCONH;

R¹ = alkyl(C₈–C₂₀), (CH₂)₃OC₁₈H₃₇, (CH₂)₁₀NHCONHMe, CH₂–C₆P₄–Ph, etc.;

R² = OMe, OEt, OCOMe, OCOC₇H₁₅, OCH₂COMe, CH₂CN, NHCOOMe, OCOOMe, NHCONHMe, or heterocycles of the pyrrole, triazole, etc. type;

R³ = H or Me;

Z = O(CH₂)_n, (OCH₂CH₂)_n, OCO(CH₂)_n, (CH₂)_n, CH₂SO₂(CH₂)_n, NHCO(CH₂)_n, NHSO₂(CH₂)_n, N(COMe)SO₂(CH₂)_n, or OCONR(CH₂)_n

(R = H, Me, COMe, COEt, or COOMe; n = 1–6);

Y = NMe₃, NMe₂CH₂CH₂OH, various heterocycles in which a quaternary nitrogen atom is incorporated, etc.;

Q = Hal, MsO, TsO, etc.

Compounds of the alkylacyl type are synthesised in accordance with the general strategy developed for the preparation of dialkyl lipids with various substituents in the glycerol skeleton using the same selective protecting groups (Bzl, Tr, Ts, benzylidene) and alkylation, acylation, and thioalkylation methods.

The syntheses of compounds containing alkylcarbamoyl and alkoxy-carbonylamino-groups have specific features. They usually involve the preparation of the corresponding disubstituted glycerol derivatives with subsequent introduction of the cationic head by traditional methods.

R² = protecting group; R³ = alkyl(C₁–C₃).

The overall strategy for the synthesis of the initial compounds 34 in the preparation of cationic lipids with an alkylcarbamoyl residue at the C(2) atom may be represented by Scheme 7.²⁵

The alkylcarbamoyl group was introduced by the interaction of compound 35 with alkyl isocyanate in the presence of an acid catalyst (AlCl₃) and a base (pyridine, triethylamine).

Compounds 36, containing alkylcarbamoyloxy- and alkoxy-carbonylamino-groups at the C(1) and C(2) atoms respectively, are synthesised in the following manner:²⁵

R¹ = protecting group; R² = alkyl(C₁₂–C₂₀); R³ = alkyl(C₁–C₄).

Compound 37, incorporating an alkylthio- and an alkoxy-carbonylamino-group at the C(1) and C(2) atoms respectively, was synthesised from the phenyloxazoline derivative 38 in accordance with Scheme 8.²⁵

R² = Alk(C₁–C₄).

The synthesis of the cationic lipids 39 and 40 with alkanoyl-methyl and cyanomethyl substituents at the C(2) atom of the glycerol fragment has been described in detail.^{20–22, 29}

R² = H, Me, COMe, COEt, or COOMe; n = 1–6;

Y = NMe₃, NMe₂CH₂CH₂OH, various heterocycles in which a quaternary nitrogen atom is incorporated, etc.;

Q = Hal, MsO, TsO, etc.

The general approach to the synthesis of lipids 41 having the 1-alkyl-2-carbamoyl structure and containing a cationic head attached via a spacer group of the acyl type is presented in Scheme 9.^{22, 30} The cationic head with a spacer of the acyl type may be obtained via the acylation of the dialkylglyceride of a dimethylaminoalkanoic acid of a suitable type followed by the quaternisation of the dimethylamino-group with methyl iodide.^{31, 32}

The positively charged lipids **42** — PAF antagonists with a carbamoyl structure — have been obtained by the following method.²⁹

f. Positively charged alkyl ether lipids with a sulfonium cationic head

The type **43** lipids are of interest for the study of the mechanism of the inhibition of the membrane-bound protein kinase C (PKC), the growth of neoplastic cells, and the replication of the HIV-1 virus.^{6, 23} They are synthesised in accordance with Scheme 10.

$R^1 = C_{16}H_{33}, C_{18}H_{37}; R^2 = Me, Et; Q = I, TsO.$

g. Positively charged lipids synthesised by the alkylthioalkylation reaction

Konstantinova et al.³³ were the first to demonstrate in lipid chemistry the possibility of using a modified Pummerer's rearrangement (the alkylthioalkylation reaction)³⁴ in the chemistry of lipids by introducing the $MeSCH_2$ group at a primary

$R^1 = C_{18}H_{37}; R^2 = Me, Et; R^1 = R^2 = C_{16}H_{33}.$

(Scheme 11) or secondary hydroxy-group (Scheme 12) of disubstituted glycerols **44–46**. Subsequent conversion of these highly reactive groups (asymmetric *O,S*-acetals) into α -bromoethers, capable of interacting readily with nucleophiles, leads to prospects for the synthesis of various modified lipids, including positively charged ones.

III. Applications of positively charged lipids

1. Cationic lipids in liposomology

Positively charged lipids form liposomes in an aqueous medium or in a buffer solution either individually or in a mixture with other natural phospholipids. For example, an active preparation, known as lipofectin, includes the cationic lipid DOTMA[†] **47** and

[†] *N*-[1-(2,3-dioleoyloxy)propyl]-*N,N,N*-triethylammonium salt.

PE; in molar proportions ranging from 1 : 1 to 3 : 7 depending on the type of cultures of the cells used in transfection.^{11, 12, 14, 35}

47

Cationic liposomes are obtained similarly from the quaternary ammonium derivatives 1–4 (DEBDA, DTAB, TTAB, and CTAB), which exert a stabilising effect on the bilayers formed by PE.^{1, 36, 37} DTAB stabilises the bilayers more effectively than the TTAB and CTAB analogues, the amount of which required to achieve a similar effect is twice as great.

The mechanism of the interaction of cationic liposomes with liposomes incorporating negatively charged or zwitterionic phospholipids has been widely investigated in recent years.^{36–39} The elucidation of the details of this process may explain the interaction of the positively charged liposomes with the cell membrane during the transfection process. It has been shown that the populations of such liposomes may interact with one another in various ways which depend on the lipid composition of the membrane surface and on the ionic strength of the medium.

It has been established that liposomes containing DOTMA and PE interact with the negatively charged membrane lipids and fuse with the cell surface. Different anions can also induce the fusion of cationic liposomes. Thus, for the DOTMA/PE (1 : 1) liposomes, the influence of the anions on the degree of fusion decreases in the sequence citrate > ethylenediaminetetraacetate > phosphate. It is of interest that these liposomes were entirely resistant to fusion in the presence of polyanions. Liposomes of the DOTMA/PE and DOTMA/PC types may fuse at a high citrate concentration. The negatively charged phosphatidylserine (PS) exerts a similar effect even in the absence of polyanions. The interaction of the negatively charged groups in PS with the quaternary ammonium group of DOTMA or DOTAP 31 is apparently sufficient for the fusion of the membranes containing these lipids, while the zwitterionic phospholipid component of these membranes is an additional and decisive factor for membrane conductivity.¹⁵

It is essential to note that the fusion of liposomes in the presence of anions is influenced significantly by the size of the liposomes. For example, liposomes 300 nm in diameter, the composition of which includes didodecylammonium bromide, fuse in the presence of dipicolinic or toluene-*p*-sulfonic acid. On the other hand, if the diameter of the liposomes is < 200 nm, no fusion occurs and only aggregation is observed.¹⁵

Fusion results in the formation of a complex between the liposomes and the anion, which is preceded by the dehydration of the surface of the liposome. Studies are planned in the future on the quantitative determination of the binding capacities of a wide variety of anions in relation to cationic lipids in liposomes and on the determination of the possible dehydration of liposomes in the presence of anions.²⁸

It has been shown that the DOTMA/PC/PE mixed liposomes are entirely resistant to fusion in the presence of polyanions. However, when they were mixed with liposomes containing negative charges on the surface, aggregates were formed readily at the physiological or lower ionic strength. The PC/PE ratio in liposomes has a considerable influence on the degree of aggregation even under the conditions where it is not followed by coalescence (i.e. the mixing of the lipids of the bilayer and/or aqueous compositions). The degree of aggregation is higher the greater the PC/PE ratio. These observations may be useful for the study of the interaction between liposomes having different lipid compositions and also for providing investigators with systems in which the interaction between liposomes is independent of the bond between ions and the lipid surface. The tendency of liposomes to become associated with one another can be readily controlled by varying the ionic composition of the medium.^{15, 28}

The mechanism of the interaction of the DOTMA/PE vesicles with the plasma membranes of cultured cells has not been elucidated. It may be that the binding of DOTMA to the negatively charged sialic acid in gangliosides leads to the destabilisation of the plasma membrane and the coalescence of the liposomes with cells. It is essential to note that cationic liposomes containing cationic amphiphiles with ether and ester bonds interact equally readily with the cell membrane. Furthermore, liposomes containing fluorescent labels are readily disrupted after being incorporated in CV-1 cells.^{28, 40} One of the most interesting properties of positively charged liposomes with a high PE content is their ability to interact with membranes containing surface proteins. Liposomes formed from DOTMA/PE are readily adsorbed on erythrocytes in a medium with the physiological ionic strength.²⁸

A fairly important property of the lipofectin preparation is its toxicity for cells *in vitro* following an increase in the concentration of the cationic lipid above a certain level. The toxicity of the preparations is different for different types of cells and depends on the duration of exposure and the density of the cell culture. It is therefore necessary to optimise the transfection parameters for each cell line.

The quaternary ammonium derivatives 1–4 are even more toxic to the transfected cells. Therefore, out of all the above compounds, the least toxic CTAB is most often employed. It is a cheaper and readily available substitute for DOTMA and DOTAP. Similar observations have been made also for another cationic lipid, namely DEBDA, which is used in studies on plant protoplasts.¹

2. Positively charged lipids as transfection mediators

One of the most interesting fields of medicine — genetic therapy — has been rapidly developing recently. It is essential for the correction of genetic cell defects and for the treatment of genetic diseases. In order to correct genetic defects, normal exogenous genes are introduced into the target cell, where they or the products of their vital activity act together with the defective molecules or replace the latter and hence assist the cell in its normal functioning.

One of the main tasks in genetic therapy is the search for methods which are suitable for the specific and effective introduction of genetic material. It has been shown that under exceptional conditions eukaryotic cells may receive DNA molecules, a proportion of which are localised in the nucleus. However, owing to its large size and charge, the spontaneous permeation of DNA into the cell and its subsequent expression into the nucleus (transfection) are difficult. For this reason, various methods facilitating this process, i.e. inducing cell fusion under specially selected conditions, or mediators of DNA gene transfection have been used. Employment of calcium phosphate, liposomes, retrovirus vectors, electroporation, and microinjection may be included among the effective methods for the transfection of genetic material. In certain cases, the application of polycations such as polylysine, DEAE-dextran, and polyornithine yields satisfactory results. However, all these methods are characterised by a low effectiveness, an unstable introduction of genes, and a poor reproducibility. Furthermore, the compounds employed in this procedure are frequently toxic to the target cells.^{11, 12}

The most modern DNA-transfection methods employ positively charged liposomes as mediators. The use of liposomes capable of transferring genetic material into cells via fusion with the cell membrane is of special interest. Cationic lipids with various structures (compounds 1–4, 11–17, and 47) form together with PE and PC positively charged liposomes which spontaneously produce complexes with polynucleotides. These complexes are adsorbed by the cell surface, fuse with the plasma membrane, and transfer the genetic material to the cytoplasm. Further study of the positively charged liposomes can therefore lead to the creation of convenient and effective systems for the introduction of various biologically active substances into the cell:

nucleosides oligo- and poly-nucleotides, hormones, proteins, and other natural and synthetic macromolecules with a negatively charged section.¹⁴

The current break-through in transfection arose from the preparation lipofectin. It is convenient to use and is effective.^{11–14, 41, 42} The DNA — lipofectin (DOTMA/PE) complex has a network of positive charges, which facilitate its interaction with the negative charges of glycolipids and glycoproteins on the surface of the cell membrane.¹¹

The quaternary ammonium derivatives 1–4 are also sometimes used for DNA transfection. Although the transfecting activity of liposomes containing these compounds is somewhat lower than the activity of lipofectin, nevertheless they can be used as cheap readily available substitutes.^{1, 13, 15, 40, 43}

Apart from DNA transfection, lipofectin is used for the effective introduction of RNA into cells of animal origin and also into the protoplasts of a number of plants. By employing this method, it is possible to introduce up to 70% of RNA.² The RNA — lipofectin complexes are used to investigate the stability of mRNA when they are introduced into cell tissues and embryos. This may lead to the development of a technology in which RNA is used as a medicinal preparation.¹³

Lipofectin is a simple and convenient preparation whereby one can obtain various specific tissue cells or cell lines infected by whole viruses or only by virus vectors in the absence of homologous virus receptors.⁴²

Communications concerning the possibility of the transfection of the vector for the expression of cDNA luciferase into the brain cells of the *Xenopus* and mouse embryos, which permits the lipofection (transfection with the aid of lipofectin) of various functional genes into the cells of the central nervous systems of embryos, have appeared recently.^{42, 44}

The bolaamphiphiles 5 and 6 are also used as ideal amphiphiles for polyanions. The positively charged end of the bolaamphiphile molecule may bind a negatively charged polyanion in aqueous solutions even if it is only sparingly soluble in the latter. However, since these compounds do not possess aliphatic chains arranged in parallel, they are unable to form a stable bilayer. They are therefore more frequently used as models for the investigation of the interaction of liposomes and cell membranes with polyelectrolytes.⁴

Cationic liposomes, prepared by the sonication of aqueous dispersions of lipids or by employing solubilising detergents, are used to incorporate horseradish peroxidase into human erythrocytes *in vitro*. The stability of the modified erythrocytes has been investigated from the standpoint of photohemolysis.³⁵

Behr *et al.*¹⁰ developed a highly effective transfection method based on the ionic binding of plasmids to the lipopolyamines 14 and 15. This procedure has been used for the transfection of lipopolyamines into the endocrine cells of the intermediate lobe of the pituitary gland. Such transfection did not entail changes in the membrane-dependent receptors and did not affect the physiological regulation of the biosynthesis of hormones. The cationic lipopolyamines 14 and 15 do not exert a toxic activity on cells and may be used for the transfection of chromaffine cells and the neurones of the central nervous system. It is of interest that the method does not affect the normal cell growth or the electrochemical characteristics of the peripheral neurones. The introduction of DNA into the epidermal human keratinocytes has also been achieved with the aid of lipopolyamines.⁴⁵

The so called lipopolylysines 13 are some of the most effective mediators of DNA transfection.⁹ Poly-L-lysine is used as the starting material for the synthesis of this preparation because of its biodegradability on entering the cell, in contrast to poly-D-lysine. This preparation is used in the individual state, since its liposomal form (with PC or PE) exhibits only 50% of the activity of the individual form in DNA transfection. Lipopolylysine preparations are at present some of the most active and relatively cheap mediators of the DNA transfection of type L929 mouse cells and human HeLa cells as well as the monkey Vero cells.

The data presented indicate the possibility of using lipofection under *in vivo* conditions. The method using DOTMA, or its analogues belonging to the series of diolealkyl derivatives containing a hydroxyalkyl chain in the quaternary ammonium head, as the cationic lipid has been recognised nowadays as optimal. These compounds enter into the composition of liposomes in a mixture with dioleoylphosphatidylethanolamine (50 mol %).^{46–48}

An aerosol method for the introduction of plasmids for the expression of chloroamphenicol acetyltransferase, which makes it possible to achieve a high lung-specific level of its production in the mouse organism *in vivo*, has been developed recently.⁴⁹

Promising results have been obtained in the lipofection of plasmids, coding the synthesis of the human growth hormone, via the introduction of the preparation intravenously into the mouse organism.⁵⁰

It has been shown that the direct intravenous introduction of DNA — cationic liposome complexes into the organisms of adult animals transfects effectively all types of tissues (the endothelial tissues of blood vessels and the parenchymal cells of the lungs, spleen, lymph nodes, and bone marrow). The expression of the genes introduced remained at a stable level for 9 weeks after transfection. At the present time, these results are being considered from the standpoint of the study of ageing processes at a molecular level.⁵¹

Furthermore, the study of organ tissues and analysis of the cardiac functions of mice and pigs after lipofection *in vivo* has not revealed any pathologies following the employment of deliberately excess doses of the DNA — liposome complex.⁵²

It is essential to note that the transfection method, employing cationic liposomes as mediators, may prove promising in the enzyme- and hormone-substitution therapy of a wide variety of diseases such as sugar diabetes, growth defects, and various blood affections (β -thalassemia, adenosine deaminase deficiency, sickle cell anaemia, etc.).^{14, 49, 50, 53}

3. The use of cationic lipids as inhibitors of the membrane-bound protein kinase C and diacylglycerol kinase

In connection with the study of the influence of lipids of the type of 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET-18-OMe) on metastases and the growth of a wide variety of neoplastic cell lines, the new quaternary ammonium derivatives of glycerolipids 20 are of great interest. These compounds proved to be effective inhibitors of the membrane-bound protein kinase C (PKC), which regulates the content of phospholipids and Ca^{2+} ions in the cell. The study of the mechanism of the action of this kinase, activated by phosphatidylserine, phorbol esters, and diacylglycerols, has shown that exogenic alkylacylglycerols and dialkyl derivatives are capable of inhibiting this kinase, which is present in HL-60 cells. A similar activity of compounds of types 23 and 32 has been observed in relation to diacylglycerol kinase (DAG).⁷ In order to investigate the molecular interaction of these enzymes with their natural activators, inhibitors, and substrates, a series of dialkyl and diacyl quaternary ammonium derivatives with various structures have been synthesised (compounds 10, 21, 23, 32, etc.)

The study of the activity of PKC in the presence of the above compounds using *rac*-1,2-dioleoylglycerol — $\text{PS} - \text{Ca}^{2+}$ mixtures as activators showed that the manifestation of inhibiting activities requires the presence in its composition of a relatively long-chain alkyl or acyl substituent at the C(1) atom of the glycerol fragment, a short-chain alkyl or acyl substituent at the C(2) atom, and also a functional group capable of forming hydrogen bonds at the C(3) atom. A similar conclusion was reached in relation to DAG when *rac*-1,2-dioleoylglycerol was used as the substrate in the investigations.

Compounds 32a,b proved to be the most active under the experimental conditions, whereas the diol type lipid 10 proved to be inactive in this instance.

During tests of 2-*O*-acetyl-1-*O*-oleoylglycerol as one of the activators, a study was made of the ability of compounds of types **21**, **23**, and **26** to inhibit PKC (obtained from the bovine brain), which made it possible to discover the influence of the structure of these compounds on the inhibition process. Table 1 presents the concentrations corresponding to 50% inhibition of PKC by compounds having different structures.^{16, 54}

The data presented permit the following conclusions:

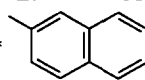

- the replacement of an oxygen atom by a sulfur atom does not alter significantly the activity (cf. compounds **23a** and **23f**);
- the long alkyl chain at the C(1) atom of glycerol plays a decisive role in the manifestation of activity (compound **23e** is inactive);
- significant differences between the activities of compounds containing methoxy- and ethoxy-groups at the C(2) atom of the glycerol fragment have not been observed (compounds **23a** and **23b**);
- the activities are influenced by a change in the length of the chain of the *N,N*-dimethylalkylammonium alcohol; thus the propanol derivative **23g** exhibits a higher activity than compound **23a**;
- the replacement of the 'inverse' choline group by a trialkylammonium group improves the inhibition of the enzyme (a free hydroxy-group alters the activity insignificantly);
- the replacement of the quaternary ammonium group by a hydroxy-group does not influence the inhibition of PKC but fully abolishes the cytotoxicity of these analogues in relation to tumour cells;
- the migration of the quaternary nitrogen atom from the glycerol skeleton to the end of the alkyl chain made up of several methylene groups has only a slight influence on the PKC activity (compounds **26a–c** and **23h**).

In conclusion, one must note that the restriction of the mobility of the glycerol on incorporation of R¹ and R² into a structure of the acetal type does not diminish the activity. Furthermore, the stereospecificity of the compounds synthesised is not a decisive factor in the inhibition of PKC.¹⁶ Preliminary experiments designed to elucidate the mechanism of the inhibition of PKC showed that the compounds quoted block its activation by phosphatidylserine.

Studies which will help to discover for these compounds a correlation between the antineoplastic activity and the ability to inhibit PKC are being prosecuted at the present time.

4. The antitumour activity of positively charged lipids

It is widely known that positively charged alkyl ether lipids influence the metabolism and growth of neoplastic cell lines. The compound ET-18-OMe and its phosphorus-free analogues

accumulate on the surface of the plasma membrane, inhibiting PKC and certain other kinases, which may be associated with the antineoplastic activity which they exhibit in vitro (HL-60 and KB cells) and in vivo (S-180 and MM46 cells).²⁰ In addition, alkyl ether lipids may accumulate selectively in tumour cells by virtue of the low activity in the latter of the enzymes which cleave ether bonds.^{28, 55} This disturbs the normal biosynthesis of the lipids of the cell membrane and the functions and integrity of the latter.

A series of cationic lipids with an antineoplastic activity have been synthesised. They can be subdivided arbitrarily into five main series:

(1) Lipids with a cationic head in the form of 'inverse' choline (Table 2).

(2) Cationic lipids of the acetal type (Table 3).

(3) Lipids with an ammonium group attached directly to the glycerol fragment (Table 4).

(4) Lipids with a cationic head attached to the glycerol skeleton via a spacer group (Table 5).

(5) Derivatives of cationic lipids of the diol type (Table 6).

All the compounds were investigated from the standpoint of their antineoplastic activity in relation to cells of different types (Tables 2–6). Comparison of the results of experiments performed under similar conditions permits a series of conclusions.

The 'inverse' cholines of the first series have largely proved less active than the compounds of the third and fourth series, the activities of which are comparable with that of the ET-18-OMe reference standard. The presence of the hydroxy-group in the

cationic head reduces the activity somewhat. The influence of the heteroatom (S or O) at the C(1) atom of glycerol has not been accurately elucidated.⁵⁴

A decrease in the length of the alkyl substituent at the C(1) atom of glycerol or its replacement by an aromatic system lowers the activity of the compound in relation to the HL-60 cells. Thus compound **23e** (Table 2) shows no activity within the limits of the measured concentrations.

^a Expressed in μmol litre⁻¹.

The restriction of rotational mobility in the presence of the acetal system at the C(1) and C(2) atoms of the glycerol fragment diminishes the antineoplastic activity of the compounds. The presence of methoxy- or ethoxy-groups at the C(2) atom does not affect the activity. However, the presence of an alkyl substituent with a long chain containing more than five carbon atoms reduces the activity of the compound sharply. The replacement of the methoxy- and ethoxy-groups by heterocyclic bases of the pyrimidine or pyridazine type induces a slight decrease in the antineoplastic activity.²⁴

Among the compounds of the fourth group, the inhibition of the growth of neoplastic cells diminishes slightly with increase in the length of the spacer group but remains similar to the inhibiting activity of ET-18-OMe.

The presence of a quaternary ammonium or a tertiary sulfonium group is essential for the manifestation of activity, the sulfonium and pyridinium derivatives being the most active.⁶

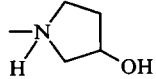

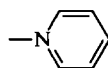

The degree of oligomerisation of the ethyleneoxy-group in compounds with the structure **29** does not play a decisive role for the activation in vitro (Table 5).²⁰ A similar conclusion can be reached also as regards compounds **49a** and **49b** with different numbers of methylene groups separating the sulfo-group from the cationic head.⁵⁶

It is of interest that compound **29**, containing the acetoacetyl group at the C(2) atom of the glycerol fragment, proved to be fairly active against the S-180 and MM46 cells in studies carried out in vivo in contrast to in vitro investigations.²⁰

numbers of methylene groups separating the sulfo-group from the cationic head.⁵⁶

It is of interest that compound **29**, containing the acetoacetyl group at the C(2) atom of the glycerol fragment, proved to be fairly active against the S-180 and MM46 cells in studies carried out in vivo in contrast to in vitro investigations.²⁰

Some of the analogues synthesised have been tested in other systems. Thus for cells of the ChaGo and K562-4 lines, the inhibition was similar to that of the cell line 77. The inhibition of the P388 cells in mouse leukemia is comparable to the activity against the KB cells. The cells of the MHC rat hepatoma, obtained from the Morris 7795 hepatoma, were inhibited 2–3 times less effectively than the cells of the 77 line.⁵

There are data⁵⁷ demonstrating that increased concentration of cholesterol in the cell membrane plays a fairly important role in reducing the toxicity of the alkyl ether lipids (AL) to the HL-60 cells.

5. The antiviral activity of positively charged lipids

Synthetic lipids of the alkyl type exhibit a broad spectrum of biological activity, including the inhibition of replication of the HIV-1 virus. The exact mechanism of their action is not entirely clear. The HIV infection is a multistage process, which begins with the binding of the HIV to the CD4 receptors of the lymphocytes. After binding, the HIV permeates into the cell either via the direct fusion of the viral coating with the plasma membrane or by virtue of the receptor-dependent endocytosis of the CD4–HIV complex.^{6,59} There are data demonstrating that the blocking of the HIV-dependent phosphorylation of the CD4 receptors by the introduction of a selective PKC inhibitor inhibits effectively the infection of the cell by the virus.

A new class of alkyl ether lipids — potential PKC inhibitors — has been investigated recently as regards their anti-HIV-1 activity. Monolayers or suspension cultures of human T-cells (CEM-ss) were used in these investigations to determine the activity of the structurally modified, phosphorus-free analogues of lipids of the alkyl ether type. The concentration corresponding to 50% inhibition of the growth of the CEM-ss cells and the formation of HIV-1 plaques as well as the decrease in viral budding (the capture by the virus of a portion of the cell membrane on permeation into the cell) were investigated.^{17,60}

The experiments established that treatment of the cells infected by HIV-1 with compounds of this type is not accompanied by an increase in the activity of the reverse transcriptase, which implies different mechanisms of the action of 3'-azido-3'-deoxythymidine (AZT) and cationic lipids.

Electron microscope studies have shown⁶⁰ that there is no viral budding on the surface of a cell membrane in cells infected by HIV-1 and treated with positively charged lipids, but intracellular vacuolar viral particles are present. These data suggests that alkyl ether lipid analogues disturb the process involving the formation of cytoplasmic vacuolar forms of HIV in T-cells. The binding of HIV-1 to CD4 receptors of the T-lymphocytes induces their phosphorylation by means of the phospholipid-Ca²⁺-dependent

R¹ = C₁₈H₃₇; R² = (CH₂)₂CH(OH)CH₂OH (**8f**);

R¹ = C₁₆H₃₃; R² = (CH₂)₂OH (**8g**), (CH₂)₃OH (**8h**);

PKC, whereupon cationic lipids, inhibiting the kinase, block the intracellular processes involving the development and multiplication of viral particles. The formation of HIV-1 plaques is inhibited via a concentration-dependent mechanism until the virus ceases to act on the growth of human T-cells.

The activities of the following compounds against HIV-1 have been investigated:

Compound	R ¹	R ²	R ³	Q
23a	C ₁₆ H ₃₃	Me	(CH ₂) ₂ OH	Br
23b	C ₁₆ H ₃₃	Et	(CH ₂) ₂ OH	Br
23d	C ₁₆ H ₃₃	Me	Me	Br
23g	C ₁₈ H ₃₇	Me	(CH ₂) ₃ OH	I
23r	C ₁₆ H ₃₃	Me	CH ₂ CH(OH)CH ₂ OH	Br
23u	C ₁₆ H ₃₃	Et	C ₅ H ₅ N ⁺ (instead of N ⁺ Me ₂ R ³)	Br
50	C ₁₆ H ₃₃	Et	OH (instead of N ⁺ Me ₂ R ³)	—

Analysis of the results (Table 7) shows that the formation of HIV-1 plaques in the CEM-ss cells is inhibited within the limits of

Table 7. Concentrations corresponding to 50% inhibition of the formation of HIV-1 plaques and the growth of CEM-ss cells.^{17,60}

^a D is the differential selectivity defined as the ratio of the concentration corresponding to the inhibition of the growth of the CEM-ss cells to the concentration corresponding to the inhibition of the formation of HIV-1 plaques.

concentrations which are not toxic to the host cells. In order to exhibit anti-HIV-1 activity, compounds of this type must possess long-chain alkyl substituents at the C(1) atom, a short-chain substituent at the C(2) atom, and a quaternary ammonium group at the C(3) atom of glycerol.

The changes in the type of cationic head and in the size of the substituents at the quaternary nitrogen atom do not influence significantly the activity of the compounds.^{17,60} However, in its absence the compound becomes inactive (for example, compound 50).

Unfortunately no data have been obtained which would make it possible to infer the inhibition of the formation of plaques of the type 2 herpes simplest virus (HSV-2) or the inactivation of the intracellular virus, which evidently indicates the selectivity of compounds of this type in their action against HIV-1. This apparently occurs because they interact with the cytoplasmic

membrane (the HIV-1 budding site) and not with the nuclear membrane (the herpes simplest budding site). In addition, the herpes virus does not require PKC for infection and its multiplication is different from that of HIV-1 (Table 7).¹⁷

Studies designed to elucidate the mechanism of the action of alkyl ether lipid analogues, inhibiting infection by HIV-1 and inducing the formation of a defective form of the virus, are being carried out at the present time. It has been shown that lipid antagonists are not inhibitors of reverse transcriptase but disturb the replication of the virus in the last stage. The choice of optimum analogues may provide specialists with effective chemotherapeutic preparations which can be used in the treatment of AIDS either individually or in combination with DNA-interactive anti-HIV-nucleosidic analogues.⁶⁰

6. Cationic lipids — analogues and antagonists of the platelet activating factor

Numerous specific and nonspecific analogues and antagonists of the platelet activating factor (PAF) have been synthesised and investigated during the last decade. Synthetic derivatives permitting the solution of the problem of the relation between structure and biological activity and the possible therapeutic activity are of special interest.

The numerous PAF antagonists with a lipid structure can be subdivided into the following types: natural phospholipid PAF antagonists, their derivatives, and synthetic compounds. These antagonists are in the main active inhibitors of the binding of PAF to its receptors. Many of them are highly specific in their biological activity with the exception of certain phospholipid analogues, which do not exhibit any appreciable antagonistic activity at high concentrations.^{26,61}

Two methods for the investigation of PAF antagonists under in vitro conditions are most widely used nowadays: inhibition of the PAF-induced aggregation of rabbit, human, and guinea pig platelets, as well as the inhibition of the specific binding of [³H] PAF to cells or isolated membranes.⁶¹ In the in vivo experiments, usually carried out on mice or rabbits, the effect of antagonists on the decrease in pressure, induced by PAF, and also the prevention of the lethal effect of high PAF doses are considered.^{47,62–67}

One of the first phospholipid PAF antagonists, namely CV-3988 (Table 8), was synthesised initially as a powerful antifungal and cytotoxic agent.⁶⁸ The next structural phosphorus-free analogue, CV-6209, proved to be approximately 80 times more active in experiments in vitro.^{26,61,63,69,70} A series of antagonists were synthesised in this connection by substituting the phosphocholine groups of PAF by quaternary ammonium groups of different types, attached to the glycerol fragment via spacer groups. In a general form, the structure of the PAF antagonists can be represented as follows:

The strength of the antagonists in relation to the PAF-induced state depends on their structure and the experimental conditions. For each series of cationic lipids, representatives of which are listed in Table 8, the concentrations corresponding to the inhibition of the PAF-induced aggregation of platelets were obtained. For the majority of them, experiments designed to investigate the influence of the antagonists on the pathological states induced by the introduction of PAF under in vivo conditions were formulated.^{25,35,61–64,71}

The principal requirements which must be met by the structure of the PAF antagonists are listed below:

(a) the long-chain substituent at the C(1) atom attached to glycerol via oxy-, thio-, carbamoyloxy-, and carbamoylthio-groups should have an optimum content of 16–18 carbon atoms;

Table 8. Concentrations corresponding to the 50% inhibition of the aggregation of blood platelets by PAF antagonists (for the experimental conditions and the type of platelets, see the literature sources).

(b) the configuration of the chiral centre must be analogous to that of PAF (*R*);

(c) the character and bulk of the substituent at the C(2) atom of glycerol must be analogous to those of acetyl;

(d) the replacement of the phosphate group at the C(3) atom by a spacer group of any kind is essential;

(e) the cationic head must have an acceptable structure.

It follows from the data presented in Table 8 that the replacement of the alkyl chain at the C(1) atom of glycerol by aromatic or heterocyclic groups with substituents of different lengths and structure did not lead to a sharp alteration of the antagonistic activity (cf. CV-6209 and **54a**).^{35, 61, 62}

No appreciable differences between the *in vitro* activities of the (*RS*)- and (*R*)(-)- and (*S*)(+)-analogues have been observed (cf. **51b**–**d**). A similar situation has been noted for the compounds SRI 63-072 and SRI 63-119.^{35, 79}

In the case where the spacer group Z is a carbamoyl derivative, the introduction of an acyl substituent into this group increases the blocking of the aggregation of platelets *in vitro* (cf. compounds **42a** and **42b**).^{62, 64, 70} However, when amide bridges, linear imide bonds, and alkyl and certain carbamoyl substituents are used in the spacer group instead of the acyl substituent, the activity decreases fairly appreciably. An increase in the size of the spacer group as a whole induces a similar effect.^{62, 70}

It is preferable to use thiazolinium and pyridinium groups as the cationic head. The presence of the ethyl substituent at the quaternary nitrogen atom in the heterocycle has then the most

favourable effect on the antagonistic activity (compound **51b**).^{35, 61, 70}

PAF antagonists help nowadays to elucidate the possible role of this natural bioregulator in various pathological changes in the organism and also its interaction with other causative agents and immunological mediators of these processes.⁸⁰ Many investigators are actively engaged in the assessment of their clinical activity. The data obtained suggest that it is possible to exert a definite therapeutic effect on asthma, allergic diseases, shock syndromes, the endointoxication of the organism, premature births, psoriasis, and many allergic diseases of the eyes.

In conclusion, it is essential to note that the creation and comprehensive investigation of new positively charged glycerolipids with the aim of discovering among them biologically active substances with an extended spectrum of therapeutic activity is an aspect of bioorganic chemistry and biotechnology of current interest.

Abstract. Data on the synthesis, transformations, and applications of adamantane derivatives containing heterocyclic substituents in the bridgehead positions are surveyed, described systematically, and analysed. The bibliography includes 202 references.

I. Introduction

Adamantane was discovered in 1933 in a study of petroleum products.^{1,2} The adamantane molecule is a rigid structure consisting of three fused six-membered carbon rings and having the shape of almost an ideal sphere. The arrangement of carbon atoms in the adamantane molecule is similar to that in the unit cell of the crystal lattice of diamond. The spatial structure, hydrophobicity, and lipophilicity of adamantane ensure favourable conditions for its transport through biological membranes. The introduction of an adamantyl radical into organic compounds changes and often enhances their biological activities. The influence of the adamantyl radical on the hypoglycemic, antitumour, immunodepressive, antibacterial, fungistatic, hormonal, analgesic, antipyretic, anti-inflammatory, cholagogic, antiarrhythmic, sedative, neuroplegic, antimalarial, and anticholine-esterase activities as well as on the central nervous system stimulating activity of the corresponding medicinal preparations have been noted.³ Among various compounds of the adamantane series, those containing heterocyclic substituents in their molecules seem to be especially interesting both from the theoretical and practical standpoints.

Despite the great interest of researchers in the chemistry of adamantane derivatives containing heterocyclic substituents and numerous examples of their practical use, no reviews surveying the literature data on the synthesis, transformations, and practical significance of heteryladamantanes have been published; only separate examples of synthesis or biological activity of heteryladamantanes have been reported.^{4–11} Among the monographs devoted to adamantane,^{12–14} only one paper¹³ contains a mention

of heteryladamantanes, synthesised before 1975; however, this study also contains virtually no data on the synthesis and properties of adamantane derivatives with heterocyclic substituents.

In our review we survey the published data on the synthesis and properties of adamantane derivatives, the bridgehead positions of which contain heterocyclic radicals either linked directly to the adamantane nucleus or separated from it by a chain of carbon atoms. We consider adamantane derivatives with heterocyclic residues the nucleus of which incorporate nitrogen, oxygen, sulfur, nitrogen and oxygen, or nitrogen and sulfur atoms, as well as residues of other heterocyclic systems.

II. Adamantane derivatives containing heterocyclic nuclei with nitrogen atoms

1. Compounds with three-membered heterocycles

Several methods have been proposed for the synthesis of heteryladamantanes containing residues of three-membered nitrogen-containing heterocycles. A series of *N*-adamantoylaziridines **1** were prepared by the reaction of the acid chlorides **2** with aziridine in the presence of triethylamine.¹⁵

R = H, Me.

From here on, Ad is adamant-1-yl, C₁₀H₁₅.

Substituted aziridines **5** have been synthesised by the interaction of the vinyl chlorides **6** with 1-aminoadamantane **7**.¹⁷

X = H₂, O.

The derivatives of 1-(adamant-1-yl)aziridin-2-one **8** have been obtained by cyclocondensation of *N*-(adamant-1-yl)amides of α-bromocarboxylic acids **9** in 60%–70% yields.^{18–20}

R = Ad (see Ref.18), Bu^t (see Ref.19, 20).

The same method has been used to synthesise compounds **10** containing two aziridinone fragments (yields 60% and 64%).²¹

R = Bu^t, Ad.

When chloramides **12** are used in this reaction instead of the corresponding bromamides, the aziridinone derivatives **11** are formed equally readily in 60%–70% yields.^{22–24}

The irradiation of 1-(adamant-1-yl)-4,4-dimethyltriazol-5-one with light from a high-pressure mercury or mercury-xenon lamp in toluene at 15 °C for 4.5 h under a nitrogen atmosphere affords a mixture of products in which 1-(adamant-1-yl)-3,3-dimethylaziridin-2-one was detected by spectral methods.²⁵

Treatment of adamantyl-containing aziridines (reduced preliminarily with lithium tetrahydroaluminate)¹⁵ and adamantyl-containing aziridinones^{23,24,26,27} with strong acids (H₂SO₄ or MeSO₃H) leads to aldehydes of the adamantane series in more than 90% yields.

R² = H: R¹ = H, Me, Ph, OH, MeO, F, Cl, Br, I, 4-ClC₆H₄;

R¹ = R² = Me; R¹ = Me, R² = OH; R¹ = EtO, R² = Et.

R ¹	R ²	R ³	Ref.
H	H	H	24, 26, 27
Me	H	H	24, 26, 27
Me	Me	Me	24, 26, 27
Me	Me	H	24

The transformation of adamantyl-containing aziridinones into aldehydes can also be carried out in the absence of acids, by heating them at 140–150 °C.²³

R = Bu, Bu^t, C₅H₁₁.

Treatment of the aziridinone derivatives **11** with HCl in Et₂O gives the salts **13** (yields 95%–96%),^{23,24} whereas the reaction of the compounds **11** with sodium hydroxide or potassium *tert*-butoxide affords the amino acids **14** (yields 63%–94%).

Lithium *tert*-butoxide converts compounds 15 into the alcohols 16 in 75%–85% yields.²⁸

R¹ = Ad, R² = Bu^t, Ad;

R¹ = Bu^t, R² = Ad.

The reaction of azomethines 17 with hydrohalic acids involves the cleavage of the aziridine ring and yields salts 18.²⁹

Ar = Ph, C₆H₄R; X = Cl, Br, I.

1-(Adamant-1-yl)aziridine exhibits antiphlogistic activity and stimulates the central nervous system.³⁰ 1-(Adamant-1-yl)-3-*tert*-butylaziridin-2-one possesses antiviral activity.²¹

The successive treatment of 1-acetyladamantane imine with ammonia and then with hydroxyaminesulfonic acid resulted in the formation of 3-(adamant-1-yl)diaziridine 19, which was converted into 3-(adamant-1-yl)diazirine 20 by the action of chromic anhydride in sulfuric acid. The compound 20 is thermally unstable and is converted on heating into a mixture of vinyladamantane and the azine 21 in a ratio of 5.1 : 1.³¹

The transformation of the diazirine 20 into vinyladamantane and the azine 21 involves the intermediate formation of the carbene AdC(Me). Diazirines of this type are of interest as

initiators of polymerisation or as reagents for introducing a tracer into cell membrane lipids.³¹

2. Compounds with four-membered heterocycles

In the search for compounds exhibiting an antiarrhythmic activity, the reaction of epichlorohydrin with the amine 7 has been studied. Thus 1-(adamant-1-yl)azetidin-3-ol 22 was obtained in a good yield.³²

A method for the preparation of 1-(adamant-1-yl)-3-methyleneazetidin-2-one 23 has been developed.³³ The method involves cyclisation of the acid chloride 24 with the amine 7 under the influence of potassium hydroxide under conditions of phase transfer catalysis; the yield of compound 23 is 40%.

The oxygen atom in the compound 23 can be substituted by sulfur by the action of the Lawesson reagent; this reaction affords 1-(adamant-1-yl)-3-methyleneazetidine-2-thione in 46% yield.³³

Ketenimine 25 enters into cycloaddition reactions with azomethines or with azobenzene; this results in the formation of the azetidine derivatives 26 or diazetidine derivatives 27.³⁴

3. Compounds with five-membered heterocycles

A number of methods have been reported for the introduction of a pyrrolidine ring into adamantyl-containing compounds. For example, in the reaction of the bromoketones 28 with pyrrolidine, the bromine atom is substituted by a pyrrolidine residue.³⁵

R = H, Me.

The alcohol 29, which causes general depression of the central nervous system, is obtained in 34% yield by refluxing ethyl 3-(adamant-1-yl)-3-hydroxy-3-phenylpropionate 30 in pyrrolidine in the presence of potassium *tert*-butoxide followed by the reduction of the compound 31 thus formed.³⁶

The addition of adamant-1-yl radical to the nitrogen atom of pyrrolidone has been accomplished in two stages: initially, pyrrolidone was refluxed with hexamethyldisilazane 32, and then the resulting *N*-silylated derivative 33 ($X = H_2$) was treated with 1-chloroadamantane in the presence of titanium(IV) chloride and chlorotrimethylsilane. The reaction product 34 ($X = H_2$) and the corresponding adamantylation product 34 ($X = O$) were obtained in a similar way from pyrrolidine-2,5-dione (yield 33%).³⁷

$X = H_2, O$.

N-(Adamant-1-yl)phthalimide 35 has been obtained in 15% yield by the reaction of the amine 7 with phthalic anhydride with subsequent cyclisation of the resulting *o*-(adamant-1-yl)amino-carbonylbenzoic acid with acetic anhydride.³⁸

N-(Adamant-1-yl)maleimide, which possesses antitumour activity and inhibits *Herpes simplex* virus, has been prepared by the reaction of the amine 7 with maleic anhydride followed by cyclisation of the resulting compound $AdNHCOCH=CHCOOH$ with polyphosphoric acid.³⁹

Heating of butyrolactone with the amine 7 and with 1-amino-3-hydroxyadamantane at 200–205 °C leads to *N*-substituted derivatives of pyrrolidone 36a and 36b in 86.5% and 71.5% yields, respectively.

$R = H$ (a), OH (b), $COOH$ (c).

The hydroxy compound 36b can also be obtained from the adamantyl derivative 36a by treating it with a mixture of nitric and sulfuric acids (0–5 °C, 2 h, yield 56.3%). The acid 36c ($R = COOH$), in its turn, can be synthesised in 69.5% yield from the hydroxy derivative and formic acid in the presence of sulfuric acid (20 °C, 5 h).⁴⁰

The compounds 36a and 36b exhibit an immunostimulating activity, which is higher for 36a. The introduction of the $COOH$ group exerts no substantial influence on the activity, but decreases markedly the toxicity.⁴⁰

N-(Adamant-1-yl)pyrrolidone and its hydrochloride have been patented as anti-inflammatory agents and also as preparations stimulating the central nervous system and decreasing the cholesterol level.²⁹ *N*-[2-(Adamant-1-yl)ethyl]pyrrolidine and *N*-[3-(adamant-1-yl)propyl]pyrrolidine hydrochlorides have also been recommended as agents influencing the central nervous system.⁴¹

Heating of the diketone 37 with ammonia in a sealed tube affords 2,5-di(adamant-1-yl)pyrrole in a very high yield (95%).⁴²

The cyclisation of compound 38 in the presence of hydrogen chloride or trifluoroacetic acid affords two different salt-type products.⁴³

Refluxing of the bromomethyl ketones 39 with aniline leads to their cyclisation into indol derivatives 40 in 48%–94% yields.^{44,45}

R ¹	R ²	n	Ref.
H	H	0	44, 45
H	H	1	44
CH ₂ Br	CH ₂ Br	0	44
Cl	NHPh	0	44

It has been found that the reaction of adamant-1-yl bromomethyl ketone **41** with 2-methylpyridine gives in 50% yield salt **42**, which then cyclises to 2-(adamant-1-yl)indolizine in 58% yield.⁴⁶

2-(Adamant-1-yl)buta-1,3-diene **43** enters into the Diels-Alder reaction with *N*-phenylmaleimide upon refluxing in benzene to give the corresponding adduct **44** in 63% yield.⁴⁷

The introduction of an adamantane nucleus into the porphyrin derivatives **45** giving rise to compounds **46** has been accomplished by the action of 3-aminomethyl-1-hydroxyadamantane or 3-hydroxyadamantane-1-carboxylic acid in the presence of methanesulfonic acid (see Table 1).⁴⁸

Following refluxing with formamide, the bromoketones $\text{Ad}(\text{CH}_2)_n\text{COCH}_2\text{Br}$ are converted into imidazole derivatives **47** in 43%–51% yields.^{44, 45}

$n = 0, 1.$

The ketone **48**, which is formed in the reaction of the bromomethyl ketone **41** with imidazole, has been reduced to the corresponding alcohol **49**, the derivatives of which have been recommended as bactericides and fungicides.⁴⁹

Japanese investigators^{50, 51} developed a method for the introduction of the adamantyl radical into heterocyclic compounds, which involves the use of organosilicon derivatives of the latter. For example, treatment of *N*-(trimethylsilyl)imidazole with 1-chloroadamantane in the presence of aluminium chloride or titanium(IV) chloride affords 4-(adamant-1-yl)imidazole in 52% yield.⁵¹

Similarly, in the reaction of 1-(trimethylsilyl)benzimidazole with 1-chloroadamantane, the adamantyl radical adds to the benzene ring rather than to the heterocyclic nucleus; hence, the reaction leads to 5-(adamant-1-yl)benzimidazole (yield 49%).⁵⁰

In a more recent study,³⁷ the *N*-adamantylation of nitrogen-containing heterocycles has been carried out by a one-pot procedure: a heterocyclic compound was initially treated with disilazane, and then 1-chloroadamantane and a Lewis acid were added to the reaction mixture; the process was completed, as a rule, at room temperature. 4-Methylpyrazoline was converted in this way into 1-(adamant-1-yl)-4-methylpyrazoline (yield 60%), while the transformation of 5-methylpyrazoline gave 1-(adamant-1-yl)-5-methylpyrazoline (yield 18%) and the product of its dehydrogenation, 1-(adamant-1-yl)-5-methylpyrazole (yield 37%).³⁷

Table 1. Yields of adamantylporphyrins 46.

1-(Adamant-1-yl)pyrazole has been obtained by heating pyrazole with 1-bromoadamantane.^{52,53}

1-(Adamant-1-yl)imidazole (yield 74%) and 1-(adamant-1-yl)benzimidazole (yield 69%) were synthesised in a similar way from 1-bromoadamantane and imidazole (or benzimidazole).⁵³

The reactions of 1-bromoadamantane with pyrazole and its alkyl analogues **50** have been studied in detail. It was found that the interaction of AdBr with pyrazole, 3-methylpyrazole, or 3,5-dimethylpyrazole under a pressure of 200 atm may afford one to three reaction products **51–53** depending on the temperature and on the ratio heterocyclic compound : bromide.⁵⁴

1 : 1	230	4	0	100	0

In a certain temperature regime, one can obtain only compounds **51**.

The hydrochlorides of iminoesters of carboxylic acids are convenient initial compounds for the synthesis of diverse heterocyclic derivatives. The reaction of methyl adamantane-1-carboximidate hydrochloride **54** with ethylenediamine gives 2-(adamant-1-yl)imidazoline in 92% yield, while the interaction of compound **54** with *o*-phenylenediamine leads to 2-(adamant-1-yl)benzimidazole (yield 71.5%).^{55, 56}

The imidazoline derivatives **55** have been synthesised in 80%–94% yields by cyclocondensation of *N*-(adamant-1-ylmethyl)ethylenediamine with hydrochlorides of various methyl carboximidates.⁵⁶

R = Me, Ph, PhCH₂, 5-nitrofuryl-2, 2-(benzimidazol-1-yl)ethyl, 3-nitro-3-methylbutyl.

The reaction of hydrochlorides of methyl iminoesters of dicarboxylic acids **56** with two equivalents of *N*-(adamant-1-ylmethyl)ethylenediamine affords compounds **57** containing two *N*-(adamant-1-ylmethyl)imidazoline fragments in 89%–95% yields.⁵⁶

A series of adamantane derivatives containing residues of two identical or different five-membered heterocyclic compounds have been synthesised from 1,3-dicyanoadamantane **58**. Its reaction with ethylenediamine in boiling cumene in the presence of hydrochloric acid gave 1,3-bis(imidazolin-2-yl)adamantane **59** in 86% yield.^{56, 57}

The compound **59** is also formed in 83% yield in the reaction of the diiminoester dihydrochloride **60** with a five-fold excess of ethylenediamine in methanol.^{56, 57}

If the reaction of the dihydrochloride **60** involves a stoichiometric amount of ethylenediamine, it leads to the compound **59** and 3-aminocarbonyl-1-(imidazolin-2-yl)adamantane **61**.^{56, 57}

The formation of the amide **61** is accounted for by the fact that one of the iminoester groups undergoes partly the Pinner rearrangement under the reaction conditions

1-(Benzimidazol-2-yl)-3-(methoxycarbonyl)adamantane **62** has been synthesised in 64% yield by the reaction of the dihydrochloride **60** with a stoichiometric amount of *o*-phenylenediamine carried out in boiling methanol.

The C(O)OMe group arises via the alcoholysis of the iminoester group.^{56,57}

When the dihydrochloride **60** is introduced in the reaction with a fivefold excess of *o*-phenylenediamine at 20 °C, 1,3-bis-(benzimidazol-2-yl)adamantane **63** is obtained in 69% yield. The same compound is formed in 58% yield on refluxing the dinitrile **58** and *o*-phenylenediamine in cumene in the presence of hydrochloric acid.^{56,57}

The adamantane derivative containing a benzimidazole residue in the 1-position and an imidazoline fragment in 3-position has been prepared in 71% yield by condensing compound **62** with ethylenediamine in the presence of the KU-2 cation-exchange resin.^{56,57}

Refluxing of the compound **62** with *o*-aminophenol in *p*-xylene in the presence of the KU-2 cation-exchange resin with continuous removal of the water liberated affords 1-(benzimidazol-2-yl)-3-(benzoxazol-2-yl)adamantane **64** in 59% yield.^{56,57}

The carboxylic acids of the adamantane series **65** react with ethylenediamine or with *o*-phenylenediamine at a temperature of 180 °C giving the imidazolines **66** (yields 49% and 56%) or benzimidazoles **67** (yields 32%–42%).⁵⁸

66: R¹ = H, OH;

67: R¹ = H; R² = H, Me, Cl, Br, OH.

Some of the compounds synthesised were noted to possess antihypertensive and antibacterial activities.⁵⁸

6-(Adamant-1-yl)benzimidazole has been obtained in 98% yield by the cyclocondensation of the bis-hydrochloride **68** with formic acid.⁵⁹

N-(Adamant-1-ylcarbonyl)-*o*-phenylenediamine is converted into 2-(adamant-1-yl)benzimidazole in 96% yield on heating with polyphosphoric acid.⁶⁰

Cyclocondensation of hydrazine or its derivatives with carbonyl compounds is a common method for the synthesis of compounds of the pyrazole series. This method is also used fairly frequently for the synthesis of adamantyl-containing pyrazole derivatives. For example, when *N*-(adamant-1-yl)hydrazine hydrochloride **69** is made to react with the tetramethylacetal of malonaldehyde, 1-(adamant-1-yl)pyrazole is formed in 63% yield; treatment of the latter compound with bromine affords the 4-bromo-derivative **70** (yield 95%). When (adamant-1-yl)pyrazole is treated with a mixture of nitric and sulfuric acids, the nitration of the pyrazole ring and the oxidation of the adamantyl fragment occur simultaneously to give compound **71**, yield 86%.⁶¹

The reaction of pentane-2,4-dione with the dihydrochloride **69** leads to 1-(adamant-1-yl)-3,5-dimethylpyrazole, which is converted into compound **72** in 86% yield on treatment with a mixture of nitric and sulfuric acids.⁶¹

The dihydrochloride **69** reacts with 3-methylpentane-2,4-dione in boiling alcohol (3 h) to give 1-(adamant-1-yl)-3,4,5-trimethylpyrazole (yield 63%).⁶²

The chlorination of 1-(adamant-1-yl)-3,5-dimethylpyrazole with chlorine carried out with cooling involves both the pyrazole ring and one of the methyl groups and leads to 1-(adamant-1-yl)-4-chloro-5-dichloromethyl-3-methylpyrazole **73** in 43% yield.⁶²

A series of derivatives of 4-(adamant-1-yl)pyrazole **74** have been prepared in 71%–93% yields by the condensation of the hydrazines **75** with the β -diketones **76** carried out in boiling alcohol (1 h), in alcohol at 20 °C (12 h), or without solvent at 130–140 °C (1–1.5 h).⁶³

In earlier papers,^{42,64} the products of the interaction of the β -ketoesters **77** with phenylhydrazine have been identified as the pyrazol-5-one derivatives **78** (yields 67%–80%). The reactions were carried out at 20 °C for 3 h in aqueous acetic acid in the case of the ketoester with R = Ad⁴² or without solvent in the case of R = AdCH₂.⁶⁴

R = Ad, AdCH₂.

The reaction of the dihydrochloride **69** with β -aminocrotonitrile affords 1-(adamant-1-yl)-5-amino-3-methylpyrazole in 40% yield, whereas the interaction of the compound **69** with methyl fluorosulfonate gives the salt **79** (yield 90%).⁶¹

Cyclocondensation of (3-hydroxyadamant-1-yl)hydrazine with 3-nitropentane-2,4-dione leads to compound **80**, which is active against anaerobic bacteria.⁶⁵

The 1-acetyladamantane derivatives, in which one or two hydrogen atoms in the methyl group have been substituted by bromine or by a functional group, have been used as the initial compounds in the syntheses of heteryladamantanes. The bicyclic compounds **81** and **82** were prepared by the condensation of the ketone **41** with 2-aminothiazole and 2-aminopyridine, respectively.⁴⁶

The hydroxy ketone **83** reacts with aldehydes and ammonia in boiling methanol in the presence of copper acetate to give the imidazole derivatives **84**.⁶⁶

R = H (54%), Prⁱ (46%), Ph (54%).

If the hydroxy ketone **83** is made to react with ammonia in the absence of aldehydes, 2-(adamantylcarbonyl)-4-(adamant-1-yl)-imidazole is obtained in 72.5% yield.⁶⁶

4-(Adamant-1-yl)-2-sulfanylimidazole (**84**, R = SH) has been synthesised in 35% yield by refluxing the hydrobromide **85** with NH_4SCN in water.⁶⁶

Some investigators have prepared adamantyl-containing pyrazole and pyrazoline derivatives using adamantyl diazomethyl ketones as the initial compounds. The condensation of adamant-1-yl diazomethyl ketone **86** with propionitrile or with acrylamide gives 3-adamantylcarbonyl-5-cyanopyrazole **87** (yield 92%) or 3-adamantylcarbonyl-5-aminocarbonylpyrazoline **88** (yield 14%).⁶⁰

An interesting reaction occurs when adamant-1-yl azidomethyl ketone is heated in xylene; the compound **86** is converted into 2-adamant-1-ylcarbonyl-4-(adamant-1-yl)imidazoline **89** (yield 73%). The authors⁶⁷ believe that the process involves the intermediate formation of nitrene, which is converted into imine, and the latter dimerises with intermolecular abstraction of water.

1-(Adamant-1-yl)-5-aryl-2-diazopentane-1,3,5-triones **90**, obtained by heating 5-aryl-2,3-dihydrofuran-2,3-diones **91** with the diazoketones **92** in tetrachloromethane, are converted in the presence of triethylamine into the pyrazolin-4-one derivatives **93** in 63–92% yields.⁶⁸

X = H, R = H, Me, OMe, Br, Cl; X = ONO_2 ; R = H, Br.

The transformation of the derivatives **90** into the corresponding pyrazolin-4-ones **93** can also be carried out with nickel chloride as the catalyst.⁶⁹

X = H, R = Cl; X = ONO_2 , R = H.

The β -chloroacrolein derivatives $\text{R}^1\text{C}(\text{Cl})=\text{C}(\text{R}^2)\text{CHO}$ offer considerable synthetic opportunities. These compounds are widely used for the synthesis of various heterocyclic derivatives including heteryladamantanes. For example, the aldehydes **94** have been converted into the pyrazole derivatives **95** by two different procedures.^{70,71} One of them⁷⁰ involved the reaction of the aldehydes **94** [Ar = 2,4,6-(NO_2)₃C₆H₂ and C₅H₅] with phenylhydrazine giving the corresponding hydrazones **96**, which were then converted into the target compounds **95**,⁷⁰ whereas according to the other procedure,⁷¹ 5-(adamant-1-yl)-1-phenylpyrazole was obtained without isolation of the intermediate hydrazone **96** (R = H, Ar = Ph).⁷¹

R	Ar	X	t/h		T / °C		Yield (%)	
			95	96	95	96	95	96
H	Ph	HCl	2	24	160	20	48	73
H	2,4,6-(O_2N) ₃ C ₆ H ₂	—	6	0.25	refluxing (AcOH)	100	41	77
Me	2,4,6-(O_2N) ₃ C ₆ H ₂	—	6	0.2	refluxing (AcOH)	100	54	62

Heating of the isoquinoline derivative **97** with an 18% solution of phosphorus oxychloride in toluene affords 3-(adamant-1-yl)imidazo[5,1-*a*]isoquinoline **98** in 90% yield.⁷²

The interaction of the ketone **41** with 2-amino-1-*R*-benzimidazoles **99** leads to the hydrobromides **100** in quantitative yields; on heating with concentrated hydrochloric acid the latter are converted into the tricyclic compounds **101**, which exhibit immunodepressant properties and are psychotropic inhibitors of cytochrome P-450.⁷³

$R = \text{Alk, PhCH}_2, (\text{CH}_2)_2\text{NEt}_2, (\text{CH}_2)_2\text{N}(\text{CH}_2)_2\text{OCH}_2\text{CH}_2$.

The derivatives of 8-(adamant-1-yl)xanthine or 8-(adamant-1-yl)thioxanthine **102** have been prepared by cyclisation of the amides **103** carried out in dioxane under the action of aqueous sodium hydroxide.⁷⁴

$X^1, X^2 = \text{O, S}; R^1, R^2 = \text{H, Alk, CH}_2\text{CH=CH}_2, \text{CH}_2\text{C}\equiv\text{CH}$.

8-(Adamant-1-yl)-1,3-dipropylxanthine, which is an antagonist of adenosine A₁, is formed upon heating 6-amino-5-(nor-adamantanecarbonylamino)-1,3-dipropyluracil with phosphorus oxychloride.⁷⁵

The salts $\text{HalCH}_2\text{CH}_2\text{NHC(R}^1\text{)=NR}^2 \cdot \text{HX}$ cyclise in the presence of alkali to give the imidazoline derivatives **104**.³⁰

$R^1 = \text{Ad}; R^2 = \text{Ph, C}_6\text{H}_5, \dots, \text{R}_n$.

1-(Adamant-1-yl)-2,2-dichloroimidazolidine-4,5-dione **105**, synthesised from (adamant-1-yl)cyanogen amide and oxalyl chloride, is a promising synthon for the preparation of adamantyl-containing derivatives of imidazolidine-4,5-dione.⁷⁶

Treatment of the dichloro-derivative **105** with water affords 1-(adamant-1-yl)imidazolidine-2,4,5-trione **106** in 97% yield.⁷⁶

To prepare derivatives of the imidazolidinetriene **106**, namely, compounds **107** and **108** (yields 62% and 92%), the product of the hydrolysis of the dichloride **105** is made to react in situ with diazomethane or with formaldehyde and morpholine.⁷⁶

The ketal **109** (yield 48%) is formed in the reaction of adamantylcyanogen amide with oxalyl chloride in the absence of moisture followed by treatment of the resulting dichloride with ethylene glycol; the reaction of the compound **109** with formaldehyde and morpholine leads to the ketal **110** in 77% yield.⁷⁶

Compound **111** is synthesised from the dichloro-derivative **105** and 2,2-diethylpropane-1,3-diol under similar conditions in 11% yield.⁷⁶

The spiro-compound **112** is prepared in 4% yield by heating the dichloride **105** with ethane-1,2-dithiol in anhydrous dioxane.⁷⁶

The successive treatment of (adamant-1-yl)cyanogen amide with oxalyl chloride in anhydrous dioxane, with triethylamine, and with secondary amines gives compounds **113** in 65%–90% yields.⁷⁶

$\text{R}^1 = \text{R}^2 = (\text{PhCH}_2)_2, (\text{Pr}^i\text{CH})_2,$
 $\text{R}^1, \text{R}^2 = -\text{O}(\text{CH}_2\text{CH}_2)_2-, -(\text{CH}_2)_5-.$

The imidazole derivative **114** is formed in 91% yield in the reaction of the nitrile **115** with the isocyanide **116** at low temperature.⁷⁷

The formation of 2-(adamant-1-yl)imidazole or 2-(adamant-1-yl)benzimidazole from adamantane-1-carboxylic acid and imidazole (or benzimidazole) in the presence of silver nitrate is a homolytic reaction. The Ad^\bullet radical is generated from adamantane-1-carboxylic acid.⁷⁸

2-(Adamant-1-yl)-1-methylimidazole has been reported⁷⁸ to exhibit antiviral activity.

The crystalline carbene **117**, which is stable in the absence of oxygen and moisture, has been synthesised in 96% yield by treating 1,3-di(adamant-1-yl)imidazolium chloride **118** with potassium *tert*-butoxide in dimethyl sulfoxide.⁷⁹

The carbene **117** reacts with carbon monoxide or with sulfur dioxide⁸⁰ in THF giving the ketene **119** (yield 34%) or 1,3-di(adamant-1-yl)imidazole-2-thione *S,S*-dioxide **120**.

Adamantyl residues have been introduced to the nitrogen atoms in 1,3,4-triazole, 1,2,4-triazole, or benzotriazole by treating these compounds with 1-bromoadamantane with heating.⁵³

Het = 1,2,4-triazol-1-yl (59%), 1,3,4-triazol-1-yl (3%),
 benzotriazol-1-yl (45%), benzotriazol-2-yl (34%).

1-(Adamant-1-yl)-1,2,4-triazole is formed in 30% yield on heating *sym*-triazine with the hydrochloride **69** in alcohol.⁵³

1-(Adamant-1-yl)-1,2,4-triazole (yield 70%) and 1-(adamant-1-yl)benzotriazole (yield 60%) have been prepared by a two-stage procedure. The first stage consists in the *N*-silylation of the corresponding heterocyclic compounds by refluxing them with disilazane **32**. In the second stage, the products of the *N*-silylation are treated with 1-chloroadamantane in the presence of aluminium chloride at 20 °C.³⁷

Japanese scientists⁸¹ have studied systematically the 1,3-dipolar cycloaddition of 1-azidoadamantane **121** to alkynes. The reactions of the azide **121** with alkynes **122** are carried out at 110 °C. The yields of the 1,2,3-triazole derivatives **123** vary from 5% to 84%.⁸¹

R ¹	R ²	Reaction time / h	Yield of 123 (%)
Ph	H	35	21 ^a
H	Ad	30	67
H	COOMe	11	84
H	CH ₂ OH	5	80 ^b
H	COOEt	50	77
CH ₂ OH	CH ₂ OH	90	32
Ph	Ph	500	17
C(Me)(Et)OH	C(Me)(Et)OH	180	5
COOMe	COOMe	24	77

^a The analogue of 123 with R¹ = H, R² = Ph is formed in 60% yield.

^b The analogue of 123 with R¹ = CH₂OH, R² = H is formed in 11%.

The alicyclic alkenes 124–127 enter into the 1,3-dipolar cycloaddition with adamantyl azide giving the 1,2,3-triazoline derivatives 128–131, their yields ranging from 40% to 70%.⁸¹

The azide 121 reacts with the ester CH₂ = CHCOOEt at 20 °C and is thus converted into 1-(adamant-1-yl)-4-ethoxycarbonyl-1,2,3-triazoline in 85% yield over a period of 336 h.⁸¹

The reaction of the azide 121 with alkenes CH₂ = CHNO₂, PhCH = CHNO₂, and PhSOCH = CH₂ is more complex. In all these cases, the adducts 132 and 133 formed initially eliminate HNO₂ and PhSOH molecules, and the reaction products are the corresponding 1,2,3-triazole derivatives 134 (yields 73% and 88%) and 135 (yield 66%).⁸¹

R = NO₂, SOPh.

The adduct 131 readily eliminates a C₈H₆O molecule giving rise to 1-(adamant-1-yl)-1,2,3-triazole 134 (yield 71%).⁸¹

To prepare the derivatives of 1,2,3-triazole 136, phosphorus ylide 137 has been used as the second component in the reaction with the azides 4-RC₆H₄N₃. The yields of the adducts 136 vary from 60% to 99%.⁸²

R (reaction time / h) = H (8), F(7), COOMe (3.5), COMe (1.5),

CHO (1), NO₂ (0.5), SO₂CF₃ (0.5), N = NPh (5),

Compounds 138 and 139, which contain two 1,2,3-triazole nuclei each, are obtained in 98% and 93% yields by the interaction of the ylide 137 with 1,4-bis(azido)benzene or with 4,4'-bis(azido)diphenyldiazene.⁸²

The aryl azides containing electron-donating substituents in the *para*-position with respect to the azido group react with the ylide **137** with difficulty or do not react at all.⁸²

The ester enolates **140** react with the azide **121** on exposure to the radiation from a mercury or mercury-xenon high-pressure lamp to give the 1,2,3-triazol-5-one derivatives **141** in 60%–70% yields.^{25,83}

R = Me, Bu^t.

Rusinov et al.⁸⁴ accomplished simultaneous introduction of an adamantyl radical and of a nitro-group by treatment of the bicyclic compound **142** with adamant-1-yl nitrate in the presence of concentrated sulfuric acid. The reaction gave a mixture of two compounds **143** and **144** in an overall yield of >70%.⁸⁴

R = H, Me; X = N, CH, CMe, CCF₃.

The 1,3,4-triazole derivatives **145**, which contain in the 2-position the residue of thioglycolic acid hydrazide, react with carbon disulfide to give compounds **146**.⁸⁵

R = CH₂CONHNH₂.

1-(Adamant-1-yl)-5-methyltetrazole has been obtained in 46% yield by the reaction of the chlorocarbonate **147** with acetonitrile and sodium azide at room temperature over a period of 20 h.⁸⁶

The tetrazoles **148** containing alkyl, alkenyl or aryl substituents in the 5-position have been prepared by the interaction of 1-iodoadamantane with silver hexafluoroantimonate and with the corresponding carbonitriles in the presence of the quaternary ammonium salt Et₄N⁺N₃⁻.⁸⁶

R = Me (71%), Et (29%), Pr (64%), Prⁱ (43%), Ph (21%),

CH₂=CH (20%), CH=CMe₂ (14%), PhCH=CH (49%).

When tetrazole is heated with the bromo-derivative of adamantane at 190–200 °C, two compounds are formed, namely, 1-(adamant-1-yl)tetrazole (yield 24%) and 2-(adamant-1-yl)tetrazole (yield 30%).⁵³

The direct adamantylation of the tetrazole ring has been carried out by treating 5-methyltetrazole and 5-phenyltetrazole with adamantan-1-ol in the presence of sulfuric acid.⁸⁷

R = Me (57%), Ph (84%).

4. Six-membered heterocycles

1-(Adamant-1-yl)-4,4-diarylpiperidines⁸⁸ and *N*-[2-(adamant-1-yl)ethyl]piperidine hydrochloride⁴¹ have been patented as stimulants of the central nervous system.

By refluxing AdBr with piperidine, pyridine, or 4-picoline, the corresponding salts have been synthesised; they have been recommended as antiviral agents.⁸⁹

In a study of reactions of pyridine and its derivatives with 1-bromoadamantane and 1-iodoadamantane, it has been shown that the successful formation of the salts **149** requires that a small amount of water be present in the reaction mixture.⁹⁰

X	R	Yield (%)
Br	H	97
I	H	96
Br	3-Me	62
Br	4-Me	80
Br	3-CONEt ₂	70
Br	4-(pyridyl-4)	98

When the reactions are carried out in the absence of water, the salts **149** are formed in low yields. The process should be carried out at 230–250 °C. The corresponding salt with quinoline is not formed.⁹⁰ Steric factors play an important role in this reaction: for

example, the salts **149** cannot be obtained from adamant-1-yl halides with 2-picoline, 2,3-lutidine, or 2,4,6-collidine.

A hydrogen atom in the adamantane molecule can be substituted by a pyridyl radical in the presence of a Gif system ($\text{Fe}-\text{O}_2-\text{Zn}-\text{AcOH}-\text{C}_5\text{H}_5\text{N}$). For example, the reaction of adamantane with pyridine in the presence of this system at 20 °C gives rise to two products: 2-(adamant-1-yl)pyridine and 1-(2-pyridyl)adamant-2-one.⁹¹

The hydrogen atom in the 2-position of pyridine can be substituted by the adamantane residue by a radical mechanism. 2-(Adamant-1-yl)pyridine is formed in 20% yield when a mixture of adamantane-1-carboxylic acid and pyridine is irradiated with a Hanovia lamp (100 W) in the presence of lead(IV) acetate under an argon atmosphere.⁹¹

A method has been developed for the substitution of the hydrogen atom at the nitrogen atom in the 2-pyridone derivatives by the adamantyl fragment.³⁷ For this purpose, this hydrogen atom is substituted by the SiMe_3 group by treating the initial compounds with disilazane **32**, and then the *N*-silylated products are made to react with chloroadamantane in the presence of aluminium chloride. The electronic nature of the substituents in the heterocyclic nucleus of the initial compound exerts the crucial influence on the yields of the reaction products. In the case where electron-withdrawing substituents (Cl or NO_2) are present in the 5-position, the yields of compounds **150** are 53% or 77%. When the initial compound contains an electron-donating methyl group in the 3-, 4-, or 5-position, the yields of the products **150** are much lower (25%, 30%, and 30%, respectively).³⁷

$\text{R} = 5\text{-Cl}, 5\text{-NO}_2, 3\text{-Me}, 4\text{-Me}, 5\text{-Me}$.

The interaction of 2-quinolone with chloroadamantane under similar conditions leads in 72% yield to (adamant-1-yl)-2-quinolone (the position of the adamantyl substituent has not been mentioned in the paper cited).³⁷

1-(Adamant-1-yl)-2-pyridone has been obtained in 30%–52% yield by the reaction of the chloro-derivative of adamantane with 2-(trimethylsilyloxy)pyridine. The reaction is carried out in the presence of aluminium chloride at 20 °C for 12 h.^{50,51}

The reaction of the compound **151** with pyridine in the presence of acetic acid under irradiation with two tungsten lamps (300 W) leads to a complex mixture of products, among which 2-(adamant-1-yl)pyridine (yield 27.5%) and 4-(adamant-1-yl)pyridine (yield 14%) have been identified.⁹²

N-(Adamant-1-yl)pyridinium salts are obtained from bromo-adamantane and pyridine. If this reaction is carried out in a sealed tube at 230 °C for 30 h, the yield of adamantylpyridinium bromide is 69%,⁹³ whereas in the reaction carried out at 180 °C for 6 h, the yield reaches 97%.⁹⁴ When bromoadamantane reacts with pyridine in the presence of sodium perchlorate in nitromethane at 0 °C for 4 h and then at 20 °C for 14 h, *N*-(adamant-1-yl)pyridinium perchlorate is formed in 54% yield.⁹⁵

Adamant-1-yl methyl ketone condenses with isatin in the presence of ammonia to give the hydroxy diketone **152**, which is converted into 2-(adamant-1-yl)quinoline-4-carboxylic acid in 94% yield in the presence of sulfuric acid. If the reaction is carried out without isolation of the compound **152**, this acid is formed in a yield of only 5%–10%.⁹⁶

2-(Adamant-1-yl)quinoline has been synthesised in 75% yield by refluxing a mixture of adamant-1-yl methyl ketone with 2-aminobenzaldehyde in an alcoholic solution of potassium hydroxide for 1 h.⁹⁶

In the presence of a weak protic acid, pyridinium chloride, 3,7-dimethylenebicyclo[3.3.1]nonane (**153**, $\text{X} = \text{CH}_2$) and 3-methylenebicyclo[3.3.1]nonan-7-one (**153**, $\text{X} = \text{O}$) react with pyridine yielding the corresponding pyridinium salts.⁹⁷

$\text{X} = \text{CH}_2$, $\text{Y} = \text{Me}$; $\text{X} = \text{O}$, $\text{Y} = \text{OH}$.

The reaction of the compound **153** ($\text{X} = \text{O}$) with piperidine in the presence of piperidine hydrochloride follows a different pathway: piperidine adds to the oxo-group, then a molecule of water is eliminated, and finally, the ring closure occurs.⁹⁸

Salts of heteryladamantanes can be obtained from the precursors of adamantane, namely, compounds **153** ($X = \text{CH}_2$) or 1,3-dehydroadamantane, via conjugated intermolecular halamination. A number of salts of 1-heteryl-3-halomethyladamantanes **154** have been synthesised by the reaction of the compound **153** ($X = \text{CH}_2$) with pyridine bases or with quinoline.⁹⁹

$X = \text{I}$: Nu — pyridine, quinoline;
 $X = \text{Br}$: Nu — pyridine, 2-picoline, quinoline.

The reactions with bromine were carried out at temperatures from -10 to 0°C over a period of 10 days, whereas the reactions with iodine were conducted at 20°C over 10 days. The yields of the salts **154** varied from 44% to 84%.⁹⁹

The salts **155** have been prepared in 28%–68% yields by the reactions of 1,3-dehydroadamantane with heterocyclic amines and iodine.^{99, 100}

Nu — pyridine, 3-picoline, quinoline, $\text{MeNCH}_2\text{CH}_2\text{OCH}_2\text{CH}_2$.

The diene **153** ($X = \text{CH}_2$) reacts with pyridine-sulfotrioxide in pyridine giving the salt **156** in 70% yield.¹⁰¹

In 1976, a new S_R reaction involving the Ad^\bullet radical was reported.¹⁰² The interaction of adamantane-1-carboxylic acid with ketones of the pyridine series in the presence of ammonium peroxydisulfate and silver nitrate at 80°C in aqueous ammonia and acetonitrile leads to the generation of adamantyl radical, which substitutes the acyl groups, the hydrogen atoms, or both in pyridine bases.

The following scheme of the homolytic *ipso*-substitution has been suggested:¹⁰²

More recently this reaction has been studied¹⁰³ in relation to other compounds and a scheme for the formation of the Ad• radical and of the $\text{SO}_4^{\bullet-}$ radical-anion has been suggested.

R = CN, COMe; A : B = 92 : 8.

C : D = 97 : 3.

4-(Adamant-1-yl)-2-ethoxycarbonylpyridine has been synthesised in 42% yield by cycloaddition of the diene 43 to the nitrile 157.⁴⁷

The reaction of the 2,3-dihydropyran derivatives 158 with water in the presence of a platinum catalyst followed by treatment in situ of the resulting 1,5-dicarbonyl compounds with ammonia leads to the pyridine bases 159, their yields being 32%–42%.⁹³

On heating with phosphorus oxychloride in an autoclave the oxonitrile 160 cyclises giving 2-(adamant-1-yl)-3,5,5-trichloro-4,5-dihydro-6-pyridinone in 41% yield; the latter is converted into 6-(adamant-1-yl)-3,5-dichloro-2-pyridone (yield 87%) on treatment with triethylamine.¹⁰⁴

6-(Adamant-1-yl)-3-cyano-2-pyridone (161, X = O) and 6-(adamant-1-yl)-3-cyano-2-pyridoselenone (161, X = Se) have been synthesised in 33% and 52% yields by refluxing the sodium derivative 162 with compounds $\text{NCCH}_2\text{C(X)NH}_2$.¹⁰⁵

X = O, Se.

The selenone 161 (X = Se) reacts with chloroacetonitrile in the presence of a 10% aqueous solution of potassium hydroxide under an inert atmosphere affording the selenopheno-[2,3-*b*]pyridine derivative 163 (yield 70%), whereas during storage in air the compound 161 is converted into the diselenide 164.¹⁰⁴

The sulfur-containing analogue **161** ($X = S$) has been synthesised in 62% yield by the cyclocondensation of the sodium derivative **162** with cyanothioacetamide. The pyridine-2-thione **161** ($X = S$) thus obtained reacts with the bromo-derivatives RCH_2Br in the presence of bases to give the sulfides **165** (yields 58%–64%).¹⁰⁶

$X = S$; $R = COOMe, COOEt, CN$.

The quinoline derivatives **166** are formed in 43%–63% yields in the reaction of the aldehydes **94** with aniline or 4-bromoaniline^{70, 71} (in some cases, the intermediate salts **167** can be isolated).

$R^1 = H, R^2 = H, Br$; $R^1 = Me, R^2 = H, Br$.

The adamantane-1-carboxamides **168** have been prepared in 72%–92% yields from secondary amines and the acid chloride $AdCOCl$ or the sulfide **169**.^{107, 108}

$R^1 = Et, R^2 = Et$;

$R^1 + R^2 = -(CH_2)_4-, -(CH_2)_5-, -(CH_2CH_2)_2O-$;

$R^3 = Me, H_2N^+ \text{ (cyclohexyl)}$;

(a) $AdCOCl, Et_2O$ (0–20 °C, 1–12 h);

(b) $AdCSR^3$ (**169**) (refluxing, 4–6 h).

The amides **168** have been converted into biologically active compounds **170** via several consecutive stages. First, they were reduced with lithium tetrahydroaluminate to amines (yields 94%–97%) and the latter were converted into the carboxylic acids **170**. The hydrochloride of the amino acid **170** [$R^1 + R^2 = -(CH_2)_5-$] was made to react with thionyl chloride and piperidine to give the corresponding amide **171** (yield 91%), which was then reduced with lithium tetrahydroaluminate to the diamine **172**. The latter can also be obtained by the reduction of the diamide **173** (yield 79%).¹⁰⁷

Hydrochlorides of the acids **170** exhibit analgesic and anti-inflammatory activities.¹⁰⁷

To synthesise the aminoketones **174**, two methods have been suggested, namely, the Mannich reaction of 1-acetyladamantane with aldehydes and arylamines and the addition of arylamines to the α, β -unsaturated ketones **175**, generated from acetyladamantane and aldehydes.¹⁰⁹

$R = \text{pyridyl-3, pyridyl-4, quinolyl-2, quinolyl-6, quinolyl-7}$;

$Ar = Ph, 2-FC_6H_4, 3-FC_6H_4, 4-FC_6H_4, 4-MeOC_6H_4, \text{naphthyl-2}$.

The aminoketones **174** possess a broad spectrum of biological activity: neurotropic, antiviral, antibacterial, fungicidal, psychotropic, and hepatoprotecting activities.¹⁰⁹

Heating of the ketone **41** with 2-aminopyridine or with 2-picoline in alcohol leads to the corresponding salts **176** (yields 96% and 50%).⁴⁶

$R = NH_2, Me$.

An unexpected result was obtained when 1-methyl-2-pyridone was heated with 2-(adamant-1-yl)ethyne-1-carbonitrile: compound **177** was found among the reaction products.¹¹⁰

The hydrobromide **85** is converted into 2,5-di(adamant-1-yl)pyrazine in 30.5% yield on treatment with hydrogen peroxide.⁶⁶

Piperazine derivatives **178** exhibiting an antiviral activity have been prepared by refluxing bromoadamantane with piperazine or with its *N*-monosubstituted derivatives.⁸⁹

R = H, HOCH₂CH₂, Ad, Ph, 3-Cl, 4-MeC₆H₃.

Hexahydropyrimidine reacts with AdBr under conditions of phase-transfer catalysis at a mercury cathode in a cell with a double G-5 diaphragm giving the corresponding *N*-adamantyl derivative in 70% yield.¹¹¹

N-(Adamant-1-yl)hexahydropyrimidine and *N*-adamantyl-containing derivatives of other pyrimidines, pyridazines, and pyrazines obtained in a similar way are active against influenza viruses of the H₂N₂A/Singapore type.¹¹¹

N-(Adamant-1-yl)piperazine, synthesised in 85% yield by heating piperazine with bromoadamantane in an autoclave, has been made to react with cinnamoyl chloride in the presence of triethylamine. The compound **179** formed in this reaction (yield 85%) enhances the cerebral circulation.¹¹²

It has been reported in a patent¹¹³ that *N*-(adamant-1-ylcarbonyl)piperazine has been synthesised in 40% yield by the acylation of piperazine with the acid chloride AdCOCl. The product of acylation was converted into the *N,N'*-diacylpiperazine **180** in 90% yield.¹¹³

Compounds of the general formula **181** have been patented as substances active with respect to the central nervous system.¹¹³

R¹ = H, Me, MeO; R² = H, Me; R³ = H, Me, MeO, Cl, F;
Z¹, Z² = CO, CH₂.

The acylation of *N*-(diphenylmethyl)piperazine with the chloride AdCOCl leads to compound **182** exhibiting high anti-histamine and antiallergic activities.¹¹⁴

1-(Adamant-1-ylcarbonyl)-3,3-diphenylpiperazine has been synthesised from 3,3-diphenylpiperazine and adamantane-1-carboxylic acid chloride in the presence of triethylamine.¹¹⁵

1,4-Dibromobuta-1,2-diene reacts readily with the amine **7** giving the dibromo-derivative **183**, which is converted into the 1,4-disubstituted piperazine **184** on treatment with benzylamine.¹¹⁶

In 1972, a new method was patented for the synthesis of the *N*-adamantylpiperazines **185**. The method involves cyclisation of the hydrochloride of (adamant-1-yl)bis(2-chloroethyl)amine **186** under the action of primary amines (the yield of compounds **185** ranges from 53% to 70%).¹¹⁷

R = cyclo-C₆H₁₁, Pr, Prⁱ, Bu, Bu^t, Ph, PhCH₂, H.

Later, this method was used to prepare a wider set of 1-(adamant-1-yl)-4-R-piperazines with R = H, Me, Et, Pr, Prⁱ, Bu^t, C₅H₁₁, cyclo-C₅H₉, cyclo-C₆H₁₁, cyclo-C₈H₁₅, Ad, Ph, PhCH₂ and CH₂CH₂OH.

The majority of the hydrochlorides **185** increase the blood pressure. The compounds with R = Et or CH₂CH₂OH have a hypotensive effect, those with R = cyclo-C₆H₁₁ slow down cardiac activity, and the compound with R = Bu^t exhibits a vasodilatory activity and an adrenaline-blocking effect.¹¹⁸

Compounds like **185** are active with respect to the central nervous system, exhibit analgesic and hypothermal activities, and modify the soporific effects of Hexanal, Medinal and chloral hydrate.¹¹⁹

1-(Adamant-1-yl)-4-(tolyl-*p*-sulfonyl)piperazine **188** has been synthesised in 87.5% yield by the condensation of the dichloro-derivative **187** with the amine **7**.¹²⁰

On refluxing in hydrochloric acid compound **188**, is converted into 1-(adamant-1-yl)piperazine (yield 84%), which reacts with the chloro-derivatives **189** to give phenothiazines **190** (yields 49%–50%),¹²⁰ the latter exhibit vasodilatory and psychotropic activities.

1-(Adamant-1-yl)piperazine and its hydrochloride react with the dicarboxylic acids **191** (in the presence of cyclohexylcarbodiimide) or with the corresponding acyl chlorides giving the diamides **192** (yields 58% and 60%).¹²¹

The diamide **192** (n = 8) possesses an immunodepressive activity.¹²¹

Treatment of 3-[2-(adamant-1-ylamino)ethyl]oxazolidin-2-one with hydrobromic acid in glacial acetic acid affords a salt, which cyclises to 1-(adamant-1-yl)piperazine on heating in butyl alcohol.¹²²

To introduce an adamantyl radical to the nitrogen atom of the cyclic diazines, two procedures have been developed. One of them involves the initial preparation of trimethylsilyl derivatives of diazines, which are then treated with 1-chloroadamantane in the presence of aluminium chloride. Compounds **193** have been synthesised in this way in 38%–53% yields.⁵⁰

X = O, R = H, F; X = S, R = H.

The second one-pot procedure is used for the synthesis of *N*-adamantyl-diazines more frequently. The *N*-trimethylsilyl derivative of diazine is prepared by refluxing the diazine with the disilazane **32**; the obtained compound is introduced directly into the reaction with 1-chloroadamantane in the presence of aluminium chloride (in CHCl₃, 20 °C).³⁷ We present below the examples of *N*-(adamant-1-yl)azines prepared in this way (yields 38%–61%).³⁷

The pyridazine derivative **194** has been obtained in 87% yield by the diene condensation of compound **43** with ethyl diazenedicarboxylate at room temperature.⁴⁷

The bis-adduct **195** formed from the cyclic sulfone **196** and an excess of 4-phenyl-1,2,4-triazoline-3,5-dione, is converted into 4,5-di(adamant-1-yl)pyridazine in 56% yield on treatment with potassium hydroxide followed by oxidation in air.¹²³

When the diamine **197** is refluxed with oxalyl chloride in toluene, 3-(adamant-1-yl)-1,4-dihydro-2-quinazolinone is formed, which exhibits anti-inflammatory activity.¹²⁴

The derivative of barbituric acid **198** has been synthesised in 7% yield by the condensation of (adamant-1-yl)cyanogen amide with cyclobutane-1,1-dicarbonyl dichloride in anhydrous dioxane followed by treatment with water.⁷⁶

The amidine **199** reacts with the ortho ester MeC(OMe)_3 to give the tricyclic compound **200** (yield 60%).¹²⁵

Treatment of adamant-1-yl aminomethyl ketone hydrobromide with aqueous ammonia in the presence of hydrogen peroxide leads to 2,5-di(adamant-1-yl)pyrimidine in 30.5% yield.⁶⁶

Several other approaches to the synthesis of pyrimidine derivatives containing an adamantane nucleus have been developed. Cyclocondensation of the ester **201** with urea or thiourea in the presence of sodium ethoxide gives rise to 6-(adamant-1-yl)uracil (**202**, X = O) (yield 21.5%) or 6-(adamant-1-yl)thiouracil (**202**, X = S) (yield 60.3%). The latter compound is converted into 6-(adamant-1-yl)-2,4-disulfanylpurimidine by the action of phosphorus pentasulfide and also into 4-amino-6-(adamant-1-yl)-2-sulfanylpurimidine (yield 60.5%) by heating with aqueous ammonia.¹²⁶

X = O, S.

6-(Adamant-1-yl)cytosine **203** was obtained in 33% yield by the condensation of the nitrile **204** with urea in the presence of sodium ethoxide.¹²⁶

Czech researchers¹²⁷ studied the condensation of compounds of the general formula $\text{R}^1\text{OCC}(\text{R}^2)(\text{Ad})\text{COR}^3$ with urea, thiourea, and guanidine. The interaction of compounds **205** with thiourea in the presence of sodium ethoxide and sodium hydride gives the thioracil derivatives **206** in 27%–68% yield.

$\text{R}^1 = \text{H}, \text{R}^2 = \text{H}; \text{R}^1 = \text{OEt}, \text{R}^2 = \text{OH}; \text{R}^1 = \text{Me}, \text{R}^2 = \text{Me}.$

The reaction of the oxoester **205** ($\text{R}^1 = \text{Et}$) with guanidine hydrochloride in the presence of sodium ethoxide affords the cytosine derivative **207** (yield 41%), which is converted into 5-(adamant-1-yl)-2,4-diamino-6-ethylpyrimidine by successive treatment with phosphorus oxychloride and phosphorus pentachloride and then with an alcoholic solution of ammonia.

The resulting compound is a 30-fold more effective inhibitor of the growth of mammary carcinoma cells than the compound **206**.¹²⁸

The low-toxicity biologically active compounds **208** have been synthesised in yields of more than 80% by the cyclocondensation of bis-esters **209** with urea or with thiourea in the presence of sodium methoxide.¹²⁹

$\text{X} = \text{O}, \text{S}; \text{R} = \text{H}, \text{Me}, \text{Et}, \text{CH}_2\text{CH}=\text{CH}_2.$

Adamantane-1-carboximidamide hydrochloride reacts with ethyl malonate or with ethyl cyanoacetate in the presence of sodium ethoxide to give 2-(adamant-1-yl)-6-hydroxypyrimidine and 2-(adamant-1-yl)-6-aminopyrimidine, respectively.¹³⁰

$\text{R}^1 = \text{COOEt}, \text{R}^2 = \text{OH}; \text{R}^1 = \text{CN}, \text{R}^2 = \text{NH}_2.$

The pyrimidine derivatives **210** ($\text{R}^1 = \text{OH}, \text{NH}_2, \text{R}^2 = \text{OH}, \text{R}^3 = \text{H}, \text{R}^4 = \text{Ad}$) inhibit liver folate-reductase and exert a cytostatic effect on tumour cells,¹³¹ whereas the compound **210** ($\text{R}^1 = \text{R}^2 = \text{NH}_2, \text{R}^3 = \text{Ad}, \text{R}^4 = \text{Me}$) has been recommended as an antitumour preparation.¹³²

The oxidation of adamant-1-yl aminomethyl ketone hydrobromide with hydrogen peroxide gives 2,5-di(adamant-1-yl)pyrazine in 30.5% yield.⁶⁶

1,2-Diaminobenzene reacts with (adamant-1-yl)glyoxal on heating in alcohol in the presence of acetic acid affording 2-(adamant-1-yl)quinoxaline in 35% yield.⁶⁰

The imidazopyrazine derivatives **211** have been obtained by the condensation of diethyl acetals **212** with 2-amino-3-benzyl-5-(4-hydroxyphenyl)pyrazine or with 3-(adamant-1-ylmethyl)-2-amino-5-(4-hydroxyphenyl)pyrazine in the presence of dilute hydrochloric acid.¹³³

R ¹	R ²	Yield of 211 (%)
Ad	Ph	44
4-HOC ₆ H ₄	Ad	63

4-(4-Methylpiperazin-1-yl)methylprotoadamantan-4-ol is converted into the salt **213** (yield 40%) on treatment with hydrogen bromide, whereas its reaction with sulfuric acid and hydrogen chloride affords the salt **214** (yield 80%).¹³⁴

Heating of (adamant-1-yl)acetic acid and (3-hydroxyadamant-1-yl)acetic acid with diamines H₂NCH₂CR₂CH₂NH₂ leads to tetrahydropyrimidine derivatives **215** (yields 30%–59%).⁵⁸

X = H, OH; R = H, Me.

Several methods have been developed for the preparation of 1,2,4-triazine derivatives containing the adamantyl nucleus. Japanese researchers³⁷ have synthesised these compounds in two stages. The first stage involves the reaction of triazine with disilazane **32** giving the trimethylsilyl derivative, which is then made to react with chloroadamantane in the presence of aluminium chloride.

On heating in xylene, the azides **216** cyclise with the elimination of nitrogen giving 3-R-6-(adamant-1-yl)-1,2,4-triazines in 58%–73% yields.¹³⁵

R = Me, Ph, Ad.

The reaction of ammonia with the diazonium salt **217** formed upon diazotisation of the (adamant-1-yl)amide of anthranilic acid gave 3-(adamant-1-yl)-3,4-dihydro-1,2,3-benzotriazin-4-one.^{136, 137}

Only one example¹³⁸ of the synthesis of a 1,2,4,5-tetrazine derivative has been reported. 2-(Adamant-1-yl)-1,3,5-triphenyl-1,2,5,6-tetrahydro-1,2,4,5-tetrazine **218** was obtained by the reaction of adamant-1-yl tosylate with 1,3,5-triphenylverdazyl.¹³⁸

5. Compounds with seven-membered heterocycles

The preparation of *N*-(adamant-1-yl)caprolactam hydrochloride has been described in a patent.²⁹ The authors noted that this compound exhibits an anti-inflammatory activity, stimulates the central nervous system, reduces the cholesterol level, and decreases appetite.

The oxaziridine derivative **219** isomerises on heating above 200 °C into *N*-(adamant-1-ylmethyl)caprolactam in 70% yield.¹³⁹

The reaction of 1-bromomethyladamantane with 7-chloro-1,4-benzodiazepin-2-one in the presence of sodium hydride leads to the *N*-alkylation product **220** in 30% yield.¹⁴⁰

III. Adamantane derivatives containing heterocyclic nuclei with oxygen atoms

1. Compounds with three-membered and four-membered heterocycles

The ketones **221** of the adamantane series enter into the reaction with oxodimethylsulfonium methylide (which is obtained by treating trimethyloxosulfonium iodide with potassium hydroxide), which affords the oxirane derivatives **222** in 88% and 83% yields.¹⁴¹

$n = 0, 1.$

2-(Adamant-1-yl)oxirane has been synthesised in 86% yield in two stages, namely, by the reaction of the ketone **41** with sodium tetrahydroborate in an alkaline medium and the subsequent treatment with aqueous sodium hydroxide.¹⁴²

The same workers¹⁴² studied the transformations of the obtained oxirane in reactions with nucleophilic and electrophilic reagents.

1-Acetyl-1-methyloxirane adds to the imine $\text{AdCH}=\text{NMe}$ in the presence of boron trifluoride etherate to give unstable aminoketone **223**; the latter eliminates methylamine under the reaction conditions and is thus converted into the unsaturated compound **224**.¹⁴³

The methods for the synthesis of oxiranes containing an adamantane nucleus have been analysed.¹⁴⁴ These methods include the epoxidation of unsaturated compounds of the adamantane series and transformation of adamantyl-containing ketones. The introduction of an adamantyl fragment into epoxy-polymers was shown to increase their thermal stability and to improve technological characteristics of compositions based on them.

To the best of our knowledge, only one study devoted to the synthesis of adamantane derivatives containing four-membered heterocycles with oxygen atoms has been published.³⁶ It presents the preparation of 2-(adamant-1-yl)-2-phenyloxetan-4-one from the hydroxy acid **225** under the action of thionyl chloride and pyrrolidine (yield 95%).

2. Compounds with five-membered heterocycles

4-(Adamant-1-yl)pentane-1,4-diol undergoes intramolecular dehydration in the presence of potassium hydrogen sulfate, which affords 2-(adamant-1-yl)-2-methyltetrahydrofuran.¹⁴⁵

When 3-(adamantoyl)acrylic acid is exposed to sunlight, it cyclises giving compound **226** in 85.5% yield; the hydroxy-group in the latter is substituted by a chlorine atom under the action of phosphorus pentachloride (yield 39.5%).¹⁴⁶

The derivatives of furanone **227** have been synthesised by heating ethyl 2-adamantoyl-2-haloacrylates with hydrohalic acids (yields 84% and 98%).¹⁴⁷

X = Cl, Br.

3,6,9-Tri(adamant-1-yl)-1-oxaspiro[4.4]nona-3,6,8-trien-2-one **228** is formed when 1-ethynyladamantane is heated with cobalt carbonyl in light petroleum in a flow of carbon monoxide.¹⁴⁸

The diene **43**, on heating in benzene, enters into diene condensation with maleic anhydride, which leads to the adduct **229** in 70% yield.⁴⁷

A mixture of adamant-1-ylcarbonyl derivatives of 2,3-dihydrofuran-2-one **230** and 2,3-dihydrofuran-3-one **231** has been synthesised by heating in benzene for 2 h the triketones **90**, which are formed from the diazoketone **86** and dihydrofuran-diones **91**. The compounds **230** and **231** can also be obtained without isolation of the triketones **90**, by refluxing a mixture of dihydrofuran-diones **91** and the diazoketone **86** in benzene for 3 h.⁶⁸

R	Yields (%)	
	230	231
H	38	7
Me	71	10
OMe	47	6
Br	14	9

The reaction of 5-phenyl-2,3-dihydrofuran-2,3-dione with the diazoketones **92** has been described in a patent.¹⁴⁹ This reaction yields one, two or three compounds depending on the nature of the substituent X in the diazoketone: for X = Br, three compounds **232**–**234** are formed, whereas for X = H, two compounds **233** and **234** have been isolated. When X = ONO₂, the reaction yields only compound **232**.

X = H, Br, ONO₂.

The hydrogen atom in the 5-position of 2-acetylfuran is substituted by an adamantyl radical in the reaction with adamant-1-yl nitrate in the presence of sulfuric acid even at -15°C ; the yield of 5-(adamant-1-yl)-2-acetylfuran is 32%.¹⁵⁰

Homolytic *ipso*-substitution in 2-acyl-5-nitrofurans **235** has been studied.¹⁵¹ The reaction of furan derivatives **235** with the Ad \cdot radical [generated from AdCOOH in the presence of $(\text{NH}_4)_2\text{S}_2\text{O}_8$ and AgNO_3 ¹⁰³] results in a mixture of three compounds: 2-acyl-5-(adamant-1-yl)furans **236**, 2-acyl-2-(adamant-1-yl)-2,5-dihydrofuran-5-ones **237**, and 2-acyl-2-(adamant-1-yl)-5,5-dinitro-2,5-dihydrofurans **238**. The authors¹⁵¹ presented the following scheme for these transformations: the reaction of the compounds **235** with the Ad \cdot radical affords pairs of more complex radicals **239** and **240**. The radicals **239** eliminate $\text{NO}_2\cdot$ to give compounds **236**. The transformation of the radicals **240** can follow two pathways: it involves either the loss of $\text{NO}_2\cdot$ resulting in the formation of the compound **237** or, conversely, the addition of $\text{NO}_2\cdot$ leading to the compound **238**.

R	Yields (%)		
	236	237	238
H	35	25	15
OMe	31.5	32	10

When 2-(trimethylsilyl)furan reacts with the chloride AdCOCl in the presence of zinc chloride, the trimethylsilyl group is substituted by the adamant-1-ylcarbonyl group giving adamant-1-yl 2-furyl ketone in 61% yield.¹⁵²

The cyclocondensation of the diketone **241** in the presence of concentrated sulfuric acid affords 2,5-di(adamant-1-yl)furan in 84% yield.⁴²

A mixture of diastereomers of 4,5-di(adamant-1-yl)-2-ethoxy-1,3-dioxolane **242** has been obtained by heating the *meso*-diol **243** with the ortho ester HC(OEt)_3 in the presence of benzoic acid.¹⁵³

When the dioxolane **242** is heated in benzoic acid at 200°C , stereoselective *cis*-elimination occurs to give *cis*-1,2-di(adamant-1-yl)ethene in 90% yield.¹⁵³

3. Compounds with six-membered heterocycles

The diene **43** in boiling toluene undergoes [4+2]-cycloaddition with the oxo-group of the diethyl ester of mesoxalic acid; the reaction affords the adduct **244** in an almost quantitative yield.⁴⁷

The electron density distribution in the α,β -unsaturated ketones **245** and in the vinyl ethers **246** is favourable for them to enter into [4+2]-cycloaddition. By heating these compounds at $180\text{--}185^{\circ}\text{C}$ in sealed tubes, the dihydropyran derivatives **247** were synthesised in 50%–88% yields.¹⁵⁴

R ¹	R ²	R ³
H	H	Ad
H	H	AdCH ₂
AdCH ₂	H	H
H	Ad	H

When the dihydropyrans **247** are treated with dilute hydrochloric acid at 20 °C, the heterocyclic ring is cleaved and the 1,5-dicarbonyl compounds **248** are obtained in 84%–92% yields.¹⁵⁴

The tertiary alcohol, 2-(adamant-1-yl)propan-2-ol, reacts with perchloric acid and carboxyanhydrides to give 2,6-dialkyl-4-(adamant-1-yl)pyrilium perchlorates **249**.¹⁵⁵

R = Me, Et, Pr.

2,6-Di(adamant-1-yl)pyrilium perchlorate is formed in 22% yield in the condensation of 1-acetyladamantane with ethyl orthoformate in the presence of sulfuric acid followed by the treatment of the reaction product with perchloric acid.¹⁵⁵

A series of adamantyl-containing heterocyclic compounds **250** with two oxygen atoms in the heterocyclic ring have been synthesised by the condensation of the ketones **251** with 5-phenyl-2,3-dihydrofuran-2,3-dione, their yields ranging from 29% to 78%.¹⁵⁶

R¹ = Br: R² = Br, NO₂; R¹ = NO₂: R² = ONO₂;

R¹ = Ph: R² = ONO₂; R¹ = ONO₂: R² = Br;

R¹ = H: R² = H, Cl, Br, ONO₂, OSO₂CH₂Ad.

IV. Adamantane derivatives containing heterocyclic nuclei with sulfur atoms

1. Compounds with three-membered and four-membered heterocycles

2-(Adamant-1-yl)-2-methylthiirane is formed in 28% yield on refluxing a mixture of 2-(adamant-1-yl)-2-methyloxirane and thiourea in isopropyl alcohol.¹⁴²

In the only study,¹⁵⁷ which reports synthesis of a compound of the adamantane series containing a four-membered heterocycle with a sulfur atom in the heterocyclic ring, two procedures have been proposed for the transformation of a five-membered ring into a four-membered ring. The cyclic sulfone **252** is converted into the epoxide **253** by reaction with 3-chloroperbenzoic acid in the presence of sodium carbonate; on treatment with boron trifluoride etherate the compound **253** isomerises into the thiete dioxide derivative **254**. Interestingly, the compound **254** is also formed in 78% yield in the reaction of the initial sulfone **252** with 3-chloroperbenzoic acid in the absence of water. This result was explained¹⁵⁷ by the fact that the peracid catalyses the isomerisation of the epoxide **253** formed into the thiete dioxide **254**.

2. Compounds with five-membered heterocycles

In the presence of tin(II) chloride, thiophene reacts with 1-bromoadamantane to give two adamantylation products, namely, 2-(adamant-1-yl)thiophene (yield 52%) and 3-(adamant-1-yl)thiophene (yield 7%). On treatment with hydrogen over W-7 Raney nickel, the resulting adamantylthiophenes are desulfurised and converted into 1-(adamant-1-yl)butane (yield 80%) and 2-(adamant-1-yl)butane (yield 85%).¹⁵⁸

Substitution reactions in 2-(adamant-1-yl)thiophene have been studied. A series of thiophene derivatives containing an adamantyl radical in the 2-position and various substituents in the 5-position were thus obtained.¹⁵⁹

All the above compounds are desulfurised in the presence of the W-7 catalyst in alcohol or in dioxane giving the corresponding adamantane derivatives containing no heterocyclic rings.¹⁵⁹

R ¹	R ²	Yield (%)
COOH	COOH	66
CHO	CH ₂ OH	60
COMe	CH(OH)Me	75
CO(CH ₂) ₂ COOH	CH(CH ₂) ₂ CO + CO(CH ₂) ₂ COOH	75 (total)
NO ₂	NH ₂	70

Two compounds, 3-(2-thienyl)adamantane-1-carboxylic acid and 3-(3-thienyl)adamantane-1-carboxylic acid have been obtained in a ratio of 2:1 in 47% overall yield by the reaction of 3-bromoadamantane-1-carboxylic acid with thiophene in the presence of tin(IV) chloride.¹⁶⁰

In the presence of concentrated sulfuric acid, adamant-1-yl nitrate reacts with thiophene derivatives containing electron-withdrawing substituents in the 2-position to give compounds **255** (yields 41% and 44%).¹⁵⁰

R = NO₂, COOH.

By means of adamant-1-ol, the adamantyl radical has been introduced into the 2,2'-dithienyl derivatives **256**.¹⁶¹

R¹ = H, R² = COMe, CHO, COOH; R¹ = NO₂, R² = H.

It is of interest that even at 20 °C, 2-(trimethylsilyl)thiophene reacts with chloroadamantane **34** to give 2,5-di(adamant-1-yl)-thiophene (yield 65%).³⁷

Cogolli et al.^{162, 163} have studied homolytic *ipso*-substitution in the series of thiophene nitro-derivatives under the action of the Ad[•] radical (generated from AdCOOH¹⁰³). The workers¹⁶² described the interaction of the Ad[•] radical with derivatives of 2-nitrothiophene, containing electron-withdrawing substituents in various positions of the thiophene ring; compounds **257** were thus prepared (yields 43%–55%).

R ¹	R ²	R ³
H	H	SO ₂ Ph
H	H	CHO
H	NO ₂	COOMe
NO ₂	H	COOMe

The reaction of Ad[•] with 5-methoxycarbonyl-3-nitrothiophene afforded 2-(adamant-1-yl)-5-methoxycarbonyl-3-nitrothiophene in 50% yield,¹⁶² whereas the interaction of this radical with 5-(methoxycarbonyl)-2-nitrothiophene gave two compounds: the normal product of *ipso*-substitution **258** (yield 55%) and the 'unusual' product **259** (yield 8%). A scheme was suggested to explain these results (Scheme 1).¹⁶³

A more complex picture has been observed in a study of the reactions of the Ad^\bullet radical with thiophene derivatives containing formyl, acetyl, or methoxycarbonyl group in various positions of the thiophene ring.¹⁶³ For example, three compounds were detected among the products of the reaction of the Ad^\bullet radical with 2,5-diformylthiophene, namely, compound **260** (yield 19%), **261** (yield 10%), and **262** (yield 56%), whereas the reaction of 2,4-diformylthiophene with the Ad^\bullet radical gave only compound **262** (yield 60%).¹⁶³

The reaction of 2,5-diacetylthiophene with the Ad^\bullet radical leads to two compounds, 2-acetyl-5-(adamant-1-yl)thiophene **263** (yield 33%) and 2,5-diacetyl-3-(adamant-1-yl)thiophene (yield 16%).¹⁶³

2,5-Di(methoxycarbonyl)thiophene reacts with the Ad^\bullet radical to give 3-(adamant-1-yl)-2,5-di(methoxycarbonyl)thiophene (yield 25%).¹⁶³

The interaction of the Ad^\bullet radical with 2-acetyl-5-formylthiophene is the most complex: four compounds have been isolated and identified among the reaction products, namely, compound **260** (yield 10%), **263** (yield 17%), 2-acetyl-4-(adamant-1-yl)-5-formylthiophene (yield 11%), and 2-acetyl-5-(adamant-1-yl)-4-formylthiophene **264** (yield 13%).¹⁶³

whereas the reaction of 2-acetyl-4-formylthiophene with the Ad^\bullet radical gave the compound **264** as the only product (yield 56%).¹⁶³

The formation of the 'unusual' products **262** and **264** in the reactions of the Ad^\bullet radical with the derivatives of 2-formylthiophene was explained¹⁶³ by assuming a scheme that includes the 1,2-shift of the formyl group.

The cyclocondensation of the aldehyde **94** ($\text{R} = \text{H}$) with thioglycolic acid **265** carried out in boiling alcohol in the presence of triethylamine over a period of 5 h gives 5-(adamant-1-yl)thiophene-2-carboxylic acid **266** (yield 4.5%) and 2-(adamant-1-yl)thiophene (yield 34%). The latter is obviously formed via decarboxylation of the acid **266** under the reaction conditions.¹⁶⁴ By conducting this reaction in DMF in an argon flow, the yields of the products can be substantially increased: the acid **266** is formed in 24.6% yield and adamantylthiophene is obtained in 53.4% yield.¹⁶⁵

The condensation of the aldehyde **94** ($\text{R} = \text{H}$) with thioglycolic acid anilide in DMF in the presence of triethylamine at 60 °C for 3.5 h led to the anilide of the acid **266** (yield 45.5%).¹⁶⁵

When the aldehyde **94** ($\text{R} = \text{Me}$) has been made to react with the acid **265**, only the decarboxylation product, 2-(adamant-1-yl)-3-methylthiophene, has been isolated in 43% yield. Ethyl 5-(adamant-1-yl)-4-methylthiophene-2-carboxylate **267** was synthesised in 71% yield from the aldehyde **94** ($\text{R} = \text{Me}$) and ethyl thioglycolate.⁷¹

The reaction of 3-(adamant-1-yl)-3-chloroacrylonitrile with ethyl thioglycolate gives the aminoester **268** (yield 40%); heating of the latter with formamide in the presence of sodium ethoxide leads to 6-(adamant-1-yl)thieno[2.3-*e*]pyrimidin-4-one **269** (yield 86.5%).⁷⁰

Treatment of 2-(trimethylsilyl)thiophene with AdCOCl in the presence of zinc chloride leads to the substitution of the Me₃Si group by the AdCO group; the reaction affords 2-(adamant-1-ylcarbonyl)thiophene in 82% yield.¹⁵²

In 1990, an interesting study was published,¹²³ which was devoted to the synthesis and some transformations of 3,4-di(adamant-1-yl)thiophene 1,1-dioxide **196**. The dioxo sulfide **270** was reduced to the diol **271** (yield 34%), which on heating with toluene-*p*-sulfonic acid is converted to 3,4-di(adamant-1-yl)thiophene (yield 60%). The latter is oxidised with 3-chloroperbenzoic acid to the cyclic sulfone **196** in 75% yield.¹²³

The diene condensation of the sulfone **196** with phenyl vinyl sulfone gives adduct **272**, which decomposes under the reaction conditions into sulfur dioxide, phenylsulfonic acid, and 1,2-di(adamant-1-yl)benzene (yield 92%).¹²³

The cycloaddition of the sulfone **196** to the dimethyl ethylenedicarboxylate also affords an unstable adduct, compound **273**, which loses sulfur dioxide under the reaction conditions and is converted into dimethyl 4,5-di(adamant-1-yl)phthalate **274** in 90% yield.¹²³

A more complex situation is observed when the sulfone **196** reacts with an excess of 4-phenyl-1,2,4-triazoline-3,5-dione. The adduct **275** of the composition 1:1 is formed initially; it reacts further with one more triazolinedione molecule giving the adduct **195** of the composition 1:2 (yield 71%). Treatment of the latter with potassium hydroxide in methanol gives the bicyclic compound **276** (yield 82%), which is transformed during storage in air into 4,5-di(adamant-1-yl)pyridazine in 82% yield.¹²³

3,4-Di(adamant-1-yl)thiophene in a solution in carbon disulfide in the presence of aluminium chloride is converted into 2,4-di(adamant-1-yl)thiophene in quantitative yield over a period of 6 days at 20 °C.¹²³

3. Compounds with six-membered and larger heterocycles

Two methods for the synthesis of 2-(adamant-1-yl)hexahydro-1,3-dithiane **277** have been reported. One of these methods involves cyclocondensation of adamantane-1-carboxylic acid with 1,3-disulfanypropane in the presence of tin(II) chloride and the complex Me₂S·BH₃, and the other method involves the reaction of the same acid with the complex **278** [obtained preliminarily from HS(CH₂)₃SH and Me₂S·BH₃] in the presence of tin(II) chloride (yield 80%).¹⁶⁶

The heterocyclic compounds **279** (yield 34%), **280** (yield 17%), and **281** (yield 3%) containing several adamantane fragments and several sulfur atoms have been synthesised by heating 1,3-bis(2-bromoethyl)adamantane with thioacetamide in the presence of potassium hydroxide.¹⁶⁷

V. Adamantane derivatives containing heterocyclic nuclei with nitrogen and oxygen atoms

1. Compounds with three-membered heterocycles

Epoxydation of Schiff's bases is a general method for the preparation of oxaziridine derivatives. The Schiff's bases **282** have been converted into the oxaziridines **283** (yield 44%–75%) by treating them with hydrogen peroxide in acetic anhydride in the presence of sulfuric acid.¹⁶⁸

$\text{R}^1 = \text{H}; \text{R}^2 = \text{H, Ph}; \text{R}^1 = \text{cyclo-C}_6\text{H}_{11}, \text{R}^2 = \text{Me};$
 $\text{R}^1 + \text{R}^2 = -(\text{CH}_2)_5-$

Oxaziridine derivatives have been synthesised by the oxidation of Schiff's bases with peracetic acid; the yields of the oxidation products varied from 47% to 56%.^{31, 139}

The oxaziridine containing no substituents at the carbon atom was obtained in 29% yield by the oxidation of the product of condensation of the amine **7** with formaldehyde.¹³⁹

The adamantyloxaziridines **283** are fairly thermally stable compounds. However, at temperatures above 200 °C they isomerise to give the nitrones **284** or amides **285**.¹³⁹

The oxaziridines **286** isomerise in the presence of iron(II) sulfate at room temperature to the amides **287** in 70%–76% yields.¹³⁹

$\text{R}^1 = \text{Ad}, \text{R}^2 = \text{Ph, furyl-2}; \text{R}^1 = \text{AdCH}_2, \text{R}^2 = \text{Ph}; \text{R}^3 = \text{Alk.}$

No compounds containing the adamantyl radical linked directly to the oxazetidine ring have been reported in the literature.

2. Compounds with five-membered heterocycles

When 1-adamant-1-ylcarbonylaziridine is heated with sodium iodide in acetone, it isomerises to 2-(adamant-1-yl)oxazoline (yield 43%).⁶⁰

2-(Adamant-1-yl)oxazoline has been synthesised by the condensation of the methyl iminoester of adamantane-1-carboxylic acid with ethanolamine (yield 93%), whereas the reaction of the hydrochloride of the same iminoester with 2-aminophenol gives 2-(adamant-1-yl)benzoxazole (yield 76%).⁵⁵

1,3-Di(benzoxazol-5-yl)adamantane **289** has been obtained by the reduction of the adamantane derivative **288** containing the methyl 2-nitrobenzoate residues in the 1- and 3-positions.¹⁶⁹

A two-stage procedure proposed for the introduction of adamantyl radical to the nitrogen atoms of 5-methylisoxazolin-3-one or 3-methylisoxazolin-5-one involves *N*-silylation of heterocyclic compounds with disilazane **32** and the subsequent treatment of the resulting silylated products **290** or **291** in situ with 1-chloroadamantane in the presence of aluminium chloride.³⁷

One of the most general methods for the synthesis of isoxazoline and isoxazole derivatives involves the 1,3-dipolar cycloaddition of carbonitrile *N*-oxides to alkenes and alkynes. In 1972, Italian investigators¹⁷⁰ described for the first time the preparation of the *N*-oxide of adamantane-1-carbonitrile **292** and carried out the 1,3-dipolar cycloaddition of the nitrile **292** to styrene and

phenylethyne. The corresponding adducts were obtained in 89% and 69% yields.

An alternative approach to the synthesis of isoxazolines and isoxazoles containing an adamantyl substituent involves 1,3-dipolar cycloaddition of *N*-oxides of nitriles of aliphatic or aromatic carboxylic acids to unsaturated adamantane derivatives. Carbonitrile *N*-oxides used in situ in these reactions are obtained either by treating hydroxamoyl chlorides with bases or by thermolysis.

The isoxazoline derivatives **293** have been obtained in 63%–98% yields from alkenes **294** of the adamantane series and the aromatic and heterocyclic carboxylic acid nitrile *N*-oxides **295** prepared from the corresponding hydroxamoyl chlorides by treating them with triethylamine.^{171, 172}

$n = 0, 1$; $\text{R}^1 = \text{Ph, 4-MeOC}_6\text{H}_4, 3\text{-O}_2\text{NC}_6\text{H}_4, 4\text{-O}_2\text{NC}_6\text{H}_4, 5\text{-nitrofuryl-2}$; $\text{R}^2 = \text{H, Me}$.

The reaction of 1-ethynyladamantane with nitrile *N*-oxides **295** under similar conditions gives isoxazole derivatives **296** in 68%–95% yields.^{171, 172}

$\text{R} = \text{Ph, 4-MeOC}_6\text{H}_4, 3\text{-NO}_2\text{C}_6\text{H}_4, 4\text{-NO}_2\text{C}_6\text{H}_4, 5\text{-nitrofuryl-2}$.

The use of the above procedure permits the preparation of isoxazoline and isoxazole derivatives from unsaturated adamantane derivatives and aliphatic carbonitrile *N*-oxides, their yields ranging from 20 to 40%. The researchers found conditions under which the yields of isoxazolines and isoxazoles increased to 65%.¹⁷²

The isoxazolines **297** and isoxazoles **298** were synthesised in 50–65% yields by the reaction of pyruvonnitrile *N*-oxide (**299**, $\text{R} = \text{MeCO}$) or hydroxyiminoacetonitrile *N*-oxide (**299**, $\text{R} = \text{HON}=\text{CH}$) with alkenes **300** or with 1-ethynyladamantane, respectively.¹⁷¹

By using aqueous sodium bicarbonate instead of triethylamine in the synthesis of isoxazoline **297** ($\text{R} = \text{HON}=\text{CH}$, $n = 0$), the yield of the latter can be increased to 92%.¹⁷¹

Compounds containing two isoxazoline nuclei **301** or two isoxazole nuclei **302** are formed in the cycloaddition of the bis(*N*-oxide) of oxalic acid dinitrile **303** to 1-allyladamantane or to 1-ethynyladamantane (yields 50 and 42%, respectively).¹⁷²

The hydroxamoyl chloride **304** on treatment with triethylamine is converted into the nitrile *N*-oxide **305**, which reacts with 1-allyl and 1-ethynyladamantane to give compounds **301** and **306** (yields 65% and 35%).¹⁷²

Compound **307** containing isoxazoline and benzimidazole nuclei and compound **308** with imidazoline and benzoxazole nuclei are obtained in 75% and 72% yields by the condensation of the iminoester hydrochloride **309** with *o*-diaminobenzene or *o*-aminophenol.¹⁷²

Most of the compounds synthesised from nitrile *N*-oxides and unsaturated adamantane derivatives exhibit a bacteriostatic activity. For example, the adamantyl derivative of isoxazoline **293** with $\text{R}^1 = 5\text{-nitro-2-furyl}$, $\text{R}^2 = \text{Me}$, and $n = 0$ is active against diphtheria and tuberculosis pathogens, the derivative with $\text{R}^1 = \text{Ph}$, $\text{R}^2 = \text{Me}$, and $n = 0$ exhibits a high tuberculostatic activity, and the compound with $\text{R}^1 = 3\text{-O}_2\text{NC}_6\text{H}_4$, $\text{R}^2 = \text{H}$, and $n = 0$ possesses a high antiviral activity.¹⁷²

5-(Adamant-1-yl)- and 5-(adamant-1-yl)-4-methylisoxazoles have been synthesised by the reaction of the aldehydes **94** with hydroxylamine hydrochloride in boiling methanol (yield 90%).¹⁶⁵

$\text{R} = \text{H}, \text{Me}$.

Refluxing of 3-(adamant-1-yl)pentane-2,4-dione **310** with hydroxylamine hydrochloride in aqueous alcohol gives rise to 4-(adamant-1-yl)-3,5-dimethylisoxazole (yield 70%).⁶⁰

He and Lin proposed¹⁷³ an original method for the synthesis of the oxazole derivatives **311**. The oximes of ketones **312** are converted into the corresponding dianions on treatment with butyllithium. The dianions are introduced into the reaction with ethyl adamantane-1-carboxylate. The resulting salts **313** cyclise to the isoxazoles **311** on treatment with sulfuric acid.¹⁷³

$\text{R}^1 = \text{Me}; \text{R}^2 = \text{H}; \text{R}^1 + \text{R}^2 = -(\text{CH}_2)_3-, -(\text{CH}_2)_4-.$

Compound **314** can be obtained in 64% yield in a similar way from diethyl adamantane-1,3-dicarboxylate and cyclohexanone oxime.¹⁷³

Biological activity of the isoxazoline derivatives has been studied.

This compound with $\text{R} = \text{Ph}$ was found to exhibit a tuberculo-static activity, and the compounds with $\text{R} = 5\text{-nitro-2-furyl}$ and 5-nitro-2-thienyl exhibit an antibacterial activity.¹⁷⁴

2-(Adamant-1-yl)-4,4-dimethylisoxazolidine-3,5-dione **315** has been obtained in 94% yield by the condensation of *N*-(adamant-1-yl)hydroxylamine hydrochloride with dimethylmalonic acid dichloride.¹⁷⁵

The amide AdC(O)NH_2 is converted initially into the salt **317** (yield 72.5%) by treating it with oxalyl chloride; the interaction of this salt with ethanol results in the formation of the ethoxy-derivative **318** ($\text{R} = \text{H}$, yield 91%). The anilide AdC(O)NHPh is converted into compound **318** ($\text{R} = \text{Ph}$, yield 56%) without isolation of the corresponding salt.^{176, 177}

On treatment with ammonia, the compound **318** with $\text{R} = \text{H}$ is converted into the diamide AdCONHCOCONH_2 , whereas refluxing of this compound in dichloromethane for 28 h leads to the acyl isocyanate AdCONCO .¹⁷⁶

Heating of *N,N'*-di(adamant-1-ylcarbonyl)hydrazine in acetic anhydride in the presence of perchloric acid affords 2,5-di(adamant-1-yl)-1,3,4-oxadiazole in 50% yield.⁶⁰

High-molecular-weight thermostable compounds **319** containing adamantyl and 1,3,4-oxadiazole fragments, which are readily moulded at temperatures above the softening point, have been prepared by heating adamantane-1,3-dicarboxylic acid, diadamant-1,1'-yl-3,3'-dicarboxylic acid, or their chlorides with the dihydrazides of the same acids in polyphosphoric acid (with a content of P_2O_5 of 85%–86%) at 140–160 °C for 6 h.¹⁷⁸

Thermostable polymers are formed in 73–89% yields when *N,N'*-diacylpolyhydrazides **321** are heated with phosphorus oxychloride in vacuo.¹⁷⁹

$n = 1-4, 7, 8.$

The furoxans **322** containing an adamantyl radical in the 4-position have been prepared by a known method involving the reaction of the *anti*-glyoximes **323** with a fuming nitric acid in glacial acetic acid. The yields of the furoxans **322** in this reaction are 60%–70%.¹⁸⁰

$R = \text{H, Me, Cl, 4-MeOC}_6\text{H}_4.$

On refluxing in *p*-xylene for 2 h the furoxan **322** ($R = \text{H}$) isomerises to the furoxan **324** (yield 22%), whereas on prolonged refluxing (13 h) the isomerisation leads to 3-(adamant-1-yl)-1,2,4-oxadiazol-5-one **325** (yield 50%).¹⁸⁰

Treatment of the furoxan **322** ($R = \text{H}$) with nitric acid ($d = 1.5$) at 20 °C for 2 h gives rise to the furoxan **322** ($R = \text{ONO}_2$) in 78% yield.¹⁸⁰

In the presence of $\text{K}_3\text{Fe}(\text{CN})_6$, the glyoximes **323** react with secondary amines giving the furoxans **326** containing residues of the secondary amines in the 5-position (yields 33%–64%).¹⁸¹

R^1	R^2	R^3	R^1	R^2	R^3
H	Me	Me	OH	Me	Me
Me	Me	Me	H	Et	Et
4-MeC ₆ H ₄	Me	Me	H	-(CH ₂) ₅ -	
Cl	Me	Me	H	(CH ₂ CH ₂) ₂ O	

The furoxans **327** have been obtained by the reaction of the nitrile *N*-oxide **328** with ammonia or methylamine followed by treatment of the resulting glyoximes **329** with potassium hexacyanoferrate(III). The yields of furoxans **327** are 37% ($R = \text{H}$) and 30% ($R = \text{Me}$).¹⁸¹

$R = \text{H, Me.}$

The furoxan **326** ($R^1 = \text{H}, R^2 = R^3 = \text{Me}$) is reduced by tin(II) chloride in hydrochloric acid to a furazan derivative, 3-(adamant-1-yl)-4-dimethylamino-1,2,5-oxadiazole **330**.¹⁸¹ The yield of the furazan **330** is 66%.

$R^1 = \text{H}, R^2 = R^3 = \text{Me.}$

The nitrile *N*-oxide **292** dimerises under mild conditions to give 4,5-di(adamant-1-yl)furoxan (yield 78%).¹⁷⁰

There is only one example of synthesis of a derivative of 1,2,3-oxadiazolidine, namely, 3-(adamant-1-yl)-1,2,3-oxadiazol-5-one **331**. This compound is formed in 80% yield in the reaction in *N*-nitroso-*N*-(adamant-1-yl)glycine with the anhydride of trifluoroacetic acid.¹⁸²

The 1,2,4-oxadiazolidine-3,5-dione derivatives **332** containing an adamantyl radical have been obtained by the condensation of the amides **333** with ethyl chloroformate in the presence of an alcoholic solution of potassium hydroxide (yields 75% and 58%).¹⁸³

R = H, Cl.

Heating of the nitrile *N*-oxide **328** in toluene affords 3-(adamant-1-yl)-1,2,4-oxadiazol-5-one **325** in 63% yield.¹⁸⁰

It has been found that the formation of the compound **325** involves cleavage of the furoxan ring, the isocyanate rearrangement of the intermediate nitrile *N*-oxide **328**, and its subsequent cyclisation.¹⁸⁰

The 1,2,4-oxadiazole derivatives **334** have been synthesised from amidoximes and *p*-chlorobenzoyl chloride¹⁸⁴ or from the orthoester $\text{AdC}(\text{OEt})_3$ ¹⁸⁵ in the presence of boron trifluoride etherate with heating (yield 40%).

X = Cl, NO₂.

Several procedures have been proposed for the synthesis of adamantyl-containing oxadiazoles. 3-R-5-(Adamant-1-yl)-1,2,4-oxadiazoles **335** have been obtained in 56%–98% yields from the hydroxamoyl chlorides $\text{RC}(\text{Cl})=\text{NOH}$ by two procedures: their thermal condensation with 1-cyanoadamantane or their interaction with the methyl iminoester hydrochloride **54** in the presence of sodium carbonate.^{56, 186}

R (time of refluxing/h) = Ph (40), 3-O₂NC₆H₄ (80),

4-O₂NC₆H₄ (110), (110).

Two alternative methods for the synthesis of the 1,2,4-oxadiazole derivatives **335** and **336** are based on the reaction of the amidoximes **337** with the iminoester hydrochloride **54** (the yields of the target compounds varied from 40% to 88%)^{56, 186, 187}

R = Me, PhCH₂, Ad,

or on the cyclocondensation of amidoximes **337** with carbonitriles **338**.

R¹ = Ad; R² = CCl₃, 2-ClC₆H₄, Ad;

R² = Ad; R¹ = Me, ClCH₂, CCl₃, 2-ClC₆H₄.

To prepare 2,5-disubstituted derivatives of 1,3,4-oxadiazole, cyclocondensation of the carboxylic acid hydrazides **339** with iminoester hydrochlorides **340** has been used. The yields of the oxadiazole derivatives were 50%–70%.⁵⁶

R = Me, Ph, , Ad.

3. Compounds with six-membered heterocycles

Refluxing of a mixture of morpholine and the 1-bromoadamantane for 8 h gives rise to 4-(adamant-1-yl)morpholine, which has been claimed as a compound possessing an antiviral activity.⁸⁹

A method for preparing 3-(morpholinomethyl)adamantane-1-carboxylic acid **341** has been proposed. The method includes three stages. The reaction of the chloride AdCOCl with morpholine affords the morpholide of this acid (yield 72%), which is then reduced with lithium tetrahydroaluminate to 1-(morpholinomethyl)adamantane (yield 97%). The latter reacts with formic acid in the presence of sulfuric acid to give the compound **341** in 11% yield.¹⁰⁷

The hydrochloride of the compound **341** exhibits analgesic, anti-inflammatory, antipyretic, and antifibrillar activities.¹⁰⁷

The salt **342** has been obtained in 42% yield from 1,3-dehydroadamantane, 4-methylmorpholine, and iodine by conjugated haloamination.¹⁰⁰

Derivatives of dihydro-1,2- and dihydro-1,3-oxazine have been prepared by diene condensation. 4-(Adamant-1-yl)-2-phenyl-3,6-dihydro-1,2-oxazine **343** has been synthesised in this way from the diene **43** and nitrosobenzene in 51% yield; the adduct **345** was obtained from the diene **344** and cyclohexene in 33% yield; and the interaction of the diene **346** and 2,3-dimethylbuta-1,3-diene gave rise to the adduct **347** (yield 59%).⁴⁷

Compound **348** has been synthesised in 50% yield by the diene condensation of adamant-1-ylcarbonyl isothiocyanate **349** with the enamine **350**.⁴⁷

A heteryladamantane, 2-(trichloromethyl)-6-thioxo-5*H*-1,3,5-oxadiazin-4-one **351**, has been obtained in 53% yield by the reaction of perchloroethyl isocyanate **352** with *N*-(adamant-1-yl)-*O*-methylthiourethane **353** in the presence of triethylamine.¹⁸⁸

On heating in benzene, AdNH_2 condenses with three formaldehyde molecules affording the derivative of 1,3,5-dioxazine **354** (yield 49%).¹³⁹

VI. Adamantane derivatives containing heterocyclic nuclei with nitrogen and sulfur atoms

1. Compounds with three-membered and four-membered heterocycles

N,N'-Bis(adamant-1-yl)sulfonamide is converted into 2,3-di(adamant-1-yl)thiadiaziridine-1,1-dioxide **355** in 92% yield by treating it with potassium *tert*-butoxide and *tert*-butyl hypochlorite in tetrachloromethane.¹⁸⁹

Diadamantylidiazene **356** is formed from the dioxide **355** when it is treated with hydrogen chloride in toluene (yield 100%) or refluxed in ethanol (yield 84%). Treatment of the dioxide **355** with potassium iodide in acetic acid leads to the initial *N,N'*-bis(adamant-1-yl)sulfonamide in 72% yield.¹⁸⁹

6-(Adamant-1-yl)-2-aminobenzothiazole is formed in the reaction of the thiourea derivative **364** with bromine (yield 40%).⁴⁵

The homolytic *ipso*-substitution in the series of benzothiazole derivatives has been studied fairly comprehensively.¹⁹²⁻¹⁹⁴ The benzothiazole derivatives **365** and the acid AdCOOH were treated with ammonium peroxydisulfate and silver nitrate in acetonitrile in the presence of aqueous ammonia at 90 °C for 20 min. The last stage of this reaction is the displacement of the substituent in the 2-position of the benzothiazole nucleus and its substitution by the adamantyl radical.¹⁹²⁻¹⁹⁴

R (yield, %) = PhSO₂ (80), PhSO (80), PhCO (55), MeCO (60), CHO (40), MeS (60), MeO (40), Br (70), Cl (50), F (50),¹⁹² CHO (40), MeCO (60), COEt (60), PhCO (55), 4-ClC₆H₄ (56), 4-MeC₆H₄CO (52), 4-MeOC₆H₄ (50),¹⁹³ NO₂ (100).¹⁹⁴

A possible scheme for this reaction has been suggested.^{192, 193}

The presence of electron-withdrawing substituents in the 5- or 6-position facilitates this reaction. The relative rates (*v*) of the substitution of the acetyl radical by the adamantyl radical in the 2-acetylbenzothiazole derivatives **366** have been measured.¹⁹³

X (*v*) = 6-CN (10.92), 6-Cl (2.30), 5-Cl (2.18), 5-MeO (1.26), H (1.0), 5-Me (0.86), 6-Me (0.6), 6-MeO (0.46).

Treatment of compound **367**, obtained by silylation of 4-methyl-3*H*-thiazolin-2-one with disilazane **32**, with 1-chloro-adamantane in the presence of AlCl₃ has led to 5-(adamant-1-yl)-4-methyl-3*H*-thiazolin-2-one **368**.³⁷

The derivatives of thiazolidin-4-one **369** inhibiting the growth of Gram-positive and Gram-negative bacteria and acting as fungicides have been synthesised by cyclocondensation of the Schiff's bases **370** with thioglycolic acid.¹⁹⁵

3-(Adamant-1-ylmethyl)-2-iminothiazolidin-4-one **371** is formed on refluxing the chloroacetamide **372** and thiourea in isopropyl alcohol (yield 58%).¹⁹⁶

The nature of the radical R in the thioamides RC(S)NH₂ plays the crucial role in their interaction with the ketones **373**. For example, the reaction of MeC(S)NH₂ with the ketones **373** affords the 4-hydroxythiazolines **361**, whereas the interaction of HC(S)NH₂ with these ketones leads to the thiazole derivatives **374**. The yields of all the compounds obtained vary from 70% to 97%. Hydroxythiazoline hydrobromides on refluxing in alcohol are converted into the thiazole derivatives **375**.¹⁹¹

R = Ad, AdCH₂, 3-ClAd, 3-BrCH₂Ad.

Compounds 376 cyclise on treatment with thionyl chloride giving the isothiazolin-3-one derivatives 377, which have been recommended as bactericides and fungicides.¹⁹⁷

n = 1, 2.

Compounds of the general formula

R¹, R² = H, Hal; R³ = Ad, AdCH₂,

were claimed as bactericides and fungicides in the same patent.¹⁹⁷

The transformation of adamant-1-ylcarbonylthiosemicarbazide 378 into the 2,5-disubstituted 1,3,4-thiadiazoles 379 has been achieved by means of cyclisation agents such as concentrated sulfuric acid or phosphorus oxychloride.¹⁹⁸ When concentrated sulfuric acid was used for R = Me and Et, the yields of the products 379 were 51% and 55%, whereas with phosphorus oxychloride in the case where R = Me, Et, 4-XC₆H₄ (X = F, Cl, Br), and PhCH₂, the yields were 61%–68%.

R = H, Me, Et, 4-FC₆H₄, 4-ClC₆H₄, 4-BrC₆H₄, PhCH₂.

The interaction of the *O*-methyl adamantane-1-carbothioate with diazomethane in a mixture of ether and methanol in the dark gives rise to two compounds: 1,3,4-thiadiazole 380 and 1,2,3-thiadiazole 381 derivatives (yields 7% and 32%).¹⁰⁸

If this reaction is carried out in the absence of methanol only one compound, 5-(adamant-1-yl)-5-methoxy-1,2,3-thiadiazole 382 is formed in 22% yield.¹⁰⁸

4-Adamant-1-ylcarbonyl-5-benzoylamino-1,2,3-thiadiazole 383 has been synthesised from the ketone 86 and benzoyl thioisocyanate with heating (yield 50%).^{60, 199}

Compound 383 and its 5-arylamino-analogues possess bactericidal and antiviral activities.¹⁹⁹

3. Compounds with six-membered heterocycles

The adamantane derivatives containing six-membered heterocyclic nuclei incorporating nitrogen and sulfur atoms can be obtained by diene condensation. Cyclocondensation of *N*-sulfenyltoluene-*p*-sulfonamide 384 with the diene 43 at ambient temperature affords the 1,2-thiazine derivative 385 (yield 89%).⁴⁷

N-(Adamant-1-ylthiocarbonyl)-*N*',*N*'-dimethylformamidine 386 reacts with methyl vinyl ketone on refluxing in benzene giving rise to the 1,3-thiazine derivative 387 (yield 36%).⁴⁷

VII. Adamantane derivatives containing other heterocyclic nuclei

The heterocyclic compound 388 containing a five-membered ring with a phosphorus atom has been synthesised by cyclocondensation of (adamant-1-yl)phosphane with phthalic acid chloride in the presence of triethylamine.²⁰⁰

At 20 °C, the nitrile *N*-oxide **292** enters into 1,3-dipolar cycloaddition with thiobenzophenone, which affords 3-(adamant-1-yl)-5,5-diphenyl-1,4,2-oxathiazole in 75% yield.¹⁶⁹

The complex of boraadamantane with tetrahydrofuran **389** reacts with carbon monoxide giving (adamant-1-yl)borodioxolane **390**, interaction of which with lithiodichloromethane gives rise to compound **391**.²⁰¹

The Lawesson reagent **392** can act as the dienophile in diene condensation. For example, the reaction of the diene **43** with this reagent at 20 °C affords the adduct **393** (yield 85%) with sulfur and phosphorus atoms in the heterocyclic moiety.⁴⁷

Compounds **394** have been synthesised in 50%–80% yields by the condensation of adamantane derivatives **395** with triethanolamine.²⁰²

$R^1 = H$; $R^2 = H, Me$; $R^3 = H, Me, Et$;

$R^1 = R^2 = R^3 = Me$; $R^4 = \text{alkylene, arylene, thienylene}$;

$R^5 = \text{alkyl}$.

III. Rigid-chain aromatic polyimides	604
IV. Conclusion	607

Abstract. The results of studies in recent years on the synthesis of polyimides with chains which are both flexible and rigid to the maximum extent are surveyed. The characteristic features of the formation of these polymers, their properties, and certain aspects of their practical applications are considered. It is shown that the thermodynamic rigidity of the macromolecules is one of the principal factors which determines the most important properties of polyimides and the materials based on them. The bibliography includes 85 references.

I. Introduction

The development of the chemistry of aromatic polyimides (API) ^{1–5} led to the formation of a large number of polyheteroarylenes exhibiting significantly different properties. One of the most important factors influencing the properties of API is the rigidity of their macromolecules. In terms of this feature, the API may be divided into two principal groups — flexible-chain and rigid-chain polyimides.

The development of the flexible-chain polyimides was stimulated by the need to obtain easily processed polyimides soluble in the usual organic solvents and having wide gaps between the glass transition and decomposition temperatures. ^{6–8} The development of the chemistry of the rigid-chain polymers was in its turn determined by the need to create very strong and high-modulus materials. ^{9, 10}

The molecular designs of the flexible-chain and rigid-chain polyimides are different. The flexible-chain API contain in the main chain asymmetric phenylene (*m*-phenylene) rings and groups which increase the flexibility of the chain (ether, thioether, isopropylidene, hexafluoroisopropylidene, etc.), ^{6–8} whereas in the rigid-chain API the macromolecular chains are extended to the maximum extent and contain predominantly symmetrical *p*-phenylene fragments and heterocycles without any groups increasing the flexibility of the chains. ¹¹

II. Flexible-chain aromatic polyimides

The most important flexible-chain API are polyimides with ether groups in the main chain, the so called polyetherimides (PEI). A wide range of PEI have been obtained as a result of the interaction of various aromatic diamines containing ether groups and the dianhydrides of aromatic tetracarboxylic acids without the same groups ^{1, 12, 13} in accordance with Scheme 1.

The values of the Kuhn segment ($A_f/\text{\AA}$), calculated and determined experimentally ^{14, 15} for certain PEI based on the dianhydride of oxybis(benzene-3,3',4,4'-dicarboxylic) acid (OBBDCA) as well as the properties of these PEI are presented in Table 1.

The use of diamines with *p*-phenylene fragments and of dianhydrides containing only one ether group led to PEI with a 30–37 Å Kuhn segment and a glass transition temperature of 255–290 °C. When the 'dianhydride R' was used instead of OBBDCA, the PEI 3a–e with a 26–32 Å Kuhn segment and a glass transition temperature of 175–215 °C were synthesised (Table 2).

In order to obtain PEI with a smaller Kuhn segment and lower glass transition temperatures it appeared useful to introduce into the macromolecule the largest possible number of ether groups, which increase the flexibility of the chain, as well as *m*-phenylene fragments. A large group of bis(phthalic anhydrides), containing at least two ether groups — bis(etherphthalic anhydrides) (BEPA) — were synthesised. The dianhydrides were obtained by the aromatic nucleophilic nitro-displacement reaction between bisphenoxides and nitrophthalimides or nitrophthalonitriles (Scheme 2).^{6–8,16–21}

The reactions of the BEPA 4–7 with aromatic diamines [*m*-phenylenediamine, bis(4-aminophenyl)ether, bis(4-aminophenyl)methane, etc.] were carried out in accordance with Scheme 3.^{22–34} The PEI were synthesised in the melt,^{22–26} in amide solvents (high-temperature polycondensation),^{27,28} or in nonpolar organic^{22,23,29,30} and phenolic^{31–34} solvents. Particular attention was concentrated on the polymers obtained on the basis of the cheap and readily available *m*-phenylenediamine. Certain properties of these polymers are presented in Table 3.

Among the PEI listed in Table 3, the polymer synthesised from the 'dianhydride A' is the most important and most readily available.

Scheme 2

Scheme 3

This polymer, containing *m*-phenylene ring, ether, and isopropylidene groups in the main chain, is extremely flexible — its Kuhn segment is 19 Å long.³⁵ It was selected as the starting material for the preparation of the ULTEM plastic, which is produced by the General Electric Company.⁶ Certain properties of ULTEM are listed in Table 4. A high transparency and rigidity combined with a high decomposition temperature and fire resistance as well as the absence of smoke formation or combustion are characteristic of this polymer.⁶

Another approach to the synthesis of flexible-chain readily processable PEI is based on the use of aromatic diamines containing several ether groups and *m*-phenylene fragments in the structure of the molecule. A large group of these diamines have been obtained by the interaction of various bisphenoxides with unsubstituted and substituted *m*-dinitrobenzenes^{36–57} by the aromatic nucleophilic nitro-displacement reaction (Scheme 4).

Table 3. The properties of polyetherimides having the general formula ^{6,18}

unnotched	1300 J m ⁻¹		

As a rule, the aromatic nucleophilic nitro-displacement reaction takes place readily, provided that the activating groups are located in the *ortho*- and *para*-positions relative to the nitro-group, but in certain cases *meta*-substituted dinitro-compounds can also be involved in the reaction.^{4,6,7}

Numerous studies^{36–49} have been devoted to the preparation of diamines from *m*-dinitrobenzene. Among them, products with the isopropylidene and hexafluoroisopropylidene 'bridging' groups are of greatest interest. The PEI involving these diamines have been synthesised in accordance with Scheme 5.

Scheme 4

The reactions were carried out in *N*-methylpyrrolidone (*N*-MP) at room temperature; the intermediate poly(*o*-carboxy)amides were cyclised directly in the reaction solution using as the catalyst either a 1 : 1 pyridine–acetic anhydride mixture or orthophosphoric acid or adding compounds which form azeotropic mixtures with the water evolved during cyclisation. All the reactions took place under homogeneous conditions. Under the conditions of catalysis by orthophosphoric acid or without the use of any catalyst, as a rule high-molecular-mass PEI with a high degree of cyclisation were obtained. Certain properties of the PEI 8 and 9 are presented in Table 5. It follows from the data in Table 5 that the PEI 8 and 9 are characterised by relatively low glass transition temperatures (180–225 °C) and high decomposition temperatures. The melt viscosity of these polymers is fairly low, which makes them suitable for processing by injection moulding.

Scheme 5

X = H: R = CMe₂ (**8**), C(CF₃)₂ (**9**); X = CF₃: R = CMe₂ (**10**)

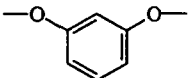

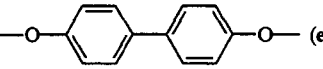

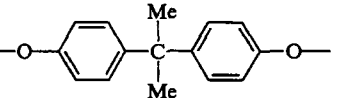

R' = bond (a), C(O) (b), -O- (c),  (d),  (e),  (f).

Table 5. The properties of the polyimides **8** and **9**.^{46, 48}

Polyimide	η_{red}^a /dl g ⁻¹	T_g /°C	$T_{5\%}$ /°C (TGA)	$10^{-3} \eta_{\text{eff}}^b$ /dl g ⁻¹	
				A	B

9b	0.55	220	492	2.8	4.9
9c	0.55	180	505	0.4	—
9d	0.68	200	517	2.8	7.7
9e	1.07	220	498	5.4	1.5
9f	0.78	200	507	2.9	6.4

^a The viscosity η measured in *m*-cresol at 25 °C. ^b The effective viscosity of the melt (capillary viscosimetry) measured at $\dot{\nu} = 2912 \text{ s}^{-1}$ (A), $\dot{\nu} = 728 \text{ s}^{-1}$ (B) ($\dot{\nu}$ is rate of shearing).

The polyimides obtained are readily soluble in organic solvents — *N*-MP, *m*-cresol, methylene chloride, chloroform, etc. The ready solubility of the polymers is determined by their structure and method of synthesis. The polymers synthesised under mild conditions are known to be more soluble than the polymers obtained at high temperatures.⁵⁸ Thus the polyimides **9a–c**, obtained in accordance with Scheme 5, are readily soluble in *N*-MP and dimethylacetamide (DMA) while the polyimides based on 2,2-[bis(*p*-aminophenoxy)phenylene]propane,⁵⁹ obtained using solid-phase high-temperature cyclisation of polyamidoacids, are insoluble in these solvents. The polyimides based on diamines with trifluoromethyl groups in the benzene ring are even more soluble.^{51, 52} The corresponding diamines were obtained in accordance with Scheme 4; 3,5-dinitro-1-trifluoromethylbenzene

and various bisphenoxides were used as the starting compounds.^{50–52} Attention has been concentrated on the diamine with the isopropylidene bridging group.

The polyimides were synthesised from this diamine and the dianhydrides of the simplest dinuclear tetracarboxylic aromatic acids in *N*-MP without a catalyst in accordance with Scheme 5.⁵² The principal properties of the polyimides **10a–c** are presented in Table 6. As can be seen, the polyimides have low glass transition temperatures (180–210 °C) combined with high decomposition temperatures. The polymers **10a–c** are soluble not only in amide, phenolic, and chlorinated solvents (like the polymers **8** and **9**) but also in cyclohexanone and butyrolactone.

Table 6. The properties of the polyimides **10a–c**.⁵²

Polyimide	η_{red} /dl g ⁻¹ ^a	T_g /°C	$T_{10\%}$ /°C (TGA)
10a	0.46	193	523
10b	0.37	190	502
10c	0.31	180	511

^a The viscosity η measured in *m*-cresol at 25 °C.

3,5-Dinitrodiphenyl ether can also be used to obtain the diamines. The interaction of the ether with various bisphenoxides leads to nitro-compounds with phenoxide side groups,^{53, 54} the reduction of which results in the formation of the corresponding amines with phenoxide side groups.⁵⁶ The polyimides **11a–d** have been synthesised from a diamine containing a hydroquinone residue.⁵⁷ The synthesis was based on Scheme 6. All the reactions were carried out homogeneously and led to high-molecular-mass polyimides with a high degree of cyclisation. The properties of the polyimides **11a–d** are presented in Table 7. The polyimides obtained were distinguished by relatively low glass transition temperatures combined with high decomposition temperatures and a ready solubility in organic solvents, which led to their being easily processed into articles.

Scheme 6

Table 7. The general properties of the polyimides 11a-d.⁵⁷

Polyimide	η_{red} / dl g ⁻¹	T_g /°C	$T_{10\%}$ /°C (TGA)	Molecular mass	Properties of films	
					σ /MPa	ϵ (%)
11a	0.67	170	520	47 000	890	4
11b	1.00	190	520	77 000	760	5
11c	0.95	188	500	—	540	5
11d	0.65	205	470	—	530	4

Almost all the polymers are soluble in amide, phenolic and chlorinated solvents, and also in cyclohexanone, acetone, and butyrolactone. The polyimides based on the diamines having the general formula 12 are even more easily processed into articles.

$R = CMe_2, C(CF_3)_2$.

Scheme 7

III. Rigid-chain aromatic polyimides

As mentioned above, the macromolecules of rigid-chain aromatic polyimides must be extended to the maximum extent and must contain symmetrical *p*-phenylene fragments and heterocyclic units without 'flexibilising bridges'. The simplest aromatic polyimides with a 'rod' geometry may be obtained from pyromellitic dianhydride or the dianhydride of biphenyl-3,3',4,4'-tetracarboxylic acid and carbocyclic (*p*-phenylenediamine, benzidine, 4',4''-diaminoterphenyl, etc.) or heterocyclic [2,5-bis(*p*-aminophenyl)pyrimidine]diamines⁶⁰⁻⁶⁴ in accordance with Scheme 7.

The high-molecular-mass poly(*o*-carboxy)amides formed in the first stage (in various amide solvents) undergo chemical or thermal cyclodehydration in the second stage, which results in the formation of insoluble polyimides. The value of the Kuhn segment was 625 Å for the polypyromellitimide based on 4',4''-diaminoterphenyl and 1750 Å for the polypyromellitimide based on 2,5-bis(*p*-aminophenyl)pyrimidine, which indicates a high rigidity of the macromolecules.⁶²

It is noteworthy that the evolution of gaseous products during the high-temperature thermal cyclodehydration limits the use of these materials in the industrial manufacture of thick-walled articles.⁶⁰

The studies by various research groups on the problem of the removal of water stimulated investigations of the synthesis of rigid-chain polyimides soluble in organic solvents. Bulky side groups are usually introduced into the macromolecule in order to improve the solubility of polymers. Typical representatives of such groups are long aliphatic segments, for example dodecyl fragments.^{65–68} The reaction of 4,4''-diamino-2,5,2',5'',5''-hexadodecyl-*p*-terphenyl with pyromellitic dianhydride in *m*-cresol at 200 °C using isoquinoline as the catalyst was carried out in accordance with Scheme 8. The polyimide **13** obtained as a result of this reaction was soluble in various organic solvents. However, it is noteworthy that the introduction of aliphatic fragments into the molecules of aromatic polyimides appreciably lowers their thermal stability — the polymers rapidly lose weight starting from 380 °C.

Scheme 8

13

R = (CH₂)₁₁CH₃.

Better results were obtained when diamines and/or dianhydrides with trifluoromethyl side groups were used as the starting components.^{69–76} Polyimides based on 2,2'-bis-(trifluoromethyl)-4,4'-diaminobiphenyl and the dianhydrides of pyromellitic, biphenyl-3,3',4,4'-tetracarboxylic, 1-(trifluoromethyl)benzene-2,3,5,6-tetracarboxylic, and 1,4-bis(trifluoromethyl)benzene-2,3,5,6-tetracarboxylic acids have been synthesised by this procedure (Scheme 9).

The synthesis is carried out in two ways — by a two-stage reaction involving the low-temperature synthesis of poly(*o*-carboxy)amides in DMA with subsequent thermal cyclisation in the solid state at 350 °C^{70,71} and by a single-stage polycyclocondensation in boiling *m*-cresol.^{72–76} The polyimide obtained from 2,2'-bis(trifluoromethyl)-4,4'-diaminobiphenyl and the dianhydride of biphenyl-3,3',4,4'-tetracarboxylic acid by polycondensation in *m*-cresol is of greatest interest.^{72–76} This polymer is soluble in hot *m*-cresol. Fibres with a low strength and low elasticity modulus have been obtained by spinning its isotropic solution, but after tenfold drawing at a temperature above 380 °C the strength and the modulus of elasticity improved greatly when a load was applied. The fibres drawn in this way had a tensile strength of 3.2 GPa and an initial modulus of elasticity in excess of 130 GPa. The fibres had excellent thermal stability and retained a high strength and modulus of elasticity at elevated temperatures.

Rigid-chain polyimides soluble in phenolic solvents have been obtained by the interaction of the dianhydride of biphenyl-3,3',4,4'-tetracarboxylic acid with 2-phenyl-*p*-phenylenediamine and 4,4'-diamino-1,1'-binaphthyl⁷⁷ in accordance with Scheme 10. The reaction was carried out in *m*-cresol or *p*-chlorophenol at 200 °C using isoquinoline or tertiary amines as catalysts. The polyimides **14** and **15** are soluble in *m*-cresol and *p*-chlorophenol and have a high viscosity combined with high glass transition temperatures and decomposition temperatures. The same diamines have been used in the reactions with the dianhydrides of 3-phenyl- and 3,6-diphenylpyromellitic acids (Scheme 10).⁷⁸ The properties of the polyimides obtained under the conditions described above are presented in Table 8.

Table 8. The properties of the polyimides 14–19.^{77,78}

Polyimide	η_{\log} / dl g ⁻¹	T_g / °C	$T_{5\%}$ / °C (TGA)	
			N ₂	air
14	0.96	341	565	572
15	4.54	—	585	498
16	0.70	—	560	501
17	2.32	—	557	555
18	1.21	—	578	557
19	3.15	404	546	467

The dianhydride of 3,6-diphenylpyromellitic acid was also made to react with *p*-phenylenediamine, 1,4-diamino-2,3,5,6-tetramethylbenzene, benzidine, 4,4'-diamino-3,3',5,5'-tetramethylbiphenyl, 4,4'-diamino-3,3'-dimethoxybiphenyl, and 4,4'-diamino-2,2'-bis(trifluoromethyl)biphenyl.⁷⁹ The corresponding polyimides were obtained in two ways — by a two-stage synthesis (low-temperature synthesis of poly(*o*-carboxy)amides in *N*-MP with subsequent chemical or thermal imidisation) and a single-stage high-temperature polycyclocondensation in boiling *m*-cresol with isoquinoline as the catalyst. Best results were achieved when the single-stage process was used.

Scheme 10

Among the rigid-chain polyimides synthesised in this way, three polymers (based on dinuclear diamines) proved soluble in *m*-cresol. It is most likely that the improvement of the solubility of these polymers is associated with the nonplanarity of the bisphe-nylene fragments (especially 2,2'-substituted ones).⁸⁰

The intrinsic viscosities of the polymers soluble in *m*-cresol (Table 9) are in the range 0.91–2.63 dl g⁻¹; these are relatively low values for rigid-chain polymers. The mass-average molecular masses of these polymers are 10 000–12 000.

Table 9. Some properties of polyimides having the general formula.⁷⁹

Ar	$[\eta]$ /dl g ⁻¹	$T_{5\%}$ /°C (TGA)	
		N ₂	air
	0.91	520	440
	2.63	475	425
	2.40	585	585

Fibres have been obtained from the polyimide with trifluoromethyl side groups by wet spinning from a hot *m*-cresol solution. The thermooxidative stability of the polyimides synthesised from 4,4'-diamino-3,3',5,5'-tetramethylbiphenyl and 4,4'-diamino-3,3'-dimethoxybiphenyl is relatively low — thermograms indicate 5% weight losses in air at 425 and 440 °C respectively. The low thermal stability of these polymers may be associated with the lack of resistance of the methoxy and methyl groups to oxidation. The thermal stability of the same polymers under nitrogen is much higher (the thermograms indicate 5% weight losses at 475 and 520 °C respectively in this instance). The presence of trifluoromethyl side groups in polyimides increases the thermooxidative and thermal stabilities of the polymers. Thermograms indicate a 5% weight loss at 585 °C in air and under nitrogen.⁷⁹

The rigid-chain polypyromellitimide **20** was obtained from 2,6-di(*p*-aminophenyl)-1,7-diphenylbenzo[1,2,4,5']biimidazole⁸¹ by high-temperature polycondensation in phenolic solvents (Scheme 11). Despite the presence of phenyl substituents, the polyimide **20** hardly dissolves in organic solvents. A polymer with a better solubility was synthesised by the interaction of the same diamine and the dianhydride of naphthalene-1,4,5,8-tetracarboxylic acid.⁸¹ The resulting polynaphthylimide **21** dissolved not only in sulfuric but also in trifluoroacetic acid as well as the tetrachloroethane — phenol mixture. The ready solubility of the polyimide is combined with a high viscosity of the solution and a very high glass transition temperature and decomposition temperature (540 °C).

Polynaphthylimides have a series of advantages over polyphthalimides (for example, they are more stable under conditions of hydrolysis and thermolysis),⁸² so that investigators have devoted much attention to the synthesis of soluble polynaphthylimides. The most significant and to some extent unexpected result was obtained in the synthesis of the polyimide from the dianhydride of naphthalene-1,4,5,8-tetracarboxylic acid and an asymmetric diamine — 2-(*p*-aminophenyl)-5(6)-aminobenzimidazole in accordance with Scheme 12.⁸³

Scheme 11

Despite the absence of substituents of any kind in the diamine and the dianhydride, the reaction occurred homogeneously and led to the high-molecular-mass polymer **22** ($M = 120\,000$),⁸⁴ which is soluble (before isolation from the reaction solution) in phenolic solvents. The polymer **22** is moderately rigid — its Kuhn segment is 320 \AA .⁸⁴ Strong and elastic films have been cast from the reaction solutions of the polyimide **22** (Table 10). After heat treatment at 140 °C for 12 h with subsequent maintenance in vacuo at 250 °C for 3 h, the properties of the films improved and after stretching the tensile strength was $930 \pm 10\text{ MPa}$ and the modulus of elasticity was $20 \pm 1\text{ GPa}$.

IV. Conclusion

The data considered above indicate considerable advances in the chemistry and technology of the flexible- and rigid-chain polyimides achieved during recent years. Novel methods of synthesis of various bifunctional and tetrafunctional aromatic monomers have been developed and the reactions involving the formation from them of high-molecular-mass polyimides have been investigated. Certain polyimides are of practical as well as academic interest. Further development of this field of polymer chemistry makes it possible to hope that new results will be obtained in the immediate future.

Abstract. The catalytic properties and the mechanism of activation of phthalocyanines in reactions with participation of hydrogen are examined. The mechanism of the catalytic action of phthalocyanines is discussed. Two types of active centres ('metallic' and 'organic') are distinguished in the phthalocyanine molecule. Problems associated with the fixation of phthalocyanine catalysts on carriers are considered. The bibliography includes 120 references.

I. Introduction

Phthalocyanines (Pc), which are structural analogues of chlorophyll and haem, were discovered in the 1920s.¹ The complexes of phthalocyanines with alkali and alkaline earth metals contain the metal in an ionic form and may be decomposed by acids and even water, whereas transition metals in complexes with phthalocyanines, which form a covalent bond, are, on the other hand, surprisingly stable.² Phthalocyanines possess a number of unusual properties and have found various applications.^{3–5}

The first information about the catalytic activity of phthalocyanines⁶ appeared in 1938. In the course of the succeeding 55 years, metal-phthalocyanines (PcM) have been used as catalysts of the oxidation of aromatic hydrocarbons^{7–20} propene,^{21–24} aldehydes,²⁵ acids,^{25,26} alkenes^{6,27} alcohols^{8,28} ketones²⁹ sulfur-containing compounds,^{30–34} and nitrogen³⁵ and carbon³⁶ oxides, of the dehydrogenation of alcohols^{37–42} and hydrocarbons,^{43–47} of photodehydrogenation,⁴⁸ of the decarboxylation of carboxylic acids,⁴⁹ of the decomposition of peroxide compounds,^{50–62} hydrazine,^{14,63,64} and formic acid,⁶⁵ of isomerisation,⁷ of polymerisation,⁵⁰ of the ortho–para conversion of hydrogen and deuterium exchange,⁶⁶ of the reduction of nitrogen oxide with hydrogen^{67–69} and with carbon monoxide,^{67,70} of electrochemical processes,⁷¹ and of the reduction of organic compounds.^{37,72–79}

II. The structure of phthalocyanines

The structure of phthalocyanines was first considered by Dent et al.⁸⁰ It was shown by X-ray diffraction^{81,82} that metal-phthalocyanines have planar molecules.

Both crystalline α - and β -modifications of phthalocyanines exist.^{83,84} The mutual phase transitions of the α - and β -forms occur on boiling in acid and organic solvents and also as a result of mechanical and thermal influences. The hypsochromic shift of the IR absorption band of phthalocyanine molecules at 720–730 cm^{-1} is regarded as a sign of the $\alpha \rightarrow \beta$ transition.⁸⁴ In a mixture of the α - and β -forms, this band is split. The distance between the molecules in the crystals of both modifications are the same (Fig. 1), but the orientations of the molecules relative to the

Figure 1. Arrangement of the molecules in the crystals of α -PcM (a) and β -PcM (b).

crystallographic axes different.⁸⁵ In the β -form, the metal atom of the chelate unit coordinates the nitrogen atoms of the neighbouring molecules, which serve as extra-ligands relative to the complex forming metal (Fig. 1). The higher stability of the β -form is attributed to the interaction between the metal atom and the nitrogen atoms of the neighbouring PcM molecules.⁸⁶ The different crystalline modifications of PcM can therefore exhibit different catalytic activities.

III. The catalytic activity of phthalocyanines and the mechanism of their activation

By virtue of their high chemical stability,⁶⁶ phthalocyanines can be used as model substances under conditions including catalytic investigations.

The wide variety of the reactions catalysed by metal-phthalocyanines⁸⁷ apparently reflect the characteristic features of their structure. As a consequence of their planar structure and the presence of an extensive electron conjugation system, the phthalocyanine molecules are fairly mobile and are capable of being coordinated to substrate molecules.

In the phthalocyanine molecule, it is possible to distinguish two types of active centres: the 'metallic' centre incorporating the complex forming metal and the 'organic' centre.⁸⁸ The latter includes the nitrogen atoms of the azo-bridges, which have an enhanced electron density. The application of quantum-chemical calculations^{89,90} made it possible to determine the electron populations and the effective charges of the individual atoms in the phthalocyanine molecule and to discover the presence of donor and acceptor centres. The electron populations of the different atoms in the PcCo molecule are characterised by the following values:⁸⁹

N(5 α)	C(1)	C(2)	C(2')	C(2'')	N(5)
5.148	3.927	3.995	4.031	4.041	5.179

It follows from these data that the nitrogen atoms behave as electron-donating centres. The effective charge on the cobalt atom (+0.359) indicates the interaction of the orbitals of the organic ligand with the atomic orbitals of the metal and electron transfer between the metal and the π -electron system of the ligand. Either the metal or the organic ligand or both centres simultaneously exhibit a catalytic activity in various reactions.⁸ The catalysis by metal-phthalocyanines is influenced by the number of electrons in the $3d^N 4s^2$ atomic orbitals of the metal and in the molecular orbitals of the ligand.⁹¹

Gudkov⁴⁷ put forward the hypothesis that O_2 may be coordinated to PcCo via the central metal atom and the organic ligand. The shielding of the central atom by ligands, for example by pyridine,⁹²⁻⁹⁴ in the axial position hinders the binding of O_2 to the metal of the chelate unit⁹⁵ and hence alters the catalytic activity of PcM in oxidation reactions. The decisive role of the central metal atom in catalysis has been confirmed experimentally.^{6,14} The bond in the $PcM \cdots O_2$ complex is formed as a result of electron transfer both from the π orbital of oxygen to the d_{z^2} orbital of the metal and by the electron transfer in the opposite direction — from the d_{π} orbital of the metal to the antibonding π^* orbitals of oxygen; the first process predominates.³⁷

EPR and electronic spectroscopic data have led to the conclusion that O_2 is coordinated to the organic part of the metal complex of phthalocyanine.⁹⁶⁻⁹⁸ Judging from the nature of the spectrum in the visible region,⁹⁷ one may postulate the coordination of O_2 to a ring nitrogen atom. The change in the nature of the EPR spectrum of phthalocyanine in the presence of O_2 ⁹⁹ made it possible also to put forward the hypothesis that oxygen interacts with the central metal atom. However, oxidation of the organic ligand by the metal ion can yield the same results. Thus both the 'organic' and the 'metallic' active centres may be catalytically active.

The studies of the mechanisms of the PcM-catalysed reactions, for example the mechanism of the dehydrogenation of isopropyl alcohol in the presence of complexes of phthalocyanines with transition and nontransition metals, where the metal atom may be shielded, are of undoubted interest.^{40-42,100} It has been suggested that the isopropyl alcohol molecule is activated on the 'organic' active centre. The coordination centre in the organic ligand is the bridging N(5) nitrogen atom, which has a lone pair and forms a bond with the hydrogen atom of the hydroxy group:

The role of the metal of the chelate unit is to ensure electron transfers via the central atom of the PcM molecule.

The dehydration of isopropyl alcohol requires two-centre coordination, where the oxygen atom of the hydroxy group transfers its electron to the metal atom, while the hydrogen atom of the methyl group forms a bond with the nitrogen atom of the chelate unit.

Thus the metal atom may be either an electron acceptor or donor and this determines the specificity of the activity of the PcM.

In the decomposition of formic acid to H_2 and CO_2 on the β -forms of Cu-, Fe-, Co-, Ni-, and Zn-phthalocyanines at 200–300 °C, zero order with respect to the substrate was observed in all cases, while the apparent activation energy was 80–100 kJ mol⁻¹.¹⁰¹ Thus the nature of the central metal atom did not affect the process. Moser and Thomas⁷ believe that the chelate unit, the CH groups of the benzene rings, the nitrogen *meso*-atoms, and the carbon atoms of the pyrrole rings may be reactive. Depending on the type of reaction catalysed, the catalytic activity may be exhibited under certain conditions by either one or several of these centres at once.

IV. Reactions with participation of hydrogen

The available information about the reactions with participation of molecular hydrogen catalysed by metal-phthalocyanines is extremely limited.^{66,102,103} It has been suggested⁶⁶ that in the ortho-para conversion of hydrogen and in deuterium exchange on PcCu and PcH₂, the H-H bond may be dissociated both heterolytically, i.e.

or homolytically, i.e.

The second pathway appears more probable.

Reaction	$E/\text{kJ mol}^{-1}$	
	PcH ₂	PcCu
$\text{p-H}_2 \xrightarrow{150-360^\circ\text{C}} \text{o-H}_2$	24	21
$\text{H}_2 + \text{D}_2 \xrightarrow{<100^\circ\text{C}} 2\text{HD}$	—	42

The apparent activation energies for the ortho-para conversion of H₂ on monomeric and polymeric PcCu are not the same. The polymeric form is capable of desorbing hydrogen in the ratio Cu:H = 1:1, which permits ready diffusion of hydrogen through the polymer.⁶⁶ An increase in the conjugation length on passing from the monomeric to the polymeric phthalocyanine may lead to the equalisation of electron density over the entire PcM molecule, which is accompanied by a decrease in the effective charges on the central metal atom and the organic ligand.

In the related cobalt-tetraphenylporphyrin-TiO₂ (CoTPP/TiO₂) catalytic system,⁶⁷ the porphyrin ring serves as the adsorption centre for hydrogen.

The study of the adsorption of hydrogen on the pre-evacuated CoTPP/TiO₂ and H₂TPP/TiO₂ showed that H₂TPP/TiO₂ and CoTPP/TiO₂ adsorb 13.5 and 19.6 mmol of H₂ per gramme of the catalyst under comparable conditions. This led to the indisputable conclusion that hydrogen is activated by the 'organic' active centre. The study of the kinetics of the reduction of NO on CoTPP/TiO₂ confirmed the dissociative nature of the adsorption of hydrogen.⁶⁷ Fig. 2 shows that nitric oxide is activated by the central metal atom.

Figure 2. Schematic illustration of the reduction of NO on CoTPP/TiO₂.

The study of the hydrogenation of ethyne by a metal tetrahydroborate in the presence of sulfonated CoTPP led to the conclusion that ethyne is activated on the central metal atom.⁷²

The following scheme has been proposed for the hydrogenation of allyl alcohol on PcNi at 100–300 °C:¹⁰⁴

Other pathways leading to the conversion of allyl alcohol, for example directly into propene, are not taken into account in the above scheme.

In addition, the hypothesis has been put forward that hydrogen is activated on the nitrogen atoms of the PcM molecule.¹⁰⁴ It was later confirmed by other investigators with the aid of adsorption methods.⁶⁷ The independence of the activation of PcM in the isopropyl alcohol dehydrogenation reaction of the nature of the central atom¹⁰⁵ led to the conclusion that the nitrogen atoms of the azo-bridges participate in the activation of isopropyl alcohol.

Thus molecular hydrogen may be activated on both the 'metallic' and 'organic' active centres of metal-phthalocyanines and metal-porphyrins. The results of the study of the hydrogenation of acetylenic alcohols on modified palladium catalysts and carriers led to the hypothesis that the C≡C bond is activated on the 'organic' centre, while hydrogen is activated on the metal.¹⁰⁶

V. Phthalocyanines on carriers

Covalent binding, coordination in the axial position, adsorption methods, and direct synthesis on the carrier surface were used for the fixation of metal-porphyrins, including phthalocyanines, on oxide carriers.⁹⁵ The last two methods are most widely used.

In order to increase the catalytic activity of metal-phthalocyanines and to facilitate the control of the selectivity of the reactions, the fixation of PcM on various carriers is resorted to.^{95, 103, 105–108} This prevents the aggregation of the complexes and makes it possible to achieve molecular dispersion.

A fivefold increase in the catalytic activity of cobalt-phthalocyanine in the oxidation of 2-mercaptoethanol after the fixation of the catalyst on the polymeric carrier was noted.¹⁰⁹ The immobilisation of H₂TPP in a polymer matrix is used for the same purposes.

The catalytic activities of monomeric and polymeric phthalocyanines, deposited on carbon carriers, in the decomposition of H₂O₂ depend on the nature of the complex forming metal and on the characteristic features of the carrier.¹⁰³ The activity of the monomeric phthalocyanines decreases in the sequence Os >> Fe > Ru > Pt > Pd, Ir, whilst that of polymeric ones diminishes in the sequences Fe > Co >> Ni > Cu and Fe > Os, Pt, Ru > Ir, Rh, Pd.

Oxide carriers with a high chemical and thermal stability are widely used for porphyrins.^{95, 107}

The selective hydrogenation of C₅, C₁₅, and C₂₀ acetylenic alcohols in the presence of PcM (M = Pd, Ni, Cu, Co), deposited on oxides (Al₂O₃, SiO₂), has been investigated⁷⁶ varying the nature of the solvent, the PcM deposition method, and the amount of the active component in the carrier. The overall scheme for the hydrogenation process can be represented as follows:

The alcohol dehydrogenation and dehydration reactions take place together with the reactions shown above.

In order to elucidate the influence of the nature of the solvent, a study has been made of the hydrogenation of a C₁₅ acetylenic alcohol in solutions in isopropyl alcohol, methanol, and hexane (0.4 M) in the presence of PcNi/SiO₂ (5% Ni).⁷⁷ The catalyst was prepared by the preliminary impregnation of SiO₂ (specific surface 200 m² g^{−1}) with an aqueous NiCl₂ solution and subsequent treatment with phthalonitrile vapour (250–320 °C), drying, and thermoevacuation. The selectivity and activity of the

catalyst obtained in this way as regards the formation of the C₁₅ ethylenic carbinol were found to be a maximum in hexane and a minimum in methanol.

The influence of the nature of the solvent on the heterogeneous catalytic system is determined by a whole series of factors. The solvent is adsorbed on the catalyst, altering the free energy of the surface and its charge,¹¹⁰ which may affect the mode of the reaction and its selectivity. The solvation constants, the adsorption coefficients, and the rate of conversion of the intermediate surface compound into the reaction products depend on the nature of the solvent.¹¹¹ The adsorption from solutions is competitive in character and the adsorption of substrates can therefore be greatly influenced by the ability of the solvent to form coordinate bonds with the catalyst.⁷⁶

Not only the activity of the catalyst in the reactions involving the hydrogenation of the C≡C bond of acetylenic alcohols but also the mechanism of the catalytic activity depend on the method used to deposit PcM on the oxide (from concentrated H₂SO₄ or benzene). Catalysts obtained by depositing Co-, Cu-, and Ni-phthalocyanines from solutions in H₂SO₄ accelerate the reduction of acetylenic alcohols to the same extent. The catalysts prepared by fixation on a carrier of a PcM from a solution in benzene and those obtained from phthalonitrile can be arranged in the following sequence in terms of their activity in the synthesis of ethylenic alcohols: PcPd > PcNi > PcCo.⁷⁶

The rate of oxidation of propan-2-ol in the presence of PcCo is higher than in the presence of PcNi.⁶⁶ It has been suggested that the catalytically active centre in this reaction is the central metal atom, as in the hydrogenation reaction.⁷⁶

Thus, depending on the method of preparation of the catalyst, different atoms or groups of atoms of the PcM molecule enter into the reaction complex.

When the PcM/oxide heterogeneous systems are used, it is necessary, as in the case of metallic catalysts on carriers, to take into account the interaction between the active component and the carrier, which not only influences the activity of the catalytic system but is also capable of altering the mode of the process.

The higher catalytic activity of PcNi/Al₂O₃ compared with PcNi/SiO₂ can be explained by the influence of the carrier on the active component of the catalyst.⁷⁶ The Ni 2p_{3/2} binding energy (E_b) in the PcNi/Al₂O₃ system proved to be lower by 1 eV than in the initial PcNi (according to a patent,⁶⁹ E_b = 865.0 eV in this case).

The catalytic properties of PcCo deposited on silica gel by direct synthesis on the surface and of PcFe/SiO₂ obtained by the joint grinding of PcFe and SiO₂¹⁰⁵ have been investigated. When the deposited catalyst is used, the reaction of isopropyl alcohol involves predominantly dehydration and not dehydrogenation. This is evidently associated with an increase, as a result of dispersion, in the number of centres responsible for dehydration or with the influence of the carrier on the catalytic activity of PcM. The catalytic activity of PcCo on silochrome, referred to unit mass of the active phase, is higher by 1–2 orders of magnitude than the activity of crystalline PcCo in the reactions of isopropyl alcohol.¹¹²

The highest activity of CoTPP in the reduction of CO is attained when TiO₂ is used as the carrier, whereas in the decomposition of H₂O₂ the best carrier is NiO.^{59, 113} When CoTPP is attached to TiO₂, electron density is transferred from the carrier to the CoTPP molecule, which is accompanied by the formation of a radical-anion and a change in the effective charge on the atoms of the chelate unit. This has been confirmed by XPES data for the binding energies (expressed in eV) in the CoTPP and CoTPP/TiO₂ systems:

	Co 2p _{3/2}	Co 2p _{1/2}	N 1s
CoTPP	781.0	796.4	397.3
CoTPP/TiO ₂	780.2	795.6	398.6

The EPR spectra of benzene solutions of CoTPP and CoTPP/TiO₂ differ appreciably (Fig. 3).¹¹³ Comparison of the electronic absorption spectra of CoTPP in a benzene solution with the spectra of CoTPP deposited on SiO₂ and TiO₂ showed¹⁰⁹ that the use of SiO₂ as the carrier alters the intensity of the absorption bands (AB), whereas new absorption bands appear when the TiO₂ carrier is employed (Fig. 4).

Figure 3. EPR spectra of a benzene solution of CoTPP (a) and of CoTPP deposited on TiO₂ (b). The spectra were obtained at -196 °C after evacuation at 20 °C.

Figure 4. Electronic absorption spectra of CoTPP in benzene solution (a) and of CoTPP deposited on SiO₂ (b) and TiO₂ (c).

An XPES study of cobalt-phthalocyanine deposited on a zeolite led to the conclusion that the carrier influences mainly the nitrogen meso-atoms.⁶⁹ Instead of the narrow N 1s singlet, characteristic of PcCo, a poorly resolved doublet was noted. The Co 2p_{2/3} binding energy hardly changed after the fixation of PcCo on the zeolite. Hence it was concluded that the nitrogen meso-atoms are nonequivalent owing to the protonation of the

immobilised complexes.^{95,114} The acid centres of the carrier are protonated:

In the fixation on oxides chemisorbed water molecules may play the role of the proton-donating species.

Detailed study of the state of the oxygen in the molecular adduct with PcCo immobilised on aluminium oxide¹¹⁵ showed that Al_2O_3 activates specifically the PcCo molecule. The bond between the complex and the surface is then formed via electron transfer from the atomic orbital of the metal in the chelate unit to an unoccupied atomic orbital of a surface aluminium atom.

On passing from the multilayer to the monolayer coverage of the oxide carrier by the phthalocyanine, the catalytic activity of the immobilised PcM increases.⁷⁶ A further tenfold decrease in the PcM concentration on the carrier results in a low catalytic activity. It is noted that the molecules of different gases (CO , O_2 , H_2) are capable of dissolving in the PcM crystal lattice.⁶⁶

One of the authors of the present review investigated the kinetics of the hydrogenation of C_5 and C_{20} acetylenic alcohols on PcCo/SiO_2 (0.2% of PcCo deposited from solution in sulfuric acid) and $\text{PcNi/Al}_2\text{O}_3$ (0.2% of Ni deposited from solution in benzene).⁷⁵ On PcCo/SiO_2 , the dependence of the half-reaction time ($\tau_{0.5}$) for ethynylmethylmethanol (a C_5 acetylenic alcohol) on $q = C_0/C_c$, where C_0 is the initial alcohol concentration and C_c the catalyst concentration, passes through a minimum. The power exponent n is -0.7 and 0.2 respectively for the left- and right-hand branches of the $\tau_{0.5} \sim q^n$ relation. The half-reaction time is directly proportional to the initial concentration of ethynylmethylmethanol.

In order to specify more precisely the site where H_2 is located in the PcM molecule, sorption studies were performed.⁷⁶ The measurements were carried out in solution in hexane at 100°C . After the introduction of the adsorbent into the reaction volume with vigorous stirring sorption of H_2 was observed. The amount of nickel-phthalocyanine corresponding to 1 g of $\text{PcNi/Al}_2\text{O}_3$ is capable of absorbing 0.4×10^{-4} of a mole of H_2 (Table 1). On dividing this figure by the number of moles of nickel in the same gramme of $\text{PcNi/Al}_2\text{O}_3$ (this is equal to 0.35×10^{-4} of a mole), we obtain ~ 1.18 . Thus it is possible to postulate that the H_2 molecule binds preferentially to the central metal atom.

Table 1. The adsorption of hydrogen on Al_2O_3 and $\text{PcNi/Al}_2\text{O}_3$ at 100°C .

Adsorbent	P_{H_2} / MPa	Amount of absorbed hydrogen, $10^4 \text{ V/mol g}^{-1}$
Al_2O_3	0.1	1.07
$\text{PcNi/Al}_2\text{O}_3$ (0.2% Ni)	0.1	1.47
	10.1	2.09
$\text{PcNi/Al}_2\text{O}_3$ (0.2% Ni) in the presence of pyridine ^a	0.1	0.82

^a The amount of pyridine introduced was 8×10^{-5} mol.

In order to test this hypothesis, the Ni atom in PcNi was shielded with pyridine. The pyridine-treated $\text{PcNi/Al}_2\text{O}_3$ sorbed hydrogen less effectively than the carrier. It is known that the pyridine introduced into the system forms an axial coordinate bond with the metal atom in the chelate unit and behaves as an electron donor in relation to the latter.^{92,93} The latter factor suggests that, like the oxygen molecule,⁴¹ the hydrogen molecule can behave as a ligand in relation to the central metal atom.

The interaction of the components of the reaction system with the nitrogen atoms of the pyrrole rings may abolish the influence of the nature of the central metal atom. For example, as a result of the strong effect of the carrier on the metal, the latter may lose the capacity to participate in the activation of hydrogen. Since $\text{PcNi/Al}_2\text{O}_3$ sorbs more hydrogen at an elevated pressure than at

atmospheric pressure (Table 1), one may postulate the coordination of H_2 also to the organic ligand. The retardation of the hydrogenation of the C_5 and C_{20} acetylenic alcohols at $P_{\text{H}_2} > 8.1$ MPa was accounted for by this factor.

The IR spectra of the initial $\text{PcNi/Al}_2\text{O}_3$ (0.2% Ni) catalyst contain absorption bands characteristic of the surface OH groups of aluminium oxide.⁷⁶ After treatment with hexane at 100°C and $P_{\text{H}_2} = 0.1$ MPa, these bands disappeared as a result of the adsorption of hexane on the carrier.¹¹⁶ In the IR spectrum of the hydrogen-treated specimen, absorption bands appeared at 1680 cm^{-1} and those at 1090 and 1165 cm^{-1} intensified (Fig. 5). Using the principle of group frequencies as a guide, the former absorption band was assigned to the vibrations of the $\text{C}=\text{N}$ bond and the last two bands were assigned to $\text{C}-\text{N}$ vibrations, although much caution must be exercised when this is done in relation to a chelate ring. The facts presented indicate that contact between the catalyst and the solvent under hydrogen weakens the interaction of the phthalocyanine ligand with the central metal atom. This may be associated with the transfer of electron density from hydrogen to the metal atom.

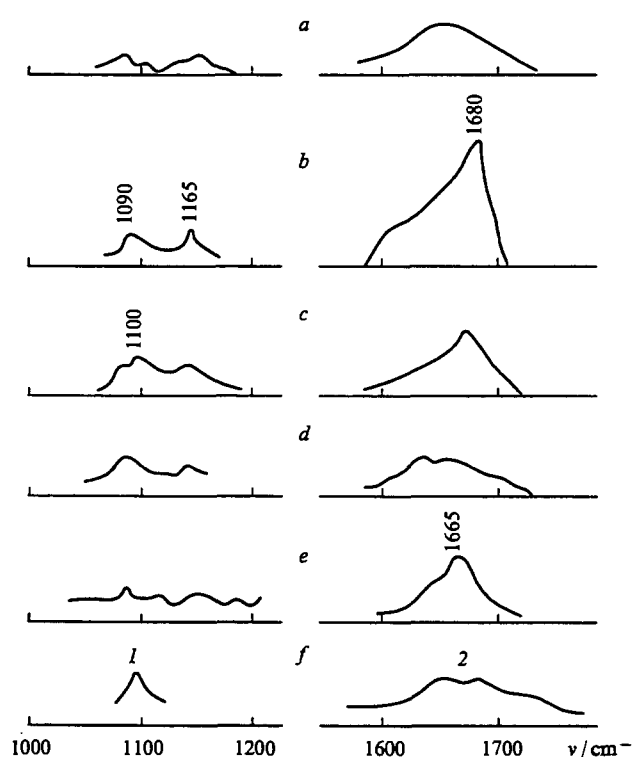

Figure 5. IR spectra of $\text{PcNi/Al}_2\text{O}_3$: (a) initial specimen; (b) specimen obtained after contact with H_2 in hexane; (c) after successive treatment with hydrogen on the C_{20} acetylenic alcohol; (d) after successive treatment with hydrogen and the C_5 acetylenic alcohol; (e) after treatment with pyridine; (f) after treatment with the C_{20} ethylenic alcohol (1) or after successive treatment with pyridine and the C_{20} acetylenic alcohol (2). Only those parts of the spectra are illustrated where a difference was observed between the specimens. The specimens for analysis were prepared as mulls in liquid paraffin.

In order to test this hypothesis, $\text{PcNi/Al}_2\text{O}_3$ was treated with pyridine which is an electron-donating extra-ligand in relation to the metal atom, after which an absorption band appears in the IR spectrum at 1665 cm^{-1} . This band was also assigned to the $\text{C}=\text{N}$ bond vibrations, the intensity of which increases as a result of the coordination. After successive treatment of $\text{PcNi/Al}_2\text{O}_3$ with hydrogen and with a C_{20} acetylenic alcohol, a decrease in the intensity of the 1680 cm^{-1} absorption band was observed, whereas the replacement of the C_{20} by the C_5 alcohol resulted in

the complete disappearance of the absorption. This suggests that acetylenic alcohols with a shorter chain are adsorbed more effectively on phthalocyanine catalysts, i.e. the series based on the adsorption capacity of alcohols, which they exhibit in relation to modified palladium catalysts, is, as it were, reversed.¹¹⁷ In addition, the acetylenic and ethylenic C₂₀ alcohols coordinated to the catalyst absorb at 1100 cm⁻¹. The 1100 cm⁻¹ absorption band is characteristic of the vibrations of the C–O bond in tertiary alcohols.¹¹⁸ Such coordination of alcohols promotes the occurrence of the dehydration reaction together with hydrogenation.

In order to elucidate the centre for the interaction of the acetylenic alcohol with PcNi, the heterogenised catalyst was treated in succession with pyridine and the C₂₀ acetylenic alcohol. This resulted in the disappearance of the absorption at 1665 cm⁻¹. The nickel in the specimen treated in this way was shielded by pyridine and the substrate could be coordinated only to the organic ligand in the PcM, namely to the nitrogen *meso*-atoms. After treatment with pyridine, the catalyst did not exhibit an activity in the hydrogenation of the C₂₀ acetylenic alcohol at 100 °C and P_{H₂} = 0.1 MPa. This can be explained by the impossibility of activating hydrogen on such a catalyst.

No changes are observed after the adsorption of substrates in the IR spectra of the PcCo/SiO₂ catalyst prepared by the adsorption on SiO₂ of cobalt-phthalocyanine from solution in concentrated sulfuric acid. This is caused mainly by the low PcCo concentration (0.2%) on the carrier surface. At this PcCo concentration on the silica gel surface (specific surface 26 m² g⁻¹), the coverage should amount to ~15% of the monolayer coverage and should consist of isolated patches. We may note that even for the 1.5-layer coverage, the molecular PcCo is deposited nonuniformly on silica gel.¹⁰⁵

The apparent activation energy for the hydrogenation of the C₂₀ acetylenic alcohol on PcCo/SiO₂ was approximately 2.3 times smaller than for the hydrogenation of the C₅ acetylenic alcohol, which has been attributed to the different adsorption capacities of these alcohols.

* * *

Thus it has been established by kinetic, adsorption, and IR spectroscopic methods that hydrogen and the acetylenic alcohol are coordinated at different active centres of the immobilised metal-phthalocyanine. The conversion of acetylenic alcohols on phthalocyanine complexes of metals, attached to oxide carriers, can be represented by the following scheme:

If it is supposed that hydrogen and the substrate are activated on different active centres (Z and Z'), then reaction (a) should include the following stages:

where A_i is the substrate and K_i, K_m, and K_n are the equilibrium constants of stages (1), (2), and (3) respectively. The surface reaction must be reversible:

where k₄ and k₋₄ are the forward and reverse rate constants for stage (4) respectively, whilst K_j is the equilibrium constant of stage (5). It is assumed that stages (1), (2), (3), and (5) are fast.

In addition account must be taken of the adsorption of the solvent (hexane) on the carrier and on the PcM.

It is postulated that the substrate and the solvent are adsorbed on the same active centres Z':

where Solv is the solvent and k₆ and k₋₆ are the forward and reverse rate constants for stage (6).

If account is taken only of the adsorption of the solvent and the occurrence of stage (5) in the reverse direction is neglected, then the rate of the reaction under static conditions can be described by the following kinetic equation:

$$W = \frac{k_4 k_{-6} K_i K_m K_n Z'_0 C_a C_H^2}{k_k C_{\text{Solv}}}$$

where C_a, C_H, and C_{Solv} are the concentrations of the acetylenic alcohol, hydrogen, and the solvent respectively and Z'₀ is the total number of active centres for the adsorption of the substrate or the solvent.

If the catalyst concentration C_c is constant and the hydrogenation takes place in concentrated solutions, account must be taken only of the adsorption of the acetylenic alcohol. The rate of reaction can then be represented in the form

$$W = k_4 K_m K_n C_k C_H^2$$

The above investigation led to the development of a procedure for the preparation of ethylenic alcohols having the general formula

by the hydrogenation of the corresponding acetylenic alcohols in the presence of PcM on Al₂O₃ or SiO₂ in an organic solvent.⁷⁶ The yield of the ethylenic alcohols reaches 99.2%–99.8%.

The following general features are characteristic of the selective hydrogenation of acetylenic alcohols on PcM immobilised on inorganic carriers: (a) the process takes place via an intermediate heteroligand complex (solvent–substrate–hydrogen–catalyst–carrier)¹¹⁹ which has a 'multistory' structure; (b) the nature and amount of the components of the complex influence the catalytic activity of the PcM and the process selectivity; (c) the reactants are activated on different active centres ('metallic' and 'organic'). The catalytic system under discussion should be regarded as homogeneous-heterogeneous, which is confirmed by the nonlinear relations between the rates of the reactions and the ratio of the concentrations of the components of these reactions.

By virtue of their unusual properties, metal-phthalocyanines are promising catalysts of many processes.¹⁰³ The immobilisation of the PcM on carriers makes it possible to achieve the maximum catalytic activity per unit mass of the active phase and to regulate the mode of reaction of the substrate. The catalytic activity exhibited by both the central metal atom and the atoms of the organic ligand in the PcM confirms the hypothesis¹²⁰ that 'organometallic' active centres are formed on deposited palladium catalysts and that the substrate and hydrogen are activated separately on centres of different nature.

Abstract. Comparative characteristics of methods for the processing and detoxification of organohalogen waste are described. It is shown that the catalytic hydrogenolysis method is the most promising. Numerous catalytic systems used for hydrogenolysis are examined, the influence of the dispersity of the catalysts on their activity is discussed, and data concerning the kinetics and mechanisms of these reactions as well as the possible elementary reactions occurring on the catalyst surface are analysed. Also discussed are the factors determining the reactivity of the C–Hal bonds in the hydrogenolytic reactions. The bibliography includes 159 references.

I. Introduction

One of the most acute problems in the creation and organisation of low-waste ecologically safe industries producing organohalogen compounds involves the processing and detoxification of the waste. An unpleasant feature of this waste is that in almost all cases they are xenobiotics, i.e. products which have no analogues in nature, and there are no natural means of combating them. On the other hand, not all the procedures for the conversion of organohalogen compounds can be used for their utilisation and detoxification. The severe ecological and economic limitations imposed on modern industries producing organohalogen substances give rise to a series of requirements as regards procedures for the treatment of waste from these industries. Such requirements include the renewability of the carbon-containing raw materials or a high commercial value of the products formed, the economic viability of the treatment, a high degree of conversion, the universality of the procedure, and the lack of toxic substances among the products. The prospects for the development of methods for the processing of organohalogen waste should be considered in the light of these requirements.

II. Comparative characteristics of the methods for the processing and detoxification of organohalogen waste

A large proportion of the existing methods for the processing and detoxification of waste from industries producing halogen-containing substances have to some extent exhausted their possibilities. In particular, the disruptive effect of tetrachloromethane on the Earth's ozone layer, discovered in recent years,^{1,2} gives rise to the problem of gradually winding-down the output of industrial chlorolysis, which is a source of this product together with tetrachloroethene. This requirement of the Montreal Protocol^{3,4} is not excessive, since the existing industrial capacity greatly exceeds the need for tetrachloroethene,^{2,5,6} while better technologies have been developed for alternative industrial processes for the production of this substance.^{5,7}

The method for the detoxification of organohalogen waste with the aid of thermal combustion is also unsuitable nowadays, since it leads to the formation of highly toxic products such as chlorine, nitrogen oxides, phosgene, and dioxins.^{1,8–11} Furthermore, thermal combustion requires a large consumption of fuel and gives rise to the irreversible loss of the hydrocarbon raw material, the evolution of carbon dioxide into the environment, and rapid wear of the equipment. The effectiveness of the method for the detoxification of toxic waste in dilute gases is low.^{1,8–12}

The catalytic combustion method is free from the majority of the above deficiencies.^{5,8,12,13} However, despite the notable progress in the development of new catalytic systems for the combustion of organohalogen waste, the range of substances susceptible to detoxification remains comparatively narrow.^{8,14} Evidently this method cannot be regarded as promising, since the irreversible loss of raw material resulting from its application does not conform to the concept of low-waste technologies.

The gas-phase thermal and catalytic dehydrochlorination processes are more attractive^{1,5,8,15–17} because they lead to the possibility of the transformation of organohalogen waste into useful products. However, the range of practical applications of these methods is significantly limited, which is associated either with the lack of demand for the dehydrochlorination products or with the impossibility of achieving the process in principle. In particular, chloromethanes, chlorobenzenes, and chlorobiphenyls cannot serve as the dehydrochlorination objects.

Hydrodehalogenation or hydrogenolysis may be regarded as the most universal and promising method for the treatment and detoxification of organohalogen waste.^{1,2,6,9–12,18–56} Together with ecological safety, it ensures in many instances the regeneration of the initial raw material, which may open a path to the

creation of low-waste technologies.[†] The regeneration of the raw material from the waste in the industrial production of vinyl chloride and chlorobenzene can serve as an example,^{55, 57, 58} chlorobenzene itself being regenerated in the latter case.^{23, 57-59} In certain cases, hydrogenolysis leads to the formation of useful products which can be used in related industries. Thus the organochlorine waste from the industrial production of *sym*-tetrachloroethane and vinyl chloride based on ethyne may be subjected to thermal hydrogenolysis with formation of gaseous ethyne, ethene, and hydrogen chloride.³⁸ After the absorption of the latter, the hydrogenolysis gases can be combined with the pyrolysis ethyne and directed to the stage in which pure ethyne is isolated. If catalytic hydrogenolysis is used in the treatment designed for the preferential formation of ethane, then the hydrogenolysis gases formed can be directed, after the absorption of hydrogen chloride from them, to the natural gas line, which proceeds to the stage in which pyrolysis ethyne is obtained. Finally, when the hydrocarbons formed as a result of hydrogenolysis cannot be returned to the technological cycle, their employment as a fuel is most rational.¹⁰ The likely usefulness of hydrogenolysis as a detoxification method is emphasised by the recently published data concerning the conversion of polychlorodibenzodioxins, polychlorodibenzofurans, and polychlorobiphenyls into ecologically safe products.⁶⁰

As regards hydrogen chloride, there are two possibilities for its utilisation. The first consists in the preparation of nongaseous hydrochloric acid. This procedure is effective in the exhaustive hydrogenolysis of C₁-C₄ organochlorine compounds, since gaseous organic products sparingly soluble in water are formed, which guarantees a high quality of the acid obtained. The second possibility presupposes the use of hydrogen chloride as the reactant in hydroxychlorination and hydrochlorination processes. This variant is more suitable for hydrogenolytic processes in which liquid organic products are formed: in this case, the hydrochloric acid formed on absorption of gases is contaminated by organic impurities and there is no commercial demand for it. An example of the use of recovered hydrogen chloride as the reactant is provided by the hydroxychlorination of benzene to chlorobenzene.¹⁶

The Exxon Company has proposed a very interesting procedure for the utilisation of the hydrogen chloride obtained in the hydrogenolysis of chlorobenzenes: the hydrogen chloride is extracted from the reaction products treating them with triethylamine⁶¹ and the resulting salt [HN(C₂H₅)₃]Cl is treated with aqueous alkali:

This regenerates triethylamine, which is returned to the technological cycle. Evidently this version of the binding of hydrogen chloride is most effective if the production of organochlorine substances is combined with the production of chlorine and sodium hydroxide in which sodium chloride serves as the raw material.

The principal advantage of the hydrogenolytic processes is the possibility of a flexible selection of the optimum type of treatment of the waste by varying the process parameters, the catalytic or initiating system, the reaction medium, and the hydrogen donors. The practical use of hydrogenolysis for the treatment of waste is not restricted to halogen-containing compounds and this method has been tested successfully on nitrogen-, sulfur-, and oxygen-containing compounds,^{15, 44, 45, 62-74} including the processes for the detoxification of sulfur and nitrogen oxides and CO.^{75, 76} The importance of the hydrogenolytic processes for the detoxification of organoelement compounds, the combustion of which leads to the formation of a series of many highly toxic products, such as

Cl₂, Br₂, sulfur and nitrogen oxides, dioxins, etc., giving rise to new acute ecological problems, must be specially emphasised.

Apart from hydrocarbons, the hydrogenolysis products include hydrogen compounds of the halogens, sulfur, and nitrogen, having distinctly acid or basic properties, which facilitates their extraction by sorption methods. The universality of hydrogenolysis as a method for the detoxification of waste has been confirmed by its effectiveness in the removal of organoelement impurities from waste water and technological gases.^{32, 40, 75, 77-80}

On the other hand, certain hydrogenolytic processes are of independent importance as a method of synthesis of valuable products on an industrial or preparative scale. This applies to the preparation of fluorohydrocarbons by the hydrogenolysis of the corresponding chlorofluorohydrocarbons^{22, 36, 48} and of nitrobenzenes from chloronitrobenzenes,⁸¹ the synthesis of substituted anilines,⁸² the conversion of aliphatic esters into higher alcohols,⁸³⁻⁸⁷ and the synthesis of sterically strained amines,⁸⁸ purine,⁴⁹ and other preparations.^{51, 52, 89, 90}

There has been an extremely interesting communication about the use of hydrogenolysis for the isolation of pure *m*-xylene from a mixture of *m*- and *p*-xylenes.²⁵ The mixture is monochlorinated, which affords a 90% yield of 2-chloro- and 4-chloro-xylenes. The latter are readily separated by distillation and are subjected to further gas-phase hydrogenolysis on a platinum catalyst deposited on activated carbon.

Finally the possibility of converting freons into ecologically safe commercial products^{4, 91-95} is of fundamental importance for the solution of the global problem of the protection of the Earth's ozone layer.

III. Hydrogenolytic methods. Prospects for their development

Hydrogenolysis may be achieved by thermal, catalytic, and reagent procedures. This classification is to some extent arbitrary because it does not reflect the entire wide variety of the reactions underlying these processes. In particular, it is to be expected that the mechanism of the catalytic action of metals differs fundamentally from the mechanism of enzymic hydrogenolysis^{97, 98} and that the metals themselves can perform various catalytic functions depending on the type of the hydrogenolytic agent. Evidently the effect of the majority of metals on gas-phase hydrogenolytic reactions involving molecular hydrogen is determined by homolytic processes on the surface,^{30, 35, 98-105} whereas the liquid-phase catalytic reactions occurring on treatment with alcohols and with formic acid and its salts¹⁰⁶⁻¹⁰⁸ involve the transfer of a hydride anion. Published data concerning the possibility of inducing catalytic reactions involving the hydrogenolysis of organohalogen compounds by microwave radiation¹⁰⁹ constitute yet another piece of evidence for the multiplicity of these processes. In this case, the catalyst (iron oxide) accumulates the radiation energy and transfers it to the chemisorbed molecule of the organohalogen compound. The latter undergoes homolytic decomposition at the C-Cl bond and initiates the radical hydrogenolytic process. The methods involving the electrochemical reduction and reductive coupling of organohalogen compounds¹¹⁰⁻¹¹⁴ may be classified as reagent methods subject only to certain stipulations.

Among the numerous hydrogenolytic methods, the catalytic and thermal methods are of practical interest. The reagent methods, involving the use of expensive hydrogen donors such as Na + ROH, LiAlH₄, Ar₃SnH,^{25, 115-117} NaBH₄,^{63, 118-121} hydrazine,⁸⁰ Zn + protic acid,¹²² and finely dispersed zinc,¹²³ are only of preparative importance.

In the present review, attention is concentrated on the catalytic hydrogenolytic reactions of organohalogen compounds, which are of greatest practical importance and have been comparatively little investigated. The data on the hydrogenolysis of organoelement compounds are used only to reveal the general characteristic features of this group of processes.

[†] In the large-scale industrial production of organochlorine substances, the creation of autonomous treatment plant is economically justified, as has been done by the Union Carbide Company, which has announced the organisation of the treatment of waste from the production of vinyl chloride with a potential output of 10 000 tonnes annually.⁴⁰

IV. Catalytic systems for hydrogenolysis. The kinetics and mechanisms of the reactions

Numerous versions of catalytic hydrogenolysis have been described in the literature. The processes are carried out in both liquid and gas phases. The choice of catalytic systems is fairly wide. The vast majority of the reactions take place on Group IB, VB, VIB, VIIB, and VIII metals, including Pt, Pd, Rh, Ru, Ir, Os, Ni, Co, Fe, Re, Mn, Mo, W, Cr, V, Cu, Ag, and Au.

The properties of metallic catalysts, namely their activity, selective action, useful lifetime, etc. can be modified by fusion with other metals, by the introduction of promoting additives, and by varying the carrier. Catalytic systems based on the Rh-Ir,¹²⁴ Cu-Rh,¹⁸ Co-Mo,⁴⁴ Ni-W,⁴⁵ Ni-Mo,^{45, 125-128} Pd-Pt, Pd-Ga, Pd-Al, Pd-Ru,¹⁰¹ Pd-Sn, Pd-Pb, Pd-Ge, Pd-K, Pd-Fe, Pd-Co, and Pd-Ag^{93, 100, 129} bimetallic alloys have been proposed. Pd, Pt, Ru, Ir, Fe, Co, Ni, Cu, Cd, Ag, Au, V, Cr, Mo, W, Bi, Al, Hg, In, Sn, Te, Si, P, As, and Sb,^{19, 24, 92, 101, 130} aluminium, boron, and titanium salts and oxides,²⁴ phosphines and phosphates,^{5, 130} alkali and alkaline earth metal hydroxides and oxides,^{24, 29, 127} and phosphonium halides³¹ are used as promoting additives to metallic catalysts. The range of carriers for metallic catalysts is fairly wide, including activated carbon,^{80, 93, 130-139} diatomites,¹⁸ aluminium oxide,^{125-129, 135, 136} chromium oxide,¹³⁵ silicon oxide,^{9, 12, 26, 39, 99, 134} iron oxide,¹³⁵ aluminosilicates,²⁴ calcium carbonate,³⁵ zeolites,^{43, 96} and barium sulfate.⁵²

Copper,^{23, 29} palladium,^{137, 138} ruthenium, platinum, and rhodium^{138, 139} salts, chromium, iron, aluminium, nickel, and molybdenum oxides,^{60, 95, 96, 140} silicon oxide,^{9, 12, 26, 39, 99} phosphine complexes of ruthenium rhodium, and iron,^{91, 106, 108} and transition metal coenzymes, namely vitamin B₁₂ (Co), the coenzyme F₄₃₀ (Ni), and hematin (Fe)⁹⁷ merit attention among other occasionally employed catalytic systems. Vitamin B₁₂ is used successfully for the treatment of organochlorine waste (C₂H₃Cl₃, C₆H₆Cl₆, C₆H₃Cl₃, C₆Cl₆, and C₂Cl₄), F₄₃₀ is employed for the hydrodehalogenation of C₆H₅CH₂Cl, *o*-ClC₆H₄CH₂Cl, C₆H₅CH₂CH₂Br, and *p*-BrC₆H₄Br to C₆H₅CH₃, *o*-ClC₆H₄CH₃, C₆H₅CH₃, C₆H₅CH₂CH₃, and C₆H₅Br respectively by formate anions, and hematin is used in the utilisation of organoelement waste such as tetrachloromethane, hexachloromethane, *cis*- and *trans*-dichloroethenes, etc.

The theoretical principles underlying the catalytic hydrogenolysis of organohalogen compounds have been investigated inadequately, while kinetic data are scattered and contradictory. The region in which the reactions occur has been reported only in rare investigations, which to a large extent vitiates the kinetic data obtained and casts doubt on the catalytic activity^{62, 99, 141} and substrate reactivity^{30, 136} series quoted in the literature. We may note that in those studies where the region in which catalytic hydrogenolysis on metals was subjected to a detailed analysis it was not possible to obtain the kinetic region. Thus the radioisotope label method showed that, in the temperature range 193-448 K, the true picture of the chemical interaction on the surface is distorted by adsorption and diffusion factors.¹⁴² Kinetic analysis of the hydrogenolysis of chlorobenzene and 1,2-dichlorobenzene on Ni-Mo/ γ -Al₂O₃ at 275-376 °C indicates that the rate of reaction is limited by adsorption and desorption processes.

Certain investigations were devoted to the solution of practical problems — the search for formal mathematical models of the processes.^{60, 143} However, such models, which are useful for the design of reaction apparatus and the optimisation of process conditions, yield little evidence for the interpretation of the mechanism of the catalytic hydrogenolysis.

Together with the temperature variations of the rates of hydrogenolysis of ethane, methylamine, and chloromethane, the structures and dispersities of the catalyst have been investigated.^{62, 98, 141} This made it possible to give the reaction rates and the pre-exponential factors for a single surface metal atom — the catalyst active centre. The variations in catalytic activity in the Re-Os-Ir-Pt-Au and Ru-Rh-Pd-Ag series are attributed

by the authors to the unequal capacities of ethane, methylamine, and chloromethane for sorption via the C-C, C-N, and C-Cl bonds on the surfaces of these metals.

However, the results obtained are to a large extent vitiated by the arbitrary assumptions adopted by the authors. In particular, one cannot neglect the relation between the activity of a single surface metal atom and the dispersity of the catalyst: it is well known that hydrogenolysis belongs to the class of structure-sensitive reactions, a characteristic feature of which is the dependence of the specific activity on the structure of the reaction centre.¹⁴⁵ The available data indicate a significant influence of the dispersity of the metallic catalysts on their activity in hydrogenolytic reactions.^{65, 102, 129, 145, 146}

It is hardly correct to determine the activity of the catalysts of the hydrogenolysis of methylamine from the rates of formation of methane and ammonia,⁶² since the authors themselves showed that at least one other side product — (CH₃)₂NH, (CH₃)₃N, (CH₃CH₂)₂NH, or CH₃CN — is formed to an appreciable extent on the majority of the catalysts which they employed (Ru, Pd, Rh, Ag, Re, Os, Pt, Ir, Au). Since the contributions of the main and side reactions depend on temperature, the attempt to determine the activation parameters does not yield reliable results and the observed isokinetic relation between the rates of these reactions cannot serve as an argument in support of a common mechanism of the hydrogenolysis of ethylamine and the side reactions complicating it on different catalytic systems.

Finally, the determination of the activities of the catalysts in the hydrogenolytic reactions of all the compounds investigated, carried out under the conditions of constant partial pressures of the substrate and hydrogen, is based on the doubtful *a priori* hypothesis that the reaction orders with respect to the reactants are equal on each catalyst. Furthermore, the presence of extrema in the catalytic activities presented above may serve as an indication that the rate-limiting stage of the process may also vary as a function of the adsorption capacity of the reactant. For a low adsorption capacity, the rate of reaction may be determined by the adsorption stage, but the greater the strength of the bonds between the chemisorbed species and the surface, the higher the rate of this stage. At the same time, the subsequent interaction of the reacting species on the surface becomes increasingly more difficult and in the limiting case it can become the stage which determines the overall rate of reaction.

The observed dependences of the reactivities of the metals on their positions in the Periodic Table can be explained also by the fact that the most favourable geometrical correspondence between the length of the chemisorption bond and the size of the unit cell of the catalyst crystal lattice is obtained in the region of the extremum.¹⁴⁷ This point of view, based on the multiplet theory of catalysis,¹⁴⁸ is confirmed by the dominant contribution of the entropy factor to the change in the specific activity of single atoms on passing from one metal to another.

The contradictory nature of the data on the kinetics of hydrogenolysis and on the catalytic activity series reflects, in our view, the complexity of the test systems due to the specificity of each catalytic system and the variations in the influence of various factors on the chemical processes occurring. The proposed reaction mechanisms are therefore valid only in specific cases and cannot be extended to other objects of hydrogenolysis. Nevertheless, from a formal point of view, the hydrogenolysis mechanisms discussed in the literature may be divided into two groups. The first group of mechanisms presupposes the adsorption of the components of the reacting systems on the catalytic surface, the interaction of the adsorbed species, and the subsequent desorption of the products from the surface (the Langmuir-Hinshelwood mechanism).^{65, 93, 126} This approach has been used to interpret data on the kinetics of the hydrogenolysis of *p*-chloronitrobenzene to *p*-chloroaniline on ruthenium and platinum catalysts.^{65, 101} A characteristic feature of the proposed mechanism is the continued adsorption of hydrogen on the catalytic surface after it has been saturated by the organic

reactant. According to the authors, the physical preconditions for this to occur are the presence of free sites on the surface owing to the strong dipole-dipole repulsion of the polar nitro-groups of the adsorbed substrate and the small size of the hydrogen molecules. A similar mechanism has been proposed for the hydrogenolysis of tetrachloromethane on the Pt/ η -Al₂O₃ catalyst.³⁵ The observed zero order of the reaction with respect to CCl₄ and the 0.5 order with respect to H₂ was justified by the authors in terms of the following scheme:

This scheme presupposes the preferential adsorption of CCl₄ on the catalyst surface:

The slight increase in the reaction orders with respect to the reactants as the temperature increases may indicate that the kinetics of the process follow the Langmuir-Hinshelwood mechanism.

Similar kinetic data have been obtained also in a study of the hydrochlorination of *cis*- and *trans*-dichloroethenes on Pt/Al₂O₃.¹³⁶ Although in view of the complexity of the systems investigated the authors themselves refrained from interpreting their data, one may suppose that the observed reaction orders with respect to the dichloroethenes indicate the adsorption saturation of the catalytic surface by the dichloroethenes and that the reaction order of 0.5 with respect to hydrogen corresponds to the dissociative nature of its adsorption.

The second group of mechanisms of catalytic hydrogenolysis is formally based on the analogy of this process with the selective oxidation reactions of hydrocarbons¹⁴⁹ and presupposes the alternate chlorination and reduction of the catalyst, which functions as a hydrogen and chlorine transferring agent between the reactants and the products.^{99, 129} This approach is based on the mechanism, proposed for the hydrogenolytic reactions of chlorobenzene on palladium-rhodium and palladium-tin alloy catalysts, which includes the following stages:

The proposed mechanism is vulnerable to criticism. Firstly, the use in it of the method of stationary concentrations leads to the kinetic equation

$$r = \frac{k_1 k_H P_{C_6H_5Cl} P_{H_2}}{k_H P_{H_2} + k_1 P_{C_6H_5Cl} + k_2 P_{HCl}}, \quad (9)$$

where $P_{C_6H_5Cl}$, P_{H_2} , and P_{HCl} are the current partial pressures of chlorobenzene, hydrogen, and hydrogen chloride respectively. The equation differs from the experimental equation

$$r = \frac{k_1 k_H P_{C_6H_5Cl} P_{H_2}^{0.5}}{k_H P_{H_2}^{0.5} + k_1 P_{C_6H_5Cl} + k_2 P_{HCl}}, \quad (10)$$

indicating a different dependence of the rate of reaction on the partial pressure of hydrogen. Secondly, the observed constants

$$k_2 > k_1 \gg k_H,$$

which follow from the mechanism proposed by the authors, are inconsistent with the available thermochemical data. Thus one should expect that the entropies of activation for reactions (6) and (7) are similar and that the difference between the constants k_1 and k_2 should be determined solely by the difference between the bond dissociation energies $D(C_6H_5-H) - D(C_6H_5-Cl) = 15.3$ kcal mol⁻¹ and $D(H-H) - D(H-Cl) = 1$ kcal mol⁻¹.¹⁵⁰ This difference between the dissociation energies should lead to the inequality $k_1 \gg k_2$, which conflicts with estimates by other workers.^{99, 129}

We believe that the kinetic data on the catalytic hydrogenolysis of chlorobenzenes presented above may be interpreted successfully within the framework of the Langmuir-Hinshelwood model. In this case, the parameters k_H , k_1 , and k_2 of Eqn (10) reflect the adsorption capacity of the components. Indeed, the high value of k_2 is inconsistent with the high polarity of hydrogen chloride and its ability to form hydrogen bonds. On the other hand, the observed dependence of the reaction rate on the partial pressure of hydrogen reflects the dissociative character of its adsorption on platinum group metals, which has been confirmed by numerous experimental data.^{144, 151}

Analysis of the kinetic data shows that they can be usually described within the framework of the Langmuir-Hinshelwood model. The conclusion concerning the dissociative character of the adsorption of hydrogen on the metal surfaces, which follows from the proportionality of the rate of the reaction (or the numerator in the kinetic equation) to $P_H^{0.5}$, is of fundamental importance. The relatively low activation energies for the overall catalytic hydrogenolytic processes (Table 1) is an additional argument in support of the dissociative adsorption of hydrogen.

Table 1. The activation energies (E /kcal mol⁻¹) for the hydrogenolytic reactions.

Reaction	Catalyst	E	Ref.
CH ₃ Cl + H ₂ → CH ₄ + HCl	Ti film	16.1	102
CH ₂ Cl ₂ + H ₂ → CH ₃ Cl + HCl	Ti film	13.4	102
CH ₂ Cl ₂ + 2H ₂ → CH ₄ + 2HCl	Ti film	13.3	102
(CH ₃) ₃ CCl + H ₂ → (CH ₃) ₃ CH + HCl	Pt film	19.0	104
(CH ₃) ₃ CCl + H ₂ → (CH ₃) ₃ CH + HCl	Pd film	18.0	104
C ₆ H ₅ Cl + H ₂ → C ₆ H ₆ + HCl	Pd/Al ₂ O ₃	25.0	129
ClHC=CHCl + H ₂ → → H ₂ C=CHCl + HCl	Pt/Al ₂ O ₃	27.5	136
CH ₃ CH ₂ F + H ₂ → C ₂ H ₆ + HF	Pd/C	12.0	30
CH ₃ CHF ₂ + 2H ₂ → C ₂ H ₆ + 2HF	Pd/C	26.0	30
CH ₃ CF ₃ + 3H ₂ → C ₂ H ₆ + 3HF	Pd/C	26.0	30

The fruitfulness of the Langmuir-Hinshelwood model is confirmed by the fact that it makes it possible to predict the inhibiting effects of the reactants and reaction products on the process and to estimate the adsorption capacities of the components. The lack of sensitivity of the hydrogenolytic reactions to the presence of acid active centres in the catalyst is apparently associated with the high adsorption capacity of hydrogen chloride: the adsorbed hydrogen chloride molecules themselves function as such centres and the contribution of the natural active centres of the catalyst to its catalytic activity becomes negligible. This may account for the failure of our attempts to modify the hydrogenolysis catalysts with alkaline reagents.

The elucidation of the nature of the elementary stages in the hydrogenolysis of haloalkanes is assisted by analysis of the composition of the products and by special studies of the mechanisms of these reactions. Evidently the substitution of the halogen by hydrogen requires the preliminary dissociation of carbon-halogen bonds. The preferential dissociation of these particular bonds is due to thermodynamic factors, which follow from the comparatively low C-Hal bond energies¹⁵⁰ and high metal-Hal bond energies. This is in fact the driving force of the chemisorption of haloalkanes. The nature of the dissocia-

tion of the C–Cl bonds on the catalytic surface has been investigated in a study¹⁰² devoted to the hydrogenolysis of chloromethane and dichloroethane on titanium, palladium, and other metallic films. The use of the ¹³C and ³⁵Cl isotopes made it possible to establish that the dissociation of the C–Cl bonds is irreversible. It was shown in the same study that the rate of deuterium exchange involving chloroalkanes is negligible compared with the rate of hydrogenolysis. A similar result had been obtained earlier in a study of the hydrogenolysis of chloroethane, bromoethane, and *tert*-butyl chloride on sputtered platinum and palladium films.^{103, 104} The composition of the products formed in the hydrogenolysis of halohydrocarbons shows that the dissociation of the C–Cl bonds is not accompanied by the synchronous attack on the latter by an adsorbed hydrogen atom or another surface intermediate and is an independent elementary stage leading to the formation of surface radicals. The latter, which are kinetically independent species, are involved in further interactions, affording various products depending on the conditions and the type of catalytic system. This is confirmed by the formation of polymerisation products together with the products of the direct substitution of the halogen by hydrogen.

The following types of interactions involving the surface radicals formed as a result of the primary dissociation of the carbon–halogen bonds are possible.

1. Radical recombination reactions. The possibility of these interactions is confirmed by the formation of hexachloroethane as one of the products of the hydrogenolysis of tetrachloromethane on nickel–zeolite catalysts and Pd–Pt, Pd–Ga, Pd–Al, and Pd–Ru metallic alloy membranes.^{43, 101} Tetrafluoroethene is also formed in the hydrogenolysis of difluoromethane on deposited Pd–Fe and Pd–Co catalysts.⁹³ We regard the appearance as a result of the hydrogenolysis of products containing twice the number of carbon atoms compared with the initial organic reactant as a result of the recombination of surface radicals. The observed discrepancy between the degrees of substitution of the carbon atoms in the primary fragments formed and in the recombination products is a consequence of the conversion of the primary fragments into new surface radicals with the same number of carbon atoms. Thus the formation of 1,1,1,2-tetrachloroethane as the product of the hydrogenolysis of tetrachloromethane on Ni–zeolite catalysts⁴³ should be regarded as the result of the recombination of the surface radicals $[\text{CCl}_3]_{\text{ads}}$ and $[\text{CH}_2\text{Cl}]_{\text{ads}}$, the latter being the product of the conversion of the $[\text{CCl}_3]_{\text{ads}}$ radical.

2. Reactions involving the elimination of chlorine radical species. One of the variants of the conversion of the surface radical $[\text{CCl}_3]_{\text{ads}}$ into the radical $[\text{CH}_2\text{Cl}]_{\text{ads}}$ may involve preliminary dechlorination with elimination of a chlorine radical species, i.e.

and the subsequent interaction of the adsorbed fragment with hydrogen. This view, put forward by Mishchenko and Senina,¹⁰⁰ makes it possible to account for the formation of appreciable amounts of methane even at low degrees of conversion under the conditions of the hydrogenolysis of tetrachloromethane. Methane is formed as the dominant substitution product also in the hydrogenolysis of difluoromethane.⁹³ Unique data have been obtained in a study⁴³ where it was shown that the hydrogenolysis of tetrachloromethane on Pt/η-Al₂O₃ leads to the exclusive formation of chloroform and methane with a constant ratio $[\text{CHCl}_3]/[\text{CH}_4]$ over the entire range of degrees of conversion. This result apparently reflects the specificity of the catalytic system employed by the authors as regards the adsorption and reactivity of the intermediate radicals responsible for the formation of CHCl_3 and CH_4 . The hydrogenolytic reactions of polyhalohydrocarbons are evidently consecutive in character.^{19, 30, 41, 136}

3. Radical hydrogenation reactions. The hydrogenation of the surface radicals leads naturally to the formation of hydrogenolysis products. This has been demonstrated kinetically in studies^{93, 102} where an increase in the proportion of the hydrogenolysis

products with increase in the hydrogen concentration was established. The participation of the surface radicals in the hydrogenolytic reaction was confirmed directly by the study of the deuteration of chloroalkanes.^{102–104} On the one hand, the isotopic composition of the alkane formed indicates the structure of the surface radical involved in the hydrogenation and, on the other, it shows that this radical is indeed hydrogenated by hydrogen (deuterium).

4. Reactions involving the elimination of hydrogen atoms. By combining reactions (1)–(3), it is possible to obtain a wide variety of products of the catalytic hydrogenolysis of halogen-containing organic compounds. The contribution of the hydrogen elimination reactions to these processes is in most cases unimportant in view of the high strength of the C–H bonds.¹⁵⁰ Nevertheless, there is direct evidence for the involvement of these reactions in certain hydrogenolytic processes. Thus, in a study of the hydrogenolysis of chloroethane,¹⁰³ the problem arose which of the two intermediates, $[\text{CH}_3\text{CH}_2]_{\text{ads}}$ or $[\text{CH}_3\text{CH}]_{\text{ads}}$, actually participates in the process. It was found that, when the hydrogenation is carried out with deuterium and not hydrogen, the compound CH_3CHD_2 is formed as the product. This made it possible to make a choice in favour of the intermediate $[\text{CH}_3\text{CH}]_{\text{ads}}$. Furthermore, this result confirms the elimination of the hydrogen atom from the intermediate adsorbed species. This possibility has been discussed in connection with a study of the hydrogenolysis of fluorohydrocarbons on a palladium catalyst deposited on activated carbon.³⁰ The probability of the dissociation of the C–H bonds in these compounds are significantly higher than in other halo-derivatives because the C–F bond is characterised by the highest energies.

5. Polymerisation reactions. The occurrence of these reactions has been confirmed by the formation of polymeric products in certain catalytic hydrogenolytic processes. Thus, the formation of a wide range of products from C₁ to C₄ has been noted in a study of the hydrogenolysis of the compounds $\text{CH}_n\text{Cl}_{4-n}$ on Ni, Co, and Fe catalysts.²¹ Polymeric products containing more than two carbon atoms are formed in the hydrogenolysis of chloromethane and dichloromethane on titanium films.¹⁰² The mechanism of the formation of low-molecular-mass polymers has been little studied. One may postulate that this reaction proceeds via the interaction of surface carbene radicals with monoradicals. The acceleration of the formation of C₁–C₄ hydrocarbons from CO and H₂ on Ni, Co, and Fe catalysts following the addition of the compounds $\text{CH}_n\text{Cl}_{4-n}$ to the reaction mixture shows that the mechanism of the formation of the low molecular-mass polymers under the conditions of catalytic hydrogenolysis is similar to the mechanism of the Fischer–Tropsch synthesis.²¹

The data on the reactivities of halohydrocarbons in catalytic hydrogenolytic reactions are fragmentary. Nevertheless, the results of quantitative investigations permit the conclusion that the reactivities of different compounds in these reactions and hence the selectivities of the latter are determined by thermodynamic, polar, steric, and adsorption factors and also by the specificity of the catalytic system.

The antiparallel changes in the rate of hydrogenolysis of different bonds and in the energies of these bonds observed in a number of instances indicate that the thermodynamic factor exerts a decisive influence on the reactivities of the compounds and the selectivities of the reactions. Thus the decrease in the reactivities of chloroalkanes on a palladium catalyst in the sequence

is accompanied by an increase in the C–Cl bond dissociation energies in the same sequence.¹⁰⁴ It has also been shown that the C–Cl bond is more reactive in hydrogenolysis on the Pd/C catalyst than the C–F bond and that at the same time $D(\text{C–Cl}) < D(\text{C–F})$.¹⁵² We may note that the examples quoted are characteristic of platinum group metals, which do not exhibit a high specificity in relation to the adsorption of compounds of different nature.

The operation of the steric factor may be due either to the shielding of the reaction centre by bulky substituents of the substrates or by the dependence of the degree of accessibility of

the catalyst active centres on the size of the species being adsorbed. Thus the inhibiting effect of *ortho*-substituents on the rate of hydrogenolysis of the C-Cl bonds of chlorobenzenes and chlorophenols is regarded as a result of the blocking effect of these substituents.^{153, 154} The dependence of the accessibility of the catalyst active centre on the size of the reactant molecules is confirmed by the fact that the adsorption saturation of the catalyst surface by the organic reactant in the hydrogenolysis of *p*-chloronitrobenzene to *p*-chloroaniline is attained sooner than saturation by hydrogen.^{65, 101}

The role of the polar factor is confirmed by the correlation between the rates of hydrogenolysis of the C-Cl bonds in *para*-substituted chlorobenzenes and polychlorobenzenes in the liquid phase on Pd/C and the electron-donating properties of the substituents in the aromatic ring.¹⁵⁵ This dependence has been attributed to the displacement of electron density towards the chlorine atom of the adsorbed substrate, which renders the attack on the latter by the electrophilic adsorbed hydrogen atom more effective. The antiparallel variation of the rate of hydrogenolysis of the C-Cl bonds and of the electron-donating capacities of the substituents in the vapour-phase process¹⁵⁶ indicates a fundamental difference between the mechanisms of the catalytic hydrogenolysis in the vapour and liquid phases. In particular, it has been suggested¹⁵⁶ that the key stage in the vapour-phase hydrogenolysis is nucleophilic attack by a surface hydride anion on the positively charged carbon atom of the C-Cl bond. In all the different mechanisms of the vapour-phase and liquid-phase processes, the polar character of the key stage is postulated in both cases and hence the dependence of the rate of hydrogenolysis on the presence or absence of polar substituents in the substrate.

If the rate of catalytic hydrogenolysis is determined by Langmuir-Hinshelwood kinetics, then the composition of the products formed may be controlled by the adsorption capacities of the reactants or their functional groups. The data quoted above, indicating that methane is formed preferentially in the hydrogenolysis of tetrachloromethane, are evidence of the decisive influence of the adsorption factor on the composition of the products.

The inhibiting effect of hydrogen chloride on the hydrogenolytic processes observed in a number of studies has been usually attributed to the adsorption of this component on the surface and the blocking of the catalyst active centres. In order to prevent the blocking of the catalyst active centres by hydrogen chloride, certain processes are carried out in the presence of added alkalis, bases, or buffer mixtures [NaOH, KOH, NH₄OH, NaOOCCH₃-N(C₂H₅)₃, CH₃COONH₄-CH₃COOH, etc.].^{41, 49, 51, 80, 155, 157} The hydrogenation of *o*-chloronitrobenzene is particularly instructive in this respect.¹⁵⁷ The hydrogenolysis of the C-Cl bond predominates in the presence of NaOH, whereas the reduction of the nitro-group predominates in its absence. These and other data suggest that there are active centres of different types on the catalytic surface, each of which is specific to a particular reaction.^{44, 45}

The specificity of the catalysts affects the relative contributions of the different reactions occurring under the conditions of the hydrogenolysis and especially the process selectivity. The role of the adsorption factor noted above is to some extent due to the specificity of the catalyst active centres in relation to the adsorption of the reactants. However, the nature of the specificity of catalytic systems is not restricted solely to adsorption interactions and in the general case one must take into account the structural characteristics of both the catalyst active centre and the reactant. This has been demonstrated in a study¹³⁶ where the hydrogenolysis of dichloroethenes on Pt/Al₂O₃ was investigated. The higher reactivity of the C-Cl bond in these reactants compared with chloroalkanes is due, according to the authors, to the stabilisation by the catalyst active centre of the quasi-tautomeric form of dichloroethene functioning as a surface intermediate in the hydrogenolytic reaction.

A similar approach has been used to account for the anomalously high reactivities of benzene derivatives.¹³⁶

The increased mobility of the fluorine atom in the hydrogenolysis of allyl, vinyl, benzyl, and aryl fluorides has been attributed to the involvement of the double bond of the adsorbed compound in the substitution of fluorine by hydrogen.¹⁵⁸

The above examples show that the specific features of the interactions on the surfaces of metallic catalysts are in many respects determined by the structural characteristics of the reactants. The soundest demonstration of this has been achieved in studies^{44, 45} where competing reactions involving the hydrogenolysis of C-X bonds and the hydrogenation of the aromatic rings of the benzene derivatives C₆H₅X (X = OH, OC₂H₅, SC₆H₅, NH₂, NHC₆H₅, F, Cl, Br) were investigated on Ni-Mo, Co-Mo, and W-Mo catalysts deposited on aluminium oxide. The correlation between the rates of ring hydrogenation and the electron-donating properties of the substituents reflects to some extent the electrophilic character of this reaction, i.e.

the successful outcome of which is determined by the stabilisation of the intermediate σ -complex. On the other hand, the high reactivity of the compounds C₆H₅X in hydrogenolysis is ensured by the presence of weak electron-donating substituents in the ring. One may postulate two possible pathways leading to hydrogenolysis on the catalytic surface:

(1) the abstraction of the substituent X by an adsorbed hydrogen atom:

(2) the substitution of the group X by a hydrogen atom via *ipso*-attack

Our attempts to observe a correlation between the rates of these reactions, on the one hand, and the heat of the hydrogenolytic reactions and the polarisability of the groups X, on the other, were unsuccessful. This confirms the need to take into

account the energetics of the interactions of the catalyst active centres with the components participating in the rate-limiting stages of the reactions.

Catalytic hydrogenolytic reactions are known to be structure-sensitive, which is manifested by the dependence of the specific activity of the catalyst on the accessibility and structures of the active centres.¹⁴⁴ The structural insensitivity of the hydrogenation reaction presupposes the independence of the activity of the catalytic centres of their structure. On the other hand, in hydrogenolysis the effective interaction between the catalyst active centre and the substrate requires the optimum combination of their structural properties and this is most clearly manifested in the presence of weak electron-donating substituents. The structural sensitivity of the hydrogenolytic reactions is confirmed by the numerous examples of the dependence of the specific activities of the catalysts on their dispersity.^{99, 101, 129, 145, 146} The important role of the modification and of the methods of preparation of the hydrogenolysis catalyst which follows from this has been confirmed by the dependence of their activities and selectivities on the temperatures of their treatment by an inert gas and reductants,^{19, 25, 39, 43, 85} the type of reductant,^{19, 25, 39, 85, 103, 132} the presence of promoting additives,^{19, 21, 24, 28, 29, 31, 132} and also on the treatment of the catalyst by gaseous reagents such HCl, Cl₂, air, H₂O, F₂, H₂S, etc.^{19, 48, 60, 103, 125, 126, 128, 159} The importance of this method of preparation of the catalyst for the specific regulation of its activity has been demonstrated by the results of a study⁴⁷ where the possibility of the 'chemical grafting' of palladium ions on the Al₂O₃ surface with variation of the ionic character of the metal was demonstrated. A vigorous correlation between the ionic character of palladium and its activity was discovered.

The data on catalytic hydrogenolysis considered above indicate the need to formulate systematic studies in which kinetic experiments would be combined with the study of the properties of the catalytic surface, the adsorption equilibria, and the influence of impurities and modification on the activities and selectivities of the catalysts. A special study of the elementary steps on the surface is also required. From the practical point of view, it is important to direct the efforts of investigators to the study of the quantitative aspects of the deactivation and regeneration of the catalysts and to the development of catalytic systems resistant to the action of contact poisons.

VI. Conclusion	638

Abstract. Studies on the direct selective oxidation of gaseous C_1 – C_4 alkanes and C_2 – C_4 alkenes to valuable oxygen-containing products (alcohols, methyl ketones, and epoxides) with the aid of the bacterial cells of gas-assimilating microorganisms are surveyed. The resting bacterial cells of the microorganisms grown on gaseous hydrocarbons possess an enzymic monooxygenase activity: they promote the insertion of an oxygen atom into the hydrocarbon molecule with formation of an oxygen-containing product. This process is effected under very mild conditions and is characterised by high selectivity and stereospecificity. It proceeds without the formation of toxic by-products. Certain problems of the practical implementation of biocatalytic oxidation processes, namely the regeneration of the monooxygenase cofactor, the reduction of the toxic effect of the oxygen-containing product formed, as well as the immobilisation of the cells on solid carriers in order to obtain an active and stable heterogeneous biocatalyst for the direct partial oxidation of hydrocarbons are considered. The bibliography includes 111 references.

I. Introduction

There has been a considerable growth of interest in recent years in the preparation of chemical compounds (the products of large scale organic synthesis) by biotechnological and biocatalytic methods. Environmentally pure processes of this kind, entailing a low energy consumption, constitute a real alternative to chemical synthesis and they are therefore being vigorously investigated and developed in all the industrially developed countries. According to certain predictions,¹ 10%–20% of chemical products will be produced by a biotechnological procedure towards the end of the 1990s. The biochemical process involving the direct selective oxidation of saturated and unsaturated hydrocarbons to valuable oxygen-containing products (chiral epoxides, alcohols, methyl ketones, and dicarboxylic acids) is particularly interesting.

The oxidative biotransformation of organic compounds, including hydrocarbon raw materials, occupies one of the leading places among industrial biocatalytic processes. Specific investigations in this field are being undertaken by large chemical companies in Japan (Nippon Mining Co., Nito Chem. Ind.), America (Exxon, Dow Chem., Monsanto, Du Pont), and Western Europe (Hoechst, Bayer, BASF), and also by Western European Universities (Wageningen Agricultural University, the Netherlands). The synthesis of the optical isomers of epoxides derived from unsaturated hydrocarbons (the properties of 31 epoxides have been described), carried out by the Japanese company Nippon Mining Co. on a semi-industrial scale using suspensions of microorganisms of the genus *Nocardia*, is of greatest interest.^{2,3} In the microbiological epoxidation of moderately long chains, the yield of the (*R*)-1,2-epoxides is 80% with an optical purity of 80%–90%.^{2,3} The optically active epoxides obtained are used in fine organic synthesis for the production of medicinal drugs, biologically active substances, and liquid crystals for electronics. Expert estimates have shown that the biotechnological methods of synthesis of the optical isomers of the epoxides may compete with the chemical methods. For example, the annual profit from the sale of the 'biotechnological' epoxypropane may reach 2–3 billion U.S. dollars.¹

The present review considers the biocatalytic approaches to the solution of the problems of the direct partial oxidation of gaseous saturated and unsaturated hydrocarbons (methane, ethane, ethene, propane, propene, butane, butene) to valuable oxygen-containing products (epoxides, alcohols, and methyl ketones). Bacterial cells possessing the required enzymic oxygenase activity are used as biocatalysts of these processes in the immobilised state and also in the form of suspensions of resting (not growing) microorganisms. The characteristic features of the microorganisms employing gaseous hydrocarbons for their growth and the intracellular enzyme systems catalysing the oxidative biotransformation reactions of gaseous hydrocarbons will be briefly described in this review. Particular attention will be devoted to heterogeneous biocatalysts based on immobilised bacterial cells for the oxidative biotransformation of propene into 1,2-epoxypropane.

II. Comparative characteristics of the direct selective oxidation reactions of gaseous hydrocarbons

The processes involving the selective oxidation of light gaseous hydrocarbons to valuable oxygen-containing products constitute the key stages in the chemical processing of gas and petroleum. Some of these processes, in particular the direct selective epoxidation of ethene, have been implemented on an industrial scale, whilst others, for example the direct partial oxidation of gaseous alkanes (methane, ethane, and propane) to valuable oxygen-containing products (alcohols and aldehydes) are at the stage of intense laboratory research. Analysis of the literature data on the selective oxidation of C₁–C₄ hydrocarbons has shown that the heterogeneous oxide catalysts widely used in these processes have fairly limited possibilities: the maximum selectivity in the formation of the target product (80%–95%) is attained only for low degrees of conversion of the initial hydrocarbon (not more than 5%).^{4–6} In order to attain a selectivity up to 70% for a conversion greater than 5%, either nitrous oxide is employed as the oxidant^{5,7} or use is made of catalysts containing precious metals (gold, palladium, and ruthenium).⁸ The literature data on the direct selective oxidation of ethane and propane to alcohols, aldehydes, or methyl ketones are very fragmentary and few in number. The main product of the oxidation of ethane is methanol mixed with ethanol,⁵ while the oxidation of propane gives rise predominantly to acrylic acid.^{9,10}

Biocatalytic processes have attracted the attention of investigators because of their unique features: low energy consumption due to the mild reaction conditions (temperature not exceeding 40 °C), a nearly 100% selectivity regardless of the degree of conversion of the initial substrate, as well as stereospecificity ensuring the formation of chiral compounds. Furthermore, owing to the absence of toxic by-products, biocatalytic processes are environmentally-friendly.

The data presented in Tables 1 and 2 demonstrate the possibilities of biocatalysis in relation to the epoxidation of propene and the hydroxylation of methane by gaseous oxygen as examples. In terms of their principal parameters (activity, yield of products), biocatalysts are at the level of the best heterogeneous chemical catalysts or are superior. The prospects for the oxidative biotransformation of hydrocarbons into valuable oxygen-containing products have been analysed in reviews^{19–21} and the possibility of the practical implementation of such a process under chemical industrial conditions has been considered. The only significant disadvantage of biotechnological processes is the low concentration of the final products in the reaction medium (as a rule an aqueous medium). It does not exceed several tens of millimoles per litre, which gives rise to problems in the isolation of the target substances. Similar problems exist also in heteroge-

Table 2. Comparative characteristics of the processes involving the direct partial oxidation of methane to methanol.

Parameter	Chemical process		Biocatalytic process ^{17,18}
	homogeneous ^a	heterogeneous ^b	
Temperatures / °C	450–550	250–350	20–40
Pressure / atm	25–65	1	1
Conversion of methane per pass (%)	9–13	4–6	27–61
Selectivity with respect to methanol (%)	38–83	83–96	~ 100
Yield with respect to methanol (%)	2–7	3–6	10–60
Productivity with respect to methanol / mmol g ⁻¹ h ⁻¹		0.001–1.7	1–7

^a According to data in Refs 5, 6, and 15. ^b According to data in Refs 5, 6, and 16.

neous catalysts for low degrees of conversion of the initial compound. They can be solved, for example, by selecting a suitable reactor design or by employing a two-phase reaction medium for the extraction and concentration of the final oxygen-containing product.

Thus biocatalytic processes exhibit a high selectivity, ensure the possibility of obtaining the stereoisomers of chemical compounds, require a small energy consumption, and are relatively environmentally clean. They are therefore competitive with the chemical processes in basic organic synthesis.

III. Microorganisms as biocatalysts of the direct partial oxidation of gaseous hydrocarbons

Evidently the first stage in the development of any biotechnological process is screening for microorganisms possessing the necessary enzymic activity. The partial oxidation of saturated and unsaturated gaseous C₁–C₄ hydrocarbons is effected predominantly by gas-assimilating microorganisms. There are only isolated examples where bacterial cells grown on liquid C₅ and higher hydrocarbons oxidise gaseous substrates. For example, suspensions of the bacterial cells of the microorganism *Nocardia*, grown on isoprene, are capable of effectively oxidising propene and butene to the corresponding epoxides.²² Other microorganisms employing C₅–C₁₈ hydrocarbons for their growth do not oxidise gaseous alkanes and alkenes.

The first gas-assimilating bacterium, using methane as the sole source of carbon for its growth, was isolated in its pure form in 1906 and up to 1954 only five species of such bacteria, called methanotrophs, had been described.^{23,24} A profound conviction that microorganisms capable of assimilating chemically inert compounds such as saturated and gaseous hydrocarbons are widely distributed in nature has arisen recently. About 200 strains of methanotrophs have been isolated from their habitats:^{25,26} fresh- and salt-water reservoirs, subterranean and waste waters, muds, soils, coal mines, and even from the rumen of ruminants.²³ Soil microorganisms of the genus *Rhodococcus* utilise propane and butane as a source of carbon.²⁷

Gas-assimilating microorganisms can be divided into the following groups:

(1) methanotrophs (the principal representatives belonging to the genera *Methylococcus*, *Methylosinus*, and *Methylomonas*) which are highly specialised microorganisms using methane as the sole source of carbon and energy; glucose and other organic compounds inhibit completely their growth;

(2) alkane-assimilating microorganisms (the principal representatives belong to the genera *Rhodococcus*, *Mycobacteria*, *Nocardia*, and *Xantobacter*), which utilise ethane, propane, and

Table 1. Comparative characteristics of the processes involving the direct partial oxidation of propene to 1,2-epoxypropane by molecular oxygen.

Characteristic	Chemical heterogeneous process ¹¹	Biocatalytic process ^{12–14}
Temperature / °C	450–550	20–40
Conversion of propene (%)	not above 15	40–80
Selectivity with respect to epoxypropane (%)	25	100
Stereospecificity	Racemic mixture	80%–90% of (<i>R</i>)-1,2-epoxypropane
Toxic side products	aldehydes, carbon monoxide, aromatic compounds	absent

butane are virtually incapable of growing on methane; glucose and certain organic acids support their growth;

(3) alkene-assimilating microorganisms (the principal representatives belong to the genera *Mycobacterium*, *Xantobacter*, and *Nocardia*), which grow on gaseous alkenes (ethene, propene, butene, and butadiene); they are also capable of utilising glucose.

The characteristic differences between the last two groups of microorganisms grown on gaseous hydrocarbons (especially on alkanes) and the same microorganisms grown on glucose or organic acids is the relatively high content of lipids in the cell and the structure of the cell wall, which is a strongly lipophilic formation.²⁸ The cells of *Mycobacterium vaccae* may serve as a typical example: such cells, grown on ethane (propane or n-butane), contain twice as much lipid as the cells grown on acetate (propionate).²⁹ These cells have another interesting feature: when acetate is replaced as the growth substrate by propane, the synthesis of lipids precedes the synthesis of nitrogen-containing compounds (proteins) and cell division, which indicates the important role of lipid materials in the assimilation by the cells of the hydrophobic hydrocarbon substrates necessary for their growth.²⁹ It has now been demonstrated that passive diffusion of the molecules towards the cell and their sorption on the cell wall take place in the initial stage of the assimilation of the hydrocarbon by the microorganisms.^{27, 30} A metabolic process involving active (with an expenditure of energy) transport of the hydrocarbon to the cell, where it is oxidised intracellularly on membrane structures (microsomes), takes place in the next stage.^{27, 28} In *Rhodococcus* sp. grown on propane, an excessive development of the outer membrane of the cell wall is observed and a well developed network of intracellular membrane structures on the periphery of the cells is clearly manifested.²⁷

All the processes involved in the oxidative microbiological transformation of hydrocarbons proceed with participation of molecular oxygen and are effected by enzymic oxygenase complexes (monooxygenases), the structure and functional role of which in the cell metabolism have been widely described in the literature.^{23, 31–33} In the present review, we shall dwell briefly on the structure of the active centre of the key enzyme effecting the primary activation of the gaseous hydrocarbon and the subsequent incorporation into the molecule of one oxygen atom with

formation of an alcohol or epoxide. Such enzyme activity of the microorganisms belonging to the second and third groups is induced by the hydrocarbon in the course of cell growth^{27, 30} (cells then grow relatively slowly and the period for the doubling of the population amounts to tens of hours). The cells grown on glucose or organic acids as a rule do not possess such activity and are incapable of transforming hydrocarbons. The Japanese strain *Nocardia corallina* B-276, the resting cells of which (grown on glucose) are capable of epoxidising alkenes, is an exception.^{34, 35} However, the yield of the epoxide is then almost twice as small as in a medium with cells grown on propene.³⁴

Depending on whether an alkane or an alkene is used as the growth substrate, enzyme complexes having different properties are induced and synthesised in the cell, namely an alkane monooxygenase or an alkene monooxygenase, which are responsible for the primary activation of the gaseous hydrocarbon.^{22, 36} The alkane monooxygenase has a broader substrate specificity than the alkene monooxygenase: it hydroxylates alkanes and epoxidises alkenes, whereas the alkene monooxygenase is only capable of epoxidising alkenes (but is incapable of hydroxylating alkanes). The microorganisms grown on alkenes are as a rule incapable of growing on alkanes. It is of interest that these two enzyme systems (or the cells of microorganisms with an induced enzyme activity) differ from one another also in their stereospecificity: the methane and alkane monooxygenases as a rule form during the epoxidation of C₃–C₄ alkenes a racemic mixture of optical isomers of the epoxides, whereas in the case where alkene monooxygenases are employed an excess (80%–90%) of the enantiomeric forms is observed. In both cases the configuration of the alkene (butene) is retained (Tables 3–7).^{22, 41} The Japanese strain *Nocardia corallina* B-276 has exceptional characteristics: regardless of the growth substrate employed (glucose, alkanes, and alkenes), one of the optical isomers of the epoxide is formed in excess within the cells of this microorganism.^{2, 3}

Two principal types of monooxygenase enzyme systems of microorganisms, capable of assimilating hydrocarbons, including gaseous ones, have now been described and characterised:

(1) monooxygenases containing an oxo- or hydroxo-bridged iron cluster in the active centre are present in the cells of methanotrophs (Fig. 1a);^{32, 33, 62}

Figure 1. The active centres for the oxidation of hydrocarbon substrates by the monooxygenase of methanotrophs³³ (a) and certain other gas-assimilating microorganisms (b).

Notation: Asp = aspartic acid residue in the protein component of the monooxygenase; Glu = glutamic acid residue; His = histidine residue; R = hydrocarbon residue in the haem molecule; ligand = low molecular-mass compounds, including substrates (hydrocarbons, oxygen, and inhibitors).

Table 3. Partial oxidation of ethene to epoxyethane by gas-assimilating microorganisms.

(2) haem-containing monooxygenases of the type of cytochrome P-450 are present in the cells of *Nocardia*,⁶³ *Rhodococcus*,⁶³ *Mycobacterium*,⁶³ *Xantobacter*,⁶⁴ and *Corynebacterium*⁶⁵ (Fig. 1b).

It is noteworthy that the term 'monooxygenase' is applied not to an individual enzyme but to the whole enzyme system, which consists of at least two to three components performing different functions (the electron transport, regulation, and oxidative functions).³² Fig. 1 illustrates the structure of the active centres of the enzyme performing the oxidative function, which consists in the incorporation of an oxygen atom into the hydrocarbon molecule with formation of an alcohol or an epoxide, while the other atom enters into a water molecule (Fig. 2).

The mechanism of the microbiological oxidation of hydrocarbons to alcohols, in particular of methane to methanol, has been thoroughly investigated. There are data showing that the rate-limiting stage of this process is the dissociation of a C-H bond.^{25,32,33} The methane monooxygenase in different strains of methanotrophs has a broad substrate specificity: it hydroxylates C_1 - C_8 alkanes with formation of primary and secondary alcohols,^{32,66} epoxidises C_2 - C_4 alkenes,^{32,54} and oxidises a series of aromatic (benzene, toluene, and styrene) and alicyclic (cyclohexane) hydrocarbons.^{32,67} The ability of methanotrophs to oxidise chloroalkenes (dichloroethene, trichloroethene, and vinyl chloride) with the aid of methane monooxygenase gives rise to prospects for their use in the purification of waste waters: in the first stage, methanotrophs oxidise the chlorinated alkene to the epoxide, which subsequently undergoes degradation with participation of the population of microorganisms, giving rise to nontoxic products — carbon dioxide and chloride ions.⁶⁸⁻⁷⁰

The so called cofactor (or coenzyme), performing the function of an electron donor, is consumed in the course of the biooxidation of hydrocarbons by a monooxygenase (Fig. 2). The natural cofactors for the monooxygenase are the reduced forms of high molecular-mass derivatives of nicotinamide [nicotinamide-adenine dinucleotides NADH or NAD(P)H].

When whole viable cells (and not cell-free enzyme extracts) are used for the oxidative biotransformations, the natural cofactors may be regenerated intracellularly as a result of the occurrence of consecutive enzyme reactions with participation of low molecular-mass substrates. For example, for the methane monooxygenase the effective electron donors are the intermediates products of methane metabolism, namely methanol,⁷¹ formaldehyde,^{41,55} and formate,^{41,55} which are oxidised by intracellular enzymes with formation of the reduced form NAD(P)H. The latter is in its turn consumed by the methane monooxygenase on the oxidation of the hydrocarbon molecule (Fig. 2).^{25,33}

It has been observed that in certain cases the addition of ethanol and ethyl acetate to the reaction medium prolongs the bioepoxidation of propene by mycobacteria. In addition, the rate of formation of epoxypropane increases in their presence.⁶⁰ Apparently these compounds participate in the regeneration of the natural cofactor of the monooxygenase in the above bacteria.

For *Rhodococcus* sp. it has not so far been possible to detect a low molecular-mass electron donor.⁵⁰ Glucose, added to a cell suspension of the Japanese strain *Nocardia corallina* B-276, promotes the regeneration of the monooxygenase cofactor.^{35,72,73} Evidently the solution of the problem of the replacement of the expensive and virtually inaccessible natural cofactors by low molecular-mass substrates may render the oxidative biocatalysis based on resting cells promising from the standpoint of its practical application.

Figure 2. The mechanism of the hydroxylation of the alkanes RH by the monooxygenase of methanotrophs³³ and a possible pathway leading to the regeneration of the coenzyme NAD(P)H as a result of the consecutive enzymic reaction.

Thus the direct selective oxidation of gaseous hydrocarbons can be achieved by biocatalytic methods involving gas-assimilating microorganisms possessing a monooxygenase activity, the process being characterised by a high selectivity and stereospecificity and occurring under mild conditions without the formation of toxic side products (the only possible product of this kind is carbon dioxide).

IV. Microbiological epoxidation of lower alkenes

The microbiological epoxidation of lower alkenes was first achieved in 1963 when it was possible to obtain 1 mg of 1,2-epoxyoctane from oct-1-ene with the aid of *Pseudomonas aeruginosa* cells grown on heptane.⁷⁴ During the last decade, the studies in this field have been carried out by scientific teams from many countries (Table 8). As already noted, certain 'biotechnological' methods of synthesis of epoxides from alkenes have been implemented on a semi-industrial scale.^{2,3} The epoxidation of gaseous alkenes is effected by microorganisms grown both on gaseous alkanes (methane, ethane, and propane) and on gaseous alkenes (ethene, propene, and butene) (Tables 3–7), the monooxygenase of the alkane-assimilating microorganisms having the ability not only to epoxidise alkenes but also to hydroxylate the terminal CH₃ group with formation of unsaturated alcohols.⁷⁸

It is of interest to note that, in the reactions involving the oxidative biotransformation of alkenes effected by *Pseudomonas oleovorans*,⁷⁸ there is no relation whatever between the chemical reactivity of the bonds being oxidised and the oxidative activity of the microorganisms. For example, oct-2-ene is not epoxidised, whereas oct-1-ene is oxidised with formation of 1,2-epoxyoctane; propene is also not epoxidised, but is transformed into allyl alcohol.

The epoxides formed during oxidative biotransformation accumulate extracellularly in the reaction medium, provided that they are not intermediates in the metabolism of the main growth substrate but are formed by virtue of the relatively broad substrate specificity of the monooxygenase. For example, ethene-assimilating mycobacteria, which effectively oxidise propene and butene, effect the extracellular accumulation of their epoxides (Tables 4–6), whereas epoxyethane undergoes further metabolic transformations, which are necessary for cell growth and biosynthesis. In order to prevent the metabolic transformations of the epoxide formed on oxidation of the growth substrate, one may add an inhibitor to the medium. For example, the inhibitor of the

further oxidation of 1,2-epoxypropane, formed by propene-assimilating cells, is the related 1,2-epoxybutane, which undergoes degradation, enabling the epoxypropane to accumulate in the medium.^{45,79}

The epoxides accumulated in the medium have a distinctive toxic activity, since they are capable of alkylating protein molecules and of decomposing membranes (this permits their use as sterilising agents in medical practice, epoxyethane being the most toxic). The inhibition by epoxides is irreversible and specific in relation to monooxygenases, while other vitally important enzymes are only slightly inactivated.⁷⁹ Various microorganisms are unequally susceptible to the action of epoxides: the most stable are the alkene-utilising microorganisms of the genus *Mycobacterium* (they withstand a concentration up to 100 mM), while the

Table 8. Microbiological epoxidation of alkenes.

most sensitive are the methanotrophs (the epoxide exerts a distinct toxic effect on the latter at a concentration less than 10 mM).⁷⁹

The following approaches have been proposed for the practical solution of the problem of reducing the toxic effect of the epoxides and of the concentration and isolation of the valuable oxygen-containing product from the reaction medium: the immobilisation of the cells on/in solid carriers, as a result of which the resistance of the microorganisms to the action of the toxic reagents

as a rule increases; the removal of the epoxide formed from the reaction zone, which is achieved either by its extraction into the solvent phase of a two-phase water-immiscible organic solvent system or by passing a gas stream with subsequent isolation of the target product by absorption in a suitable organic phase.

These approaches may be clearly illustrated in relation to the epoxidation of propene (Table 9). The gas-utilising microorganisms are immobilised mainly via their entrapment into

natural organic gels (alginate, carrageenan), in the matrix of which the cells remain virtually intact (integrity, metabolic activity) and retain a fairly high transforming activity and stability.^{12, 13, 60, 80, 83–88, 90} The principal deficiency of organic gels is their swellability, inducing a high hydrodynamic resistance to the flow, and also their decomposition during use by chemical and biological factors.

Another method for the immobilisation of bacterial cells is adsorption (adhesion) on the surfaces of inorganic carriers (silicates, oxides, and carbon materials).^{31, 50, 55, 56, 60, 71, 81, 89} Under these conditions, biofilms are formed as a rule. Covalent immobilisation is used rarely, since the cross-linking agents used for the formation of covalent bonds (dialdehydes and carbodiimides) are usually toxic to cells.

The immobilisation of microorganisms in the mesophases of nonionic surfactants (of the type of polyoxyethylene n-dodecyl ethers with different molecular masses), formed in a water–organic solvent (hexadecane) two-phase system, leads to interesting prospects.⁸² The *Mycobacterium* E3 cells immobilised in this way exhibit the maximum epoxidising activity (Table 9).⁸²

Another nontrivial approach to the immobilisation of enzymes and bacterial cells involves the sealing of the biologically active material with the aid of a gel-forming system within the pores of an inorganic carrier.⁹¹ In essence, this is a double immobilisation method, which combines the advantages of the incorporation of the cells into gels (high biocatalytic activity and stability) and of the use of inorganic carriers (high mechanical strength and resistance to degradation). The heterogeneous biocatalyst obtained in this way exhibits a relatively high enzyme activity and is stable both in storage and under operating conditions (Table 9).⁵⁰

One of the main problems in the immobilisation of enzymes and cells is that of the selection of the optimum carrier and immobilisation procedure. Nowadays the immobilisation of enzymes and cells is approached purely empirically, predominantly on the basis of the tradition which has arisen in a particular research group. However, analysis of a large volume of literature data and our own results enables us to formulate certain general

principles governing the immobilisation and stabilisation of enzymes and microbial cells on/in solid matrices.

The stabilisation of immobilised enzymes and cells is ensured by the mutual correspondence of the characteristics of the biologically active material and the carrier. In the first place, the biomolecule (cell) must correspond exactly to the size of the support pores, as a result of which a multipoint interaction is achieved. For the stabilisation of bacterial cells and the maintenance of their viability in the immobilised state, it is essential that the morphology of the porous space of the carrier should definitely correspond to the biologically active material: the ratio of the pore size to the size (length) of the microorganism should range from 1:5 and the pores of the given size should occupy ~70% of the porous space.⁹² In other words, 1–10 µm macropores should predominate in the support texture.

Another principle is the mutual chemical correspondence of the biomolecule (cell) and the carrier (gel) surface, particularly from the standpoint of their hydrophilic–hydrophobic characteristics.⁹³ For example, microorganisms with a hydrophobic cell wall are sorbed most strongly on a hydrophobic carrier surface (or in a hydrophobic mesophase) and exhibit a relatively high biocatalytic activity and stability.⁸² The practical implementation of the mutual correspondence principles, particularly in the case of the immobilisation of individual enzymes, as a rule promotes the formation of active heterogeneous biocatalysts, which are more stable by a factor of tens and thousands than their homogeneous analogues.

Unfortunately, on immobilisation of whole bacterial cells the stabilisation of the enzyme activity by virtue of the interaction of the microorganisms with the surface of optimum carriers (selected taking into account the mutual correspondence) is not quite so marked and striking as in the case of enzymes. The enzyme activity of whole bacterial cells apparently depends to a large extent on the intracellular microenvironment of the enzymes, which is determined only indirectly by the state of the immobilised bacterial cells.

The mechanisms of the initiation and stabilisation of enzyme activity in immobilised microorganisms may be different in each specific case. For example, an increase in activity may be

promoted by the improvement in gas exchange and in the distribution of nutrient substances,^{94,95} by the structural rearrangement of the membranes leading to an increase in permeability and the acceleration of transport of substrates into the cell,^{96,97} by the change in the physiology of the cells under the influence of the stress accompanying the immobilisation procedure,⁹⁸ etc. Evidently the main advantage of the immobilisation of microbial cells consists in the possibility of obtaining biocatalysts in a heterogeneous form, which makes it possible to carry out biocatalytic processes in a continuous regime in bioreactors of different design and with repeated employment of the biologically active material. The matrix stabilises fairly frequently the enzyme activity of the immobilised bacterial cells and also increases the resistance of the microorganisms immobilised on the carrier surface to the effect of toxic compounds.

Another approach to the solution of the problem of overcoming the inhibiting effect of epoxides on the cells of gas-utilising microorganisms consists in the removal of the epoxide from the reaction zone. Two-phase water-organic solvent (as a rule, n-hexadecane) systems with extraction of the epoxide into the organic phase^{61,83,84,86} and/or the removal of the epoxide, for example epoxyp propane, from the gas stream (where its fraction at 35 °C is ~ 3% of all the molecules⁸⁶) by absorption in di-n-octyl phthalate or by acid hydrolysis in sulfuric acid solution (pH 1, 30 °C) are used for this purpose.⁸⁴ The immobilisation of microorganisms promotes an increase in the resistance of bacterial cells to the action of the organic solvent apparently as a result of the presence of an aqueous microenvironment in the vicinity of the solid carrier surface.

In conclusion, it must be emphasised yet again that certain gas-assimilating microorganisms of the genera *Mycobacteria* and

Nocardia are capable of epoxidising unsaturated hydrocarbons stereospecifically, so that only one of the optical isomers is formed in excess, accumulating extracellularly in the reaction medium (Tables 4–7). Another procedure for the preparation of optical isomers of epoxides is based on the fact that certain microorganisms of the genera *Xantobacter*⁹⁹ and *Nocardia* H8¹⁰⁰ are capable of the degradation (utilisation) of only one of the stereoisomers of the racemic mixture, whereas the other isomer of the epoxide accumulates in the medium.

Thus the epoxidation of light alkenes (ethene, propene, and butene) can be achieved by means of the enzymic monooxygenase complexes of alkane- and alkene-utilising microorganisms in free or immobilised forms (Tables 4–7 and 9). One of the main ways of increasing the effectiveness of the alkene bioepoxidation processes is the reduction of the inhibiting effect of the epoxides, which accumulate in the reaction medium and exhibit a very pronounced toxicity. For this purpose, the processes are optimised by employing, for example, immobilised microorganisms in water-organic solvent two-phase systems.

V. Microbiological hydroxylation of gaseous alkanes

As already mentioned, the direct selective oxidation of saturated hydrocarbons to valuable oxygen-containing products (alcohols, aldehydes, ketones, and acids) is the main problem in the chemical processing of natural gas by homogeneous and heterogeneous catalytic methods. The partial oxidation of alkanes is traditionally carried out on oxide catalysts (for example, catalysts based on V₂O₅ or MoO₃), the key parameter of the processes being selectivity. The biotechnological approach to the direct single-

Table 10. Partial single-stage oxidation of gaseous hydrocarbons to alcohols and methyl ketones by atmospheric oxygen with participation of gas-assimilating microorganisms.

^a The activity is expressed in $\text{nmol min}^{-1} (\text{mg protein})^{-1}$ [$\text{mol min}^{-1} (\text{mg dry cells})^{-1}$] and is determined as the rate of the extracellular accumulation of the oxidation product in the reaction medium. The maximum reaction rates quoted in the literature are presented.

^b Immobilised by covalent binding to DEAE cellulose.

stage oxidation of alkanes by atmospheric oxygen to alcohols and methyl ketones with the aid of the cells of gas-assimilating microorganisms is demonstrated in Table 10.

In the microbiological hydroxylation of alkanes, certain additional problems, which do not exist in the epoxidation of alkenes, arise. One of them involves the search for an effective inhibitor of the further bioconversion of the alcohol formed in the reaction (see the Scheme in Table 10). The point is that, during the growth of microorganisms on saturated hydrocarbons, the primary activation of a C–H bond of the hydrocarbon by the bacterial monooxygenase results in the formation of molecules of a primary or secondary alcohol (Fig. 2), which are converted by alcohol dehydrogenase into an aldehyde or methyl ketone respectively.^{23, 25, 27} The aldehyde molecules then undergo further metabolic transformations, leading to the incorporation of carbon into the biomass, whereas the methyl ketones accumulate in the reaction medium. The problem of the search for an effective universal inhibitor of alcohol dehydrogenase, which would interrupt the cell metabolism at the stage involving the formation of a primary or secondary alcohol, has still not been solved and it apparently should be solved individually in each specific case. Cyclopropanol, pyrazole, and the sodium salt of ethylenediaminetetraacetic acid (EDTA) are the most effective of the inhibitors of bacterial alcohol dehydrogenases investigated (Table 10).

As in the microbiological epoxidation of alkenes, the concentration of the final oxygen-containing product (an alcohol or a methyl ketone) in the reaction mixture does not exceed several tens of millimoles per litre. The hydroxylation process is retarded as a function of time. The causes of this retardation may be as follows: an increase in the rate of bioconversion of the alcohol formed; the consumption of the cofactor (electron donor) required for the oxidative biotransformation of the hydrocarbons; the toxic effect of the alcohol or methyl ketone, accumulated in the reaction medium, on the microbial cell.

Thus the problems of reducing the toxic effect of the oxygen-containing product formed, of the regeneration of the monooxygenase cofactor with the aid of available low molecular-mass substrates of the coupled enzymic reactions, and the isolation of the final oxygen-containing product from dilute buffer solutions arise when the hydroxylation process is carried out. In addition, it is necessary to solve also the problem of inhibiting the further bioconversion of the alcohol formed. The procedures for overcoming some of these difficulties were described above.

There is so far no need for the practical implementation of the biocatalytic alkane hydroxylation processes, since in the basic industrial organic synthesis traditional chemical procedures for the synthesis of alcohols (of methanol from the synthesis gas and of ethanol by the hydration of ethene) are widely employed. In terms of their economic parameters, in particular in terms of the cost of the final oxygen-containing product, they cannot at the moment be competed with.

VI. Conclusion

The alternative biotechnological procedures for the direct selective oxidation of gaseous C_1 – C_4 alkanes and C_2 – C_4 alkenes make it possible to obtain valuable oxygen-containing products — alcohols and epoxides. The single-stage oxidative transformations of hydrocarbons can occur with participation of the bacterial cells of gas-assimilating microorganisms with the necessary monooxygenase enzyme activity. The biocatalytic processes are distinguished by a low energy consumption, because they are carried out under mild conditions and at low temperatures (below 40 °C), by a high selectivity (close to 100%) independent of the degree of conversion of the initial substrate, and, what is most important, by stereospecificity. One optically active stereoisomer may predominate in the oxygen-containing product, which is impossible when the analogous chemical processes are performed. It is at present still too early to consider the replacement of the large scale organic synthesis in industry by oxidative biocatalytic processes, but the scientific investigations performed in this field, which are at the boundary between microbiology and organic chemistry, are quite timely and promising.

The problem of the quantitative evaluation of the inductive effect: correlation analysis

A R Cherkasov, V I Galkin, R A Cherkasov

Contents

I. Introduction	641
II. Inductive effect of substituents in the chemistry of organic and organoelement compounds	642
III. The problem of a unified scale of inductive constants	646
IV. An additive model of the inductive effect	647

Abstract. Published data concerning the quantitative estimation of the inductive interaction of functional groups in organic and organoelement compounds are systematically described. Studies carried out by the authors and devoted to the elaboration of a new model of the inductive effect, permitting theoretical calculation of inductive constants of various substituents at any reactive centre, are surveyed. The possibility of using this approach to solve some important theoretical problems associated with the inductive effect such as the inductive influence in organoelement compounds and the inductive effects of alkyl groups is discussed. The bibliography includes 132 references.

I. Introduction

The relationship between the structure and reactivity of organic and organoelement compounds is a fundamental problem in modern chemistry. The overall interaction of a substituent with a reaction centre is usually considered to consist of inductive, resonance, and steric components. The correct separation of these components is one of the main problems hampering further development of quantitative organic chemistry and correlation analysis. The difficulties in solving this problem are associated with the fact that, within the framework of widely used empirical methods in which the influence of substituents is quantitatively evaluated based on standard reaction series, it is extremely difficult (if possible at all) to elaborate any reliable criteria for dividing the overall effect into its elementary constituents. Numerous attempts undertaken along these lines have always been based on certain postulates and assumptions that initially looked quite justified, but sooner or later, following subsequent development of theory and experimental methods, these came into question and were criticised or, in some cases, even totally rejected. A great number of various experimental scales of inductive constants have been developed, the physical meaning of which are quite obscure and the limits of applicability difficult to predict.

This accounts for the interest aroused in recent years in the quantitative evaluation of various effects of substituents by nonempirical methods. Among the latter, nonempirical procedures for the calculation of the total energy of a system and of its constituents, i.e. *ab initio* quantum-chemical calculations, are undoubtedly the most strict. However, the use of these calculations for real reaction series, which are of interest for researchers, is held up for a number of objective reasons. The main reasons are the capacity of computers and of software and the fact that these calculations are very time-consuming and expensive. Therefore, *ab initio* calculations are in fact inexpedient for the vast majority of known reaction series, especially for those involving complex organic and organoelement compounds.

This fact, in its turn, stimulated the development of various non-quantum-chemical calculation methods, the low accuracy of which is largely counter-balanced by their simplicity and intelligible mathematics. Besides, their accuracy is often quite sufficient for the solution of particular problems arising in the studies of reactivities and reaction mechanisms. In our opinion, the most promising approach is the construction of certain models for the manifestation of an effect, these models being usually based on fairly simple physical laws and thus having quite obvious physical meaning. Our experience in the field of the steric effect^{1–3} has demonstrated that modelling is an extremely effective method for the quantitative evaluation of the influence of substituents. For example, the model of the frontal steric effect developed by us makes it possible not only to calculate adequately the steric effect of any substituent at any reaction centre with high accuracy but also to solve many other problems that are difficult to solve or cannot be solved in terms of existing empirical scales.

Thus, it can be said with confidence that modelling is the most promising method for the quantitative analysis of reactivity in physical organic chemistry and in correlation analysis.

In this review we consider the main approaches to the quantitative evaluation of the inductive influence of substituents only within the limits needed to understand the essence of this problem, so as not to duplicate the data covered by reviews and monographs published previously.^{4–11} Attention is focused on the possibility of modelling the inductive effect in order to develop a unified versatile approach to the quantitative theoretical evaluation of the inductive constants of any substituent at any reaction centre. We believe that our model of the inductive effect gives a reliable tool to researchers for the evaluation of the relationship between the structure and the reactivity of organic and organoelement molecules.

II. Inductive effect of substituents in the chemistry of organic and organoelement compounds

The idea of the mutual influence of atoms and groups appeared long ago during the development of the theory of chemical structure. Later, investigations of the characteristic features of intramolecular interactions have occupied a prominent place in chemical research. Numerous approaches to the evaluation of the electronic interactions between functional groups in a molecule have been elaborated. Among them, the theory of electron displacements, within the framework of which views on the inductive effect have been developed, is considered the most adequate.⁴

The term 'induction' derives from the Latin word *inductio*. By analogy with the inductive effect in electrostatics, the inductive effect in the theory of reactivity has been historically interpreted as the variation of the electron density on an atom or functional group under the action of certain factors.

The history of the development of opinions on the inductive effect as well as their current application to the theory of reactivity have been surveyed in the monograph by Vereshchagin,⁴ which we repeatedly cite.

In our review, we briefly outline the most significant aspects of the problem in question that relate directly to the quantitative description of the inductive influence of substituents.

1. The nature of inductive effect and the mechanism of its transfer

Although there is no strict mathematical description of the nature of the inductive effect, this is generally clear and reduces to the classical view that electron density flows from the atom with a lower electronegativity to the atom with a higher electronegativity. As early as 1916, Lewis described for the first time the consecutive displacement of the electron pairs forming the bonds along a chain of atoms in relation to chloroacetic acid. Later, this served as the basis for the development of the theory of electron displacements.¹²⁻¹⁴ However, there is still no clear knowledge concerning the mechanism by which the inductive influence is transmitted. Two possible mechanisms for the propagation of this effect are discussed in the literature, both having their pros and cons and their adherents and opponents.

The first mechanism described long ago by Lewis suggests that the influence is transmitted along the bonds by their consecutive polarisation. The electronic asymmetry arising due to the difference between the electron-withdrawing properties of two atoms linked together can propagate along the molecule by a mechanism similar to the electrostatic induction.^{4, 13}

According to this mechanism, each atom or a group of atoms is characterised by the coefficient of conduction of the inductive influence. The conduction coefficient Z does not depend on the position of the unit (atom) between a substituent and a reaction centre. The overall attenuation of the effect in a chain consisting of bridging units $X-A-B-C-Y$ is proportional to the product of the coefficients of attenuation of the inductive influence on each of the intermediate atoms, so

$$\sigma(XABC) = \sigma(X)Z(A)Z(B)Z(C),$$

and for a chain consisting of identical atoms it is written as

$$\sigma(XA_n) = \sigma(X)Z^n(A).$$

The parameters Z are calculated from empirical relations connecting either the σ -constants of the substituents containing and not containing the conducting group (σ - σ method)

$$Z(B) = \frac{\sigma(BX)}{\sigma(X)},$$

or the corresponding reaction parameters ρ (the ρ - ρ method)

$$Z(CH_2) = \frac{\rho(CH_2Y)}{\rho(Y)}.$$

If there exist several paths for the transmission of the inductive influence of a substituent, i.e. the substituent and the reaction centre are separated by several conducting systems, the inductive effect is assumed to propagate along these systems independently and in an additive manner. In the general case, in terms of the 'bond' mechanism, the intensity of an inductive effect should depend on the number of bonds separating the substituent and the reaction centre.

An alternative mechanism of the transfer of inductive effect involves interaction of functional groups through space. This induction mechanism is purely electrostatic in its nature and, like the concept of electron density displacement along bonds, it has been known for a long time. This approach was proposed for the first time by Ingold, who postulated that the intensity of an inductive influence should depend on the presence of an electric field in the space directly adjacent to the molecule.¹⁴ Later, the electrostatic mechanism of the influence of substituents was called the 'field effect'. It has been assumed to occur via electrostatic ion-ion, ion-dipole, and dipole-dipole interactions, the intensity of which is described by various functions of the distance r^{-n} ($n = 2-4$).⁵ In this case, the intensity of the inductive interaction of a substituent with a reaction centre depends directly on intramolecular distances.

In recent years, preference has been given to the field mechanism of the inductive effect; an increasing number of scientists are apt to consider the inductive interaction in terms of the electrostatic concept.^{4, 15} Strictly speaking, the transmission of the influence 'along bonds' and 'through space' should not be regarded as alternative mechanisms. Whereas the field theory accounts well for the very fact of the Coulomb stabilisation of charges arising in a molecule, the nature of their appearance, i.e. the mechanism of the intramolecular redistribution of the electron density, still remains obscure. In any case, electron density redistribution can hardly be conceived without participation of molecular orbitals.

2. Quantitative methods for the evaluation of the inductive effect

The methods that permit the quantitative description of each of the constituents of the overall influence of substituents on the reaction centre (inductive, resonance, and steric) can be divided conventionally into three main groups. Empirical approaches according to which the influence of a substituent is inferred from data on the reactivity or the physical properties of molecules have found the widest application. As a rule, standard procedures of regression analysis are used. The second group of methods is based on quantum-chemical calculations (*ab initio* and semiempirical methods) or on the use of fundamental characteristics of atoms, groups, or molecules that obey particular empirical relations. Methods that involve the construction of formal models of the corresponding interactions based, as a rule, on fairly simple physical laws should also be assigned to this group. Finally, a separate group includes topological approaches, which occupy a certain intermediate position between the methods belonging to the first and second groups.

a. Empirical methods. Inductive interaction constants

Experimental methods for the evaluation of the influence of substituents are based on the possibility of representing the variation of Gibbs free energy in a reaction (ΔG) or the Gibbs energy of activation as a sum of independent constituents^{5, 7, 16}

$$\Delta G = \Delta G_I + \Delta G_R + \Delta G_S.$$

Each term reflects the contribution of a particular substituent effect — inductive (I), resonance (R), or steric (S). The principles of linearity of free energy (LFE) and polylinearity (PL) make it

possible to perform mathematical formalisation of the problem of the relationship between structure and reactivity.

Quantitative evaluation of the inductive influence of substituents became possible for the first time within the framework of the approach developed by Hammett. Based on the LFE principle, he proposed an empirical equation (which has gained wide acceptance) to describe the ionisation of substituted benzoic acids¹⁷

$$\lg(K/K_0) = \rho\sigma,$$

where K and K_0 are the ionisation constants of the corresponding substituted and unsubstituted acids, σ is a universal constant specific for a substituent in the benzene ring, which remains invariable over a reaction series, and ρ is a constant reflecting the sensitivity of the reaction centre to the variation of the influence of a substituent. Since substituents in the benzene ring (especially those occupying the *para*-position) can exert influence by both inductive and resonance mechanisms, the Hammett constants σ are considered to reflect the overall effect, i.e. they incorporate the inductive and resonance constituents.

Later, the Hammett method was modified many times, but the vast majority of these modifications referred to the chemistry of aromatic compounds.⁶ For the series of aliphatic compounds, the Hammett relation, as a rule, did not hold. Taft suggested that in the case of aliphatic compounds, steric substituent effects are significant. Hence, for the Hammett relation to be obeyed, steric effects should be separated from electronic effects. Taft accomplished this task based on standard reaction series of the alkaline and acid hydrolysis of alkyl carboxylates.¹⁸

$$\sigma^* = \frac{1}{2.48} \left[\lg \left(\frac{k}{k_0} \right)_B - \lg \left(\frac{k}{k_0} \right)_A \right],$$

$$\lg \left(\frac{k}{k_0} \right)_A = E_s,$$

where σ^* is a substituent constant depending only on its inductive influence, k and k_0 are rate constants for the reactions involving the given compound and the standard compound with the CH_3 substituent, respectively, and E_s is the substituent constant reflecting its steric influence; the indices A and B refer to the otherwise identical reactions of alkaline and acid hydrolysis of fully substituted esters of carboxylic acids. The factor 2.48 was introduced in order to reduce the σ^* scale to the scale of Hammett σ -constants. This procedure was used to determine the purely inductive constants for aliphatic groups.

Another model, which permits direct determination of the inductive influence of substituents, was proposed by Roberts and Moreland in 1953.¹⁹ In this model, dissociation constants for a series of 4-substituted bicyclo[2.2.2]octanecarboxylic acids are used.

In these systems, the resonance mechanism for the transfer of substituent influence to the reaction centre is impossible, and the substituents are reliably removed from the reaction centre owing to the rigid cyclic structure, as in the case of the benzene ring. Thus the steric effect of the substituents is reduced virtually to zero, and the influence of substituents on the reaction centre in the molecules of bicyclooctanecarboxylic acids occurs exclusively by the inductive mechanism. The σ^1 -constants (sometimes, designations σ_1 and σ' are used), which are based on the dissociation of a series of bicyclooctanecarboxylic acids, reflect only the inductive influence of the corresponding substituents.

In place of the bicyclooctanecarboxylic acids, other rigid polycyclic systems can also be used, for example, 3-substituted adamantane-1-carboxylic acids, 3-substituted bicyclo[1.1.1]pen-

tane-1-carboxylic acids, *trans*-4-substituted cyclohexanecarboxylic acids, and quinuclidinium ions.⁴ The inductive constants of substituents determined for these reaction series correlate fairly closely with one another; this confirms the legitimacy of the neglect of all effects except for the inductive effect in this case. However, the specific structure of these model systems does not make it possible to cover the whole set of substituents.

σ -Constants, free from a contribution due to direct polar conjugation, are also used as a measure of the inductive influence of substituents. Substituted benzoic acids are used as the standard reaction series for the determination of these constants. As a rule, only compounds with *meta*-substituents are included in the basic sets; insulation series of compounds, i.e. those in which the reaction centre is separated from the aromatic ring by a saturated group, are used as secondary reaction series. The idea of using insulation reaction series was proposed for the first time by Jaffé,²⁰ who suggested that substituted benzoic acids should be used as a standard reaction series and arylacetic and arylcarboxylic acids should be used as insulation series.

Later this method was widely developed.²¹ A large number of qualitatively similar scales of inductive constants, which have been obtained by the separation of the inductive influence from the conjugation effect in aromatic systems, have been proposed. However, it should be noted that constants 'free from direct polar conjugation' can be regarded as inductive constants only conventionally, because in the standard series of substituted benzoic acids (used in all these approaches), the possibility of conjugation of the aryl and carboxyl groups cannot be ruled out.⁴

At present, a large number of inductive constants for hundreds of diverse substituents have been determined; these constants form more than a dozen of the most extensively used scales. As a rule, they correlate well with one another. Thus, we can say with confidence that the empirical inductive constants, based on standard reaction series, properly reflect the donor-acceptor properties of substituents and can be adequately used in quantitative organic chemistry.

It is also noteworthy that the approach developed by Hammett and Taft for the analysis of organic compounds proved applicable to the reactivity of organoelement compounds.

For example, Jaffé et al.²² noted that the ionisation constants of arylboric 1 and arylarsenous 2 acids obey the Hammett equation, which is also applicable to some other reactions of these compounds.^{20, 23}

Numerous attempts have been undertaken to use the Hammett-Taft equation for a description of the reactivity of organosilicon compounds. In particular, it was found that the rates of reactions of organosilanes ($\text{R}_n\text{SiH}_{4-n}$) with alcohols, amines, and phenols correlate with the σ - and σ^* -constants of substituents.⁶ However, these attempts can hardly be considered successful, due to the known specific character of organosilicon compounds. For example, it has been proposed²⁴ to introduce new σ_{Si} -constants for organosilicon compounds which reflect, like the Hammett constants, the overall effect of a substituent on a reaction centre.

Relations, similar to the Hammett equation, can also be used to describe the reactivity of organomagnesium and organomercury compounds.⁶ Jaffé^{20, 23} has noted a good correlation of the σ -constants for some organoantimony compounds. In addition, the existence of a correlation between the dissociation constants of various metal complexes and the σ -constants of the substituents in the ligand molecules has been noted in a number of papers. In particular, the Hammett equation appropriately describes the instability constants for Ni- and Ag-pyridinates, Ni- and Fe-1,10-phenanthroline complexes, copper complexes of aromatic carboxylic acids, etc.⁶ In recent years, an ever increasing number

of papers have been published in which correlation equations have been used to describe the reactivity of organometallic compounds, for example, derivatives of zirconium,²⁵ vanadium,²⁶ nickel,²⁷ ruthenium,^{28,29} cobalt,³⁰⁻³² etc.

However, the correlation analysis equations have found the most extensive application in the evaluation of the reactivity of phosphorus compounds. Jaffé²² has shown that the ionisation constants for arylphosphonic acids **3** obey the Hammett equation.

Later, other examples of using correlation equations in the chemistry of trivalent and pentavalent phosphorus derivatives were found. The most general approach to the problem of correlation analysis of the reactivities of organophosphorus compounds (OPC) has been developed by Kabachnik and Mastryukova.^{8,9} They suggested that the dissociation of oxygen-containing acids of tetracoordinated phosphorus should be used as the basic reaction series for OPC and introduced special phosphorus σ^P -constants as a measure of the influence of substituents on the dissociation constant of P(IV) acids in water at 25°C:

$$\lg K = \lg K_0 + \rho \Sigma \sigma^P,$$

where K_0 is the dissociation constant for phosphinic acid $\text{H}_2\text{P}(\text{O})\text{OH}$ [in this case, $\sigma^P(\text{H}) = 0$].

The σ^P -constants have been actively used for many years and are still used to analyse the reactivities of diverse classes of organophosphorus compounds. For example, it has been shown that the $\Sigma \sigma^P$ values correlate linearly with the dissociation constants of various phosphorus-based oxygen- and dithio-acids in aqueous alcohol,³³ with the basicity constants of phosphines,³⁴ with the rate constants for the addition of bromine to esters of vinylphosphonic and phosphonic acids,³⁵ and with benzylolation constants of sodium phosphorus dithioates,³⁶ etc.

These constants have been widely used in our laboratory for the interpretation of the reaction mechanisms and reactivities of thio-derivatives of phosphorus acids; their complex-formation properties,³⁷⁻⁴¹ dissociation constants,⁴²⁻⁴⁴ oxidation potentials,⁴⁵ rate constants for addition reactions,⁴⁶⁻⁵¹ specific solvation energies,^{52,53} and some other properties⁵⁴⁻⁵⁶ have been described in this way. The reactivities of OPC toward reactions involving functional groups attached to the phosphorus atom were described by the σ^P -constants most adequately. However, the use of σ^P for reactions in which the tricoordinated and, especially, tetracoordinated phosphorus atoms themselves act as the reaction centres was not always successful.

Kabachnik and Mastryukova⁹ suggested that the relative contributions of the inductive (σ_I^P) and resonance (σ_R^P) constituents to the σ^P -constants vary on passing from one reaction to another.

$$\lg \frac{k_1}{k_2} = \rho(\sigma_I^P + \alpha \sigma_R^P).$$

It is notable that this equation has been used successfully in a study of the kinetics and mechanism of cyanoethylation of phosphorus dithio-acids.^{49,50}

With the progress of $\sigma\rho$ analysis in organophosphorus chemistry, the opinion has emerged that the σ^P -constants are compound parameters, since they include inductive, resonance, and steric constituents, which can be adequately described by virtue of the classical 'carbon' constants.^{57,58} This is confirmed, for example, by the strictly linear relationship between the steric effects of substituents at phosphorus and carbon atoms.^{59,60}

Consequently, it became widely believed that the nature of substituent effects in the chemistry of organic and organoelement compounds was the same,⁴ and that it was therefore reasonable to use the classical 'carbon' constants in the analysis of reactivities of organoelement compounds.

However, this approach does not necessarily work, and the reactivity of the corresponding classes of compounds is often described much more adequately by the 'special' organoelement constants than by the classical 'carbon' ones.

It should be noted that at present, the question of linearity of the inductive influences of substituents on carbon and heteroatomic (organoelement) reaction centres is not completely clear. This problem is still a sore spot in the quantitative theory of reactivity of organoelement compounds.

At the same time, the data accumulated to date make it possible to conclude that empirical inductive constants are fairly versatile, at least in classical organic chemistry, and that they apparently reflect adequately the inductive influence of substituents.

It should be noted that the methods for the determination of the empirical inductive constants are not at all restricted to the approaches based on consideration of quantitative data on reactivities. It is well known that substituents influence the physical properties of molecules in the ground state. Innumerable examples of correlations of σ constants with diverse physical properties, which are associated in one way or another with the electron density distribution, have been found.^{4,61} Based on these correlations, a large number of extensively used empirical scales of substituent constants have been developed.⁶² Characteristics obtained by NMR,^{4,6,55,63} NQR,^{4,14,64} IR,^{4,6,14,65,66} and photoelectron spectroscopy,⁴ as well as data on dipole moments and polarisability of molecules^{4,6,14,67} are used most frequently for this purpose.

It has been reported that the Hammett equation can be applied to the solution of some mass-spectrometric problems⁶ and to the description of the solvatochromic effect.⁶ Correlation equations have found application in polarography,^{18,25,26,41,68} in the interpretation of fluorescence spectra,⁶⁹ in studies of some gas-phase processes,⁷⁰⁻⁷³ and in the rationalisation of scintillation activity data.⁶ The optical rotation of β -D-galactosides⁶ as well as parameters describing the activity of enzymes,⁷⁴ the electrical conductivity of some crystalline compounds, etc. are correlated with the σ -constants of substituents. The number of known correlations is constantly increasing, since more and more experimental data are quantitatively interpreted in terms of the correlation equations.

Thus, the inductive and other substituent constants can adequately describe both the reactivities and the physical properties of diverse organic and organoelement compounds.

However, the dependences obtained are not necessarily suitable for the determination of new substituent parameters, although they often provide information on the spatial structures of molecules and on the nature and mechanisms of various intramolecular interactions.

In recent years, an increasing number of new complex substituents have appeared in organic and, especially, in organoelement chemistry. These substituents have not been described and some of them cannot in principle be described quantitatively within the framework of empirical methods. Moreover, as noted above, none of the empirical approaches claims or can claim to be a physical model, capable of disclosing the nature and mechanism of the transmission of the inductive influence. In addition, none of the approaches described above possesses a versatile mathematical technique establishing the quantitative relationship between the structure and reactivity of organic and organoelement compounds. Therefore, it is no wonder that interest in the quantitative evaluation of substituent effects based on nonempirical and semiempirical methods has grown so sharply in recent years.

b. Semiempirical methods for the evaluation of inductive effects

Methods based on the formal analysis of a structure with the aim of identifying the correlation between the structure and a property (topological methods) have been used in theoretical organic chemistry for a long time.

The development of the topological approach is largely associated with the application of the methods of graph theory.⁷⁵ An abstract model of the structure, the so-called 'molecular graph', is normally characterised by two matrices, namely, by the adjacency matrix A , in which A_{ij} elements are equivalent to elements A_{ji} and are equal to 1 if the nodes i and j are linked by an edge and to 0 if they are not linked, as well as by the distance matrix D , in which D_{ij} elements are equivalent to D_{ji} and correspond to the number of edges situated on the way from the node i to j . The topological indices are quantitative characteristics of these graphs and are various combinations of elements of both matrices reflecting particular aspects of the molecular structure.

The topological index was used for the first time by Wiener,⁷⁶ who introduced the index W , which denoted the number of edges needed to connect all the pairs of nodes to one another and indicated the degree of branching in the molecule. Later, other indices similar to W were introduced, for example, the index I ,⁷⁷ the Altenburg index,⁷⁸ the Platt index f ,⁷⁹ and the index N_2 derived from it.⁸⁰ The Hosoya index Z ⁸¹ reflects the distance between all the disconnected nodes. The Gutman (M),⁸² Randić (χ),⁸³ and Kier (h_x)⁸⁴ indices show the degree of substitution at each node of the graph.

A new group of information indices I_{pc} and I'_{pc} has been introduced by Bonchev.⁸⁵ These are combinations of W , Z , and χ indices. The group of centric Balaban indices⁸⁶ — the centric index α , the binormal quadratic index α' , and the binormal centric index α'' — reflect the structure of a tree-like graph. These indices are also related to the geometrical structure of the molecule.

All the indices listed above are used in chemistry. Correlations of the topological indices with various parameters have been found, for example, with solubility, boiling point, density, diamagnetic susceptibility, heat of atomisation, formation, and vaporisation, and molar volume. High-quality relationships between the topological indices and steric parameters (molecular volume, molecular refraction, and surface area of the molecules) have been obtained.^{1,57} The correlations of the topological indices with the steric constants from the E_s and V_x empirical scales have been established successfully.

The use of graph theory within the framework of the global 'structure-property' problem frequently leads to adequate results. However, the use of topological indices suffers from obvious drawbacks. Not all the characteristic features of molecular structure are taken into account (for example, the conformation is ignored) and, what is more important, the physical meaning of these indices is obscure. Despite the fact that in some cases the topological indices correlate with electronic parameters (ionisation potential, electron affinity, polarisability, chemical shifts in NMR spectra, optical density, etc.),^{1,57} one cannot speak of serious application of the graph theory to the evaluation of electronic effects of substituents.

Together with the purely topological method for the evaluation of the influence of the structure of molecules on their properties, which does not reflect the distribution and redistribution of the electron density, there exist a number of approaches which take into account to a certain extent the mutual arrangement of atoms and groups.

The modelling of interactions based on the structural characteristics and geometrical parameters in relation to the inductive effect has been accomplished by various procedures. The best known is the Dewar method developed for naphthalene derivatives. Several modifications of this method exist. In terms of one of them, the Hammett constant is described by a two-parameter equation:^{4,74}

$$\sigma = \frac{F_D}{r} + Mq,$$

where F_D is the substituent field (inductive) constant, r is the distance from this substituent to the reaction centre expressed in terms of the aromatic carbon-carbon bond lengths, M is the mesomeric constant, and q is excess charge. The first term describes the field effect and the second term corresponds to conjugation. The F_D and F'_D constants obtained in various modifications of the Dewar method are somewhat different.

Further development of the Dewar approach has been associated with the introduction of other initial scales of substituent constants. For example, the $F_D(S)$ scale, which has been elaborated for the analysis of ^{19}F NMR spectra and which takes into account not only the distance from the substituent to the reaction centre but also the orientation of substituents with respect to the C—F bond,⁴ differs substantially from other scales.

The method of additive determination of inductive constants suggested by Taft,^{4,5} who was the first to introduce the additivity principle for the inductive influence, can be regarded as being 'conventionally topological'. According to this method, the overall inductive influence of a complex substituent is determined by the inductive effects of fragments incorporated in it.

The Dewar approach and the Taft method share the common property that they are based on the analysis of substituent constants themselves, i.e. they can be classified as empirical methods. In addition, both approaches take into account in a certain way the geometry and the electronic structures of molecules: according to Dewar, the influence of substituents on the reaction centre is determined by the distance separating them in space, whereas according to Taft, it is determined by the number and nature of the fragments separating them.

The approach developed in the studies of Tatevskii,^{87,88} which permits quantitative description of intramolecular interactions in saturated hydrocarbons and their derivatives of the same type by virtue of bond increments, is also noteworthy. C—C and C—X bonds are divided into types according to the hybridisation of the carbon atoms and into sub-types according to the number of hydrocarbon substituents at each of them. Both scalar properties — energy characteristics, specific volumes, densities, refractions, etc. — and such properties as bond polarities and dipole moments have been considered within the framework of this approach.

The key feature, which distinguishes semiempirical methods from empirical methods, is that the constants can be calculated theoretically rather than found directly from correlations with the physicochemical properties or reactivity data.

c. Non-empirical methods for the evaluation of the inductive effect

Among non-empirical methods for the evaluation of the inductive influence of substituents, the quantum-chemical approach should undoubtedly be considered the most rigorous. The quantum theory permits the calculation of molecular energies and charges on atoms (the electron density distribution). Thus, consideration of the calculated parameters over a reaction series with variation of a substituent, precluding the conjugation effect, provides a direct path to the description of inductive interactions.

The simplest approach involves the separation of the contributions of the inductive and resonance constituents to the variation of the reaction free energies found by quantum-chemical calculations in a good approximation. Another method involves correlation of the σ_I basic set with the quantum-chemical characteristics of the charge distribution in the molecules incorporating the corresponding substituents.⁴

For various mechanisms of transmission of the inductive influence, different quantum-chemical calculation models are chosen. For example, *ab initio* calculations carried out under the assumption that the inductive influence is transmitted 'along bonds' result in uniform attenuation in *n*-alkyl radicals of the electron density variations caused by the substituent.^{4,62}

In recent years, the method of 'isolated molecules' has been widely used for the modelling of the field effect. In conformity with this method, *ab initio* calculations are carried out in parallel for two systems: for the molecule under study and for a pair of simplest isolated molecules arranged so that the interacting fragments in them are oriented in exactly the same way as in the molecule under study (the X—H H—H system). Thus the value $\Delta q = q_{\text{H(X)}} - q_{\text{H(H)}}$ characterises the inductive effect of the substituent X and proves proportional to the inductive $\sigma_{\text{I(X)}}$ -constant.⁸⁹ This approach served as the basis for the introduction of a new scale of 'theoretical field' constants of substituents T_{F} , determined from the charge variation on the β -hydrogen atom in *para*-substituted styrenes.^{4, 90}

However, the extensive use of quantum-chemical calculations in the analysis of substituent effects is hampered by the insufficient level of their development. In addition to the fact that these methods are time-consuming and require the use of complex software, the level of which does not always correspond to the complexity of the problems solved, quantum-chemical calculations are held up by a number of other objective factors.⁹¹ In particular, the use of various approximations sometimes leads to results that disagree with one another or are even fundamentally contradictory. For example, the charges on the hydrogen atoms in alkanes calculated by various methods can differ not only in magnitude but also in sign.^{4-6, 89}

Thus, it is not surprising that attempts are made now and then to develop formal non-quantum-chemical models for intramolecular electrostatic interactions. The principles of the construction of such models were formulated most clearly by Remick,⁹² Smith and Eyring,⁹³ and Del Re,⁴ who considered dipole moments, and by Pacey et al.,⁹⁴ who analysed the standard enthalpies of formation of substituted alkanes.

Thus, studies on the influence of substituents on the dissociation constants of acids played an important role in the development of the Bjerrum-Kirkwood-Westheimer electrostatic theory. According to this theory, the energy of interaction of the anion resulting from the dissociation of an acid containing a polar substituent, with the substituent dipole⁴ is expressed by the following equation:

$$\lg \frac{K_{\text{X}}}{K_{\text{H}}} = 2.303 \Delta p K = \frac{1}{kT} e \frac{\mu \cos \theta}{\epsilon r^2},$$

where K_{X} and K_{H} are the dissociation constants for the substituted and unsubstituted acids, respectively, μ is the dipole moment in the substituent, ϵ is the dielectric permeability of the medium, r is the distance between the charge and the dipole, and θ is the angle between the vectors r and μ .

Since the parameters for effective dielectric permeabilities were selected empirically, it was necessary to develop a procedure for calculating the ϵ value. This problem was solved by Kirkwood and Westheimer⁹⁵ in terms of a model based on a molecular cavity placed into a continuous dielectric medium. Later this model was repeatedly modified and widely used for the description of the chemical properties of compounds^{4, 95-108} and for the interpretation of some experimental data that cannot be described quantitatively within the framework of the classical correlation analysis involving the Hammett-Taft equation.^{107, 108}

It should be noted that all models based on the electrostatic theory suggest that the charges and dipoles are constant, the electron displacements remaining beyond their consideration. However, it is the laws of electrostatics that ensure the basic similarity between the influence of substituents on the energy characteristics and on the electron density distribution.⁴

* * *

Thus, neither nonempirical approaches nor the construction of electrostatic interaction models currently provides a universal description of the inductive effect; therefore, these approaches

cannot compete with empirical methods for the determination of inductive constants. In turn, experimental approaches based on data on the reactivities and physical properties of compounds do not allow one to reveal comprehensively the physical nature of intramolecular interactions and so do not possess sufficient prognostic potential.

III. The problem of a unified scale of inductive constants

The diversity of approaches to the evaluation of inductive effects in the description of reactivities of organic and organoelement compounds points to a need for the development of a universal scale of inductive constants, which would be suitable for use in any field of organic and organoelement chemistry. Three approaches to the solution of this problem can be suggested:

- (1) the use of several scales in various fields, according to their maximum efficiency;
- (2) the search for a universal scale with several parameters;
- (3) the calculation of the total energy of the system in each particular case.

The first approach reflects the current situation in chemistry: numerous scales of various constants of substituent are currently in use, their success being as a rule difficult to predict, especially in the chemistry of organoelement compounds. Furthermore, a strategy for choosing a particular scale does not exist, and one can hardly be expected in the near future.

The calculation of the total energy of a system is, of course, the most universal method to account for the inductive effect and also of other effects. However, as noted above, a wide use of molecular mechanics and quantum chemistry for the quantitative evaluation of reactivity still seems not to be realisable in the near future.

At present, the second approach, namely, the search for a universal scale having a clear physical meaning, is the optimal method. The interrelations of the existing scales and numerous examples of their use in organic and organoelement chemistry, which indicate the common nature of substituent effects, serve as prerequisites for this approach. The universal scale should be based on structural calculations, since empirical scales depend too much on the particular conditions and on the accuracy of experiments. Finally, the universal character of this scale should be based on extensive experimental verification; in other words, it should describe the maximum possible number of experimental data, a high quality of correlation being maintained.

Obviously, the development of a unified theoretical scale of inductive constants requires the elaboration of a quantitative model of inductive interactions involving intelligible mathematics (as we have done previously for the evaluation of steric constants within the framework of the model of the frontal steric effect.¹⁻³)

The main statement of our steric model is the principle of simple mechanical shielding of the reaction centre by substituents, which hamper the access of the second reagent to it. In conformity with this, the steric constant of a substituent R_{s} is determined in terms of this model from a fairly simple additive equation:^{1-3, 59}

$$R_{\text{s}} = 30 \lg \left(1 - \sum \frac{R_i^2}{4r_i^2} \right), \quad (1)$$

where R_i is the atomic radius of the i -th atom in the substituent and r_i is the distance from this atom to the reaction centre.

The scale of the R_{s} -constants obtained within the framework of the frontal steric effect model is in good agreement with experimental scales and describes adequately the steric influences of diverse substituents. The model possesses a clear physical meaning and permits not only adequate and accurate calculation of the steric effect of any substituent at any reaction centre but also the solution of many other problems that are difficult to solve or cannot be solved in terms of the existing empirical scales. Extensive verification of the applicability of this model to

hundreds of diverse organic and organoelement series revealed no limitations on the use of this approach.¹

It is of interest that an essentially similar approach involving a virtually identical mathematical technique was suggested later by Japanese researchers.^{109, 110} A number of other examples of the successful use of a variety of models for the quantitative analysis of reactivities and substituent effects have been presented in a review.¹

Thus, our experience and analysis of the recent literature data make it possible to state with confidence that modelling as a method for the quantitative evaluation of the influence of substituents represents a clear-cut world trend in the development of quantitative organic chemistry and correlation analysis.

We therefore believed that the use of formal modelling in relation to the problem of the inductive effect could also prove an effective and fruitful approach. In a series of papers we have described a fairly simple model of the inductive effect, which permits the correct theoretical calculation of the inductive constants of diverse substituents at virtually any reaction centre.^{15, 111–119} The essence of the model developed by us, its use in solving practical problems of correlation analysis, and in solving some theoretical problems concerning the inductive effect are presented in the subsequent Section of this review. We believe that this model, owing to its accessibility and relatively simple mathematics, could be quite useful in the everyday practical work of chemists who deal with quantitative organic chemistry and correlation analysis.

IV. An additive model of the inductive effect

1. Basic postulates of the model

Taking into account the fundamental and extensively studied properties of the inductive effect, we developed an approach that makes it possible to model with high accuracy the inductive constants of organic and organoelement substituents and groups in the Taft scale.¹¹¹

According to this approach, the inductive effect of a substituent is determined by the sum of the inductive influences of the atoms contained within it:

$$\sigma^* = \sum_{i=1}^n \frac{(\sigma_A)_i}{r_i^2}, \quad (2)$$

where σ^* is the Taft inductive constant of the substituent; n is the number of atoms in the substituent; and r_i is the distance from a particular atom to the reaction centre; in our model a tetracoordinated carbon atom was chosen as the reaction centre.

The empirical parameter $(\sigma_A)_i$, which we introduce here, determines the capability of an i -th atom of exerting the inductive effect and depends on the chemical nature of the element and on its valence state. We calculated the atomic constants σ_A for a wide range of elements in various valence states by substituting empirical 'tabulated' σ^* -constants in Eqn (2) and solving it for σ_A . The resulting values are presented in Table 1.

This additive approach makes it possible to describe with a relatively high degree of accuracy the inductive constants of diverse substituents, i.e. of virtually all substituents for which the σ^* -constants are available (Table 2).

The σ^* -constants found experimentally (σ_{exp}^*) for most frequently encountered organic substituents form a high-quality correlation with the corresponding constants (σ_{calc}^*) found from Eqn (2). The constant term of this correlation is equal to zero and the slope is equal to unity;¹¹¹ this corresponds entirely to the mean values of these parameters.

$$\sigma_{\text{calc}}^* = (-0.078 \pm 0.022) + (1.029 \pm 0.012) \sigma_{\text{exp}}^* \\ N = 146, R = 0.988, S = 0.148.$$

Table 1. Empirical atomic (σ_A) and group (σ_G) constants, obtained from experimental Taft constants.

Substituent	σ_A	Substituent	σ_G
–F	5.88±0.29	–C=C–	0.94±0.15
–Cl	7.62±0.64	>C=O	3.29±0.24
–Br	8.91±0.73	–COOR	4.48±0.14
–I	9.71±1.24	–NO ₂	10.23±0.29
–O–	3.25±0.06	–CN	7.56±0.45
O=	7.52±0.70	–C≡C–	3.86±0.08
–S–	5.03±0.12	>S=O	8.69±0.55
S=	17.14±1.72	>SO ₂	11.14±0.46
>S=	5.90±0.59	>C=S	8.24±0.19
>S≡	4.20±0.72	–NCS	5.24±0.48
–N<	1.78±0.16	–NCO	4.51±0.42
N≡	11.06±1.54	–NC	6.72 ^a
–N≡	4.89±0.77	–NO	3.55 ^a
>C<	0.00	–N ₃	4.51 ^a
>C=	0.70±0.14	–SCN	10.6 ^a
–C≡	2.90±0.58	≥N→O	7.17 ^a
–P<	1.23±0.32	≥P=O	4.38±0.21
–P≡	1.588±0.24	≥P=S	2.52±0.16

^a Group constants are estimated on the base of unity values of σ^* .

Similar high-quality dependences have been obtained for aromatic,¹¹² organoelement,¹¹³ and charged¹¹⁴ substituents [Eqns (3), (4), and (5), respectively]:

$$\sigma_{\text{calc}}^* = (0.046 \pm 0.025) + (0.944 \pm 0.014) \sigma_{\text{exp}}^* \quad (3)$$

$$N = 127, R = 0.985, S = 0.156,$$

$$\sigma_{\text{calc}}^* = (0.023 \pm 0.015) + (0.994 \pm 0.010) \sigma_{\text{exp}}^* \quad (4)$$

$$N = 124, R = 0.993, S = 0.162,$$

$$\sigma_{\text{calc}}^* = (0.081 \pm 0.093) + (0.999 \pm 0.092) \sigma_{\text{exp}}^* \quad (5)$$

$$N = 29, R = 0.986, S = 0.310.$$

The final dependence, describing more than 400 points, has a correlation coefficient of 0.99,¹¹⁴ i.e. the theoretical inductive constants correspond completely to the experimental data.

$$\sigma_{\text{calc}}^* = (0.031 \pm 0.012) + (0.991 \pm 0.006) \sigma_{\text{exp}}^*$$

$$N = 427, R = 0.991, S = 0.130.$$

The high level of additivity of the model suggested makes it possible to determine the inductive effects of substituents not only using the σ_A -constants of atoms but also (for convenience) using σ_G -constants for groups, which can be obtained similarly to σ_A -constants from an equation resembling Eqn (2).¹¹¹ The σ_G -constants for functional groups most frequently encountered in organic chemistry (C=O, COOR, CN, NO₂, etc.) are also listed in Table 1. The use of the group constants does not diminish the accuracy of the calculations of inductive constants,¹¹¹ which confirms a certain integrity and the high degree of additivity of our approach.

Table 2. Experimental and theoretical [calculated from Eqn (2)] Taft inductive σ^* -constants.

2. Inductive effect and the conformation of a substituent

Obviously, within the framework of the model under consideration, the inductive effect of a particular substituent is substantially dependent upon its conformation. In particular, the parameters r_i in Eqn (2), which correspond to the distances from each of the atoms constituting the substituent to the reaction centre, are sensitive to the conformation. On the one hand, this is an argument in favour of the model proposed, because the inductive effects of substituents depend in reality on their conformations.⁴ On the other hand, such a conformational sensitivity may appear at first glance to be an undesirable factor, since the exact conformation of a substituent is not necessarily known and, furthermore, the conformation can change during a reaction or activation.

However, it is easy to see that the number of such substituents in real reaction series is relatively small. For the majority of substituents, the problem of conformational uncertainty either does not exist at all or is easily solved if the occurrence of a particular conformation amongst several possible conformations is obvious. Thus, relying on the above majority of substituents, we can proceed to the reverse procedure, i.e. to determine the conformation in which a substituent exists (for those substituents for which the degree of conformational uncertainty is quite large). In this case, one should merely calculate the inductive effects for each of the possible conformations, compare the values obtained with the experimental inductive constant, and choose the value that is in best agreement with the whole series. An example of such a sort of conformation analysis is presented in Table 3 for the substituents CH₂COR and for *trans*-CH=CHCH₂COOR. We calculated the inductive constants for various possible types of orientation of these substituents with respect to the reaction centre and compared the results with the corresponding experimental values.

It is seen that the acylmethyl substituent has a clear-cut transoid orientation, which is evidently sterically more favourable.

Table 3. Theoretical (σ_{calc}^*) and experimental (σ_{exp}^*) σ^* -constants for the acylmethyl and *trans*-alkoxycarbonylpropenyl substituents.

Substituent	Conformation	σ_{calc}^*	σ_{exp}^*
CH ₂ COR	<i>cis</i>	1.41	
	<i>trans</i>	0.69	0.69
<i>trans</i> -CH=CH–CH ₂ COOR	<i>cis</i>	0.65	0.69
	<i>trans</i>	0.58	

In the case of the *trans*-alkoxycarbonylpropenyl substituent, the difference between the inductive constants of the two conformations considered is relatively small; we present this example in order to demonstrate that conformational transitions do not necessarily exert a substantial influence on the inductive constant.

In any case, the above analysis indicates that the conformational sensitivity of the model under consideration is not a drawback; conversely, this makes the model more flexible and more useful for practical purposes.

3. Critical analysis of the model and its physical meaning

It is clear that our approach to the description of the inductive effect of substituents in terms of the additive Eqn (2) is in essence purely formal. At the same time, the dependence of the σ^* -constants on the reciprocal of the squared distance to the reaction centre confirms in general the electrostatic field nature of the inductive effect, because it reflects the involvement of Coulomb interactions. Besides, good agreement between the

calculated and experimental inductive constants, which is manifested in the high quality of the correlations, indicates that σ_A -constants reflect the actual ability of various elements to exert an inductive influence, depending on their chemical nature and valence state. This raises the question as to what is the physical meaning of the elemental constants σ_A .

To find out what factors largely determine the nature of the σ_A -constants we studied¹¹¹ the quantitative dependences of σ_A -constants on various physical and geometrical parameters used most frequently in the analysis and interpretation of inductive interactions by multifactor regression analysis; a number of interesting regularities were thus identified.

For example, for a broad selection of elements, σ_A -constants follow high-quality correlations with the difference between the electronegativities of a given element and carbon (reaction centre) and with the covalent radius (R) of the element in the corresponding valence state squared:^{111, 115}

$$\sigma_A = 7.840 \Delta\chi R^2. \quad (6)$$

It is obvious that this dependence is in good agreement with both the magnitude and sign of inductive constants.

Eqn (6) indicates that the σ_A -constant, reflecting the ability of an atom to exhibit an inductive effect, depends not only on its electronegativity, which is certainly the motivating force in the displacement of electron density, but is also directly proportional to the surface area of its valence shell (R^2), i.e. to its ability to delocalise the arising charge. Thus, the magnitude of the inductive effect of a particular element (substituent) is determined both by the 'potential difference' ($\Delta\chi$) between this element and the reaction centre and by its 'capacity'.

It should be noted that numerous attempts have been made to find a direct relationship between the inductive constants and some known physical parameters characterising in one way or another the ability of an atom to attract electrons, such as electronegativity,^{120, 121} ionisation potential,¹²⁰ electron affinity,¹²⁰ dipole moment,^{4, 6} degree of ionic character of the bond,^{4, 74} etc., all of which were unsuccessful. However, one would hardly expect that any one parameter alone would be sufficient to describe quantitatively the inductive effect. Even if this were the case, the dependence obtained would be far from simple. This is demonstrated, in particular, by Eqn (6).

It is noteworthy that Eqn (6) almost agrees with the known^{4, 74, 122, 123} dependences of electronegativity on atom size

$$\chi = \frac{aZ}{R^2} + b, \quad (7)$$

which forms the basis for the so-called 'geometrical' systems of electronegativity, for example, the widely used Allred-Rochov scale.^{4, 74, 122, 124} In addition, dependences of the following form are known

$$\chi = \frac{aZ}{R} + b, \quad (8)$$

[Pritchard-Skinner¹²³ and Gordon ($b = 0$)¹²⁴ equations].

From a comparison of relations (6)–(8), it follows unambiguously that the σ_A constants found by us are directly related to the effective nuclear charge Z , or, more precisely, to the difference between the effective nuclear charge of the given atom and that of carbon (ΔZ).

Thus, the σ_A constants have a clear physical meaning, which, in its turn, can throw light on the nature of the inductive effect itself.

Combination of Eqns (2) and (6) gives the following final expression for a Taft inductive constant:

$$\sigma^* = 7.840 \sum_i \Delta\chi_i \frac{R_i^2}{r_i^2}, \quad (9)$$

where $\Delta\chi_i$ is the difference between the electronegativities of the i -th atom in the substituent and the reaction centre, R_i is the covalent radius of the i -th atom, and r_i is the distance from this atom to the reaction centre.

A number of interesting corollaries and relations follow from Eqn (9) (some of them are considered below). In addition, this equation permits the direct calculation of the inductive constant of any substituent at any reaction centre from the fundamental characteristics of atoms and groups.

The relatively complex form of Eqn (9) accounts for the fact that numerous attempts made by various workers to describe quantitatively the inductive effect in an analytical form have so far been unsuccessful, although in some cases and for relatively small selections of substituents, quite satisfactory results have been obtained (see, for example, a number of papers^{4, 6, 120}).

4. Use of the additive model of the inductive effect in the analysis of reactivities of organoelement compounds

The inductive influence of substituents on reaction centres other than carbon is a fundamental problem in the modern theory of reactivity of organoelement compounds.

As noted above, the reactivities of organoelement compounds in correlation analysis are often evaluated using scales of 'special' electronic constants (for example, 'silicon' σ_{Si} or 'phosphorus' σ^P constants).^{4, 74} Like Hammett constants, these values reflect the inductive interaction, conjugation, and steric shielding, i.e. the overall influence of a substituent on a reaction centre. Thus, the special scales are applicable in those cases where the ratios of the constituents forming the overall effect of a substituent and the structure of the reaction centre are similar to those in a standard reaction series for which the constants have been determined.

At the same time, interest in the possibility of using the classical 'carbon' scales of inductive constants to describe the reactivities of organoelement compounds has been frequently shown. Thus, no unified approach to the problem of the linearity of variation of the inductive effects of substituents at various reaction centres has been elaborated so far. Since there is no self-consistency of the operating scales, their use is limited, and their physical meaning is obscure, it is impossible to make a correct comparison of inductive interactions in the chemistry of organic and organoelement compounds.

In our opinion, this problem could be solved fairly legitimately by considering the inductive effects of substituents at carbon and non-carbon reaction centres within the framework of a certain unified approach, which operates with the calculated values of the inductive constants and thus ensures the possibility of their comparative analysis.

We have attempted^{116–119} to solve the problem of linearity of the inductive influences of substituents at carbon and heteroatom reaction centres, which is now of prime importance in the chemistry of organoelement compounds. Solution of this problem would make it possible to identify the limits within which the classical carbon inductive constants are applicable to the evaluation of reactivities of organoelement compounds.

In terms of our approach, the inductive constant of a substituent at a heteroatom reaction centre is either directly calculated from Eqn (9), based on the fundamental characteristics of the reaction centre and of the atoms incorporated in the substituent, or calculated using the basic Eqn (2). In the latter case, an intrinsic ability to exert an inductive influence on the given reaction centre is assigned to each atom and is determined by the magnitude of the corresponding atomic σ_A -constant found from Eqn (6).

It is clear that by analysing the σ_A -constants calculated theoretically for the same atoms at different reaction centres, one can find out whether there is a linear correlation between the inductive influences of atoms and substituents at carbon and non-carbon reaction centres. Using the method of regression analysis, we compared the calculated $\sigma_A(X)$ -constants (reflecting the ability of atoms to exert an inductive influence on heteroatom reaction

centres X) with the $\sigma_A(C)$ -constants, used for the calculation of the inductive effects of substituents at a carbon atom. We obtained correlations of the following form

$$\sigma_A(X) = A_0 + A_1\sigma_A(C). \quad (10)$$

The A_0 and A_1 parameters of the dependences obtained are listed in Table 4. Analysis of these values makes it possible to conclude that the closer the 'inductive' electronegativities of the X and C atoms to each other, the higher the quality of the corresponding correlations and more correct the use of the 'carbon' inductive constants to describe the inductive effect of substituents at the atom X.

Table 4. The parameters of correlations of type (10), which relate the $\sigma_A(X)$ -constants of atoms at various reaction centres (X) to the corresponding values of the $\sigma_A(C)$ -constants.

Si	0.33 ± 0.05	0.98 ± 0.01	0.998	0.267
Se	-3.34 ± 0.54	0.92 ± 0.09	0.892	2.54
-C≡	-9.82 ± 1.09	1.39 ± 0.19	0.830	5.10
O=	-28.13 ± 3.13	2.18 ± 0.57	0.631	14.65
>P=	-1.94 ± 0.21	1.07 ± 0.03	0.985	1.00

It should be noted that the above correlations cover the whole array of σ_A -constants, including those points corresponding to extremely electron-donating and extremely electron-withdrawing atoms. However, even this broad range of magnitude of σ_A -constants ensures a high quality of correlations of type (10) only if the electronegativity of the reaction centre X deviates from that of carbon by no more than 0.2 unit.

Thus, in the general case, the inductive constants of substituents at different reaction centres are not proportional to one another, i.e. there is no linearity of the inductive effect in the chemistry of organic and organoelement substituents, despite the fact that the nature of inductive interactions certainly remains invariable. Now it is clear that the classical inductive constants of substituents must be used for analysing the reactivities of organoelement compounds with great caution. In addition, it is obvious that the smaller the difference between the electronegativity χ of the reaction centre X and the electronegativity χ_C of carbon and the greater the difference between the electronegativities of the atoms forming the substituent and the electronegativity of carbon, the more correct the use of carbon constants.

It should be noted that since our approach permits fairly easy theoretical calculation of the inductive constant of any substituent at any particular reaction centre, the above problem simply no longer exists within the framework of our model. Thus, in all probability, the use of this model for the quantitative evaluation of the inductive influences of substituents in the reactivities of organoelement compounds will be the most legitimate. This chiefly refers to alkyl substituents, the inductive influence of which is still one of the most acute and disputed problems.

5. The problem of the inductive influence of alkyl substituents

At present, the inductive influence of alkyl substituents is still one of the most uncertain problems in the correlation analysis of the reactivities of organic and organoelement compounds. When the inductive influence of substituents in various reaction series is considered, the points corresponding to alkyl substituents deviate most substantially from the general correlation plots. Hence, it is no wonder that the question of the inductive effects of alkyl substituents has caused the most prolonged discussion in the literature which has not yet been completed.⁴

At present, the overwhelming majority of researchers are inclined to believe that alkyl substituents are incapable of participating in any significant electronic interactions; therefore, their inductive influence is frequently regarded as zero.¹²⁵⁻¹²⁸

However, a number of examples indicate that the inductive effects of alkyl substituents are significant and differ from one another.¹²⁹ Furthermore, correlations have been obtained that relate the inductive constants of alkyl substituents in the Hammett scale to the 'special' constants, reflecting the influence of alkyl groups on non-carbon reaction centres, for example, on the phosphorus atom.⁵⁷ Based on these correlations, the overall influence of alkyl substituents on the phosphorus atom was divided into inductive and resonance constituents. As this was done, the substituents at the phosphorus atom (including alkyl groups) were assumed not to shield sterically the reaction centre due to the large size of the latter.⁹

However, it was later found that, apart from the inductive and resonance constituents, the 'special' constants also incorporate a steric component. Thus, when the overall effect of the substituents on the reaction centre is divided into elementary parts, all three types of interaction should be taken into account.^{57, 130, 131} Moreover, a linear correlation between the inductive and steric influences has been found. This served as additional evidence for the illegitimacy of the inductive constants of alkyl substituents and for the presence of the residual contribution of steric interactions to them. The notion of 'pseudo-inductive' influence of alkyl substituents has even appeared.⁵

Thus, it can be stated that at present, opinions on the inductive effect of alkyl substituents differ widely and are uncertain. Evidently, this is caused by the absence of reliable criteria and of a reliable technique for the division of the overall effect of substituents into inductive, resonance, and steric constituents. In addition, even in those scales in which the inductive constants of alkyl substituents differ from zero, they are still fairly small; in view of the error in the determination of empirical constants, this makes the evaluation of the inductive influence of alkyl groups based on standard reaction series doubtful.

It is also noteworthy that conformations of alkyl substituents are quite diverse, which can make the division of their influence on a reaction centre into elementary contributions even more complicated. At the same time, in view of the fact that almost all real reaction series involve large numbers of alkyl and alkyl-containing substituents, it is clear that a versatile and legitimate approach to the estimation of their inductive influence needs to be developed.

The consideration of inductive effects of alkyl substituents within the framework of the model suggested by us unambiguously implies that it is improper to consider the inductive influence of alkyl groups to be zero. This can be done legitimately only in those cases where a saturated carbon atom acts as the reaction

centre,¹³² whereas in all other situations, as follows from Eqn (9), the inductive effects of alkyl groups can not only be significant but also quite strong (especially in the chemistry of organoelement compounds for which the $\Delta\chi$ value in Eqn (9) is the highest).

Theoretical analysis of the inductive influence of alkyl substituents in terms of our model makes it possible to identify yet another important feature in an analytical form. Since the electronegativities of carbon and hydrogen atoms are close, it is clear that the $\Delta\chi$ values for all the atoms in an alkyl substituent at each particular reaction centre are virtually identical; therefore, in Eqn (9), this value can be factored out from the summation sign. Thus, the inductive influence of alkyl groups is proportional to the sum of the ratios of the squared covalent radii of the atoms incorporated in it to the squared distances from these atoms to the reaction centre:

$$\sigma_{\text{Alk}}(X) = 7.840 \Delta\chi_i \sum_i \frac{(R_i^2)_i}{r_i^2} \quad (11)$$

Within the framework of the frontal steric effect model developed by us previously, a similar ratio was obtained as a measure of the steric shielding of a reaction centre by an atom defining the steric constant R_s of the corresponding substituent. In particular, this follows from Eqn (1), which can be transformed into the simpler expression (12), because, for small values of the argument x , the function $\lg(1-x)$ is known to be linearly related to x :

$$R_s = \text{const} \sum_i \frac{(R_i^2)_i}{r_i^2} \quad (12)$$

Thus, Eqns (11) and (12) indicate that there is a linear relationship and an intrinsic genetic connection between the inductive and steric effects of alkyl substituents. However, this cannot be interpreted as evidence for the illegitimacy of the inductive constants of alkyl groups and for the presence of the residual steric contribution in them, as has usually been done in recent years.⁵

In order to confirm experimentally this statement we calculated the inductive constants for alkyl substituents at various reaction centres in terms of our model and compared the results with the steric constants R_s of the corresponding alkyl groups at the same reaction centres.¹³² The parameters of the resulting correlations are presented in Table 5. It should be noted that the correlation coefficients are about 0.99, i.e. a strictly linear correlation between the inductive and steric influences of alkyl groups really exists.

The results obtained indicate that the sensitivities of reaction centres to the inductive influence of alkyl radicals are dissimilar: the greater the difference between the electronegativities of the reaction centre and carbon, the more significant the inductive effect of alkyl groups on this centre and the more clear-cut its dependence on the number of atoms in the substituent.

Thus, in terms of our inductive model, the problem of the inductive influence of alkyl substituents receives a strict and simple solution which, in our opinion, adequately accounts for the contradictory set of data published on this topic.

Hence, the model of the inductive effect that we have developed permits more than just the legitimate theoretical calculation of the inductive constant of any substituent at any reaction centre for the purposes of the correlation analysis of the reactivities of organic and organoelement substituents. This model also makes it possible to solve many other important problems associated with the inductive effect that cannot be currently solved in terms of other approaches.

Table 5. Parameters of the linear correlations connecting the steric (R_s) and inductive (σ^*) constants of alkyl substituents at various reaction centres ($N = 13$)

$$\sigma_{\text{Alk}}^* = A_1 + A_2 R_s(\text{Alk}).$$

Methods for the measurement of ion mobilities and applications

G V Karachevtsev

Contents

I. Introduction	657
II. Ion mobilities	657
III. Mobility spectrometers and their applications	658
IV. Conclusion	660

Abstract. The results of studies of ion mobilities in gases, yielding information about ion-molecule interaction potentials, are surveyed. The principles of the operation and the characteristics of the ion mobility spectrometers are described. Examples of the applications of plasma chromatography in the study of ions are presented. The bibliography includes 70 references.

I. Introduction

The term mobility of ions is defined as the ratio of the rate of their directed uniform motion through a gas to the strength of the electric field inducing this motion. Ion mobilities in gases are widely used in both fundamental and applied branches of science. For example, the parameters of the interaction potentials have been determined and the bond dissociation energies, equilibrium bond lengths, and vibrational frequencies have been obtained from the mobilities of chromium, cobalt, and nickel ions in helium and neon at different temperatures.^{1,2} Such information is of interest in the study of the physical and chemical characteristics of low-temperature plasma.

Analytical instruments based on measurements of ion mobilities have been developed in recent years. These instruments are known under different names: ion mobility spectrometers,³ drift spectrometers, and plasma chromatographs.^{4,5} The methods for the analysis of ions in these instruments consist in the study of the dependence of the mobilities of ions on their masses and, in a more general case, on the type of ions. Such devices do not require the

creation of a high vacuum, which significantly simplifies their design compared with other analytical apparatus in which ionisation processes are employed (for example, mass spectrometers and electron spectrometers).

A schematic illustration of a drift spectrometer is presented in Fig. 1. A packet of ions with different mobilities is injected into the drift tube with a uniform electric field and an increased gas pressure. The initial packet is then divided into several packets in accordance with the number of different types of ions in the initial packet.

As in mass spectrometers, the ionisation in plasma chromatographs may be achieved by corpuscular radiation and photoradiation and by laser desorption as well as electro- and thermo-sputtering methods.^{6–9}

II. Ion mobilities

Data on ion mobilities in gases have been published in a series of communications.^{10–24} The mobilities of ions depend on their masses, structures, and the effectiveness of energy exchange during their motion in an electric field in gases.

For electric fields usually employed in plasma chromatography at atmospheric pressure, the mobility coefficient K is independent of the electric field strength E . The mobility coefficient is linked by the Einstein relation to the ion diffusion coefficient D

$$K = 1.16 \times 10^4 \frac{D}{T},$$

where the dimensions are $\text{cm}^2 \text{V}^{-1} \text{s}^{-1}$ for K , $\text{cm}^2 \text{s}^{-1}$ for D , and K for T .

The average energy of the ions in the electric field is determined by the parameter E/N (N is the density of the gas) measured in townsend (1 Td = 10^{-17}V cm^2). In plasma chromatography, the typical values of the quantities E/N are 1–2 Td.

Under these conditions, the elastic scattering of ions is determined by the polarisation capture occurring over distances appreciably greater than the geometrical dimensions of the molecule and ion. The mobility coefficient under standard conditions ($N = 2.69 \times 10^{19}$ molecules in 1 cm^3 , $T = 273 \text{ K}$) can be obtained by means of the following expression:

$$K = 13.85 \left(\frac{1}{m} + \frac{1}{M} \right)^{0.5} \alpha^{-0.5},$$

where m is the mass of the ion in a.u., M the mass of the molecule in a.u., and α the polarisability of the molecules in \AA^3 .

The mobility is linked to the reduced mobility K_0 by the relation

$$K_0 = K \frac{273}{T} \frac{P}{760}.$$

Here P is the total pressure in mm Hg.

Figure 1. Schematic illustration of a drift spectrometer. (1) Ion shutter ensuring the passage of ions from the ion source to the drift tube (2); (3) ion detector; A, B, C — packets of ions with different mobilities.

Received 13 May 1995

Uspekhi Khimii 65 (8) 712–717 (1996); translated by A K Grzybowski

With increase in the energy of the relative motion of the ion and the molecule, the radius for the capture of the ion by the molecule diminishes and short-range exchange interactions begin to be manifested between the molecule and the ion. The mobility coefficient begins to depend on the electric field:

$$K = K_{(0)} \left[1 + \alpha_1 \left(\frac{E}{N} \right)^2 \right].$$

Here $K_{(0)}$ is the mobility in a zero electric field and α_1 is a coefficient which takes into account the deviation of the interaction potential from the polarisation potential. Over short distances, this deviation is responsible for the temperature dependence of the mobility coefficients. For example, with increase in temperature during the drift of Li^+ ions in helium, whereupon the short-range exchange forces become repulsive, the mobility coefficient increases, whereas in the drift of H^+ ions, where short-range attractive forces operate, it diminishes.²⁵

We may note that the dependence of the average kinetic energy of the ion w on the temperature of the gas and the rate of drift v is determined by the Vanier formula

$$w = 1.5kT + 0.5mv^2 + 0.5Mv^2,$$

which is frequently employed in kinetic studies.

III. Mobility spectrometers and their applications

The spectrometers, the principle of the operation of which is based on the separation of ions in terms of their mobilities, can be used jointly with the usual high-vacuum mass spectrometers. Such combination requires the overcoming of appreciable technical difficulties, namely the mutual adjustment of the regions of the high and low gas pressures along the ion path,^{26,27} but its advantage is that it ensures the possibility of solving problems inaccessible to each separate method. For example, an apparatus has been described^{28,29} in which a quadrupole mass analyser is placed at the outlet from the plasma chromatograph (Fig. 2) Such devices make it possible to identify accurately the ions constituting a particular chromatographic peak.

Figure 2. Schematic illustration of tandem drift spectrometer-mass spectrometer apparatus. (1), (2), A, B, C — as in Fig. 1, (3) quadrupole mass analyser.

Another version is possible where the plasma chromatograph is placed after the mass-spectrometric analyser (Fig. 3).³⁰ The carbon clusters C_n^+ , obtained by evaporating graphite on exposure to laser radiation in a helium atmosphere with subsequent hyper-sonic expansion, have been investigated with the aid of such tandem apparatus.^{2,31} The ions of the C_n^+ cluster were accelerated, passed through a mass analyser, retarded, and injected into a drift tube. In this case, it was possible to investigate the structure of ions having the same elemental composition. In particular, the drift times of the $\text{C}_3^+ - \text{C}_6^+$ clusters are the same for each particular C_n^+ ion. For the $\text{C}_7^+ - \text{C}_{10}^+$ ions, there are two resolved mobility

Figure 3. Schematic illustration of a tandem mass spectrometer-drift spectrometer apparatus. (1), (2), A, B, C — as in Fig. 1; (3) mass analyser.

peaks in each case, which corresponds to the presence of two isomeric forms of the clusters — cyclic and linear. The ions having the cyclic clusters have higher mobilities than the linear ones. For the C_{32}^+ cluster, it was found that the composition comprises 23% of monocycles, 71% of bicycles, 2.4% of open fullerenes, and 3.2% of fullerenes. Similar information is available for all the clusters up to C_{61}^+ (Fig. 4).³¹

Figure 4. Dependence of the reduced mobility coefficients K_0 for the ions C_n^+ on n for different clusters. (1) Linear clusters; (2) monocyclic clusters; (3) planar polycyclic clusters; (4) open fullerenes; (5) fullerenes.

The theory of the mobility of carbon cluster ions taking into account the geometry and vibrational excitation of the clusters has been examined.³² It was shown, for example, that the mobility increases with increase in the vibrational energy of the cluster. It was observed with the aid of ion mobility spectrometry that the protonation of aniline in the gas phase leads to two isomeric forms.³³ The addition of a proton to the nitrogen atom is most preferred. The addition of a proton to the benzene ring is less probable. Such ions have a higher mobility than the ions protonated at the nitrogen atom.

Other studies of the isomers with the aid of plasma chromatography have also been described.³⁴

The plasma chromatograph can be used effectively as a highly sensitive selective detector in gas chromatography.³⁵ The design of the spectrometers, the method for the introduction of the specimens, and the interpretation of the spectra have been described in detail.³⁶ The plasma chromatograph usually consists of two consecutively arranged drift tubes. The first contains the source of radioactive radiation (a foil containing ^{63}Ni). This tube serves as the reactor for ion-molecule reactions, pure nitrogen, which can usually be obtained from liquid nitrogen, being normally used as the carrier gas. However, the water impurity remains even in highly purified nitrogen, leading, as a result of ion-molecule reactions, to the formation of stable positive ions of the type $\text{H}^+(\text{H}_2\text{O})_n$ and $\text{NO}^+(\text{H}_2\text{O})_n$. When purified air is used as the

carrier gas instead of nitrogen, the composition of the positive ions hardly changes, while the negative ions are of the type $O_2^-(H_2O)_n$.

The addition of trace amounts of organic substances to the carrier gas leads to reactions of the carrier gas ions with the impurity molecules; the products incorporate the impurity molecule. The second tube, fitted with a grid for the injection of ions, serves as an ion-drift spectrometer for the measurement of the spectrum of the ions in terms of their mobilities in the electric field. The spectrum is obtained by employing a weak electric field, which directs the ions formed in the reactor to the drift tube of the spectrometer. The packet of cluster ions moves in the inert pure nitrogen atmosphere, the directions of the streams of ions and nitrogen being opposed (in order to diminish the penetration of the carrier gas, containing the impurity, into the region of the analyser). During the motion of the ions through the drift tube, they are separated into packets with different mobilities. The heavier ions usually have smaller mobilities. The pulses of ions having different masses are recorded with the aid of an electrometer amplifier. The scan of a single spectrum in the mass range up to 400 a.m.u. takes 20 ms. Several hundreds of such spectra are usually summed and averaged in order to increase the accuracy of the experiment. A synchronous detector which integrates the signal during a short time interval moving slowly along the time axis relative to the pulse being injected, is used for this purpose.

The Fourier transformation has been used recently in ion mobility spectrometry.³⁷ The mobility interferogram is obtained with a single transfer of pulses to the modulating grids at the inlet to and outlet from the mobility spectrometer. The pulses are supplied from a rectangular pulse generator with a frequency scan. By applying the Fourier transformation to the interferogram, the usual ion mobility spectrum is obtained. The theory of the method has been described and examples of the measurement of the mobility spectra have been presented (Fig. 5).³⁷ This method may increase the rate of recording of the mobility spectrum and the sensitivity, which is particularly important when the mobility spectrometer is used as the detector for chromatographs.

The detectable amounts of impurities in 100 cm³ of air are 10^{-9} – 10^{-8} g for plasma chromatographs. The use of larger masses of the specimen (10^{-6} g and above) leads to the saturation of the response, the complete consumption of the reactant ions, and the formation of dimeric impurity ions. The interpretation of the mobility spectra then becomes difficult. The ion mobility spectra are also greatly distorted when a drift gas containing impurities which may enter into ion–molecule interactions with the test ions is employed. A discrepancy arises with the mobilities

predicted by the classical theory when fast ion–molecule reactions take place in the system during a period shorter than the drift time. Typical examples of such reactions are the solvation and desolvation of ions by the water molecules present as an impurity in the drift gas.

A useful employment of the ion cluster formation process is also possible, for example, in order to increase the resolving power of plasma chromatographs.³⁸ If the sizes and masses of the ions are similar but the rates of formation of clusters are different, then the addition of cluster-forming gas to the carrier gas leads to an appreciable difference between the masses of the ions analysed and hence between their mobilities. The kinetic characteristics of the ion–molecule processes are similar in plasma chromatography and high pressure mass spectrometry.^{39–42}

Reference data on the kinetic parameters of ion–molecule processes have been published.^{43,44} The rate constants for exothermic bimolecular ion–molecule processes for low ion energies are determined by the long-range charge–induced dipole and charge–permanent dipole forces. These constants are usually of the order of 10^{-9} cm³ s⁻¹ and lower values have been found only in a few instances.⁴⁵

The rate constants for termolecular ion–molecule association reactions are determined by the rate constants for the corresponding bimolecular processes and the lifetimes of the ion–molecule ‘collision’ complexes formed.

The rate constants for termolecular ion–molecule association processes are 10^{-32} – 10^{-21} cm⁶ s⁻¹.^{43,46}

We shall consider the typical conditions in the operation of plasma chromatograms. With the aid of a radioactive radiation source with an activity of ~ 10 μ Ci at atmospheric pressure, it is possible to obtain $\sim 10^{11}$ ions per second. At atmospheric pressure, the carrier gas flow rate is 100 ml min⁻¹, the electric field strength is 250 V cm⁻¹, the duration of the ion-injecting pulse is 0.2 ms, and the recording scanning pulse has the same duration. The spectra are usually obtained with a drift tube temperature of 100–150 °C and for a length of the drift region of 8 cm. For example, the mobility coefficient for the Cl⁻ ion at 150 °C is 4.7 cm² V⁻¹ s⁻¹. This yields a drift time of 8 ms. Watts and Wilders⁴⁷ made a detailed study of the resolving power of a plasma chromatograph. The formula obtained for the determination of the resolving power in the ideal case (when the resolving power is limited by diffusion) is

$$R = 2(EL)^{0.5},$$

where E is the electric field strength in V cm⁻¹ and L the length of the drift tube in cm.

Watts and Wilders⁴⁷ studied the influence of the initial width of the ion packet and of the volume charge of the ions on the resolving power. For example, when account is taken of the finite duration of the ion packet, the formula for the resolving power assumes the following form:

$$R = \frac{L/v + t/2}{(48.4DL/v^3 + t^2)^{0.5}},$$

where t is the duration of the ion packet, v the ion drift velocity, and D the diffusion coefficient.

For small electric field strengths

$$E < 4\pi en,$$

where n is the concentration of ions, a negative influence of the space charge of the ions on the resolving power may be observed. For example, when $E = 2$ V cm⁻¹ and $L = 10$ cm, then appreciable distortion of E due to the space charge will occur for $n = 10^5$ cm⁻³.

Mathematical methods for the reconstruction of poorly resolved peaks are widely used to increase the resolving power. For example, the spectra of chlorine and bromine isotopes have been resolved by this procedure.⁴⁸ Computers are used widely for the recording and treatment of spectra of different types.⁴⁹

Figure 5. Schematic illustration of a mobility spectrometer with Fourier transformation. (1) and (2) as in Fig. 1; (3) ion collector; (4) generator of rectangular pulses with a variable frequency ω ; (5) electrometer amplifier, analogue–digital transformer, and memory device ensuring the generation of the ion mobility interferogram; (6) Fourier transformation ensuring the generation of the ion mobility spectrum.

One of the principal elements of the design of plasma chromatographs is the grid ion filter. The filters may be of different types. The Tyndall filter consists of two wire grids close to one another and fixed at right angles to the axis of the drift tube. A potential is applied to the grids, i.e. there is a potential difference between them. As a result of this, the ions are not transmitted through the grid for most of the time. However, the potential difference changes sign periodically, which enables the ions to pass through the grid and enter the drift space.

It has been suggested⁵⁰ that the Tyndall filter be modified by employing microchannel plates. Such plates are beginning to be employed widely in various experimental techniques.⁵¹ The design of the modified filter is convenient during assembly, ensures a parallel arrangement of the end faces, is mechanically stable, and is not short-circuited on contamination by conducting particles. The channels in such filters have diameters of 40–80 μm and are perpendicular to the surfaces of the plates (to ensure the effective transmission of ions).

The Bradbury–Nielson filter consists of a single grid made of wires arranged at short distances from one another. A sinusoidal potential is applied between the alternating wires of the grid, the average potential on each wire being equal to the potential of the uniform drift field in the plane of the grid. The ions which reach the grids at the moments when the instantaneous alternating potential is close to zero pass through the filter. A modification has been proposed also for this filter, in which foil strips are employed instead of wires.⁵²

Ion mobility spectrometers in which the electric field vectors and the gas flow rates are directed to one side were examined above. Ion separators with the gas stream directed at right angles to the electric field in which the ions drift have been proposed (Fig. 6).⁵³ Such geometry leads to an increase in the resolving power. However, this requires a much greater stability of the gas flow rate compared with the usual geometry.

Figure 6. Schematic illustration of an ion mobility spectrometer with a perpendicular arrangement of the electric field and gas flow direction. (1) Ion source; (2) ion selector; (3) ion recorder; v_0 = gas flow rate; v_1 = velocity of ions; E_1 , E_2 = electric field strengths.

Another probable advantage of this scheme is the measurement of the ion spectrum without employing a pulse technique — by recording constant ionic currents at different points in the plane of the collector. The ions are carried away by the gas stream at a steady rate and drift in the electric field at right angles to the stream at rates which depend on the mass of the ions. Heavy ions reach the plane of the collector at a long distance from the inlet, whilst light ions reach it at a short distance, since the drift velocity of light ions is usually greater than the drift velocity of heavy ones.

A procedure has been proposed^{54–56} for the modification of the ion separation method with the gas flow rate and electric field strength vectors arranged at right angles, to one another. The method is based on subjecting the ions to constant and variable electric fields. When the ions are subjected to such an influence, there is an appreciable increase in the effectiveness of the separation, which is determined not only by the difference between the mobilities but also by the difference between the first derivatives of the mobilities with respect to the electric field. Spectrometers in which this modification procedure of the ion separation method is employed have been constructed by the

Ekotek Company (Novosibirsk). The present author and Chentsov have estimated the resolving power of a spectrometer of this type.⁵⁷

IV. Conclusion

The studies on ion mobilities in gases, initiated at the end of the last century by Thomson, Rutherford, Townsend, and Langevin, are still of interest both for fundamental science and for analytical techniques. In fundamental science, such studies make it possible to obtain data on the compositions, structures, and reactivities of ions, which permits a deeper understanding of the general problems of molecular structure and chemical reactivity. Data on gas-phase reactions are also of interest for high-energy chemistry, including radiation chemistry and the chemistry of low-temperature plasma. For example, the rate of recombination of positive and negative ions in plasma is determined directly by the mobilities of these ions.⁵⁸

Definite progress has been noted recently in the improvement of the experimental methods for the study of ion mobilities. Experiments carried out at low temperatures^{59–61} showed that at $T < 10$ K ion mobilities in helium diminish sharply and become lower than the polarisation limit, which may be a consequence of the manifestation of quantum effects. Further theoretical experimental studies are needed to elucidate the nature of the observed low-temperature effects. They may yield information about the mechanisms of low-temperature chemical processes.

The laser technique is being applied to an increasing extent in studies of ion mobilities and not only for the generation of the ions but also for the measurement of the velocity distribution of the drifting ions.⁶² Systems in which the drift tube–laser combination is used may compete with the drift tube–mass spectrometer systems. One may probably expect an expansion of studies in this promising direction. Mobility spectrometers are being increasingly used for analytical purposes. Apart from the studies indicated above concerning their application in the investigation of carbon cluster isomers, there have been studies of the isomers of metallocarbon clusters.^{63–65}

It has been shown that the metal atom may be both incorporated in the carbon network and accommodated in the cavity of fullerene. A further increase in the complexity of the objects investigated is also possible. Studies concerning the application of plasma chromatography for the identification of traces of vapours of drugs and explosives have been continued over many years. In the latest study on the detection of vapours of explosives by plasma chromatography, multiphoton laser ionisation was employed to generate the ions.⁶⁶ Studies on the drift of ions in gases in an electric field continue to develop vigorously.^{67–70}

Physicochemical aspects of the adsorption of sulfur dioxide by carbon adsorbents

S A Anurov

Contents

I. Introduction	663
II. General characteristics of the adsorption of SO ₂ by carbon adsorbents	664
III. The nature of the active centres for the adsorption of SO ₂ on carbon adsorbents	672
IV. Conclusion	674

Abstract. Literature data on the chemistry of the adsorption of sulfur dioxide on carbon adsorbents are surveyed and described systematically. The influence of various factors (the nature of the carbon matrix, the activation method, the chemistry of the adsorbent surfaces, temperature, the composition of the gas stream, etc.) on the sorption of SO₂ by activated carbons and semicokes is examined. The possible ways in which sulfur dioxide interacts with the carbon surface are discussed. The bibliography includes 128 references.

I. Introduction

The protection of the environment from pollution is one of the most important and complex socioecological problems. Nowadays approximately 2.5 billion tonnes of pollutants are discharged into the atmosphere annually.¹ The oxides of carbon, nitrogen, and sulfur, dust, ammonia, and various hydrocarbons are massive pollutants of air. Among them, sulfur dioxide, which on entering the atmosphere is capable of forming sulfuric acid, constitutes the greatest hazard. The acid residues in the form of rain or smoke have a negative effect on human health and the flora and fauna and cause the disintegration of constructional materials. Sulfur dioxide is formed mainly by the combustion of fuel in thermal electric power stations. Nonferrous metallurgy and to a lesser extent the sulfuric acid industry and the regeneration of sulfur by the Klaus method are sources from which large amounts of SO₂ are emitted.

In 1980, major plants, involving solely the combustion of fuel, discharged about 145 million tonnes of SO₂ into the atmosphere in countries of the European Economic Community. In most of the industrially developed countries, governments have adopted measures designed to achieve a sharp reduction of the discharge of sulfur dioxide. The 1989 EEC directive prescribes a reduction in the evolution of SO₂ in three stages and specifies the control periods during which these stages must be completed:² 1993, 1998, and 2003 (Table 1). This will make it possible not only to solve the most important ecological problem but also to economise on

Table 1. The volumes of SO₂ discharged into the atmosphere in EEC countries.

valuable sulfur-containing raw material for the production of sulfuric acid and other chemical products.

Depending on the conditions under which sulfur dioxide is evolved, different methods are applied to remove it from gas streams. One of the most rational and promising procedures involves processes whereby SO₂ is extracted by carbon adsorbents (activated carbons and semicokes), which make it possible to obtain sulfur dioxide in a form suitable for its subsequent use — as a gas enriched in SO₂, liquid sulfur dioxide, elemental sulfur, as well as sulfuric acid. A number of processes for the removal of SO₂ from effluent gases have been devised on the basis of carbon adsorbents.^{3–8} Almost all of them have passed successfully through pilot and experimental-industrial tests and some have been introduced into industry.

Although the carbon adsorption method is already used in industry, the question of the chemistry of the interaction of sulfur dioxide with a carbon surface still remains open. The growing interest in this problem can be accounted for not only by its scientific importance² but also by the necessity to formulate the principal requirements which must be met by carbon adsorbents capable of extracting effectively sulfur dioxide from gas streams.

There are fairly numerous literature data on the adsorption of sulfur dioxide by carbon materials, but there are virtually no surveys devoted to a critical analysis of the experimental data. The review which we published earlier⁹ as well as the attempt by

Loskutov and Khlopotov¹⁰ to survey the available data are incomplete and morally obsolete and do not reflect the entire depth of the problem. In the present review, we have attempted to fill the existing gap.

II. General characteristics of the adsorption of SO₂ by carbon adsorbents

1. The forms of the bond between SO₂ and the carbon surface

The study of the chemistry of the sorption of SO₂ by carbon adsorbents presupposes the elucidation of the nature of the stages involving the adsorption of sulfur dioxide from a complex gas mixture containing SO₂, O₂, N₂, CO₂, H₂O and other components with subsequent conversion of SO₂ into the final product as well as the establishment of the role played in these stages by individual components of the surfaces of the carbons and semicokes.

The transition of sulfur dioxide to the adsorbed state cannot occur immediately as a result of a single elementary step. The process involving the adsorption of a SO₂ molecule consists of a series of consecutive stages. The characteristics of the sorption process depend on the nature of the sorbent, the technological conditions of the sorption, and the chemical composition of the gas being purified. However, it is always possible to differentiate typical primary or secondary reactions occurring when the gas mixture passes through a layer of the carbon adsorbent.

The primary adsorption processes, occurring when SO₂, O₂, and water vapour are present simultaneously in the gas, can be described by the following equations:¹¹⁻²¹

Next there is a possibility of secondary transformations of the adsorbed components:

On real surfaces, particularly when activated carbons and semicokes are employed, a large set of sorbed forms usually arises. By no means all of them participate directly in the sorption of SO₂. Their influence on the adsorption of sulfur dioxide is manifested, in particular, by the fact that they alter in some way the properties of the carbon surface or simply block individual sections which constitute active centres for the adsorption of SO₂.

The hypothesis of the existence of two forms of bond between carbon dioxide and the carbon surface, each of which is characterised by a definite heat of adsorption and desorption temperature, has been put forward.²²⁻³¹ Analysis of the isobars for the desorption of SO₂ from carbon adsorbents leads to this conclusion. In virtually all cases, there are horizontal sections in the temperature range 100–150 °C (Fig. 1). At low temperatures (< 150 °C), the weakly bound sulfur dioxide, retained on the surface by van der Waals forces, is desorbed. The removal of this portion of SO₂ is achieved rapidly, in 10–20 min, which indicates a low energy of the bond between this form of sulfur dioxide and the surface (Fig. 2, curve 1). If the temperature is raised to 200 °C, the amount of desorbed SO₂ hardly increases.

Above 200 °C, the strongly bound form of SO₂, retained by chemical forces, is desorbed. The chemical nature of the interaction of this portion of SO₂ with the surface is also indicated by the rate of desorption: the process takes place slowly and is completed in 50–90 min (Fig. 2, curve 2).

This view on the forms of the bonds between sulfur dioxide and the carbon surface has been confirmed, on the one hand, by the heats of adsorption and, on the other, by the results of spectroscopic analysis. Thus the heat of adsorption of the part of sulfur dioxide weakly bound to activated carbons and semicokes is

Figure 1. Isobars for the desorption of sulfur dioxide from carbon adsorbents: (1) SKT; (2) AR-3; (3) AG-5; (4) IGI; (5) KAD; (6) BAU.

in all cases less than 50 kJ mol⁻¹.³²⁻³⁹ This makes it possible to claim that this component of the SO₂ is a physically adsorbed form, which is retained on the surface by dispersion forces. The presence of molecularly sorbed SO₂ on the surfaces of carbon adsorbents is indicated also by the existence of the 1350 cm⁻¹ absorption band in the IR spectra of virtually all the Russian and foreign carbon materials saturated by sulfur dioxide.^{40,41}

The strongly bound form of sulfur dioxide has a higher heat of adsorption (> 80 kJ mol⁻¹). In the IR spectra of activated carbons and semicokes, intense absorption bands in the region of 950, 1050, 1170, and 1250 cm⁻¹, associated with sulfur compounds having different degrees of oxidation,^{40,41} correspond to this form. This makes it possible to postulate the occurrence of chemisorption processes.

The ratio of these two forms is determined, on the one hand, by the nature of the adsorbents and, on the other, by the adsorption conditions. The maximum degree of adsorption of sulfur dioxide in the physical form, not exceeding 50% of the overall degree of adsorption, is attained when SO₂ is sorbed from a dry oxygen-free gas. In all cases, the physical adsorption of SO₂ takes place and then, as a result of the chemical reaction with the surface compounds, a particular form of chemisorbed sulfur dioxide arises.

As will be shown below, chemisorption represents the interaction of the adsorbed molecules of sulfur dioxide with basic

Figure 2. Kinetics of the desorption of sulfur dioxide from the activated carbon AR-3 at different temperatures (°C): (1) 150; (2) 350

oxygen-containing functional groups on the surfaces of carbon adsorbents, which results in the formation of an active complex of the type $C-SO_2$ with a definite chemical reactivity. If it is assumed that each chemisorbed SO_2 molecule occupies only one active centre, it is possible to estimate approximately the total number of primary active centres on the surfaces of adsorbents and the area occupied by the sulfur dioxide molecules. For example, the AR-3 activated carbon with a specific surface $S_{BET} = 730 \text{ m}^2 \text{ g}^{-1}$ can sorb sulfur dioxide from a dry oxygen-containing gas in the maximum amount $a = 125 \text{ mg g}^{-1}$, i.e. 2 mmol g^{-1} . The cross-sectional area of the SO_2 molecule (average diameter $3.38 \times 10^{-10} \text{ m}$) is $S = 8.967 \times 10^{-20} \text{ m}^2$. The overall area occupied by the chemisorbed SO_2 molecules is then

$$S_{\Sigma} = SaN_A = 8.967 \times 10^{-20} \times 2 \times 10^{-3} \times 6.02 \times 10^{23} = 108 \text{ m}^2,$$

which corresponds to 1/7 of the surface of the charcoal (N_A is the Avogadro number). The number of active centres per m^2 of the surface of the charcoal is

$$\frac{aN_A}{S_{BET}} = \frac{2 \times 10^{-3} \times 6.02 \times 10^{23}}{730} = 1.65 \times 10^{18}.$$

The factors which determine both the adsorption capacity of the adsorbents with respect to SO_2 as well as the process chemistry itself are of special interest from the technological point of view. Such factors may be the pore structure of the adsorbent, the quantitative and qualitative composition of the ash, and also the chemical nature of the surface. Furthermore, the process conditions may be of great importance: temperature, composition of the gas mixture, etc.

2. The influence of the pore structure of the adsorbents

One of the most important factors influencing the adsorption capacity of sorbents is known to be their pore structure.^{42,43} It is to be expected that, in the case of purely physical adsorption and when all the micropores of the adsorbent are accessible to the given adsorbate, the adsorption capacity of carbon materials is greater the greater their porosity. This hypothesis has been tested experimentally⁴⁴⁻⁴⁷ using as adsorbents both Russian and foreign industrial activated carbons of different origin and subjected to activation by different methods: SKT, AR-3, AG-3, AG-5, KAD-iodine, and BAU (Russia), Norit-2RL-Extra (the Netherlands), A-G (Poland), and experimental specimens of activated carbons IGI (Russia) and WJ-4 (Poland), the active coke K-14 (Poland), the semicokes PK-1 and PK-2 obtained by pyrolysis from brown coal from the Irsha-Borodinsk deposit, as

well as the German carbon black of the Corax LHS type. The parameters of the porous structures of some of the adsorbents investigated are presented in Table 2.

Fig. 3 presents experimental data on the static adsorption of sulfur dioxide from a dry oxygen-free mixture at 25 °C. Among the Russian adsorbents, the highest capacity with respect to SO_2 over the entire range of concentrations investigated is shown by the brown coal semicokes PK-1 and PK-2 (curves 1 and 2). The static adsorption capacities of these adsorbents at a sulfur dioxide concentration in the gas undergoing purification of 0.1 vol.%

are respectively 100 and 110 mg g⁻¹.³¹ Among the activated carbons, the highest adsorption capacities are shown by SKT and AR-3 specimens (45.4 and 67.2 mg g⁻¹ respectively),³¹ whilst among the foreign carbon materials the Polish activated coke K-14 has the highest adsorption capacity (50.3 mg g⁻¹).

However, in all cases the adsorption capacities of the carbon sorbents investigated with respect to sulfur dioxide were not correlated with the parameters of their porous structure (the total pore volume, the volumes of the mesopores and micropores, and the limiting volume of the adsorption space W_0) and also with the specific surface. Nevertheless, Grzybek et al.⁴⁷ attributed the increased adsorption capacity of the K-14 coke to the presence in the latter of a definite number of supermicropores. This variety of pores has not been observed in the remaining adsorbents.

Thus the impression is created that the porous structures of carbon adsorbents of different origin and subjected to activation by different methods do not by themselves exert a decisive influence on their adsorption capacities with respect to sulfur dioxide.

However, this conclusion cannot be extended to carbon adsorbents obtained from a single initial material and using a single activation method. Semicoke formation has been achieved^{48,49} by the thermal pyrolysis of brown coal from the Irsha-Borodinsk deposit at 500–800 °C without access of air. The adsorbents synthesised had specific surfaces ranging from 250 to 500 m² g⁻¹. Sulfur dioxide was adsorbed on the specimens obtained at 25 °C from a stream of nitrogen containing 1 vol.% of SO₂. The results are presented in Fig. 4, from which it follows that the adsorption capacity of the semicokes with respect to SO₂ is directly proportional to the specific surface area.

Figure 4. Dependence of the adsorption capacity of the semicoke PK-2 with respect to SO₂ on its specific surface area.

Thus the specific surface of the carbon adsorbents affects their adsorption capacity with respect to SO₂, but only when the same

initial material and the same chemical activation methods are used. An indirect confirmation of this conclusion has been obtained in a study of the influence of the chemistry of the surfaces of carbon materials on the adsorption of sulfur dioxide.^{50,51}

3. The influence of the qualitative and quantitative composition of the ash

The qualitative and quantitative compositions of the ash in activated carbons may be extremely varied and depend as a rule on the nature of the raw materials used to prepare the adsorbents and on the method for their activation. The ash content in the industrial adsorbents ranges from 1 mass % to 17 mass % and the principal components of the ash are compounds of alkali and alkaline earth metals, nickel, iron, manganese, copper, etc. (Table 3).^{52–55} Taking into account the high reactivity of sulfur dioxide, it was natural to expect that the presence of ash in carbon adsorbents exerts a definite influence on its adsorption. This was first noted in studies^{44,46,55–57} in which only the qualitative conclusion was reached that the adsorption capacities of carbons with respect to sulfur dioxide increase with decrease in the ash content. This question has been investigated in greatest detail in a recent study employing Merck and C.Erba activated carbons subjected to complete or partial deashing.⁵⁵ The ash content in the charcoals varied from 0.12 mass % to 3.28 mass %. Sulfur dioxide was adsorbed in the temperature range 130–170 °C from a gas mixture with a composition similar to flue gas containing 0.2 vol.% of SO₂. The thermal desorption of SO₂ from the saturated adsorbent was achieved at 360 °C in a stream of nitrogen.

Figure 5 shows how the ash content in the carbons investigated, the adsorption temperature, and the number of 'adsorption-desorption' cycles influence the adsorption capacities of the specimens with respect to sulfur dioxide. With increase in the duration of the operation (the number of cycles), the adsorption capacities fell in almost all the specimens. However, the capacities of the high-ash adsorbents fell, other conditions being equal, much faster than those of the low-ash specimens. Furthermore, the process was significantly influenced also by temperature: at 170 °C, a more marked decrease in adsorption capacity was observed than at 130 °C.

With increase in the duration of use, the parameters of the porous structures of the high-ash components were greatly impaired — in the first place, the number of micropores and mesopores diminished with a consequent decrease in the specific surface. For example, the specific surface of the C.Erba activated carbon containing 3.28 mass % of ash fell after 10 cycles by approximately 10% (from 835 to 750 m² g⁻¹). Similar but much less marked changes occurred in the low-ash specimens: during this period, S_{BET} for the C.Erba carbon subjected to preliminary deashing (down to 0.12 mass % of ash) diminished only from 850 to 835 m² g⁻¹, i.e. by 1.6%.

Activated carbons with an increased ash content are oxidised more readily than the low-ash carbon materials. Thus, in the

Table 3. Chemical composition of the ash in carbon adsorbents (mass %).

Figure 5. Dependence of the adsorption of sulfur dioxide ($\{\text{SO}_2\}_0 = 0.2 \text{ vol.}\%$) on the Merck and C.Erba activated carbons on the number of 'adsorption-desorption' cycles at 170 °C (a), 150 °C (b), and 130 °C (c) and for different ash contents (mass %): (1) 0.12; (2) 0.13; (3) 1.92; (4) 3.28.

thermal desorption stage at 360 °C, specimens containing more than 3 mass % of ash underwent appreciable oxidation accompanied by the partial surface combustion of the adsorbents and the evolution of CO_2 into the gas phase. The concentration of the bound oxygen in the high-ash carbons then increased by more than 20%, which naturally led to a sharp increase in the number of acid functional groups on their surface. A similar phenomenon is characteristic also of specimens containing 0.12 mass % to 0.13 mass % of ash, but, after similar 10 'adsorption-desorption' cycles, the concentration of oxygen on the surface increased by less than 2%. As will be shown below, the oxidised carbon should have *a priori* a lower adsorption capacity with respect to sulfur dioxide than the initial activated carbon.

Finally, the ash content itself in the low-ash adsorbents remains stable, like the sulfur content in the ash, during the above cycles, whereas in the high-ash specimens the above parameters increase from cycle to cycle. In all probability, this can be explained by the interaction of the adsorbed sulfur dioxide with individual components of the ash, which leads ultimately to the formation of stable compounds of the type of metal sulfates, which do not dissociate at the given temperatures and accumulate in the carbons.

Thus the presence of ash in the carbon adsorbents reduces the adsorption capacity with respect to SO_2 owing to the impairment of the parameters of the porous structure, a decrease in the specific surface, an increase in the degree of oxidation of the surface, and the conversion of the ash components to sulfates, which do not decompose in the course of regeneration and remain on the surface of the adsorbents, blocking the SO_2 specific adsorption centres.

4. The influence of the chemical nature of the adsorbent surfaces

The adsorption and catalytic properties of activated carbons and semicokes are to a large extent determined by the nature of their surfaces. Two types of surface functional groups of carbon materials are distinguished — acidic and basic.^{58–62} Four groups of oxides with different acidities have been identified in oxidised carbons — carboxylic, lactone, phenolic, and carbonyl groups.⁶³ It has been suggested that these groups do not constitute a separate phase but are fragments of a single complex group of

the type of phenolphthalein.⁶⁴ The question of the nature of the basic oxides on the carbon surface still remains open, although the hypotheses of the existence of chromene, quinonoid, benzo-pyrene, and pyrone structures have been put forward.^{65–68}

Numerous investigations have been directed recently to the elucidation of the problem of the influence of the chemistry of the surfaces of carbon adsorbents on the adsorption of sulfur dioxide.^{30, 31, 50, 51, 69–71} It was natural to suppose that basic surface groups are centres for the adsorption of SO_2 molecules. Treatment of the usual carbon adsorbents with air at high temperatures or with nitric acid is known to lead to the appearance of acid oxides on their surfaces and to a gradual disappearance of basic oxygen-containing groups.^{72, 73} The surfaces of the Merck⁵⁰ and AR-3 activated carbons and of the PK-2 semicokes⁵¹ have been modified in this particular way, which made it possible to synthesise adsorbents with different contents of basic functional groups. These specimens were in fact used to identify the centres for the specific adsorption of SO_2 .

A sample of the adsorbent (2–4 g) was saturated at 20 °C with sulfur dioxide in its mixture with nitrogen containing 0.3 vol.% of SO_2 until the attainment of a state of equilibrium. After equilibration, two-step thermal desorption of SO_2 from the carbon sorbents was carried out: initially the process was performed in a stream of nitrogen in the course of 3 h at 150 °C, after which the temperature was raised to 350 °C and the specimen

Figure 6. The influence of the concentration of basic functional groups (BFG) on the overall adsorption of sulfur dioxide on carbon adsorbents (a) and on the adsorption of SO_2 in the weakly bound (b) and strongly bound (c) forms at 25 °C ($\{\text{SO}_2\}_0 = 1 \text{ vol.}\%$): (1) SKT; (2) Merck; (3) semicoke PK-2.

was subjected to a stream of nitrogen for 2 h. The SO_2 evolved was trapped in a Drechsel bottle filled with a 5% H_2O_2 solution. The sulfuric acid formed was titrated with 0.05 M NaOH solution in the presence of blue bromophenol.

The influence of the concentration of basic functional groups on the adsorption of sulfur dioxide by various adsorbents can be seen from Fig. 6. The presence of basic oxygen-containing groups on the surfaces of carbon adsorbents has a significant effect on their overall adsorption capacity with respect to SO_2 : the amount of adsorbed SO_2 is proportional to their content (Fig. 6a). Thus the AR-3 activated carbon, which has a low adsorption capacity (about 40 mg g^{-1}), has at the same time few basic oxygen-containing groups ($0.090\text{--}0.127 \text{ mequiv. g}^{-1}$), while carbons with a high adsorption capacity ($140\text{--}160 \text{ mg g}^{-1}$) are also characterised by a high content of basic surface oxides ($0.500\text{--}0.660 \text{ mequiv. g}^{-1}$).

Figures 6b and 6c illustrate the influence the content of basic functional groups in the specimens on the adsorption of SO_2 in the weakly bound (a_1) and strongly bound (a_2) forms. The degree of adsorption of SO_2 in both forms increases in all cases with increase in the content of basic oxides. However, comparison of the relations in Figs 6b and 6c permits the conclusion that the adsorption of SO_2 in the strongly bound form is more sensitive to the presence of basic surface groups and hence to their acid-base characteristics than the adsorption in the weakly bound form.

Figure 7 shows how the concentration of basic oxides on the surface of Merck carbon affects the rate of sorption of SO_2 . It is seen from the figure that the adsorption capacities of specimens containing few basic surface groups are low and are determined mainly by physical adsorption — equilibration occurs rapidly (after 20–30 min). At a high concentration of basic functional groups, the sorption of SO_2 is slow and equilibrium is attained only after 60–90 min. This demonstrates yet again that in this

Figure 7. Kinetics of the adsorption of sulfur dioxide ($[\text{SO}_2]_0 = 0.3 \text{ vol. \%}$) on the activated Merck charcoal at 25°C and at the following concentrations of the basic functional groups (mequiv. g^{-1}): (1) 0.685; (2) 0.610; (3) 0.493; (4) 0.190; (5) 0.116; (6) 0.112.

case adsorption includes also chemisorption: almost half of the adsorbed dioxide corresponds to the strongly bound SO_2 .

Thus the concentration of basic functional groups on the surface of carbon materials determines their adsorption capacities with respect to SO_2 . It has a stronger influence on the adsorption of sulfur dioxide in the strongly bound form (heat of adsorption $> 80 \text{ kJ mol}^{-1}$). The amount of weakly bound sulfur dioxide (heat of adsorption $< 50 \text{ kJ mol}^{-1}$) is influenced mainly by the structural characteristics of the adsorbents and in particular by their specific surface areas.

5. The influence of temperature

The question of the influence of temperature on the equilibrium adsorption capacities of carbon adsorbents has been thoroughly investigated.^{20, 21, 39, 74–87} The isotherms illustrated in Fig. 8 correspond to the first type in Brunauer's classification.⁸⁸ A steep

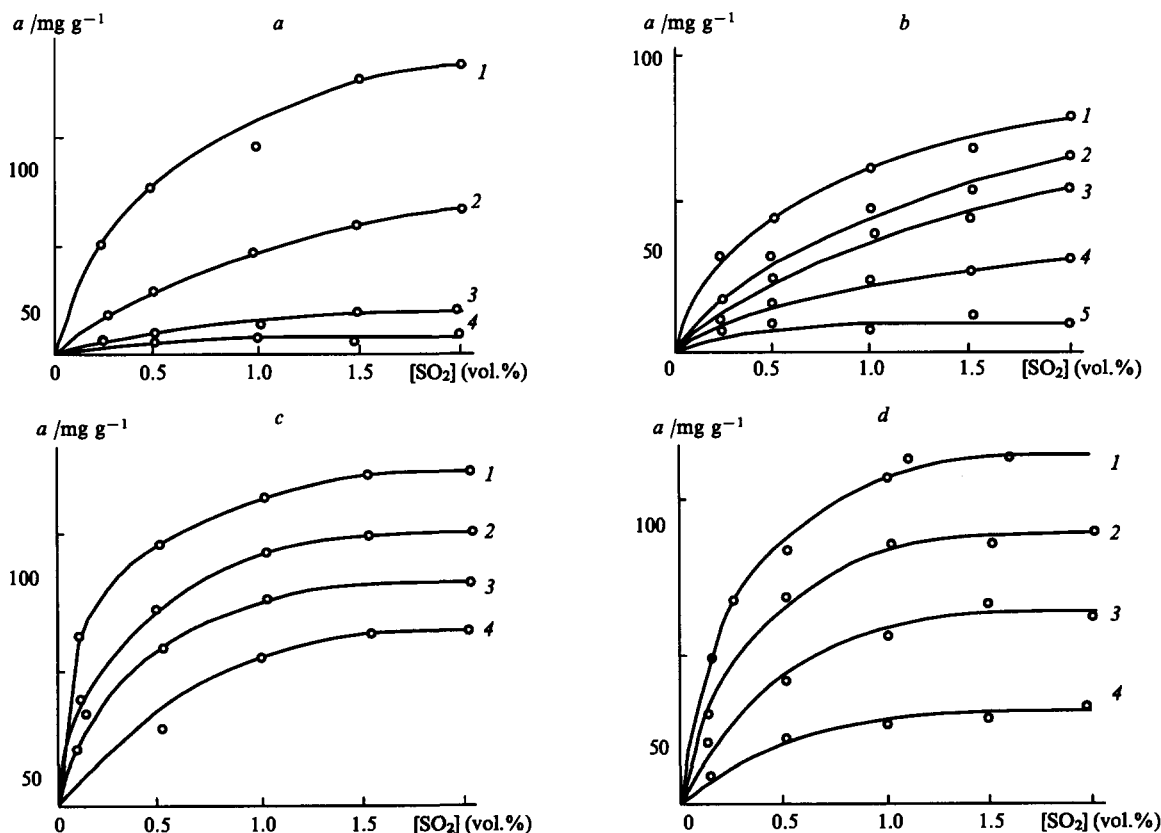

Figure 8. Isotherms for the adsorption of sulfur dioxide on the activated carbons SKT (a), BAU (b), AR-3 (c), and KAD (d) at different temperatures ($^\circ\text{C}$): (1) 25; (2) 50; (3) 100; (4) 150.

rise in the isotherms in the region of relatively low SO_2 concentrations is characteristic of almost all the specimens. This means that carbon adsorbents can serve as an effective means for the extensive removal of sulfur dioxide from gases and can be used to treat gases with a low SO_2 content. With increase in temperature from 20 to 150 °C, the capacities of the adsorbents considered fall by 50%–90% when the SO_2 content in the initial gas mixture is about 1 vol.%. However, at low concentrations of sulfur dioxide (up to 0.5%) the adsorption capacity depends little on temperature, which shows that they would not be useful for the purification of gases with low concentrations and at an elevated temperature.

An increase in temperature has a negative effect on the overall amount of adsorbed sulfur dioxide.^{22, 24} However, the fraction of SO_2 retained on the carbon surface by chemical forces, i.e. as a result of the interaction with basic sulfurous groups, increases approximately by 10% as the temperature rises from 20 to 100 °C, after which it remains constant (Fig. 9). At temperatures above 50 °C, the fraction of chemisorbed SO_2 is in all cases greater than the fraction of the sulfur dioxide bound to the carbon adsorbents by dispersion forces and reaches 55%–70%. Almost all the SO_2 adsorption isotherms on carbon adsorbents can be satisfactorily fitted by the Langmuir monomolecular adsorption equation⁸⁹ or by the Freundlich equation.⁹⁰

Figure 9. The influence of temperature on the ratio of the weakly and strongly bound forms of SO_2 on the surfaces of carbon adsorbents ($[\text{SO}_2]_0 = 1 \text{ vol.}\%$): (1) SKT; (2) AR-3; (3) PK-2.

6. The influence of oxygen

The influence of oxygen on the adsorption of sulfur dioxide was already noted in the very first studies devoted to the interaction of SO_2 with a carbon surface.^{11, 14, 25, 91–93} However, systematic investigations began only recently and this was associated with the appearance of the hypothesis that the chemical nature of the surfaces of the adsorbents affects SO_2 sorption process.

It was shown above that the sorption of SO_2 from an oxygen-free gas mixture includes chemisorption with formation of a stable chemical compound on the surface. The contribution of chemisorption, which does not exceed 45%–70% of the total amount of the sorbed sulfur dioxide, is determined by the acid–base properties of the adsorbent and the adsorption temperature. Evidently the presence of oxygen in the gas phase should promote chemisorption and in all probability the degree of conversion of SO_2 should increase in parallel with increasing O_2 concentration in the gas.

The adsorption of sulfur dioxide on activated carbons in the presence of oxygen has been investigated in detail in a number of studies.^{26, 29, 51, 84, 94–97, 126} Fig. 10 illustrates the influence of the concentration of the oxygen in the gas stream on the adsorption capacities of the SKT and AR-3 carbons with respect to SO_2 .^{57, 91} In all cases, sulfur dioxide is sorbed in the form of weakly bound (physically bound) and strongly bound (chemically bound) forms,

Figure 10. The influence of oxygen concentration in the gas mixture on the overall adsorption of sulfur dioxide by activated carbons (a) and on its physical (b) and chemical (c) adsorption at 25 °C ($[\text{SO}_2]_0 = 1 \text{ vol.}\%$) (1) AR-3; (2) SKT.

the fraction of the chemisorbed SO_2 depending to a large extent on the O_2 concentration in the gas and on the process temperature.

The adsorption capacities of sorbents increase with increasing O_2 content in the gas mixture. The degree of adsorption of SO_2 from a gas containing 10 vol.% of O_2 at 20 °C is approximately 30% greater than the degree of its adsorption from an oxygen-free gas mixture. A further increase in the O_2 content in the gas stream (above 10%) does not lead to an increase in the equilibrium adsorption capacity — virtually all the curves reach a plateau. In all cases, the increase in the adsorption capacities of carbons is caused exclusively by chemisorption processes. As can be seen from Fig. 10b, the amount of physically sorbed sulfur dioxide tends to decrease with increase in the O_2 concentration. As the adsorption temperature rises, this trend weakens and at 100–150 °C the quantity a_1 is almost independent of the O_2 concentration.

On the other hand, the amount of chemisorbed SO_2 increases with increase in the oxygen concentration in the gas mixture (Fig. 10c). At high temperatures, the $a_2 = f[\text{O}_2]$ relation is linear. At low temperatures, an increase in the oxygen content in the gas undergoing purification to above 10 vol.% hardly affects the adsorption of SO_2 in the strongly bound form.

According to a number of investigators,^{51, 96, 97, 126} such influence of the oxygen concentration on the adsorption of sulfur dioxide can be explained by the active sorption of oxygen by carbon adsorbents in the temperature range 0–150 °C. Physical adsorption of oxygen takes place initially, after which it is bound by chemical forces to the most active sections of the carbon's surface, i.e. it passes to the chemisorbed state. Basic oxides, which, as shown above, are centres for the specific adsorption of sulfur dioxide molecules, are formed as a result on the surfaces of activated carbons.^{67, 68, 98, 99} Thus the presence of oxygen in the gas mixture promotes an increase in the total number of SO_2 adsorption active sites, which naturally increases the adsorption capacities of activated carbons with respect to sulfur dioxide.

Table 4. Characteristics of the oxidised adsorbents.

Oxidation conditions		Content of oxygen-containing groups / mequiv. g ⁻¹				
temperature / °C	O ₂ concentration (vol. %)	carboxylic	lactone	phenolic	carbonyl	basic

In order to test this hypothesis, a series of experiments were performed in which the influence of the treatment of carbon adsorbents with oxygen on the chemical state of their surfaces was investigated.⁵¹ The initial adsorbents were maintained for 2 h in a stream of nitrogen at 350 °C, after which they were cooled to the required temperature, continuing the passage of dried N₂ through them. After this, a measured amount of oxygen such that its content was 3 vol.% or 5 vol.% was introduced into the gas stream. The subsequent treatment of the adsorbents by the oxygen-containing mixture was carried out for 2 h at 20 or 100 °C. The conditions of the preceding experiments, in which there was no sulfur dioxide in the gas, were thus virtually reproduced.

After the adsorption of oxygen, the chemical state of the adsorbent surface was studied by the neutralisation method.⁶³ The results presented in Table 4 show that the initial AR-3 carbon possesses predominantly basic groups. The SKT activated carbon contains in addition an appreciable number of acid groups, mainly lactone and carboxy-groups.

Treatment of the adsorbents with nitrogen at 350 °C with subsequent adsorption of oxygen altered in all cases the chemical nature of the carbon surface: the surface acidic groups of virtually all types vanished and the number of basic groups, which constitute some of the sulfur dioxide adsorption centres, increased. The increase in the concentration of basic groups naturally increases the adsorption capacities of the carbons with respect to SO₂.

7. The influence of water vapour

The influence of water vapour on the sorption of SO₂ by carbon adsorbents has been the subject of numerous investigations.^{13, 20, 22, 23, 26, 100} An appreciable increase in the adsorption capacities of activated carbons in the adsorption of SO₂ from moist gas streams has been noted. The views of many investigators on this phenomenon reduce to the postulate that water, which has a considerable chemical affinity for the chemisorbed SO₂, abstracts it from the carbon surface and transfers it to the liquid phase. Thus the blocked SO₂ sorption active centres are liberated and can again participate in the process.

In all probability, a weak point in the above hypothesis is that water is regarded merely as an 'abstracting agent'. Furthermore, studies of the influence of water on the sorption of SO₂ have almost always been performed in the presence of O₂, which naturally has a definite effect on the course of the process itself. A study was therefore made¹⁰¹ of the joint adsorption of sulfur dioxide and H₂O both in the absence of oxygen from the gas mixture and in its presence. The studies were performed by the thermal desorption method on SKT and AR-3 activated carbons and on the PK-2 semicoke. In another series of experiments, the

saturated adsorbents were washed with distilled water and the content of H₂SO₃ and H₂SO₄ was then determined by titration.

a. The influence of water vapour on the adsorption of SO₂ from an oxygen-free mixture

Fig. 11 shows how water vapour influences the adsorption capacity of the SKT activated carbons.¹⁰¹ The ratio of the contributions of physical adsorption and chemisorption in the sorption of SO₂ from a moist oxygen-free gas is determined not only by the nature of the adsorbent and the process temperature⁹⁵ but also by the water vapour content of the gas being purified. The appreciable increase in the adsorption capacity with increase in the H₂O content is due to the increase in the amount of chemisorbed sulfur dioxide (Fig. 11, curve 3), since the physical adsorption of SO₂ (*a*₁) tends to diminish over the entire range of water vapour concentrations (curve 2). This means that the presence of water on the surfaces of carbon adsorbents promotes the appearance of new centres for the chemical adsorption of SO₂.

Figure 11. Dependence of the adsorption of sulfur dioxide from an oxygen-free mixture on the activated carbon SKT on the concentration of water vapour adsorption in the gas at 50 °C: (1) overall adsorption; (2) physical adsorption; (3) chemisorption.

The results of the chemical analysis of aqueous extracts, obtained as a result of the washing of saturated adsorbents with water, indicate the presence of sulfuric and sulfurous acids (Fig. 12). The amount of sulfur dioxide washed off the adsorbent in the form of sulfuric acid increases slightly with increase in the concentration of water vapour in the gas. On the other hand, the content of sulfurous acid increases to a much greater extent. This permits the conclusion that in the presence of water vapour the

Figure 12. The influence of the concentration of water vapour on the composition of the aqueous extract from the carbon SKT saturated with sulfur dioxide at 50 °C: (1) sulfurous acid; (2) sulfuric acid.

degree of oxidation of sulfur dioxide to the trioxide does not increase. In all probability, the increase in the amount of chemisorbed SO_2 and hence the overall increase in the adsorption capacity of the carbons are induced by other chemical causes, which have a bearing on the presence of water on the surfaces of the adsorbents.

The mechanism of the adsorption of water vapour on activated carbons has been examined in detail.^{58, 102, 103} It has been established that the adsorption capacity of a carbon in relation to water vapour depends greatly on the number of chemically bound oxygen atoms present on the surface as part of the composition of acidic surface oxides, which play the role of primary adsorption centres for water molecules. At low equilibrium pressures, adsorption is ensured mainly by the formation of hydrogen bonds between the water molecules and the primary adsorption centres. The adsorbed water molecules are secondary adsorption centres, which may include other molecules as a result of the formation of hydrogen bonds. With increase in pressure, the probability of adsorption increases as a consequence of the increase in the number of secondary adsorption centres, i.e. the adsorbed molecules themselves.

Bearing in mind the ability of sulfur atoms to form hydrogen bonds,¹²⁷ one may postulate that in the case under consideration the preliminary adsorption of water on the carbon surface results in the appearance of a second variety of adsorption centre, namely adsorbed H_2O molecules, which may retain sulfur dioxide with the aid of hydrogen bonds. Thus, in the presence of water vapour in the gas phase, there are two types of active centres for SO_2 molecules on the carbon adsorbents: basic surface groups^{30, 50, 51} and the protons of the sorbed water molecules, capable of forming hydrogen bonds with sulfur dioxide.^{23, 26} It is natural to postulate that an increase in the concentration of adsorbed water entails also an increase in the number of centres of the second type, which means an increase also in the total number of SO_2 adsorption centres. As a result, the adsorption capacities of the carbon adsorbents with respect to sulfur dioxide increase when the latter is sorbed from a moist gas.

However, one must not forget the possibility of the interaction of some of the sorbed H_2O molecules with the sulfur dioxide chemisorbed on the basic surface centres, resulting in the formation of sulfuric acid.¹¹ The molecules of the latter do not in all probability form strong bonds with the active centres and may be displaced to other sections of the adsorbent surface by virtue of diffusion, liberating the active centres for further oxidation of SO_2 . A slight increase in the amount of sulfuric acid formed in the adsorption process with increase in the H_2O concentration (Fig. 12, curve 1) can be explained by the fact that each active centre of the first type participates repeatedly in the oxidation process.

The sulfur dioxide bound by hydrogen bonds to the adsorbed water is not in the oxidised state and may be washed off the

surfaces of the adsorbents with water in the form of sulfurous acid. This accounts for the marked increase in the H_2SO_3 concentration with increase in the concentration of H_2O (Fig. 12, curve 2). On the other hand, under thermal desorption conditions, SO_2 may be removed from the surface only at temperatures in excess of 200 °C. This is in fact the reason why the quantity a_2 increases with increase in the concentration of H_2O (Fig. 11, curve 3).

In conclusion, we may note that the influence of temperature on the adsorption capacities of carbon adsorbents is less marked than the influence of the concentration of water vapour. This can be explained by the partial compensation for the decrease in adsorption capacity with increase in temperature by the increase in the content of water vapour in the gas stream.

b. The influence of water vapour on the adsorption of SO_2 from a mixture containing oxygen

Analysis of literature data shows that the adsorption capacities of carbon adsorbents in the sorption of SO_2 from a gas containing simultaneously oxygen and water vapour are higher than in all the preceding cases. Fig. 13 shows how the concentration of water vapour influences the adsorption capacity of the AR-3 activated carbon and its components (a_1 and a_2) at 50 °C and a constant oxygen concentration of 5 vol.%.¹⁰¹ With increase in the water vapour content in the gas being purified, the capacity of the adsorbent with respect to SO_2 also increases over the entire range of H_2O concentrations solely as a result of the chemisorption of sulfur dioxide (a_2). The fraction of SO_2 bound to the carbon surface by physical forces diminishes steadily.

Figure 13. Dependence of the adsorption of sulfur dioxide from a gas containing 5 vol.% O_2 on the carbon AR-3 on the concentration of water vapour at 50 °C: (1) overall adsorption; (2) physical adsorption; (3) chemisorption.

According to the results of the chemical analysis of the solutions formed when the saturated adsorbents are washed with water, the liquid phase contains sulfurous and sulfuric acids (Fig. 14). The fraction of sulfurous acid in the wash waters ranges from 15% to 45% depending on the system parameters and increases with increasing concentration of water vapour.¹²⁸ On the other hand, the concentration of H_2O in the gas being purified hardly affects the content of sulfuric acid. In all probability, the high H_2SO_3 content in the wash waters can be accounted for by a deficiency of oxygen in the system, which prevents more complete oxidation of sulfur dioxide.

The results of the study of the influence of the oxygen concentration on the sorption of sulfur dioxide from a moist gas are presented in Fig. 15. They show that the amount of the oxidised product, washed off the adsorbents in the form of H_2SO_4 , increases with increase in the O_2 content. At an oxygen concentration of 10 vol.% in the gas being purified, virtually complete oxidation of SO_2 is already attained: only sulfuric acid is present in the solution formed.

Figure 14. The influence of the concentration of water vapour on the composition of the aqueous extract from the carbon AR-3 saturated with sulfur dioxide at 50 °C in a gas containing 5 vol. % of O₂ (1) sulfurous acid; (2) sulfuric acid.

As in all the previous cases, an increase in temperature has a negative effect on the adsorption capacity, although this is manifested to a much smaller extent because the chemical component of the adsorption process is less subject to the influence of temperature.

Figure 15. The influence of the concentration of oxygen on the composition of the aqueous extract from the carbon SKT saturated with sulfur dioxide at 50 °C in a gas containing 10 vol. % of H₂O: (1) sulfurous acid; (2) sulfuric acid.

III. The nature of the active centres for the adsorption of SO₂ on carbon adsorbents

1. Infrared spectroscopic study of the interaction of SO₂ with carbon adsorbents

IR spectroscopy is one of the few methods of physicochemical analysis which make it possible to assess quantitatively the nature of the processes occurring in the sorption of sulfur dioxide by optically opaque bodies such as carbon adsorbents, to discover the possible reactions between the components of the gas mixture, and also to identify the final products and the sites of the specific adsorption of SO₂ molecules.

Fig. 16 presents typical IR spectra of the Russian industrial activated carbons SKT, AR-3, and BAU, as well as a cellulose-based carbon adsorbent after their evacuation to a residual pressure of 10⁻⁴ mm Hg at 350 °C for 2 h.^{40,41,104-107} In virtually all cases, weak absorption bands at 1750 and 1710 cm⁻¹ and also moderately intense bands at 900 and 725 cm⁻¹ are observed in the spectra of the activated carbons. Evidently the 1750 and 1710 cm⁻¹ bands may be assigned to the stretching vibrations of the carbonyl groups.¹⁰⁸

The 1600 cm⁻¹ band is attributed to the C=O structures, in which the bond length is greater and the bond multiplicity is smaller than in the carbonyl groups absorbing at higher frequencies.¹⁰⁹ Similar structures are formed with participation of the π

Figure 16. IR spectra of activated carbon evacuated to a residual pressure of 10⁻⁴ mm Hg at 350 °C: (1) AR-3; (2) SKT; (3) BAU; (4) KAD-iodine; (5) gaseous SO₂.

electrons of condensed aromatic systems. In all probability, they can be assigned to the radical-ion structures C=O[•], which are intermediate forms on the way to the formation of carbonyl groups strongly bound to the carbon surface.^{104,106,107,110}

The absorption bands in the range 1340–1480 cm⁻¹ are characteristic of the deformation vibrations of the COOH groups.¹¹¹ The assignment of the bands in the range 1110–1130 cm⁻¹ gives rise to difficulties. The band with a frequency of about 1120 cm⁻¹, observed in the spectrum of oxidised carbon black and graphite oxide, has been assigned¹¹²⁻¹¹⁴ to the stretching vibrations of the C–OH bond, while the similar band (1065 cm⁻¹) in the spectrum of graphite oxide has been assigned¹¹⁵ to the stretching vibrations of the C–OH enolic group. Finally, the absorption in the range 1000–1180 cm⁻¹ is characteristic of the stretching vibrations of the C–O bond.¹⁰⁸

Cooling of the adsorbents in a stream of air after preliminary evacuation at 350 °C leads to the appearance of intense absorption bands at 1800–1830, 1750–1770, 900, 725, and 1230–1250 cm⁻¹ in the IR spectra of the specimens (Fig. 17, curve 2). The presence of doubled bands (at 1830 and 1770 cm⁻¹) in the region of the deformation vibrations of the carbonyl groups C=O and also of intense bands at 900 and 725 cm⁻¹ indicates the

Figure 17. IR spectra of the activated carbon BAU evacuated to a residual pressure of 10⁻⁴ mm Hg at 350 °C (1) and subjected after this procedure to cooling in air to 20 °C (2).

dehydration of the carboxy-groups and the formation of cyclic aromatic systems with participation of π electrons.¹⁰⁶

The intense 1250 cm^{-1} absorption band is characteristic of the vibrations of the C—O—C groups. This means that the most probable form of the basic surface oxides, formed on oxidation of the carbon in a stream of air, comprises unsaturated lactones, in particular α - and γ -pyrones or their derivatives:

Thus IR spectroscopic analysis confirms indirectly the existence on the surface of carbon adsorbents, in an anion-exchange form, of the pyrone structures predicted by Voll and Boehm.^{67,68}

Analysis of the IR spectra of activated charcoals and semicokes saturated by sulfur dioxide from complex gas mixtures permits the conclusion that the adsorption of SO_2 on various carbon adsorbents proceeds via a single mechanism. The physical adsorption of sulfur dioxide, which does not require the presence on the surface of any kind of active centre, is accompanied by the appearance of absorption bands within the comparatively narrow range $1330\text{--}1360\text{ cm}^{-1}$ and at 1150 cm^{-1} (Fig. 18).

Figure 18. IR spectra of the activated carbon AR-3: (1) after evacuation to 10^{-4} mm Hg at 350°C ; (2) after saturation with sulfur dioxide at 50°C ; (3) after evacuation at 20°C ; (4) after saturation with sulfur dioxide at 100°C ; (5) after preliminary adsorption of SO_2 at 20°C and subsequent saturation with oxygen; (6) after preliminary adsorption SO_2 and O_2 at 20°C and subsequent saturation with water vapour.

Another portion of the sulfur dioxide is chemisorbed on particular active centres. The bathochromic shift of the 1740 cm^{-1} band, which is characteristic of the stretching vibrations of the carbonyl group, after the adsorption of SO_2 (to 1700 cm^{-1}) and also the fact that the C=O bond remains perturbed also after the removal of the physically sorbed SO_2 indicate that the surface carbonyl groups, playing the role of an electron donor, actually participate in the chemisorption of sulfur dioxide.

One cannot rule out also the interaction of SO_2 with the surface OH groups. Since the change in the stretching vibration frequency of the OH groups of the adsorbents persists also after the removal from the surface of weakly bound sulfur dioxide, one may postulate that SO_2 does not form hydrogen bonds with these groups. At the same time, the positions of the absorption bands of the OH groups and their appreciable half-width indicate the existence of a hydrogen bond. The only explanation of this may be the interaction of the adsorbed SO_2 with the surface hydroxy-groups involving the formation of bisulfites. However, judging

from the intensity of the 1075 cm^{-1} band in the spectrum, the contribution of such interaction is low.

After the adsorption of sulfur dioxide in the presence of water vapour, a broad intense band at 3600 cm^{-1} as well as a moderately intense band in the range $1045\text{--}1073\text{ cm}^{-1}$ appear in the IR spectra of virtually all the adsorbents. These refer respectively to the vibrations of the OH groups of the adsorbed water and of the S—O bisulfites. It is natural to postulate that sulfurous acid is formed on the surfaces of the adsorbents as a result of the interaction of sulfur dioxide with the adsorbed water molecules.

The adsorption of the molecular form of SO_2 may not involve solely the formation of a physical bond with the surface. There is also a possibility of strong adsorption, observed for example, on the SKT and BAU activated carbons. It has been noted¹¹⁶ that SO_2 is capable of forming molecular complexes with pyridine, triethanolamine, and triethylamine, in which sulfur dioxide exhibits the properties of an electron pair acceptor. The absorption bands corresponding to the S—O vibrations, undergo a bathochromic shift in the spectra of such complexes compared with the absorption bands of the free molecule. The surface O^{2-} ions may serve as electron donors in the formation of a complex with the adsorbed SO_2 .^{117,118}

The presence of oxygen in the gas leads to the oxidation of the chemisorbed SO_2 with formation of sulfate ions:

The spectrum of the SO_4^{2-} ions depends to a large extent on the presence of water vapour in the system.

Thus the study of the IR spectra has shown that the strength and nature of the interaction of sulfur dioxide with the surfaces of carbon adsorbents are determined both by the chemical nature of the latter and the composition of the gas mixture. Part of the SO_2 is then sorbed as a result of dispersion (physical) forces in the form of molecularly adsorbed sulfur dioxide. This process, which is not related to the presence on the surface of particular active centres, is accompanied by the appearance of absorption bands in the comparatively narrow range $1330\text{--}1360$ and at 1150 cm^{-1} .

Another portion of sulfur dioxide is bound to the surface by stronger (chemical) forces. This chemisorbed SO_2 is converted on the surfaces of activated carbons and semicokes into sulfur compounds with different degrees of oxidation.

2. The chemistry of the adsorption of SO_2 from a dry oxygen-free mixture

It was shown above that the amount of sulfur dioxide chemisorbed from a dry gas is directly proportional to the concentration of basic functional groups on the carbon surface. At the same time, spectroscopic data indicate unambiguously the existence of pyrone structures on carbons having basic properties. One can therefore postulate that the centres for the specific sorption of SO_2 molecules from a dry oxygen-free mixture are basic oxygen complexes or more precisely, the carbonyl groups of pyrone derivatives. By virtue of the presence of the electron lone pair on the oxygen atom, the carbonyl group possesses weakly basic properties and interacts chemically with sulfur dioxide, which exhibits in this instance the properties of a Lewis acid:

The slight change in the vibration frequency of the OH groups on virtually all activated carbons and semicokes after the removal of the physically adsorbed SO_2 indicates the involvement in the process of surface hydroxy-groups:

The formation of sulfite compounds on the surfaces of carbon adsorbents has been confirmed also by the existence of absorption bands at 1070, 1025, and 950 cm^{-1} in the IR spectra of all the adsorbents.

Thus the strongly bound form of SO_2 may be regarded as the intermediate sulfite compound $\text{C}-\text{OSO}_2$, in which the sulfur retains the +4 oxidation state. The amount of heat evolved in this process should not be large. Indeed, the isosteric heats of adsorption are 25–63 kJ mol^{-1} depending on the type of adsorbent. At low temperatures, the final product of the adsorption-catalytic process remains on the adsorbent surface and blocks the active sites. At fairly high temperatures, the chemisorbed SO_2 passes to the gas phase in the form of sulfur dioxide.

When the carbon adsorbent saturated with sulfur dioxide comes into contact with water, the chemisorbed SO_2 is abstracted from the surface in the form of sulfuric acid:

The process proceeds at room temperature and is accompanied by the transfer of electrons from the sulfur atom to the oxygen atoms and the reduction of the surfaces of the adsorbents with formation of electronic defects of the type of oxygen vacancies.

3. The chemistry of the adsorption of SO_2 from a dry oxygen-containing mixture

If O_2 is present in the gas phase during the adsorption of sulfur dioxide by carbon adsorbents, then not only chemically but also physically adsorbed oxygen participates in the oxidation of SO_2 . Detailed study of the catalytic properties of carbon in the oxidation reactions of various substances led to the conclusion that the process proceeds via a radical-chain mechanism.^{119–123} In conformity with this hypothesis, oxygen radical-ions are formed in the first stage of the process as a result of the transfer of electrons from heteroatoms via conjugated bonds to physically sorbed O_2 :

The next oxidation stage determines the order of the reaction with respect to oxygen (0.5) and the overall rate of the process:

The sources of electrons for the formation of superoxides are structural nitrogen atoms and the CN groups, which enter the lattice of the carbon adsorbents, as well as variable-valence metals (M) introduced into the adsorbents to activate and modify them:^{121, 124, 125}

The oxygen radical-ion structures ($\text{O}^{\cdot-}$ and $\text{O}_2^{\cdot-}$) the existence of which on the surfaces of activated carbons and semicokes is confirmed by the presence of an intense 1600 cm^{-1} absorption band in the IR spectra, actually initiate the conversion of SO_2 into SO_3 :

etc.

Another part of SO_2 enters into reactions (1) and (2) with the basic surface oxides of the carbon adsorbents, namely with the carbonyl groups of the pyrone structures and also with the surface hydroxyls, which is indicated by the presence of the 1075 and 1025 cm^{-1} absorption bands characteristic of sulfides in the IR spectra of virtually all activated carbons saturated with sulfur dioxide in the presence of O_2 . Furthermore, after the desorption of the weakly bound SO_2 , a change in the OH group vibration frequencies is observed in the adsorbents.

Thus the centres for the adsorption of sulfur dioxide from dry oxygen-containing mixtures are the oxygen radical-ions $\text{O}^{\cdot-}$ and $\text{O}_2^{\cdot-}$ as well as the carboxy- and hydroxy-groups of the pyrone structures.

4. The chemistry of the adsorption of SO_2 from a moist oxygen-containing mixture

If the gas streams contain water vapour and oxygen, then, apart from the centres in which reactions (1) and (2) as well as (7) and (8) occur, additional centres for the adsorption of sulfur dioxide appear on the surfaces of carbon adsorbents. The latter are the protons of the preadsorbed H_2O molecules.^{23, 26} The appreciable increase in the adsorption capacities of carbons and semicokes under these conditions is due to the formation of hydrogen bonds between SO_2 and the water molecules sorbed beforehand. Sulfurous acid appears on the surfaces of the adsorbents as a result:

However, the role of water vapour does not reduce solely to the formation of new active centres for the adsorption of sulfur dioxide. In all probability, some of the H_2O molecules react during adsorption on the carbon surface with the chemisorbed sulfur dioxide (in the form of either SO_3 or $\text{SO}_3^{\cdot-}$), forming sulfurous and sulfuric acids. The acids do not form a strong bond with the active centres and are displaced by diffusion to other sections of the surfaces of the adsorbents, liberating the active centres for further chemisorption of new SO_2 molecules. Thus each active centre can participate repeatedly in the adsorption process.

In the presence of oxygen, sulfurous acid is oxidised to sulfuric acid, i.e.

which is in fact the final product of the adsorption of sulfur dioxide on carbon adsorbents. The presence of H_2SO_4 on the surface has also been confirmed by IR spectroscopic analysis (there are absorption bands at 1160 and 1240 cm^{-1} in the IR spectrum).

IV. Conclusion

Summarising, one may say that the adsorption of sulfur dioxide on carbon adsorbents from gas mixtures of different composition is an adsorption-catalytic process, which consists of several stages and leads to the formation of compounds of sulfur in different oxidation states. The adsorption of sulfur dioxide occurs only on adsorbents in an anion-exchange form; oxidised carbon hardly adsorbs SO_2 .

Two types of bonds between sulfur dioxide and the carbon surface are distinguished — a weak bond which is characterised by a heat of absorption $< 50 \text{ kJ mol}^{-1}$ and may be ruptured at a temperature $< 150^\circ\text{C}$, and a strong bond (heat of adsorption $> 80 \text{ kJ mol}^{-1}$) ruptured at temperatures above 200°C . The weak bond is due to van der Waals forces and corresponds to the physical adsorption of SO_2 . The strong bond is formed as a result of chemical interaction between sulfur dioxide and the surface compounds and corresponds to the chemisorption of SO_2 . In the latter case, the most likely centres for the specific adsorption of sulfur dioxide are surface carbonyl and hydroxy-groups of the pyrone structures and their derivatives, which have basic properties, the oxygen radical-ions (O^- and O_2^-), as well as the protons of the adsorbed water molecules.

The degree of oxidation of the adsorbed SO_2 depends on the nature of the adsorbent, the process temperature, and also the presence of O_2 in the gas mixture. Sulfur dioxide is partly oxidised to SO_3 also when SO_2 is sorbed from a dry oxygen-free gas. This is ensured by the oxygen weakly bound the carbon surface and forming part of the composition of the basic surface functional groups. The presence of water vapour in the gas phase promotes an increase in the adsorption capacity as a result of the formation of a strong hydrogen bond between the molecules of the pre-adsorbed water and SO_2 , but the amount of oxidised sulfur dioxide does not increase under these conditions.

The removal of the reaction products from the adsorbent surfaces can be achieved by heating the adsorbents in a stream of an inert gas or by washing with water. The liberated active centres can again participate in the process.

The carbon adsorbents employed in the processes involving the removal of sulfur dioxide from industrial and ventilation gases must satisfy the following principal requirements:

- they must have an extensive pore structure;
- they must exist in the anion-exchange form, i.e. they must possess basic properties;
- they must contain an appreciable amount of structural nitrogen;
- as far as possible, they must include in their composition catalysts for the oxidation of sulfur dioxide to the trioxide.

Abstracts. Data concerning the experimental method for the estimation of the mechanical workability of heat-resistant polymers, based on relaxation measurements, as well as concerning procedures for the fitting of stress relaxation and creep curves with the aid of new memory functions are surveyed. The influence of the chemical structures of various heat-resistant polymers (aromatic polyethers and polyamides, polyimides, polybenzoxazoles, polyoxadiazoles, etc.) on their relaxation behaviour is analysed in detail. Attention is concentrated on the relaxation transitions manifested in the glassy state. The mechanism of the deformation and relaxation in heat-resistant polymers, investigated with the aid of the positron annihilation method, is described. The relaxation behaviour of heat-resistant aromatic polymers down to the temperature of liquid helium is considered. Attention is drawn to the relaxation behaviour. The bibliography includes 167 references.

I. Introduction

Studies on the synthesis and properties of heat-resistant polymers began about 40 years ago and have continued fairly vigorously to the present day. Naturally, in the first investigations attention was concentrated on the limiting strength and deformation properties. However, it soon became evident that, in terms of the strength and deformation on rupture, it is impossible to infer objectively the mechanical workability of the materials. Indeed, a polymeric material is never used when subjected to near breaking loads; even under extreme conditions, the polymers can always realistically operate provided that they are subjected to loads and deformations significantly below the limiting values. Naturally, whatever the load and deformation, relaxation processes develop,

the essential feature of which is that at a constant deformation the stress is not constant, as for ideally elastic materials, but relaxes, i.e. diminishes with time. Accordingly, a creep process develops — an increase in deformation with time. The kinetic data for the relaxation processes depend on temperature, i.e. both are manifested whatever the type of load and not only for a constant deformation and load. These processes in fact determine the true mechanical workability of the polymers. The study of relaxation transitions by the dynamic mechanical analysis is particularly important. Such transitions are associated with the freeing of the molecular mobility of different kinetic units, which play an enormous role in the establishment of the properties of the polymer. The study of the mechanism of these transitions and of the influence on the latter by the chemical structure of the heat-resistant polymer has attracted the attention of investigators.

Evidently the above relaxation processes and transitions are important also for composite materials and blends. Significant attention has been devoted in recent years to the mechanism of the relaxation and deformation processes in heat-resistant polymers subjected to a large deformation. The application of positron diagnostic methods (positron annihilation) directly in the relaxation and deformation process made it possible to obtain new data on the changes in the microporous structure of the material. Many questions are associated with the analysis of the nonlinear mechanical behaviour of heat-resistant polymers when the parameters of the relaxation process depend on time and are not constant. Finally, one of the most interesting phenomena, observed in the study of heat-resistant aromatic polymers, consists in the manifestation by the latter of appreciable deformations at low temperatures, down to the temperature of liquid helium, relaxation processes also developing at these temperatures.

All the above questions are dealt with in the present review.

It is noteworthy that the available data on this field were reviewed in 1975 and 1981.^{1,2} New heat-resistant aromatic polymers as well as new methods for the investigation of their relaxation properties have now appeared. The results of the study of the relaxation properties of these polymers using new methods constitute the main content of the review.

II. The influence of the chemical structure of heat-resistant polymers on their mechanical workability estimated from relaxation measurements

There are several approaches to the estimation of the mechanical workability of polymeric materials. According to one of them,³ a generalised characteristic which makes it possible to take into account the relaxation processes and the viscoelastic behaviour of polymers, is the temperature dependence of the critical stresses, which limits the region of the mechanical workability of the material. A method has been proposed for the estimation of the critical stresses in solid materials^{3,4} the essential feature is as follows. A series of relaxation curves for different deformations ϵ_0 are plotted at a constant temperature. Fig. 1 presents as an example curves of this kind for the polyimide PM-69

With increase in the deformation ϵ_0 , the stress relaxation curves shift upwards to the region of higher stresses.⁴ However, on further increase in ϵ_0 , the stress relaxation is appreciably accelerated and the relaxation curves begin to shift towards lower stresses (Fig. 1, curve 7). Under these conditions, an appreciable decrease in stress is observed over the entire temperature range for the polyimide only in the initial period of the relaxation process and the decrease in stress intensifies only as ϵ_0 approaches a value close to the yield strength.

Figure 1. Stress relaxation for polyimide at 220 °C and different initial deformations (%): (1) 2; (2) 3; (3) 4; (4) 6; (5) 8; (6) 10; (7) 12.

After this isochronous dependences of the relaxing stress σ on ϵ_0 are plotted, each of which corresponds to a definite duration of the relaxation process. The isochronous relations as a rule have a maximum, the stress corresponding to the latter being referred to as critical and being designated by σ_c . By carrying out experiments at different temperatures T , one obtains isochronous relations between σ_c and T characterising the possibility of the retention in the material of the maximum stresses σ_c at a specified time t_r .

The isochronous relations for the relaxing stresses in the polyimide PM-69 at different temperatures and for a duration of the stress relaxation of 180 min are presented in Fig. 2. The maximum corresponding to σ_c arises for deformations ϵ_c ranging from 11.2% at 20 °C to 3.3% at 320 °C. This shows that the polyimide is capable of being used over a wide range of deformations without attaining mechanical softening. The isochronous relations for the polyimide have virtually no linear sections, which indicates the nonlinearity of the mechanical properties of the polyimide.

In order to estimate the mechanical workability of the polymeric material from the σ - ϵ_0 isochronous relations obtained

Figure 2. Isochronous variations of the relaxing stress for a process duration of 180 min at different temperatures (°C): (1) 20; (2) 70; (3) 120; (4) 170; (5) 220; (6) 270; (7) 320.

at different temperatures, the temperature dependences of the critical stresses are plotted.

The temperature dependences of the critical stresses for the polyimide PM-69 and polybenzoxazole (PBO) are presented in Fig. 3.

are presented in Fig. 3. The region bounded by these curves and the coordinate axes defines the conditions under which the polymer may be used without softening and without being disrupted (the region of mechanical workability). Having compared the curves in Fig. 3, we may note that the critical stresses and temperatures for the polyimide are higher over the entire temperature range than for PBO.

Figure 3. Temperature variations of the critical stresses in PBO (curve 1) and polyimide (curve 2) for a relaxation process duration of 180 min.

In the method for the estimation of mechanical workability,³ the temperature dependences of the critical stresses, obtained for different durations of the relaxation process, are replotted as dependences of the critical stress on the duration of relaxation t_r . The duration of the retention of the critical stress under stress relaxation conditions is a kinetic characteristic of the mechanical workability of the polymer.

The dependences of $\lg t_r$ on $\lg \sigma_c$ for PBO at different temperatures are presented in Fig. 4. Similar dependences have been obtained for the polyimide⁴ and other heat-resistant polymers. In terms of logarithmic coordinates, the $\lg t_r$ - $\lg \sigma_c$ relations for PBO are linear up to 170 °C, whereas at 220 °C a linear section is hardly observed. A linear $\lg t_r$ - $\lg \sigma_c$ relation is as a rule characteristic of other heat-resistant polymers over a very wide temperature range.

Figure 4. Dependence of the duration of the relaxation process t_r for PBO on the critical stresses at different temperatures (°C): (1) 20; (2) 70; (3) 120; (4) 170; (5) 220.

The slope of this relation, $\tan \alpha$, is a kinetic characteristic of the rate of the relaxation process along the linear sections of the $\lg t_r - \lg \sigma_c$ relations. The temperature dependences of $\tan \alpha$ for PBO and PM-69, obtained from experiments⁴ on the stress relaxation under compression conditions, are presented in Fig. 5. Evidently, the temperature dependences of $\tan \alpha$ are not identical for all the polymers.

Figure 5. Temperature variation of $\tan \alpha$ for the polyimide PM-69 (curve 1) and PBO (curve 2).

For PBO in the range of comparatively low temperatures, $\tan \alpha$ diminishes somewhat, whilst above 120 °C it increases sharply. In the case of the polyimide, the temperature dependence of $\tan \alpha$ is more pronounced below 120 °C, the rate of relaxation diminishing on further increase in temperature. This shows that in the middle of the temperature range of the glassy state at ~ 120 °C, a transition occurs in both polymers as a result of which the rate of the relaxation processes begins to change. It must be emphasised that the higher the absolute value of $\tan \alpha$ the lower the extent to which the relaxation of critical stresses is manifested. For materials used in rigid constructions, the relaxation of critical stresses must be as small as possible. In terms of this feature, the polyimide is somewhat superior to PBO over the entire temperature range. It is noteworthy that the temperature variation of $\tan \alpha$ for the polyimide consists not of two sections, as has been observed for other heat-resistant polymers, but of three. Along the first section in the region of comparatively low temperatures, $\tan \alpha$ decreases fairly rapidly with increase in temperature; this is followed by a low-slope section, after which $\tan \alpha$ diminishes, which indicates a sharp acceleration of the relaxation near the

softening temperature. Such a dependence is apparently common to heat-resistant polymers; the middle section, where the relaxation of critical stresses is relatively insensitive to temperature, may be of greatest practical importance.

The equation

$$t_r = B\sigma_c^{-\tan \alpha}, \quad (1)$$

where B is a constant for the material, is used to describe the relations between t_r and σ_c .³

The nature of the relations between $\tan \alpha$ and T changes at the temperature of the relaxation transition in the solid glassy state $T_{ss} \approx 120$ °C (Fig. 5) and may be described by the following equation:

$$\tan \alpha = \begin{cases} a + kT & \text{as } T \leq T_{ss} \\ a' + k'T & \text{as } T > T_{ss} \end{cases}, \quad (2)$$

where a , k , a' , and k' are constants.

The nature of the temperature dependences of the parameter B for PBO and the polyimide also changes near 120 °C. This is reflected by the different values of the coefficients in the relations describing the temperature dependence of the parameter B .

$$B = \begin{cases} A_0 \exp \frac{U}{TR} & \text{as } T \leq T_{ss} \\ A'_0 \exp \frac{U'}{TR} & \text{as } T > T_{ss} \end{cases}, \quad (3)$$

where A_0 and A'_0 are pre-exponential factors and U and U' are the activation energies for the relaxation process.

The coefficients in Eqns (2) and (3) are listed in Table 1. Knowing these parameters, it is possible to predict the mechanical behaviour of the polymers over a wide range of temperatures and stresses.

Table 1. The coefficients in Eqns (2) and (3).

Polymer	a	k	a'	k'	$\lg A_0$	$\lg A'_0$	U	U'
PBO	69	-0.109	112	-0.216	-33.9	-163.4	649	1619
PM-69	118	-0.226	45	-0.04	-100.4	-11.4	1264	565

Note. For all the values of the coefficients presented here, σ_c is expressed in MPa, the time t_r in s, and U in kJ mol⁻¹ in calculations by Eqns (2) and (3).

It is noteworthy that the data presented above for PBO and the polyimide have been obtained⁴ from measurements of the relaxation processes under the conditions of uniaxial compression. In another study,⁵ such measurements were carried out under the conditions of uniaxial elongation. One of the differences in the mechanical behaviour of PBO under the conditions of uniaxial compression and elongation is that in the latter case the maxima in the isochronous relations are absent in the temperature range 22–100 °C. The stresses arising in the polymer with the maximum possible deformation are therefore adopted as the critical stresses σ_c (Fig. 6). The acceleration of the relaxation processes at higher temperatures (210–250 °C) for PBO induced the appearance on the isochronous curves of distinct maxima corresponding to the critical stresses.

We may note that it is possible to discover, from the isochronous relations on the one hand, the specified deformation ε_0 capable of maintaining the maximum possible stresses and, on the other, the duration of the retention of the stress of this magnitude in the polymer.

In order to determine the region of the mechanical workability of PBO under extension conditions, we shall consider the temperature dependence of the critical stresses for constant

Figure 6. Isochronous dependence of the stress on deformation for PBO at 150 °C and different durations of the relaxation process (min): (1) 1.5; (2) 30; (3) 60; (4) 360.

durations of the relaxation process. If a straight line corresponding to the isothermal state is drawn in Fig. 7, it is possible to determine the function $t_r = f(\sigma_c)$. This relation makes it possible to establish the maximum temperature at which the polymer can withstand a stress of a particular magnitude over a specified time t_r .

Figure 7. Temperature dependence of the critical stresses for PBO corresponding to different durations of the relaxation process (min): (1) 1.5; (2) 9; (3) 30; (4) 60; (5) 360.

An analytical relation between σ_c and t_r has been obtained⁵ in the form

$$\lg t_r = A[1 - \exp(-B\sigma_c^{-C})], \quad (4)$$

where the parameters A , B , and C depend on temperature. These parameters are listed in Table 2.

Table 2. The parameters A , B , and C in Eqn (4) for PBO.

$T/^\circ\text{C}$	A	B	C
150	4.39	24.1	9.65
175	4.47	5.91	2.63
200	4.56	4.25	2.08
220	5.03	3.24	1.83
230	4.51	1.77	1.41

Note. For all the coefficients quoted, the time t_r is expressed in s and σ in kg cm^{-2} in calculations by Eqn (4).

Figure 8. Temperature dependence of $\tan \alpha$ for PBO.

The most important parameter, characterising the kinetics of the relaxation process, is the slope of the linear section of the $\lg t_r - \lg \sigma_c$ relation. For polybenzoxazole, the temperature dependence of the slope $\tan \alpha$ has a characteristic form (Fig. 8); in the range 20–130 °C, $\tan \alpha$ depends only slightly on temperature. Above 130 °C, it diminishes sharply, which indicates the acceleration of the relaxation processes. Such a dependence makes it possible to divide arbitrarily the temperature range of the glassy state into sections, along which the rates of the relaxation processes are different, a sharp acceleration of the relaxation processes being observed in the middle of the temperature range of the glassy state. In this respect, the given polymer behaves similarly to other heat-resistant polymers.

Such substates cannot be observed by the dynamic mechanical analysis, with the aid of which the temperature dependences of the components of the complex modulus of elasticity E^* and of the loss factor $\tan \delta$ are determined at a particular frequency. The relaxation transitions, observed by the dynamic mechanical method, are manifested at temperatures other than those of the transitions observed from the temperature dependence of the parameters of the static stress relaxation. This is evidently associated with the nonlinearity of the mechanical behaviour, which is manifested for the deformations (several %) specified during tests on polymers under static stress relaxation conditions. We shall deal below with this important question whilst analysing the mechanical behaviour of other heat-resistant polymers.

The relaxation properties of two polymers have been studied in detail:⁶ polyoxadiazole (POD)

and the polyimide PI-2

The temperature dependences of the critical stresses σ_c for these polymers are presented in Fig. 9. The difference in the viscoelastic behaviour of polyoxadiazole and the polyimide may be noted.

Figure 9. Temperature dependence of σ_c for PBO (a) and the polyimide PI-2 (b) corresponding to different durations of the relaxation process (min): (1) 0.5; (2) 1.5; (3) 15; (4) 60.

At high temperatures, the polyimide PI-2 is superior to POD as regards mechanical stresses which the polymer can withstand without softening for the same temperature and duration of the relaxation process. This is quite natural since PI-2 has a higher glass transition temperature (380 °C compared with 335 °C for POD). However, in the temperature range from 270 to 70 °C, polyoxadiazole is superior as regards critical stresses to PI-2 in the region of comparatively low temperatures.

The temperature dependences of $\tan \alpha$ for the above polymers have been analysed by comparison with other polymers.⁶ These relations are presented in Fig. 10. The temperature dependences of $\tan \alpha$ for polymers of different classes are not the same. The following feature is characteristic of PDO, polyarylate, and a number of other polymers: within a certain range of comparatively low temperatures, $\tan \alpha$ remains almost constant or actually increases, while in the centre of the temperature range, corresponding to the glassy state, it begins to decrease sharply. On further increase in temperature, the sharp decrease in $\tan \alpha$ slows down and a smooth decrease is observed down to the glass transition temperature. This shows that, long before the glass

Figure 10. Temperature dependence of $\tan \alpha$ for polyoxadiazole (1), polyimide (2), PBO (3), and the polycarbonate based on bisphenol A (4).

transition temperature is attained, a relaxation transition takes place as a result of which the relaxation processes in the solid glassy state are rapidly accelerated. In essence we are dealing with a solid-solid transition, the latter differing from the γ - and β -transitions, determined by the dynamic mechanical analysis from the temperature variation of the mechanical loss factor. We shall refer to the transition in the solid glassy state described above as the T_{ss} transition. We shall trace the manifestation of the T_{ss} transition for polymers of different structure (Fig. 10).

A weak temperature dependence of $\tan \alpha$ over a wide temperature range is characteristic of polyoxadiazole and the polyimide PI-2. Thus $\tan \alpha$ for polyoxadiazole hardly depends on temperature up to 220 °C and only then begins to decrease appreciably, particularly at 300 °C, i.e. near the glass transition temperature. This trend is even more marked for the polyimide; a sharp decrease in $\tan \alpha$ is observed only at 320 °C, $\tan \alpha$ retaining a virtually constant value over a wide temperature range. In terms of this feature, the above polymers have a significant advantage compared with PBO and polyarylate, because their relaxation properties hardly depend on temperature up to the glass transition temperature.

It was noted above that the absolute value of $\tan \alpha$ characterises the rate of relaxation of the critical stresses, i.e. the workability of the polymer under extreme conditions. The higher the value of $\tan \alpha$, the less the extent to which the critical stresses relax. In this respect, PBO is significantly superior to POD and PI-2 in the temperature range 20–120 °C, but the disadvantage is lost as the temperature rises.

Thus heat-resistant aromatic polymers can be divided into two classes taking into account their relaxation properties. The first class includes polymers in which the stress relaxation within a certain range of comparatively low temperatures is manifested to only a slight extent even under extreme conditions (on exposure to critical stresses). However, in the middle of the temperature range of the glassy state observed, the relaxation stress increases sharply, which may lead to the loss of mechanical workability long before the attainment of the glass transition temperature. The second class includes polymers in which the stress relaxation is much more marked (this is indicated by the low values of $\tan \alpha$), but the parameters of the relaxation processes are stable up to the glass transition temperature even under extreme conditions. Such polymers are POD and PI-2.

Consequently, if the conditions of use of the polymeric material requires it to retain the stresses established in it, then polymers of the first class must be chosen as such materials. However, these may be usable over a comparatively narrow temperature range. On the other hand, if the polymeric materials must exhibit distinct viscoelastic properties, polymers of the second class must be chosen.

The mechanical behaviour of the following polymers has been investigated:⁷

the polyamidoimide

the polyarylate

the aromatic polyamide (Phenylon S-4)

and POD.

In the investigation mentioned above, film specimens were studied under the conditions of uniaxial elongation. For all the heat-resistant systems investigated, a series of relaxation curves were obtained at a constant deformation ϵ_0 over a wide range of variation of the latter in the region of linear and nonlinear viscoelasticity (up to disruptive deformation at different temperatures over a wide range of temperatures of the glassy state of the polymers).

The critical stresses σ_c and their temperature variations were determined from these curves. Such a variation for the polyarylate is presented in Fig. 11, while the temperature variations of $\tan \alpha$

Figure 11. Temperature dependence of the critical stresses in polyarylate for different durations of the relaxation process (min): (1) 1; (2) 3; (3) 10; (4) 30; (5) 60.

for all four polymers are shown in Fig. 12. When account is taken of the temperature variations of $\tan \alpha$, it is possible to divide the temperature range of the glassy state for the systems investigated into sections where the rates of the relaxation processes are

Figure 12. Temperature dependence of $\tan \alpha$ for polyamidoimide (a), POD (b), Phenylon S-4 (c), and polyarylate (d).

different. For all the systems, a sharp acceleration of the relaxation processes is then observed in the middle of the temperature range of the glassy state.

An appreciable expansion of the temperature range in which the parameters of the relaxation behaviour are found to be independent of temperature is characteristic of polyoxadiazole and phenylon S-4 films: compared with polyarylate and polyamidoimide films, the temperature range in which $\tan \alpha$ is constant increases up to 140 °C.

As mentioned above, the critical stress σ_c depends on the time t_r and relaxes in exactly the same way as the usual stresses σ . With increase in process time, the relaxation σ_c slows down and as $t_r \rightarrow \infty$ the relaxation becomes negligible. The corresponding values of σ_c will be referred to (conventionally) as equilibrium critical stresses and will be designated by $\sigma_{c\infty}$.

The temperature dependence of $\sigma_{c\infty}$ confines the region of stresses and temperatures in which there are no rapid relaxation processes, i.e. limits the region of the mechanical workability of the polymers under the conditions of stress relaxation. Fig. 13 presents the temperature variations of $\sigma_{c\infty}$ for four polymers. The influence of the structure of the polymers on their relaxation behaviour may be analysed on the basis of these relations. The first factor to which attention must be drawn is the marked difference between the critical stresses for all the systems in the range of low temperatures. Naturally, the higher the glass transition temperature of the polymer the higher are the temperatures at which finite equilibrium stresses are retained. However, an increase in the heat resistance of the polymer (in particular in the glass transition temperature) promotes a significant increase in the mechanical stresses capable of being retained in the polymeric material under the conditions of stress relaxation and at low temperatures (Fig. 13). At 22 °C the critical equilibrium stress is 53 MPa for the polyamidoimide, 70 MPa for POD, 75 MPa for the polyarylate, and 103 MPa for phenylon S-4.

Figure 13. Temperature dependence of the equilibrium critical stresses in Phenylon S-4 (1), polyarylate (2), POD (3) and polyamidoimide (4).

Thus, if the polymeric material is required to retain its workability at high mechanical stresses, then preference must be given to heat-resistant aromatic polymers even in the region of low temperatures.

Extrapolation of the temperature variations of the equilibrium critical stresses to their zero value makes it possible to determine the glass transition temperature of an amorphous

polymer, which is smallest among all the glass transition temperatures determined at finite rates of application of mechanical and thermal influences. This temperature apparently constrains the actual temperature range in which the solid polymer may be used as a constructional material without breaking under the influence of stresses (up to critical stresses).

The crystallisation of polymers is known to increase significantly their strength and resistance to mechanical disruption. For example, phenylon, a crystalline aromatic polyamide, withstands much greater stresses in the temperature range 22–220 °C, without breaking or softening, compared with other heat-resistant systems, although their glass transition temperatures are higher than that of phenylon (Fig. 13). A sharp decrease in the equilibrium critical stresses has been observed for phenylon, although at comparatively low temperatures its mechanical workability is significantly greater. Thus, provided that it is possible, the crystallisation of heat-resistant systems is an effective means of expanding the region of workability towards higher stresses.

It was noted above that the plotting of the temperature variations of the critical stresses is one of the procedures for generalising the results of relaxation measurements. Another method for such generalisation involves the application of the principle of the temperature–time analogy (TTA). According to this principle, one plots master $\lg E_r - \lg(t/a_T)$ relaxation curves, where a_T is the shift factor. Curves are plotted by displacing the $\lg E_r - \lg t$ relaxation curves at different temperatures along the $\lg t$ axis. Fig. 14 presents the initial relaxation curves and the master curve for PBO,⁵ as well as the temperature variation of the shift factor. The latter is a complex function which does not obey the Williams–Landell–Perry equation over the entire temperature range of the glassy state. Each substate has its own $\lg a_T = f(T - T_0)$ relation.

The occurrence of transitions from one substate to another must be taken into account for objective estimation of the mechanical workability of the polymer under the conditions of

stress relaxation. If the polymer is used as a constructional material at temperatures close to the glass transition temperature, it can be subjected to very small loads for a short time. However, when polymeric materials are used under the conditions of variable temperatures, where a transition from one substate to another, involving a sharp acceleration of relaxation processes, is observed, the mechanical workability may be lost at a temperature much lower than the glass transition temperature. Thus the region of stable mechanical workability of PBO is in the temperature range 22–125 °C, which corresponds to a substate in which the rate of relaxation processes is relatively insensitive to temperature.

Fig. 15 presents the initial relaxation curves and the master relaxation curve for PI-2.⁶ The generalised curve for PI-2 is smooth and only a slight decrease in E_r with increase in $\lg t$ is observed.

The temperature variations of the shift factor $\lg a_T$ are well described by the power function

$$\lg a_T = C(T - T_0)^n, \quad (5)$$

where C is a constant for the material, T_0 the reduction temperature, and n the power exponent.

The possibility of describing the dependence of $\lg a_T$ on $T - T_0$ by a power function has been demonstrated also for other heat-resistant polymers.⁸ The quantities C and n depend on the deformation ε . This indicates the nonlinearity of the mechanical behaviour of the polymers. The dependences of C and n on ε are as follows:

$$C = C_0 e^{\gamma \varepsilon}, \quad (6)$$

$$n = a\varepsilon + b, \quad (7)$$

where C_0 , γ , a , and b are constants for the material.

The viscoelastic behaviour of a series of heat-resistant polymers under isothermal stress relaxation conditions was characterised above. The study of the behaviour of heat-resistant

polymers under creep conditions is also of fundamental interest, because in many cases such polymers are used under precisely such conditions. However, one should note that few investigations of this kind have been made.⁹⁻¹²

The characteristics of the viscoelastic behaviour of heat-resistant bulky polymers under isothermal creep conditions have been investigated in relation to PBO.¹¹ The experiments on creep over the entire range of temperatures and stresses possible for the given polymer made it possible to characterise fully the region of its mechanical workability and to compare it with the similar region under stress relaxation conditions.

Fig. 16 presents, as an example, creep curves obtained at a constant temperature and for different stresses. Evidently the consecutive increase in stress at a constant experimental temperature leads to a steady displacement of the creep curves into the region of greater deformations. The nonmonotonic (accelerated) increase in deformations and in the rate of creep with increase in stress has been observed in the region of high temperatures and stresses.

Figure 16. Creep curve at 210°C for different stresses (MPa): (1) 10; (2) 15; (3) 20; (4) 25.

In order to generalise the experimental data on creep, two procedures are used. The first involves the plotting of isothermal dependences of the creep deformation on stress; the critical stresses σ_c , above which the acceleration of the creep process

Figure 17. Regions of mechanical workability for PBO under isothermal stress relaxation (region 1) and creep (region 2) conditions.

begins, are determined from the bend in these relations. The $\sigma_c - T$ temperature relation yields a characteristic of the mechanical workability of a heat-resistant material under creep conditions. The regions of workability of PBO under creep and stress relaxation conditions may be compared in Fig. 17. Evidently, the curves confining the region of the workability of PBO are similar, which indicates that the processes underlying the viscoelastic behaviour are common to such cases.

The relaxation properties of a polyimide film based on pyromellitic dianhydride and bis(4-aminophenyl) ether have been investigated in just as much detail under creep conditions.¹²

Apart from the procedure described above, another method has also been used to generalise data on creep, which involves the plotting of master $I = \varepsilon/\sigma$ compliance curves using the principle of the temperature-time analogy. For this purpose, the $\lg I - \lg t$ relations at different temperatures but for constant stresses are shifted along the $\lg t$ axis by an amount $\lg a_T$ until they coincide with the master curve.

The master compliance curves for the polyimide film for different levels of stress are presented in Fig. 18. Evidently, the master compliance curves diverge appreciably, which indicates a nonlinear mechanism of their behaviour. A similar analysis has

Figure 18. Master compliance curves for a polyimide film corresponding to different stresses (MPa): (1) 50; (2) 70; (3) 90; (4) 110.¹²

been carried out for PBO.¹¹ The relaxation properties of polyphenylquinoxaline (PPQ)

and PI-2 (the chemical structure of the polyimide is shown above) have been investigated as a function of the prehistory of their preparation from solutions.¹³ Pure solvents and their mixtures with a small amount of precipitants were used as solvent media. The addition of precipitants (~2%–5% relative to the solvent) leads to the formation of films with an enhanced strength and a significantly greater deformability. When films are prepared from solution, it is possible to regulate the rate of stress relaxation and creep (Fig. 19). Master compliance curves have been constructed by the horizontal shift along the $\lg t$ axis of compliance curves obtained at a single temperature but for different stresses (Fig. 19a) and for a single stress but at different temperatures (Fig. 19b). In all cases, the compliance of the films obtained from a mixture of the solvent and a precipitant is greater than that of the films obtained from the solvent alone.

Having analysed the relation between three parameters — the intrinsic viscosity $[\eta]$, the Huggins constant K_H , and the second virial coefficient A_2 — Matevosyan et al.¹³ concluded that, judging from the values of A_2 and K_H , the thermodynamic quality of the solvents is impaired after the addition of a small amount of the precipitant. This is quite reasonable. However, judging from the values of $[\eta]$, this property improves. Apparently, the addition of small amounts of the precipitant gives rise to a specific interaction between the polar groups of the polymer and the solvent molecules, which leads to a considerable anisometry of the molecules and to an increase in swelling. As a consequence of this, $[\eta]$ increases, while the mechanical properties of the film obtained from complex solvent media are appreciably superior to those of films obtained from the pure solvent. When large amounts of the precipitant are added, $[\eta]$ diminishes and the properties of the films are markedly impaired. This in fact accounts for the anomalous increase in $[\eta]$.

Thus, by changing the composition of the solvent medium in the preparation of heat-resistant aromatic polymer films from solutions involving the addition to the latter of a small amount of a precipitant, it is possible to regulate within wide limits the relaxation as well as the strength and deformation properties of

the films. This is also indicated by the data obtained in a study¹⁴ of the strength and relaxation properties of films based on the copolymer of phenylquinoxaline (PQ) and naphthoylenebenzimidazole (NBI) having a regular structure.

These systems are characterised by a regular alternation of various heterocyclic fragments, which is in fact responsible for their improved solubility in organic solvents compared with copolymers having an irregular structure and obtained by the interaction of various bis(*o*-phenylenediamines) with 1,4-bis-(phenylglyoxalyl)benzene and the dianhydride of naphthalene-1,4,5,8-tetracarboxylic acid.¹⁵

The high viscous characteristics of the copolymers based on PQ-containing bis(*o*-phenylenediamines) made it possible to obtain films from them. These films have been prepared¹⁴ from two solvent media: *m*-cresol and a 3:1 tetrachloroethane (TCE)–phenol mixture.

The initial and final relaxing stresses[†] for films obtained from the TCE phenol mixture are lower at all temperatures than for films obtained from *m*-cresol (Fig. 20). A significant difference is observed at ~150 °C, where the relaxation processes occur most vigorously. On the one hand, this confirms the existence of a pronounced relaxation transition in the range of temperatures far from the glass transition temperature. On the other hand, this indicates a significant influence of the prehistory of the specimens prepared from the same polymer on their relaxation behaviour.

A similar result has been observed in the analysis of creep data. The specimen prepared from the tetrachloroethane-phenol

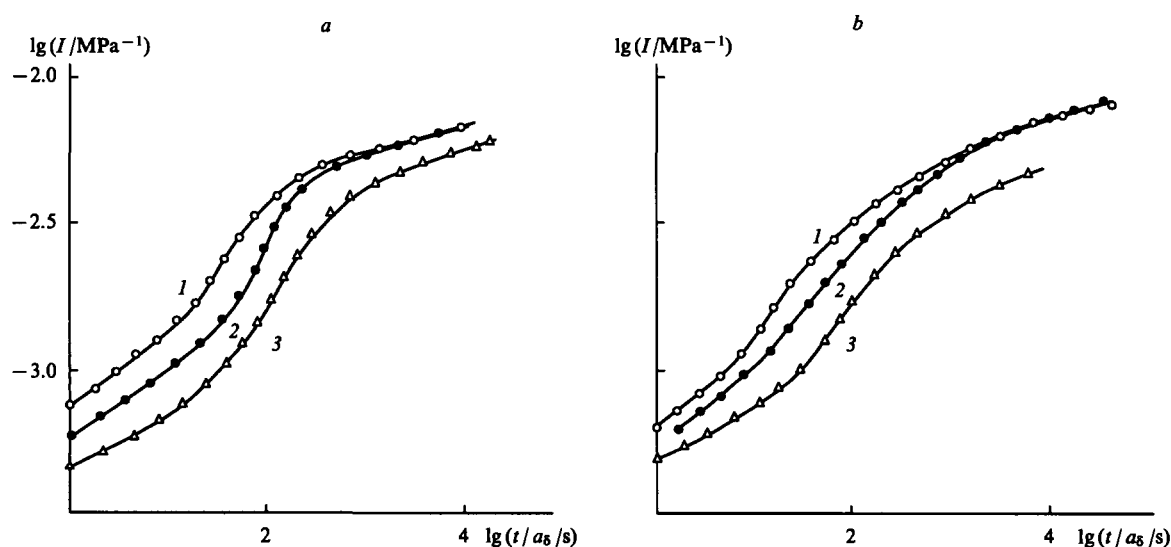

Figure 19. Master compliance curves for polyphenylquinoxaline corresponding to different stresses (*a*) and temperatures (*b*). The films were obtained from chloroform with added 5% of ethanol (1), 2% of toluene (2), and pure chloroform (3).

Figure 20. Temperature dependences of the initial (curves 1 and 2) and final (curves 3 and 4) relaxing stresses for copolymer films obtained from *m*-cresol (curves 1 and 3) and from the TCE:phenol = 1:3 mixture (curves 2 and 4). Initial deformation 3%.

mixture has a significantly greater creep deformation at various stresses than the specimen obtained from *m*-cresol. In order to account for these data, the quality of the solvent medium was examined in relation to the polymer. The quality of the solvent may be estimated with the aid of a new solubility criterion introduced by the present author and his coworkers.^{16,17} It has the form

$$\mu \leq 1.374\Phi(\Phi - \sqrt{\Phi^2 - 1 + a}) = \beta, \quad (8)$$

where $\mu = \delta_p^2/\delta_s^2$ (δ_p and δ_s are the solubility parameters of the polymer and the solvent),

$$\Phi = \frac{4(V_p V_s)^{1/3}}{(V_p^{1/3} + V_s^{1/3})^2}, \quad (9)$$

(V_p and V_s are the molar volumes of the repeat unit of the polymer and the solvent respectively), and $a = \gamma_{ps}/\gamma_s$ (γ_{ps} is the interfacial tension at the polymer-solvent boundary and γ_s is the surface tension of the solvent).

The results obtained¹⁴ are presented in Table 3, from which it is seen that in the case of PPQ the quantity μ is much smaller than β for both solvents. Consequently PPQ should dissolve readily in both solvents (which has in fact been observed experimentally), while the presence of PQ units in the copolymer should lead to the appearance or a significant improvement of the solubility when PQ rings are combined with other heterocycles.

Table 3. Solubility criteria for different polymer: solvent pairs.

Solvent	μ	β
PPQ polymer unit		
<i>m</i> -Cresol	0.851	1.100
TCE: phenol	0.897	1.082
PNBI polymer unit		
<i>m</i> -Cresol	0.980	1.080
TCE: phenol	1.080	1.070

On the other hand, μ for polynaphthoylenebenzimidazole (PNBI) either differs very little from β being smaller, or is greater than the latter; this means that the polymer dissolves very sparingly or is insoluble, which has also been observed experimentally. In the case of a heterounit polymer containing PQ and NBI units, solubility should be observed for different ratios of the PQ and NBI units.

As regards the influence of the quality of the solvent medium, it can be seen from Table 3 that the inequality of the criteria (8) is

enhanced on passing from the TCE-phenol mixture to *m*-cresol. Consequently, on passing from *m*-cresol to the TCE-phenol mixture, the quality of the solvent is somewhat impaired. According to the results of Matevosyan et al.¹³, this should lead to an increase in deformability both under the conditions of continuous uniaxial extension and under creep conditions. In the measurement of the stress relaxation for films obtained from solvents of a poorer thermodynamic quality, the relaxation processes should be more far-reaching, and, other conditions being equal, the decrease in the relaxing stresses should be more pronounced, which has been confirmed experimentally.¹⁴

The results of relaxation measurements carried out under isothermal conditions were examined above. Such experiments require a very long time. However, the method for the determination of the regions of mechanical workability described by the present author³ may prove useful in characterising the mechanical behaviour of polymers over a wide range of temperature and stresses.

The essential feature of the method consists in the measurement of the stresses which arise in the specimen during its thermal expansion whilst retaining a constant deformation imposed initially under the conditions of uniaxial compression. With increase in temperature, the stresses in the specimen increase as a consequence of thermal expansion, and then, as a result of its softening under load, they begin to diminish and become zero on complete softening of the specimen. The temperature dependences of the stress for polyketone A are presented in Fig. 21.¹⁸

The geometrical locus of the maxima on these curves together with the coordinate axes confine the region of stresses and temperatures in which the solid polymeric material is not disrupted and does not soften under the specified conditions of the tests.

Apart from polyketone A, polyketones B and C having the following structure have also been investigated:¹⁸

Figure 21. Region of the workability of polyketone A, the arrow indicates the softening temperature, which is close to the melting point.

We shall compare the heat resistances of all three polyketone specimens. For this purpose, we shall combine on one figure the curves confining the regions of the workability of these polymers (Fig. 22). It is seen from the figure that specimens A and B have virtually identical heat resistances and are significantly inferior to specimen C in this respect. All this is valid for the region of comparatively large mechanical stresses. As regards the region of small stresses at high temperatures, preference must be given to the partly crystalline specimens A and B. This is confirmed by the data presented in Fig. 21. For polyketone A, the mechanical stresses appreciably diminish after passing through a maximum, but, with increase in temperature, this decrease slows down and the curves form a 'loop'. The stresses relax very slowly and become zero at a high temperature, close to the melting point. Such relaxation behaviour is characteristic of semi-crystalline polymers.

Figure 22. Curves confining the region of the mechanical workability of polyketones A, B, and C.

Thus the crystallisation of aromatic polyketones does not lead to an increase in heat resistance in the region of large mechanical stresses, where the softening of the specimen is associated with the properties of the amorphous component. However, crystallisation increases significantly the temperature at which the specimen softens fully (in the region of low mechanical stresses or in their complete absence).

The influence of the degree of conversion into a monolithic form on the relaxation properties of an aromatic polyimide having the following chemical structure has been studied:¹⁹

The need for such investigations arises because the processing of aromatic heat-resistant polymers by traditional methods (for example by hot pressing) does not always lead to the formation of monolithic specimens, although it is known that even in the nonmonolithic form heat-resistant polymers are capable of withstanding large mechanical loads at elevated temperatures. The following question arises in this connection: to what extent do the

mechanical properties of truly monolithic specimens differ from those of nonmonolithic specimens comprising materials pressed at high temperatures and pressures and consisting of individual grains of the initial powder?

Analysis of the relaxation behaviour of the polyimide¹⁹ showed that the master relaxation curves for specimens with different degrees of conversion into a monolithic form are disposed fairly close to one another. Consequently nonmonolithic specimens of this heat-resistant specimen have good mechanical characteristics close to those for the truly monolithic material.

The mechanical behaviour of heat-resistant aromatic polymers at low temperatures is of special interest. In the early studies,²⁰⁻²⁴ it was already noted that the stability of the heat-resistant polymers is fairly high at low temperatures. A high deformability even at -270°C is characteristic of these polymers.²² Heat-resistant polymers are therefore of significant interest as cold-resistant materials for use in structures associated with cryogenic techniques. However, the characteristic features of the relaxation mechanical behaviour of such polymers at low temperatures have been investigated only recently (one should note that Perepechko and Voloshilov^{23,24} carried out a dynamic mechanical analysis of the polymers).

The stress relaxation and creep processes have been studied in detail for PBO and POD.²⁵ In the study of the stress relaxation and creep in PBO and POD, it was established that the relaxation processes in such polymers are pronounced in the region of low temperatures. Analysis of experimental data on the stress relaxation showed that, over the entire temperature range employed (from 20 to -145°C), a shift of the relaxation curves into the region of higher stresses is observed during the growth of deformation. Under these conditions, the increase in deformation is accompanied by an appreciable acceleration of the relaxation in the initial period. Fig. 23 presents as an example the relaxation curves for PBO at -75°C and for different initial deformations. A decrease in temperature to -145°C leads to a significant retardation of the relaxation processes.

Figure 23. Stress relaxation curves for PBO at -75°C and different initial deformations (%): (1) 4; (2) 6; (3) 8; (4) 9; (5) 10.

A similar pattern in the variation of the relaxation processes is observed in the study of the behaviour of the above polymers under creep conditions. As an example, Fig. 24 presents creep curves for POD at -120°C and for different initial stresses. Evidently, an increase in the applied stress at a constant experimental temperature leads to a steady displacement of the creep curves towards greater deformations. Under these conditions, more marked relaxation processes are observed following an increase in stress. With decrease in temperature, the creep weakens appreciably, although at -50 and -75°C it is manifested quite strikingly.

Figure 24. Creep curves for POD at -120°C and different initial stresses (MPa): (1) 120; (2) 180; (3) 220; (4) 260; (5) 290.

It was noted above that, when the temperature is varied in the region of the glassy state, a change in the rate of relaxation processes and the appearance of relaxation transitions are characteristic of heat-resistant polymers. Such transitions have been discovered for heat-resistant polymers in the study of their relaxation properties in the region of raised temperatures. We shall now consider the relaxation transitions at low temperatures.

The temperature dependence of the parameter $\tan \alpha$ for PBO is presented in Fig. 25. Evidently, this relation consists of two sections. In the range from 293 to 203 K, the quantity $\tan \alpha$ changes only slightly. With decrease in temperature in the range from 203 to 128 K, it begins to increase sharply. The greater the value of $\tan \alpha$, the smaller the extent to which the relaxation of stress is manifested. A decrease in temperature leads to a significant alteration of the segmental and group mobilities of macromolecules, which is ultimately reflected in the rate of relaxation.

Figure 25. Temperature dependence of $\tan \alpha$ for PBO; deformation 8%.

Thus the temperature dependence of $\tan \alpha$ for PBO makes it possible to observe a relaxation transition at 203 K in the low-temperature region and to identify subregions with different rates of the relaxation processes.

In the range of positive temperatures, a distinct T_{ss} transition is observed for PBO within the glassy state, so that one may conclude that the appearance of several T_{ss} transitions is characteristic of heat-resistant polymers. It must be emphasised yet again that one is dealing with transitions discovered under the conditions of static relaxation measurements, where the degree of deformation is greater by many orders of magnitude than under the conditions of dynamic mechanical analysis, i.e. when the nonlinearity of the mechanical behaviour plays a significant role.

The experiments described above, involving the study of the mechanical behaviour of heat-resistant polymers, were carried out in the range of temperatures from room temperature to the temperature of liquid nitrogen. Subsequently, the temperature range was extended²⁶ down to the temperature of liquid helium. PBO and PI-2 were studied.

The stress-strain curves for PBO and the polyimide PI-2 at different temperatures are presented in Fig. 26. The results showed that the above heat-resistant polymers do not undergo brittle rupture down to 77.3 K. The stress-strain curves have fluidity plateaus, which indicates mechanical softening. The strength properties increase linearly by a factor of ~ 2 – 2.5 on cooling from 300 to 77.3 K.

A quasi-brittle rupture accompanied by a sharp sound, takes place at 4.2 K. In this case, the specimens are deformed up to $\varepsilon = 8\% - 10\%$ for PBO and $\varepsilon = 6\%$ for the polyimide PI-2.

Above 77.3 K, the polymeric specimens did not lose their integrity on deformation up to 25%. At 77.3 K (in liquid nitrogen), the specimens are deformed further up to $\varepsilon \approx 20\%$ beyond the fluidity plateau and then disintegrate, the rupture being accompanied by a sharp sound.

In order to obtain a more objective deformation and rupture picture for heat-resistant polymers at low temperatures, tests have been carried out at different rates of deformation.²⁶ The rate of deformation has little effect on the strength properties of PBO and the polyimide at low temperatures (the changes amount to 10%–20%). The results indicate an anomalous influence of the rate of compression on the strength characteristics of PBO. Thus, on raising the rate of compression from 0.1 to 1 mm min⁻¹, the strength does not increase, as is usually observed, but actually decreases. This is characteristic of all test temperatures. Such an effect can be accounted for only by the different nature of the structural transformations occurring as the rate of compression is changed.

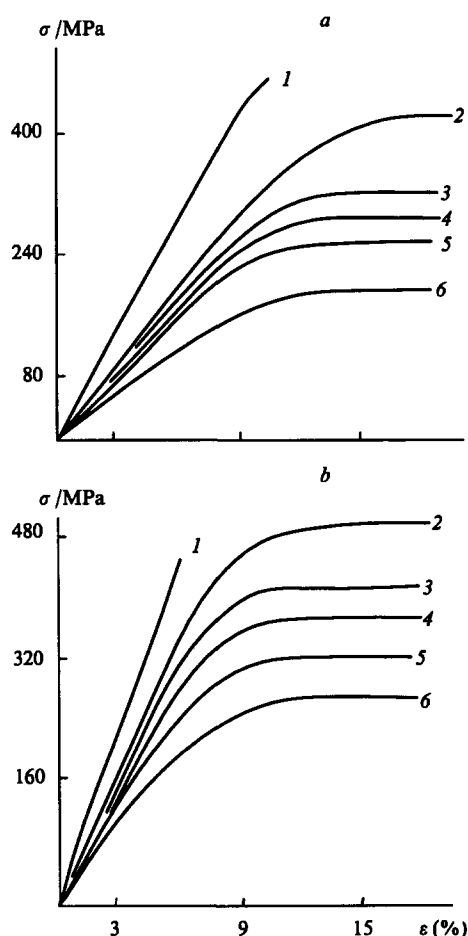

Figure 26. Uniaxial compression curves for PBO (a) and the polyimide PI-2 (b) at different temperatures (K): (1) 4.2; (2) 77.3; (3) 103; (4) 150; (5) 200; (6) 300.

Table 4. The yield stresses for a series of polymers during thermocycling.

Polymer	Temperature range of thermocycling /K	σ_y (MPa) for different numbers of thermocycles												
		0	10	50	100	200	300	400	500	600	700	800	900	1000
MK-M-3	(77–398)±5	88	85	85	85	86	88	87	87	—	—	—	—	—
PBO	(77–473)±5	199	204	200	200	201	200	192	188	—	—	—	—	—
PI-2	(77–473)±5	270	272	271	272	274	273	267	268	263	280	270	268	269
F-4	(77–473)±5	17	15.5	15	16.5	15.4	12.9	—	—	—	—	—	—	—
PKIT	(77–423)±5	191	210	174	189	181	181	192	199	—	—	—	—	—

Another procedure used in the tests for cold resistance consists in the thermocycling of the polymer materials and the study of the influence of such thermocycling on their mechanical properties. This procedure has been used²⁷ for a number of polymers: the polycarbonate MK-M-3,²⁸ the fluoroplastic F-4,[†] the polyimide PI-2, PBO, and the polyketone PKIT having the following chemical structure:

$m:n = 0.7:0.3$.

The resistance of the test polymers to the effects of repeated thermocycles was determined by analysing the state of the PI-2, PBO, and F-4 specimens after heating to 473 ± 5 K, the PK-M-3 specimen after heating to 398 ± 5 K, and the PKIT specimen after heating to 423 K and subsequent rapid cooling with liquid nitrogen.

After a definite number of thermocycles, some of the specimens were used to obtain stress-strain curves at room temperature. The average values of the yield stress σ_y determined from them as a function of the number of thermocycles are presented in Table 4. After 500 thermocycles, the mechanical properties of PK-M-3 hardly changed.

For PBO, the influence of thermocycling up to 300 cycles is also insignificant. On further use, a slight impairment of its properties begins and after the attainment of 500 cycles σ_y diminishes by 5%.

The mechanical properties of the polyimide PI-2 did not change on thermocycling and the polyketone PKIT also showed a high resistance to thermocycling.

In contrast to heat-resistant aromatic polymers, the fluoroplastic (fluoroplast) F-4 exhibited an extremely low resistance to thermocycling. Its yield stress diminishes after only 10 cycles. After 100 cycles, the cracking and disintegration of the specimens begin. It may be that this is associated with the transformation of the crystal structure of the fluoroplastic as a result of cyclic temperature changes.

III. Stress relaxation and creep curves

In the early studies of the stress relaxation and creep processes for heat-resistant aromatic polymers, the Kohlrausch equation

$$\sigma(t) = \sigma_0 \exp\left(-\frac{t}{\tau_r}\right)^k + \sigma_\infty, \quad (10)$$

† Equivalent to Teflon (Translator).

was widely used. Here $\sigma(t)$ is the current (relaxing) stress, σ_0 the initial stress which develops at the moment of the completion of the 'instantaneous' creation of the deformation, τ_r the relaxation time, and σ_∞ the 'equilibrium' stress.

The memory function, leading to this equation, has the form²⁹

$$f(t-\tau) = \frac{E_1}{\tau_r} k \left(\frac{t-\tau}{\tau_r}\right)^{k-1} \exp\left[-\left(\frac{t-\tau}{\tau_r}\right)^k\right], \quad (11)$$

where E_1 is the modulus of elasticity, t the finite duration of relaxation time, τ the current relaxation time, and k a constant for the material.

A similar memory function for the description of the creep process has been used by Bronskii:³⁰

$$\varphi(t-\tau) = I_1 \frac{m}{\theta} \left(\frac{t-\tau}{\theta}\right)^{m-1} \exp\left[-\left(\frac{t-\tau}{\theta}\right)^m\right], \quad (12)$$

where I_1 and m are constants for the material and θ is the retardation time. When this memory function is substituted in the Boltzmann equation, we obtain the following relation for the description of creep under the conditions $\sigma = \sigma_0 = \text{const}$:

$$\varepsilon(t) = \sigma_0 I_\infty \left\{ 1 - \exp\left[-\left(\frac{t}{\theta}\right)^m\right] \right\}. \quad (13)$$

Here $I_\infty = I + I_1$ is the equilibrium compliance, I the 'instantaneous' compliance, and σ_0 the constant stress for which creep is measured.

Eqn (13) describes satisfactorily the creep of polymeric materials. The creep hardly changes after the specimen has been exposed for some time to a constant stress. However, in many instances the so called steady creep section is observed on the creep curves, but the deformation increases with time approximately in accordance with a linear law. To a first approximation, this can be taken into account by formulating the creep memory function in the form

$$\varphi(t-\tau) = I_1 \frac{m}{\theta} \left(\frac{t-\tau}{\theta}\right)^{m-1} \exp\left[-\left(\frac{t-\tau}{\theta}\right)^m\right] + \frac{1}{\eta}, \quad (14)$$

where η is the viscosity of the system.

Having substituted Eqn (14) in the Boltzmann equation, we obtain

$$\varepsilon(t) = \sigma_0 I_\infty \left\{ 1 - \exp\left[-\left(\frac{t}{\theta}\right)^m\right] \right\} + \frac{\sigma_0}{\eta} t, \quad (15)$$

where $\sigma_0 I_\infty = \varepsilon_0$ is the equilibrium deformation.

The most complex question in fitting the Kohlrausch equation to the stress relaxation and creep curves concerns the reliability of the estimation of the parameters of this equation. A detailed description of the procedure for the determination of the parameters of Eqn (15) may be found in the communication of Askadskii et al.³¹

Creep curves for a series of linear and network solid polymer systems based on heat-resistant polymers have been calculated. The parameters of Eqn (15) for such systems are listed in Table 5.

Table 5. Parameters of Eqn (15) for a series of linear and network solid polymer systems.

No.	System	ε_0 (%)	θ /min	m	$10^{-14} \eta$ /P	ξ^a
1	Polyarylate F-2	15.42	1.89	0.37	8.94	0.85

3	Composition based on 100 parts of F-2 and 50 parts of the epoxy polymer UP-612	8.59	0.097	0.096	6.14	0.16
4	Polyarylate F-2 preheated at 200 °C for 20 h	6.34	3.89	0.093	1.97	0.046
5	Composition based on 100 parts of F-2 and 10 parts of the epoxy polymer UP-612	4.98	0.0084	0.0036	3.77	0.063

^aThe sum of squares of the differences between the calculated and experimental quantities.

The calculated points, obtained with the aid of Eqn (15) and the data in Table 5, fit satisfactorily on the experimental creep curves for different polymers (Fig. 27). The sum of squares of the differences between the calculated and experimental values is in the range from 0.046 to 0.85 (Table 5).

Figure 27. Creep curves for linear and network systems determined for stresses of 400 MPa (curves 1 and 4) 200 MPa (curve 2), 1200 MPa (curve 3), and 600 MPa (curve 5) at 150 °C (curves 1 and 4), 240 °C (curve 2), 20 °C (curve 3), and 90 °C (curve 5).

In further studies of the relaxation properties of heat-resistant polymers, the stress relaxation and creep curves were fitted using new memory functions, proposed by the present author.³² These memory functions are based on the consideration of the change in the entropy of the specimen during stress relaxation. The first memory function was obtained by analysing the kinetics of the interaction of the relaxators and the transition of the 'product' of this interaction to a nonrelaxing material. The term 'relaxator' is applied to various kinetic units, including individual groups of atoms (links, segments), which interact with one another within the limits of their kinetic volumes; undergoing a change in structure during the processes, they are converted into nonrelaxing materials. Here we are dealing not with a chemical interaction but with an interaction of a physical kind. For example, the

formation of microblocks — regions with the densest packing playing the role of physical network nodes — may be assigned to such interactions. During stress relaxation, the microblocks may break down and appear at other sites, which leads ultimately to a decrease in the relaxing stresses. One can consider also other instances of interactions of this kind. For example, the interaction of microdefects within the limits of individual microcavities may lead to their fusion in the course of stress relaxation and to the removal of the stress concentration. Thus, the kinetic units may be of different nature. This leads to the appearance of subsystems which may interact weakly with one another. However, one can apparently identify isotypical units which determine the course of the relaxation process.

If the relaxators considered are isotypical, the memory function assumes the form³²

$$T_1(\tau) = -\frac{S_0}{k_B m_1} \{ [(\alpha - \alpha_0) \ln(\alpha - \alpha_0) + (1 - \alpha + \alpha_0) \ln(1 - \alpha + \alpha_0)]^{-1} - 0.5 \}, \quad (16)$$

where S_0 is the initial entropy of the system (specimen), k_B the Boltzmann constant, $m_1 = m_1^* \int_0^\infty T_1^*(\tau) d\tau$ [here m_1^* is the total number of microheterogeneities in the specimen and $T_1^*(\tau)$ is the time-dependent factor of the memory function, enclosed in braces, in Eqn (19) (see below)], α is the fraction of relaxators relative to the total number of kinetic units in the system, and α_0 the fraction of relaxators which have reacted by the time when the creation of a constant deformation has been completed (the quantity α_0 was assumed³² to be constant for all the materials and equal to 10^{-10}).

The quantity α depends on time and hence the entropy production takes place during the relaxation process i.e. the entropy increases as a consequence of the mixing of the relaxators and nonrelaxators.

Two types of memory functions have been considered.³² As noted above, the first is based on the allowance for the kinetics of the interaction of the relaxators, which is described by an irreversible n th order reaction. In this case, the time variation of α assumes the form

$$\alpha(\tau) = \frac{1}{(1 + k^* \tau / \beta)^\beta}, \quad (17)$$

where $k^* = k c_0^{n-1}$, k is the rate constant for the interaction of the relaxators, c_0 their initial concentration, n the reaction order, and $\beta = (n-1)^{-1}$.

The memory function (16) has a physical significance only when $\alpha(\tau) \geq 0.5$. Here one may note that, if we have a system comprising heterotypical kinetic units where each type introduces a perceptible contribution to the relaxation process, then we have not one but several interaction constants. In this case, the function (16) becomes complicated and this leads formally to the appearance of a spectrum of relaxation times. However, experiments and calculations have shown (see above) that a satisfactory description of the stress relaxation is attained in the presence of only one interaction rate constant.

The second memory function, based on the consideration of the diffusion in the material of the specimen of the nonrelaxators formed, has the form

$$T_2(\tau) = -\frac{S_0}{k_B m_2} \left[\frac{1}{a\tau^\gamma \ln(a\tau^\gamma) + (1 - a\tau^\gamma) \ln(1 - a\tau^\gamma)} + \frac{1}{\ln 2} \right], \quad (18)$$

where $m_2 = m_2^* \int_0^\infty T_2^*(\tau) d\tau$ [here m_2^* is the total number of diffusing microheterogeneities in the specimen and $T_2^*(\tau)$ is the time-dependent factor of the function $T_2(\tau)$ enclosed in square brackets in the equation] and $a\tau^\gamma$ is the fraction of sites occupied at time τ by kinetic units during their random wandering in the lattice³³ (here a is the velocity of an elementary migration step, while γ characterises the influence of constraints).

We shall consider in greater detail the memory functions based on the analysis of the kinetics of the interaction of relaxators and their conversion into a nonrelaxing material.

If this process is considered as an irreversible n th order reaction, then substitution of Eqn (17) in Eqn (16) leads to the following expression:

$$T_1(\tau) = -\frac{S_0}{k_B m_1} \left\{ \left[\frac{1}{(1 + k^* \tau / \beta)^\beta} - \alpha_0 \right] \ln \left[\frac{1}{(1 + k^* \tau / \beta)^\beta} - \alpha_0 \right] + \left[1 - \frac{1}{(1 + k^* \tau / \beta)^\beta} + \alpha_0 \right] \ln \left[1 - \frac{1}{(1 + k^* \tau / \beta)^\beta} + \alpha_0 \right] \right\}^{-1} - 0.5 \quad (19)$$

In a simplified version, when $k^* \tau \ll 1$, the function (19) simplifies to³²

$$T_1(\tau) = -\frac{S_0}{k_B m_1} \{ (k^* \tau + \alpha_0) [\ln(k^* \tau + \alpha_0) - 1] \}^{-1} \quad (20)$$

In order to employ these memory functions in fitting the strain relaxation or creep curves, it is essential to find their integrals for different durations of the relaxation process. Such a procedure has been carried out³⁴ with the aid of a computer for different pairs of the parameters k^* and β and for different process times ranging from 0.5 to 10^5 arbitrary units. The tabulated integrals of the time-dependent factor of the memory function (19) have been published.³⁴

The interaction of the relaxators has been considered^{32, 34} as a unilateral irreversible n th order reaction, i.e. it was assumed that the interacting relaxators are converted into a nonrelaxing material and that this process is irreversible. This factor in fact required the introduction of the condition $\alpha(\tau) \geq 0.5$. In another study,³⁵ the interaction of the relaxators was considered as a reversible bilateral n th order reaction, the kinetic equation for which assumes the form

$$-\frac{d\alpha}{d\tau} = k\alpha^n - k(1 - \alpha)^n \quad (21)$$

Eqn (21) has been formulated subject to the condition that the rate constants for the direct and reverse reactions are the same and equal to k . As a result of this, at the time when the system reaches equilibrium the fractions of the relaxators and nonrelaxators become identical and equal to 0.5.

In order to find the dependence of the degree of conversion α on the time t , the Runge-Kutta numerical method for the automatic selection of the integration step was used.³⁵ The integrals of the time-dependent factor of the function $T_3(\tau)$ were found by computer. This integral has the form $\int_0^t T_3^*(\tau) d\tau$, where

$$T_3^*(\tau) = \{ [(\alpha - \alpha_0) \ln(\alpha - \alpha_0) + (1 - \alpha + \alpha_0) \ln(1 - \alpha + \alpha_0)]^{-1} - 0.5 \} \quad (22)$$

The values of $T_3^*(\tau)$ for different parameters k and β have been published.³⁵

In order to be able to use the functions $T_1(\tau)$, $T_2(\tau)$, and $T_3(\tau)$ to fit the stress relaxation curves, it is essential to substitute them in the Boltzmann equation

$$\sigma(t) = \sigma_0 \left[1 - \int_0^t T_i(\tau) d\tau \right] \quad (23)$$

where σ_0 is the initial stress.

On substituting the functions $T_1(\tau)$, $T_2(\tau)$, and $T_3(\tau)$ in the above equation and going over to the relaxing modulus, we obtain

$$E_r = E_0 \left[1 + \frac{S_0}{k_B m_1} \int_0^t T_1^*(\tau) d\tau \right] \quad (24)$$

$$E_r = E_0 \left[1 + \frac{S_0}{k_B m_2} \int_0^t T_2^*(\tau) d\tau \right] \quad (25)$$

$$E_r = E_0 \left[1 + \frac{S_0}{k_B m_3} \int_0^t T_3^*(\tau) d\tau \right] \quad (26)$$

The time-dependent factors of the functions $T_1^*(\tau)$, $T_2^*(\tau)$, and $T_3^*(\tau)$ are described by Eqns (18) and (19) (the expressions in braces) and Eqn (22) jointly with Eqn (21) respectively.

If Eqns (24)–(26) reproduce satisfactorily the experimental relaxing modulus curves, then the $E_r - \int_0^t T_1^*(\tau) d\tau$, $E_r - \int_0^t T_2^*(\tau) d\tau$, and $E_r - \int_0^t T_3^*(\tau) d\tau$ plots should be linear and their slopes should be respectively $E_0 S_0 / k_B m_1$, $E_0 S_0 / k_B m_2$, and $E_0 S_0 / k_B m_3$; the intercepts on the ordinate axis should be equal to E_0 .

In order to implement the above procedure, it is necessary to have the tabulated integrals $\int_0^t T_1^*(\tau) d\tau$, $\int_0^t T_2^*(\tau) d\tau$, and $\int_0^t T_3^*(\tau) d\tau$. Such data are available.^{34, 35} A computer program, with the aid of which the curves may be fitted has also described in the above communications. Its essential feature is that the values of the above integrals in the form of three sets for different pairs of parameters k^* and β and also α and γ are first introduced into the computer memory. Next each experimental $E_r(t)$ relation is fitted by the linear equation (24), (25), or (26) and the pairs of parameters k^* and β and also α and γ , for which the sum of squares of the deviations of the experimental values of $E_r(t)$ from the calculated ones is a minimum and the correlation coefficient r is a maximum, are chosen automatically.

The stress relaxation curve fitting procedures described above are suitable only in the region of linear mechanical behaviour, where the parameters of the relaxation process are independent of the deformation level. We shall consider briefly the methods for the fitting of relaxation curves also in the nonlinear region of the mechanical behaviour, which is more characteristic of polymers.

At the present time, the commonest method for the fitting of stress relaxation curves in the nonlinear region of mechanical behaviour is one based on Il'yushin's principal cubic theory.³⁶ According to this theory, the relaxation modulus is fitted initially in the linear region of viscoelasticity and then fitting involves the introduction of yet another parameter and the employment of the same memory function but with different parameters—the parameters of the relaxation curves in the nonlinear region. Another procedure involves the employment of equations containing a fractional power exponent of the time, the exponent being assumed to depend on the degree of deformation³⁷ kept constant during the relaxation process. A satisfactory agreement between the experimental and calculated curves is achieved in both cases, but the physical significance of the new parameters introduced is not elucidated.

An approach to the description of the stress relaxation curves in the nonlinear region with the aid of physically well-founded parameters, entering into the memory functions presented above, has been proposed.³⁸ The essential feature of this fitting procedure is as follows: we formulate an expression for the temperature dependence of the rate constant

$$k^* = k_0^* \exp \left(-\frac{\Delta U}{RT} \right),$$

where k_0^* is the pre-exponential factor and ΔU the activation energy for the interaction of the relaxators.

During the deformation of polymers, their free volume is known to increase (in this case, the free volume is understood as the 'empty volume', which represents the difference between the true volume of the polymeric body and the van der Waals volume of the atoms which they occupy in the polymeric body.³⁹ On pronounced deformation of solid (glassy and crystalline) poly-

mers and on transition to the yield stress, the free volume increases to a fairly large value, which facilitates significantly the jumps of kinetic units from one position to another. This actually leads to enforced elasticity, i.e. to enforced softening of the material. It has been postulated³⁸ that the activation energy for the interaction of relaxators decreases with increase in the mechanical stress σ and the rate constant for the interaction of the relaxators was formulated as follows:

$$k^* = k_0^* \exp\left(-\frac{\Delta U_0 - \delta E_r \varepsilon_0}{RT}\right), \quad (27)$$

where E_r is the relaxation modulus, ΔU_0 the initial activation energy for the interaction of the relaxators, $\sigma_r = E_r \varepsilon_0$ the relaxing stress, and δ the fluctuation volume in which the elementary step in the interaction of the relaxators takes place. Then

$$\alpha(\tau) = \left[1 + \frac{\tau k_1^* \exp(\delta E_r \varepsilon_0 / RT)}{\beta}\right]^{-\beta}, \quad (28)$$

where $k_1^* = k_0^* \exp(-\Delta U / RT)$.

The fitting procedure consists in the determination of the value of δ for which the function $\varphi(\delta)$, representing the sum of squares of the deviations of the experimental values from the calculated ones, is a minimum:

$$\varphi(\delta) = \sum_{i=1}^n (E_{i2} - E_{i1})^2,$$

where n is the number of experimental points and E_{i2} and E_{i1} are the values of the relaxation modulus calculated by Eqn (24) and determined experimentally respectively. The calculations are performed on a computer. The algorithm for the calculations consists in the following steps: the relaxation moduli for the experimental relaxation curves are introduced successively into the computer in order of increasing deformations ε_0 . Each curve introduced, except the first, is compared with the curve which is the average of the relaxation moduli derived from the curves introduced previously. If each modulus for the same relaxation time is smaller for the curve introduced than for the average curve and the arithmetical mean of the relative deviations exceeds 10%, it is assumed that such a curve refers to the nonlinear region of mechanical behaviour. The parameters of the memory function corresponding to the linear region are then calculated for the average curve and the curve referring to the nonlinear region is fitted on their basis.

The relaxation curves for polyoxadiazole have been fitted³⁸ at different temperatures and for different deformations. The results of the calculations are presented in Table 6. In addition to the data in Table 6, we may note that the rate constant k^* for the interaction of the relaxators at both temperatures is 0.1 min^{-1} ; the values of β , $(S_0/k_B m_1) \times 10^4$, and r_1/r_2 [the ratio of the correlation coefficients for the memory functions $T_1(\tau)$ and $T_2(\tau)$ in the nonlinear region of mechanical behaviour] at 21 and 170 °C are respectively 7.2 and 5.2, 0.3 and 0.2, and 0.9991/0.9952 and 0.9981/0.9639. In curve fitting by the method of Askadskii and Valetskii,³⁸ the correlation coefficients at the temperatures indicated are 0.9999 and 0.9997 respectively. Polyoxadiazole having the following structure was investigated:

In terms of absolute magnitude, the correlation coefficients in curve fitting by the above method³⁸ are appreciably greater and much more stable than in fitting by the method of Il'yushin.³⁶

Table 6. The results of the fitting of the parameters of the memory functions for POD in the linear and nonlinear regions of mechanical behaviour.

$\varepsilon(\%)$	$\delta / \text{kJ mol}^{-1} \text{ MPa}^{-1}$	r^a
Temperature 21 °C

6.67	0.724	0.9864
Temperature 170 °C		
5.68	0.477	0.9991

^aThe correlation coefficient obtained in fitting by the method of Il'yushin.³⁶

Furthermore, it was noted that the memory function $T_1(\tau)$ fits the relaxation curves for solid polymers in the linear region more satisfactorily than the function $T_2(\tau)$.

We shall consider the results of the study of the relaxation properties of a series of heat-resistant polymers using the memory functions described above. The stress relaxation has been studied in detail⁴⁰ for two polymers—polyoxadiazole and polyimide.

Fig. 28 presents the time variations of the relaxation modulus for POD and polyimide at 20 °C. The data corresponding to the

Figure 28. Time variation of the relaxation modulus E_r at 20 °C for polyoxadiazole (a) and polyimide (b) in the linear (curve 1) and nonlinear (curves 2–12) regions.

a: (1) single averaged relation; $\varepsilon(\%)$: (2) 5.56; (3) 6.67; (4) 7.23; (5) 7.78; (6) 8.33;
b: (1) single averaged relation; $\varepsilon(\%)$: (2) 4.46; (3) 5.02; (4) 5.56; (5) 6.82; (6) 8.33; (7) 8.99; (8) 10.23; (9) 11.57; (10) 12.36; (11) 13.95; (12) 15.34.

linear region of mechanical behaviour were averaged and a single relaxation relation was obtained. A deviation from the average relation towards a decrease in E_r is observed at $\varepsilon_0 = 5.56\%$ for polyoxadiazole (Fig. 28a). In the range of ε_0 from 1.7% to 5.0%, linear mechanical behaviour is observed. In terms of this feature, polyoxadiazole is superior to other known polymers, for which the region of nonlinear behaviour begins at significantly smaller deformations.

For polyimide, the deviations from linear mechanical behaviour are observed already at $\varepsilon_0 = 4\%$ (Fig. 28b), while the region of linear mechanical behaviour covers the range of ε_0 from 1.7% to 3.4%, i.e. significantly shorter than the analogous range for polyoxadiazole.

At higher temperatures, the range of deformations in the region of linear behaviour becomes narrower but not uniformly. Fig. 29 presents the temperature variation of the limiting deformation ε_{lim} , for which a linear viscoelastic behaviour is still observed. For polyoxadiazole, ε_{lim} is significantly greater than for polyimide. A common feature of these polymers is a small decrease in ε_{lim} with increase in temperature and also the existence of a region in which ε_{lim} is independent of temperature after which, as the glass transition temperature is approached, ε_{lim} decreases.

The results of the fitting of stress relaxation curves in the linear region of viscoelastic behaviour are presented in Tables 7 and 8.

For the above polymers, the memory function $T_1(\tau)$ 'works' best, its employment leading to a correlation coefficient close to unity, i.e. the experimental and calculated values of E_r are the same. Curve fitting with the aid of the memory function $T_2(\tau)$ leads to a significantly smaller correlation coefficient. Since the memory function $T_1(\tau)$ describes the kinetics of the relaxation of relaxators and their conversion into a nonrelaxing material while the memory function $T_2(\tau)$ describes the kinetics of the diffusion of these kinetic elements in the material, in the given instance the

rate of the relaxation process is limited by the rate of reaction of the relaxators. The same conclusion has been reached⁴¹ in the analysis of the relaxation behaviour of polybenzoxazole.

The results of the analysis in the form of parameters of the relaxation process and the correlation coefficient r are presented in Tables 9–11.

These data make it possible not only to follow the temperature variation of the parameters of the relaxation processes but also to reach definite conclusions about the changes in the process mechanisms and about the relaxation transitions within the temperature range of the glassy state. We shall therefore consider them in greater detail.

We shall compare the values of all the parameters and the correlation coefficients r when the memory functions $T_1(\tau)$ and $T_3(\tau)$ are used. It can be readily shown (Tables 9 and 10) that all

the parameters and the values of r determined with the aid of the memory functions $T_1(\tau)$ and $T_3(\tau)$ are virtually the same. We may recall that the memory function $T_1(\tau)$ was obtained in the analysis of a unilateral n th order reaction of the relaxators, while the memory function $T_3(\tau)$ was found taking into account the reversible interaction. Consequently, when account is taken of the impossibility of the interconversion of relaxators and non-relaxators, there is no appreciable change in the process kinetics at least for the times t during which the experiment was performed (up to 6 h). This conclusion is in full agreement with the analogous conclusion in another study.³⁵

It is seen from the tables that the correlation coefficients r are very large and approach unity when the memory function $T_1(\tau)$ or $T_3(\tau)$ is employed. When the memory function $T_2(\tau)$ is used (Table 11), the correlation coefficients are significantly lower in the range of comparatively low and high temperatures than the values of r obtained with the aid of the functions $T_1(\tau)$ and $T_3(\tau)$. In the range of moderate temperatures (from 125 to 200 $^\circ\text{C}$), the correlation coefficients are very high when the function $T_2(\tau)$ is

employed [approximately the same as those obtained with the aid of the functions $T_1(\tau)$ and $T_3(\tau)$]. Hence one may conclude (from the standpoints considered) that in the temperature ranges 22–100 $^\circ\text{C}$ and 210–230 $^\circ\text{C}$ the rate-limiting stage of the stress relaxation process is the interaction of the relaxators and their conversion into a nonrelaxing material.

In the temperature range 125–200 $^\circ\text{C}$, the rates of interaction and diffusion of the kinetic units become comparable, as a result of which the relaxation process is described with approximately the same accuracy by all the memory functions. One may note that the correlation coefficients r obtained when the memory function $T_2(\tau)$ is used becomes actually higher than the value of r obtained with the aid of the $T_1(\tau)$ and $T_3(\tau)$ memory functions. This temperature range, in which both mechanisms operate at equal rates, is transitional. The occurrence of a distinct relaxation transition in this temperature range for PBO has been described;⁴ for example, the temperature variation of σ_c for PBO has a characteristic form (Fig. 7): along the first section in the range 22–100 $^\circ\text{C}$, the critical stress depends only slightly on temperature, in the range 100–200 $^\circ\text{C}$, a sharp decrease in σ_c is observed, while in the range 200–230 $^\circ\text{C}$ the decrease becomes less marked.

In the region of the T_{gs} transition, the mechanism of the relaxation process changes (Tables 9–11). The rate constant for the interaction of relaxators increases in this range, but the number of relaxators m_1 increases and there is also a sharp increase in the number of kinetic units m_2 participating in the diffusion process. As a result of all these factors, the rates of interaction of the relaxators and of the diffusion of kinetic elements become comparable. With increase in temperature, the rate of interaction of the relaxators increases while the number of relaxators becomes small and changes only slightly with increase in temperature. The same may be said also about the diffusion process.

Another example of the application of the above approach to the analysis of the relaxation behaviour of polymers is the study of the relaxation processes of polyketones subjected to hydrostatic extrusion.⁴²

Numerous aromatic polyketones, including cardo-polyketones, have now been described. These polymers are amorphous or partly crystalline and they are preformed by injection moulding or by pressing. The principal physicomechanical parameters of the polymers are regulated by varying the parameters of the synthesis.⁴³

The possibilities for regulating the structures and properties of these polymers by mechanical treatment have been investigated.^{42,44} One of the promising methods for such treatment is hydrostatic extrusion, which makes it possible to achieve large plastic deformations of the polymers without disruption.

The results of studies of the hydroextrusion process and the structures and physicomechanical properties of the extruded materials — poly(aryl ether ketone) (PAEKN) and poly(aryl ether ketone) based on phenolphthalein (PAEKP) — have been published.⁴²

The polymers were synthesised by nucleophilic substitution of an activated aromatic halogen.

Note. For the memory function $T_1(\tau)$, the quantity k^* is proportional to the rate constant for the interaction of the relaxators; the time-dependent factor of the memory functions, $m_1^* k_B / S_0$ and $m_2^* k_B / S_0$, are proportional to the number of microheterogeneities in the specimen.

The stress relaxation curves were determined for the initial and hydroextruded specimens, hydroextrusion being performed up to different degrees of extension λ and at different temperatures T_e (however, always below the glass transition temperature T_g).

For a detailed description of the kinetics of the relaxation processes, the $\sigma(t)$ relations were fitted with the aid of the memory functions $T_1(\tau)$ and $T_2(\tau)$. These memory functions were also used to characterise the relaxation properties of an aromatic polyketone based on isophthalic and terephthalic acids.¹¹ The results of the calculations are presented in Table 12.

Analysis of the parameters of the above memory functions shows that the Boltzmann equation with the memory function $T_1(\tau)$ reproduces best the course of the stress relaxation, although in a number of instances the correlation coefficient r is also fairly close to unity when the memory function $T_2(\tau)$ is used. With increase in λ the quantities σ_0 and σ_∞ as a rule increase. The most significant increase in σ_0 and σ_∞ is characteristic of extruded PAEKN specimens, which have a semi-crystalline structure. The increase in $m_1^* k_B / S_0$, observed for the deformed polymer, indicates an increase in the number of relaxators in the material, the rate of interaction of which in the extruded specimens is on the whole higher than in the cast materials. This is entirely reasonable provided that the relaxators are understood as different kinds of microheterogeneities, which are converted into nonrelaxing structures faster the higher the level of the internal stresses (the latter naturally increases on deformation).

Thus hydroextrusion improves the elastic and relaxation characteristics of aromatic polyketones. In this sense, the most promising material is PAEKN, which is capable of undergoing a structural transition from the amorphous to a partially semi-crystalline modification during the deformation process.

IV. Low-temperature relaxation processes and transitions in heat-resistant polymers

Much attention is devoted nowadays to the analysis of the mechanisms of the relaxation transitions in aromatic polymers, because these transitions influence significantly the macroscopic properties, which depend on the mobility of the structural

elements. Questions of both methodological (methods used for the measurements, the presence of impurities in the monomers analysed) and structural (deliberate alteration of the chemical structure of the repeat unit in the macromolecule for a more clear-cut identification of the mechanisms of the transitions) natures arise in such an analysis. In the dynamic mechanical analysis of heat-resistant aromatic polymers, it is necessary to take into account the fact that many of them contain highly polar groups capable of retaining firmly the solvent with which they are in contact either during synthesis or during the preparation of film materials from solution. The presence of residual solvent promotes the appearance of additional losses and failure to take this into account may lead to erroneous interpretations of the transition mechanism.

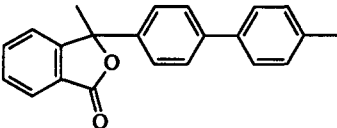

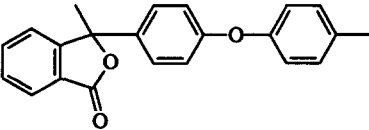

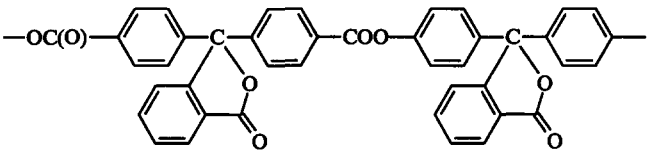

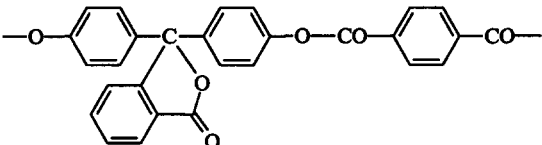

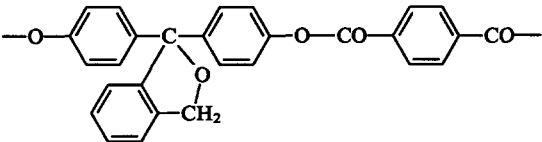

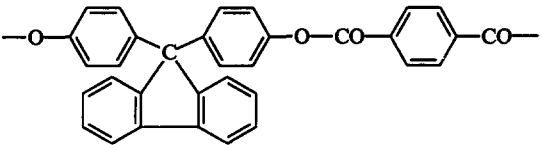

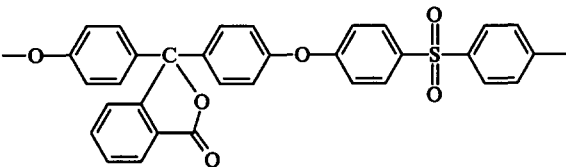

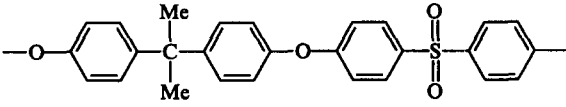

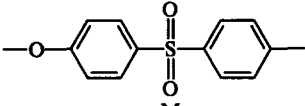

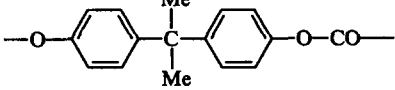

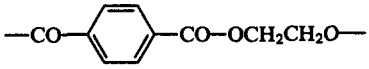

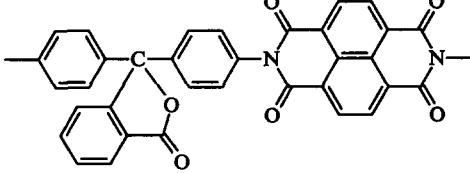

The low-temperature relaxation transitions in heat-resistant polymers have been investigated by numerous workers.^{45–61} Attention was especially concentrated on the temperatures and mechanism of the β -transition. The mechanism of the β -transition has been associated with loss of water in the case of polyimides⁴⁶ and, in another study,⁴⁷ with the interplanar slip in the crystalline regions.

The influence of residual solvents and moisture on the nature of the relaxation transitions has been studied in detail^{51,52} in relation to the polyimide obtained from naphthalene-1,4,5,8-tetracarboxylic acid and anilinephthalein. The diffuse maxima of the loss factor $\tan \delta$, which appear on the plot of temperature variation of $\tan \delta$ for this polyimide, are smoothed out on heat treatment, which eliminates moisture and residual solvents.

It is sometimes assumed that hinge atoms or groups, positioned between aromatic rings, are responsible for the relaxation transitions in aromatic polymers. In order to answer more exactly the questions of the influence of such groups, a specially synthesised series of polyarylenephthalides have been investigated.⁵¹ In this series, polyesters are replaced by polyethers and further by polyphenylenes (Table 13). In other words, particular hinge groups are 'taken away' in succession from the polymers as far as the complete elimination of all types of such groups.

Fig. 30 presents the temperature variations of E' and $\tan \delta$ for a series of such polyheteroarylenes (polymers 1–3 in Table 13).

Table 13. The chemical structures and β -relaxation and glass transition temperatures for a series of heat-treated heat-resistant polymer films.

12		-120	119	—	—

^a Temperature at the β -peak maximum.

Figure 30. Temperature dependences of E' (curves 1–3) and $\tan \delta$ (curves 4–6) for the initial (a) and heated (b) films of a series of polyheteroarylenes. Number of compounds in Table 13; (1) and (4), 1; (2) and (5) 2; (3) and (6) 3.

Two principal sections may be seen on the temperature variation of the storage modulus E' . The loss factor maxima at -96 , -93 , and -75 °C for the heated polymer 1, 2, and 3 films and at -100 , -95 , and -80 °C for the initial films correspond respectively to a sharp decrease in the storage modulus. Thus, both in the presence and absence of hinge atoms and groups in the main chain, the β -transition is manifested for all the polymers in approximately the same range of temperatures. Consequently, these hinge groups are not responsible for the β -transition.

For all the polymers 1–3, intense loss factor peaks are observed in the intermediate range -30 to 200 °C. Heat treatment at T_g for each polymer smoothes out these peaks to a large extent for polymers 1 and 2, but does not affect appreciably their intensity for polymer 3, containing a highly polar ester group in the main chain. The increase in the polarity of the polymer for the series of bridges between aromatic rings $-$, $-O-$, $-COO-$ leads to an increase in the intensity of the intermediate peaks and influences significantly the relative height of the β -peak. Whereas for the heat-treated polymer 1 and 2 films the increase in the intensity of the β -process is caused mainly by the removal of the residual water and the solvent, for polymer 3, with an ester group in the backbone, this is apparently associated with the redistribution of the intermolecular interactions, limiting the movement of the segments of the chain responsible for the low-temperature transition. Furthermore, the presence of a highly polar ester group in the main chain of polymer 3 intensifies the intermolecular interaction, expanding greatly the region of β -relaxation towards higher temperatures. For polymer 2, containing an ether group in the main chain, this effect is much weaker. The introduction of the polar groups $-O-$ and $-COO-$ into the main chain lowers the glass transition temperature from 420 to 270 and 340 °C for polymers 2 and 3 respectively.

Thus the introduction of ether and ester groups into the main chain of the polymer expands and displaces the maximum of the β -peak towards higher temperatures, on the one hand, but reduces the glass transition temperature, on the other. The contributions of the $-O-$ and $-COO-$ groups to the shift are then directly opposed in relation to the β - and α -transitions.

It may be postulated that the limited rotation of the phenylene groups relative to collinear bonds is responsible for the β -relaxation. However, the observed behaviour cannot be accounted for by this simple mechanism. Indeed, since the hinge atoms and groups facilitate the movement of the phenylene rings (this leads to an increase in the flexibility of the chain and a decrease in T_g), the temperature of the β -transition should be lowered on introduction of the hinge groups. In fact, it increases (Fig. 30 and Table 13).

In the analysis of the mechanism of the β -transition, it is essential to take into account the fact that the polymer in the glassy state consists of a complex system of interacting macromolecules responsible for the existence of regions with different degrees of order and for the relaxation transitions in the main chain of the polymer. From this standpoint, the β -relaxation transition may be accounted for by the freeing of the mobility of large chain segments in the least ordered regions. With increase in temperature, the movement in the more ordered (or more cross-linked as a result of the impurities present in the polymers) regions is freed, such movement being characterised by a higher activation energy necessary to overcome the intermolecular interaction forces. On vitrification, the most ordered and cross-linked segments of the chain are freed. The relative contribution of the polymer chain segments ordered in different ways, taking into account intermolecular interaction, to the overall process involving the freeing of mobility may be determined, for example, in terms of the dynamic loss modulus. The presence of the crystalline

phase in the polymer expands the number of regions with different types of order in chain segments on the assumption that additional energy scattering mechanisms arise. The distribution spectrum of regions with differently ordered chain segments is determined primarily by the specific chemical structure of the chain, the molecular mass distribution, the presence of branches, the impurities present in the polymer, the method of preparation of the test specimen, and also the test conditions.

Even if the hinge atoms and groups are absent from the aromatic polymer, β -relaxation is nevertheless manifested. Hence follows the unambiguous conclusion that these are not the groups responsible for the β -transition.

Most investigators associate the mechanism of β -relaxation with the freeing of the molecular mobility of the aromatic rings.⁴⁸⁻⁵⁹ Approximately the same conclusion was reached by Eisenberg and Cavrol.⁶² The results obtained in their study by means of dynamic mechanical analysis indicate that the β -transition in polyimides is associated with the rotation of rigid *p*-phenylene segments and the imide groups around the hinges. However, the authors⁶² believe that the β -transition is manifested by a broad maximum at a positive temperature lower than the glass transition temperature.

The acoustic properties of poly(phenylene sulfide) have been investigated.⁶³ The β -relaxation in this polymer was observed in the temperature range from 193 to 223 K for an amorphous specimen (judging from the temperature variations of the mechanical loss factor). According to the ideas of Lukashov et al.,⁶³ the β -relaxation is associated with the vibrational motion of the phenylene groups in the main chain of the polymer. In the region of α -relaxation, poly(phenylene sulfide) exhibits two transitions due to the freeing of the segmental mobility at two levels of the supermolecular organisation of the polymer. Annealing of the polymer leads to an increase in the transition temperatures in the β -relaxation region.

The influence of flexible alkoxy-groups of different length, located in repeat units of rigid-chain polyesters, on the viscoelastic behaviour of these systems has been investigated.⁶⁴ The results of dynamic mechanical analysis have shown that these polymers have a complex relaxation spectrum. In order to explain the observed spectrum, the authors resort to the concept of different kinds of molecular motion in combination with structural rearrangements on heating. In certain cases, properties typical of liquid-crystal systems were observed.

The relation between the structure and relaxation properties of copolymeric poly(arylene ether ketones) has been investigated.⁶⁵ Different copolymers were synthesised by the partial substitution of hydroquinone in the polyetherketone by resorcinol or hexafluorobisphenol A. In the former case, the dynamic viscosity and the storage modulus for copolymers with a low resorcinol content increased with increase in temperature. The copolymers with a high content of resorcinol residues did not exhibit such unusual behaviour.

The thermal and thermooxidative stabilities, the coefficient of thermal expansion, the glass transition temperature, and the dielectric properties have been investigated in detail for the polyimide having the following structure:⁶⁶

the glass transition temperature of this polymer is $\sim 287^\circ\text{C}$, its coefficient of thermal expansion is $6.98 \times 10^{-6} \text{ K}^{-1}$, and the dielectric constant of films, measured after ageing at 50% humidity, amounts to 2.8–2.9 in the frequency range from 0.1 kHz to 1 MHz.

Relaxation properties have also been investigated for oriented systems (fibres and films) obtained from heat-resistant polymers.

The relation between structure and mechanical properties for highly modular fibres of poly[2,5(6)benzoxazole] has been investigated.⁶⁷ It was found that the modulus of elasticity of the fibres increases from 91 to 133 GPa as a result of treatment of the fibre at 525°C , while the deformation at break falls from 4.3% to 2.0%; the strength of the fibre remains unchanged under these conditions and is above 2.1 GPa. The increase in the modulus is attributed to the development of three-dimensional crystalline order in the fibre.

About all the technologically important fibres are manufactured from linear heat-resistant polymers, such as polyimides, polyoxadiazoles, aromatic polyamides, etc. The modulus and strength of such fibres, measured along the fibre axis, are determined by the strength of the covalent bonds in the chains of these polymers. It has been suggested⁶⁸ that the reduced strength and modulus at right angles to the fibre axis are associated with the weak (compared with chemical bonding) intermolecular interaction involving the formation of hydrogen bonds and dipole–dipole and dispersion interactions arising between the polymer chains in the fibre. An increase in compressive strength in the fibres may be achieved by cross-linking the macromolecules. The authors^{68,69} therefore prepared and characterised three linear polymers with two conjugated triple bonds in each repeat unit:

The third polymer — poly(dipropargyl terephthalate) — crystallises in the solid state on precipitation with water. The crystallisation is in this case the initial stage of the cross-linking process. Thus self-cross-linking fibres may be obtained by a wet method.

The dynamic mechanical properties and relaxation transitions of the new thermoplastic polyimide

have been studied.⁷⁰ The polyimide films were investigated directly after casting and after zone stretching in order to increase the degree of orientation.⁷¹⁻⁷³ The zone stretching of the polyimide leads to an increase in the modulus of elasticity over the entire temperature range investigated and is accompanied by an increase in the glass transition temperature and a decrease in the mechanical loss factor.⁷⁰

The birefringence of fibres based on heat-resistant polymers has been studied.⁷⁴⁻⁷⁹ A critical analysis of the results has been published.⁸⁰

The influence of the thickness of the coating on the orientation of the chains and the order in polyimides has been investigated.⁸¹ It was found by X-ray diffraction that substrate prepared polyimide films are oriented in such a way that the polyimide chains are preferentially arranged within the plane of the film. The degree of orientation then increases with increase in the content of the rigid polyimide, for example of the kind:

With increase in the thickness of the film, the average degree of orientation falls and the coefficient of volume expansion increases.

The strength and relaxation properties under stretching and compression conditions have been investigated for fibres based on poly-*p*-phenylenebenzobisoxazole and poly-*p*-phenyleneterephthalamide.⁸²

V. The mechanism of the relaxation processes in heat-resistant polymers

The question of the mechanism of the relaxation processes arising on deformation of glassy polymers has attracted constant attention of investigators. The question of the possibility of comparatively large deformations in heat-resistant aromatic polymers has acquired particular interest, such a possibility of existing down to the temperature of liquid helium.

The mechanism of the relaxation process involving the viscoelastic strain recovery of a polyimide film after its preliminary deformation up to a specified elongation has been studied.⁸³ The viscoelastic strain recovery curves (the time variations of the deformation after the specimen has been freed) were fitted with the aid of the memory functions $T_1(\tau)$ and $T_2(\tau)$.

The Boltzmann equation for the viscoelastic strain recovery curves assumes the following form:

$$\varepsilon(t) = \varepsilon_0 \left[1 - \int_0^t T_1(\tau) d\tau \right] \quad (29)$$

or

$$\varepsilon(t) = \varepsilon_0 \left[1 - \int_0^t T_2(\tau) d\tau \right], \quad (30)$$

where ε_0 is the initial deformation at which the load is removed and the shrinking process begins at a constant temperature.

The experiments were performed⁸³ for a commercial PM polyimide film, which was stretched under creep conditions up to the deformation $\varepsilon_0 = 10\%$. The load was then removed and the contraction of the specimen was measured.

The fitting of the strain recovery curves by Eqns (29) and (30) demonstrated⁸³ that these curves are best fitted with the aid of the memory function $T_1(\tau)$ (Table 14). Consequently, from the standpoints considered, the relaxation process in the shrinkage of the specimen after loading is limited by the stage involving the interaction of the relaxators. The rate constant is then small (Table 14). When a load is applied at an elevated temperature, the quantity $k_B m^*/S_0$ is significantly greater than at room temperature.

If the mechanism of the relaxation processes described above is indeed associated with the formation and redistribution of microheterogeneities in the polymeric material, then analysis of positron annihilation in the relaxing specimen may provide an experimental confirmation of this mechanism, because it is precisely with the aid of this method that one can estimate the volumes and nature of the microcavities having dimensions comparable to or somewhat exceeding those of the repeat units of the heat-resistant polymers. The authors⁸³ therefore measured the annihilation spectra in both the initial polyimide specimen and in the prestretched specimen and also during its contraction after the removal of the load.

The measurements showed that the positron annihilation process in the polyimide differs significantly from that usually observed in the majority of polymers. The annihilation spectrum in the polymers is characterised by the presence, as a rule, of three or four components with average lifetimes from 10 ps to 4 ns.⁸⁴⁻⁸⁶ However, a different structure of the spectrum was observed for the polyimide, which was found to have only one, and short-lived, component with $\tau_0 = 0.388$ ns (Fig. 31). The time distribution can be fitted satisfactorily by a single decay line, the slope of which defines the average lifetime.

Figure 31. Spectrum of positron lifetimes in the initial polyimide film; N = number of counts in the channel.

The lifetime and the structure of the spectrum suggest that the annihilation in the polyimide occur in the positron state without the formation of a positronium atom of the kind characteristic of metals and semiconductors with a high mobility of electrons and an ordered crystal structure.

In this sense, the polyimide has an electronic structure unique for polymers, characterised by a high degree of uniformity of the electron density function.

In relation to interaction with positrons, the microstructure of the initial (undeformed) polyimide film is defect-free. However,

Figure 32. The lifetimes and intensities of the components in the spectra with polyimide the initial polyimide specimen (1) and polyimide specimens subjected to preliminary extension, measured for strain recovery durations of 1 h (2) and 24 h (3).

after deformation, the time aspects change (Fig. 32 and Table 15). Instead of the one component in the deformed specimen, two components are observed: with shorter (τ_1) and longer (τ_2) lifetimes. After strain recovery for 24 h at room temperature, an increase in the lifetimes of both components and a decrease in the intensity of the longer-lived one are observed. The nature of the changes occurring suggest that a rearrangement of the supermolecular structure of the polyimide occurs on deformation: the intermolecular bonds are broken and microdefects — free volumes sufficient to accommodate a positron — are formed. For the long-lived component, the time τ_2 should reflect in this case the changes in the average size, whilst the annihilation intensity I_2 should reflect the concentration of such defects. Similar changes in the spectra have been observed on formation and annealing of defects in metals and semiconductors. These changes are usually analysed with the aid of the positron capture model.⁸⁷ The model reflects qualitatively well changes in the time spectra of the polyimide during its deformation. The decrease in the lifetime of the 'short' component, associated with the annihilation in the defect-free part of the polymer, is due to the high rate of capture in the deformed specimen. After the partial contraction during the strain recovery process, the concentration of the defects falls and the lifetime τ_1 approaches that characteristic of the initial polymer. The intensity I_2 for the long-lived component, formed as a consequence of the annihilation of positrons on defects, also decreases under these conditions. The quantities calculated from the rate of capture spectra for the deformed and partially relaxed specimens are presented in Table 15. The increase in the lifetime τ_2 can be accounted for by the coagulation (the combination of small defects into larger ones) during strain recovery or by the rapid

relaxation of the small pores and hence by the increase in the average capture radius.

The concentration of microdefects after partial relaxation falls by a factor greater than 7, whereupon the free volume induced by deformation diminishes, by a factor of 4.⁸³ The values obtained show that both processes take place — the fusion of the microdefects and the relaxation of the smallest defects — although the intensity of the latter is apparently greater.

Thus a one component spectrum is characteristic of the initial polyimide film. In the deformed specimen, at least two components are observed in the time spectra and are associated with the annihilation of positrons in the free state and the state corresponding to trapping in micropores, which arise on extension. During the relaxation of the structure, the lifetime increases and the intensity of the annihilation of the defective component diminishes. The results obtained with the aid of the positron capture model describe satisfactorily the observed changes in the time distribution and suggest that the structure of the free volume changes on relaxation not only as a result of the rapid recombination of the smallest pores but also as a consequence of the recombination of small pores with formation of long-lived large microcavities.

On the basis of the analysis, the following model of the annihilation of positrons and the mechanism of the relaxation process associated with the latter have been proposed:⁸³ before deformation, all the positrons are annihilated in the state corresponding to their enclosure in small traps with a binding energy slightly exceeding the thermal energy, while after deformation fairly extended regions appear (compared with the positron diffusion length) in which the concentration of small traps (~ 10 nm in size) appreciably diminishes with the simultaneous appearance of loosened regions with deep positron capture centres, in which the positron lifetimes are longer; relaxation takes place in such a way that the pores formed on deformation recombine and in addition increase in size as a result of fusion.

Consequently, having measured the lifetime of the positrons, it is possible to obtain data on the changes in the structure of the unoccupied volume occurring after the deformation of the polyimide film. However, in order to interpret the information obtained, it is necessary to study in detail the nature of the components of the complex annihilation time spectrum characteristic of the nonequilibrium state of the polymer. The problem formulated could not be solved with the aid of one of the positron methods^{84,85} and for this reason a combined study has been carried out⁸⁸ of the annihilation of positrons in the deformed polyimide by measuring the lifetime of the positrons and the angular correlation of the annihilation emission.

Two series of experiments have been described.⁸⁸ In the first series, the polyimide film was subjected to uniaxial extension deformation by 20%. The film was then freed from the clamps and was allowed to relax freely. The lifetime spectra were recorded on a freely relaxing film at 1.5 h intervals. The parameters of the angular correlations were determined at 1 h intervals for 24 h.

In the second series of experiments, the stress relaxation process was investigated for the deformation $\varepsilon_0 = 20\%$. The characteristics of the angular correlations were determined for a film with fixed ends. The measurements were performed with the aid of a device which made it possible to deform specimens directly in the measuring chamber. At the same time the stress relaxation curves themselves (time variation of the stress) were recorded together with the strain recovery curves (time variation of the deformation).

The positron lifetimes obtained from the spectra are presented in Table 16 and in Fig. 33. In the structure of the time spectrum, fitted by three components, changes were observed, after deformation, in the annihilation characteristics, which then gradually relaxed to those characteristic of the initial polyimide specimen.

Three components were differentiated: the lifetime of the first short-lived (170–220 ps) component depended greatly on the relaxation time; the lifetime of the second component

Table 15. Characteristics of the positron annihilation spectra for polyimide film specimens.

Note. τ_p , τ_1 , and I_2 are characteristics of the positron lifetime spectra quoted subject to errors of ± 1 , ± 10 , and ± 1.5 respectively; FWHM is the full width at half maximum of the overall spectrum quoted subject to an error of ± 0.05 ; Γ_1 is the FWHM for the first Gaussian quoted subject to an error of ± 0.07 ; θ_p and I_p are the characteristics of the parabolic component of the angular correlation spectrum quoted subject to errors of 0.07 and 1.5 respectively.

(388 ± 10 ps) was independent or depended only slightly on the state of the specimen, but appreciable changes in the intensity of this component were observed; the characteristics of the third component did not change during the experiment.

Experiments involving the measurement of the angular correlation (together with the measurement of the lifetime of the positrons) have also been performed.⁸⁸ Being unable to analyse in detail the results of these measurements we shall only note that, in the experiments with fixed ends (under the conditions of stress relaxation), an increase in the unoccupied volume after deformation

and its subsequent slow relaxation, occurring as a result of the decrease in the concentration of micropores, are well manifested.

Overall, the changes in the macroparameters and microparameters of the polyimide films during the stress relaxation and strain recovery processes after deformation have been revealed by the positron diagnostic method. Nonmonotonic changes in the characteristics of the positron lifetime spectra and the angular correlations of the annihilation photons were observed during the strain recovery period. Two regions corresponding to changes in the positron-sensitive properties of the polyimide, associated with rapid and slow relaxation processes, were differentiated and differences were observed in the nature of the relaxation of the microporous structure of the polymer as a function of the deformation and strain recovery conditions. The observed effects are due to the formation of regions with local freeing of the molecular mobility.

All these experimental facts show that, during the stress relaxation process, the microporous structure of the polymer is rearranged, which is expressed by redistribution of the dimensions of the micropores and their fusion with one another. In this connection, it is of interest to compare the data obtained by the positron diagnostic method with the results of curve fitting with the aid of memory functions (Table 17). In the case of stress relaxation in the linear region of the mechanical behaviour, the correlation coefficient r , obtained using the memory function (19) is close to the value found with the aid of the memory function (18) and amounts to approximately unity. Consequently, the interactions of the relaxators and the diffusion of the microheterogeneities in the specimen take place at approximately the same rate. The fluctuation volume δ is 25.6 \AA^3 per repeat unit of the polymer on $\sim 20\%$ deformation.

Under the conditions of stress relaxation and the recovery of the dimensions of the specimen, the quantities $m_1^*k_B/S_0$ and $m_2^*k_B/S_0$, proportional to the number of microheterogeneities in the specimen, are approximately the same after the removal of the load; on the other hand, $m_2^*k_B/S_0 > m_1^*k_B/S_0$ which indicates a greater number of active microheterogeneities participating in their diffusion in the material. The rate constant for the interaction of the relaxators in the case of stress relaxation is significantly lower (in the linear region of mechanical behaviour) than in the strain recovery relaxation process.

Since the concepts 'relaxator' and 'micropore' are comparable, one may conclude that the relaxation parameters obtained are in good agreement with the microstructural characteristics determined by the positron annihilation technique. During the relaxation of a free film, more favourable conditions are created for the diffusion of micropores and the formation of large and stable packing defects.

We shall now consider the results of a study designed to analyse the mechanisms of the deformation and relaxation in heat-resistant polymers capable of crystallising and of giving rise to a liquid crystal state.

Wierschke et al.⁸⁹ carried out a theoretical study of the moduli for single poly-*p*-phenylenebenzobisthiazole chains. The study was carried out by the molecular orbital method within the framework of the AMI semiempirical approximation. As a result of the investigation of rigid-chain polymers containing different heteroatoms in the repeat unit, it was found that the charge distribution and the nature of the bonds change on deformation. The moduli of elasticity of the chains obtained in this way were found to be greater than the quantities measured for the real materials. This is attributed both to the presence of heterogeneities in them and to the inadequacies of the computational method itself, which systematically predicts unduly high moduli. These have been mentioned by Shoemaker et al.⁹⁰ The results of the study by Wierschke et al.⁸⁹ permit a comparative analysis of the influence of the chemical structure of heat-resistant polymers on the rigidity of their chains and their mechanical properties.

The moduli of elasticity of the crystalline regions were measured by X-ray diffraction for poly(ether ketone), poly(ether ketone), and poly(*p*-phenylene sulfide).⁹¹ This permitted a further study of the way in which the mechanical properties are related to the conformation of molecular chains and also to the intermolecular interaction in these polymers.

The crystallisation and morphology (which depends on the content of the *meta*- and *para*-isomers) of poly(aryl ketone ketones) have been investigated.⁹² The poly(aryl ketone ketones) were synthesised from diphenyl ether and terephthalic and isophthalic acids. The polymers of this type have two different crystal structures. The addition of the *meta*-isomer diminishes the equilibrium melting point and the rate of crystallisation but increases the flexibility of the chains and the capacity for recrystallisation.

The transition in the crystal phase of the thermoplastic polymer with $T_g = 216^\circ\text{C}$ ⁹³

has been investigated.⁹⁴ It was shown that this polyimide is semi-crystalline and may contain one or two crystalline phases. The mechanical properties of the polyimide films depend significantly on the type and level of crystallinity. Crystallinity promotes a significant increase in the modulus compared with the amorphous polymer, but reduces the capacity for deformation. Its extensive strength depends on the crystal form.

The mechanical properties of different heat-resistant polymers have been studied.^{95–100} Among many heterocyclic polyethers, poly(arylene ether benzimidazole) exhibits the greatest strength. This was demonstrated by tests on nonoriented films of this material.¹⁰¹ The influence of molecular mass on the mechanical properties of heat-resistant polymers

synthesised from 1,3-bis(4-fluorobenzoyl)benzene and 5,5'-bis-[2(4-hydroxyphenyl)-benzimidazole], has been investigated.¹⁰² With decrease in molecular mass, the glass transition temperature and the temperature corresponding to 5% weight loss also diminish. However, the molecular mass does not influence (in the range investigated) the strength of these films and their moduli of elasticity.

Information about the structures and properties of rigid-chain aromatic polymers in the liquid-crystalline state may be found in a review.¹⁰³ Among other investigations in this field, we may mention the study¹⁰⁴ in which the mechanism of the plastic deformation in thermoplastic and thermosetting polyimides and their interpenetrating networks was studied.

VI. Networks, blends, and composites based on heat-resistant polymers

Prepregs based on epoxy-resins have been investigated with the aim of reducing brittleness.¹⁰⁵ The prepregs were modified with aromatic and heat-resistant thermoplastics. The epoxy-resins include systems based on the diglycidyl ethers of bisphenol A and bisphenol F, triglycidyl-*p*-aminophenol, and tetraglycidyl-di-aminophenylmethane. A poly(ether sulfone), polysulfone, and polyimide were chosen as the modifying thermoplastics. It was shown that the brittleness of the epoxy-resins and their relaxation behaviour depend significantly on the type and amount of the modifying agent. The results of dynamic mechanical analysis showed that the modification has only an insignificant influence on the shear modulus and the glass transition temperature. It is noteworthy that, in explaining the results obtained for the initial resins and the composites based on them, the authors¹⁰⁵ did not take into account the chemical interaction between the epoxy-resin and the heat-resistant aromatic polymers.

Materials based on epoxy-resins, modified with different amounts of a polyetherimide, have been obtained.^{106,107} The mechanical properties of these materials have been studied in detail.¹⁰⁸ Attention was concentrated on the breakdown rigidity and the rate of liberation of energy. These characteristics increased with increasing content of the polyetherimide as the modifying agent. The authors were able to attain a decrease in the

brittleness of the materials by introducing the poly(ether imide). Under these conditions, the mechanical behaviour is influenced significantly by, for example, parameters such as the initial length of the crack and phase separation processes. Different methods for the reduction of the brittleness of epoxy-resins by the introduction of a second component, which forms an independent phase during the curing process, were proposed in this connection.^{109–114}

Mention may be made of yet another study¹¹⁵ in which the relaxation behaviour of epoxy-resins with added polyetherimide was investigated in detail by means of dynamic mechanical analysis. It was found that the curing temperature and the composition of the blend influence significantly the storage modulus E' , the loss modulus E'' and the mechanical loss factor $\tan \delta = E''/E'$. The quantity E' depends only slightly under these conditions on the content of the polyetherimide in the region of the glassy state. The opposite behaviour occurs in the region of transition from the glassy to the rubbery state: E' increases with increasing content of the poly(ether imide) and the glass temperature shifts under these conditions to the high temperature region. In the rubbery state, E' diminishes with increasing content of the poly(ether imide), which indicates a decrease in the degree of crosslinking. The loss factor $\tan \delta$ decreases with increasing content of the polyetherimide and the $\tan \delta$ maximum shifts at the same time towards higher temperatures with increasing curing temperature. The presence of only one maximum indicates the compatibility of the components.

In order to improve the compatibility of the components, one may use a chemical reaction between them.¹¹⁶ This possibility has been implemented in relation to poly(ether ketones). Poly(ether ketones) reacted with polycarbonate, affording the corresponding block copolymers. Despite the fact that the initial components [the poly(ether ketone) and the polycarbonate] were incompatible, the block copolymers based on them were found to be homogeneous and exhibited one α -transition. The moduli of elasticity of the block copolymers were greater than those calculated assuming additivity.

The preparation of blends of heat-resistant polymers with thermoset resins is an effective procedure for improving the mechanical properties of composites. Two approaches to the improvement of the mechanical properties of composites have been described.^{117–119} The first provides for the preparation of 'thermoplastic polymer – thermoset polymer alloys'. The second is associated with the preparation of a system in which thin sheets of heat-resistant thermoplastic polymers serve as spacers in the initial composition with the thermoset polymer. The results of the application of both approaches to the improvement of the mechanical properties of composites have been published.^{120–122} The diglycidyl ether of resorcinol and polyimide oligomers with the following terminal amino-groups were employed in the above studies:

The application of these approaches made it possible not only to improve the mechanical properties of composites but also to facilitate the performance of thermosetting systems.

Graphite-reinforced plastics based on the cyclophane resins

have been investigated.¹²³ The structure of these resins gives rise to a high thermal stability and glass transition temperature and promotes effective cross-linking via their end groups. An effective procedure for the improvement of the mechanical relaxation properties involves also the preparation of semi-interpenetrating polymer networks, in which the linear component is a copolymer based on polyimide.¹²⁴

Analysis of the results of the above studies shows that the most promising ways of improving the mechanical properties of heat-resistant polymers and of developing new types of the latter consists in the synthesis of network systems comprising aromatic oligomers, using, for example, the polycyclotrimerisation reaction, and the preparation of networks with the aid of chemical reactions between oligomers (for example, epoxy oligomers) and heat-resistant aromatic polymers containing in the main chain reactive groups, which can interact chemically with the reactive groups of the oligomer. In certain cases, it is possible to obtain satisfactory mechanical properties without the employment of chemical reactions between the components of the blend. The results of a series of studies, with which we shall deal briefly below, confirm this conclusion. The mechanical behaviour of binary blends of poly(ether sulfone) and poly(phenylene sulfide),¹²⁵ poly(ether sulfone) and poly(ether ketones),^{126–130} poly(ether ketone) and poly(ether imide),^{131, 132} polyamidoimide and an aromatic polyamide,¹³³ polyimides with different types of chemical structure,^{134, 135} polybenzimidazole and polyimides,^{136–142} polybenzimidazole and polyarylate,¹⁴³ and poly(ether ketones) and poly(ether sulfone)¹⁴⁴ has been investigated.

We shall consider in greater detail the results of a study¹⁴⁵ in which binary blends based on two aromatic polyamides

and three poly(ether sulfones)

were investigated.

Films made of blends of these polymers were obtained by casting from solutions in *N,N*-dimethylacetamide and *N*-methyl-2-pyrrolidone. These films were investigated by dynamic mechanical analysis, differential scanning calorimetry, and IR spectroscopy; the ultimate mechanical characteristics were also measured. The principal result of this study was the observation of crystallisation induced by the presence of the second component, which entails an increase in the heat resistance of the systems, particularly after their annealing. Test results were achieved for blends based on compounds **D** and **F**. The initial films, for example those prepared from polymers **D** and **F**–**H**, were transparent, but after heat treatment they became opaque and their quality improved.

Thermotropic liquid-crystalline polymers are used nowadays to improve the mechanical properties of heat-resistant polymers. One of the methods of preparation of composites with a high strength and rigidity involves the blending of liquid-crystalline polymers with thermoplastics. There have been fairly numerous studies (see, for example, Refs 146–157) in which the improvement of the mechanical properties of heat-resistant polymer matrices was achieved by adding thermotropic liquid-crystalline polymers to them. Among the heat-resistant polymers, such studies have been performed for poly(ether ketone), poly(ether imide), poly(phenylene sulfide), and polycarbonate. The phenomenon of synergism is characteristic of certain blends of the above polymers and liquid-crystalline polymers.

A series of publications^{156–158} have been devoted to the problem of mechanical anisotropy, which has been observed in blends of liquid-crystalline polymers with heat-resistant aromatic systems.

The studies^{159–162} in which an approach to the preparation of molecular composites was proposed are of significant interest. A molecular composite consists of rigid-chain rod-like polymers, introduced into a polymer matrix, which is made up of a flexible-chain polymer with coiled macromolecules. The rigid-chain macromolecules then serve as strengthening elements of the composite. For example, a graft copolymer based on a rigid-

chain polybenzobisthiazole (main chain) and a polyetherketone (side chain) has been synthesised.¹⁶³

A detailed study of the relaxation properties of this system by dynamic mechanical analysis has been described.¹⁶⁴

In estimating the relaxation properties, it is important to take into account the microphase separation process, which may occur when thermoplastics are blended with thermosetting systems and may also arise on hardening of the composite. The results of studies^{109, 165, 166} in which composites based on blends of a polyethersulfone with an epoxy resin are instructive in this respect. Hardening results in the formation of a two-phase system, which promotes an improvement in the mechanical properties (a decrease in brittleness). Detailed measurements of the enthalpy relaxation have been made for such systems. Subject to a satisfactory fitting of the relaxation curves (for example, with the aid of the Kohlrausch–Williams–Watts function), such measurements can be used to predict the long-term behaviour of polymeric materials under ageing conditions.

Another example of a combined investigation of the relaxation properties may be found in a study¹⁶⁷ in which the behaviour of a blend of the poly(ether sulfone)

and the polyimide

was investigated. These polymers are compatible and their behaviour was investigated by differential scanning calorimetry, dynamic mechanical analysis, and rheological methods. For a polyimide content > 10% microphase layer separation occurred and was manifested by a sharp alteration of the rheological properties. The author also did not rule out the occurrence of a cross-linking process, which may be superimposed on the microphase layer-separation process.

VII. Conclusion

Analysis of the results of relaxation measurements for heat-resistant aromatic polymers permits a series of conclusions about the characteristic features of their mechanical behaviour. One of these conclusions, which at first sight may appear trivial, is that heat-resistant aromatic polymers are capable of withstanding for a long time much greater mechanical loads than traditional plastics in the region of not only high but also moderate and low temperatures. This conclusion is based on the results of measurements of stress relaxation and creep, which show that both processes are less marked than for the usual plastics. Therefore, in creating constructional materials which can be used not only at high but also at low temperatures and for large loads, preference must be given to heat-resistant aromatic polymers. At the same time, it has become evident that, in order to discover the advantages of one set of polymers over others, relaxation measurements are not only desirable but also essential.

One should bear in mind that, even within the class of heat-resistant polymers itself, the structure of the latter has an appreciable influence on their mechanical relaxation properties. For example, in terms of critical stresses, polyimide is superior to PBO; the rate of stress relaxation in polyimide is lower than in PBO. On the other hand, in the range of comparatively low temperatures, polyimide is inferior to PBO in terms of these features.

In dynamic mechanical analysis, heat-resistant aromatic polymers exhibit a series of relaxation transitions associated with the freeing of the molecular mobility of individual groups and segments. A study of the mechanism of these processes by synthesising and investigating a series of polymers in which different hinge atoms and groups are deliberately 'taken away' demonstrated unambiguously that the β -transition in these polymers is associated with the freeing of the molecular mobility of phenylene groups.

However, attention should be concentrated on the characteristics of the mechanical behaviour of heat-resistant polymers, which are manifested in the analysis of relaxation transitions under the conditions of static measurements of stress relaxation and creep. The essential feature of the transitions is that, within the range of the glassy state at temperatures greatly below the glass transition temperature, the relaxation processes are accelerated sharply and the critical stresses are reduced. These transitions play a significant role in an objective assessment of the mechanical workability of polymers. If the polymer is designed for use at variable temperatures and is to be subjected to appreciable mechanical loads, then, on heating to the transition temperature, the mechanical workability may be lost long before the glass transition temperature. The occurrence of these transitions is undoubtedly associated with the linearity of the mechanical behaviour, whereupon appreciable deformations result in a change of the relaxation parameters of the polymer.

Another characteristic feature of the relaxation behaviour of aromatic heat-resistant polymers is that, over a fairly wide temperature range within the region of the glassy state, the parameters of the relaxation processes are relatively insensitive to temperature. This temperature range confines the region of the stable workability of the polymers and it is desirable to take it into account when selecting a polymeric material for each specific task.

One of the significant features of the mechanical behaviour of aromatic polymers is their ability to develop large deformations (i.e. to undergo nonbrittle disruption) in the region of low and ultra-low temperatures. Even at the temperature of liquid helium, the deformation of aromatic polymers attains a large percentage value and relaxation processes are also manifested at these temperatures. Analysis of the mechanisms of deformation and relaxation with the aid of the positron annihilation method has shown (in relation to polyimide) that these polymers have a unique electronic structure and a very narrow size distribution of their pores. It may be that this is the cause of the surprising behaviour at

low temperatures. Aromatic polymers also have another significant advantage over the usual ones (for example, Teflon) — they are capable of withstanding an enormous number of thermocycles over a temperature range from 200 °C to the temperature of liquid nitrogen without loss of mechanical strength.

Finally, many aromatic polymers contain in their chains functional groups (ester, amide, imide, etc. groups) capable of interacting with the functional groups of thermoset oligomers and of curing them. This property is used in creating composite materials based on traditional polymers (for example, epoxy resins), which are strengthened when heat-resistant polymers are introduced into them and lose their brittleness.

Abstract. The methods for the affinity modification of proteins, specific to nucleic acids, by activated nucleic acid analogues and their components, are considered. The active groups introduced into proteins or nucleic acids and the symmetrical cross-linking agents used to obtain covalent protein–nucleic acid complexes are listed. The methods for the analysis of covalently linked protein–nucleic acid adducts as well as procedures for the identification of the aminoacids in the protein participating in the formation of bonds with nucleic acids are surveyed. The bibliography includes 112 references.

I. Introduction

There are comparatively few methods which make it possible to determine the groups in the protein participating in protein–nucleic acid recognition. The most accurate of these is X-ray diffraction (XRD). However, owing to the poor resolution of X-ray diffraction patterns, the difficulty of isolating sufficient amounts of the protein, and also the differences between the conformations of the macromolecules in solution and in the crystal, this method has not found extensive application. Furthermore, it is not always possible to obtain and isolate specific complexes between proteins and DNA. There are also problems associated with their crystallisation.

Site-specific mutagenesis and chemical modification of the proteins also yield valuable information about the interaction of proteins with nucleic acids, but such experiments require, at least to a first approximation, the knowledge of location of the protein region responsible for this process. A method which makes it possible to identify this region is covalent attachment of proteins to nucleic acids (NA).

Numerous methods for the attachment of proteins to nucleic acids are known at the present time. We have attempted to arrange systematically the available literature data on this question. In our view, the existing methods for the affinity modification of proteins by nucleic acids can be divided into three groups:

- the attachment of proteins to nucleic acids by exposure to different types of radiation;
- chemical methods for the covalent attachment of proteins to nucleic acids;
- covalent attachment of nucleic acids to enzymes based on the mechanisms of the functioning of the latter.

Nucleic acid analogues containing different active groups are usually employed for the affinity modification of the protein. Such groups may be introduced into heterocyclic bases and carbohydrate residues via the terminal or internucleotide phosphate group of the nucleic acid. So, to our mind it is necessary to concentrate attention also on the approaches for the activation of nucleic acids used in each of these methods for the covalent attachment of proteins to nucleic acids.

In the concluding section of the review, the approaches to the identification and isolation of covalent protein–nucleic acid complexes and for the determination of the peptides in the protein bound covalently to the nucleic acid are surveyed. The possibilities for the application of the method involving the covalent attachment of nucleic acid–specific proteins to nucleic acids for the probing of the mechanisms of their interaction are considered.

II. Covalent attachment of proteins to nucleic acids by exposure to different types of radiation

1. Irradiation with UV light

When complexes between proteins and nucleic acids or their analogues are irradiated with UV light, the side chains of the protein become covalently attached to the heterocyclic base residues closest to them (the so-called ‘zero length cross-linking’).

a. Irradiation of complexes between proteins and unmodified nucleic acids with UV light

This method for covalent attachment is used in relation to a wide range of biological systems: from cell nuclei up to isolated and purified proteins in complexes with synthetic oligonucleotides. The conditions for the irradiation of various systems in order to obtain protein–nucleic acid complexes in the appropriate buffer

solutions are surveyed in Table 1. It is seen from the data presented that the irradiation time varies from 1 min to 4 h and the wavelength is as a rule 254 nm. Under these conditions, the yield of the conjugate varies from 0.1% to 70%. Owing to the complexity of the system, in certain cases it was not possible to determine the yield of the final conjugate, so that the stoichiometry of the complexes is presented instead. It reflects the number of protein molecules per DNA molecule or the number of base pairs of the DNA bound covalently to one protein molecule.

On irradiation with UV light of a protein–nucleic acid complex, the 5,6-double bond of the pyrimidines is excited, which leads to its rupture; a biradical is formed at the 5,6-positions in the pyrimidine ring and reacts with the side chains of the protein.²¹ This reaction mechanism has been established in a detailed study of the products of the irradiation of uracil in the presence of cysteine (Scheme 1).

Scheme 1

R = CH₂CH(NH₂)COOH.

Compounds A, B, E, and F are formed on irradiation with light at a wavelength > 290 nm in the presence of acetophenone, which is a 'trap' for the radicals. It has been suggested that the reaction is reversible. The product C is formed in solutions containing free radical generators, for example oxygen or riboflavin. The irradiation conditions depend on the energy required for the formation of the radical: when the solution contains oxygen, a wavelength of 254 nm is employed, while in the presence of riboflavin the wavelength is 290 nm. Compound C is probably obtained from E as the primary product. Compound D is apparently formed similarly to C, via a free radical in the 5-position in uracil.²²

At the present time, there is no unanimous view in the literature concerning the mechanism of the covalent cross-linking of unmodified nucleic acids with proteins on exposure to UV light. In a number of studies, for example in that of Welsh and Cantor,²¹ it has been suggested that such cross-linking is nonspecific and depends not on the nature of the side chain of the amino acid residue but on the distance between it and the heterocycle. On the other hand, other workers (see Refs 3, 22, and 23) noted the specificity of the formation of the covalent cross-link in relation to definite amino acid residues, for example Ser, Ile, Thr, Arg, and Lys.

Saito et al.³ believe that, when complexes between proteins and nucleic acids are irradiated with UV light, a cross-link is formed between the thymine residue and the ε-amino-group of lysine. The deoxythymidine–L-Lys model system was used to investigate this reaction (Scheme 2).

It was established that, on irradiation with light at a wavelength > 280 nm, the adduct L-Lys–thymidine is not formed. On exposure to UV light, thymidine also interacts with Arg. The reaction involves the α-amino-group of Arg and not the guanidine residue, i.e. Arg in the protein may react with thymidine on irradiation only when it is N-terminal.

The method for the UV irradiation of proteins and nucleic acids considered in this Section has its advantages and disadvantages.

^d S-Adenosyl-L-methionine. ^e The yield calculated relative to SAM is indicated.

The former include the possibility of identifying the amino acid residue closest to the nucleic acid. However, the absence of a covalent adduct after irradiation does not imply the absence of contact between the nucleic acid and protein, since it may be that the activation of the components of the complex by UV irradiation

is insufficient for the reaction to occur. A disadvantage of the method is also the damage to the structure of the nucleic acid and the protein for a high intensity and long duration of the irradiation. Under these conditions, the mutations occurring in nucleic acids interfere with the study of the conjugate (for example, owing to a change in mobility in the gel). The inactivation of the protein, which may occur either as a result of its breakdown on irradiation or owing to covalent cross-linking, cannot serve as a test for the formation of a protein–nucleic acid complex.

b. Irradiation with UV light of complexes of proteins with modified nucleic acid analogues

The cross-linking of proteins to photosensitive nucleic acid analogues is used for the determination of the topology of nucleic acid–protein complexes. Nucleic acids where a bromine atom or the azido-group has been introduced in the 5-position in pyrimidine bases and in the 8-position in the purine bases are used as analogues of this kind.²⁴ The above chemical groups are exposed in the major groove of the double helix. They do not induce a significant change in its structure and do not prevent protein–nucleic acid recognition.

The conditions governing the cross-linking of the bromo- and azido-substituted nucleic acid analogues to proteins are summarised in Table 2. The table shows that the irradiation conditions for the modified nucleic acid analogues are milder than for the unmodified nucleic acids. The yields of the covalently bound

protein–nucleic acid conjugates are fairly large and in certain systems amount to 60%.

The introduction of photosensitive groups into a heterocyclic base alters the reaction mechanism. Irradiation of the complexes of bromo-substituted nucleic acid analogues with a protein is accompanied by the loss of the bromine atom and the formation of an unpaired electron in the 5-position of the uracil residue, which may react in different ways with the protein side chains, giving rise to a covalent cross-link.²¹ The only condition for the occurrence of such cross-linking is the proximity of the side chain of the aminoacid residue and of the free radical. Wolfes et al.²⁵ believe that the interaction of the bromine-containing substrates with the Gly, Ser, Phe, Tyr, Trp, Cys, and Met residues, having aliphatic chains or aromatic rings, as possible free radical acceptors is most likely. The mechanism and specificity of this reaction were not investigated in greater detail. Among the advantages of the method considered one should mention the high sensitivity of the modified nucleic acids to UV irradiation, as a result of which the probability of mutations in the nucleic acids and in the protein diminishes owing to the smaller intensity and duration of the irradiation.

The azido-substituted nucleic acid analogues are even more effective in the covalent binding reaction.⁴⁰ In the case of nucleoside residues containing the azido-group in the 8-position in the purine bases or in the 5-position in the pyrimidine bases, the mechanism of the formation of the covalently bound protein–nucleic acid complex is much more complicated. On irradiation with UV light, the photochemical elimination of a nitrogen atom results in the formation not of a radical but of a nitrene, which may react nonselectively with the closest groups regardless of their electrophilicity or nucleophilicity.³⁷ An indirect demonstration of this mechanism has been achieved in a spectrophotometric study of the consequences of the UV irradiation of N₃-dUTP.⁴⁰ After only 20 s, the maximum at 288 nm, corresponding to the azido-derivative of dUTP, vanishes completely. The decrease in absorption after photolysis indicates the rupture of the conjugated ring system of the heterocyclic base (possibly as a result of an intramolecular rearrangement initiated by the formation of the nitrene).

The particular value of the azido-derivatives of nucleic acids consists in the fact that the azido-group is fairly small and does not prevent the formation of hydrogen bonds between the protein and the nucleic acid. Furthermore, the introduction of the azido-group in the 5-position in the pyrimidine residues does not alter the *anti*-conformation of the heterocyclic base of the nucleoside and only induces a slight distortion of the nucleic acid structure.^{40, 41} Reich and Everett⁴¹ compared the kinetic parameters of the interaction of the methyltransferase *EcoRI* with the cofactor SAM (*S*-adenosyl-L-methionine) and also its analogues containing the azido-group in the 8-position of the heterocyclic base. It was found that the constants for binding to the enzyme in the absence of DNA are of the same order of magnitude for the native cofactor and its azido-analogues, amounting to 4.8 and 12.9 μM respectively. The catalytic constant (k_{cat}) and the Michaelis–Menten constant (K_{M}) for SAM and 8-azido-SAM in ternary complexes with the enzyme and with the 12-membered DNA duplex hardly differ, amounting to 4.3 s⁻¹ and 0.335 μM for the native cofactor and to 5.0 s⁻¹ and 0.710 μM respectively for the modified compound. These results indicate the insignificant nature of the changes in the structure of the nucleoside following the introduction of the azido-group. When acted upon by UV light, 8-azido-SAM becomes covalently attached to the enzyme. The specificity of the covalent attachment has been demonstrated by its inhibition on addition of the unmodified cofactor.⁴¹

Another advantage of the azido-derivatives is the fact that the conversion of the azido-group into the nitrene occurs at a much lower intensity of the UV light, which makes it possible to avoid

damage to DNA on irradiation. The initial rates of disruption of the heterocycle on irradiation with UV light at a wavelength of 254 nm have been compared.⁴⁰ It was established that a decrease in maximum absorption for N₃-dUMP was 7000 times faster than for dTTP and 1150 times faster than for br⁵dUMP. Thus the azido-analogues are much more reactive in relation to proteins. There are no data on the specificity of their action.

Thymidine and deoxyguanosine in which the keto-group has been replaced by the thio-group have been tried as photosensitive analogues of nucleosides.³³ It was established that the DNA duplexes modified in this way become covalently attached to restriction–modification enzymes *EcoRI* and *EcoRV* (the conditions for their irradiation are presented in Table 2). It was shown in control experiments that the enzymes themselves retain fully their activity after irradiation; the irradiation of enzymes with unmodified DNA does not lead to the formation of covalently bound adducts; incubation of the components of the complex without irradiation also does not induce the formation of conjugates.

By introducing 4-thiothymidine residues into genes coding for 5S rRNA and tRNA^{Tyr} of the yeast *Saccharomyces cerevisiae*, the interaction of such DNA with transcription factors — TFIIC and TFIIB — was investigated. It was shown that the modification does not prevent the formation of noncovalent specific complexes with the proteins considered. Photoattachment occurred after the preincubation of the complexes on irradiation with UV light at a wavelength of 300 nm for 15 min. The method made it possible to identify the subunits of the transcription factors in contact with particular regions of the transcribed DNA.⁴²

The modification of mRNA and certain ribosomal RNA with the 4-thiouridine residue has been used in the study of the topography of ribosomes in early stages of the transcription.^{43–48} It was shown that, in the transcription involving T7-polymerase, 4-thiouridine triphosphate is incorporated in the synthesised RNA strand in the same way as the unmodified nucleoside triphosphates.^{43–48} When ribosomes containing the modified components were irradiated with UV light at a wavelength > 300 nm for 10 min, cross-links were formed between mRNA and the ribosomal RNA^{43–47} as well as RNA–protein cross-links. The ribosomal proteins bound covalently to a synthetic analogue of mRNA containing the 4-thiouridine residue have been identified.⁴⁸ The method has been used to determine the proteins spatially in close proximity to mRNA at different transcription stages.

We shall consider two possible mechanisms of the reaction of proteins with nucleic acids containing a 4-thiopyrimidine base: in the presence of oxygen and in its absence.³³ In the latter case, the protein is attached to the C(6) atom of the pyrimidine ring with the simultaneous reduction of the 5,6-double bond. The reaction proceeds via a radical mechanism, which involves the elimination of a hydrogen atom from 4-thiopyrimidine in the excited state.

In the presence of oxygen, the 4-thiopyrimidines in the nucleic acid are oxidised to the corresponding 4-sulfonates, which are highly reactive and are subjected to nucleophilic attack by the aminoacid residues of the protein with substitution of the sulfonate group.

There are data concerning the mechanism of the photoattachment of nucleic acids containing 6-thiodeoxyguanosine to proteins. It is believed that they form sulfonate derivatives as a result of irradiation.³³

Another type of activation of nucleic acids involves the formation of oligoribonucleotides or oligodeoxyribonucleotides in which the photoactivated group is not attached directly to the heterocyclic base. Thus oligoribonucleotides containing a dinitrobenzene ring with the azido-group and linked to the 5'-phosphate group via ethylenediamine have been used for the affinity modification of ribosomal proteins.⁴⁹

X = ribonucleoside residue

Mitchell et al.³⁸ modified tRNA with *N*-(*p*-azidobenzoyl)glycine by attaching it to the 3-(3-amino-3-carboxypropyl)uridine residue (the irradiation conditions are presented in Table 2). The mechanism of the reaction involving the attachment of nucleic acids modified in this way to proteins does not differ from that considered above, since in this case too the main photoactivated reactive group is the azido-group.

Apart from the nitrene, a carbene may be used for the covalent attachment to proteins. The formation of a carbene from the diazine-derivative of the nucleic acid is induced by irradiation with UV light.³⁹ The active group — 3-trifluoromethyl-3-(*p*-carboxybenzoyl)diazine — was attached to the internucleotide phosphate in the DNA duplex. As a result of irradiation with UV light at a longer wavelength (Table 2), this group decomposes, affording a carbene. It is postulated that the carbenes are more reactive than the nitrenes and, furthermore, that irradiation with UV light at a longer wavelength is preferable, since it prevents the degradation of the protein.

c. The use of laser radiation

Not only a mercury or mineral lamp but also a laser may be used as a source of UV light. The difference between laser irradiation and the usual irradiation consists in the extremely high power and brief duration of the light pulse. Laser radiation was first used for the covalent attachment of proteins to nucleic acids in relation to the complex between the *E. coli* RNA polymerase and the phage T7 DNA. The reaction mixture was irradiated with a single pulse having an energy of 120 mJ (irradiation time 20 ns, wavelength 248 nm). Depending on the concentration of mercaptoethanol, the yield of the complex varied from 5% to 20%.

The mechanism of the covalent attachment of proteins to nucleic acids on exposure to laser irradiation does not differ from that of the attachment on irradiation by light from a mercury or mineral lamp. However, the use of a brief pulse and the presence of mercaptoethanol as the 'trap' for the long-lived radicals formed on irradiation made it possible to characterise in greater detail the intermediate compounds formed on irradiation by a laser. The lifetime of the radicals formed on irradiation is calculated from the formula

$$\frac{f_0}{f_q} = 1 + K_q t,$$

where f_0 and f_q are the yields of the product of the covalent attachment in the absence and in the presence of mercaptoethanol respectively, K_q is the rate constant for the trapping of radicals, and t the lifetime of the radical.⁵⁰ It was established that $t = 25\text{--}4000$ ns and that approximately half of the radicals are long-lived. Since the lifetime of a particular conformation of the DNA-protein complex proved to be much greater than the duration of the laser pulse, it became possible to 'freeze' a particular structure of the test object, but this is interfered with by the long-living radicals because the latter may react with the protein already after the transition of the system to another state (the so-called diffusion of radicals). In order to avoid such artefacts, it has been suggested that mercaptoethanol be used as a 'trap' for the long-lived radicals.

The yield of the product of the covalent attachment of a protein to the nucleic acid under the influence of laser radiation depends linearly on the irradiation dose, which indicates that only one photon participates in each cross-linking step and that the excitation of only one of the components of the complex is sufficient for the reaction. An advantage of the method is smaller

damage to DNA compared with other methods, the protein fully retaining its native state under these conditions.⁵⁰

On exposure to laser irradiation, the DNA modified with the psoralen furanoside residue can also be attached to proteins, which has been demonstrated in relation to their attachment to the RNA polymerase of the bacteriophage T7.⁵¹ The irradiation was carried out with the aid of an argon laser having a broad radiation spectrum and a maximum at 366 nm. For an equimolar ratio of DNA and the protein in the reaction mixture, approximately 80% of the DNA is attached covalently to the RNA polymerase. It has been observed by electrophoresis that several isomeric covalent protein-nucleic acid complexes are formed. Degradation of the RNA polymerase under these conditions was not observed. An increase in the irradiation intensity led to a linear growth of the yield of the covalent adducts. The advantages of this method are the short irradiation time and the possibility of 'freezing' the equilibrium states of the DNA-protein complex, which makes it possible to investigate the kinetic constants for this process. Two mechanisms of the attachment of DNA, modified by psoralen furanoside, to a protein have been proposed: (1) via the formation of a singlet oxygen atom, radicals, or radical-ions; (2) by direct photoattachment. It is noteworthy that evidence in support of one of these photoactivation pathways has not been found, but the covalent attachment yield is directly related to the influence of external conditions on the stability of the protein-nucleic acid complex.⁵¹

2. Irradiation from γ -sources

Irradiation from γ -sources has also been used to obtain DNA-protein conjugates. For this purpose, the corresponding complexes were placed in a saturated solution of nitrous oxide.^{52,53} A nucleosome became the object of such studies. A nucleosome consists of a repeating chromatin unit and incorporates DNA consisting of 200 nucleotide pairs and the histones H2A, H2B, H3, and H4.⁵⁴ The study of this system is important for the understanding of the mechanisms of the storage of genetic information.

The covalent attachment of histones to DNA occurs on exposure to γ -irradiation. The formation of a covalent bond between the pyrimidine residues of DNA and the tyrosine residues of the protein has been postulated.⁵³ The tyrosine-cytidine system in an aqueous solution of nitrous oxide has been used to model the formation of the DNA-histone conjugate.⁵² The reaction mechanism is as follows. Irradiation of the solution induces the formation of several types of radicals. Hydroxyl radicals react with cytosine and tyrosine, becoming attached to the C(5) carbon atom in the first case and to the aromatic ring with formation of dihydrocyclohexadienyl radicals in the second. Two possible reaction propagation pathways are presented in Scheme 3.

Dizdaroglu et al.⁵³ considered the possibility of the interaction of tyrosine with thymidine on γ -irradiation. Overall, the mechanism of this reaction is similar to that considered above for cytidine, but the radicals are formed as a result of the abstraction of a hydrogen atom from the methyl group of thymidine and not via the 6-position of the heterocycle (as in the case of cytidine).

R = ribose residue, R' = $\text{CH}_2\text{CH}(\text{NH}_2)\text{COOH}$.

The presence of oxygen molecules diminishes the probability of the formation of a covalent protein-nucleic acid complex, since oxygen forms peroxy radicals on interaction with the pyrimidine residues.

R = ribose residue, R' = CH₂CH(NH₂)COOH.

Arundel et al.⁵⁵ suggest that the covalent attachment of DNA to proteins from HCA-1 cells after their treatment with *N*-methylformamide and γ -irradiation takes place via this mechanism. *N*-Methylformamide does not apparently participate directly in the formation of a cross-link and acts only as a radical trap in order to increase the radiosensitivity of the cells.

Irradiation from γ -sources ensures a specific interaction of DNA with aromatic aminoacid residues in close proximity. However, a serious obstacle to its wide scale employment is the need to use a saturated solution of nitrous oxide, which does not promote the formation of protein-nucleic acid complexes. Furthermore, hard γ -radiation induces mutations.

3. Modification of the protein

Modification of the protein side chains with psoralen via the corresponding 'stem' (Y) is most frequently employed.

Y = -NH(CH₂)₂S-, -NMe(CH₂)₂NMe-,
 -NMe(CH₂)₂O(CH₂)₂NMeC(O)(CH₂)₂S-;
 R = protein

In the formation of the protein-nucleic acid complex, psoralen is intercalated in the double helix. When such a complex is irradiated with UV light, monoadducts with an internal cross-link between the furocoumarin and pyrimidine residues are formed. The 3,4- or 4',5'-double bonds of furocoumarin and the 5,6-double bond of the pyrimidine residue participate in the

attachment. This results in the formation of four-membered rings (Scheme 4).^{21, 56}

By altering the length of the stem connecting psoralen to the protein, it is possible to attach it at both short and long distances from the sites of the interaction of the protein and the nucleic acid. A disadvantage of the method is that it is necessary to know beforehand which site in the protein has to be modified.

III. Chemical methods for the covalent attachment of proteins to nucleic acids

For the covalent attachment of proteins to nucleic acids by means of a chemical reaction not involving the generation of radicals with the aid of irradiation, it is necessary either to increase the activity of one of the components of the protein-nucleic acid complex or to introduce into the system a symmetrical cross-linking agent, capable of forming a covalent bond with both components of the complex. Aldehydes are usually employed as agents of this kind.

1. The use of symmetrical cross-linking agents

Formaldehyde is used more often than other chemical agents for the covalent attachment of DNA to a protein. The cross-linking of DNA and histones in the nucleosome of the calf thymus nucleus has been achieved in this way. The aim of the study was to identify the sites of contact between DNA and the proteins or to achieve the fixation of protein-nucleic acid complexes in order to prevent their separation during further study on centrifugation and on exposure to other severe treatments.^{57, 58}

Another example of the application of this method is the probing of the structure of the *E. coli* RNA polymerase and its complex with the lac UV5 promoter.⁵⁹

Formaldehyde has also been used to determine the contacts between mRNA or pBR322 DNA with proteins. In this case, covalent attachment was achieved in 3 h at 37 °C on treatment of exponentially growing *E. coli* cells with a 0.75% solution of formaldehyde.⁶⁰

Formaldehyde reacts with the ϵ -amino-group of Lys, affording a hydroxy-methyl derivative, which reacts in its turn with the amino- and imino-groups of DNA.^{21, 57} Formaldehyde also interacts with the DNA adenine and cytosine residues via the exocyclic amino-groups, the protons participating in the formation of Watson-Crick pairs not being involved (Scheme 5).⁶¹

Scheme 6

The endocyclic imino-group of cytosine also reacts with formaldehyde. Furthermore, formaldehyde is attached to the endocyclic imino-groups of the thymine and uracil residues.⁶² Thus the reaction involving the covalent attachment of proteins to nucleic acids on treatment with formaldehyde is specific to lysine residues in the protein but is nonspecific in relation to the heterocyclic bases in the nucleic acid. An advantage of the method is the possibility of the covalent attachment of the protein to DNA without rupturing the structure of the double helix of the latter. Under these conditions, the groups of atoms located in both the major and minor grooves of DNA enter into the reaction. However, the method considered leads to a large number of protein-protein cross-links, which complicates the analysis of the results of the covalent attachment in complex systems, for example in *E. coli* cells.⁶⁰ Apart from formaldehyde, ketones, for example acetophenone and benzophenone, may be used as the cross-linking agents.

Glutaraldehyde and 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide have also been used as symmetrical cross-linking agents. The former reacts with the primary amino-groups of both the protein and the nucleic acid to form Schiff bases. The carbodiimide interacts with the primary amino-groups only of single-stranded DNA.²¹

Cohen et al.⁶³ and Hearst⁶⁴ indicate the possibility of the formation of a bond between DNA and the protein by coordination via the Cr^{6+} ion in the form of a symmetrical covalent or coordination complex between DNA and the enzyme polyadenosyldiphosphoribosylsynthetase. This type of binding has not been investigated, although the conjugates have already been isolated.

2. Activation of nucleic acids

One of the methods for the activation of nucleic acids is acid treatment, which leads to the elimination of purines from DNA. The aldehyde formed as a result of the opening of the furanose ring may react with the amino-groups of the protein to form a Schiff base.⁶⁵ However, this reaction cannot be used directly for the preparation of covalent protein-nucleic acid complexes, since the low pH values and the high ionic strength during the acid treatment interfere with the formation of specific protein-nucleic acid complexes. Levina et al.⁶⁶ therefore proposed that DNA be subjected to preliminary alkylation at the guanine and adenine residues with the aid of dimethyl sulfate and subsequent heating in a neutral medium. The aldehyde groups formed in the DNA interact with the amino-groups of the protein. Next, β -elimination results in the rupture of one of the DNA strands at the site of attachment to the protein. This approach made it possible to determine the sites of contact between DNA and the protein in nucleosomes⁶⁷ and in the complexes between RNA polymerase and the lac UV5 promoter.⁶⁸

A similar method has been used for the probing of the structure of the hyperacetylated region in nucleosomes. The cell nuclei were treated with dimethyl sulfate for 12 h, after which DNA was depurinated with piperidine with subsequent reduction by sodium tetrahydroborate. This resulted in the formation of covalently bound nuclear particles, in which DNA was attached to the H1/H5 histones.⁶⁹

This method has been used in combination with two-dimensional diagonal electrophoresis for the identification of the proteins forming discrimination contacts with the DNA of the cowpox virus.⁷⁰

A disadvantage of the DNA depurination method, used for the covalent attachment of DNA to DNA-specific proteins, is the distortion of the steric structure of the DNA double helix arising from the multiple methylation of the heterocyclic bases.

Another method for the preparation of protein-nucleic acid conjugates is the modification of the nucleic acid fragments at the heterocyclic bases and the phosphate groups by active alkylating agents.

A procedure for the introduction of a bromoacyl residue into cytidine has been proposed (Scheme 6).⁷¹ The hydrazino-group,

R = protein

introduced into the 4-position of the cytosine ring, interacts with bromopyruvate, which combines with an SH group of the protein. Glutathione has been used as the donor of the SH group in a model system. The optimum conditions for this reaction have been selected. The covalently bound complex of RNA with the protein in the 30S ribosomal subparticle of *E. coli* has been obtained in this way.⁷¹

In another study⁷², the bromoacetyl residue was attached to the 5'-phosphate group of an oligodeoxyribonucleotide. The active derivative of the oligonucleotide obtained — $\text{BrCH}_2\text{CONH}(\text{CH}_2)_2\text{NH-d(pTCTAG)}$ — was used for the affinity modification of the protein of gene 5 of the bacteriophage $\phi 1$. The conditions in the cross-linking reaction were optimal for the formation of a specific protein-nucleic acid complex. The maximum yield of the covalent complex was 20% for a reaction time of 24 h. The decrease in the yield of the protein-nucleic acid complex in the presence of sodium chloride (to 1.3%) and in the presence of competing attachment inhibitors — oligonucleotides not containing an alkyl group (to 9.4%) — demonstrates the specificity of the cross-linking. Since bromoacetate interacts with the nucleophilic centres of the protein, it has been suggested⁷² that the SH group of the cysteine residue of the protein of gene 5 of the bacteriophage $\phi 1$ is alkylated.

Derivatives of oligoribonucleotides containing alkylating groups at the 2',3'-end (G) or the 5'-end (H) have been proposed for the study of the topography of ribosomes.

X = ribonucleoside residue,
B = heterocyclic base residue.

Compounds G and H are active alkylating agents and react with ribosomal proteins. The optimum reaction time is believed to be the time required for the half-conversion of the *N*-chloroethyl-*N*-methylamino-group into the ethyleneimmonium cation as a result of the elimination of the chloride ion. The reaction mixtures are incubated at 25 and 37 °C. The yield of the covalent protein–nucleic acid complex is between 10% and 30%.⁴⁹

This method for the introduction of an active group suffers from a disadvantage associated with the modification of only the terminal residues of the oligoribonucleotides, but it has many advantages because of the reactivity of the alkylating groups.

Nucleic acid analogues containing activated terminal phosphate groups are also used for the affinity modification of proteins. The cyclic substituted trimetaphosphate and *N*-cyclohexyl-*N'*-(4-methylmorpholino)ethylcarbodiimide are used as activators. The reaction time is 10 min and the yields of the product of cross-linking to ribosomal proteins are between 1% and 7.5%.⁴⁹

The mixed anhydrides of phosphoric and mesitylenecarboxylic acids in an aqueous medium can phosphorylate different compounds containing nucleophilic groups, for example primary and secondary amines and mercapto-compounds.⁷³ This permits their application in the reaction with a protein. Nucleic acid analogues mesitylated at the terminal phosphate have been used for the covalent attachment to RNase A,⁷⁴ mitochondrial ATPase, myosin,^{73, 75, 76} and other proteins (Scheme 7).

R = protein, Nu = nucleophilic group of the protein,
B = heterocyclic base residue.

The advantages of the mesityl derivatives of oligonucleotides are their stability in aqueous media and low reactivity, which reduces the probability of a nonspecific modification of the protein. According to the results of Sokolova and Tretyakova,⁷⁷ the reactions of the mixed anhydrides of mesitylenecarboxylic and phosphoric acids with strong nucleophiles proceed in several hours, whilst those with weak nucleophiles take several days. The results of the covalent attachment of the mixed anhydride of mesitylenecarboxylic acid and ATP or AMP to myosin were followed from the irreversible inhibition of the enzyme. The reaction time was 1–2 h. In order to obtain the conjugate of RNase A with an oligodeoxyribonucleotide, use was made of reagents such as d[MsC(O)pApApA], d(ApApApMsCO), and d(MsC(O)pTpApGpT), where Ms is the 2,4,6-trimethylbenzoic acid residue. For complexes with a high association constant, the yield of the conjugate was 2%–4% relative to the protein for a reaction time of 7 days. The decrease in the yield of the covalent protein–nucleic acid complex to 0%, which has been noted following a gradual increase in the ionic strength of the solution and when complexes with a low association constant were employed, demonstrates the specificity of the cross-linking.⁷⁴

Shabarova and coworkers⁷⁸ proposed DNA duplexes, containing, in a specified position in the sugar-phosphate backbone, a substituted pyrophosphate group instead of the natural phosphodiester linkage, as affinity reagents for covalent attachment to nucleic acid-recognising proteins. It was established that, in

single-stranded oligodeoxyribonucleotides in an aqueous medium, the anhydride component of the substituted pyrophosphate group is readily and quantitatively cleaved at the phosphorus atom on treatment with nucleophiles via a nucleophilic substitution mechanism. The substitution is accompanied by the formation of a covalent bond between the fragment of the oligodeoxyribonucleotide, bound to the disubstituted phosphate group, and the nucleophile.

NuH = nucleophile,

RO and R'O = fragments of oligodeoxyribonucleotides.

It was shown that the functional groups of the side chains of glutamic acid and arginine may also serve as nucleophiles.⁷⁹

The DNA duplexes containing a substituted pyrophosphate group have been used successfully for the affinity modification of the restriction–modification fragments of *Rsa*I and *Eco*RI⁸⁰ and of the restriction endonuclease *Eco*RII.⁷⁹ These enzymes 'recognise' definite sites in DNA and hydrolyse (restriction endonucleases) or methylate (DNA methyltransferases) them in strictly defined positions. The specificity of their covalent attachment to DNA duplexes with a monosubstituted pyrophosphate internucleotide bond has been demonstrated.^{79, 80}

The advantages of reagents of this type consist in the fact that the substituted pyrophosphate group does not introduce serious changes into the structure of the DNA duplexes; the chemical reaction between the nucleophilic group of the protein and the reactive group of the substrate proceeds at a 'zero distance' between them and, in contrast to photoactive reagents, does not require external activation (for example UV or γ -irradiation). This precludes the possibility of the distortion of the real pattern of the protein–nucleic acid contacts in the interpretation of the results. The disadvantages of the use of DNA duplexes containing a substituted pyrophosphate internucleotide group for the affinity modification of proteins include the need for a close proximity of the nucleophilic group of the protein and the activated group of the nucleic acid and also the lability of the bond formed between the 5'-phosphate group of the oligodeoxyribonucleotide and certain aminoacid residues.

IV. Covalent attachment of nucleic acids to enzymes based on the mode of enzyme action

In the course of the interaction of an enzyme with a nucleic acid, there is a possibility of the formation of a covalently linked protein–nucleic acid intermediate, which then decomposes with formation of the reaction products. In order to achieve the covalent attachment of the protein to the nucleic acid for the study of the structure of the complex by X-ray diffraction or for the determination of the aminoacid interacting with the substrate, it is sufficient to fix this complex at the stage involving the formation of a covalent compound between the enzyme and the nucleic acid.

One of the examples of the use of an enzymic reaction for the preparation of covalent adducts between enzymes and nucleic acid substrate analogues (substrates) is the study of thymidylate synthetase in the interaction with 5-fluoro-2'-deoxyuridine monophosphate (π^5 dUMP). Thymidylate synthetase is an enzyme which transfers a methyl group from 5,10-methylenetetrahydrofolate to uridine with formation of thymidine. The formation of a noncovalent ternary complex, which is converted into a covalent adduct between the protein and the uridine, has been postulated in the interaction of the protein with two substrates. The thiol group of the enzyme attacks the 6-position of the uracil residue in such a way that the C(5) atom can react as a carbanion with methylenetetrahydrofolate.⁸¹ After the transfer of the methyl group from

methylenehydrofolate to the 5-position of uridine, the protein group is eliminated from the 6-position simultaneously with a proton from the 5-position. If a fluorine atom is introduced in place of the hydrogen atom removed, the reaction is blocked at the protein elimination stage.⁸²

The decrease in the growth of lymphocyte cells in a medium containing fl⁵dUMP is also evidence in support of the formation of a covalent adduct, the quantitative characteristics of the process being the same as those of the inactivation of thymidylate synthetase, i.e. the inhibition of cell growth can be accounted for by the interaction of the modified nucleotide with this enzyme.⁸²

The use of the covalent attachment method is of interest because it makes it possible to determine exactly the stage in which the complex is fixed and to discover the role of the covalently bound aminoacid residue. Under these conditions, the modified nucleotide undergoes the same conformational changes as the substrate. Hence the application of reagents of this kind opens a path to hitherto uninvestigated stages of the catalysis.⁸³ Thus studies have been made^{84,85} of the stereochemical mechanism of the methylation of deoxyuridylylate in relation to the covalent ternary complex of thymidylate synthetase with fl⁵dUMP and 5,10-methylenetetrahydrofolate or 10-propargyl-5,8-dideazafofolate. The high stability of the complexes made it possible to obtain crystals and to investigate their structures by X-ray diffraction. It was shown that, in the formation of the ternary complex, thymidylate synthetase undergoes conformational rearrangements involving four aminoacid residues at the C-end of the protein, which are in immediate proximity to the aromatic ring of the fl⁵dUMP inhibitor.⁸⁵ It has been suggested that before elimination the reaction product undergoes a conformational isomerisation and the pathways leading to its occurrence have been discussed.⁸⁴

The enzymes forming covalent conjugates with the substrate include also DNA [C(5)-cytosine]methyltransferases. It has been virtually demonstrated that they all function via a universal mechanism, according to which in the first stage the nucleophilic aminoacid is attached to the 6-position in the cytosine being modified. In the second stage, the methyl group is transferred from the cofactor SAM to the C(5) carbon atom of cytosine. The introduction of a substituent, which is bound to the carbon atom via a stronger bond than hydrogen, in the 5-position of the base being modified fixes the protein–nucleic acid complex at the covalent adduct stage. It has been suggested that a fluorine atom be used as a substituent of this kind.⁸⁸

The interaction of the modification enzyme *Eco*RII with a DNA duplex containing an azacytidine residue has been investigated.⁸⁶ The formation of the adduct was detected electrophoretically. It was shown that the introduction of azacytidine into the cell system leads to a sharp increase in the expression of the given gene. Bearing in mind the inhibiting effect of this reagent on the methylase *Eco*RII, this fact can be regarded as evidence for the negative regulation by this enzyme of the expression of its gene.⁸⁷

DNA duplexes containing the 5-fluoro-2'-deoxycytidine (fl⁵dC) residue are used for the determination of the aminoacid residues participating in the catalytic step in the methylation of DNA by DNA [C(5)-cytosine]methyltransferases. The conjugate of the methylase *Hae*III with a DNA duplex containing fl⁵dC has been isolated. The substrate in the conjugate was methylated at the C(5) atom of the heterocyclic base. Owing to the presence of fluorine in the 5-position of cytosine, the protein was not split off from the C(6) atom.⁸⁸ Analogous conjugates of DNA duplexes containing fl⁵dC with the enzymes *Eco*RII^{89,90}, *Hha*I,⁹¹ and *dcm*-methyltransferase of *E. coli* K-12⁹² have been isolated. The presence of a covalent complex was demonstrated electrophoretically and detected by autoradiography. The stability of the adduct in denaturing solutions — 6 M urea and 1% solution of sodium dodecyl sulfate (SDS) — was tested. After the denaturation of the protein, the bond between the modified DNA and the methylase in the presence of the cofactor was retained. Kinetic study of the reaction showed that both the enzymic methylation

process and the reaction involving the covalent attachment of the protein to DNA are first-order processes. The results confirm the reaction mechanism proposed previously (Scheme 8).

SAM = S-adenosyl-L-methionine,
SAH = S-adenosyl-L-homocysteine,
Enz = enzyme.

Analysis of the adducts obtained showed that in all cases the Cys residue forms a covalent bond with the carbon atom in the 6-position in cytosine.^{89,90,92} Further studies on these lines lead to the possibility of a detailed description of the stereochemical pathway of the methyl group transfer reaction.⁹¹

The universality, postulated for DNA [C(5)-cytosine]methyltransferases, extends also to the methyltransferases which interact with RNA. tRNA (m⁵U54)methyltransferase was investigated by Gu and Santi.⁹³ A covalent adduct of this enzyme with tRNA, containing the fl⁵dU residue, was obtained. It proved possible to detect a covalent complex between tRNA (m⁵U54)methyltransferase and RNA, which was stable when treated on a nitrocellulose filter and in electrophoresis under denaturing conditions. It was shown that such adducts are capable of participating in a further methylation reaction and that their formation reaction is reversible.⁹⁴

The preparation of intermediate covalent complexes between topoisomerases and DNA has been described. Topoisomerases are enzymes which alter the number of superturns in cyclic covalently closed DNA, initiating single-stand breaks in DNA.⁹⁵ The topoisomerase of the type I cowpox virus binds specifically to DNA and forms covalent adducts by cleaving the phosphodiester linkage and forming a new bond with the terminal phosphate group produced at the break point. The enzyme recognises in DNA the conservative sequence 5'-(C/T)CCTT-3'. After the uncoiling of the DNA strand, the enzyme transfers the end of the DNA linked to it to the 5'-terminal region of the same strand with regeneration of the covalently closed plasmid ring. The presence of covalent conjugates at an intermediate stage has been demonstrated by transferring the oligonucleotide residue from the complex to the 5'-end of the oligonucleotide and also by blocking the enzymic reaction by an antibiotic inhibiting the activity of topoisomerases, as a result of which the DNA strand remains broken.⁹⁶

It has been suggested⁹⁷ that irreversible inhibitors of the enzymic reaction be employed. Thymidylate synthetase was inhibited by an analogue of uridine triphosphate containing in the 5-position one of the reactive groups: COCH₂Br, CH₂NHCOCH₂I, or NO₂. Such compounds convert reversible enzyme–inhibitor complexes into irreversibly covalently bound complexes. The mechanism of their activity has not been determined accurately, but a possible pathway has been proposed for this process (Scheme 9).

By employing the reagents considered, it is also possible to probe the groups of atoms in the protein which participate in the methylation of the heterocyclic base.

An interesting method involving the employment of tRNA, containing the br⁵U residue, for covalent attachment to amino-

R = ribose triphosphate residue

acyl-tRNA synthetase without activation by UV light has been described.⁹⁸ Although numerous pieces of evidence for the formation of an intermediate covalent adduct between aminoacyl-tRNA synthetase and the uracil ring exist, such compounds had not been obtained earlier. The introduction of a halogen atom, which is highly electronegative, into the heterocyclic base increases the sensitivity of the carbon atom in the 6-position to nucleophiles. The adducts with halogenated uracil derivatives are therefore capable of further rearrangements, leading to the formation of a covalent enzyme-substrate complex. The development of this process leads to the formation of bromouracil and the appearance of a ribose residue at the site occupied previously by 5-bromouracil and of the free enzyme in accordance with Scheme 10.

Optimum conditions for the prevention of the decomposition of the covalent complex were selected: the use of a sulfhydryl reducing agent and of a tenfold excess of 5-bromouridine. The success of the new method was demonstrated in relation to alanine aminoacyl-tRNA synthetase. The inactivation of the enzyme by br⁵U containing tRNA was investigated. It was shown that the elimination of uracil leads to the regeneration of the activity of the protein. The results obtained demonstrate the existence of an intermediate covalent adduct in the functioning of aminoacyl-tRNA synthetases.

V. Methods for the identification and isolation of covalent protein-DNA complexes

For the identification and isolation of covalent protein-nucleic acid adducts, use is made, for example, of the ability of one of the components of the complex to be adsorbed on a carrier and also of the difference between the chemical or physicochemical properties of nucleic acid component of the covalent adduct and of its protein component. Thus, in contrast to the protein, DNA binds to a nitrocellulose filter only under certain conditions. On the other hand, DNA, attached covalently to the protein molecule having an affinity for some kind of polymeric carrier (for example, nitrocellulose), acquires the ability to be precipitated on such filters. The new property can be used to separate the reacted DNA from the free DNA and also to demonstrate that covalent attachment has taken place.

A property of the protein which may be used to identify the covalent adduct is the immune response, i.e. the formation of a specific complex of the given protein with an antibody. In this case, the immunochemical approach may be used to isolate protein-DNA conjugates and for their purification.

The protein bound to the nucleic acid also acquires new features, in its turn, characteristic of the nucleic acid component. One of the applications of this phenomenon is the sedimentation method for the isolation of the attached protein in the case where it is fairly small and does not alter the sedimentation constant of the free nucleic acid in a density gradient. When cells or cell nuclei are irradiated in vivo, this property proves very useful for the isolation of conjugates from complex cell systems. For example, the first stage in the purification of covalent adducts of chromosomal proteins with DNA from a cell culture of *D. melanogaster* tissues has been centrifugation in a CsCl gradient in order to isolate DNA-containing cell fractions.⁴ Gel filtration can also be used for such purposes.

Extraction methods for the isolation of conjugates are associated with the solubility of one of the components in an organic substance, for example of the protein in phenol. The solubility of the protein component in an organic medium promotes the transfer of the covalently bound nucleic acid into the organic phase, whereas the unreacted nucleic acid remains in the aqueous solution.²¹

Examples of the application of methods most frequently used in practical investigations are presented below.

1. Binding to a polymeric carrier

In order to isolate covalent complexes of the DNA adenine methyltransferase (Dam methylase) from *E. coli* with SAM, the protein component of the conjugate was precipitated on a glass filter with 10% trifluoroacetic acid. The presence of a covalent bond between the methyltransferase and the cofactor was demonstrated with the aid of a radioactive label (³H or ¹⁴C) in SAM. As a control, a similar procedure was carried out with a non-covalent complex between the methyltransferase and SAM.¹⁸

The covalent adducts of a DNA-recognising protein from the type 2 adenovirus with ³²P-p(dT)₁₄ were filtered through nitrocellulose filters and washed with solutions containing NaCl or SDS in order to decompose noncovalent specific complexes. The yield of the covalent protein-nucleic acid complex was determined from the radioactivity of the residue on the filter. The same approach (binding on a nitrocellulose filter) was used to purify the covalent adducts of tRNA (m⁵U54)methyltransferase and RNA.⁹³ Toyo Roshi 51 paper filters were used in another study¹⁶ instead of the nitrocellulose filters.

In order to isolate the proteins from the nuclear extract of mouse hybridoma B-cells, participating in the specific recognition of definite DNA sequences, their complexes with oligonucleotides, incorporating not only the binding site but also a 10-membered dA sequence at the 3'-end, were irradiated with UV light. The covalent adducts obtained were isolated on oligo-dT-cellulose. In this case, the elimination of 'unattached' proteins

from the complex was achieved by the formation of an oligo-dA · oligo-dT duplex on a polymer matrix.⁹⁹

Yet another example of the use of a polymeric carrier for the isolation of protein–nucleic acid conjugates is the hybridisation of the products of the treatment with formaldehyde of *E. coli* cells with single-stranded DNA immobilised on cellulose and complementary to the pBR322 plasmid. The conjugates of mRNA and pBR322 DNA with proteins are then separated from the remaining cell material. After being split off from the covalent RNA complex, the protein components were analysed by electrophoretic methods (Laemmli's methods).⁹⁹

2. Electrophoretic isolation methods

Electrophoresis is the most effective method for the isolation of covalently bound protein–nucleic acid conjugates. In the electrophoretic methods of analysis, there is a possibility of the simultaneous determination of both the protein component (by staining with an appropriate dye) and of the nucleic acid (from the ³²P radioactivity). There are two versions of this method differing in the presence or absence of a denaturing agent in the supporting medium.

Thus the isolation of covalent protein–nucleic acid complexes by the 'retardation' method in 1% agarose gel not containing denaturing agents has been described.¹⁰⁰ Covalent adducts of *E. coli* topoisomerase with an oligonucleotide were also identified in a nondenaturing 4.5% polyacrylamide gel.⁹⁶

Two-dimensional electrophoresis in a nondenaturing medium has a greater resolving power. In this case, the reaction mixture is separated initially in one direction, after which one of the components of the protein–nucleic acid complex is subjected to degradation by a chemical or enzymic method and electrophoresis is carried out in the perpendicular direction.²¹ DNA-binding proteins of the cowpox virus, attached covalently to the viral DNA, were identified in this way. The electrophoretic separation in the first direction was carried out in a polyacrylamide gel (the linear acrylamide concentration gradient was from 5% to 15%). In the second direction, the concentration of acrylamide was constant at 12.5%. The proteins were detected from the radioactivity of the ¹²⁵I introduced with the aid of the Bolton–Hunter reagent. The set of marker proteins, used in the electrophoresis in the second direction, made it possible to determine the molecular masses of the attached proteins.

However, the use of nondenaturing gels does not usually afford the complete certainty that the protein–nucleic acid complex is indeed covalent. Denaturing agents, for example SDS or urea, are therefore introduced into the gel. Gel electrophoresis in Laemmli's version with SDS as the denaturing agent is usually employed. The gel concentration varied in different investigations from 10% to 15%.^{10, 17, 19, 25, 29, 33, 34, 87, 101, 102} Preliminary treatment of samples from the SDS procedure with 2-mercaptoethanol, including maintenance for several minutes at 95 °C, guaranteed the complete decomposition of the noncovalent protein–nucleic acid complexes and also the denaturation of the protein. The attachment of nucleic acid fragments to the protein has only a slight influence on the electrophoretic mobility of the latter, because it is abolished by the large negative charge on SDS, while the increase in the mass of the protein after the attachment of the nucleotide or oligonucleotide to the latter is negligible compared with its intrinsic mass. After the electrophoretic separation, the gels are usually stained with a Coomassie dye in order to determine the protein bands and are then dried and autoradiography is carried out in order to visualise the nucleic acid fragments. In the study of Pelle and Murphy,⁵ before determining the positions of the complexes in the gel the latter were transferred by electroblotting on to a nitrocellulose membrane.

After the irradiation of the complexes of a polypeptide present in the transcription complex of the pea and DNA containing br⁵dU the samples were treated with DNase I (in certain experiments an additional treatment with snake venom phosphodiester-

ase was performed).²⁸ After this, they were analysed by electrophoresis in a dilute (5%) polyacrylamide gel.

Nucleic acid was decomposed similarly by micrococcal nuclease and bacterial alkaline phosphatase after the covalent attachment of DNA to histones. A ³²P label was then introduced into the residual oligonucleotide with the aid of polynucleotide kinase (before deposition on a 15% polyacrylamide denaturing gel).⁶⁹ The need for the degradation of DNA is due to its large size and hence low electrophoretic mobility.

The protein component of the complex with nucleic acid can also be subjected to partial cleavage. *N*-Chlorosuccinimide is used for this purpose. After the treatment of the complexes with *N*-chlorosuccinimide, the reaction mixture is deposited on a 10% SDS-containing polyacrylamide gel. The positions of the bands of the partly degraded protein–nucleic acid complex are determined autoradiographically. The set of products of the partial decomposition of such compounds by *N*-chlorosuccinimide is specific to each protein and may be used for the rapid determination of the macromolecules recognising a definite sequence in DNA or RNA.¹⁰³

After covalent attachment to DNA, GCN4 activator of the transcription from yeast was analysed electrophoretically in a gel with another type of denaturing agent—urea. For the denaturation of the 'unattached' complexes, the reaction mixtures were treated with alkali and deposited on a 10% polyacrylamide gel containing 8 M urea. The covalent protein–nucleic acid complex was detected autoradiographically.³⁰

3. Chromatographic isolation methods

Chromatographic methods are more rarely used for the analysis of covalently bound protein–DNA complexes because large amounts of substances are required for the spectrophotometric detection of the reaction products. Nevertheless, for example, in the study of Barbier et al.,²⁶ a mixture of the *lac* repressor with br⁵dU-containing DNA was separated chromatographically on a Sephadex column after irradiation with UV light. When a 200 mM potassium phosphate buffer containing 500 mM KCl was used, the unbound repressor separated from the covalent complex, which was indicated by a well resolved peak. The separation process was followed spectrophotometrically from the absorption at 260 and 280 nm.

The covalent complex of the T4 endonuclease V with an oligonucleotide containing a phenyldiazirine derivative has been isolated on a phosphocellulose column.³⁹

The method for the isolation of the covalent complexes of the methyltransferase *Hae*I with an oligonucleotide containing the fl⁵dC residue by fast protein liquid chromatography (FPLC) on a MonoQ column in a linear NaCl concentration gradient from 0 to 1 M proved effective.⁸⁸

4. Immunochemical methods for the isolation of protein–nucleic acid covalent complexes

Several examples of the use of immunochemical methods for the isolation of protein–nucleic acid covalent complexes have been described in the literature.

The replication protein A was irradiated together with oligonucleotides. After the reaction, the protein and the covalent protein–nucleic acid complex were separated from the unreacted oligonucleotides with the aid of monoclonal antibodies. The reaction mixture was then analysed by the retardation method in a gel.¹³

The proteins from the extract of cell cytoplasm, attached covalently in vitro to nucleic acids, were isolated with the aid of antibodies obtained by the vaccination of mice.⁵

After the covalent attachment of histones to DNA, high-molecular-mass complexes were isolated with the aid of antibodies specific to the acetylated histones.⁶⁹

The protein component of the covalent adduct was determined by the immune precipitation of one of the proteins of the transcription factor II (TBP subunit) after its covalent attachment to DNA as a result of irradiation with UV light.⁴²

VI. Determination of peptides in a protein bound covalently to nucleic acid

The final aim of the covalent attachment of a protein to nucleic acid is the determination of the aminoacids or domains of the protein coming into contact with nucleic acids. To do this, the protein is fragmented after its covalent attachment and its component forming a covalent adduct with the nucleic acid is determined. Numerous methods, both chemical and enzymic, are employed for this purpose.¹⁰⁴ Depending on the conditions, mild acid hydrolysis leads to the formation of large or small protein fragments, but its effect is as a rule nonspecific in relation to particular aminoacid residues and the set of peptides obtained is not reproduced when the hydrolysis of the same protein is repeated. The secondary and tertiary structures of the protein exert some influence on this process. There are also reagents which cleave the peptide bond at a particular aminoacid when the latter is C- or N-terminal. For example, BrCN hydrolyses a specific bond in proteins when methionine is NH₂-terminal.^{105, 106} Bromocyanogen has also been used to determine the DNA-binding domains of the restriction enzymes *EcoRI* and *EcoRV* after their irradiation with UV light in a complex with DNA duplexes containing br³dU residues. Since methionine is rarely encountered in proteins, this made it possible to locate only those regions in the enzymes to which DNA is bound.²⁵ A disadvantage of the method is the severe conditions in the treatment (80% formic acid), under which only the C—C bonds formed on irradiation of protein—nucleic acid complexes with UV light are stable.

The enzymic fragmentation of the protein component of the covalent adduct with the nucleic acid proceeds under milder conditions and is fairly specific when particular proteinases are employed. Rarely and frequently cleaving proteinases are distinguished, which is determined primarily by their specificity and also by the frequency with which certain aminoacids are encountered in proteins. For example, the endopeptidase Lys-C cleaves

proteins into fairly large fragments, which are easier to analyse. However, when this enzyme is employed, it is not possible to locate accurately the active region of the protein. Trypsin is the most frequently employed enzyme. It cleaves the protein specifically at the peptide bonds formed by the carboxy-groups of lysine or arginine.¹⁰⁴ Since the range of aminoacids recognised by them is greater than for the endopeptidase Lys-C, the size of the peptides formed on cleavage is smaller and their number is greater. This complicates the isolation of the peptide bound covalently to the nucleic acid, on the one hand, but it permits a more accurate location of the attached aminoacid, on the other.

When covalent protein—nucleic acid adducts are cleaved by proteolytic enzymes, a large set of peptides is formed, including the protein fragments unattached to the nucleic acid, one or several peptides bound covalently to the nucleic acid, and the products of the hydrolysis of the proteinase itself, because it too may hydrolyse its own peptide bonds (autoproteolysis). In order to avoid autoproteolysis, specially modified trypsin, which hardly undergoes any self-decomposition, is used. For a more complete and exhaustive hydrolysis, the protein is also denatured by 8 M urea, but, since this may prove insufficient, it is treated further with iodoacetamide.¹⁰⁷ After treatment with iodoacetamide, the concentration of urea may be reduced to 2 M, whereupon the effectiveness of the cleavage by trypsin increases sharply, which makes it possible to reduce the trypsin : protein mass ratio to 1 : 25. For this ratio, the autoproteolysis of trypsin is no longer a problem.¹⁰⁸ Table 3 presents the most frequently used methods for the fragmentation of proteins in covalent protein—nucleic acid complexes. In each specific case, the choice of the proteolysis conditions is determined by the effectiveness of the operation of the proteinase (or the chemical reagent) and by the stability of the protein—nucleic acid conjugates. Since the nucleic acid may protect the protein against proteolysis, an individual selection of the protein : proteinase (or reagent) ratio and of the method for

Table 3. Methods for the cleavage of the protein component of the protein—nucleic acid conjugates.

Enzyme or reagent	Enzyme (reagent) concentration or enzyme : substrate mass ratio	Buffer solution for proteolysis	Time /h	Incubation temperature /°C	Ref.
Trypsin	1 : 3.7	83.3 mM tris-HCl, pH 8.0, 16 mM CaCl ₂ , 2 M urea	72	37	51
	1 : 10	2 M urea	4	37	34

the denaturation of the protein–nucleic acid complex (urea or SDS) is necessary.

After the successful fragmentation of the proteins in their covalent complexes with nucleic acids a new problem arises — the isolation of one or several peptides which were involved in the formation of the covalent adduct with the nucleic acid. Several approaches to the solution of this problem have been described in the literature: the use of electrophoretic methods, extraction into organic solvents, and a different kind of chromatographic purification. Conditions for electrophoresis designed to separate peptides with molecular masses ranging from 1 to 5 kDa have been selected.¹⁰⁹ Phenol extraction of peptides is also used. One purification stage is usually insufficient for the separation of the target compound from other substances, so that column chromatography is almost always used at one of the purification stages.^{108, 109}

Table 4 presents the chromatographic conditions used for the isolation and purification of peptides bound covalently to nucleic acids. For the selection of the column, sorbent, eluent, and other

chromatographic separation conditions, the investigator may use the literature data (Table 4) taking into account the individual features of the conjugate investigated.

After isolation and purification, the amino acid sequence of the peptide is determined.^{108, 110}

Cases are possible where the aim — the determination of the peptide bound covalently to DNA — proves to be unattainable because of the instability of the adduct, insufficient amounts of the protein, and the lack of the necessary equipment. Indirect data are then employed to find the amino acid cross-linked to the nucleic acid. These include the determination of the nature of the bond between the nucleic acid and the protein. Such determination is based on the difference between the reactivities of the functional groups and their hydrolytic stabilities.

If the nucleic acid is attached to the protein via the terminal phosphate group, then, owing to the instability of the covalent complex, problems involving the determination of the peptide usually arise. The phosphodiester or phosphotriester bond formed as a result of the attachment of the protein to hydroxyaminoacids

Table 4. Conditions for the isolation by chromatographic methods of peptides (products of the proteolysis of protein–nucleic acid conjugates) attached covalently to nucleic acids (the separation temperature is not indicated).

Column	Initial eluent	Gradient ^b	Separation time /min	Consumption of eluent /ml min ⁻¹	Detection method ^c	Ref.

is labile under alkaline conditions, the stability of the bond being influenced by the nature of the aminoacid. Thus the adducts with hydroxyaminoacids are more sensitive to alkaline hydrolysis than the adducts with tyrosine. By measuring the dependence of the stability of the covalent protein–nucleic acid complex on the pH, it is possible to reach a conclusion about the nature of the aminoacid bound to the nucleic acid. The phosphodiester nature of the bond may be demonstrated with the aid of snake venom and calf spleen phosphodiesterases, which are able to hydrolyse such bonds.¹¹¹

The nature of the bond between the modification enzyme *EcoRI* and an oligonucleotide has been determined.⁸⁰ The conjugate proved stable in 0.1 M sodium hydroxide solution, but was hydrolysed in 0.1 M hydrochloric acid or in 4 M solution of hydroxylamine at pH 5. This suggested the formation of a covalent bond between the phosphate group of the oligonucleotide and the amino-group of Arg or Lys or the imino-group of His.

VII. Probing the DNA recognising proteins mode of action via cross-linking assay

The covalent attachment method makes it possible to investigate indirectly the protein–nucleic acid interaction because a specific complex is fixed at the binding stage. By varying the parameters of the cross-linking, it is possible to fix different recognition stages.

The complex of the restriction endonuclease *NaeI* and an oligodeoxyribonucleotide duplex containing the *br*³²dU residue has been irradiated with UV light in order to determine the number of enzyme subunits and substrate molecules in the catalytically active enzyme–substrate complex.¹¹² On photoactivation of the substrate in the complex with the protein, a covalent complex was produced. An increase in the reaction time led to the appearance of yet another conjugate. The mobility of the new covalent complex in the polyacrylamide gel corresponds to a macromolecule with a molecular mass approximately twice as great as that of a single *NaeI* subunit. The covalent attachment after additional irradiation time probably resulted in the attachment of a second enzyme molecule to the substrate. This finding constitutes yet another confirmation of the fact that the restriction endonuclease *NaeI* binds to two substrate molecules in the form of a dimer.

The covalent attachment of nucleic acids to proteins on exposure to laser radiation provides even greater possibilities for the indirect study of the mechanism of the protein–nucleic acid interaction. Because of the very short duration of the pulse, it is possible to determine the physicochemical parameters of the protein–nucleic acid recognition — the binding constant.¹⁰¹ The method based on the 'freezing' of the equilibrium states has been used¹⁰¹ for the protein coded for by the 32 gene of the bacteriophage T4 (gp32). This protein binds preferentially to single-stranded DNA. Since during the duration of the pulse there is insufficient time for the protein to pass from one conformational state to another, the yield of the covalent attachment is proportional to the amount of the protein–nucleic acid complexes existing at the given instant, which is determined by the complex formation constant. The dependence of the yield of the product of the covalent attachment on the formation constant of a complex between gp32 and oligo(dT) (known from the literature) was found and the equilibrium constants for other analogous systems were calculated (for example, for the equilibria between gp32 and shorter oligonucleotides, for the same complexes in other buffer solutions, and for the analogous proteins of the same system of the bacteriophage T4). Since the yield of the product of the covalent attachment of gp32 to (dT)_n increases in jumps as a function of the length of the oligomer (up to *n* = 7, there is virtually no covalent attachment of gp32 to the oligodeoxyribonucleotide, while at *n* = 7 the yield of the adduct increases sharply), it has been suggested that the minimum area for the deposition of the protein gp32 on DNA corresponds to seven nucleotide residues. The repeated increase in the yield of the covalent adducts for *n* which is

a multiple of seven confirms this hypothesis, since the deposition of two gp32 molecules on the oligodeoxyribonucleotide now becomes possible.¹⁰¹

Hockensmith et al.¹⁰² chose as the objects of study the proteins coded for by the genes 44 (gp44), 45 (gp45), and 62 (gp62) of the bacteriophage T4, which require nucleotide cofactors as well as Mg²⁺ ions. In the absence of gp45 and also at its low concentrations, DNA forms preferentially covalent adducts with gp44, but, starting from the equimolecular ratio of gp45 and the complex gp44/gp62, the effectiveness of the affinity modification of gp62 increases. Since the protein gp45 has a DNA-dependent ATPase activity, the influence of gp62 on the kinetic parameters of the functioning of gp45 was demonstrated. The nature of the dependence of the covalent attachment of gp44 and gp62 on the gp45 concentration indicates a conformational rearrangement of the DNA-recognising system of the bacteriophage T4 for the equimolecular ratios of all the components. Knowing the yields of the products of the covalent attachment of the proteins considered to (dT)₁₆, (dT)₂₀, (dT)₁₆·(dA)₂₀, (dA)₁₆·(dT)₂₀, and (dT)₂₀·(dA)₂₀, simulating single-stranded DNA, the complexes of the primer and the template, and DNA duplexes with 'blunt' ends, it is possible to determine the disposition of gp32, gp45, and gp62 on the primer, on the template, or on the primer–template complex.

Summarising the foregoing, one should note that a change in the effectiveness of the affinity modification of nucleic acids by proteins reflects conformational transitions and also more complex multisubunit interactions of the latter.¹⁰¹

VIII. Conclusion

Thus the application of the affinity modification method leads to extensive possibilities for the analysis of the structures and mechanisms of the functioning of the proteins interacting with nucleic acids. The principal requirements which must be met by the procedure involving the covalent attachment of a protein to nucleic acids is the creation of optimum conditions for the protein–nucleic acid recognition. The modifications carried out must not distort seriously the structures of the components of the complexes and hence affect the process involving the recognition of nucleic acid analogues by nucleic acid-specific proteins. In our view, the most promising in this sense are the bromo- and azido-substituted nucleic acid analogues as well as nucleic acids containing an activated internucleotide phosphate group. The moderate reactivity of such compounds ensures the specificity of the covalent attachment, since the reaction with the protein becomes possible by virtue of the mutual approach of the reacting centres of both components of the complex.

IV. Biodegradation of poly(hydroxyalkanoates)	731

Abstract. The mechanism of bacterial synthesis of polymers and copolymers of hydroxyalkanoic acids is described. The structural and physicochemical properties of polymers obtained by biosynthesis are identical to those of the polymers obtained by polymerisation of lactones. Polymers and copolymers of hydroxyalkanoic acids are readily crystallisable flexible-chain polymers, capable of forming films and fibres when the degree of polymerisation is higher than 500–600. These compounds are biodegradable. The rate of biodestruction, which leads mainly to oligomeric products, depends on the chemical nature of the compound, on the degree of tacticity in the polymeric chain, and on the degree of ordering in the polymeric substrate. The bibliography includes 105 references.

I. Introduction

The increase in the production and consumption of various polymeric materials has led to increased environmental hazard, including the greenhouse effect. There are some other reasons for this phenomenon, for example:

- the increase in the amount of organic fuel being combusted;
- the increase in the amount of organic raw materials being processed to target products including processing of waste materials;
- the decrease in forest area due to the increase in tree-felling and in the processing of wood;
- the accumulation of waste polymeric materials incapable of biodegradation.

Therefore, the challenge arises to develop new energy-saving methods for the synthesis and processing of polymers accompanied by minimal amounts of CO₂ discharged to the atmosphere. This problem can be solved, for example, by developing biotechnological processes for the synthesis of film-forming and fibre-forming polymers.

Conventional technological schemes for the production of basic polymers [for instance, cellulose, poly(ethylene terephthalate), polypropylene, polyhexanamide, and copolymers of acrylonitrile] require 18–55 GJ of energy per ton of the product. Similar energy expenditure is needed to isolate the target products of microbiological synthesis; however, in this case, the amount of

CO₂ liberated decreases sharply, and the biomass obtained can be included in the hydrocarb energy-chemical cycle.¹

Among the film-forming and fibre-forming polymers that can be synthesised using the microbiological approach, polyesters based on hydroxyalkanoic acids are of considerable interest. Recently, it has been found that some microorganisms are capable of synthesising thermoplastic regular homopolymers and copolymers of β -hydroxyalkanoic acids containing C₁–C₁₁ side groups. Such polymers can undergo biodegradation at a controlled rate.

Comparison of the physicochemical properties of poly(hydroxyalkanoates) (PHA) synthesised by the microbiological method with those of the PHA obtained by polymerisation of the corresponding lactones demonstrated that they are identical, although the primary structures of the polymers are somewhat different. The characteristic features of the polymerisation of lactones were analysed for the first time by Sazonov;² later, studies along these lines were continued.^{3–6} It should be noted that many of the PHA synthesised proved to be biodegradable,⁷ which is very important from the ecological standpoint. PHA are of considerable interest as film-forming and fibre-forming polymers and also as molecular plasticisers compatible with many synthetic and natural polymers.

II. Microbiological synthesis of poly(hydroxyalkanoates)

The target-directed synthesis of polymers based on hydroxyalkanoic acids and their lactones was undertaken for the first time by Van Natta et al.⁸ At present, PHA can be obtained by ionic, hydrolytic, radiation-induced, and UV-induced polymerisation or copolymerisation of β -lactones, δ -lactones, and some other lactones.² Some PHA, for example, poly(ϵ -hydroxyhexanoate) [P(6HH)], are industrial products.

The possibility of using bacterial methods to synthesise PHA was recognised more than 20 years ago, when the accumulation of poly(3-hydroxybutanoate) [P(3HB)] granules in the cytoplasm of the *Alcaligenes eutrophus* bacterium was observed. It was shown that this polymer acts as a reserve compound, i.e. as a source of carbon and energy, for this bacterial culture.^{9–11}

The bacterial P(3HB) is a high-molecular-weight ($\bar{M}_w > 10^5$), readily crystallisable, thermoplastic, biocompatible, and biodegradable polymer.¹² The industrial production of this polymer based on biotechnological processes using *A. eutrophus*¹³ and *A. latus*¹⁴ bacteria was established by the ICI company (UK). By now, procedures for the preparation and properties have been reported for many other polymers built of units of the general formula $\sim[\text{O}-\text{CH}(\text{R})-\text{CH}_2-\text{C}(\text{O})]_n\sim$, where R is a (C₁–C₁₁) saturated,^{15–17} linear unsaturated,^{18–19} or branched unsaturated

alkyl,¹⁹ haloalkyl,²⁰⁻²² or aryl²³ radical. It has been shown that microbiological synthesis can be used for the preparation of thermoplastic aliphatic polyesters not only from β -hydroxycarboxylic acids, but also from α -,²⁴ γ -,^{25,26} and δ -hydroxycarboxylic acids.

1. Synthesis of poly(hydroxyalkanoates)

Biosynthesis of homopolymeric and copolymeric PHA by various bacterial strains has been studied in detail by many researchers (Table 1).

Table 1. Bacterial synthesis of various homopolymeric and copolymeric PHA.

Strain	Polymer	Ref.
<i>Alcaligenes eutrophus</i>	(3HB)	27
	(3HB-co-3HP)	24
	(3HB-co-4HB)	26, 28-30, 35
	(3HB-co-3HV)	14, 17, 31, 32
	(3HB-co-5HV)	33
<i>Alcaligenes latus</i>	(3HB-co-3HP)	34
<i>Pseudomonas oleovorans</i>	(3HO)	18
	(3HH-co-3HO)	22

Note. 3HP is 3-hydroxypropionate, 4HB is 4-hydroxybutyrate, 3HV is 3-hydroxyvalerate, 5HV is 5-hydroxyvalerate, 3HH is 3-hydroxyhexanoate, and 3HO is 3-hydroxyoctanoate.

The physicochemical and structural characteristics of PHA obtained using different bacterial strains are very similar.

The biosynthesis pathway of PHA has been considered in detail in relation to the generation of P(3HB) by the *A. eutrophus* culture.^{17,28,31} The block diagram of this process is shown in Fig. 1. The formation of aliphatic acids and their derivatives in organisms is known³⁶ to result from the metabolism of carbohydrates, and the first stage of their formation is one of the last stages of the biodegradation of monosaccharides. The hydroxy-acids thus obtained are subsequently biopolymerised.

Figure 1. Block diagram of the biosynthesis of poly(hydroxyalkanoates).

The metabolism of carbohydrates occurring with the active participation of the nucleotide adenosinetriphosphate leads to the formation of the compound

coenzyme A (CoA-SH). The acetate of this coenzyme [CoA-SC(O)CH₃] plays an important role in the synthesis of poly-(3-hydroxybutanoate).

P(3HB) and other bacterial PHA are synthesised at 30–35 °C via a series of heterogeneous reactions occurring on the surface of enzymes (Fig. 2).²⁷ Recently, blocks of DNA codons responsible for the synthesis of these enzymes have been determined.^{29, 30, 33} The mechanism of the action of the corresponding enzymes on the

P_a is poly(oligo)hydroxyalkanoates.

Figure 2. Scheme for the enzymic synthesis of P(3HB) with participation of D-(-)-3-hydroxybutyryl-CoA.

dynamics of the synthesis and depolymerisation of P(3HB) has also been considered.³⁷ The polymerase generated by *A. eutrophus* was found to be a polypeptide with $\bar{M}_w = 63\,940$ containing five cystine units, three of which ensure the conformational stability of the enzyme and the other two provide the binding of a hydroxyalkanoic acid molecule on the enzyme surface through the HS groups (Fig. 2). The scheme for this process in relation to the synthesis of P(3HB) is presented in Fig. 3. In the first stage, the enzyme 3-ketothiolase catalyses the reversible condensation of two CoA-SC(O)CH₃ molecules to give the acetoacetyl derivative CoA-SC(O)CH₂C(O)CH₃.

In the second stage, the NADPH-dependent enzyme, acetoacetyl-CoA-reductase (hydrogenase), catalyses the reversible reduction of the acetoacetyl derivative of coenzyme A to D-(-)-3-hydroxybutanoyl-CoA.

The third stage involves a reversible redox reaction catalysed by the NAD-specific dehydrogenase, in which the L-form of 3-hydroxybutanoic acid arising via an independent pathway is converted into the acetoacetyl derivative. The reaction mixture is thus 'fed' with the monomer.

In the fourth stage, the enzyme P(3HB)-polymerase (synthase) catalyses the heterogeneous stereospecific synthesis of P(3HB). The activity of the P(3HB)-polymerase remains virtually invariable during the synthesis of the polyester.

In the fifth stage, depolymerisation of P(3HB) to D-(-)-3-hydroxybutyric acid can occur under the action of the enzyme P(3HB)-depolymerase.

The sixth stage involves the oxidation of the hydroxy-acid with NAD-specific-dehydrogenase to acetoacetic acid, which reacts in the seventh stage with CoA-SH to give CoA-SC(O)CH₂C(O)CH₃.

Evidently, the acetoacetyl derivative of coenzyme A arises as an intermediate both in the synthesis and in the biodegradation of

Figure 3. Scheme for the biosynthesis and biodestruction of P(3HB)²⁷ (fructose and butyric acid as the medium); PPi is the amide of nicotinic acid; 'TCA-ring' is the ring of tricarboxylic acids; and ED is the dehydrogenase.

Figure 4. Dynamics of the synthesis of P(3HB) (Q is the polymer yield) with the *Alcaligenes eutrophus* bacteria (1), and of the variation of the molecular weight (\bar{M}_n) of the polymer (2).²⁷

P(3HB). The dynamics of the synthesis of P(3HB) and of the change in the molecular-mass characteristics of the resulting polyester are illustrated in Fig. 4.

The sequence of chemical transformations occurring during the biosynthesis of P(3HB) includes three stages:

The generation of the polymeric chain:

The growth of the macromolecule:

The termination of the polymeric chain:

Here, E is the enzyme and k_i , k_g , and k_t are the rate constants for the chain generation, chain growth, and chain termination, respectively. All three stages are considered as pseudo-first-order reactions.

Under the isothermal conditions of the synthesis, the rate constants k_g and k_t depend on the presence of monomeric carbon sources in the culture medium in which the bacterial strains are grown. As applied to the biosynthesis of P(3HB), this is illustrated by the following data:²⁷

Content/ g dm ⁻³	Rate constants/ h ⁻¹	
	10 ³ k_g	10 ² k_t
Fructose		
5	5.8	28
10	6.6	28
20	6.0	72
Butyric acid		
5	11.2	116
10	8.0	58
20	4.4	150

HOROH = HOCH₂C≡CCH₂OH, HO(CH₂)₄OH, HOCH₂C(CH₃)₂CH₂OH, *cis*-HOCH₂CH=CHCH₂OH.

With the assumptions that the duration of the chain generation stage is much shorter than those of the other stages of the synthesis and that the number of enzyme molecules remains constant during the synthesis, the overall kinetics of the synthesis can be described by the following equation:

$$\bar{P}_n = \frac{\int_0^t R_g dt}{[E] + \int_0^t R_t dt} = \frac{k_g[E]t}{[E] + k_t[E]t}, \quad (1)$$

where \bar{P}_n is the number-average degree of polymerisation, R_g is the rate of the polymeric chain growth, $R_g = k_g[E]$; R_t is the rate of the polymeric chain termination, $R_t = k_t[E]$; and $[E]$ is the concentration of the polymerase. All the kinetic parameters of the process are assumed to be constant during the synthesis. It is clear that the number of P(3HB) molecules produced over the period of time t is

$$N_t = k_g[E]t\bar{P}_{n,t}^{-1} = [E] + k_t[E]t. \quad (2)$$

It follows from equation (2) that $[E]$ can be evaluated from the plot of N_t against t by extrapolating the N_t value to the region $t \rightarrow 0$. It was found that the concentration of the polymerase $[E]$ does not depend on the nature and on the initial concentration of monomeric carbon sources present in the culture medium. Calculations showed that the number of P(3HB)-polymerase molecules is 18 000 per cell.

The accumulation of the polymer in the biomass reaches 75 mass %. Initially, products with $\bar{M}_w = 2 \times 10^6$ are formed; however, during the polymerisation, the \bar{M}_w value decreases to 6×10^5 , whereas the polydispersity of the polymer remains virtually invariable during the whole enzymic cycle: $\bar{M}_w/\bar{M}_n = 2.0 \pm 0.2$. When carbohydrates, hydrocarbons, and acids are no longer present in the culture medium, biodegradation of the polyester begins.

2. Biosynthesis of copolymers of poly(hydroxyalkanoates)

The composition and properties of copolymers obtained by copolymerisation of various hydroxyalkanoates depend only slightly on the bacterial strain chosen. However, the introduction of various monosaccharides as well as alkanes,¹⁸ alkenes,^{18,33} alkanolic acids,^{16,40,41} or alkenolic acids^{19,42} into the culture medium makes it possible to achieve the reproducible synthesis of various PHA copolymers (Table 1). The biosynthesis of poly-(3-hydroxybutyrate-co-3-hydroxypropionate) [P(3HB-co-3HP)], containing 0% to 80% of 3HP units, has been reported.²⁶ The structure and physical properties of the P(3HB-co-3HP) copolymers were studied by ¹H and ¹³C NMR spectroscopy, X-ray analysis, gel-permeation chromatography, differential scanning calorimetry (DSC), and dielectric and dynamic mechanical spectroscopy.

In the primary structure of the copolymers obtained, the 3HB and 3HP units were distributed randomly along the polymeric chain; the molecular weight of these copolymers lies in the range $(1.1 - 3.5) \times 10^5$.

Statistical P(3HB-co-4HB) copolymers with compositions varying over the whole range have been obtained by adding 4-hydroxybutyric acid, butane-1,4-diol, and γ -butyrolactone to the culture medium.^{25,26} The biosynthesis of P(3HB-co-3HV) has been carried out, and characteristic features of its primary structure have been studied.^{9,43-48}

Copolymers of PHA containing brominated repeating units (up to 2–3 mass %) have been prepared²² by cultivation of *Pseudomonas oleovorans* in culture media containing ω -bromoalkanoic acids and octanoic and nonanoic acids. It was noted that in the presence of a bromoalkanoic acid alone, the synthesis of PHA does not occur.

The proportion of bromine-containing units in the PHA remains virtually constant during the synthesis, whereas the yield of PHA initially increases and then decreases asymptotically as the content of carboxylic acids in the culture medium decreases.

The distribution of different units along the chain in all the copolymers of PHA studied is described adequately in terms of Bernoulli probability statistics, and the mole fractions of the copolymers in the polymeric product are described by the Leibnitz formula. For example, the following polynomial is valid for the estimation of the distribution of units in P(3HV-co-3HH-co-3HU), where 3HU is the residue of 3-hydroxyundecanoic acid:^{49,50}

$$P_i = \frac{x+y+\dots+z}{x! \cdot y! \cdot \dots \cdot z!} P_{HV}^x P_{HH}^y \dots P_{HU}^z, \quad (3)$$

P_i is the mole fraction of a comonomer; P_{HV} , P_{HH} , and P_{HU} are the mole fractions of the corresponding comonomers in the PHA.

The polynomial coefficients x , y , \dots , z in the formula (3) characterise the number of probable combinations of the units in the copolymer. The legitimacy of this approach to the description of the primary structure of the macromolecules of PHA copolymers has been confirmed by computer analysis.

Block copolymerisation opens up additional opportunities for varying the primary structure of the PHA. A variant of such synthesis has been described.^{51,52}

The synthesis of a (3HB)_x block copolymer is shown in Scheme 1, and the synthesis of a polyurethane is presented in Scheme 2.

The resulting PHA derivatives exhibit elastomer properties over a fairly broad temperature range and are biodegradable.

The possibility of the enzymic synthesis of high-molecular-weight block copolymers of aliphatic polyesters has recently been considered.⁵³

III. Structure and properties of poly(hydroxyalkanoates)

The possibilities for technical application of PHA depend on the sum of their physicochemical characteristics and on the physico-mechanical properties of the polymeric materials based on them (films, fibres). The presence of the ester bond in the polymeric chain and weak interchain interaction account for a series of specific properties of these polymers. Some physicochemical properties of fibre-forming polymers with $\bar{M}_n = 2 \times 10^4$ based on poly(ϵ -hexanamide) [P(6HA)] and poly(ϵ -hydroxyhexanoate) [P(6HH)] are presented in Table 2.

Table 2. Glass transition temperature (T_g), melting point (T_m), density, and heat capacity at 25 °C of P(6HA) and P(6HH).⁵⁴

Polymer	T_g /°C	T_m /°C	ρ_{25} /kg m ⁻³		C_p /kJ kg ⁻¹ K ⁻¹
			amorphous state	crystalline state	
P(6HA)	52	220	1090	1230	1.512
P(6HH)	-70	69	1081	1200	1.343

The polymeric chains of poly(hydroxyalkanoates) are markedly more flexible than those of the analogous polyamides. PHA obtained by both chemical and microbiological methods are readily crystallisable thermoplastic materials.⁴⁸ Some physicochemical characteristics of various homopolymeric PHA are given in Table 3. These polymers are readily soluble in dichloromethane, dimethylformamide, and some other solvents. The specific features of the supermolecular organisation of a polymeric substrate, including its self-ordering (crystallisation), depend on the special conditions of its synthesis⁵ or biosynthesis,^{7,55,59} on the tacticity of the primary structure of the macromolecules,⁷ and on the conditions of annealing.^{60,61}

For example, rapid cooling of P(3HB) melts leads to its transition to the amorphous state.⁶² However, this polymer readily crystallises, the rate of the accumulation of the crystalline phase being substantially dependent on the temperature of crystallisation (Fig. 5); more precisely, the rate at which spherulites grow increases with temperature and passes through a maximum at $T_c = 80-90$ °C. Crystallographic characteristics of P(3HB), P(3HV), and of P(3HB-co-3HV) copolymers of various compositions have been reported.³² The influence of the degree of crystallinity of PHA on the structural and mechanical properties of these thermoplastic elastomers has been considered.⁶³ These polymers exhibit highly elastic properties both above and below the temperature range of transition to the plastic state (T_p).⁶⁴ When the polymeric substrate is heated above T_p , the proportion

^a T_{mc} is the temperature at which the rate of crystallisation is a maximum;

^b δ is a solubility parameter; ^c P(6HH) is poly(6-hydroxyhexanoate);

^d P(10HD) is poly(10-hydroxydecanoate); ^e P(3H3MB) is poly(3-hydroxy-3-methylbutyrate).

Figure 5. Influence of the temperature of crystallisation (T_c) on the rate of growth of spherulites (V) for P(3HB-co-3HV) copolymers; proportion of the 3HV units, mass %: (1) 0; (2) 8; (3) 95; (4) 82; (5) 19; (6) 71; (7) 34; (8) 55.

of the highly elastic component in the total deformation decreases. On cooling below T_p , the segments of the PHA macromolecules are capable of self-ordering due to the formation of crystalline domains. The appearance of the crystalline domains in the amorphous PHA determines the effect of 'physical links' between the chains in amorphous regions.

It has been suggested⁶⁵ that the hardening of thermoplastic elastomers occurring below T_p can be represented as a 'physical' gel formation. In conformity with this approach, as the degree of crystallinity (α_c) of the polymeric substrate increases, the crystalline domains are converted into crystalline 'clusters'. The size distribution of these 'clusters' is fairly broad. When the critical level of self-ordering ($\bar{\alpha}_c$) is reached, the polymer transforms from the liquid state into the solid state, and the highly elastic component of deformation somewhat decreases. This effect of hardening of the PHA polymeric substrate is referred to as 'the gel formation point' (GP), and its structure is defined as the 'critical gel'. The above description of the hardening of readily crystallisable elastomers (PHA) is similar to that of 'chemical' gel formation studied in detail previously.^{66,67} It is clear that the GP characterises the stage of molecular structuring, during which $\bar{M}_n \rightarrow \infty$, i.e. the kinetic individuality of the chains is lost.

The crystallisation of PHA on cooling has been studied.⁶⁵ The dynamics of the variation of the modulus of elasticity $G(t)$ (defined as the ratio of the stress to the deformation at constant deformation), of the modulus $G''(\omega)$ (defined as the ratio of the stress component that is in phase with the sinusoidally varying deformation component to the magnitude of this deformation), and of the modulus of loss $G''(\omega)$ (defined as the ratio of the stress component phase shifted by 90° with respect to deformation to the magnitude of this deformation) were studied. At constant deformation amplitudes, the $G''(\omega)$ value is a measure of energy dissipation. Since $G(t)$ and $G'(\omega)$ correspond to the stored elastic energy and since the dynamic change at frequency ω is qualitatively equivalent to the change in the nonequilibrium properties at $t = \omega^{-1}$, the $G(t)-t$ and $G'(\omega)-\omega$ dependences plotted in logarithmic coordinates are, to a first approximation, mirror images with respect to the modulus axis of the corresponding plots describing stress relaxation.⁶⁸

According to Winter and Chambon,⁶⁹ in the GP region for $t_0 < t < \infty$, one can write

$$G(t) = St^{-n}. \quad (4)$$

Here, S is the strength of the 'gel' and n is the 'relaxation exponent'. These parameters are the characteristics of a critical 'gel'. At the point of gel formation, the relation $G'(\omega) \sim G''(\omega) \sim \omega^n$ holds at $0 < \omega < \omega_0^{-1}$. In other words, the above dependences plotted in logarithmic coordinates are similar. The loss angle (δ_k) in the GP is independent of ω . Since

$$\delta_k = \frac{\pi}{2} n,$$

then

$$\tan \left[\frac{G''(\omega)}{G'(\omega)} \right] = \tan \left(\frac{\pi}{2} n \right). \quad (5)$$

The latter dependence permits evaluation of the GP of 'physical' gels from $\tan \delta_k$, which has been demonstrated in relation to various crystallisable polymeric systems.⁷⁰ A study of these dependences for P(3HO) showed that the dynamics of crystallisation of PHA depend substantially on the initial temperature of the melt (T_i) and on the temperature of crystallisation of the amorphous polymer obtained by fast cooling (Fig. 6). For example, at 15 °C and 20 °C, the crystallisation of a thermoplastic P(3HO) elastomer occurs by the 'physical' gel formation mechanism with the manifestation of the GP. However, crystallisation of this polymer at 30 °C occurs by a different mechanism. When a P(3HO) melt heated to 90 °C or above is abruptly cooled, the GP is clearly manifested. At lower temperatures of the melt, no GP is observed. Recently,⁷¹ kinetic and thermodynamic aspects of the flexibility and self-ordering of P(3HO) macromolecules in a block have been studied by means of ¹³C NMR spectroscopy. It should be noted that the kinetic features of crystallisation of PHA of identical compositions are somewhat different depending on whether the polymer has been obtained by chemical synthesis or by biosynthesis: in the latter case, the rate of self-ordering is somewhat higher. This is believed⁷² to be due to the plasticising effect of the residual lipids and proteins present in PHA preparations isolated from the biomass.

The crystallographic lattice parameters of P(3HB-co-3HP) specimens with compositions varying over the whole range have been reported.³⁴ It was shown that the rate of radial growth of the copolymer spherulites, containing 11 mol % of 3HP units, under isothermal conditions is approximately 100 times lower than that for homo-P(3HB). Under the conditions of isothermal crystallisation, the degree of crystallinity of the polymeric substrate decreases as the content of the 3HP units in the polymer increases. The crystallographic lattice parameters remain almost constant as the content of 3HB units increases up to 37 mol %. Crystallisation and structural features of the crystalline phase of P(3HB-co-3HV) copolymers have been studied.^{32, 43, 44, 72, 73} Crystallisation of these copolymers has been investigated using films obtained from both melts^{73–75} and solutions.⁴³

Figure 6. Variation of the $G'(\omega)$ (continuous line) and $G''(\omega)$ (dashed line) moduli as functions of the temperature of crystallisation of P(3HO); $T_i = 90$ °C; $\omega = 1$ rad s⁻¹; T_c /°C: (1) 15; (2) 20; (3) 30.

Crystallographic characteristics of the P(3HB-co-3HV) copolymers of various compositions are listed in Table 4.

Table 4. Structural characteristics of bacterial copolymers P(3HB-co-3HV).³²

Specimen	Type of the lattice	Parameters of the lattice/ nm			α_c (%)	ΔH_0^a /J g ⁻¹
		<i>a</i>	<i>b</i>	<i>c</i>		
P(3HB)	P(3HB)	0.573	1.315	0.596	73	130

P(3HV)	P(3HV)	0.952	1.008	0.556	—	—

^a ΔH_0 is the enthalpy of melting.

When the content of a comonomer is low, the dynamics of crystallisation of PHA copolymers and the structure of the crystalline phase hardly differ from the corresponding characteristics of the homopolymers. In this case, the units of the comonomer act as 'defects' in the crystallographic lattice of the polymeric substrate. However, in some cases, when the distinctions between the sizes and structures of different units are small, the effect of isomorphism is observed.⁷⁶ The ability of the P(3HB-co-3HV) copolymers to form common crystallographic lattices over a wide range of comonomer ratios has led Bluhm et al.⁴⁴ to the hypothesis of diisomorphism, i.e. of the possibility for 3HV units to be incorporated in the crystallographic lattice of P(3HB) and for 3HB units to be incorporated in the lattice of P(3HV). This conclusion was made in a study of the isothermal crystallisation of PHA copolymers in the temperature range from 0 °C to 80 °C by high-resolution ¹³C NMR spectroscopy. It was found that an increase in the temperature of crystallisation results either in a decrease in the degree of crystallinity of the polymeric substrate, when the content of the 3HV units is low, or in its increase, when the content of these units is high (> 50%), which is in agreement with the Bluhm hypothesis.⁷⁷ The rate of radial growth of spherulites of P(3HB-co-3HV) of various compositions in the temperature range from 0 °C to 120 °C is shown in Fig. 5. The maximum rate of growth of the copolymer spherulites is lower than that for P(3HB) and is observed at lower T_c values. It is noteworthy that the physical characteristics of these copolymers depend on the stress of the polymeric material (Table 5).

Table 5. Crystallinity and melting points of P(3HB-co-3HV).

Specimen	Deformation, ϵ_0 (%)	T_m /°C		α_c (%) (25 °C)		
		DSC	IGC	DSC, $\Delta H/\Delta H_0$	X-ray analysis	IGC

A study of the mechanism of crystallisation of P(3HB-co-3HV) carried out by DSC and by inverse gas chromatography (IGC) has shown⁷⁴ that the melting point of the copolymers decreases with an increase in the content of 3HV units even in the case where the degree of crystallinity remains the same. Apparently, the differences between the melting points (T_m) determined by DSC and IGC are due to the differences in the morphology of PHA specimens. The authors cited⁷⁴ believe that the evaluation of the crystallinity of PHA specimens from their density, which has been proposed in another study,⁷⁸ does not permit one to obtain correct characteristics of the self-ordering of these polyesters.

The physicochemical and mechanical properties of P(3HB-co-4HB) copolymers have been studied over the whole range of comonomer ratios.²⁶ Some physicochemical characteristics of these copolymers are given in Table 6.

Table 6. Physicochemical properties of copolymers P(3HB-co-4HB).²⁶

Proportions of comonomers (mol %)		$10^{-3}\bar{M}_n$	\bar{M}_w/\bar{M}_n	T_c /°C	T_m /°C	ΔH_0 /J g ⁻¹	α_c (%)
(3HB)	(4HB)						
100	0	768	1.9	4	177	130.0	59 ± 5
94	6	494	2.1	-1	162	96.2	56 ± 5

0	100	93	2.4	-50	54	89.7	—

Copolymerisation may lead to a sharp decrease in T_m , in the enthalpy of self-ordering ΔH_0 , and in the degree of crystallinity of PHA (α_c). The mixed amorphous and crystalline nature of the polymeric substrate (for both homopolymeric and copolymeric PHA) has been illustrated by the results of studies of the temperature dependences of relaxation spectra.^{34, 39, 62, 79} The apparent activation energy of the relaxation processes (ΔE_a) is ~ 180 kJ mol⁻¹ (see a published study³⁴). The thermal stability of PHA depends largely on the primary structure of the polymeric substrate. The dynamics of thermal decomposition of linear polyesters of various structures have been analysed.⁸⁰ A kinetic model for the thermodestruction of PHA has been suggested.⁸¹ At 200–300°C this process can formally be described by the following first-order equation:

$$\bar{P}_{n,t}^{-1} = \bar{P}_{n,0}^{-1} + k_d t, \quad (6)$$

where $\bar{P}_{n,0}$ and $\bar{P}_{n,t}$ are the number-average degrees of polymerisation of PHA at the beginning of the isothermal heating and after a period of time t , respectively. The polydispersity of the polymer hardly changes during the process: the ratio \bar{M}_w/\bar{M}_n remains constant.

It has been shown that the thermodestruction decelerates as $\bar{P}_{n,0}$ decreases and that the mechanism of the process depends on the presence of free terminal COOH groups; in the presence of terminal COOH groups, the thermodestruction proceeds by a thermal depolymerisation mechanism, the yield of the corresponding lactone reaching 99% and that of oligomers being only 1%.⁸²

Melts of poly(3-hydroxy-3-methylbutyrate) P(3H3MB), which is a polyester with $T_g = 76$ –77 °C and $T_m = 245$ °C (see Table 3), are fairly stable under a nitrogen atmosphere up to 260–270 °C. As for poly(3-hydroxy-2,2-dimethylpropionate P(3H2MB)), it is thermostable under these conditions up to 300 °C. The maximum rate of thermal depolymerisation (T_{md}) of this polymer has been observed at 450 °C.⁸² When the methyl group is substituted by an alkyl group, the T_{md} value decreases. The larger the alkyl side chain in PHA, the

lower the T_{md} value. The following results were obtained for $\sim[\text{OCH}_2-\text{C}(\text{CH}_3)_2-\text{C}(\text{O})]_n$ polymers:

R	$T_{md}/^\circ\text{C}$
CH ₃	~ 450
CH ₂ CH ₃	415
CH ₂ CH ₂ CH ₃	405
CH ₂ C(CH ₃) ₃	445
CH(CH ₃)CH ₂ CH ₃	390

It has been found²⁶ that when the P(3HB-co-94%4HB) copolymer is kept under nitrogen at 100 °C, its $\bar{P}_{n,0}$ value remains constant. At higher temperatures, thermodestruction becomes more intense, but the \bar{M}_w/\bar{M}_n ratio still remains virtually invariant. The rate of the destruction (k_d) [Eqn (6)] of P(3HB-co-94%4HB) increases from 1.1×10^{-5} to 4.5×10^{-5} min⁻¹ as the temperature is raised from 150 °C to 180 °C. The thermodestruction of this copolymer in this temperature range is also described as statistical depolymerisation. The temperature range in which the thermal depolymerisation occurs shifts depending on the primary structure of the PHA.

The physicochemical properties of films and fibres based on PHA depend essentially on the primary structure of these polyesters and on their molecular-weight characteristics. By analysing the 'load-elongation' curves recorded at 23 °C, Nakamura et al.²⁶ have found the following parameters for P(3HB-co-94%4HB) films: modulus of elasticity 5 MPa, rupture stress (G_r) 39 MPa, ultimate elongation (ϵ_u) 500%. In relation to poly(11-hydroxyundecanoate), it has been shown⁸³ that at $\bar{P}_n \approx 100$, the formation of films and fibres proceeds unsatisfactorily, whereas at $\bar{P}_n \geq 600$, high-strength fibrous and film materials can be obtained.

A systematic study of the sorption activity of films based on bacterial P(3HB) toward vapours of various liquids has been carried out.⁸⁴ It has been found⁸⁵ that the presence of impurities in a polymer has an influence on the supermolecular structure of the polymeric substrate and thus leads to changes in moisture absorption properties and in the thermal stability of the polymer. It was shown⁸⁵ that diffusion coefficients depend on the vapour concentration and on the thermodynamic parameters of the solvents. For example, the empirical dependence of the diffusion coefficient of acetone on the concentration of its vapour in the sorption of acetone by a P(3HB) film is described by the formula $-\ln D = 9.97 - 0.0975$.

It has been shown in numerous studies that PHA possess a remarkable compatibility (in solutions, melts, and in the solid state) with various natural and synthetic polymers as well as biocompatibility. However, since this property of PHA is largely specific, it will be considered elsewhere.

IV. Biodegradation of poly(hydroxyalkanoates)

Studies performed at ICI⁸⁶ have demonstrated the possibility of effective biodegradation of high-molecular-weight P(3HB) in soil, sea water, bottom-dwelling sediments, and aerobic and anaerobic waste water. Sixteen strains of soil microorganisms were isolated, which are capable of using PHA as an exogenous carbon source and of producing extracellular depolymerases for this purpose. Strains of *Pseudomonas lemoigenes*^{87–90} and *Alcaligenes faecalis*^{91, 92} bacteria can degrade P(3HB) to give trimers and tetramers in the former case or dimers of 3-hydroxyalkanoic acids in the latter case. Recently, PHA depolymerase has been isolated in a pure state from the *Penicillium funiculosum* fungus,⁹³ and the degradation activity of this enzyme toward polymeric and copolymeric PHA has been demonstrated.^{94, 95} As noted above, biodegradation of PHA begins when monomeric carbon sources (monosaccharides, carboxylic acids and their derivatives) are no longer present in the culture medium. During the biodegradation of PHA, \bar{P}_n and the content of PHA in the biomass decrease. At the same time, the number of polymeric chains N_r remains virtually constant. This is due to the fact that the extracellular

PHA-depolymerase is an exo-hydrolase, which destroys the polymeric chain by cleaving the terminal units of 3-hydroxyalkanoic acids.²⁷ Moreover, the polydispersity of the PHA polymeric substrate remains virtually constant and lies in the range $\bar{M}_w/\bar{M}_n = 2.0 \pm 0.3$ even at fairly high degrees of conversion.

It has been found^{7,96} that soluble extracellular P(3HB)-depolymerase produced by *A. eutrophus* can degrade native P(3HB) granules to give monomeric D-(-)-3-hydroxybutyric acid (see Fig. 2). However, information on the structure and properties of this enzyme is quite scarce. It is believed that P(3HB)-depolymerase is a serine esterase having active HO groups.^{92,97} The following sequence of processes has been proposed to describe the destruction of P(3HB) catalysed by this enzyme:²⁷

Here, E-OH is P(3HB)-depolymerase. A scheme for this heterogeneous process is shown in Fig. 7. According to a hypothesis,²⁷ the terminal carboxyl groups in P(3HB) react with the positively charged sites on the enzyme 'surface' to yield an active complex. In the case where fructose and butyric acid are used as initial carbon sources in the culture medium, the rate of anaerobic biodegradation of P(3HB) is illustrated by the following data:

Concentration /g dm ⁻³	Biodegradation rate /g h ⁻¹ dm ⁻³
Fructose	
5	0.013
10	0.027
20	0.025
Butyric acid	
5	0.023
10	0.023
20	0.034

The rate of biodegradation of P(3HB) depends substantially on the primary structure of PHA: structural regularity of the chain, and the nature and the sequence of the units in the chain.

The influence of stereoregularity of P(3HB) macromolecules on the dynamics of biodegradation of this polymer has been studied.⁷ For this purpose, electrophoretically homogeneous P(3HB)-depolymerase was isolated from the *Penicillium funiculosum* fungus. The molecular weight of this protein was 38 000. The protein had an isoelectric point at pH 5.8, and its maximum hydrolytic activity was observed at pH 5.5–6.2 and at 30 to 35 °C.⁹⁸ The rate of the biodestruction of PHA is substantially higher than the rate of typical chemical hydrolysis of a polymeric substrate under the same conditions.^{99–103}

Stereoregular PHA were obtained by polymerisation of stereoisomers of β -butyrolactone (BL) in the presence of ionic catalysts according to the following scheme:

The polydispersity of the resulting samples of P(3HB) was low ($\bar{M}_w/\bar{M}_n \approx 1.1–1.5$), the proportion of isomeric units in the copolymers ranging from 50% to 100%. The P(3HB)-depolymerase isolated can catalyse hydrolysis of (R)-P(3HB) but proves inactive with respect to (S)-P(3HB).⁷ As the proportion of (R)-3HB units in the (S,R)-P(3HB) copolymer increases, the rate of biodestruction increases and reaches a maximum when the content of the (R)-3HB units is 75 mol % (Fig. 8). Further increase in the content of the (R)-3HB units (to more than 90 mol %) results in a decrease in the rate of biodestruction. Biodegradation of a P(3HB) copolymer containing (S)- and (R)-units in a 1:1 ratio leads to oligomers with $\bar{P}_n = 3 \pm 1$. The biodegradation of PHA copolymers has also been studied by other workers.^{95, 104}

Figure 7. Scheme for the hydrolytic biodestruction of P(3HB) under the action of P(3HB)-depolymerase.²⁷

Figure 8. Influence of stereoregularity on the rate of biodegradation of P(3HB); β is the content of the (*R*)-isomer in the stereocopolymer P(3HB), and V_B is the biodestruction rate.

The ability of the extracellular P(3HB)-depolymerase isolated from *Alcaligenes faecalis* to catalyse the hydrolysis of P(3HB-co-4HB) copolymers at 37 °C in a 0.1 M phosphate buffer (pH 7.5) has been studied.²⁶ Data on the dynamics of the variation in the mass of PHA films are shown in Fig. 9. As the content of the 4HB units in the P(3HB-co-4HB) copolymer increases up to 28 mol %, the rate of film destruction increases; however, when the content of the 4HB units exceeds 85 mol %, the rate of destruction diminishes and becomes lower than that in the case of homo-P(3HB).

The dependence of the rate of biodestruction on the composition of P(3HB-co-3HP) is presented in Table 7.

Biodestruction of the P(3HB-co-3HP) at 37 °C in a 0.1 M phosphate buffer (pH 7.5) in the presence of electrophoretically homogeneous P(3HB)-depolymerase isolated from *Alcaligenes faecalis* has been studied.³⁴ As the content of the 3HP units in the copolymer increases up to 20 mol %, the rate of the surface bioerosion of P(3HB-co-3HP) films increases. For higher contents of these units, the rate of destruction of copolymers decreases somewhat. The investigators believe³⁴ that this is due to the specificity of P(3HB) depolymerase.

The rate of the enzymic destruction of PHA has been studied in relation to the P(3HB-co-3HH) copolymer.¹⁰⁵ The influence of the primary structure of the macromolecules of PHA copolymers on the dynamics of biodestruction has been illustrated by Hori et al.⁵¹ The films of polyurethanes synthesised from PHA blocks, various diols, and hexamethylene diisocyanate and having

Figure 9. Dynamics of biodestruction of P(3HB)-co-4HB films in aqueous dispersions of P(3HB)-depolymerase at 37 °C and pH 7.5; proportion of (4HB)-units in the copolymer, mol %: (1) 28; (2) 10; (3) 6; (4) 0; (5) 85; (6) 94; M_p is the mass loss.

Table 7. Influence of the composition of P(3HB-co-3HP) on the crystallinity of the polymeric substrate (α_c) and on the loss of mass (M_p) of films during biodestruction.³⁴

PHA	α_c (%)	M_p (%)
P(3HB)	60 ± 5	5.1 ± 1.7
P(3HB-co-7% 3HP)	43 ± 5	17.2 ± 3.4
P(3HB-co-11% 3HP)	41 ± 5	21.7 ± 3.4
P(3HB-co-20% 3HP)	28 ± 5	31.7 ± 5.1
P(3HB-co-37% 3HP)	19 ± 5	26.6 ± 3.4
P(3HB-co-43% 3HP)	16 ± 5	26.3 ± 3.4

$\bar{M}_n = 1.98 \times 10^5$ and $\bar{M}_w/\bar{M}_n = 2.0$ lost about 70% of their mass following the biodegradation at 30 °C for four weeks, whereas the PHA polymer itself was depolymerised by 93%. The variation of the rate of biodegradation of PHA copolymers as a function of the copolymer composition is due to the difference in the degree of structural ordering of the polymeric substrates: as the degree of crystallinity decreases, the rate of destruction increases (see Table 7). Analysis of the biodegradation dynamics makes it possible to conclude that this process is governed by both the specificity of PHA depolymerase and the ordering of the structural elements of the polymeric substrate.

* * *

Film-forming and fibre-forming PHA can be obtained by biosynthesis in fairly high yields and with relatively low power consumption. By varying conditions of the biosynthesis, one can alter the composition and properties of the resulting compounds over a wide range. Polymers and copolymers of hydroxyalkanoic acids are readily crystallisable thermoplastic polymers with flexible chains. They are capable of forming homogeneous mixtures with various natural and synthetic film-forming and fibre-forming polymers, which permits them to be used as high-molecular-weight plasticisers and as diverse additives that change the relaxation spectra of polymeric materials. The biocompatibility of various PHA is also of considerable interest. Many homopolymeric and copolymeric PHA are biodegradable, which accounts for the efficiency of their practical application for the development of polymeric materials that are biodegraded at a controlled rate.

This work was supported by a grant of the International Soros Science Education Program (ISSEP).

Abstract. The data on new monosaccharides detected in O-antigenic polysaccharides of Gram-negative bacteria have been surveyed. The results of isolation and structure determination of these unusual monosaccharides have been arranged and described systematically. The NMR spectroscopy techniques are shown to be promising for the O-antigenic polysaccharides structure determination. The information about fine structure of monosaccharides which constitute the base of important class of microbial polysaccharides, is of great significance for applied studies, first of all, the design and synthesis of biologically active substances. The bibliography includes 216 references.

I. Introduction

Carbohydrate-containing biopolymers are among the major components of the living cell where they play a role of building blocks and energy donors and provide for the normal course of some highly specific biological processes coupled with the specific properties of the cell surface. Of those, the most abundant ones are polysaccharides (PS) made up of monomeric units, i.e., monosaccharides. The biological functions of PS specifically correlate with their structure. This structure–function relationship is especially well-defined in PS localised on the cell surface of Gram-negative bacteria. These PS determine the specificity of cell interactions with the environment which reflects on the fine immunochemical characteristics of the bacterium (serological reactions), on the specificity of cell interaction with bacteriophages (phage transformation of the microbial cell) and host tissues as well as on other highly specific biological processes.

The biological specificity of PS is determined by the peculiarities of the molecular structure of these biopolymers which, in turn, depends on the structure of the monomers (monosaccharides) in the biopolymer, their sequence in the polymeric chain and the mode of binding of the monomeric units. Whereas the first two factors, the monomeric composition and the sequence of the monomeric units, are not specific for the PS structure only but also for the structure of proteins and nucleic acids, the last factor determines the type of intermonomer binding and is unique to PS.

This is due to the multifunctionality of monosaccharide residues containing several hydroxy groups at chiral carbon atoms. The existence of several hydroxy groups provides for the formation of several sterically unique intermonomer glycosidic bonds, thus giving rise to a complex (often branched) polymeric chain and increases manifold the possibility of variations in the structure of PS built up from these monomers.

Another circumstance which greatly favours the existence in Nature of a broad spectrum of polysaccharide structures is the diversity of the monomeric units which may serve as building blocks for the polymeric carbohydrate chain. Whereas the diversity of nucleic acids is provided by only four nucleotides, and the number of amino acids in most proteins does not exceed 12–15, the diversity of PS is provided by more than a hundred monosaccharides and their derivatives.

Among the immense variety of PS isolated from natural sources, the most diversified (as regards their structure and monosaccharide composition) and most thoroughly studied are the PS of the outer cell membrane of Gram-negative bacteria. The primary structure of many of those has been established. These PS are important constituents of complex biopolymers, the so-called lipopolysaccharides (LPS)¹ localised on the cell surface of Gram-negative bacteria. Lipopolysaccharides consist of the lipid component (lipid A) incorporated into the microbial cell outer membrane, and the polysaccharide chain which, via a short oligosaccharide (so-called 'core') is attached to the lipid. The polysaccharide chain is exposed on the cell surface and is in direct contact with the environment, thereby providing, together with proteins, a unique pattern ('membrane mosaic') which determines the ultimate specific characteristics of the bacterial surface.

These PS are somatic bacterial antigens generally termed O-antigenic polysaccharides. They represent regularly arranged block polymers which only in rare instances occur as homopolymers but are usually composed of repeating oligosaccharide units, each of which contains 2 to 8 monosaccharide residues.² It may appear that such block organisation of the biopolymer restricts the number of plausible structures of O-antigenic PS. However, actually, because of the above peculiarities (great diversity of intermonomer glycosidic bonds, possibility to form branched chains and a great number of structurally distinct monosaccharides or their derivatives), the number of plausible structures of oligosaccharide units (and, consequently, of corresponding PS) is enormous amounting to tens of thousands (even when the polymer units are built up of only 3–4 monosaccharides).

It should be stressed that in contrast to PS of plant and animal cells, which are as a rule built up of a limited number of the most

commonly occurring monosaccharides, PS of microbial origin contain a large number of less abundant monosaccharides often detected exclusively in these biopolymers. Very likely, only antibiotics, many of which also contain unusual monosaccharides, may effectively compete with their great diversity.

So far, the biosynthesis of monosaccharides present in PS, including some structurally unusual ones, has been studied in considerable detail. The pathways of formation of various monosaccharide structures from primary photosynthetic products have been elucidated: these shed more light on the diversity of the monomers utilised by microorganisms for the synthesis of the O-antigenic PS chain. These data have been considered in the review of Shibaev.³

In many cases structurally unusual monosaccharides or their derivatives play the role of the immunochemical dominant group, i.e., of the component that contributes most to the biological specificity of PS. This becomes especially apparent when an unusual component occupies the position of a side-chain substituent of the main linear chain of the biopolymer.

An example of a rare or even unique monomer of microbial PS may be a monosaccharide containing unusual structural groups. Their representatives in O-antigenic polysaccharides are deoxyhexoses, deoxyheptoses, aminodeoxy sugars, aminouronic acids and nonulosonic acids carrying amino groups. In addition to well-known *O*- and *N*-acetyl monosaccharide derivatives and their *O*-methyl ethers, O-antigenic PS have been found to contain, highly specific for this class of biopolymers, *O*- or *N*-acyl derivatives formed by acylation of monosaccharides by hydroxy or dihydroxy acids and amino acids. Another example of unusual derivatives are amides of uronic acids, including those formed by amino groups of amino acid residue. In current literature such fragments are generally termed 'non-carbohydrate substituents'. The monomers containing such unusual *O*- and *N*-substituents were mostly discovered during the last 10–15 years, and their number is rapidly increasing. Their identification and localisation in the polymeric chain is an indispensable part of the modern-day structural chemistry of polysaccharides.

It is especially worth noting that the vast body of experimental material obtained by analysis of the structure, chemical properties and pathways of synthesis of novel monosaccharides (and their non-carbohydrate substituents) present in O-antigenic PS has been found to be extremely important not only for understanding the nature of the biological specificity of carbohydrate polymers but also for further progress in carbohydrate chemistry in general. The data for novel, unusual combinations of functional groups in the monosaccharide molecules have considerably expanded our concepts of the reactivity and stereochemistry of monosaccharides and culminated in the discovery of some novel reactions, giving a new impetus to the elaboration of new methods of organic synthesis. The availability of a great number of carbohydrates differing in their structure has considerably enriched the methodological arsenal of NMR spectroscopy, for which these derivatives served as perfect model compounds.

The present review is dedicated to the consideration of mostly chemical aspects of the problem: it deals with isolation, determination of structure, identification and chemical properties of novel unusual monosaccharides or their unusual derivatives present in O-antigenic PS as monomeric units. In some instances data are given about the same or structurally related monosaccharides found in microbial PS unrelated to O-antigenic PS of Gram-negative bacteria. Some of the data concern the synthesis of certain monosaccharides. Such syntheses were undertaken with the purpose of confirming their structure or obtaining a corresponding, not easily available monosaccharide or its derivative in larger amounts needed for further analysis and application to the solution of research problems or practical tasks. Of the extensive body of synthetic material, we have focussed our attention only on those syntheses that either have a fundamental importance or are novel, effective and practical.

The data on the structure of PS themselves comprising these monosaccharides have been reviewed in one of the recent reports² which also concerns the localisation and type of binding of the monomers in the polysaccharide chain.

Earlier published reviews^{4–6} dedicated to O-antigenic PS covered mainly biological and, particularly, microbiological aspects.

II. General observations concerning isolation, determination of structure and identification of monosaccharides and their derivatives present in O-antigenic PS

In order to determine the structure or to identify an unusual component of the polysaccharide chain by comparison with an authentic sample, the component is sometimes isolated in the individual state as such, as one of its standard derivatives (e.g., acetate) or in a modified form (e.g., as a corresponding alditol). However, the use of contemporary physico-chemical methods, and in the first place, NMR spectroscopy, often permits a conclusion about the structure of the unusual monomer directly in the process of establishment of the structure of the PS itself by using a non-destructive method. In recent studies identification of an already known component of a PS is often performed during the spectral analysis of PS by characteristic signals in the NMR spectrum.

1. Isolation of unusual monosaccharides or their derivatives

The initial O-antigenic polysaccharide is obtained by selective degradation of LPS routinely isolated by extraction of the microbial mass with aqueous phenol.⁷ This is followed by mild acid hydrolysis of LPS with dilute acetic acid, after which the polysaccharide is isolated by a standard, specific for the given PS procedure (for example, ion-exchange chromatography is effectively used for PS containing acidic groups).[†]

After establishment of the presence of an unusual component by conventional monosaccharide analysis of PS or by preliminary analysis of its NMR spectrum, the isolation of the monosaccharide in the pure state is achieved by acid hydrolysis of the PS followed by chromatographic separation of the resulting mixture. For a successful solution of this problem, two mutually exclusive conditions often have to be met: (i) cleavage of the glycosidic bond of the monomer to be isolated during its splitting off from the polysaccharide chain, and (ii) avoidance of partial or even complete degradation of the monomer upon hydrolysis. For example, it is well known that monosaccharides containing one or several deoxy units are unstable in acid media and, although the glycosidic bonds of these monosaccharides are readily cleaved, isolation of the corresponding monomers may pose serious problems. At the same time, the glycosidic bonds of uronic acids or amino sugars having a nonacylated amino group are distinguished by increased resistance to hydrolysis which largely prevents the isolation of the corresponding native monomer in the individual state.

This task is further complicated by the situation when a complex monomer, a monosaccharide derivative containing a non-carbohydrate substituent, is to be isolated. Clearly, in this case the hydrolysis must not be accompanied by cleavage, modification, destruction or rearrangement of the substituting group. If after hydrolysis the unchanged non-carbohydrate substituent can be successfully isolated and identified, a new problem arises as to which monosaccharide of the polymeric chain is concerned and how the substituent is bound.

[†] Examples of standard procedures for isolation and purification of various types of PS can be found in the many-volume monograph *Methods in Carbohydrate Chemistry* Vols I–IX (New York: Academic Press, 1965–1993).

The hydrolytic conditions used to isolate novel components of PS may vary widely depending on the experimental goal. This is pertinent to the choice of the acid (hydrochloric, sulfuric, trifluoroacetic) and its concentration as well as the temperature and duration of hydrolysis. Most commonly, the hydrolytic conditions are selected experimentally, taking into account preliminary data on the monosaccharide composition of the biopolymer. Sometimes, for the isolation of an unusual component, special conditions are applied which may not be suited for achieving complete hydrolytic cleavage of the polysaccharide. In other cases, acetolysis (treatment of PS with an acetic anhydride-acetic acid mixture in the presence of sulfuric or another strong acid, e.g., hydrochloric acid) is used instead of acid hydrolysis; in this case monosaccharides are isolated in the form of full acetates.

Currently, solvolysis with anhydrous HF at reduced or room temperatures is used for depolymerisation of polysaccharides.⁸ The distinctive feature of this method is that it cleaves the glycosidic bonds without any effect on bonds cleaved by hydrolysis, e.g., amide bonds. In particular, the method is used effectively to isolate complex derivatives of monosaccharides with their non-carbohydrate substituents attached.

When an unusual monomeric component fails to be isolated, a short oligosaccharide fragment (usually a disaccharide or a trisaccharide) containing this monosaccharide is obtained. For this purpose, in addition to selective acid hydrolysis, other conventional procedures for partial cleavage of the polysaccharide chain are used, such as oxidation with periodic acid (periodate oxidation) with subsequent Smith degradation,⁹ and in some cases deamination of an amino sugar present in the PS chain is carried out.¹⁰ This simplifies considerably the determination of the structure of the unusual component of a short oligosaccharide in comparison with its identification within PS, mass spectrometry and NMR spectroscopy being helpful tools in the process.

Chromatographic techniques are now being used almost exclusively to isolate monosaccharides, their derivatives and short oligosaccharide fragments from hydrolysates. Preliminary qualitative estimation of the composition of the hydrolysate and identification of an unusual component are carried out using paper chromatography (PC) or thin-layer chromatography (TLC) and by various modifications of liquid or gas-liquid chromatography. On the basis of the preliminary data, the most appropriate method is selected for preparative isolation of the desired component (a monomer or an oligosaccharide).

2. Chemical methods used to establish the structure

With the development of physico-chemical techniques, classical chemical methods used for establishing the structure of monosaccharides and their derivatives gradually lose their significance, although some of them still remain practicable. If a previously unknown monosaccharide was isolated in the pure state, its structure can be determined by routine approaches commonly employed in monosaccharide chemistry, such as methylation and periodate oxidation, which had especially wide application at early stages of microbial PS analysis. The first of these methods (see Practical Guide¹¹) is based on the conversion of free hydroxy groups of a mono-, oligo- or poly-saccharide into *O*-methyl groups. Their localisation in the resulting derivative by using mass spectrometry makes it possible to establish the position of other substituents, deoxy units, and details of the monosaccharide structure.

Oxidation of a monosaccharide with periodate⁹ results in the cleavage of the carbon-carbon bonds between adjacent atoms carrying hydroxy groups which prompts a conclusion about their location and the presence of deoxy units in the monosaccharide. Currently, this method is used widely for selective cleavage of the PS chain with the ultimate goal of obtaining short fragments and is followed by mild acid hydrolysis and reduction (Smith degradation) of the oxidised PS.⁹

Other chemical conversions used to establish the monosaccharide structure involve deamination of amino sugars, as a result

of which the amino group is first deacetylated and the amino sugar derived is treated with nitrous acid (see review¹⁰). This reaction is also employed for selective degradation of the PS chain.^{12,13} In some cases other reactions of monosaccharides, e.g., conversion of monosaccharides into anhydro sugars, lactonisation of uronic acids, etc., may become helpful.

Sometimes, in order to identify a monosaccharide by comparison with the authentic sample, the former is converted into its derivative, e.g., *O*-acetate or *O*-trimethylsilyl ether. Reduction of a monosaccharide with NaBH₄ to the corresponding alditol is especially useful. The latter is converted into the acetate and identified either by direct comparison with an authentic sample or using mass spectrometric analysis.

To establish the absolute configuration of a monosaccharide, this is converted into a glycoside by interaction with an optically active alcohol (most commonly with butan-2-ol or octan-2-ol). The absolute configuration of the initial monosaccharide is inferred from the chromatographic mobility of the glycoside.

Chemical methods used to establish the structure of unusual derivatives of monosaccharides are mostly confined to their degradation into the constituent fragments: a monosaccharide and a non-carbohydrate substituent. To this end, hydrolytic cleavage of a hydroxy group or an amino acid group that is acylating one of the hydroxy groups in the monosaccharide is performed, after which the acid is isolated for further identification. The substitution site in the monosaccharide is determined by one of routine chemical or physicochemical methods.

It should be noted that at the present time such tasks, as well as establishment of the structure of novel monosaccharides, are more easily and effectively accomplished by application of physico-chemical methods alone, while chemical methods are used in counterflow syntheses of new monosaccharides or their unusual derivatives for unambiguous and final identification. Synthesis of novel monosaccharides is usually achieved by regio- and stereo-selective transformation of one of the available monosaccharides by methods routinely used in carbohydrate chemistry. Examples of different syntheses of this sort will be given below.

3. Mass spectrometric analysis

One of the physicochemical methods used to study the structure of sugars is mass spectrometry. The stipulation of the principles for fragmentation of monosaccharide molecules^{14,15} and of alditols derived by their reduction^{16,17} using electron impact has made it possible to use mass spectrometry for effective establishment of their structure. Currently, the most commonly used is mass spectrometry of alditols characterised by more simple and unambiguous fragmentation of the molecule.

For this purpose, a monosaccharide or its derivative is reduced with borohydride or, in special cases, with sodium borodeuteride. This results in the formation of an alditol, in which the primary alcohol group (which often comprises deuterium, CHD-OH, providing the 'labelling' of the group essential for further elucidation of the structure on the basis of the mass spectrum) corresponds to the aldehyde group of the original molecule. The alditol thus obtained is converted into the full acetate which is further subjected to mass spectrometry. It should be emphasised that in the majority of cases this method permits the preservation of the non-carbohydrate substituents present in the monosaccharide and makes mass spectrometry a helpful tool for the analysis of complex derivatives of monosaccharides.

Fragmentation of alditols by electron impact has been studied thoroughly.¹⁸ In particular, a correlation has been established between the relative ease of cleavage of the carbon-carbon bonds in alditols and the nature of the substituent at the carbon atom. On the basis of these data, standard procedures have been developed for establishment of the structure of monosaccharide components of PS (see reviews^{19,20}).

The mode of degradation of carbon-carbon bonds in alditols by electron impact appears to be especially informative in the analysis of the structure of deoxy and aminodeoxy sugars as well

as of monosaccharides containing non-carbohydrate substituents. Such substituents (e.g., a residue of a hydroxy or an amino acid) are also subject to fragmentation by well-known pathways and easily identified, the fragmentation of the alditol skeleton indicating the position of the non-carbohydrate substituent.

Regrettably, mass spectrometric analysis does not allow a conclusion about the stereochemistry of the monosaccharide, since the spatial arrangement of the substituents at the chiral carbon atoms of the monosaccharide skeleton does not appreciably influence the cleavage of the carbon-carbon bonds. Numerous attempts to use mass spectrometry for determination of the configuration of monosaccharides failed and, therefore, NMR spectroscopy is now being used more frequently to establish the polysaccharide structure.

4. NMR spectroscopy

NMR spectroscopy is the major procedure designed to establish the structure of carbohydrates and structurally unusual monomeric components of PS. Sometimes, this method allows a solution of this problem without isolation of monosaccharides in the pure state, directly on the basis of the NMR spectrum of the polysaccharide, and the establishment of the complete structure of PS on the basis of the spectral data alone, i.e., by a non-destructive approach.

Almost all presently known versions of ^1H and ^{13}C NMR spectroscopy are used in polysaccharide chemistry; the use of each of those modifications is defined by the specific goal to be sought (see reviews ²¹⁻²⁶). The techniques based on the measurement of nuclear Overhauser effects (NOE) in the ^1H NMR spectra, which allows a direct determination of the relative spatial position of protons in the monosaccharide molecule, has acquired special importance in recent years.

Among new approaches expressly designed to solve structural problems of polysaccharide chemistry, special mention should be made of computer analysis of ^{13}C NMR spectra.^{24,27} This approach is meant, primarily, for determining the type of binding and the sequence of monosaccharide units in the polysaccharide chain. However, it often appears to be a helpful tool for elucidation of the structure of monosaccharides in PS, particularly, for the determination of their configuration. Thus, this method is now being widely employed for establishment of the absolute configuration of the monosaccharide without its isolation, i.e., directly within the polysaccharide chain.²⁴ The method is based on the determination of the magnitude of the so-called glycosylation effects, i.e., changes in the chemical shifts of the given carbon atoms in the ^{13}C NMR spectrum depending on the stereochemical features (including the absolute configuration) of the neighbouring monosaccharide unit in the polymeric chain.

5. Other physicochemical methods

An important physicochemical constant used in the structural analysis of sugar derivatives is the specific optical rotation. This value is readily determined with a high degree of accuracy and reproducibility and not only serves as an important criterion of the purity of the preparation obtained but is also routinely used for identification of the compound studied by comparison with an authentic sample. The absolute configuration of the monosaccharide under study as well as of oligosaccharides and other derivatives containing this monosaccharide unit can also be determined from the specific optical rotation; for this purpose, the experimentally determined specific optical rotation is compared with the theoretically calculated value for the given monosaccharide or its derivative using Klein's rule.²⁸

In what follows, the description of individual representatives of monosaccharides and their derivatives present in O-antigenic PS will include concrete data on the use of the physicochemical methods mentioned above; this is confined to a brief consideration of only the most important spectral characteristics of the monosaccharide that are critical and sufficient for the elucidation of its structure.

III. Unusual monosaccharides forming a part of O-antigenic PS

1. Pentoses and hexoses

The majority of aldopentoses and aldohexoses widely distributed in Nature are common components of microbial PS. D-Glucose, D-galactose and D-mannose have a peak incidence among hexoses, while D-ribose among pentoses. D-Xylose and D-arabinose are far less abundant.²

Aldoses of the L-series are not common in microbial PS. Thus, only PS of two *Pseudomonas* species contain L-xylose.^{29,30} This sugar was identified by conventional methods of carbohydrate analysis as the acetate of the corresponding alditol.²⁹ The absolute configuration of the (–)-2-octyl glycoside derivative of L-xylose was determined by GLC.³⁰

2. Deoxyhexoses

Unlike hexoses which enter into polysaccharides predominantly as D-isomers, deoxyhexoses occur more frequently as L-isomers. Thus, 6-deoxyhexoses, L-rhamnose and L-fucose are common constituents of O-antigenic PS,² whereas D-isomers of these monosaccharides are rare. The D-isomers were isolated in the individual state after acid hydrolysis of PS of *Pseudomonas cepacia* or as O-methyl ethers after hydrolysis of methylated PS and identified by conventional methods. Their absolute configuration was established either by calculation according to Klein (e.g., see Ref. 31) or by GLC of alkyl glycoside derivatives with optically active alcohols (e.g., see Ref. 32). Sometimes, the absolute configuration was determined by a computer analysis of the structure of PS based on their ^{13}C NMR spectra (e.g., see Ref. 27).

Some PS were found to contain even more rare 6-deoxyaldoses. Thus, 6-deoxy-L-talose (1) was detected in PS of several *Pseudomonas* species (*P. fluorescens*,³³ *P. maltophilia*,³⁴ *P. pseudomallei*³⁵) as well as in PS of a strain of *Escherichia coli*.³⁶ This sugar was isolated in the pure state from acid hydrolysates of PS and identified using PC and TLC by comparison with an authentic sample obtained from glycosides of the terpene series.³⁷ Its structure was confirmed by mass, ^1H and ^{13}C NMR spectra, whereas the L-configuration was evident from the specific optical rotation.

6-Deoxy-L-altrose (2) was detected in *Yersinia enterocolitica*^{38,39} as a component of a homopolysaccharide composed of the pyranose units of this sugar as well as in PS of *Y. pseudotuberculosis* serovar VB, where its furanose form is present in the side chain.⁴⁰ The monosaccharide was identified by direct comparison with the sample isolated earlier from terpene glycosides.³⁷ Its structure as 6-deoxyaldose was corroborated by mass spectrometry and NMR spectroscopy,³⁸ whereas its L-configuration was determined from the specific optical rotation.

There is evidence⁴¹ that a PS of *Y. enterocolitica* contains 6-deoxy-D-gulose (3) which failed to be isolated in a sufficiently pure state. Its structure was established by comparison with an authentic sample³⁷ using electrophoresis in borate buffer. The stereochemistry of 6-deoxy-D-gulose was determined by analysis of the ^1H NMR spectrum of a partially purified sample. This spectrum contained signals corresponding to the CH_3 group of

6-deoxyhexose and the coupling constant values ($J_{2,3} = 3.5$, $J_{3,4} = 1.5$, $J_{4,5} = 2.25$ Hz) were consistent with the *gulo*-configuration. The absolute configuration was established from the ^{13}C NMR spectrum of the polysaccharide.

6-Deoxyaldoses can be easily synthesised by routine methods, i.e., by introducing a 6-deoxy unit into the corresponding aldoses. An example is provided by the synthesis of rarely occurring D-rhamnose from D-mannose⁴² (Scheme 1).

Scheme 1

Methyl 2,3-*O*-isopropylidene- α -D-mannopyranoside (4) was converted into the 6-iodo derivative 5 by selective tosylation of the primary hydroxy group and subsequent treatment with NaI. Hydrogenation of the latter over Raney nickel followed by elimination of the isopropylidene group gave the methyl glycoside of D-rhamnose 6.

Other monodeoxyhexoses have not yet been found in O-antigenic PS. Of particular interest is the fact that 2-deoxyhexoses, widespread in many natural glycosides, are absent from bacterial PS at all. There is also no evidence for the presence of 3-deoxyhexoses in PS. The only representative of 4-deoxyhexoses in O-antigenic PS is 4-deoxy-D-*arabino*-hexose (7) detected in some strains of *Citrobacter* (e.g., in *Citrobacter* O36 its pyranose units form a homopolysaccharide,⁴³ whereas in *Citrobacter* PCM 1487 it is present in the side chain of O-antigenic PS⁴⁴). The monosaccharide 7 is distinguished by very high lability and could not be purified after acid hydrolysis of PS, although the reduction of the hydrolysate gave the alditol 8. The mass spectrum of the acetate of 8 contained peaks of the fragments with m/z 303 and 231 and the corresponding secondary fragments which clearly indicates the presence of a C(4)-deoxy unit. The stereochemistry of 7 was determined on the basis of the ^1H NMR spectrum of the polysaccharide itself; the presence of two signals of H(4) at 1.751 (a) and 1.528 (e) ppm also corroborates its structure. The D-configuration was assigned to the monosaccharide 7 on the basis of the specific optical rotation.

3. 3,6-Dideoxyhexoses

This type of deoxy sugars is widely spread in PS of Gram-negative bacteria and is typical of PS of the genus *Salmonella*.² 3,6-Dideoxyhexoses were detected as components of PS even in pioneer studies of O-antigenic PS of microorganisms. Identification and determination of the structure of 3,6-dideoxyhexoses isolated from various *Salmonella* species demonstrated a direct

correlation between the structure of O-antigenic PS of a certain bacterium and its immunochemical properties. These studies, which dated back to the 1950's, had a great historical impact, for they actually opened up a way for extensive systematic chemical investigations into microbial O-antigenic PS.

Up to the present, five representatives of 3,6-dideoxyhexoses of various configurations are known that are present in PS of a rather large number of Gram-negative bacteria. They are: D-*arabino*-hexose (tyvelose 9), D-*ribo*-hexose (paratose 10), D-*xylo*-hexose (abequose 11), L-*arabino*-hexose (ascarylose 12) and L-*xylo*-hexose (colitose 13). Among these, the first three monosaccharides, which were first discovered by Westphal and Lüderitz during their study of PS of *Salmonella*, are the most widespread.⁴⁵ These compounds are attached as side chains to the main chain of the biopolymer and represent the immunodominant groups, i.e., they determine the immunochemical characteristics of the given microorganism (see review⁴⁶). Thus, PS of *S. paratyphi* contains paratose, PS of *S. typhimurium* abequose, *S. typhi* PS tyvelose.^{2,47} The *Salmonella* of serogroups A–D contain as an indispensable component one of these three 3,6-dideoxyhexoses.

Two species of *Salmonella* were also found to contain colitose⁴⁸ first discovered in PS of *Escherichia coli* O111.⁴⁹ Later, 3,6-dideoxyhexoses were found in PS of other Gram-negative bacteria. Thus, all the five representatives mentioned above were identified in PS of various strains of *Yersinia pseudotuberculosis*;^{50–57} ascarylose was found in PS of *Vibrio cholerae* O3,⁵⁸ abequose in PS of *Citrobacter freundii*,^{59,60} tyvelose in PS of *Eubacterium saburreum*,⁶¹ while colitose occurred in PS of one of *Escherichia coli* strains.⁶²

All the 3,6-dideoxyhexoses mentioned above can be isolated in the individual state after acid hydrolysis of the corresponding PS. Their glycosidic bond which, as with other deoxy sugars, is hydrolysed much more easily than typical glycosidic bonds makes possible their selective cleavage. At the same time, they have increased lability towards acids and their isolation presents some difficulties.

Originally, the structure of 3,6-dideoxyhexoses was established by classical methods. An example is abequose (Scheme 2). The positions of its deoxy units were determined by periodate oxidation of the alditol 14 obtained by the reduction of abequose 11 with LiAlH_4 . Oxidation of the alditol 14 gave formaldehyde, acetaldehyde and malonic aldehyde proving the position of deoxy units at C(6) and C(3) of the hexose skeleton.⁴⁶ The establishment of the absolute and relative configurations of abequose, as with other 3,6-dideoxyhexoses, was possible at that time only by comparison with authentic samples. For this purpose, the synthesis of some representatives of 3,6-dideoxyhexoses was carried out.

More recently, mass spectrometry of alditol acetates obtained by reduction of 3,6-dideoxyhexoses came into routine practice as a means for the establishment of the structure of their skeleton. These derivatives exhibit a peculiar fragmentation which indicates

‡ *Eubacterium saburreum* is not a Gram-negative bacterium.

the position of deoxy units. By way of illustration, the mass spectrum of the alditol acetate **15** obtained by reduction of the *O*-methyl ether of abequose isolated from the hydrolysate of methylated PS of *S. typhimurium* contains fragments with *m/z* 175, 131 and 117 indicating the presence of deoxy units at C(6) and C(3).⁶³

However, the positions of deoxy units in the monosaccharide can be more easily detected by ¹³C NMR spectroscopy. All the spectroscopic characteristics of 3,6-dideoxyhexoses are now well known and readily detectable directly in the NMR spectra of the corresponding PS: a signal in the region 16.0–18.0 ppm shows the presence of a methyl group at C(6), whereas a signal in the region 33–40 ppm the presence of a deoxy unit at C(3).⁶⁴

The configuration of 3,6-dideoxyhexoses, namely, the stereochemistry of C(2) and C(4) can well be defined by the ¹H NMR spectra, the coupling constant values between the C(3)H₂ group and protons at C(2) and C(4) being the most characteristic ones. According to the general regularities, these constants have higher values (11–12 Hz) for *a,a*-protons and lower values (3–5 Hz) for *a,e*- and *e,e*-protons. Thus, the corresponding values for paratose¹⁰ are $J_{3a,4} \approx J_{2,3a} \approx 11$ Hz and $J_{3e,4} \approx J_{2,3e} \approx 4$ Hz, respectively; those for abequose are $J_{2,3e} \approx 4.5$, $J_{2,3a} \approx 12$, $J_{3a,4} \approx 3$ Hz. Identification of 3,6-dideoxyhexoses is now carried out directly from the NMR spectra of the PS itself.

The above data are pertinent to the pyranose form of 3,6-dideoxyhexoses, in which these deoxy sugars are present in almost all bacterial PS. The only exception is PS of *Yersinia pseudotuberculosis* IB, where a 3,6-dideoxyhexose is present in the furanose form.⁵²

Several methods of 3,6-dideoxyhexose synthesis have been described; all are based on the introduction of deoxy units into hexoses having a regular structure by classical methods. This synthesis was originally undertaken to establish the structure of dideoxyhexoses isolated from natural PS.

Of considerable historical importance is the synthesis of the abequose derivative **11** from methyl 3-deoxygalactoside **16** (Scheme 3).⁶⁵ The latter was selectively tosylated at the primary hydroxy group; the tosylate **17** (R = OTs) was converted into the iodide **17** (R = I), reduction of which gave the methyl abequoside **18**. The same methyl abequoside can also be obtained by direct reduction of the tosylate **17** with LiAlH₄. In a similar way, the derivatives of tyvelose (**9**) and paratose (**10**) were synthesised from 3-deoxymannoside and 3-deoxyglucoside,⁶⁶ respectively. Later, paratose was synthesised by direct introduction of a halogen atom at C(6) of a 3-deoxyglycoside.⁶⁷

Currently, it has become necessary to develop preparative methods for the synthesis of considerable amounts of 3,6-dideoxyhexoses for the purpose of creating artificial antigens

Scheme 2

Scheme 3

and diagnostic tools. The synthesis of three most important 3,6-dideoxyhexoses⁶⁸ (tyvelose, paratose, abequose) from the most readily available material, the methyl glycoside **19**, is depicted below (Scheme 4).

Scheme 4

To synthesise abequose, methyl α -D-glucopyranoside **19** was converted into the 4,6-*O*-benzylidene derivative **20** and further into its dibenzoate **21**. After elimination of the benzylidene group, the diol **22** (R = H) was converted into the 4,6-di-*O*-tosylate **22** (R = Ts); its treatment with a base gave 6-*O*-tosylate of the 3,4-anhydro sugar **23**. Reduction of the anhydro sugar with LiAlH₄ was accompanied by regio- and stereo-specific opening of the epoxide ring and hydrogenolysis of the *O*-tosyl group resulting in the formation of the abequose derivative **18**.

During the synthesis of tyvelose, the benzylidene derivative **20** was subjected to selective tosylation to give the 2-*O*-tosylate **24**. The latter was converted into the 2,3-anhydro derivative **25** which

was converted into the 3-deoxy derivative **26** by the action of LiAlH_4 . After elimination of the benzylidene group and selective tosylation of the hydroxy group at C(6) of the triol **27** ($\text{R} = \text{H}$), the corresponding tosylate **27** ($\text{R} = \text{Ts}$) was reduced and the tyvelose derivative **28** was isolated.

Finally, the paratose derivative **30** was obtained by treatment of the glucopyranoside **19** with tribromoimidazole in the presence of triphenylphosphine (cf. published data⁶⁹) followed by reduction of the dibromide **29** by hydrogenolysis over Raney nickel or with Bu_3SnH in the presence of azo- N,N' -bis-isobutyronitrile.

A rather simple synthesis⁷⁰ of the ascarylose derivative **33** from L-rhamnose is also known (Scheme 5). Methyl 2,3-O-benzylidene- α -L-rhamnopyranoside **31** (readily produced by treatment of methyl rhamnoside with benzaldehyde dimethylacetal in the presence of toluenesulfonic acid) interacts with N -bromosuccinimide with a regiospecific opening of the benzylidene ring to give the 3-bromo derivative **32**, which is reduced with LiAlH_4 into the methyl glycoside of 3,6-dideoxy-L-arabino-hexose (ascarylose) **33**. Colitose⁷¹ was synthesised from the 3,4-O-benzylidene derivative of α -L-fucose by a similar scheme.

Scheme 5

4. Heptoses

Up to the present, only three heptoses, L-glycero-D-manno-heptose, D-glycero-D-manno-heptose and D-glycero-D-altro-heptose, have been identified as components of O-antigenic PS. The first of these is also a common component of the LPS core of Gram-negative bacteria (see review⁷²).

L-Glycero-D-manno-heptose **34** was isolated⁷³ after acid hydrolysis of PS of *Pseudomonas cepacia* IMV 673/2 using ion-exchange chromatography in borate buffer. Its structure was established in the following way. The PS was oxidised with a calculated amount of sodium periodate and then reduced with NaBH_4 . Products of the hydrolysis of the PS thus modified contained mannose resulting from the cleavage of the C(7)–C(6) bond of the heptopyranoside unit. This finding provided evidence for the manno-configuration of the C(2)–C(5) fragment of the monosaccharide and was confirmed by ^{13}C NMR spectroscopic data from the original PS. The retention time of the heptose fraction in a sugar analyser and its ^{13}C NMR spectrum were fully consistent with the corresponding parameters for the enantiomeric D-glycero-L-manno-heptose but differed from that for D-glycero-D-manno-heptose, thus confirming the relative configuration of the monosaccharide as a whole. Its absolute configuration was evident from the specific optical rotation ($[\alpha]_D = +4.8^\circ$) and confirmed by analysis of the glycosylation effects in the ^{13}C NMR spectrum of the polysaccharide.

D-Glycero-D-manno-heptose **35** was found in PS of *Vibrio cholerae* O21 where it is present in the main chain.⁷⁴ The monosaccharide **35** was isolated in the pure state from the acid hydrolysate of PS. In the ^1H NMR spectrum of the methyl

heptoside pentaacetate, the chemical shifts of the signals and the coupling constants for the protons at C(2)–C(5) practically coincided with those for methyl α -D-mannoside tetraacetate, thus corroborating the configuration of the heptose fragment C(2)–C(5). In GLC analysis the mobility of the heptitol acetate derived from the heptose differed from that of the heptitol obtained from L-glycero-D-manno-heptose, and the specific optical rotation ($[\alpha]_D = +74^\circ$) was indicative of the D-configuration.

More recently, D-glycero-D-manno-heptose was also isolated from PS of *Vibrio cholerae* O3.⁵⁸ Its presence was demonstrated by conventional monosaccharide analysis of PS, and its structure confirmed by ^1H NMR spectroscopy of the polysaccharide itself as well as by mass spectrometric analysis of the disaccharide fragment **36** (isolated by acid hydrolysis of the methylated PS followed by reduction with NaBD_4) which contained a heptose residue and an aminodeoxyalditol residue bound to it. The presence in the mass spectrum of a fragment with m/z 263 and the corresponding secondary ions with m/z 231 and 199 as well as of fragments with m/z 45 and 89 indicated the O-methyl ether of a heptose. The final confirmation of the D-glycero-D-manno-heptose structure was provided by counterflow synthesis.

Several procedures for the synthesis of glycero-manno-heptose are known which employ conventional methods of synthesis of higher sugars. The most practicable is shown in Scheme 6.⁷⁵ Thus, benzyl 2,3,4-tri-O-benzyl- α -D-mannopyranoside **37** was subjected to Swern oxidation resulting in the aldehyde **38** whose interaction with HCN gave a mixture of isomers. The cyanohydrin **39** having the D-glycero-D-manno-configuration was isolated by chromatography and reduced to the amino sugar **40** ($\text{R} = \text{NH}_2$) which was further converted into the D-glycero-D-manno-heptose derivative **40** ($\text{R} = \text{OH}$) by treatment with nitrous acid. To obtain the L-glycero-isomer, the aldehyde **38** was condensed with allyloxy-methylmagnesium bromide and the main isomeric alcohol **41** ($\text{R} = \text{allyl}$) having the L-glycero-configuration was chromatographically isolated from the resulting mixture; its deallylation gave a derivative of L-glycero-D-manno-heptose **41** ($\text{R} = \text{H}$).

Scheme 6

D-Glycero-D-*altro*-heptose **42** was found in PS of *Campylobacter jejuni* O23, together with 6-deoxy-D-*altro*-heptose and their 3-O-methyl ethers, the relative amount of these components of antigenic PS being dependent on both the bacterial strain and, seemingly, on cultivation conditions.⁷⁶ The heptose **42** present in the main chain of PS was isolated after acid hydrolysis of PS in a mixture with its 1,6- and 1,7-anhydro derivatives. The presence in the monosaccharide of the heptose skeleton was confirmed by the mass spectrum of the alditol obtained by reduction. To establish the configuration of the heptose, the polysaccharide was subjected successively to oxidation with a calculated amount of periodate, the glycol system of the C(6)–C(7) fragment is oxidised first, reduction with NaBH₄ and methanolysis. As a result, methyl D-altroside was isolated and identified corroborating the configuration of the heptose fragment C(2)–C(5). The configuration of C(6) was established by direct comparison of the corresponding alditol acetate with an authentic sample obtained from synthetic D-glycero-D-*altro*-heptose. A similar procedure was used to determine the structure of the 3-O-methyl ether of the heptose **42** present in the same PS.⁷⁶

The synthesis of D-glycero-D-*altro*-heptose was carried out⁷⁷ by stereospecific elongation of the carbon chain at C(6) of the glucose derivative **43** by the method of Donadoni⁷⁸ with subsequent inversion of configuration at C(2) and C(3) (Scheme 7). The aldehyde **43** obtained by Swern oxidation of methyl 2,3,4-tri-O-benzyl- α -D-glucopyranoside was converted into the thiazole derivative **44** by reaction with 2-trimethylsilylthiazole. Treatment of the derivative **44** with formic acid and subsequent debenzyla-tion resulted in a mixture of heptoses epimeric at C(6), from which the isomer having the D-glycero-configuration **45** (R = H) was isolated. This was converted into the 7-O-*tert*-butyldiphenylsilyl ether **45** (R = TBDPS) and then into the 4,6-O-benzylidene

Scheme 7

derivative **46** (R = H) which was further converted into the corresponding 2-O-tosylate **46** (R = Ts). The tosylate **46** was routinely converted into the 2,3-epoxy derivative **47** which after treatment with NaOH and *trans*-diaxial opening of the oxide ring gave the monosaccharide derivative **48** having the *altro*-configuration. Elimination of the protective groups resulted in D-glycero-D-*altro*-heptose **42** whose configuration was confirmed by NMR spectroscopic data. The synthetic monosaccharide and that isolated from natural PS were identical.⁷⁶

5. Deoxyheptoses

Only two representatives of this class have thus far been detected among monosaccharide components of O-antigenic PS. Both of them are 6-deoxyheptoses.

6-Deoxy-D-*manno*-heptose **49** was detected in PS of *Yersinia pseudotuberculosis* where it is attached as a side chain to the main chain.⁵⁴ The presence of a 6-deoxyheptose in PS was first proved by analysis of the ¹³C NMR spectrum which contains signals characteristic for deoxyaldoses at 34.1 ppm (a methylene group of deoxyaldoses) and 59.0 ppm (a CH₂OH group of deoxyaldoses). The presence in PS of the 6-deoxyheptose **49** was also confirmed by mass spectrometric data of the O-methyl ether of the deoxyheptose glycoside obtained in the pure state after methanolysis of methylated PS.⁵⁴ This heptose was also found in *Pseudomonas pseudomallei* where it forms a homopolysaccharide.³⁵ Its structure and stereochemistry were confirmed by ¹H NMR spectroscopic data: in particular, the coupling constant values were consistent with the *manno*-configuration ($J_{2,3} = 3.5$, $J_{3,4} = 9.1$, $J_{4,5} = 9.5$ Hz). The absolute configuration of **49** was established from the specific optical rotation. The structure of the monosaccharide **49** was also corroborated by counterflow synthesis.

6-Deoxy-D-*altro*-heptose **50** was found in PS of *Campylobacter jejuni* O23A and O23B.⁷⁶ It was isolated in a mixture with its anhydro derivative after acid hydrolysis of PS. The structure of the monosaccharide **50** was confirmed by direct comparison with a synthetic sample of the corresponding alditol hexaacetate, and its D-configuration was established by GLC analysis of glycosides with (*R*)- and (*S*)-butan-2-ols.

The synthesis of 6-deoxy-D-*altro*-heptose⁷⁹ was performed as depicted in Scheme 8.

Scheme 8

Methyl 2,3,4-tri-*O*-benzyl- α -D-altropyranoside **51** ($R = H$) was converted via 6-*O*-triflate **51** ($R = CF_3SO_2$) into the nitrile **52** ($R = CN$) which, in turn, was converted into a derivative of 6-deoxy-D-altro-heptose **52** ($R = CH_2OH$) by successive reduction with DIBAH, hydrolysis of the resulting imine and reduction of the corresponding aldehyde with $NaBH_4$. The corresponding derivative of 6-deoxy-D-manno-heptose was similarly obtained from the mannose derivative.⁷⁹

6. Branched monosaccharides

Monosaccharides having a branched carbon chain are a rare class of sugars. These monosaccharides are sometimes found in antibiotics, although some of their representatives were recently detected in O-antigenic PS where they can be localised both in the main chain of the biopolymer and in side chains.

Two representatives of this monosaccharide class were isolated in the pure state after acid hydrolysis of PS of the Gram-negative bacterium *Coxiella brunetti* phase I.⁸⁰ One of those appeared to be identical by its chromatographic characteristics to 6-deoxy-3-*C*-methylgulose (virenose) earlier detected in the antibiotic virenomicin.⁸¹ The structure of the monosaccharide isolated from the O-antigenic PS was also confirmed by the mass spectrum of the fully acetylated alditol **53**. Fragmentation of this compound corresponded to the structure of the parent monosaccharide; in particular, the presence of fragments with m/z 231 and 245 and the corresponding secondary fragments indicated the type and the site of the chain branching. Direct comparison of the natural monosaccharide with the samples of the corresponding monosaccharides of the *manno*-, *talo*- and *gulo*-series isolated from other natural products demonstrated its *gulo*-configuration. However, the specific optical rotation of this monosaccharide differed from that of virenose, for which the D-configuration had been established.⁸¹ Based on these data, the monosaccharide from PS of *Coxiella brunetti* was ascribed the structure of 6-deoxy-3-*C*-methyl-L-gulose **54**.

The second monosaccharide isolated from O-antigenic PS of *Coxiella brunetti* was assigned the structure of 3-*C*-hydroxymethyl-L-lyxose **55**. Successive methylation of PS, acid hydrolysis of methylated PS, reduction of the resulting mixture of methylated monosaccharides with $NaBD_4$ and their acetylation resulted in a mixture of alditol acetates, from which the acetate of the partially methylated alditol **56** corresponding to the branched monosaccharide was isolated. Its fragmentation in mass spectrometric analysis fully confirmed the structure of the skeleton and the positions of the hydroxy groups in the monosaccharide as can be evidenced, in particular, from the presence of fragments with m/z 205, 206 and 118. Determination of configuration of the monosaccharide **55** and its assignment to the L-lyxose series was made by the authors on the basis of synthetic data.

Two other structurally complex monosaccharides belonging to branched octoses were found in O-antigenic PS of several serotypes of *Yersinia*. They were isolated in the individual state after acid hydrolysis of PS and found to be similar in structure with the only difference the configuration of one of the chiral centres. One of those, yersiniose A, was isolated from *Y. pseudotuberculosis* serovar VI,⁸² while the second one, yersiniose B from *Y. enterocolitica* serovar O4,32.⁸³ Reduction of yersinioses A and B with $NaBH_4$ and subsequent acylation resulted in tetraacetates of the corresponding alditols **57**. In this case, one of the hydroxy groups failed to be acetylated under standard conditions that showed its localisation at the tertiary carbon atom. The mass spectra of both alditol tetraacetates appeared to be identical; their fragmentation demonstrated that both yersinioses are 3,6-dideoxy-4-*C*-(1'-hydroxyethyl)hexoses with the identical structure of the carbon skeleton and positions of the hydroxy groups. The same result was obtained by mass spectrometry of methyl glycosides of both monosaccharides.

The NMR spectra of yersinioses A and B also appeared to be almost identical. Thus, the ^{13}C NMR spectrum of yersiniose A contained signals at 13.4 and 16.4 (two CH_3 groups), 35.9 (CH_2 group) and 75.8 ppm (tertiary carbon atom). The signal of C(1) with a low-field chemical shift indicated the D-configuration of the monosaccharide. The 1H NMR spectrum of yersiniose A contained signals at 4.71 [$J_{1,2} = 8.25$ Hz, H(1)], 3.80 [$J_{2,3e} = 5.22$ and $J_{2,3a} = 11.82$ Hz, H(2)], 1.85 [$J_{3a,3e} = 13.86$ Hz, H(3)], 4.18 [$J_{5,6} = 6.63$ Hz, H(5)] and 1.30 ppm [H(6)].

Higher values of the coupling constants ($J_{1,2}$ and $J_{2,3a}$) for yersiniose B present in the β -form show the axial orientation of H(2), whereas NOE data revealed interaction between H(1) and H(5) [i.e., the axial position of H(5)] and the proximity of H(3a) and the CH_3 group of the side chain, thus indicating the equatorial position of the side chain at C(4). These data suggest that yersiniose B has the *xylo*-configuration. Comparison of the ^{13}C NMR spectra for yersinioses A and B revealed that both of them are 3,6-dideoxy-4-*C*-(1'-hydroxyethyl)-D-*xylo*-hexopyranoses **58**. The only distinction between them is in the stereochemistry of the asymmetric centre C(7) in the side chain. This problem was solved by counterflow synthesis of the yersinioses.

To this end, a general procedure for the synthesis of 3,6-dideoxy-4-*C*-(1'-hydroxyethyl)hexoses was elaborated which, in principle, permits the synthesis of any kind of branched octoses of this type. Leaving aside the consideration of relationships between different configurations of the chiral centres in isomeric octoses of this series (see Ref. 84), it is worth noting that the solution of the particular problem of determination of the absolute configuration of the chiral centre C(7) of the isomeric yersinioses, required a stereospecific synthesis of compounds having the D-*xylo*-configuration and distinguished by only the geometry of the chiral centre present in the side chain.

Scheme 9

This rather complex synthesis^{84,85} is depicted in Scheme 9. As the initial compound, 1,6-anhydro- β -D-glucopyranose (levoglucosan **59**) was used, which via a standard set of reactions was converted into 4-*O*-allyl-3-*O*-mesyl-2-*O*-tosyllevoglucosan **60** and then into 1,6:2,3-dianhydro-4-*O*-allyl- β -D-allopyranose **61**. Reduction of the epoxide **61** and subsequent *O*-benzylation gave 1,6-anhydro-4-*O*-allyl-2-*O*-benzyl-3-deoxy- β -D-ribo-hexose **62**. Elimination of the allyl protective group and Swern oxidation of the liberated hydroxy group gave the key intermediate of the synthesis, a derivative of the keto sugar **63**. Its reaction with 2-lithium-2-methyl-1,3-dithiane resulted in a mixture of two alcohols **64a** and **64b** epimeric at C(4) which were separated chromatographically. The structure of the isomers differing in only the configuration at C(4) was established by NMR spectroscopy (including NOE measurements). It appeared that the alcohol **64** has the D-xylo-configuration of the pyranose ring; namely, this compound was selected for further synthesis.

Treatment of the alcohol **64a** with a mixture of HgCl_2 and CdCO_3 gave the ketone **65** which after reduction with NaBH_4 and subsequent benzylation produced two epimeric (with regard to the chiral centre of the side chain) alcohols **66** and **67** in a 2:1 ratio. The absolute configuration of the new chiral centre C(7) in the alcohols **66** and **67** was established by spectroscopic analysis and NOE measurements of isopropylidene derivatives obtained by debenzilation of the initial alcohols **66** and **67**. The side chain of the monosaccharide derivative **67** appeared to have the D-glycero-configuration, and that of **66** the L-glycero-configuration.

To convert the alcohols **66** and **67** into the corresponding yersinioses, the former were exposed to very mild acetolysis and subsequent methanolysis which opened the 1,6-anhydro ring without any accompanying elimination of the *O*-benzyl groups (which might result in a complex mixture of pyranose and furanose forms of yersinioses). The resulting glycosides **68** and **69** ($\text{R} = \text{OH}$) with a free hydroxy group at C(6) were thus obtained. This group was substituted with bromine by treatment with $\text{Ph}_3\text{P}-\text{CBr}_4$ in pyridine. After separation and catalytic hydrogenolysis with simultaneous removal of the benzyl groups, the resulting bromides **68** and **69** ($\text{R} = \text{Br}$) were converted into glycosides of the synthetic yersinioses **70** and **71**. Their comparison with the corresponding derivatives of natural yersinioses isolated from PS using various versions of NMR spectroscopy (of which NOE analysis was the most important one) allowed establishment of the configuration of the chiral centre of C(7) in both monosaccharides. It was found that yersiniose A is 3,6-dideoxy-4-*C*-(L-glycero-1'-hydroxyethyl)-D-xylo-hexopyranose, while yersiniose B 3,6-dideoxy-4-*C*-(D-glycero-1'-hydroxyethyl)-D-xylo-hexopyranose.

A structurally unique higher monosaccharide with a branched chain has recently been detected in PS of *Pseudomonas caryophylli*.^{86,87} This monosaccharide was isolated in the pure state after acid hydrolysis of PS and called caryophillose. Its ^{13}C NMR spectrum suggested the presence of six CHOH groups (signals around 68–78 ppm), two CH_3 groups (signals in the region 16–17 ppm), two methylene groups (signals in the region 29–32 ppm) and one tertiary carbon atom carrying a hydroxy group (signal at 74 ppm). Reduction of caryophillose with NaBD_4 resulted in a branched alditol which upon acetylation gave the heptaacetate **72**. The fact that one of the hydroxy groups was not acetylated demonstrated its attachment to the tertiary carbon

atom. The type of fragmentation in the mass spectrum of the acetate **72** as well as ^{13}C NMR spectroscopic data indicated that caryophillose comprises 12 carbon atoms, two methyl groups and two methylene units, has a branched chain and is a 3,6-dideoxy-4-*C*-(1',3',4',5'-tetrahydroxyhexyl)hexose.

Determination of the stereochemistry of caryophillose was a challenge. This problem was solved using NMR spectroscopy (including NOE measurements).

Briefly, the essence of this complex study is as follows. Acid methanolysis of the monosaccharide gave two isomeric methyl glycosides of caryophillose **73** and **74**, and one internal glycoside **75**.

The glycoside **73** formed by closing of the pyranose ring via the hydroxy group at C(5) was isolated as a mixture of α - and β -anomers and had the 4C_1 conformation of the pyranose cycle (as could be evidenced from NMR spectroscopic data). Its 1H NMR spectrum suggested the lack of protons at C(4), thus confirming the site of branching of the carbon chain determined from the mass spectrum of the alditol **72**. An NOE study revealed interaction between H(5) and H(3a) in the glycoside **73** which proved the axial position of H(5). The equatorial position of the aliphatic chain C(1')-C(6') was evident from the spatial proximity of H(5) and H(1') of the side chain. Based on these data, the pyranose ring and, correspondingly, the C(1')-C(6') fragment of caryophillose were assigned the *xylo*-configuration. To establish the spatial structure of this aliphatic fragment of caryophillose was a more complicated task which was solved by complex analysis of the NMR spectra of the glycosides **74** and **75** and of some other derivatives.

The glycoside **74** isomeric with the glycoside **73** was formed by closing of the pyranose ring via the hydroxy group at C(1') of caryophillose (this was accompanied by stereospecific formation of the β -glycoside alone). The data of the 1H NMR spectrum suggest the glycoside **74** to be in the 1C_4 conformation. NOE measurements with the glycoside **74** and its *O*-acetate reveal that H(1') is closed to the axial methoxy group and, consequently, occupies the axial position as well. Hence, C(1') in the C(1')-C(6') chain has the (*S*)-configuration.

The glycoside **75**, isolated by acid methanolysis of caryophillose, is formed as a result of intramolecular glycosylation involving the hydroxy group at C(3'). Glycosylation gives a bicyclic system containing a furanose ring. The structure of the glycoside **75** was reliably established: the compound has the composition $C_{12}H_{22}O_7$ (as can be evidenced from the FAB mass spectrum); its ^{13}C NMR spectrum is completely consistent with the structure **75**. In the ^{13}C NMR spectrum of the acetate of **75**, the signal of the proton at C(3') (3.88 ppm) lacked the characteristic shift which might result from the presence of a heminal acetoxy group; consequently, C(3') is linked by an acetal (i.e., glycosidic) bond corroborating the accepted structure of the glycoside **75**. The conformation of the glycoside **75** was established by NOE measurements for the protons at C(2) and C(3) as well as at C(1'), C(2') and C(3') in the glycoside **75** itself and its *O*-acetate,

which suggest, in particular, that C(3') has the (*S*)-configuration. To establish the relative configuration at C(4') and C(5') of caryophillose, the 4,1':3',5'-di-*O*-isopropylidene derivative **76** was prepared from the glycoside **73**. NOE measurements for H(3') and H(5') in the 3',5'-*O*-isopropylidene group, forming 1,3-dioxane ring with the chair conformation, show their *cis*-diaxial orientation and *trans*-diaxial position relative to H(4'). Therefore, it was concluded that C(4') and C(5') have the (*R*)-configuration.

The absolute configuration of the C(1)-C(6) and C(1')-C(6') fragments of caryophillose was established mainly on the basis of circular dichroism measurements for each of these fragments.⁸⁸ Methylation analysis revealed that in the PS chain the neighbouring residues of caryophillose are linked by the glycosidic bonds at the hydroxy group localised at C(3'). Therefore, periodate oxidation of the original PS results in the cleavage of the bonds between C(4') and C(5') as well as between C(1') and C(4). As a result, reduction of the oxidation product gives rise to compound **77**, which is a glycoside of 3,6-dideoxy- α -ribo-hexose (paratose), and 1,4-dihydroxybutan-3-ol. The structure of this compound was confirmed by NMR spectroscopy. Methanolysis of the glycoside **77** gives α - and β -glycosides of paratose **78** (R = H) and 1,3,4-trihydroxybutane **79** (R = H). Analysis of the circular dichroism spectra by the method of Nakanishi⁸⁸ was carried out for the *p*-bromobenzoates **78** and **79** (R = *p*-BrC₆H₄CO). A change in the Cotton effect as a function of wavelength indicates that C(2) in the glycoside **78** has the (*R*)-configuration, and C(3') in **79** the (*S*)-configuration.

These data suggested that the caryophillose present in PS is 3,6-dideoxy-4-*C*-(*D*-*altro*-tetrahydroxyhexyl)-*D*-*xylo*-hexopyranose **73**, which is a cyclic form of the higher branched sugar, 3,6,10-trideoxy-4-*C*-[(*R*)-1'-hydroxyethyl]-*D*-*erythro*-*D*-*gulo*-decaose **80**.

7. Amino sugars

Monosaccharides containing amino groups (amino sugars) of various structure are widespread in bacterial PS. Many of them contain several deoxy units and amino groups in various combinations which contributes largely to the great diversity of known natural amino sugars.

a. Aminodeoxyhexoses

Derivatives of 2-amino-2-deoxyhexoses having the D-gluc-, D-galacto- or D-manno-configuration (glucosamine, galactosamine and mannosamine) are among the most common components of PS of microorganisms. Most often, they are present in the polysaccharide chain as N-acetyl derivatives, although N-acyl derivatives comprising residues of other organic acids are also known (see Section 4).

At the same time, O-antigenic PS have been found to contain only one representative of 2-amino-2-deoxyhexoses with the L-configuration, namely, 2-acetyl-amino-2-deoxy-L-glucose **81** detected in PS of *Pseudomonas cepacia* O1.⁸⁹

The monosaccharide **81** gave qualitative reactions for amino sugars; the mass spectrum of the aminodeoxyalditol acetate derived was identical to that of the well-known derivative obtained from the D-isomer. The fragmentation observed demonstrated the presence of an acetyl-amino group at C(2). This finding was also confirmed by ¹³C NMR spectroscopic data: the spectrum of PS contained a signal of C(2) at 54.23 ppm. Finally, the structure of this amino sugar was also corroborated by analysis of a disaccharide fragment obtained after Smith degradation of PS. The unusual L-configuration of the monosaccharide was established on the basis of GLC of its glycosides with optically active butan-2-ol and octan-2-ol, by its specific optical rotation⁸⁰ and by comparison of the circular dichroism spectrum of the derived aminodeoxyalditol with that of the corresponding D-isomer.

b. Aminodideoxyhexoses

Derivatives of 2-amino-2,6-dideoxyhexoses are widespread in O-antigenic PS. Two of these, 2-amino-2,6-dideoxy-D-glucose (D-quinovosamine) **82** and 2-amino-2,6-dideoxy-L-galactose (L-fucosamine) **83** are common components of O-antigenic PS.² Their enantiomers, L-quinovosamine **84** and D-fucosamine **85** occur less frequently. L-Quinovosamine was found in PS of *Shigella boydii*, *Proteus vulgaris*, *Pseudomonas fluorescens*, etc.,² while D-fucosamine in *Pseudomonas fluorescens* and some species of *Pseudomonas aeruginosa*.² These 2-amino-2,6-dideoxyhexoses are present in the polysaccharide chains as various N-acyl (most frequently N-acetyl) derivatives. They can be isolated in the pure state from acid hydrolysates of PS or after solvolysis of PS with liquid HF. Currently, these monosaccharides are identified directly by the NMR spectra of PS themselves.

An example of more rare amino sugars of this type present in microbial PS is 2-acetyl-amino-2,6-dideoxy-L-mannose **86** (L-rhamnosamine) detected in *Escherichia coli* O3.⁹⁰ The monosaccharide was isolated in the pure state after acid hydrolysis. Its structure was established by classical methods: periodate oxidation yielded acetaldehyde, thus suggesting the presence of a methyl group (the 6-deoxy fragment); based on different ion-chromatographic behaviour of the monosaccharide and the derivatives of other 2-amino-2,6-dideoxy sugars, the monosaccharide was assigned the structure of an L-rhamnose derivative.

It is interesting to note that another very rare monosaccharide of this class, 2-acetyl-amino-2,6-dideoxy-L-talose **87** (pneumosamine), was identified long ago in a capsular polysaccharide of *Streptococcus pneumoniae* type 5; however, its structure was not strictly confirmed.⁹¹

Among other monoaminodideoxyhexoses, O-antigenic PS contain derivatives of 3-amino-3,6-dideoxyhexoses present in the PS chain as N-acyl derivatives (most frequently, as acetyl but sometimes also as derivatives of hydroxy and amino acids; see Section 4). Among monosaccharides of this type, derivatives of 3-amino-3,6-dideoxy-D-galactose **88** (3-amino-3-deoxy-D-fucose) are rather common components of many PS.² An analogue of 3-amino-3,6-dideoxy-D-galactose, 3-amino-3,6-dideoxy-D-glucose **89** (3-amino-3-deoxyquinovose), was found in O-antigenic PS of several species of Gram-negative bacteria: in *Escherichia coli*,⁹² *Hafnia alvei*,⁹³ *Proteus penneri*,⁹⁴ *Pseudomonas fluorescens*,⁹³ *Vibrio mimicus*.⁹⁵ The L-isomer, 3-amino-3,6-dideoxy-L-glucose, was isolated from O-antigenic PS of *Vibrio anguillarum*.⁹⁶ This is the only example of 3-amino-3,6-dideoxyhexoses with the L-configuration detected in O-antigenic PS. This sugar was earlier detected in the LPS core⁹⁷ of *Aeromonas hydrophila* III.

Derivatives of these aminodideoxyhexoses including those of glucose with the L-configuration were isolated from PS in the individual state after acid hydrolysis or solvolysis with liquid HF and, to simplify analysis, converted into N-acetates. To this end, they were deacylated (the N-acyl substituent was eliminated) and then N-acetylated by a routine procedure. The structure of the 3-acetyl-amino-3,6-dideoxyhexoses thus obtained was established by physicochemical methods and confirmed by counterflow synthesis.

An example is the establishment of the structure of 3-acetyl-amino-3,6-dideoxy-D-glucose.^{95,98} The mass spectrum of the full acetate of the aminodeoxyalditol **90** derived from the amino sugar by reduction and subsequent acetylation contained fragments with m/z 230 and 216 which unambiguously indicated the position of the acetyl-amino group at C(3) and of the deoxy unit (CH_3 group) at C(6). This finding demonstrated that the parent sugar has the 3-acetyl-amino-3,6-dideoxyhexose structure.

This conclusion was also confirmed by the ^{13}C NMR spectrum containing signals at 18 ppm (CH_3 group) and 55–58 ppm [NHAc -substituent at C(3)]. The ^1H NMR spectrum of the full acetate of the amino sugar glycoside was characterised by the coupling constant values of $J_{2,3}$, $J_{3,4}$ and $J_{4,5}$ exceeding 10 Hz, thus suggesting the *gluco*-configuration of the monosaccharide. Finally, the specific optical rotation ($[\alpha]_D = +26^\circ$) showed that it belongs to the D-series.

The structure of 3-acetyl-amino-3,6-dideoxy-D-galactose⁹⁹ was also confirmed by analysis of the mass spectrum of the corresponding aminodeoxyalditol acetate which exhibited characteristic fragmentation. The ^{13}C NMR spectrum of this compound contained signals at 17 and 52 ppm, and the ^1H NMR spectrum demonstrated the *galacto*-configuration (the coupling constant values were: $J_{2,3} = 10$, $J_{3,4} = 4$, $J_{4,5} = 1$ Hz). The D-configuration was established by comparison with a synthetic authentic sample and confirmed by the specific optical rotation. It is interesting to note that initially this monosaccharide was erroneously assigned the D-*gluco*-configuration,¹⁰⁰ and this error was corrected later.⁹⁸

The structure of 3-acetyl-amino-3,6-dideoxy-L-glucose, the only monosaccharide in this group having the L-configuration,^{96,97} was established by the same methods, and its absolute configuration determined by circular dichroism.

Several methods for the synthesis of 3-amino-3,6-dideoxy-aldoses are known. These compounds were obtained by the classical Fischer–Bayer method (condensation of dialdehydes prepared by oxidation of 6-deoxyhexose glycosides with nitromethane followed by reduction of the nitro group). As an example, we refer to the synthesis of a derivative of 3-acetyl-amino-3,6-dideoxy-L-glucose (Scheme 10).¹⁰¹

Scheme 10

Methyl- α -L-rhamnopyranoside **91** was oxidised by periodate, and the dialdehyde **92** derived was condensed with nitromethane in the presence of sodium methoxide. The resulting isomeric 3-nitrohexoses **93** were reduced over Raney nickel; the corresponding amino sugars were *N*-acetylated, and then methyl 3-acetyl-amino-3,6-dideoxy- α -L-glucopyranoside **95** was isolated from the resulting mixture of the amino acetates **94** by chromatography in a 26% yield. Other aminodeoxyhexoses can be synthesised by conventional methods based on inversion of the configuration at certain carbon atoms (e.g., see Ref. 102).

The third group of amino sugars present in O-antigenic PS are derivatives of 4-amino-4,6-dideoxyhexoses, although they seem to be less common than their 3-amino analogues. By now, three hexoses of this type having the D-*gluco*-, D-*manno*- or D-*galacto*-configuration have been identified. The amino groups in these monosaccharides are acylated (usually, acetylated).

4-Amino-4,6-dideoxy-D-glucose **96** (4-amino-4-deoxy-D-quinovose, viosamine) was first identified as the *N*-acetyl derivative in PS of *Escherichia coli* O7 where it is present in the main chain.¹⁰³ As an *N*-acyl derivative carrying the *N*-acetylglycine residue, it was also found in PS of *Shigella dysenteriae* 7,^{104,105} and as the *N*-formyl derivative in PS of *Francisella tularensis* 15 (tularemia pathogen).¹⁰⁶ Recently this sugar was also detected in PS of *Vibrio anguillarum*¹⁰⁷ and in O-antigenic PS of *Hafnia alvei* 1205 having an unusual polysaccharide chain similar to that of teichoic acids.¹⁰⁸

The monosaccharide **96** was isolated as a structurally complex *N*-acylated derivative after treatment of PS with liquid HF and, to simplify analysis, further converted into the *N*-acetyl derivative. Its structure was studied by physicochemical methods. The mass spectrum of the fully acetylated aminodeoxyalditol **97** derived contained fragments with m/z 288 and 158 as well as the corresponding series of secondary ions indicating the presence of a deoxy unit at C(6) and of an acetyl-amino group at C(4). Such a structure was confirmed by ^{13}C NMR spectroscopic data [signals at 18.0 ppm for a CH_3 group and at 58.2 ppm for C(4)]. The *gluco*-configuration of the monosaccharide was established by ^1H NMR spectroscopic data, and the absolute configuration was confirmed by the specific optical rotation ($[\alpha]_D = +17^\circ$) which almost coincided with the corresponding value for the synthetic sample (see below).

At present, identification of this aminodeoxy sugar (as well as of its isomers) is performed almost exclusively on the basis of NMR spectral data of the initial PS themselves.

4-Amino-4,6-dideoxy-D-mannose **98** (4-amino-4-deoxy-D-rhamnose, perosamine) was first detected as an *N*-acyl derivative with 2-deoxy-L-*glycero*-tetronic acid in O-antigenic PS of *Vibrio cholera* Inaba (Asian cholera pathogen) where it forms a homopolysaccharide.¹⁰⁹ Later, it was found as the *N*-formyl derivative in a homopolysaccharide in O-antigenic PS of *Brucella melitensis* (brucellosis pathogen).¹¹⁰ As some other *N*-acyl derivatives, it is present in PS of several species of *Salmonella*,^{111,112} *Escherichia coli*,^{113,114} *Yersinia*¹¹⁵ and *Xanthomonas*.¹¹⁶ Since 4-amino-4,6-dideoxyhexoses are very unstable in acid media, they were isolated as *N*-acyl derivatives exclusively by solvolysis of PS with liquid HF.

The monosaccharide **98** was identified by the mass spectrum of the corresponding aminoalditol acetate which appeared to be identical with that of the alditol derived from the *gluco*-analogue. That this monosaccharide belongs to the *manno*-series was first demonstrated by deamination with nitrous acid of deacetylated PS: hydrolysis of deaminated PS revealed the presence of D-rhamnose and 6-deoxy-D-allose which could be formed only when the original monosaccharide contained the NH_2 group at C(4) and had the *manno*-configuration.¹⁰⁹ Later, it was confirmed by ^1H NMR spectroscopic analysis of the PS itself that this monosaccharide belongs to the *manno*-series (the coupling constant values were: $J_{2,3} = 4.5$, $J_{3,4} = 10$, $J_{4,5} = 10$ Hz). The absolute configuration of the monosaccharide was established by its conversion into a glucoside with (–)-butan-2-ol.

4-Amino-4,6-dideoxy-D-galactose **99** (4-amino-4-deoxy-D-fucose, tomosamine) occurs less frequently and has thus far been found only in O-antigenic PS of *Escherichia coli* O10¹¹⁷ and *Pseudomonas fluorescens*.¹¹⁸ In the former PS the amino sugar is *N*-acylated by the residue of 3-hydroxybutyric acid and localised in the side chain attached to the main chain of the PS; in the latter case the PS is *N*-acetylated. The amino sugar was isolated after solvolysis of PS with liquid HF ; its structure was established by ^1H NMR spectroscopic data: the position of the *N*-acyl group was proved by a low-field shift of H(4), and the *galacto*-configuration was concluded from the coupling constant values: $J_{2,3} > 10$, $J_{3,4} \sim 4.5$, $J_{4,5} \sim 1.8$ Hz.¹¹⁸

Synthesis of several 4-amino-4,6-dideoxyhexoses was carried out by using a general approach well-known in sugar chemistry: introduction of an amino function into a neutral monosaccharide via the corresponding azide. By illustration, let us consider the synthesis of tomosamine and viosamine¹¹⁹ derivatives from glucose (Scheme 11).

Scheme 11

Methyl-2,3-di-*O*-benzyl- α -D-glucopyranoside **100** was converted into the dimesylate **101**, which after interaction with KI, hydration of the corresponding monoiodide and repeated mesylation gave the 4-*O*-mesylate of 6-deoxyglucose **102**. The reaction of the compound **102** with sodium azide accompanied by inversion of the configuration gave the azide **103** hydration of which was accompanied by removal of the benzyl groups to yield the glycoside of tomosamine **99a**. To obtain the *gluco*-analogue, double inversion at C(4) was used: the mesylate **102** was converted into a galactose derivative by reaction with sodium benzoate. The derivative of 4-amino-4,6-dideoxyglucose **96**

($\text{R} = \text{H}$) (viosamine) was obtained via the corresponding azide after debenzoylation and mesylation of the galactose derivative.

c. Diaminotrideoxyhexoses

PS of some Gram-negative bacteria were found to contain amino sugars of unusual structure, which belong to 6-deoxyhexoses containing two amino groups at C(2) and C(3) or at C(2) and C(4) and only one hydroxy group. Diaminotrideoxyhexoses are distinguished by high lability to acids and usually cannot be isolated in the pure state. Their structure was mostly established by NMR spectroscopic and mass spectrometric data for oligosaccharide fragments isolated by partial cleavage of the corresponding PS.

The only representative of 2,3-diamino-2,3,6-trideoxyhexoses in O-antigenic PS is a derivative of 2,3-diamino-2,3,6-trideoxy-D-mannose **104** (2,3-diamino-2,3-dideoxy-D-rhamnose) containing *N*-formyl and *N*-acetyl substituents at the amino groups at C(3) and C(2), respectively.

This monosaccharide is a component of PS of *Escherichia coli* O119, where it occupies the position of a lateral substituent of the polysaccharide chain and is an immunochemical determinant.¹²⁰ Its structure was established on the basis of the following data. The PS was oxidised two times with periodate, and the subsequent Smith degradation resulted in the oligosaccharide **105** containing a diaminotrideoxyhexose residue. This finding was confirmed by mass spectrometric data: the FAB mass spectrum of the PS contained a fragment with m/z 215 suggesting the presence of a diaminotrideoxyhexose residue carrying *N*-formyl and *N*-acetyl substituents as well as the corresponding secondary fragments, thus indicating the localisation of the formyl residue at the amino group at C(3). The complex NMR spectra of the tetrasaccharide **105** contained signals of the diaminotrideoxyhexose residue. In the ^{13}C NMR spectra the signals of C(2) and C(3) (52.11 and 53.03 ppm) demonstrated the presence of the acylamino groups at these atoms. The signals at 165 and 168 ppm indicated the presence of a formylamino group, and the signal at 176.36 ppm indicated the presence of an acetylamino group. The signal at 17.86 ppm corroborated the presence of the CH_3 group at C(6). Application of the INEPT technique to NMR spectroscopic analysis revealed localisation of the *N*-acetyl group at C(2) and the *N*-formyl group at C(3).

In the ^1H NMR spectra the coupling constant values ($J_{2,3} = 4.0$, $J_{3,4} = 10.3$, $J_{4,5} = 9.5$ and $J_{5,6} = 6.1$ Hz) suggested the *manno*-configuration for the monosaccharide.

The absolute configuration of the monosaccharide **104** was evident from the NOE data: irradiation of H(1) of this sugar caused a strong effect on the adjacent H(2) in the chain of the oligosaccharide **105** mannose residue. This finding suggested that both monosaccharides have the same absolute configuration. Since mannose had the D-configuration, the novel monosaccharide was also assigned the D-configuration. Therefore, the novel sugar was identified as a derivative of 2,3-diamino-2,3,6-trideoxy-D-mannose.

2,4-Diamino-2,4,6-trideoxyhexoses are more common in PS. Thus, derivatives of 2,4-diamino-2,4,6-trideoxy-D-glucose **106** (bacillosamine) were first detected in PS of the cell wall of *Bacillus licheniformis*¹²¹ and, later, in O-antigenic PS of several species of *Pseudomonas aeruginosa*,¹²² *Pseudomonas aurantiaca*,¹²³ *Vibrio cholerae* O3^{58,124} and *Fusobacterium necroforum*.¹²⁵ A derivative of this amino sugar with the acetylated amino group at C(2) and the amino group at C(4) acylated with 3-hydroxybutyric acid was isolated in the pure state from PS of *P. aeruginosa* O3 only after

solvolysis with liquid HF.¹²² The ¹³C NMR spectrum of the monosaccharide indicated the presence of a CH₃ group (18.3 ppm) at C(6) and of amino groups at C(2) and C(4) (57.6 and 56.8 ppm). High coupling constant values for the ring protons ($J_{2,3}$, $J_{3,4}$ and $J_{4,5} \approx 10$ Hz) demonstrated unambiguously the *gluco*-configuration of this monosaccharide. The absolute D-configuration was evident from the specific optical rotation ($[\alpha]_D = +36^\circ$). All the characteristic signals of the NMR spectra of the monosaccharide **106** mentioned above were also found in the spectra of the PS itself and of its fragments.

For final establishment of the position of the amino groups and localisation of the acyl substituents by routine degradation of PS, the alditol **107** was obtained by solvolysis with anhydrous HF followed by reduction with NaBH₄ and methylation involving the NH groups. The mass spectrum of the alditol **107** contained fragments with m/z 202 and 246 which confirmed the presence of an *N*-acetyl group at C(2) and of a *N*-hydroxybutyryl group at C(4).¹²²

In subsequent studies, this diamino sugar was not isolated and its identification was carried out by NMR spectroscopy of the initial PS. Mass spectrometry of PS fragments obtained by their cleavage made it possible to establish the structure and localisation of *N*-acyl groups. For instance, it was found that bacillosamine in PS of *Vibrio cholerae* O3 is acetylated at the amino group at C(2) and acylated by the residue of 3,5-dihydroxyhexanoic acid at the amino group at C(4) (see Section 4).⁵⁸

2,4-Diamino-2,4,6-trideoxy-D-galactose (**108**), a monosaccharide isomeric with bacillosamine and having an acetylated amino group at C(2), was found in O-antigenic PS of *Shigella sonnei*.¹²⁶ The monosaccharide **108** failed to be isolated in the pure state even by solvolysis with HF, and its structure was determined on the basis of the ¹³C NMR spectrum of PS which contained signals similar to those observed for its *gluco*-isomer: 17.3 (CH₃ group), 56.6 and 53.0 ppm [C(2) and C(4) substituted by the amino groups]. The D-configuration was assigned to the monosaccharide based on the results of deamination and subsequent hydrolysis of PS. The formation as the main product of 2-acetylamino-2,6-dideoxy-D-glucose and (after reduction) of small amounts of a mixture of 2-acetylamino-2,4,6-trideoxyhexoses allowed a conclusion that the monosaccharide has the *galacto*-configuration.

No more unambiguous proof of the amino sugar configuration is given. The presence in the ¹H NMR spectrum of PS (at pH 10) of a signal at 3.15 ppm with small coupling constant values also confirmed the axial position of the free amino group at C(4) and, correspondingly, the *galacto*-configuration of the monosaccharide.

8. Hexuronic acids

Many O-antigenic PS contain acidic monosaccharides. The presence of such components in PS localised on the surface of the microbial cell confers specific properties on the bacterial envelope. In some cases it protects the cell from external aggressive factors and offers an alternative to the microbial capsule which fulfils a similar protective function in encapsulated bacteria. At the same time, the presence of acidic components in O-antigenic polysaccharides strongly influences the character of the somatic antigen, since it is precisely the acidic monosaccharide that often plays the role of the immunodominant group.

The most common acidic monosaccharides present in the polysaccharide chain of O-antigenic PS are hexuronic acids. Two of those, D-glucuronic and D-galacturonic acids are widespread in nature and are common components of microbial PS of a number of Gram-negative bacteria belonging to different species. Procedures for their identification have been well developed and standardised and their chemistry has been studied in a sufficiently great detail. Uronic acids bearing one or two amino groups occur as well.

a. 2-Amino-2-deoxyhexuronic acids

O-Antigenic PS have been found to contain some representatives of 2-amino-2-deoxyhexuronic acids with the *D-galacto*-, *D-manno*-, *L-galacto*-, *L-gulo*- and *L-altro*-configuration. In an effort to isolate and to establish the structure of aminuronic acids at various stages of analysis of microbial PS, different approaches were employed depending upon the degree of sophistication of the physicochemical approaches developed at the time when the particular study was carried out. Recent trends are towards the use of NMR spectroscopy of PS for establishment of the structure of aminuronic acids and their fragments and of mass spectrometry of alditols derived by their reduction. Of chemical methods, the most often used is the reduction of the carboxy group of a uronic acid resulting in formation of the corresponding easily identified 2-acylamino-2-deoxyhexose. This allows a direct conclusion about the structure of the initial aminuronic acid including its absolute configuration.

2-Amino-2-deoxy-D-galacturonic acid **109** in the form of its derivatives is found in O-antigenic PS more frequently than other sugars of this class. It is detected in PS of *Shigella dysenteriae* 7,¹⁰⁵ some serotypes of *Pseudomonas aeruginosa*,¹²⁸⁻¹³⁰ *Salmonella arizonae*¹²⁷ and *Vibrio anguillarum*¹⁰⁷ as well as in some capsular PS. A homopolysaccharide built up of residues of this aminuronic acid has long been known as the Vi-antigen of Gram-negative bacteria.¹³¹ The amino group of this and other aminuronic acids is usually acylated (most commonly acetylated), while the carboxy group is free. In PS of some bacteria the carboxy group is present as an amide; sometimes the same PS contains various proportions of both free acid and its amide. 2-Acetylamino-2-deoxy-D-galacturonic acid and its amide as well as other aminuronic acids can be isolated in the pure state using various procedures for PS cleavage: solvolysis with liquid HF, acid hydrolysis, methanolysis, etc.^{127, 128} To separate the amide of *N*-acetylaminogalacturonic acid from the free acid and to isolate it in the pure state, the following approach was used: the PS was first reduced with NaBH₄ in the presence of a water-soluble carbodiimide (the uronic acid residue was thereby converted into 2-acetylamino-2-deoxygalactose, while the amide residue was not reduced) and subjected to solvolysis with liquid HF.

To determine the structure of aminogalacturonic acid derivatives, they were converted into the acetates of the corresponding alditols, and the amides of galacturonic acid into the acetates of the aldonic acid amides. Then, their structure was established by mass spectrometry. Significantly, this approach made it possible to keep the *N*-acyl group residues unchanged and to determine their structure. For example, the presence in the mass spectrum of the acetate of the amide of 5-acetyl-amino-5-deoxygalactonic acid **111** (obtained by reduction and acetylation of the amide of 2-acetyl-amino-2-deoxygalacturonic acid **110**) of fragments with *m/z* 331 and 144 suggests the presence of an *N*-acetyl-amino group in the amide **110** and reveals its position.

The structure of 2-amino-2-deoxygalacturonic acid can be established on the basis of NMR spectroscopic data. Thus, the ^{13}C NMR spectrum contains a signal due to the carboxy group at 173–176 ppm and a signal of C(2) substituted by the amino group at 49–51 ppm. The assignment of the acid to the *galacto*-series was done on the basis of the ^1H NMR spectrum: the coupling constant values for the ring protons were: $J_{2,3} = 11$, $J_{3,4} = 3$ and $J_{4,5} = 1.5$ Hz. The specific optical rotation ($[\alpha]_D = +17.9^\circ$) corroborated the absolute configuration of the monosaccharide.

Polysaccharides of some other serotypes of *Pseudomonas aeruginosa* were found to contain the L-isomer of the acid **109**, 2-acetyl-amino-2-deoxy-L-galacturonic acid **112**,^{122,132} which, like its D-isomer, is a component of the main chain of PS. The presence in PS of the uronic acid was also evident from spectral data: the IR spectrum contained an absorption band at 1740 cm^{-1} and the ^{13}C NMR spectrum a signal at 175 ppm belonging to the carboxy group.

Reduction of PS with NaBH_4 and subsequent hydrolysis resulted in isolation and identification of 2-acetyl-amino-2-deoxy-L-galactose (*N*-acetyl-L-galactosamine), thus confirming finally the structure of the monosaccharide **112** including its absolute configuration.

A derivative of 2-amino-2-deoxy-D-mannuronic acid **113** was found in O-antigenic PS of *Vibrio cholerae* O5.¹²⁴ The acid **113** was not isolated in the pure state, and its structure was established by a non-destructive method based on a detailed analysis of NMR spectra of the PS itself. Thus, the ^{13}C NMR spectrum of the aminomannuronic acid residue contained a carboxy group signal at 160–170 ppm; in addition, the presence of the carboxy group of the uronic acid was evident from the absence of H(6) signals in the ^1H NMR spectrum in combination with a characteristic pH dependence of the H(5) proton shift. For confirmation of the acid **113** structure, the polysaccharide was reduced with NaBD_4 and hydrolysed. As a hydrolytic product, a derivative of 6-[$^2\text{H}_2$]-mannosamine was isolated and identified by mass spectrometry as the acetate of the corresponding alditol. The *manno*-configuration of the acid was corroborated by NMR spectroscopic data of the initial PS. The absolute configuration was suggested on the basis of the glycosylation effects determined from the ^{13}C NMR

spectrum taking into account the type of substitution of the adjacent unit in the polysaccharide chain.

The derivatives of the two other 2-amino-2-deoxyuronic acids, 2-acetyl-amino-2-deoxy-L-guluronic acid and 2-acetyl-amino-2-deoxy-L-alturonic acid, are very rare in occurrence and have thus far been found only in O-antigenic PS.

2-Acetyl-amino-2-deoxy-L-guluronic acid **114** was found in PS of *Alteromonas macleodi* 2MM.¹³³ Its structure was established by a non-destructive method. The presence of the uronic acid residue was confirmed by the signals corresponding to the carboxy group (177.7 ppm) and C(2) substituted by an amino group (52.4 ppm) in the ^{13}C NMR spectrum of the polysaccharide and was also corroborated by a low-field shift of the H(2) signal in the ^1H NMR spectrum (4.38 ppm). The *gulo*-configuration of the acid is evident from the ^1H NMR spectrum of the polysaccharide, in which the coupling constant values for the ring protons are characteristic of the *gulo*-series ($J_{2,3} = 9$, $J_{3,4} = 4.0$, $J_{4,5} = 2$ Hz). The absolute L-configuration of the acid was suggested on the basis of NOE measurements for PS and construction of molecular models.

2-Acetyl-amino-2-deoxy-L-alturonic acid **115** was found in PS of *Shigella sonnei*, phase I.^{126,134} It was isolated in the pure state by acid methanolysis of PS followed by *N*-acetylation. Its reduction with NaBH_4 gave 2-acetyl-amino-2-deoxy-L-altrose identified by comparison with an authentic sample using the specific optical rotation.¹³⁴ More recently,¹²⁶ the ^{13}C NMR spectrum of the acid **115** containing, in particular, signals at 175.6 (COOH) and 56.8 ppm [C(2)] was recorded. The L-configuration of the acid was confirmed by the fact that ninhydrin oxidation of 2-acetyl-amino-2-deoxyaltrose derived by its reduction gives L-ribose.¹²⁶

b. 2,3-Diamino-2,3-dideoxyhexuronic acids

These structurally unique acidic monosaccharides are rare in occurrence and have thus far been detected only in O-antigenic PS of several strains of *Pseudomonas aeruginosa* and one of their representative has been found in PS of *Bordetella*. These monosaccharides are unstable in acid media and not all of them could be isolated in the pure state; determination of their structure posed considerable difficulties which could be obviated by structural analysis of oligosaccharide fragments obtained by partial degradation of PS in combination with a thorough analysis of the NMR spectra of the PS themselves.

Currently, derivatives of 2,3-diamino-2,3-dideoxyuronic acids having the D-*gluco*-, D-*manno*-, D-*galacto*- and L-*gulo*-configurations are known.

2,3-Acetyl-amino-2,3-dideoxy-D-glucuronic acid **116** was found in PS of *P. aeruginosa* O6.^{135,136} Using this acid as an example, a scheme for structural analysis of these unusual monosaccharides has been elaborated (Scheme 12). The presence in PS of a free carboxy group was confirmed by the presence in the IR spectrum of a band at 1740 cm^{-1} . Solvolysis of PS with liquid HF performed at room temperature gave the disaccharide **117** containing a uronic acid. Successive reduction of the disaccharide with NaBH_4 followed by oxidation with HIO_4 , repeated reduction with NaBH_4 and carboxyl reduction resulted in the compound **118**. Strong acid hydrolysis of **118** and its subsequent *N*-acetylation gave 2,3-diacetyl-amino-2,3-dideoxyhexose **119**. The structure of the acid **119** was established by mass spectrometric analysis of the alditol acetate **120** derived from **119**.

Scheme 12

The mass spectrum of the compound **120** contained fragments with m/z 288, 215 and 144; such fragmentation, which is characteristic of 2,3-diacetyl-amino-2,3-dideoxyhexitol acetates, was previously observed for synthetic samples.¹³⁷

The ^{13}C NMR spectrum of the disaccharide **117** contained signals belonging to the carboxy group (176 ppm) and C(2) and C(3) substituted by the amino group (54.9 and 56 ppm). High coupling constant values of the ring protons in the ^1H NMR spectrum of the monosaccharide **116** ($J_{2,3} = 11.5$, $J_{3,4} = J_{4,5} = 10.0$ Hz) indicated its *gluco*-configuration. The acid **116** was assigned to the D-series on the basis of direct comparison of the diacetyldiaminohexose **119** derived by reduction of **116** with a synthetic sample of 2,3-diacetyl-amino-2,3-dideoxy-D-glucose.¹³⁸

Derivatives of 2,3-diamino-2,3-dideoxy-D-mannuronic acid **121** were found in PS of several serotypes of *Pseudomonas aeruginosa* where they are present in the main chain as one or two residues.^{139,140} The amino groups of the acid appeared to be substituted by acetyl and acetimidoyl (acetamidino) groups. It should be noted that the latter is unique for carbohydrate derivatives and was first detected in O-antigenic PS. The presence of an acetimidoyl group offered some difficulties in elucidation of

the structure of diaminomannuronic acid derivatives and originally prompted an erroneous conclusion about the presence in PS of a monosaccharide containing a condensed pyrano-imidazoline system.^{139,140} Subsequently this error was corrected.¹⁴¹ Therefore, to simplify the structural analysis, the polysaccharide or its fragments were treated with triethylamine to convert the acetimidoyl group into a more common acetyl group.

The structure of the acid **121** was established by the scheme described above for the *gluco*-analogue. Evidence for the presence of a carboxy group was derived from the band at 1725 cm^{-1} in the IR spectrum of PS. Successive solvolysis of PS with liquid HF, reduction with NaBH_4 , oxidation with HIO_4 , repeated reduction with NaBH_4 , treatment with triethylamine (conversion of the *N*-acetimidoyl into the *N*-acetyl group) and carboxyl reduction gave the trisaccharide derivative **122**.
