Substituents in the 5-position of compounds **56** and in the 4-position of compounds **57–59** not only substantially determine the neurotoxicity of these substances, but are also essential for their biodegradability under the action of various oxygenases.

Unfortunately, so far no commercial products among compounds **56–61** have been developed.

Interestingly, the first analogue of organophosphorus insecticides has been recently found among natural compounds. Antibiotic NK-901093 (**68**), which is an enol cyclophosphate, was isolated from *Streptomyces* sp. At a concentration of 0.1 mg litre⁻¹, this compound causes 100% mortality in mosquitoes and suppresses the activity of cholinesterase at concentrations four orders lower than that of malaoxon.¹¹¹

IV. Pyrethroids and other compounds

Recent years have been marked by the rapid rise in manufacture of pyrethroids, and the value of their sales has taken the first place among all types of insectoacaricides. Although it is worth mentioning that the real pyrethroid boom had already virtually abated in the 80's. In the 90's, the main emphasis in the research and manufacture of pyrethroids is made on the development of new technologies including the isolation of pure diastereomers and enantiomers for reduction of the usage rates of these compounds and minimisation of their impact on the environment. Apart from that, much attention is paid to the development of numerous multicomponent preparation forms, including mixtures, for their usage not only in farming but in the household, public health and industry.

The scope of the synthetic works on pyrethroids over recent years was not so large. The most interesting result in this field was the synthesis of fluorine- and silicon-containing derivatives of previously known synthetic pyrethroids. In the case of the synthesis of fluorinated pyrethroids, the fluorine atoms and fluorine-containing groups were introduced in both the acidic part of the molecule and the aromatic ring to make these compounds more stable toward hydrolysis and the action of oxygenases. Among these compounds, phenothrin (**69**) and bioallethrin (**70**) analogues containing the difluoroisobutenyl group¹¹² and an analogue of cyfluthrin (**71**) bearing a difluorocyclopropylidene moiety are worth mentioning.¹¹³

Compound **71** causes 100% mortality in *Spodoptera eridania*, *Aphis gossypii* and *Diabrotica undecimpunctata* at concentrations of 0.6, 2.5 and 2.5 mg litre⁻¹, respectively.

However, only two analogues of pyrethroids devoid of the ester group, viz., experimental insecticides flufenprox (**72**) and silafluofen (**73**), are of certain practical interest.^{114, 115}

Flufenprox (**72**) has good economical and ecological characteristics, high insecticidal activity in doses of 75–300 g ha⁻¹ against a broad range of pests, and is harmless for warm-blooded animals and bees.

Silafluofen (**73**), which belongs to the group of silaneofans, is used against lepidopterans, dipterans, coleopterans, hemipterans, homopterans, etc., but is ineffective against aphids and whiteflies.

Analogues of silafluofen (**74**) containing the difluorinated double bond possess the high insecticidal activity.¹¹⁶

From the other groups of insectoacaricides, it is worth mentioning thiourea derivatives. Studies of the biological properties of several hundreds of di-, tri- and tetra-substituted thioureas has led to the preparation diafenthion, 1-*tert*-butyl-3-(2,6-diisopropyl-4-phenoxyphenyl)thiourea **75**. This is effective against sucking pests such as mites, aphids and whiteflies on cotton and vegetables. Upon UV irradiation or *in vivo*, compound **75** is converted into the corresponding carbodiimide **76**.^{117, 118} It is the latter that acts as an insecticide. This intermediate blocks the activity of mitochondrial ATPase and therefore is classified as an oxidative phosphorylation decoupler.¹¹⁸

A number of other compounds were also synthesised, which are converted after elimination of a part of the molecule into carbodiimide **76**. These are, for example, 1,4-disubstituted tetra-

zoline-5-thione (77) and 3-thioxo-1,2,4-oxadiazol-5-one (78). Field tests for these compounds have also given good results.¹¹⁹

In the author's opinion, all these studies represent a fine illustration of a propesticidal approach to the development of novel insectoacaricides.

In conclusion, some general tendencies in the manufacture and application of insectoacaricides should be noted. In 1996, the production of active principles of this group of insecticidal preparations had reached 680 000 tons with a total value of \$US 8.7 billion. According to the forecast, in 2001 the value of the insecticide sales will reach 10.5–10.7 billion dollars.

These figures show that in the beginning of the XXIst century (the author assumes that in the near future) the programmes for control of harmful insect and phytophagous mites will be based on the use of the chemical preparations despite certain recent achievements in the development of biological methods for plant protection, first of all, in the selection of transgenic plants resistant to pests. The portion of traditional preparations such as organophosphorus compounds, carbamates and pyrethroids will constitute not less than 80%–85% of all manufactured insectoacaricides. At the same time, the proportion of preparations with new modes of action will be gradually increased.

The wide assortment of preparations makes possible the successful application of technologies of integrated plant protection, which ensure the minimal impact of chemicals on the environment and prevent the development of resistant populations of arthropods.

Abstract. Nuclear quadrupole resonance and X-ray data on the electronic effects of substitution of acidoligands and reconstruction of the coordination polyhedra in adducts (complexes) of tin(IV), germanium(IV) and silicon(IV) tetrahalides due to the change in the central metal coordination number are surveyed and systematically described. The σ - and π -electron density redistribution over the central metal–halogen bonds resulting from substitution or reconstruction of the coordination polyhedra from pseudooctahedral to trigonal-bipyramidal geometry is discussed. The bibliography includes 55 references.

I. Introduction

Redistribution of electron density upon substitution or reconstruction of the central atom coordination polyhedron in coordination compounds is a fundamental problem of the chemistry and stereochemistry of heteroligand complexes. Whereas the importance of this problem in the coordination chemistry of transition elements is widely known, the electronic effects in the chemistry of main group elements have been studied less extensively. Electronic effects of substitution as well as their steric manifestations are extremely diverse in such compounds, the resulting changes in the metal–halogen bonds being sensitive to details of the electronic structure of the whole adduct, *viz.*, the central metal, ligands and substituents. In most earlier publications, the electronic mechanism of substituent influence was discussed based on the position of ligands in various rows, AO occupancies determined by approximate quantum-chemical calculations and X-ray data. However, all these characteristics related only indirectly to the phenomenon in question, because the contribution of the substituents to the changes in the appropriate parameters is as a rule not unique and sometimes not predominant. Often, the results thus obtained do not allow determination of both the extent of the influence and even its direction. As a result, many important questions of the electronic mechanism of ligand influence in main

group element coordination compounds remain still open. In particular, quantitative data on electron density redistribution over the atomic σ and π orbitals as a result of either substitution of acidoligands or change in the adduct geometry, caused by the change in the central atom coordination number, were very scanty.

The intention of this review is to bring to the attention of researchers a feasibility of quantitative description of electron density redistribution in Main Group IV element coordination compounds using nuclear quadrupole resonance (NQR) spectroscopic data. Here we discuss only static influence of substituents, which reflects processes in a system in the ground state. In this case, a parameter can be used as a measure of substituent (ligand) electronic influence if it satisfies at least two requirements: first, it characterises a system in its ground state and second, it is changed predominantly under this influence. In this respect, NQR spectroscopic parameters seem to be quite suitable, since they are the ground-state characteristics of a system directly relating to the electron density distribution in the vicinity of a quadrupolar nucleus.

NQR spectroscopy investigates interactions between nuclei having nonzero quadrupole moment Q (all the nuclei with spin $I > 1/2$ have such a moment) and their local electric environment. The latter is characterised by the electric field gradient (EFG)

$$q_{ij} = \frac{\partial E_i}{\partial j} = \frac{\partial^2 U}{\partial ij},$$

where E_i is the strength of the electrostatic field, U is the electrostatic potential at the nuclear site and $i, j = x, y, z$. The directly measured spectroscopic parameters are the quadrupole coupling constant (QCC)

$$\text{QCC} = \frac{e^2 Q q_{zz}}{h},$$

where e is the charge on the electron and h is the Planck constant, and the EFG asymmetry parameter

$$\eta = \frac{|q_{xx} - q_{yy}|}{q_{zz}}.$$

Because the values of QCC and η depend directly on the electron density distribution around the nucleus under study, any weak disturbance of the electron density upon introduction of a substituent is clearly reflected in the NQR spectra. The physical

principles of the NQR phenomenon, the scope and limitations of NQR spectroscopy in application to problems of inorganic and coordination chemistry have been reviewed.¹

X-Ray diffraction analysis is yet another approach to the study of substituent effects. However, one should bear in mind that the changes in interatomic distances depend on numerous factors which form the optimum crystal packing and are not necessarily related to the effects of substitution. Comparison of NQR and X-ray data allows one to determine the changes in effective charge on atoms upon the appropriate bond lengthening, which, in turn, helps to outline the range of variation of interatomic distances under the influence of substituents. The use of the two experimental techniques providing complementary pieces of information, on such important properties of compounds as electron density distribution and spatial arrangement of atoms, permits avoiding indirect estimations in the study of the problem on a quantitative level.

This review presents the results of NQR spectroscopic studies on the σ - and π -electron density redistribution over metal–halogen bonds in tin(IV), germanium(IV) and silicon(IV) halide complexes and adducts resulting from the substitution and/or change in the central atom coordination number. The following series are considered: $M\text{Hal}_4 \rightarrow M\text{Hal}_4\text{L} \rightarrow M\text{Hal}_4\text{L}_2$, $\text{SnHal}_4\text{L}_2 \rightarrow \text{R}_n\text{SnHal}_{4-n}\text{L}_2$ and $[\text{SnHal}_6]^{2-} \rightarrow [\text{RSnHal}_5]^{2-}$, where $M = \text{Sn, Ge and Si}$; $\text{Hal} = \text{Cl, Br and I}$; $\text{R} = \text{Alk and Ph}$; and L are oxygen- and nitrogen-containing ligands.

II. Electronic effects of substitution in adducts of tin(IV) halides

The problem of electron density redistribution over the atomic σ and π orbitals of metal–halogen bonds upon substitution in tin(IV) adducts of the type $\text{SnHal}_4\text{L}_2 ([\text{SnHal}_6]^{2-}) \rightarrow \text{R}_n\text{SnHal}_{4-n}\text{L}_2 ([\text{RSnHal}_5]^{2-})$ seems to be most intriguing. The solution of this problem requires the knowledge of the complete set of NQR spectroscopic parameters for the complexes and adducts of parent tin tetrahalides including the asymmetry parameters η of the halogen atoms. In this respect, iodostannates are most suitable for NQR studies, because the iodine (^{127}I) nuclear spin is $I = 5/2$ and the QCC and η values in the iodo adducts can be found, provided both resonance transition frequencies, ν_1 ($\Delta m = 1/2 - 3/2$) and ν_2 ($\Delta m = 3/2 - 5/2$) are observed.¹ No additional experiments are necessary in this case, whereas they are necessary for determining η in chlorostannates, because only two degenerate quadrupole levels and one transition frequency are available for chlorine nuclei with $I = 3/2$, which precludes simultaneous determination of the QCC and η values from the known relationship

$$\nu = \frac{e^2 Q q_{zz}}{2h(1 + \eta^2/3)^{1/2}}.$$

The EFG asymmetry parameter provides additional information on the electron density distribution around the nucleus in question, because η is a measure of the bonding electron cloud axial asymmetry. Hence the problem of measuring η on the $^{35,37}\text{Cl}$ nuclei with $I = 3/2$, which are most often subject to NQR studies, is considered by spectroscopists as being of current interest, and various attempts were undertaken to solve it. Most determinations of η on the ^{35}Cl atoms were made by Zeeman studies of single crystals.^{1,2} These measurements provide high precision of the η values and permit determination of the orientation of the EFG axes with respect to the crystallographic axes of the specimen. However, this approach substantially reduces the number of the compounds that can be examined, eliminating those air- or moisture-sensitive as well as presenting problems for the crystal growth.

The number of reports on the determination of η in crystalline powders is much less. The majority of the results published by foreign authors were obtained using the CW technique, which as a

rule gives low accuracy of measurements². The advantages of pulsed methods over stationary ones for measuring η in powders were outlined in the review.¹ One approach was based on the Fourier-analysis of slow beats of the spin echo envelope in external magnetic fields of 15–100 G. In powders of chlorine-containing compounds, this provided values of η in reasonable agreement with those available for the appropriate single crystals.³ This approach was applied for determination of η in organic and organoelement compounds.^{4–7} Later, it was modified⁸ to be used for measuring η in a large number of adducts of tin, germanium and silicon tetrachlorides.^{9–12}

The determination of η in compounds in question enables one to escape the σ -approximation, to take into account the electron density distribution over the tin–halogen σ and π orbitals and to juxtapose trends in electron density redistribution upon substitution of different groups for acidoligands. Within the Townes and Dailey theory approximations, the measured NQR spectroscopic parameters (QCC and η) are related to the halogen atom valence p -orbital occupancies Np_i ($i = x, y, z$) and electronic characteristics of metal–halogen bonds as follows:

$$U_p = \frac{e^2 Q q_{zz}}{e^2 Q q_0} = \left| \frac{Np_x + Np_y}{2} - Np_z \right| = \sigma - \frac{\pi}{2}, \quad (1)$$

$$\eta = \frac{q_{xx} - q_{yy}}{q_{zz}} = \frac{3(Np_x - Np_y)}{2Np_z - (Np_x + Np_y)} = \frac{3(\pi_x - \pi_y)}{2U_p}, \quad (2)$$

where $e^2 Q q_{zz}$ is the QCC value at the halogen atom, $e^2 Q q_0$ is the atomic QCC produced by a single electron on the valence p_z orbital of the halogen atom;

$$Np_z = 2 - \sigma,$$

$$Np_x = 2 - \pi_x,$$

$$Np_y = 2 - \pi_y;$$

$$\pi_x + \pi_y = \pi; \quad i + \sigma + \pi = 1,$$

where i , σ and π are the ionic, covalent and π -character of the bond.

Whereas the mutual ligand influence in similar transition metal compounds is known to alter the metal–halogen bonds in such a way that the *trans*-influence is prevailing and is accompanied by a slight change in the *cis*-bonds, the resulting changes in the Sn–Hal bonds due to the introduction of substituents R into $[\text{SnHal}_6]^{2-}$ or SnHal_4L_2 were found to be sensitive to details of the electronic structure of the whole adduct, *viz.*, to the AO energies for the central atom, the halogen atoms and substituents as well as to the oxidation state of the central atom. Depending on the oxidation state of the central metal and its position in the Periodic Table, *cis*-weakening, or *trans*-weakening or *cis*-weakening accompanied by a relatively smaller *trans*-influence can prevail, both strengthening and weakening being possible in principle. Various theoretical approaches have been developed to describe the effects of substituents (ligands) in main group element complexes.

Based on the model of equivalent orbitals applicable to compounds having covalent two-electron two-centre bonds, the mechanism of ligand influence was described as purely inductive.¹³ As a result of substitution, the M – Hal bonds were predicted to undergo changes so as to provide prevailing of *cis*-over *trans*-influence. In the approach using the canonical σ -MO within the perturbation theory approximations, the atomic orbital energies of the halogen ligands and substituents were assumed to be close to each other.¹⁴ According to this approach a *trans*-influence prevailing over relatively weak *cis*-influence was expected as the contribution of the np orbitals of the central atom became more pronounced. A consideration which took into account all the transitions between the occupied and vacant MOs suggested that the central atom valence basis set involved mostly ns and np orbitals rather than the vacant nd -AOs.¹⁵ The resulting

change in the the M—Hal bond character upon substitution was determined in this case by a relationship between the energies of the levels for the valence *ns*- and *np*-AOs of the central atom and *s*-AOs of typical ligands. This means that the influence was expected to be essentially different for the compounds of Groups II–IV (type I) and VII (type II) elements. Thus the substitution $[\text{MHal}_6]^{2-} \rightarrow [\text{RMHal}_5]^{2-}$ in complexes of the Main Group IV element was predicted to result in contraction of the $[\text{MHal}_6]^{2-}$ octahedron along the *z* axis and its expansion in equatorial directions, if substituent R is more electropositive than Hal, whereas the octahedron will be expanded along the *z* axis and contracted in the *x*, *y* directions, if R is more electronegative than Hal.

A model of hypervalent (HV) orbital-deficient bonds¹⁶ applied to tin(IV) compounds¹⁷ suggests that the central atom valence basis involves only *ns* and *np* orbitals. According to this model, in the parent $[\text{SnHal}_6]^{2-}$ complex, the 5*s* orbitals of the tin atom participate in the formation of three equivalent three-center *sp*-hybrid hypervalent (HV-I) bonds Hal—Sn—Hal, each involving only one 5*p* orbital of the tin atom. The σ -level energies of the substituents R in adducts (complexes) $\text{R}_n\text{SnHal}_{4-n}\text{L}_2$ and $[\text{SnHal}_6]^{2-}$ are then close in value to those of the *p* levels of the central atom, while the σ -level energies of the acidoligands are close in value to those of the *s* levels of the tin atom.

In alkyl- and dialkyl-substituted complexes, occupation of a_1^* MOs occurs, which are antibonding with respect to the equatorial ligands. Because the a_1^* MOs contain a remarkable contribution from the *s* orbital of the central atom, the *s*-character of the equatorial bonding orbitals is reduced, so that the corresponding bonds (HV-II) are weakened compared to the bonds HV-I in the parent unsubstituted complex $[\text{SnHal}_6]^{2-}$. On the other hand, alkyl substituents R cannot form stable hypervalent bonds with tin, because R is less electronegative than the tin atom, so that the Alk—Sn bonds are ordinary covalent two-centre two-electron bonds.

Thus, for the adducts and complexes $\text{R}_n\text{SnHal}_3\text{L}_2$ and $[\text{R}_n\text{SnHal}_5]^{2-}$, the model of hypervalent orbital-deficient bonds predicts weakening of the Sn—Hal bonds at the *cis*-position to the alkyl substituent compared to the bonds in the initial SnHal_4L_2 or $[\text{SnHal}_6]^{2-}$ compounds. The weakening can be accompanied by *trans*-influence, presumably strengthening of the Sn—Hal bond at the *trans*-position to the substituent R.

Using NQR, the electronic effects of substitution were observed experimentally: the direction of the *trans*-influence was determined and the relative importance of the effects of *cis*- and *trans*-influence was quantitatively compared. Most clear manifestations of both effects were obtained for pseudooctahedral complexes of the type $[\text{R}_n\text{SnHal}_5]^{2-}$ and molecular adducts $\text{R}_n\text{SnHal}_{4-n}\text{L}_2$ where the tin atom is in its highest oxidation state and either one or two acidoligands (Hal) are substituted for alkyl groups R, which considerably exceed the halogen ligands in donating power. The effects of substitution were especially strong in these compounds, and we discuss here how the substitution influences the σ - and π -electron density distribution in the complexes and molecules of adducts.

Tables 1 and 2 list the NQR spectroscopic parameters measured for the substituted tin(IV) compounds and their unsubstituted precursors, hexahalostannates $\text{Cat}_2\text{SnHal}_6$ (Cat is cation) and pseudooctahedral adducts of tin tetrahalides SnHal_4L_2 . The appropriate Sn—Hal interatomic distances wherever available are also given in these tables. As is seen from Tables 1 and 2, the *cis*- and *trans*-influence of the substituents is clearly reflected in the NQR spectra, which enables one to compare their contribution to the resulting electron density redistribution on a quantitative scale. In Tables 3 and 4, the halogen atom valence p_σ orbital occupancies (N_{p_z}) and p_π orbital occupancy differences ($\Delta N_{p_\pi} = N_{p_x} - N_{p_y}$), estimated from the NQR data, are given for the adducts and complexes of parent unsubstituted and mono- and dialkyl(diphenyl)-substituted tin halides $[\text{R}_n\text{SnHal}_5]^{2-}$, $\text{R}_n\text{SnHal}_3\text{L}_2$, $\text{R}_2\text{SnHal}_2\text{L}_2$. The main sources of inaccuracy in the

determination of the spectroscopic parameters as well as the reliability of interpreting the spectral data were discussed in a review.³ Based on the estimated values of the atomic orbital occupancies, the effective charges (ρ) on the halogen atoms and their variation ($\Delta\rho$) as a result of the introduction of the substituents R were determined

$$\Delta\rho = \frac{\rho(\text{R}_n\text{SnHal}_{4-n}\text{L}_2) - \rho(\text{SnHal}_4\text{L}_2)}{\rho(\text{SnHal}_4\text{L}_2)}. \quad (3)$$

Similarly, the variation of the Sn—Hal bond distances (Δd) was estimated in compounds whose structures were studied

$$\Delta d = \frac{d(\text{R}_n\text{SnHal}_{4-n}\text{L}_2) - d(\text{SnHal}_4\text{L}_2)}{d(\text{SnHal}_4\text{L}_2)}. \quad (4)$$

The values of Δd are also listed in Tables 3 and 4.

The NQR spectra provide evidence for a profound electron density redistribution upon substitution. The negative effective charge on the halogen atoms in the *cis*-position to the substituent R increases in absolute magnitude with respect to the corresponding parent compounds hence yielding the positive values of $\Delta\rho$ (Tables 3 and 4). On the halogen atoms in the *trans*-position to the substituent, the absolute magnitude of the charge falls as compared to that in the parent unsubstituted adduct. The negative values of $\Delta\rho$, found for the *trans*-halogens in all the adducts studied, indicate that the *trans*-influence of substituents R always acts in these compounds as *trans*-strengthening of the Sn—Hal bonds. The only exception was the adduct $\text{EtSnCl}_3(\text{DMSO})_2$ (Table 3), in which strong donor ligands compensate the effect of *trans*-strengthening (and accordingly *trans*-shortening). The introduction of an ethyl group into a $[\text{SnCl}_6]^{2-}$ complex (its singlet NQR spectrum points to the equivalence of all the chlorine atoms) results in the formation of the complex $[\text{EtSnCl}_5]^{2-}$ characterised by an NQR spectrum with a spectroscopic splitting of 6 MHz between the frequencies, assigned to the chlorine atoms in *cis*- and *trans*-positions relative to the substituent R. The effective charges on the appropriate chlorine atoms differ on average by 0.1 e. The difference between the characteristics of the *cis*- and *trans*-bromine atoms in the complex $[\text{BuSnBr}_5]^{2-}$ is even more pronounced: the splitting of the corresponding ^{81}Br NQR frequencies exceeds 50 MHz, whereas the difference in effective charges on the corresponding Br atoms reaches 0.16 e (see Ref. 3).

It is evident that such values of frequency shifts and spectroscopic splittings are mainly due to the intramolecular electronic rather than crystal-field effects. A correlation between the ^{35}Cl NQR frequencies and Sn—Cl bond lengths was examined for a large number of chlorine-containing tin compounds including hexacoordinate tin(IV) complexes of the types $\text{Cat}_2\text{SnHal}_6$ and $\text{Cat}_2\text{R}_n\text{SnHal}_5$ with various cations and anions, electroneutral adducts of types SnCl_4L_2 and $\text{R}_2\text{SnCl}_2\text{L}_2$ and compounds $\text{R}_n\text{SnCl}_{4-n}$, where the tin atom is tetracoordinate and both terminal and bridging chlorine atoms are available.¹⁹ Tin(II) compounds $\text{SnCl}_2 \cdot x\text{H}_2\text{O}$ ($x = 0, 1.5, 2$) were also taken into consideration. The results of the analysis showed that the maximum contribution of the crystal field to the frequency shifts and Sn—Cl bond lengths in these compounds does not exceed 2 MHz and 0.05 Å, respectively. These contributions are evidently less in crystallochemically similar chlorine-containing compounds listed in Tables 3 and 4. Their further decrease occurs on going to more covalent tin(IV) bromo- and iodo compounds. It should be added that the relative changes of the effective charges on atoms are considered as the measure of substituent effects rather than their absolute values. Thus the electronic effect of the ethyl substituent in pentachloroethylstannate was estimated from changes in the effective charges on the chlorine atoms compared to those in the parent hexachlorostannate with the same cation, which implies that the crystal field contributions to the ^{35}Cl NQR frequencies of both pentachloroethyl- and hexachloro-stannate are virtually the same.^{20, 21}

Table 1. ^{35}Cl and ^{81}Br frequencies [$\nu(^{35}\text{Cl})$ and $\nu(^{81}\text{Br})/\text{MHz}$], EFG asymmetry parameters (η) in the NQR spectra of SnHal_4L_2 , $[\text{SnHal}_6]^{2-}$, $\text{R}_n\text{SnHal}_{4-n}\text{L}_2$ and $[\text{RSnHal}_5]^{2-}$ at 77 K and Sn–Hal bond distances (d).^{9–11, 18, 19–22, 23}

Note. Resonance frequencies of chemically equivalent iodine atoms are averaged over crystallographically inequivalent positions. The values expected by analogy to those measured for the related compounds are given in braces.

^a Calculated. ^b The unit cell comprises two crystallographically independent molecules of the adduct. ^c Triphenylphosphine oxide.

As is seen from Tables 3 and 4, the prevailing effect of substitution is, in agreement with the earlier conclusions,¹⁷ weakening of the *cis*-Sn–Hal bonds relative to the substituent R as compared to the Sn–Cl bonds in the corresponding non-substituted complexes (adducts). The elongation of the Sn–Hal bond by 0.1 Å is accompanied by an increase in the effective negative charge on the chlorine, bromine and iodine atoms by *ca.* 0.08, 0.1 (see Ref. 18) and 0.12 e (see Ref. 12), respectively. It is noteworthy that according to the X-ray data the elongation of the *cis*-Sn–Hal bond relative to the substituent R is the same for all the monoalkyl-substituted adducts of any halogen element, amounting approximately to 0.1 Å. The similar bond elongation is accompanied by an increment of the negative charge on the corresponding halogen atom, which points to an increase in *cis*-weakening due to the alkyl group in the order Cl < Br < I.^{12, 18}

Phenyl substituents also weaken the appropriate Sn–Hal bonds, although to a lesser extent. The effective charges born by the iodine atoms in dialkyl- and diphenyl-substituted adducts $\text{R}_2\text{SnI}_2\text{L}_2$ were estimated¹² to differ, on average, by 0.08 e. In adducts of mono-substituted tin halides, both *cis*-weakening and *trans*-strengthening are also more pronounced in alkyl-substituted adducts than in phenyl analogues (Tables 1 and 3). Variations of the effective charges on the halogen atoms in *cis*- and *trans*-positions to the substituent R as well as their valence p_π orbital occupancies resulting from substitution can clearly be compared on a quantitative scale. As follows from comparison of the absolute magnitudes of $\Delta\rho$ (Table 3), a negative charge increment on the halogen atoms, *i.e.*, the effect of *cis*-weakening of the Sn–Hal bond as a result of substitution, is 2–3 times as strong as that of *trans*-strengthening. Comparison of the corresponding

^a In the absence of the experimental data, it was assumed that $\eta = 0$; from symmetry considerations, the real η -value should not exceed 5%–10%.

^b At $\eta = 4\%$.

values for ΔNp_π shows that the equatorial π -bonds in monoalkyl-substituted adducts remain virtually undisturbed by *cis*-weakening, whereas *trans*-strengthening seems to involve both σ - and π -bonds. In most of the $\text{RSnHal}_3\text{L}_2$ compounds, *trans*-strengthening of the Sn–Hal bond occurs only if η is non-zero, hence revealing disturbance of the halogen π -system. In chlorine-containing adducts, the η -values, at which *trans*-strengthening takes place, show the tendency to an increase as the donating power of either substituent R (provided the ligand L remains the same) or ligand L (provided the substituent R remains the same) decreases. Thus, *trans*-strengthening in the adduct $\text{PhSnCl}_3(\text{HMPT})_2$ can only be observed when the η -value for the appropriate chlorine atom reaches 6.7%, whereas in its ethyl analogue $\text{EtSnCl}_3(\text{HMPT})_2$, it is observed at $\eta = 0$ and reaches 3% at $\eta = 4\%$. However, *trans*-strengthening in the adduct

$\text{EtSnCl}_3(\text{THF})_2$ is only possible at $\eta > 7\%$. Although the contribution of the π -system to chemical bonding in tin adducts is small, the above tendency is clearly seen from the NQR data.

As a whole, the electronic effects of substitution in the adducts with known structure were found to correlate to their structural manifestations, although in the adducts of mono-substituted tin chlorides, a shortening of the Sn–Hal bond in the *trans*-position to the substituent R was small and comparable with the standard deviation values. In $(\text{MeNH}_3)_2\text{EtSnCl}_5$, no shortening of the *trans*-bond Sn–Hal compared to the parent unsubstituted complex was found by X-ray analysis,¹⁹ whereas the absolute value of

the effective charge on the *trans*-ligand decreased by more than 5%, the appropriate frequency shift exceeding 1 MHz. The frequency shifts at the chlorine atoms in *trans*-positions to the substituent observed in the NQR spectra of all compounds studied notably exceeded the errors of measurement, so that the effect of *trans*-strengthening was readily revealed in terms of a decrease in the effective charge on the corresponding chlorine atom. The NQR parameters are more sensitive to the influence of substituents than the interatomic distances (Tables 3 and 4); this is however not unexpected, considering that the substituent influence is governed by the electronic effects, whereas the NQR parameters directly reflect the electron density variations on the atom under study.

It is worthwhile to compare redistribution of the electron density in adducts of mono-substituted tin halides with different mutual arrangement of the ligands L. For instance, in Tables 1 and 3, the data are summarised for the adducts *cis*-EtSnCl₃(DMSO)₂ (**1**) and *trans*-PhSnCl₃(HMPT)₂ (**2**), whose strong donor ligands L are competitive in donating power with the substituents R. One can see that *cis*-weakening of the Sn–Hal bonds in the adduct **1**, where the ligands DMSO are in *cis*-position to each other, is less pronounced than that in the ethyl-substituted adducts with weaker donor ligands L. Moreover, in agreement with X-ray data, *trans*-strengthening of the Sn–Hal bond in **1** gives way to *trans*-weakening. By contrast, *trans*-strengthening of the Sn–Hal bond exists in the molecule **2** with *trans*-position of the HMPT ligands relative to each other, as follows from the NQR frequency shift, and *cis*-weakening in this adduct is stronger than in **1**, although the phenyl group is a weaker ‘influencing’ substituent than the ethyl group.

Introduction of the second substituent R to give an adduct R₂SnHal₂L₂ increases the *cis*-lengthening (weakening) of the Sn–Hal bond in an approximately additive manner. As a result, in the adducts of dialkyltin dichloride, dibromide and diiodide the effects exceed 25%, 40% and 50%, respectively, the appropriate Sn–Hal bond elongation being ~ 0.2 Å. Whereas the *cis*-weakening effect of the phenyl substituents is less than that due to the ethyl groups, the effects due to different alkyl groups are approximately the same, as one can see from the data for Me₂SnBr₂(py)₂, Et₂SnBr₂(py)₂ and Bu₂SnBr₂(bipy)₂ (Table 4). It thus follows that the variations from 22% to 41% in *cis*-weakening of the Sn–Br bonds in the adducts of dialkyldibromostannates are caused by different contributions of the ligands L into the combined effect of *cis*-weakening: THF < TMU < DMSO ≈ py ≈ bipy < HMPT.

In studies of adducts of dialkyl(diphenyl)diiodostannates it was found^{12,25} that the elongation of the Sn–I bond with respect to that in the parent adduct was accompanied by a dramatic increase in η at the iodine sites. Such an increase was observed in five of six adducts studied by NQR (Table 5), which implies that the iodine valence $5p_{\pi}$ orbitals were notably disturbed as a result of the substitution, which gives rise to an essential increase in the occupancy difference $\Delta Np_{\pi} = Np_x - Np_y$. NQR spectroscopic and X-ray diffraction data for the two adducts were correlated in order to understand the reason for this disturbance.²⁶

As one can see from Table 5, the largest increase in η upon replacement of two iodine atoms by the groups R is observed in the adducts Ph₂SnI₂(HMPT)₂ (**3**) and Et₂SnI₂(DMSO)₂ (**4**). The ¹²⁷I NQR spectrum of the adduct **3** consists of two sets of lines corresponding to two crystallographically inequivalent iodine sites having close spectroscopic characteristics. The introduction of the phenyl groups resulted in the elongation of the Sn–I bonds by 0.165 Å on average with respect to those in the nonsubstituted adduct SnI₄(TPPO)₂ whose structure is known and spectroscopic characteristics are similar to those in the yet as structurally unstudied adducts SnI₄(HMPT)₂ and SnI₄(TMU)₂ (Table 2). As the comparison of the iodine valence orbital occupancies in substituted and nonsubstituted adducts shows (Table 5), the substitution results in an increase in the iodine valence $5p_{\sigma}$ orbital occupancies (Np_z), which is a natural consequence of the *cis*-weakening of the Sn–I bonds. The latter is however accompanied by a notable increase in the iodine valence $5p_{\pi}$ orbital occupancy difference ($\Delta Np_{\pi} = Np_x - Np_y$) from 0.019 in nonsubstituted SnI₄(TMU)₂ to 0.06 in the adduct **3**.

The obvious suggestion accounting for such an increase in η in compound **3** is that secondary non-valence intra- or intermolecular contacts exist in this compound that involve the iodine atoms. The results of the X-ray study do not, however, support this suggestion: no secondary contacts were found in the structure of **3**.²⁶

In the crystals of the adduct **4**, two crystallographically inequivalent iodine positions (characterised by substantially different spectroscopic parameters) were identified by NQR. According to the X-ray diffraction data, the coordination polyhedron around tin is an octahedron with *trans* ethyl groups and *cis* DMSO molecules (Fig. 1a). Both DMSO molecules occupy disordered positions, so that the sulfur atom of one DMSO molecule occupies the positions at the opposite sides of the O(1)C(5)C(6) plane, whereas in the other molecule, both sulfur and oxygen atoms are sited at disordered positions. Table 6 lists the bond lengths and angles for the prevailing configuration of the

Figure 1. Structure of the adduct $\text{Et}_2\text{SnI}_2(\text{DMSO})_2$:²⁶ (a) molecular structure of $\text{Et}_2\text{SnI}_2(\text{DMSO})_2$, illustrating disorder in the DMSO ligands; occupancies of the atomic positions are given in parentheses; (b) crystal structure of the adduct showing non-valence contacts (dotted lines); only prevailing conformation retained.

adduct molecule. In the structure of the adduct **4**, the intramolecular $[\text{S}(2) \cdots \text{O}(1) = 3.06 \text{ \AA}$, $\text{S}(1) \cdots \text{I}(1) = 4.11 \text{ \AA}]$, and intermolecular $[\text{S}(2) \cdots \text{I}(2') = 3.79 \text{ \AA}]$ contacts (Fig. 1 b) were found, hence revealing at least one of the reasons for the increase in the value of η (39.1%) in this adduct.

On the plot giving the effective charge on the iodine atom as a function of the respective Sn–I bond lengths (Fig. 2), deviation of the point 7, corresponding to the I(1) site in the adduct **4** from the correlation line is a maximum. Note that the effective charges were evaluated assuming that the occupancy of one of the iodine $5p_\pi$ orbitals (Np_x) was equal to 2.²⁶ As Fig. 2 shows, such an assumption results in a good correlation between $-\rho$ and the Sn–I bond lengths for all the points in the adducts discussed except that for the I(1) atom in compound **4**. The effective charge

Figure 2. Correlation between the effective charges on the iodine atom ($-\rho$) and interatomic Sn–I distances (d):¹² (1) $\text{EtSnI}_3(\text{HMPT})_2$, (2) $\text{Et}_2\text{SnI}_2(\text{HMPT})_2$, (3) $\text{SnI}_4(\text{Ph}_2\text{SO})_2$, (4) $\text{EtSnI}_3(\text{Ph}_2\text{SO})_2$, (5, 6) $\text{Ph}_2\text{SnI}_2(\text{HMPT})_2$, (7, 8) $\text{Et}_2\text{SnI}_2(\text{DMSO})_2$, (9, 10) $\text{SnI}_4(\text{TMU})_2$.

on this atom (for the same values of experimentally measured QCC and η) for the point 7 to fit the correlation line should be equal to -0.69 e (Table 5), which gives the following iodine valence orbital occupancies: $Np_z = 1.778$, $Np_x = 1.979$ and $Np_y = 1.933$. Thus, the deviation of the point 7 from the correlation serves as indirect evidence that the assumption $Np_x = 2$ underestimates the Sn–I π -bonding character for the I(1) atom involved in secondary contact to sulfur. This contact is associated with the transfer of $\sim 0.042 \text{ e}$ from the iodine valence $5p_\pi$ orbitals.

The probable reason for the increased η -value (39.1%) in the adduct **3**, where no shortened contacts were found, was sought in the analysis of contributions of the iodine valence $5p$ orbital occupancies into the measured value of η . It was shown that despite similar values of the asymmetry parameters at the iodine sites in **3** and the I(1) site in **4** the difference $\Delta Np_\pi = Np_x - Np_y$ in the latter adduct is less than in the former one. As has been mentioned above, the alkyl substituents weaken the respective Sn–I bonds to a greater extent than the phenyl groups, thus producing higher occupancy of the iodine $5p_\sigma$ orbitals. A sharp increase in the experimentally measured η -value occurs, at the fixed $\Delta Np_\pi = Np_x - Np_y$ difference, as the σ -electron density at the iodine atom (Np_z) increases (Fig. 3), i.e., the enhanced *cis*-weakening of the Sn–I bond due to substitution results, at a given ΔNp_π difference, in an increase in the asymmetry parameter η caused by the increased contribution to the latter of the iodine valence $5p_\sigma$ orbitals. Indeed, the closely similar values of η in **3** and at the I(1) site in **4** are associated with a relatively smaller iodine $5p_\pi$ orbital occupancy difference in the latter adduct, since the alkyl substituents favour an increase in σ -electron density on the iodine atoms to a larger extent than the phenyl groups do.

Thus, an increase in the η -value in the adduct **4** (Table 5) is caused by the combined contribution of the iodine valence $5p_\sigma$ orbitals, whose occupancy increases upon substitution, and the shortened I $\cdots$ S contacts responsible for an increase in ΔNp_π . As to the increased ΔNp_π difference in the adduct **3**, this is most

Table 6. Bond lengths (d) and bond angles (α) in the adduct **4**.²⁶

Figure 3. Measured value of the EFG asymmetry parameter (η) at the iodine atom as a function of its valence π -orbital occupancy difference ($Np_x - Np_y$) for various σ -orbital occupancies (Np_z);²⁶ (1) is the point corresponding to the point (7) and (2), to the points (5) and (6) on the plot of Fig. 2.

probably associated with the interaction of the iodine π -system with those of the phenyl rings. This suggestion is supported by the fact that in the $\text{Et}_2\text{SnI}_2(\text{HMPT})_2$ adduct, which is a dialkyl analogue of **3** comprising no cyclic fragments in the ligands and substituents, the alkyl groups did not give rise to an increase in ΔNp_π and consequently in the EFG asymmetry parameter η . However, replacement of the ethyl by phenyl substituents affected dramatically the asymmetry parameter η , although no proper structural manifestations could be registered by X-ray diffraction. This is one of a few examples illustrating a possibility to detect, using NQR, the electronic effects, whose structural manifestations lie below the sensitivity of X-ray experiments. Yet another example was given above in the effects of *trans*-strengthening. The accuracy of their determination in chlorides is, as a rule, comparable to the standard deviations, whereas the corresponding variations of the NQR parameters notably exceed the errors of measurement. It is however to be noted that there are many other systems in which π - π interactions were clearly revealed by X-ray studies. For instance, the π - π interactions between the iodine atoms and phenyl rings were earlier found by X-ray in several imidazopyridinium salts.²⁷

The NQR and X-ray data yield complementary pieces of valuable information. A correlation between them on a quantitative scale contributes to the further progress in understanding the electronic effects of substitution in adducts and complexes of tin(IV) halides, augmenting the current view by information on relative importance of the σ - and π -electron systems in electron density redistribution.

III. Electronic characteristics of M – Hal bonds in hexa- and pentacoordinate adducts of tin(IV) tetrachlorides; similarities and differences

In this section, the M – Hal bond reorganisation in adducts of tin tetrachlorides resulting from the change in the central metal coordination number is discussed. The data on electron density redistribution due to spatial rearrangement of adducts, especially those of silicon and germanium, are scanty. The literature on ^{35}Cl NQR studies of hexa- and pentacoordinate adducts of tin tetrachloride is more extensive. However, *cis*–*trans* isomerism of hexacoordinate tin(IV) adducts complicated comparative studies of the bond electronic characteristics in these compounds, because no reliable spectroscopic criteria of either isomerism or assignment of the ^{35}Cl NQR frequencies in *cis*-isomers to axial–equatorial chlorine atoms were available.

NQR studies of pseudooctahedral adducts SnCl_4L_2 have received major attention. The subjects of investigations were the structures of the compounds,^{28–34} charge distribution over acceptor molecules,^{33–39} relation of the ligand donating power to the strength of the produced adducts judging from spectroscopic data⁴⁰ and identification of isomers based on their NQR spectra.^{40–42} A bibliography on these problems covering the period since 1980 to the beginning of the 90's may be found in a review.⁴³

Studies on isomerism of pseudooctahedral adducts of tin tetrachloride show⁴⁰ that the frequency splitting in the NQR spectra of *cis*-isomers (*i.e.*, the difference between the frequencies of equatorial and axial chlorine atoms) cannot serve as a reliable criterion of isomerism, because its magnitude decreases as the donating power of ligands L increases. For strong adducts, this prevents the spectroscopic identification of *cis*- and *trans*-isomers. An unambiguous identification of isomers is further complicated where the NQR spectra of *trans*-isomers are affected by crystal-field effects, which enhance the frequency splitting, and mask their difference from the spectra of *cis*-isomers. Temperature dependences of the NQR frequencies of equatorial and axial chlorine atoms do not always clarify the situation.^{41,42} For the isomers with established *cis*-configuration, the assignment of resonance frequencies to equatorial–axial atoms is also ambiguous. According to the X-ray data available on a relatively few *cis*- SnCl_4L_2 adducts, the number of adducts whose axial Sn–Cl bond distances are shorter than the equatorial ones is approximately the same as that whose axial Sn–Cl bond distances exceed equatorial. The identification of a large number of SnCl_4L_2 isomers was made⁴⁰ assuming that in NQR spectra of both *cis*- and *trans*-isomers the ^{35}Cl frequencies of the atoms making a linear Cl–Sn–Cl fragment are close to each other if the donating powers of ligands L are similar. As a result, the higher ^{35}Cl frequencies in the NQR spectra of *cis*-isomers were erroneously assigned to linear Cl–Sn–L fragments.

Thus, a considerable body of experimental data showed that neither frequency splittings and line multiplicity nor temperature dependence of the NQR frequencies can be recognised as reliable criteria for identification of isomers. However, the symmetry considerations suggest that the EFG asymmetry parameters at axial–equatorial chlorine sites may possibly serve as such criteria, although the values of η and QCC cannot be simultaneously found, without additional experiments, from only one transition frequency for nuclei with $I = 3/2$ having two degenerate quadrupole levels. Conventional Zeeman NQR experiments with single crystals are however complicated and tedious, serious limiting factors being duration of experiments and problems of growing large single crystals of tin tetrachloride adducts, most of which are hygroscopic.

Attempts at experimental determination of η at the chlorine atoms in powder samples were undertaken⁸ using a modified approach³ based on Fourier analysis of slow beats of the spin-echo envelope in an external magnetic field. The experiment was run according to the scheme: NQR spectrometer $\longleftrightarrow$ programmer and digitiser $\longrightarrow$ box-car integrator $\longrightarrow$ computer. The programmer and digitiser were adapted to the tube levels of NQR signals. Instead of the conventional Fourier transform used in NMR spectroscopy, the data processing involved expansion of a signal to harmonics followed by numerical integration for determining the expansion coefficients. As a result, the accuracy of the analysis increased, whereas its duration remained shorter than the time of signal accumulation. The Fourier transform programme was used which yielded a graphic representation of both the accumulated spectrum of slow beats and its expansion into harmonics. This easy-to-grasp form of representation of the results enabled the authors to monitor the data processing checking the operation for errors. The accuracy of η measurements performed by this procedure even on weak ^{35}Cl signals was fairly high.

In subsequent experiments, the results of determination of η in a number of *cis*- and *trans*-isomers of SnCl_4L_2 adducts con-

firmed¹¹ that the EFG asymmetry parameters can actually be used for identification of isomers (Tables 7 and 8). Thus the magnitudes of η on axial chlorine atoms in *cis*-isomers appeared to be zero unless lattice contributions raised its value by several percent. On equatorial Cl atoms of both isomers, the η -values were usually noticeably higher, varying around 10% in the majority of the compounds.

For comparison, the results of Zeeman analysis of single crystals at 297 K, 293 K and 235 K available for several hexacoordinate adducts, are also listed in Tables 7 and 8.^{44–46} They are in reasonable agreement with those obtained with powder samples: the magnitudes of orbital occupancies and effective charges on the chlorine atoms derived from both experiments are consistent with each other. The approach for measuring η in powder samples simplified the experiment and markedly cut its time. The important benefit to the user consists in avoiding a tedious long-term procedure of growing large single crystals required for the NQR Zeeman experiments.

The determination of the total set of NQR spectroscopic parameters (the transition resonance frequencies ν , quadrupole coupling constant QCC and EFG asymmetry parameter η) for a number of adducts, which became possible due to the use of powder samples, revealed the regularities of electron density redistribution between axial–equatorial bonds (Fig. 4) which thereafter allowed identification of *cis*- and *trans*-isomers of some adducts that had not been studied structurally based only on the NQR frequency measurements.¹⁰

The ³⁵Cl NQR frequencies assigned to the axial chlorine atoms in the spectra of all the *cis*-isomers examined¹⁰ appeared to be higher and the σ -electron density on the respective Cl atoms lower than those on the equatorial chlorine atoms. The frequency ranges assigned to axial and equatorial Cl atoms did not virtually overlap, so that the corresponding frequencies in the spectra of *cis*-isomers were found in the intervals (MHz) $17.5 < \nu_e < 19.8 < \nu_a < 22.0$, whereas the region covered by the ³⁵Cl frequencies in the spectra of *trans*-isomers was slightly shifted downwards: $17.2 < \nu_e < 19.4$. The effective charges on the Cl atoms were practically insensitive to the kind of isomerism of the adduct, their magnitudes being approximately the same on both

Figure 4. The diagrams of ³⁵Cl NQR spectra of pseudooctahedral adducts: *trans*-SnCl₄L₂ (a), *cis*-SnCl₄L₂ (b), trigonal-bipyramidal adducts SnCl₄L (c) and parent tin tetrachloride (d). axial and equatorial chlorine sites and in both types of isomers (Tables 7 and 8).

The results of the study cited (Ref. 10) show that the *cis*-isomer of adduct SnCl₄L₂ can be identified by the presence in its NQR spectrum of the ³⁵Cl signals at frequencies above 19.8 MHz, which should be assigned to the axial Cl–Sn–Cl fragments. More than 80% of *trans*-isomers examined so far gave NQR spectra with the ³⁵Cl average frequencies below 18.3 MHz, while 80% of *cis*-isomers had them above 19.3 MHz. It is to be emphasised however that the above regularities in electron density distribution are only valid for the molecular adducts, whose chlorine atoms are bonded only to the central atom and are not involved in secondary inter- or intramolecular interactions.

Table 7. ³⁵Cl NQR spectroscopic parameters for *trans*-isomers of hexacoordinate adducts of tin tetrachloride at 77 K and the M–Cl bond characteristics.⁹

For the latter compounds, the results of X-ray study are consistent with those of NQR measurements: their axial Sn – Cl bond distances were found to be shorter than the equatorial ones. However, it is clear that the EFG asymmetry parameter on the chlorine atom will increase, if this atom is involved in additional (inter- or intramolecular) interactions, as it is observed in $\text{SnCl}_4(\text{SeOCl}_2)_2$.⁴⁵ The respective ^{35}Cl frequency in the NQR spectrum of the adduct decreased, and the ratios between the axial – equatorial resonance frequencies and Sn – Cl bond distances were inverted (Table 8).

The spectroscopic regularities found for the isomeric chloro adducts are not universal. Tin tetrabromide and tetraiodide adducts show different positional order of the NQR frequencies assigned to axial and equatorial halogen atoms due to different relationships between the electron-donating (withdrawing) properties of ligands L and halogens and relatively lesser contribution

to the EFG of crystal-field effects as compared to the contribution of their own valence orbitals. This is illustrated in the results of NQR studies of hexacoordinate adducts SnBr_4L_2 .²³ Although the ^{81}Br frequency ranges assigned to axial and equatorial Br atoms in the NQR spectra of *cis*-isomers also did not overlap (Table 9), their mutual positions were inverted with respect to those in the ^{35}Cl NQR spectra of the chloro analogues, *i.e.*, the ^{81}Br NQR frequencies of axial bromine atoms were lower than those of equatorial in all the *cis*-isomers studied: $112 < \nu_a < 126$ MHz; $128 < \nu_e < 142$ MHz. In agreement with the NQR data, the results of X-ray studies available for the *cis*- SnBr_4L_2 adducts gave axial Sn – Br bond distances exceeding the equatorial ones.²³ In the spectra of *trans*-isomers, the ^{81}Br NQR frequency range was relatively larger than the corresponding ^{35}Cl frequency range in the spectra of chloro adducts, the former interval covering almost the entire $(\nu_e + \nu_a)$ frequency range of *cis*-isomers:

$115 < \nu_e < 138$ MHz. Thus, the ^{81}Br NQR frequency ranges in the spectra of *cis*- and *trans*-isomers of the SnBr_4L_2 adducts were found to overlap. This implies that, unlike in the related chloro adducts, the EFG asymmetry parameters at the Br nuclei in the bromo adducts should be measured for the spectroscopic identification of isomerism. The mutual position of the ^{81}Br frequency ranges assigned to axial–equatorial bromine atoms indicates the prevailing electronic influence of ligands on the electron density redistribution in *cis*- and *trans*-isomers of the adducts SnBr_4L_2 .

As a whole, the NQR results on isomers of hexacoordinate adducts SnHal_4L_2 show^{9, 11, 18, 23} that the measurement of the EFG asymmetry parameters along with examination of the spectroscopic shifts, splittings and temperature dependence of the resonance frequencies made it possible to identify the type of isomerism of the adducts from their NQR spectra, even though the latter exhibit complicated patterns of the shifts and splittings. The average NQR frequency shifts at halogen atoms in adducts with respect to their frequencies in parent SnHal_4 can serve as a measure of the strength of the adducts formed provided the resulting increase in the halogen σ -electron density in the acceptor is mainly due to intramolecular electronic effects, the contributions of the crystal-field effects being much less significant.

Table 10 lists the ^{35}Cl NQR spectroscopic parameters for trigonal-bipyramidal adducts of tin(IV) having the coordination number 5. The corresponding spectra differ notably from those for pseudooctahedral adducts (Tables 7 and 8). They comprise the triplets from equatorial Cl atoms at frequencies slightly different from those of the parent tetrachloride, and the singlets from axial chlorine atoms, shifted considerably to lower frequencies, which indicates that the electron density in such adducts is mainly transferred from the ligands L to the axial chlorine atoms.

In both trigonal-bipyramidal and pseudooctahedral adducts, the asymmetry parameters on equatorial chlorine atoms exceed those on the axial atoms and vary within similar limits. Accordingly, the corresponding valence $3p_\pi$ orbital occupancy differences are also close to each other. The main difference between these two types of adducts consists of the magnitudes of the $3p_\sigma$ orbital occupancies (Np_z) at equatorial chlorine sites. In trigonal-bipy-

amid adducts, the absolute values of Np_z are by 0.1 lower than those in the pseudooctahedral adducts, whereas the spectroscopic and electronic characteristics of their Sn—Cl axial bonds differ insignificantly. As is seen from Tables 7, 8 and 10, the overall effective charge $|\sum \rho|$ on all the chlorine atoms in the octahedral adducts is markedly larger than that in the parent tetrachloride SnCl_4 , while in trigonal-bipyramidal adducts, the corresponding difference is small. This supports a conventional idea of relatively larger extent of charge transfer in octahedral adducts. The NQR data on pseudooctahedral adducts show that the overall σ -electron density on chlorine atoms in *trans*-isomers is on average slightly higher than that in *cis*-isomers.

IV. Penta- and hexacoordinate adducts of silicon and germanium tetrachlorides

The ^{35}Cl NQR spectroscopic parameters and M—Cl bond characteristics in adducts MCl_4L (M = Si, Ge) are summarised in Table 11, which clearly demonstrates the similarities of the spectral patterns to those of the related tin compounds: the NQR spectra of the adducts of all three elements consist of triplets from equatorial atoms, slightly shifted relative to the frequencies of parent tetrachlorides MCl_4 , and lower-frequency singlets from axial chlorine atoms. However, the electronic characteristics of equatorial M—Cl bonds in adducts of different central metals M are markedly different. Thus η on the equatorial chlorine atoms was found to increase considerably in the order: $\text{Sn} < \text{Ge} < \text{Si}$. In silicon adducts, this increase was accompanied by a fall of the ^{35}Cl frequencies with respect to both the germanium and tin adducts and CCl_4 , which can be accounted for by an increase in the π -character of the Si—Cl bonds. The participation of the chlorine

$3p_\pi$ orbitals in bond formation results in their reduced occupancies Np_x and Np_y , whose sign in equation (1) is opposite to that of the $3p_\sigma$ orbital occupancy Np_z . This causes a decrease in both U_p and frequency with respect to those for the purely σ -bonded chlorine atom. In the latter case, the value of e^2Qq_{zz}/h becomes a measure of the chlorine valence $3p_\sigma$ orbital occupancy. One cannot make an independent estimation of the M—Cl bond σ - and π -characters, *i.e.*, determine three unknowns, σ , π_x and π_y from two equations (1) and (2). A spatial arrangement of ligands is however possible where the central atom M can interact with only one chlorine p_π orbital ($3p_x$), the occupancy of the other ($3p_y$) remaining undisturbed ($Np_y = 2$). Denoting $\pi_x = \pi$, we obtain equation (2) in the form

$$\eta = \frac{3\pi}{2U_p}, \quad (5)$$

so that η becomes a measure of the M—Cl π -bonding. One can now determine both parameters, σ and π , from equations (1) and (5). Such an arrangement is often the case in trigonal-bipyramidal adducts MCl_4L . The estimation of their M—Cl bond σ - and π -characters (Table 11) shows that in the silicon adducts the decrease in the equatorial ^{35}Cl frequency and increase in η result from substantial increase in the Si—Cl π -bonding. In the germanium adducts, the π -bonding is relatively weaker, whereas in SnCl_4L the η values exhibit a further considerable fall. They comprise a significant contribution from external charges, which is more pronounced than in analogous germanium and silicon adducts because of the larger Sn—Cl bond ionicity. This is supported by relatively higher values of η on axial Cl atoms in comparison with equatorial in the SnCl_4L adducts than in related silicon and germanium adducts.

Only a few results of NQR studies are currently available on pseudooctahedral adducts of silicon and germanium tetrahalides (Table 12), most important being the value of the asymmetry parameter η on the chlorine atoms in the only *cis*-isomer of the adduct SiCl₄L₂. This enables one to assign the ^{35}Cl NQR frequencies to equatorial and axial chlorine atoms and find that their positional order on a frequency scale is inverted with respect to that in analogous tin adducts: unlike in the latter, the lower-frequency components in the spectra of silicon adducts are assigned to axial Cl atoms. Unfortunately, lack of data on *cis*-isomers does not allow one to conclude whether this order is typical of silicon adducts.

Table 13 lists the M—Hal bond characteristics and effective charges on halogen sites in all the spectroscopically examined pseudooctahedral (MCl₄L₂) and trigonal-bipyramidal (MCl₄L)

Table 13. Average effective charges ($-\rho$) on chlorine atoms and chlorine valence $3p$ orbital occupancies ($Np_\sigma = Np_z$, $\Delta Np_\pi = Np_x - Np_y$) in adducts MCl₄L and MCl₄L₂.

adducts of silicon and germanium tetrachlorides. The corresponding characteristics for SnCl₄L₂ and SnCl₄L averaged over all the known examples are also included in the table. One can see that the chlorine $3p_\pi$ orbital occupancy differences at equatorial sites ($\Delta Np_\pi = Np_x - Np_y$) in all the hexacoordinate adducts MCl₄L₂ (M = Si, Ge, Sn), are close to each other, the main difference between the adducts consisting in the chlorine $3p_\sigma$ orbital occupancies. The absolute magnitudes of the effective charge ρ on the equatorial chlorine atoms vary in the order: Sn $\sim$ Si > Ge. When the adduct of pseudooctahedral configuration is compared to that of trigonal-bipyramidal geometry, one can find that the axial M—Cl bond characteristics differ insignificantly in both types of the adducts, whereas the equatorial bonds are markedly different, the difference being determined by the nature of the central atom. The effective negative charge on the equatorial chlorine atom increases in absolute value as the coordination number of the central atom increases (Table 14). In the tin adducts, this increase in the charge is nearly fully induced by the increase in chlorine $3p_\sigma$ orbital occupancy, whereas in the germanium and especially in the silicon adducts, it is provided by both the increased chlorine $3p_\sigma$ orbital occupancy and reduced ΔNp_π . This may be accounted for by the increased local symmetry of the Cl site in a crystal as well as the M—Cl bond elongation accompanying an increase in the coordination number. In germanium tetrachloride adducts, the contributions of the $3p_\sigma$ - and $3p_\pi$ -systems to the effective charge increment on the Cl atom amount in absolute magnitude to 0.104 and 0.059, respectively; in the silicon adducts, the contribution of the chlorine $3p_\pi$ orbitals to the respective increment exceeds that of the $3p_\sigma$ orbitals (0.079 and 0.069, respectively).

Table 14. Average values of effective charges on equatorial chlorine atoms and chlorine valence $3p$ orbital occupancies in adducts MCl₄L and MCl₄L₂ and variations of their absolute magnitudes ($\delta\rho$, δNp_σ , $\delta\Delta Np_\pi$) due to the change MCl₄L $\rightarrow$ MCl₄L₂.

Adduct	$-\rho(\text{Cl})/\text{e}$	Np_σ	ΔNp_π	$\delta\rho/\text{e}$	δNp_σ	$\delta\Delta Np_\pi$

Thus, the NQR data available on the trigonal-bipyramidal SiCl₄L and GeCl₄L adducts provide evidence that the $3p_\pi$ -systems of the equatorial Si—Cl and Ge—Cl bonds contribute considerably to the bond formation, the estimated π -character amounting on average to 0.1 and 0.08, respectively. It should be noted however that the NQR data enable one to compare an extent of participation of the equatorial chlorine $3p_\pi$ electrons in the M—Cl bonding, whereas the question of the mechanism of the π -interaction remains open. In addition, the magnitude of ΔNp_π may not be a measure of the M—Cl bond π -character in pseudooctahedral adducts SiCl₄L₂ and GeCl₄L₂, if the electron density is withdrawn from both chlorine $3p_\pi$ orbitals; in this case, the true extent of the π -character will be higher than that estimated from ΔNp_π . This also holds for the parent tetrachloride molecules having slightly distorted tetrahedral structures.⁴⁸

The variation of the chlorine valence p orbital occupancies upon adduct formation was discussed based on the results of PM3 calculations of model acceptor molecules and adducts MCl₄L and MCl₄L₂ (M = Si, Ge, Sn).^{37,38} The M—Cl bond π -character was

identified by the authors with the magnitude of ΔNp_π determined in the parent tetrachlorides by the NQR experiments.⁴⁷

For SiCl_4 and GeCl_4 , such an estimation gave $\pi = 0.007$, which resulted in the considerably overestimated absolute value of the negative effective charge on the chlorine atom: $\rho(\text{Cl}) = 0.618$ and 0.525 e in SiCl_4 and GeCl_4 , respectively. Hence, the entire charge on the chlorine atoms $|\sum \rho(\text{Cl})|$ was 2.472 e in SiCl_4 and 2.1 e in GeCl_4 , which notably exceeded in absolute magnitude the appropriate charges in adducts MCl_4L , namely, 1.983 e in $\text{SiCl}_4 \cdot \text{NMe}_3$ and 1.912 e in $\text{GeCl}_4 \cdot \text{NMe}_3$.

The contradictions arisen were accounted for^{37,38} by the difference between the symmetry of free MCl_4 molecules (T_d) and the symmetry of the same molecules in the adducts (D_{3h} in MCl_4L and D_{4h} in MCl_4L_2). The results of PM3 calculations showed that the total effective charge on the chlorine atoms $|\sum \rho(\text{Cl})|$ in hypothetical MCl_4 molecules, whose symmetry and $\text{M}-\text{Cl}$ bond distances are the same as those in the corresponding adducts, was reduced as a result of the molecular spatial rearrangement only (the charge transfer being ignored) up to 2.184 e in SiCl_4 and 1.988 e in GeCl_4 . However, it is to be noted that similar characteristics ($|\sum \rho(\text{Cl})|$) of the MCl_4 molecules in the adducts $\text{SiCl}_4 \cdot \text{NMe}_3$ and $\text{GeCl}_4 \cdot \text{NMe}_3$ estimated from the orbital occupancies using the PM3 approach^{37,38} decrease accordingly:

Atom	a/e	Np_z	$Np_x + Np_y$	$Np_x - Np_y$	$-\rho/\text{e}$	$\sum \rho(\text{Cl})/\text{e}$
$\text{SiCl}_4 \cdot \text{Me}_3\text{N}$						
Cl	a	1.579	3.911	0.016	0.490	1.504
Cl	e	1.440	3.898	0.044	0.338	—
$\text{GeCl}_4 \cdot \text{Me}_3\text{N}$						
Cl	a	1.481	3.903	0.019	0.384	1.176
Cl	e	1.381	3.883	0.055	0.264	—

One can see that the calculated η values at the equatorial Cl atoms in the adducts in question (16.4% in $\text{SiCl}_4 \cdot \text{NMe}_3$ and 20.7% in $\text{GeCl}_4 \cdot \text{NMe}_3$)^{37,38} do not reflect even qualitatively the trends observed in experiments (see the measured magnitudes of η in Table 11).⁴⁷ Hypothetical molecules MCl_4 having the D_{4h} symmetry and $\text{M}-\text{Cl}$ bond distances characteristic of those in pseudooctahedral adducts MCl_4L_2 were calculated to give the largest values of η at the chlorine atoms, namely, $\eta \approx 31\%$ in SiCl_4 , 37% in GeCl_4 and 33% in SnCl_4 .^{37,38} Meanwhile, the experimental Z values at chlorine atoms did not exceed 15% in any of the measured MCl_4L_2 adducts (Tables 7 and 8), unless this atom is involved in secondary inter- or intramolecular interactions, as in the adducts $\text{SnCl}_4(\text{SeOCl}_2)_2$ and $\text{SnCl}_4(\text{EtOH})_2$ (Table 8). Moreover, the average values of η at the equatorial chlorine atoms in the adducts SiCl_4L_2 and GeCl_4L_2 are notably lower than in the related trigonal-bipyramidal adducts SiCl_4L and GeCl_4L .

There is no question that spatial reconstruction of an acceptor molecule upon complexation is accompanied by electron density redistribution. However, the orbital occupancies calculated within the PM3 approximations do not account for the inconsistency between the effective charges on the chlorine atoms in free acceptor molecules and their adducts,^{37,38} nor the reasons for the increase in the π -character of the $\text{M}-\text{Cl}$ equatorial bonds in the adducts MCl_4L ($\text{Sn} < \text{Ge} < \text{Si}$) found in NQR experiments.⁴⁷

But no inconsistency arises if one takes into account that the T_d symmetry of the parent tetrachloride molecules allows for the participation of both chlorine $3p_\pi$ orbitals in bond formation, whereas one can measure by NQR only the difference between their occupancies. Let us take the values of Np_x and Np_y in SiCl_4 (fitting the measured NQR frequencies and η), which give rise to the $\text{Si}-\text{Cl}$ bond π -character typical of the equatorial $\text{Si}-\text{Cl}$ bonds in the adducts SiCl_4L (for example, $\pi = 0.093$, $Np_x = 1.957$, $Np_y = 1.950$). One can find herefrom that the corresponding effective charges on the Cl atoms in the SiCl_4

molecules ($\rho = -0.49$ e, $\sum \rho(\text{Cl}) = -1.96$ e) are consistent with those in the SiCl_4L adducts ($-2.1 > \sum \rho(\text{Cl}) > -2.3$ e, see Table 11), hence allowing for the charge transfer from the ligand L to the acceptor SiCl_4 .

The problem of electron density distribution in Main Group IV element chloro complexes has received much attention in Refs 34–39. The results of semiempirical quantum-chemical calculations were reported, and their conformity to the data obtained using the NQR, Mössbauer and X-ray fluorescence spectroscopies were discussed. It was found that upon complexation, the positive charge on the central atom of the acceptor molecule increases with respect to that in the free MCl_4 molecule, which is in agreement with the results of other publications.⁴³ It was however noted that according to the X-ray fluorescence spectroscopy data ($\text{Cl}K_\alpha$ -shifts), the electron density on the chlorine atoms in the adducts MCl_4L_2 either remains unchanged or decreases as compared to free MCl_4 . The reader is referred to a review⁴³ where the criticism of this conclusion was given.

The quantum-chemical calculations of the trigonal-bipyramidal adducts $\text{SiCl}_4 \cdot \text{NMe}_3$ (**5**), $\text{SiCl}_4 \cdot \text{CO}(\text{NMe}_2)_2$ (**6**) and pseudooctahedral $\text{SiCl}_4 \cdot (\text{py})_2$ adduct (**7**) were made within the MNDO approximations.^{49–52} The changes in silicon, nitrogen, oxygen and chlorine valence p orbital occupancies as well as the effective charges on the appropriate atoms were considered as functions of the reaction coordinate of complexation, the considered separation between the components of the adducts varying from infinity ($d = 200$ Å) to 1.5 Å. As the calculated heats of formation showed, the most energetically favourable structures of **5** and **6** were those with the ligand L in axial and equatorial positions of the bipyramid, respectively, which is in agreement with their ³⁵Cl NQR spectral patterns (Table 11).

When the shape of the SiCl_4 molecule changes from tetrahedral to that in the adduct **5** (at $d = 200$ Å), the effective charge on the silicon atom decreases in absolute magnitude by 0.116 e, and that on the equatorial chlorine atom, by 0.059 e, whereas the absolute magnitude of the negative charge on the axial chlorine atom increases by 0.061 e. When the components of **5** approach each other to reach $d = 2.25$ Å, at which distance the heat of adduct formation is a minimum, the effective charge on silicon begins to grow. At the same time, the negative charge on nitrogen decreases and that on chlorine, increases in absolute value, the increment being larger on the equatorial Cl atoms. It was estimated^{50,52} that the formation of **5** results in the transfer of electron density of 0.2 e from the donor (mainly, from the nitrogen lone pair p_x orbital) to the acceptor (mainly, to the equatorial chlorine p_σ orbitals) molecule, which is in good agreement with experiment.⁴⁷ However, low sensitivity of this semiempirical method to the chlorine $3p_\pi$ orbital occupancies was noted. The calculated differences between the equatorial chlorine $3p_x$ and $3p_y$ orbital occupancies in the adduct **5** were negligibly small, whereas the experimental asymmetry parameters η on these atoms were large, the corresponding ΔNp_π values contributing considerably to the effective charge values (Table 11). Thus, the estimation of the effective charge on chlorine atoms from the calculated orbital occupancies^{50,52} is not quite reliable.

A similar calculation for the adduct **6**^{51,52} with a tetramethyl-urea ligand occupying an equatorial position shows that the formation of **6** also results in the transfer of the charge from the donor to chlorine atoms of the acceptor molecule, but in this case, the electron density is mainly transferred to the axial chlorines. The donor atoms are carbon of the carbonyl group, one of the nitrogen atoms and hydrogens from the dimethylamino groups, both p_σ and p_π orbitals of the carbonyl group contributing to the charge transfer. An increase in positive charge on silicon and in negative charge on oxygen upon adduct formation is caused presumably by polarisation of the $\text{Si}-\text{Cl}$ and $\text{Si}-\text{O}$ bonds.^{51,52} The p_σ orbital occupancies of the axial (1.591 e) and equatorial (1.523 e) chlorine atoms in **6**, found by the MNDO calculations, are in agreement with the observed trends (Table 11), while the

values of Np_x and Np_y at the equatorial chlorine atoms showed, as in **5**, poor agreement with experiment.⁴⁷

The results of MNDO calculations of **5**, **6** and pseudooctahedral **7** adducts were summarised⁵² to conclude that the formation of all the three adducts results in an increase in positive charge on the silicon atom, the conclusion being supported by the Mössbauer and X-ray fluorescence spectroscopy data^{34–36} available on the adducts of Main Group IV element tetrachlorides. The increasing charges, positive on silicon and negative on nitrogen, gave the authors⁵² grounds to believe that the electrostatic interactions resulting in polarisation of the bonds contribute considerably into the electron density distribution upon complexation. The electrostatic interactions initiate the charge transfer: the estimated total charge located on the acceptor fragment of the adduct was negative (-0.523 e in **7**) and that on the donor fragments, positive ($+0.206$ e per pyridine ring in **7**).

In order to compare the chlorine orbital occupancies calculated within the MNDO approximations with those derived from the NQR experiment the assumption was made⁵² (in the absence of the published η values) that the values of η at the equatorial chlorine atoms in pseudooctahedral adducts SiCl_4L_2 are similar to those for trigonal-bipyramidal adducts SiCl_4L . Thus, the value $\eta = 0.4$, which is the average for the SiCl_4L adducts, was used to estimate Np_x (at $Np_y = 2$) at the equatorial Cl atoms in **7**. This gave $Np_x = 1.909$ and $\Delta Np_\pi = 0.09$, the latter being considerably overestimated compared to the correct value $\Delta Np_\pi = 0.015$ derived from the recently measured η in $\text{SiCl}_4 \cdot 2\text{py}$. As was noted above, the values of ΔNp_π at the equatorial chlorine atoms, derived from the NQR spectra of SiCl_4L_2 and GeCl_4L_2 , are markedly lower than those in analogous trigonal-bipyramidal adducts. But even this correct magnitude of ΔNp_π exceeded considerably the value $\Delta Np_\pi = 0.004$ (and hence $\eta = 0.016$) found by the MNDO calculations.⁵² Therefore, for the pseudooctahedral adduct **7**, the MNDO approach also gave an η value in poor agreement with experiment (Tables 11 and 12).

It was however reported⁵³ that the results of calculations of η can be in much better agreement with the experiment if one takes into account that the EFG (q_{zz} , q_{xx} , q_{yy}) at the quadrupole atom is produced not by its entire valence p shell, but its less diffuse part which can be determined by *ab initio* calculations of a large

number of molecules in the split valence basis set 6-31G* using full optimisation of the molecular geometry.

It is reasonable to discuss how the differences in the M–Cl bond characteristics influence the formation by silicon, germanium and tin tetrachlorides of pentacoordinate adducts with ligands of various donating power. Before discussing this problem, the bonding in the parent tetrachlorides should be considered in more detail. Note once more that the values of η measured in tetrahedral MCl_4 molecules and octahedral adducts MCl_4L_2 using spin-echo technique and powder samples^{9,47} were in agreement with those measured with single crystals of similar compounds,^{44–46,48} whereas earlier experiments^{54,55} using continuous-wave techniques for measuring η with powder samples of MCl_4 (M = Si, Ge, Sn), yielded the asymmetry parameters η , whose values were an order of magnitude higher than those given in Tables 10 and 11, which is unlikely on symmetry grounds. An independent estimation of the M–Cl bond σ - and π -characters from equations (1) and (2) is impossible in these molecules, because η at chlorine sites is equal to zero ($Np_x = Np_y$), and two unknowns, σ and π , remain in equation (1). The probable intervals for the values of M–Cl bond σ - and π -characters in MCl_4 were found based on the data obtained for the adducts MCl_4L .⁴⁷ The magnitude of the entire effective charge $|\sum \rho(\text{Cl})|_{\text{MCl}_4}$, born by all the chlorine atoms in the parent molecule MCl_4 , was varied with respect to the related value for the adducts $|\sum \rho(\text{Cl})|_{\text{MCl}_4\text{L}}$, assuming that the latter is at least no less than the former: in fact, an increase in the entire effective charge on the chlorine atoms $|\sum \rho(\text{Cl})|_{\text{MCl}_4}$, depending on the amount of charge transferred from the donor L, is normally observed upon adduct formation.

For the silicon compounds, the results of varying the difference $\Delta = |\sum \rho(\text{Cl})|_{\text{SiCl}_4\text{L}} - |\sum \rho(\text{Cl})|_{\text{SiCl}_4}$ showed that the strengthening of the equatorial Si–Cl bonds by virtue of both σ and π orbitals is expected in the adduct with respect to SiCl_4 as Δ varies in the interval $0 < \Delta < 0.18$ e (Table 15). This implies that if the extent of charge transfer from the ligand L is small (due, for instance, to the weak donating power of ligands L), the adduct formation will be accompanied by an additional charge transfer from the equatorial chlorine atom σ and π orbitals to the axial ones. When the extent of charge transfer is increased, so that Δ varies in the interval $0.18 < \Delta < 0.21$ e, weakening of the equa-

Table 15. Variation of chlorine valence $3p_z$ orbital occupancies (δNp_σ) and equatorial M–Cl bond π -character ($\delta\pi$) in adducts MCl_4L in relation to the difference Δ between the total effective charges on the chlorine atoms in the adduct and parent tetrachloride MCl_4 .

torial Si—Cl bonds through the π -mechanism is expected, *i.e.*, increase in the electron density will partly localise on the equatorial chlorine atom $3p_\pi$ orbitals of the acceptor molecule being withdrawn from their $3p_\sigma$ orbitals until Δ reaches 0.21 e, after which the weakening will occur through the σ -system also.

The variation of Δ should evidently proceed within reasonable limits. The situation where the π -bonding in SiCl_4 exceeds the equatorial Si—Cl bond π -character in the adducts seems improbable. From the other side, the assumption of pure σ -bonds in SiCl_4 leads to the conclusion that the total σ -electron density in the acceptor molecule decreases considerably upon adduct formation, which is also unlikely. It thus follows that the most probable limits for variation of Δ , associated with the formation of the adducts SiCl_4L , are $0 < \Delta < 0.30$ e.

Similarly, strengthening of the equatorial Ge—Cl bonds in the adducts GeCl_4L with respect to GeCl_4 is first expected as the extent of charge transfer increases within $0 < \Delta < 0.22$ e, which is then followed by their weakening at $\Delta > 0.22$ e. But unlike the silicon adducts, the Ge—Cl bond strengthening involves the π -system only, whereas the chlorine $3p_\sigma$ orbital occupancy can only increase, whatever small extent of charge transfer may be in the germanium adducts (Table 15). The range for variation of Δ associated with the formation of the adducts GeCl_4L ($0 < \Delta < \sim 0.40$ e) is here larger than for the silicon adducts. As to the adducts SnCl_4L , their equatorial Sn—Cl bonds weaken at $\Delta > 0.13$ e.

Thus, the NQR data, if not providing the undisputable absolute magnitudes of the electronic characteristics, reveal considerable difference between the equatorial M—Cl bonds in trigonal-bipyramidal adducts of silicon, germanium and tin tetrachlorides. This difference determines specific changes in their σ - and π -components when going to the adducts of pseudooctahedral configuration. Several characteristic distinctions, depending on the nature of the central atom M and donating power of ligand L, were revealed when the electron density redistribution due to formation of pentacoordinate adducts by the parent MCl_4 molecules was compared using the NQR data.

V. Conclusion

The NQR spectroscopic data refine our understanding of the electronic effects due to substitution and spatial rearrangement of the coordination polyhedra in adducts and complexes of tin, germanium and silicon tetrachlorides. They provide information on the relative contribution of the σ - and π -systems to the electron density redistribution. The results of NQR studies of adducts and complexes of monoalkyl(phenyl)-substituted chloro, bromo and iodostannates enabled one to estimate and compare the contributions of their σ -electron systems to weakening of the Sn—Cl bonds in *cis*-positions relative to the substituents. An estimation of the effective charges on the halogen atoms in *cis*- and *trans*-positions to the substituents made it possible to compare quantitatively the contributions of *cis*-weakening and *trans*-strengthening to the resulting electron density redistribution in the adduct due to replacement of the acidoligands; participation of the halogen π -electron system in the M—Cl bond *trans*-strengthening was revealed. The NQR spectra provide evidence that the length of the chain in the alkyl groups of the substituent influences insignificantly the overall *cis*-weakening of the Sn—Cl bonds. This permitted one to estimate the contribution of the ligands L to the Sn—Cl bond weakening in the presence of the alkyl groups in dialkylidibromostannates. An examination of dependence of the EFG asymmetry parameters at the iodine atoms in the adducts of type $\text{R}_2\text{SnI}_2\text{L}_2$ on the iodine valence orbital occupancies showed that an increase of the halogen σ -electron density due to *cis*-weakening leads to an increase in η at a fixed $\Delta N p_\pi = N p_x - N p_y$ difference.

Comparison of the NQR and X-ray diffraction data enabled one to correlate on a quantitative basis the change in the Sn—Hal

bond lengths with the effective charge increments on the appropriate halogen atoms. The NQR spectroscopic parameters directly determined by the electron density distribution at the halogen atoms were found to be more sensitive to the electronic effects than the interatomic distances. However, X-ray data on the spatial arrangement of atoms and atomic groups, especially in isomers, appeared to be very important for the correct assignment of resonance lines and hence correct interpretation of the NQR spectra. However, examples are known where the electronic effects registered by NQR gave structural evidences below the accuracy of X-ray experiments. Thus the structural effects of *trans*-strengthening in adducts and complexes of monoalkyl(phenyl)tin trichlorides were small, so that the corresponding *trans*-shortening was comparable with the standard deviation values, whereas the electronic effects involved were registered by NQR with an accuracy notably exceeding the errors of measurement. Similarly, no structural evidence for any intermolecular (interligand) interactions were found by X-ray in the adduct $\text{Ph}_2\text{SnI}_2(\text{HMPT})_2$, whose ^{127}I NQR spectral patterns were consistent with a considerable disturbance of the iodine valence π -electron system caused seemingly by the π - π interactions between the iodine atom and phenyl rings of the substituents.

The measurement of the EFG asymmetry parameters at chlorine atoms in pseudooctahedral adducts SnCl_4L_2 enabled one to find a spectroscopic criterion of *cis*–*trans* isomerism of the adducts. The type of isomer could be identified, using this criterion, by measuring the ^{35}Cl NQR frequencies only. The identification of isomers led to better understanding of the electronic reorganisation of the adducts as a result of their rearrangement from pseudooctahedral to trigonal-bipyramidal geometry. It was found that the transformation $\text{SnCl}_4\text{L}_2 \rightarrow \text{SnCl}_4\text{L}$ is accompanied by an insignificant change in the axial Sn—Cl bond character. The equatorial Sn—Cl bond π -system also remains undisturbed by this transformation. The main influence was exerted on the equatorial halogen atom valence $3p_\sigma$ orbitals, whose occupancies decreased on average by 0.1 e.

The measurement of η at chlorine atoms in analogous adducts of germanium and silicon tetrachlorides demonstrated both similarities and differences between the M—Cl bond characteristics. According to the NQR data, the equatorial M—Cl (M = Sn, Ge, Si) bond π -character considerably increases in the trigonal-bipyramidal adducts in the order $\text{Sn} < \text{Ge} < \text{Si}$ ($0.03 < 0.08 < 0.1$, respectively). On going from these adducts to the adducts of pseudooctahedral configuration, the axial M—Cl bond exhibits only minimal changes. However, the electron density redistribution over the σ - and π orbitals of the equatorial M—Cl bonds strongly depends on the nature of the central atom: an increase in the coordination number of the latter results in an increase in absolute magnitude of the effective charges on the equatorial chlorine atoms. In tin adducts, this increase is completely provided by the increased halogen $3p_\sigma$ orbital occupancy, whereas in the silicon adducts, the charge increment, caused by the reduced chlorine $3p_\pi$ orbital occupancy difference (0.079), exceeds that contributed by its $3p_\sigma$ orbital (0.069).

The difference between the bonds of tin, germanium and silicon tetrachlorides causes the different character of σ - and π -electron density redistribution upon formation of trigonal-bipyramidal adducts with ligands L of various donating powers.

Abstract. The review summarises the results of studies on the redox reactions involving sterically hindered quinones and pyrocatechols (phenols) occurring in glassy and single-crystal matrices. Exposure of these systems to light results in the transfer of a hydrogen atom or an electron from the phenol to the quinone accompanied by the formation of radical pairs, *viz.*, two paramagnetic species existing in the triplet state. Studies of the transformations in single-crystal matrices enabled separation of the mechanisms of electron and hydrogen atom transfer. Synchronous transfer of two hydrogen atoms from two sterically hindered phenol molecules to *o*-benzoquinone is also possible. The bibliography includes 39 references.

I. Introduction

The simplest quinones can be considered as model systems that mimic biologically important quinoid compounds (plastoquinones, ubiquinones, vitamin K, flavin adenine dinucleotide, *etc.*). Therefore, studies of the photochemistry of quinones are of undeniable interest due to elucidation of their role as electron acceptors in photosynthesis. For example, photoreduction of quinones results in semiquinone radicals, which are active species in electron transfer reactions in biological systems. Studies of photoreduction reactions in the liquid phase make use of methods of flash photolysis with optical detection of intermediate products and chemically induced dynamic polarisation of electrons and nuclei, while studies of these reactions in the solid state are carried out with the use of ESR spectroscopy. Although the ESR data obtained in the solid state are essentially depleted due to unaveraged rotational dipole–dipole electron–nucleus interactions, studies of solid-state processes and the identification of the radical species formed in these processes are still of special interest.

The present review generalises the results of studies dealing with the solid-state photoreduction of quinones and quinone-like systems with sterically hindered phenols.

A characteristic feature of sterically hindered phenols and their derivatives is that they are readily involved in redox reactions to give relatively stable radicals. The application of radio-

frequency spectroscopic methods gave strong impetus to the studies on the structure and reactivity of phenoxyl-type radicals and promoted progress in the chemistry of this class of compounds; this resulted in the synthesis of metal complexes with paramagnetic ligands.^{1,2} The rather high stability of phenoxyl radical species and the relative simplicity of their ESR spectra made it possible to solve diverse structural and kinetic problems based on the analysis of the hyperfine structure (HFS) of the spectra.^{2–4} Taken together, all this has made the sterically hindered phenols–quinones system a convenient model for studying the photooxidation by the ESR method.

UV irradiation of aromatic ketones in the presence of hydrogen or electron donors results in the reduction of carbonyl groups.^{5–7} In a discussion of the elementary act of transfer of an H atom from a hydrogen donor (AH) to an excited quinone (Q*), Porter suggested in 1958 two possible variants of this process: (1) transfer of a hydrogen atom as a whole (one-step process) and (2) transfer of an electron followed by transfer of a proton (two-step process).⁸

In certain cases, it was possible to detect the formation of both neutral and radical-ion intermediates in these systems and to demonstrate the independence of their formation and dark decay. This fact implies that the solid-state reactions of this type are quite unusual.

Irradiation of a solution of 3,6-di-*tert*-butyl-1,2-benzoquinone (**1**, 3,6-Q) and 2,6-di-*tert*-butyl-4-methylphenol (**2**) in toluene or CCl₄ results in the phototransfer of an H atom from the phenol **2** to the quinone **1** accompanied by the formation of 2,6-di-*tert*-butyl-4-methylphenoxyl (**3**) and 3,6-di-*tert*-butyl-2-hydroxyphenoxyl (**4**, 3,6-SQH[•]) radicals, as indicated unambiguously by the HFS of the spectra of these species (Fig. 1 *a*).

Figure 1. ESR spectra of a solution of 3,6-di-*tert*-butyl-1,2-benzoquinone (1,3,6-Q) and 2,6-di-*tert*-butyl-4-methylphenol (2) in CCl_4 (UV irradiation, 30 °C) (a) and of radical pairs (3,6-Q + NEt_3) (b) and (3,6-Q + phenol 2) (c) in solid phase (toluene, 77 K).

On the other hand, irradiation of quinone **1** in the presence of amines results in semiquinone (SQ) radical anions.⁹

HFS of the ESR spectra of biradicals formed upon photolysis of the quinone **1**–phenol **2** system at 77 K points to their triplet state (Fig. 1 b,c). A similar pattern is also observed for the efficient dipole–dipole interaction of unpaired electrons of two mono-radical species located in a solid phase at a distance of up to 7–10 Å from each other (radical pairs).

A theoretical consideration of systems in a triplet state enables an experimental determination of the zero splitting parameters (D and E) from the lines of the fine structure corresponding to the allowed transitions ($\Delta m_S = 1$).¹⁰ The parameter D (in mT) in the point dipole approximation depends on the distance between the radical centres: $D = 3g\beta/r_{\text{av}}^3$, where g is the spectroscopic splitting factor, β is the Bohr magneton, and r_{av} is the average distance between the unpaired electrons. In this approximation, r is defined as $r_{\text{av}}(\text{\AA}) = 14.06 D^{-1/3}$. As regards the parameter E , $E \neq 0$ in the absence of axial symmetry, while $E = 0$ in the case of axial symmetry where the system should have, at least, a three-fold axis.

The recorded absorption ($\Delta m_S = 1$, $g = 2$) due to reorientation of one electron spin in the external magnetic field (H) and in the field of the other electron of the radical pair (RP) is anisotropic in principle. Therefore, two components are distinguished for chaotically oriented RP, which correspond to RP oriented along the direction of H , i.e., parallel ($D_{\parallel}$) and perpendicular ($D_{\perp}$); in this case, $D_{\parallel} \approx 2D_{\perp}$.

In addition, the ESR spectra of triplet systems often display forbidden transitions ($\Delta m_S = 2$) in the range $g = 4$ (half-field signal); the intensity of these increases with a decrease in the distance between the electron spins. The signal with $\Delta m_S = 2$ is intrinsically isotropic, as it originates from simultaneous reorientation of two electrons of the RP in the field H .

Detailed analysis of the ESR spectra of single crystals of phenols doped with quinones and similar compounds and subjected to photolysis made it possible to reveal fundamentally new types of solid-state reactions, viz., synchronous transfer of two hydrogen atoms from a single-crystal phenol matrix to a quinone, relay transfer of a hydrogen atom in the system 2,6-di-*tert*-butylphenol–2,6-di-*tert*-butyl-1,4-quinonediazide, and tunnel transfer of a hydrogen atom in the dark decay of RP in a single

crystal of 2,6-di-*tert*-butylphenol doped with 2,6-di-*tert*-butylquinoneimine.

The effects of abnormal relaxation of RP detected due to the different saturation of certain lines of the fine structure proved to be useful in the study on the chemical polarisation of nuclei in liquid solutions of the above systems. In certain cases, X-ray diffraction analysis of single crystals of phenols made it possible to determine specific ways of reverse transfer of a hydrogen atom in the dark decay of the RP. Analysis of kinetic curves of the RP decay showed the possibility of intramolecular migration of a hydrogen atom in semiquinone radicals.

Thus, detailed investigations into the spectral and relaxation characteristics of RP can provide additional information regarding the nature of the RP and the mechanism of processes resulting in their formation.

II. Radical pairs of phenoxy radicals in frozen solutions

Specific features of solid-state phototransfer of a hydrogen atom in frozen solutions have been studied for the system 2,4,6-tri-*tert*-butylphenol (**5**)–3,6-di-*tert*-butyl-1,2-benzoquinone (**1**) as an example.¹¹ The ESR spectra of the radical pairs formed upon photolysis of the phenol **5** and the quinone **1** in Nujol at 77 K (Fig. 2) attest to the formation of two types of RP, viz., RP_1 with $r_{\text{av}} = 5.4 \text{ \AA}$ and RP_2 with $r_{\text{av}} = 6.3 \text{ \AA}$. The lines corresponding to the $D_{\perp}$ component of RP_1 coincide with the lines of the $D_{\parallel}$ component of RP_2 . A study of the static saturation of these types of RP showed that the RP_1 lines are saturated with much greater difficulty than the RP_2 lines (Fig. 3) because of efficient relaxation in RP_1 due to stronger spin–spin interaction of unpaired electrons. It was shown that the accumulation of RP_1 and RP_2 during photolysis by filtered light ($\lambda = 365\text{--}460 \text{ nm}$) occurs in parallel, but the ratio of their maximum concentrations at 77 K is 1 : 4. The presence of two types of RP in this system is due to the formation of ‘sandwich’ donor–acceptor complexes (Fig. 4) between the quinone **1** and the phenol **5** (NMR data) in which

Figure 2. ESR spectra of radical pairs formed after 10-min irradiation of frozen solutions of 3,6-Q and 2,4,6-tri-*tert*-butylphenol (**5**) in Nujol at 77 K with light at a wavelength of 365–450 nm (a, b) and after 6 min of annealing the samples at 133 K (c, d).

The spectra were recorded at a microwave irradiation power of 150 (a, c) and 0.2 mW (b, d).

Figure 3. Dependence of saturation of RP_1 (1, 2) and RP_2 (1', 2') formed upon irradiation of solutions [3,6-Q + 2,4,6-tri-*tert*-butylphenol (5)] (1, 1') and (3,6-Q + OH-deuterated 2,4,6-tri-*tert*-butylphenol) (2, 2') in Nujol on the microwave irradiation power (ρ).

Figure 4. Tentative structure of the complex of the quinone 1 with the phenol 5.

the distances between the oxygen atoms of the OH group of the phenol 5 and two carbonyl groups of the quinone 1 [O(1)...O(2) and O(1)...O(3)] differ noticeably. In addition, account of the electric dipole interaction between the oxygen atoms of the OH group of the phenol 5 and the carbonyl groups of the quinone 1 in the sandwich complex (Fig. 4) shows that the relative depth of the proton trap at the O(2) atom is greater than that at the O(3) atom by 0.2 kcal mol⁻¹. As a result, the ratio between the equilibrium concentrations of RP_1 and RP_2 is approximately equal to 1:4, which is consistent with the experimental data. The hydroxyphenoxyl radical 4 formed is characterised by intramolecular migration of a hydrogen atom between the oxygen atoms at a frequency of $\nu \approx 10^9$ s⁻¹ (at 300 K) or $\nu \approx 10^3$ s⁻¹ (at 77 K), which is much slower than the ESR time scale (10^{-6} – 10^{-10} s).¹²

As a result, the spectra of RP_1 and RP_2 are recorded separately.

Studies of the dark decay of RP_1 and RP_2 showed that both types of pairs decay in the same way and that the kinetics of this process is stepwise, which is probably caused by the heterogeneity of the matrix. The similarity of the character of accumulation and decay of RP_1 and RP_2 is apparently due to intramolecular migration of the H atom in the hydroxyphenoxyl radical, which causes the kinetic interrelation between the states determining the existence of both pairs. It should be noted that multiple cycles of generation and subsequent dark decay of the pairs do not result in the consumption of the starting reagents, which suggests that only two processes occur in these and similar systems, *viz.*, photo-

Table 1. The values of fine structure constants D (mT) for neutral and radical-ion (D^i) pairs formed upon irradiation of the system quinone 1 – pyrocatechol 6 with light at $\lambda = 480$ –650 nm in various solvents.

Solvent	D_1 (C,C') ^a	D_2 (B,B') ^a	D^i	ΔD^i (see ^b)
3-Methylhexane	25.7	14.6	22.5	0.5
1,1,2,2-Tetrachloroethane	24.2	14.2	21.1 ^c	0.9
Toluene	24.9	14.3	–	0.5
Carbon tetrachloride	23.1	12.5	22.9	–
Pentane	25.5	14.2	22.0	0.9
Hexane	24.5	13.4	21.5	1.6
Heptane	24.7	13.9	20.9	0.9
Octane	23.5	12.4	21.4	0.7

Decalin	23.3	12.6	–	0.9

^a D_1 and D_2 are dipole–dipole coupling constants for neutral RP with the perpendicular components C,C' and B,B'. ^b ΔD^i is the change in D^i after 30 min of dark annealing at 77 K. ^c In this case it was possible to measure E , which was found to be 0.47 mT.

transfer of the hydrogen atom from the phenol to the quinone and its reverse transition in the dark process.

A detailed study of the dependence of the structure of RP formed in the system quinone 1–3,6-di-*tert*-butyl-1,2-dihydroxybenzene (6, 3,6-QH₂) in glassy frozen solutions at 77 K on the solvent nature (Table 1) and the wavelength of the incident light was carried out.^{13,14} Irradiation of this system with light at $\lambda = 365$ –500 nm results in the phototransfer of a hydrogen atom with formation of three types of neutral RP,[‡] which differ in their fine structure parameters. The kinetic characteristics of accumulation and decay of all of these types of RP are identical due to the intramolecular migration of the H atom in the phenoxyl radical 3,6-SQH[•], and hence, the difference between the accumulation and decay curves of the RP disappears.

However, irradiation of this system with light at $\lambda = 480$ –650 nm gives, in addition to the types of pairs specified above, one more type which has an intermediate D value and corresponds to a radical-ion pair formed due to the phototransfer of an electron:

The kinetic stability of this type of RP is much smaller (Fig. 5) than that of neutral ones.

An important feature of radical-ion pairs is the absence of an induction period in their accumulation curves; this made it possible to draw the conclusion that the formation of the neutral and radical-ion pairs occurs independently, *i.e.* the two processes occur in parallel.^{14,15} The main argument for the suggested mechanism of the formation of neutral and radical-ion pairs is the increase in the relative photoyield of ionic RP in comparison

[‡] In solution, the quinone 1 and the pyrocatechol 6 give donor–acceptor complexes;¹³ in this case, the phototransfer of an H atom formally results in four types of RP (generally, four localisation variants of two H atoms on four O atoms are possible in each hydroxyphenoxyl radical; however, the parameters D of two of these variants are equal).

Figure 5. Kinetic curves of decay of ionic (1) and neutral (2) radical pairs in 3-methylhexane.

with that of the neutral ones (Fig. 6) with an increase in the wavelength of the incident light (λ). Similar results were obtained for the photoreduction of *p*-benzoquinone in an ethanolic solution at room temperature.¹⁶ The long-wave threshold for the generation of neutral semiquinone radicals is 450 ± 10 nm, while that of radical ions is 580 ± 10 nm.¹⁶ Hence, the transfer of a hydrogen atom requires irradiation in a shorter wavelength range than that required for the electron transfer. This feature of ionic RP is apparently due to the formation of donor–acceptor complexes in which the single-electron phototransfer is facilitated.¹⁷

Figure 6. Dependence of the relative photoyield of radical-ion pairs $[Q^{\bullet-} \cdots AH^{\bullet+}]/[QH^{\bullet} \cdots A^{\bullet}]$ in different solvents on the wavelength of the exciting light. The abscissa axis represents the value of λ corresponding to the maximum of the transmission band of a set of light filters (the half-width of the transmission band was 50 nm); (1) toluene; (2) 1,1,2,2-tetrachloroethane; (3) 3-methylhexane.

III. Characteristic features of photoreduction of quinones in single crystals of organic hydrogen donors

Doping of single-crystalline phenolic compounds with sterically hindered quinones enabled the development of new interesting systems characterised by specific behaviour when exposed to photoirradiation. Single crystals of 3,6-QH₂ doped with 3,6-Q (10^{-2} mol litre⁻¹) were obtained¹⁸ and the ESR spectra of radical pairs formed upon irradiation of this system ($\lambda = 425\text{--}475$ nm) at 77 K were studied. Figure 7 shows the ESR spectra of single-crystalline 3,6-QH₂ doped with 3,6-Q (Fig. 7a) and a polycrystalline sample obtained from a melt of

Figure 7. ESR spectra of a single crystal of 3,6-QH₂ doped with 3,6-Q (10^{-2} mol litre⁻¹) (a) and a polycrystalline sample obtained from a melt of the corresponding single crystals (b, c); (a) is the single-crystal sample 10 min after irradiation with light at a wavelength of 425–475 nm; (b) is the polycrystalline sample 10 min after the irradiation; (c) is the polycrystalline sample during irradiation in the ESR spectrometer resonator.

The components *A* and *A'* can be assigned to RP with $D = 7.5 \pm 0.2$ mT and $r_{av} = 7.2$ Å; *B* and *B'*, to the perpendicular components $D_{\perp}$; *C* and *C'*, to the parallel components $D_{\parallel}$. The additional short-lived components *D*, *D'* and *D₁*, *D₁'* belong to RP with $E = 0$. The parallel components of the short-lived RP coincide with those for the stable RP.

the corresponding single crystals (Fig. 7b,c). The calculated value of parameter $D = 28.6 \pm 0.4$ mT for this system corresponds to the mean distance between the unpaired electrons, $r_{av} = 4.6$ Å.

The equality between the $D_{\parallel}$ components of short-lived and stable RP suggests that their r_{av} are approximately equal to 4.6 Å. The essential difference in the stability of the RP in question enables one to assign the short-lived RP to radical-ionic ones ($AH^{\bullet+} + Q^{\bullet-}$) formed upon phototransfer of an electron. Stable RP ($A^{\bullet} + SQH^{\bullet}$) result from the phototransfer of an H atom. As in glassy frozen solutions (see Section II), the long-wave threshold of the formation of stable RP is 460 ± 15 nm, while that of radical-ionic RP is 560 ± 15 nm. It should be noted that irradiation of a sample with light at $\lambda = 475$ nm for 2 h virtually does not give stable RP. Analysis of the ESR spectra of radical pairs shows that the fraction of the radical-ion pairs is 99.9%, and their subsequent dark decay occurs without conversion into stable neutral RP.¹⁵ These data confirm the conclusions on the independence of two photoreduction mechanisms of excited 3,6-Q made for glassy frozen solutions.

Single crystals of 3,6-QH₂ were studied by the X-ray diffraction method.¹⁹ They were found to have a tetragonal structure (space group $I4_1/a$). Analysis of packing of the 3,6-QH₂ molecules in the crystal indicates that they form a helix relative to a four-fold axis (4₁) (Fig. 8) with a rotation angle of 90° relative to each other.

The X-ray diffraction data were compared with those of ESR spectroscopy by calculating the zero splitting parameters (*D* and *E*) for the case where one 3,6-QH₂ molecule is replaced by 3,6-Q

Figure 8. Fragment of a projection of the unit cell of 3,6-QH₂ on the *xy* plane.

and two identical 3,6-SQH[•] radicals are formed upon irradiation. The values of *D* were calculated for various pairs of adjacent molecules using the method described in Ref. 20. The spin densities on various atoms in the 3,6-SQH radical were taken from Ref. 21 where they are given with an accuracy of 15%. The transfer of the H atom (Fig. 8) can occur through the channels O(1)–O(1') and O(1)–O(2'). The calculated values of *D* are 33.55 mT for the channel O(1)–O(1') and 33.4 mT for the channel O(1)–O(2'). These values are virtually identical and differ from the experimental one by 14% (*D*_{exp} = 28.6 mT). Since the spin density distribution in 3,6-SQH[•] was estimated to the same accuracy, the agreement between the theoretical and experimental *D* values may be considered as satisfactory. By comparing the theoretical and experimental angular dependences *D*(θ), where θ is the angle between the axis *x* (Fig. 8) and the direction of the external magnetic field *H* (the crystal rotates around a four-fold axis), it was shown that the O(1)–O(2') channel of the transfer of the H atom is more efficient.¹⁹

The interest in the photoprocesses in single-crystal matrices is caused by the fact that single crystals of sterically hindered phenols doped with quinones have diverse crystal structures and unit cell parameters, which depend on the structure of the phenol. In turn, this determines the specific features of the photo- and dark processes of the H atom transfer in each particular case.

It is known that in some redox processes, the transfer of two electrons can occur within one elementary act.²² Studies^{13,23,24} of the transfer of H atoms in single crystals of sterically hindered phenols doped with quinones showed the possibility of synchronous transfer of two H atoms from the phenol single-crystal matrix to quinones. The ESR spectra that appear upon photoirradiation ($\lambda = 285\text{--}470$ nm) of single-crystalline 2,6-di-*tert*-butyl-4-methylphenol doped with 3,6-Q are given in Fig. 9. Visually, the single crystals of the phenol **2** have a two-fold axis (axis *z*) and two faces parallel to this axis; the axis *y* is chosen along these faces. The spectral pattern shown in Fig. 9*a* corresponds to the direction of the external magnetic field *H* along the axis *z*. Six groups of lines of the fine structure of the RP formed comprise HFS lines, which indicates unambiguously the interaction of the unpaired electrons with the protons of two equivalent methyl groups in the phenoxyl radicals **3** present in the pair. Each component of the fine structure contains seven lines with a binomial intensity distribution, $a_{\text{H}}^{\text{Me}} = 0.53$ mT. Such a pattern can only be caused by the transfer of two H atoms from two matrix molecules of the phenol **2** to the quinone **1**:

Figure 9. ESR spectra of a single crystal of the phenol **2** doped with 3,6-Q (10^{-3} mol litre⁻¹) (a) (*b* is the forbidden signal of single-crystalline phenol **2** ($\Delta m_S = 2$) in half-field) and polycrystalline sample (*c*).

The isotropic forbidden signal ($\Delta m_S = 2$) also contains seven lines (Fig. 9*b*) from two equivalent methyl groups. The HFS constant in this system is half that in the original radical existing in solution ($a_{\text{H}}^{\text{Me}} = 10.7$ mT), which also proves the existence of two phenoxyl radicals **3** in the triplet state. In other words, along with the dipole–dipole interaction of two unpaired electrons giving fine structure lines, their strong isotropic exchange interaction due to overlapping of the wave functions of the unpaired electrons is observed.²⁵ The presence of six groups of fine structure lines (*A, A', B, B'* and *C, C'*) in the single-crystalline phenol **2** suggests the possibility of three orientations of the three RP with respect to the external magnetic field *H*; on the other hand, only one type of RP with $D = 15.8 \pm 0.3$ mT ($r_{\text{av}} = 5.4$ Å) is observed in the polycrystalline matrix of this sample (Fig. 9*c*).

The spectral pattern is completely the same in the system phenol **2**–3,5-di-*tert*-butyl-1,2-benzoquinone (3,5-Q). Thus, one can state that the transfer of two H atoms from two molecules of the phenol **2** to the quinone 3,5-Q accompanied by the formation of two phenoxyl radicals **3** existing as a pair also occurs in this case.

The photoirradiation of the same single-crystalline phenol matrix doped with 2,6-di-*tert*-butyl-1,4-benzoquinone (**7**, 2,6-Q) results in a spectral pattern where the fine structure components of the three types of RP contain HFS from only one methyl group (a quadruplet with a 1:3:3:1 intensity ratio, $a_{\text{H}}^{\text{Me}} = 0.53$ mT) (Fig. 10). This indicates unambiguously that the transfer of only one H atom occurs.

Figure 10. ESR spectrum of irradiated single crystal of the phenol **2** doped with 2,6-di-*tert*-butyl-1,4-benzoquinone.

It should be noted that the D parameter (13.4 mT) in this polycrystalline sample is noticeably smaller than that in the sample doped with 3,6-Q; this suggests that the relative arrangement of molecules of the corresponding quinones and the phenol **2** in these systems is different in principle.

The question arises as to the mechanism of phototransfer of two H atoms in the system phenol **2**–3,6-Q. It was shown that the RP accumulation in this system is proportional to the radiation intensity, *i.e.*, the transfer of two H atoms is not a two-quantum process. In addition, the long-wave threshold frequency of the RP formation in the single-crystalline phenol **2** doped with 3,6-Q is in the range from 290 to 330 nm, while in glassy frozen solutions where the transfer of one H atom occurs the long-wave threshold frequency of the RP formation is 560–630 nm; this indicates that a much smaller energy (by a factor of 1.7–2.2) is required for the phototransfer of one H atom. Let us note that the long-wave threshold frequency of the RP formation in the system single crystal of the phenol **2**–2,6-Q where phototransfer of one H atom occurs is noticeably higher: $\lambda = 390$ –445 nm. These data altogether support the one-quantum mechanism of phototransfer of two H atoms in the system single crystal of phenol **2**–3,6-Q (or 3,5-Q). Nevertheless, the principal proof of a one-quantum process is that the RP yields, or, in other words, the efficiencies of phototransfer of one and two H atoms in all three systems (phenol **2**–3,6-Q, phenol **2**–3,5-Q and phenol **2**–2,6-Q) are all almost the same. In the case of the two-quantum process, the efficiency of phototransfer of two H atoms would be much lower.

It was found in a study of the kinetics of RP decay in all the three systems that it is exponential and is the same in the systems phenol **2**–3,6-Q and phenol **2**–3,5-Q ($k = 10^4 \text{ s}^{-1}$, $E_a = 23.8 \text{ kJ mol}^{-1}$) but differs strongly from the kinetics of RP decay in the system phenol **2**–2,6-Q ($k = 10^8 \text{ s}^{-1}$, $E_a = 22.8 \text{ kJ mol}^{-1}$). Apparently, the decay of RP occurs due to the reversible dark transfer of H atoms.

Thus, it has been shown that the phototransfer of two H atoms requires much higher excitation energy and that this act occurs due to the absorption of one quantum of light.

IV. Other quinoid systems in hydrogen atom transfer reactions in single-crystalline phenols

The interest in the use of 2,6-di-*tert*-butyl-1,4-quinonediazide (2,6-QN) as a potential acceptor of an H atom from phenolic hydrogen donors is due to the fact that the photoirradiation of 2,6-QN results in its dissociation into a carbene **9** (2,6-SQN) and molecular nitrogen.^{26–28}

Figure 11 *a* shows a part of the ESR spectrum of the carbene **9** in single-crystalline phenol **2** doped with 2,6-QN upon irradiation

Figure 11. ESR spectra of the carbene **9** (*a*), the radical pair appearing upon irradiation of a single crystal of the phenol **2** doped with 2,6-QN (77 K) (*b*) and a polycrystalline sample obtained from a melt of single crystals of the phenol **2** and 2,6-QN (*c*); (*I*, *I'*) are perpendicular components of RP_1 ; (*2*, *2'*) are perpendicular components of RP_2 .

with light at a wavelength of $\lambda = 530 \pm 20 \text{ nm}$ at 77 K. In this case, two triplets (1:2:1) are observed which correspond to the interaction of unpaired electrons with benzene ring protons.⁸ This spectrum corresponds to the high-field transition $\Delta m_S = \pm 1$. Depending on the sample rotation angle, four sets of triplets, which reflect four orientations of the 2,6-QN molecules in a single crystal, are observed.²⁷ Depending on the conditions, it is possible to observe two types of radical pairs in the system phenol **2**–2,6-QN, *viz.*, RP_1 ($D = 13.2 \text{ mT}$, $r_{av} = 6.0 \text{ \AA}$) and RP_2 ($D = 3.9 \text{ mT}$, $r_{av} = 8.9 \text{ \AA}$) (Fig. 11 *b,c*). The fine structure parameters were determined from the spectra of polycrystalline samples.

The radical pairs RP_1 and RP_2 appear upon irradiation with light at $\lambda \leq 420 \text{ nm}$ and $\lambda \leq 350 \text{ nm}$, respectively.

In the short-term (30 s) irradiation at 77 K, only the spectrum of RP_2 and the carbene is observed. After a period of three days, the signal of the carbene disappears, but the intensity of the signal of RP_2 ($D = 3.9 \text{ mT}$) increases. The rate of RP_1 formation at the beginning of photolysis with light at $\lambda \geq 310 \text{ nm}$ at 77 K is practically zero and its increase is observed after some time; this is apparently due to the transfer of an H atom from the phenol **2** to the carbene **9** with the formation of two phenoxyl radicals, *viz.*, **3** and **10**.

§ The magnitude of D for the system phenol **2**–2,6-Q is comparable with the magnetic field strength in the ESR spectrometer.

The characteristic time of RP_1 accumulation ($D = 13.2$ mT) is 30 min at 110 K. As the temperature is increased to 300 K, the RP_2 species disappear and only the RP_1 species remain.

These data suggest that there are two different processes of the H atom phototransfer. Specifically, these include the phototransfer of itself (the formation of RP_2) resulting in the formation of a 'primary' pair,

and the reaction of the carbene with the matrix (the formation of RP_1).

The eight groups of lines containing a multiplet (1 : 4 : 6 : 4 : 1) correspond to different orientations of RP_1 relative to the external magnetic field H in the single crystal. The relative intensity of the lines corresponding to each type of pairs depends on the photo-reaction efficiency, *i.e.* on the orientation of the 2,6-QN molecules relative to the direction of the incident light.

The photoselection effect in the photolysis of 2,6-QN has been studied in detail.²⁸ The line positions vary as the crystal is rotated relative to the external magnetic field, but the hyperfine coupling (HFC) remains unchanged and corresponds to the interaction of the unpaired electrons of the carbene **9** with four equivalent protons ($a_H = 0.6$ mT). The hyperfine structure (multiplet) originates from the interaction of the unpaired electrons of RP_1 with three protons of the methyl group in the radical **3** and the H atom at the *para* position of 2,6-di-*tert*-butylphenoxyl (radical **10**).

This conclusion was confirmed by a study of photoreactions that occur in the matrix of the phenol **2** with a deuterated OH group. In this case the multiplet is transformed into a quadruplet due to the HFC only with the hydrogen atoms of the methyl group.²⁸

The particular channels of the H atom phototransfer were determined from X-ray diffraction data²⁴ on the phenol **2** crystal structure and with consideration of the spin density distribution in the phenoxyl radicals formed.

The experimental results obtained allow one to assume a different mechanism of the RP_1 and RP_2 formation as well. The radical pair RP_2 (the 'primary' RP) eliminates N_2 to give the 'secondary' RP_1 ; the difference between the r_{av} of the unpaired electrons is due to the change in the spin density distribution in the radical partners of the phenoxyl radical **3** and the relative change in the distances between the radicals in the corresponding pairs.

The formation of symmetric RP was observed in the photolysis of single-crystalline 2,6-di-*tert*-butylphenol (**11**) doped with 2,6-QN.²⁹ Two types of RP were detected in the ESR spectra of this system due to different orientations of the RP in the crystal. Owing to the specific features of the 2,6-di-*tert*-butylphenol crystal lattice, the phototransfer of an H atom can involve two

possible different RP orientations relative to the external magnetic field. The small magnitude of the fine structure parameter D (4.3 mT) in this case suggests a large distance between the radical centres. X-Ray diffraction data and calculations of the D and E hyperfine structure parameters and data on the spin density distribution in phenoxyl radicals suggest that the RP are formed in this case through a two-step (relay) process.^{30, 31}

The carbene **9** formed in the photolysis abstracts the *para*-hydrogen atom from the nearest 2,6-di-*tert*-butylphenol molecule to give a phenoxyl radical (**10**) and a phenyl radical (**12**). In turn, the phenyl radical abstracts an H atom from the nearest 2,6-di-*tert*-butylphenol molecule. In this manner, an RP is formed from rather remote phenoxyl radicals. Experiments with OH-deuterated single crystals confirmed the formation of such RP with identical hyperfine structures, which proves the validity of the suggested relay scheme of the H atom transfer.

The ESR spectra of the radical pairs formed upon photolysis of single-crystalline phenol **2** doped with 2,6-di-*tert*-butyliminoquinone ($\lambda = 350$ nm) and those of the corresponding polycrystalline sample are given in Fig. 12. The spectrum of the polycrystal (Fig. 12*b*) implies the formation of only one type of RP ($D = 12.2 \pm 0.2$ mT). The observed combination of the fine structure lines suggests different orientation of radical pairs relative to the external magnetic field due to the crystal structure of the phenol **2**.²⁸

The nature of the radicals that form RP in a single crystal of the phenol **2** doped with 2,6-di-*tert*-butylquinoneimine was established using computer modelling based on the set of HFS

Figure 12. ESR spectra of the radical pairs formed upon photolysis of a single crystal of the phenol **2** doped with 2,6-di-*tert*-butyliminoquinone (*a*) and the corresponding polycrystalline sample (*b*).

lines (Fig. 12 *a*).^{30,31} It was found that the HFS is due to the interaction between the unpaired electrons and four equivalent protons, which implies the phototransfer of the H atom and formation of the corresponding phenoxyl and aminyl radicals.

The multiplet is formed by three protons of the methyl group and the proton of the aminyl radical. The long-wave threshold frequency of the RP formation in this system is 430 ± 10 nm, which corresponds to the quinoneimine absorption band. The interpretation of the RP spectra was confirmed completely by experiments with single crystals of deuterated phenol 2.³⁰

The exponential character and an unexpectedly large kinetic isotope effect ($k_H/k_D = 10^3$) of the dark RP decay allow one to assume the tunnel character of the H atom reverse transfer.³²

The redox properties of 2,4,6,8-tetrakis-*tert*-butylphenoxazin-1-one (**13**) are rather similar to those of sterically hindered *o*-quinones. The phenoxazinyl radical **14** formed in the reduction of phenoxazinone **13** manifests high stability and very characteristic ESR spectrum with a hyperfine coupling constant $a_N = 0.9$ mT.³³

The high spin density on the nitrogen nucleus makes it possible to obtain additional information on the structure of paramagnetic complexes incorporating this ligand and on the structural changes in RP formed upon phototransfer of the hydrogen atom in single crystals of 3,5-QH₂ doped with the phenoxazinone **13**.³⁴

Figure 13 presents the optical absorption spectra of 3,5-QH₂ and the phenoxazinone **13**. The ESR spectra of single-crystalline 3,5-QH₂ doped with the phenoxazinone **13** contain only a combination of lines of the original pyrocatechol and phenoxazinone, *i.e.*, no additional bands are present.

On irradiation of single-crystalline phenol **2**, RP of various types appear in the absorption band of the phenoxazinone (Fig. 14 *a, b*). Analysis of the spectral pattern obtained suggests

Figure 13. Optical absorption spectra of 3,5-QH₂ (*I*) and phenoxazinone **13** (*2*).

Figure 14. ESR spectra of the radical pairs formed upon photolysis of a single-crystalline 3,5-QH₂ doped with the phenoxazinone **13** (*a, b*) and polycrystalline sample (*c*). Microwave power /mW: (*a*) 1, (*b*) 50.

that there are six types of RP with different spectral characteristics (*D*) and hence with different distances between the radical centres. The radical pairs RP₁–RP₄ appear upon irradiation with light at $\lambda \leq 600 \pm 20$ nm, RP₅ at $\lambda \leq 520 \pm 20$ nm and RP₆ at $450 \leq \lambda \leq 550$ nm. The observed RP have the following dipole–dipole coupling constants: $D_1 = D_2 = 1.6$, $D_3 = 8.0$, $D_4 = 13.0$, $D_5 = 25.0$ and $D_6 = 0.7$ mT. The values of D_3 , D_4 and D_5 were determined from the spectra of polycrystalline samples (Fig. 14 *c*), and those of D_1 and D_2 , from studies of the dependence of these parameters on the angle relative to the external field.

Studies of the dark decay of RP₁–RP₆ at 77 K showed that the kinetic curves are satisfactorily linearised in the $I/I_0 - \log(t/t_0)$ coordinates,³⁴ which indicates that there is a set of different rates of reverse transfer of the H atom from the radical **14** to the 3,5-SQH[•] radical. This situation is typical of processes occurring in solids and is determined by the structural features of the RP formed in this system. In the case under consideration, the distribution of the RP decay rates can be determined by the small changes (~ 0.1 Å) in the position of the phenoxazinone **13** in the crystal lattice of 3,5-QH₂. Moreover, the presence of six types of RP and, hence, the difference in their kinetic behaviour can be due to different arrangement of hydrogen atoms at the oxygen atoms of the 3,5-SQH[•] radical (non-equivalent shielding of the oxygen atoms by the *tert*-butyl groups) and in the radical **14**.

Photolysis of the system 3,5-QH₂–phenoxazinone **13** in the region from 450 to 550 nm at 77 K gives rise to RP₆ with additional HFS caused by the nitrogen nucleus of the radical **14** (Fig. 14); the intensity of the signal is small under these conditions.

The existence of reversible temperature evolution of RP₃ and RP₆ in the temperature range from 20 to 77 K has also been shown.³⁴ Only the ESR spectrum of RP₃ (Fig. 15a) was observed during irradiation of a single crystal at 55 K. The spectrum of RP₆ was observed when the irradiation was terminated and the temperature was decreased to 20 K (Fig. 15b); the components of this spectrum contain HFS from the ¹⁴N nucleus ($a_N = 0.9$ mT). This temperature-reversible transformation is caused by spin density redistribution in the radical **14** as a result of H atom intramolecular transfer between the nitrogen and oxygen atoms (Fig. 16).

V. Anomalous relaxation in the ESR spectra of radical pairs

The ESR spectra of radical pairs sometimes show anomalies which can provide additional information on the interaction of the spin centres.

For example, anomalies have been reported³⁵ such as changes in the widths of the fine structure lines for the RP formed upon the hydrogen atom phototransfer in single-crystalline 3,5-QH₂ doped with 3,5-Q (system A) and in single-crystalline 3,3',5,5'-tetrakis-*tert*-butyl-6,6'-dihydroxydiphenylmethane doped with 2,6-Q (system B). Figure 17 shows the ESR spectra of the system A obtained upon irradiation with light at $\lambda > 720$ nm. It can be seen that at low power of the microwave field (0.02 mW), the fine structure components have identical intensities, while at high power (2 mW), the high-field component has a considerably higher intensity implying shorter relaxation time.

Figure 17. ESR spectra (a) and diagram of magnetic levels of the radical pair energy (b) for the system 3,5-QH₂–3,5-Q.

The times of spin–lattice (T_1) and spin–spin (T_2) relaxations for the low- and high-field components were determined from the saturation curves using the technique described in Ref. 36 and based on a model of non-interacting Bloch packets:

$$T_1 = 5.7 \times 10^{-4}, \quad T_2 = 6.6 \times 10^{-7} \text{ s (low-field component);}$$

$$T_1 = 1.2 \times 10^{-4}, \quad T_2 = 2.8 \times 10^{-7} \text{ s (high-field component).}$$

The system B was found to behave similarly.

In the systems studied, the ESR spectra at low power of the microwave field are centrosymmetric at any orientations of single crystals relative to the external magnetic field. Therefore, a mechanism of interaction of triplet levels was suggested³⁹ which dictated nonsymmetrical relaxation of the fine structure components but did not result in their asymmetry relative to the centre of the spectrum. Additional relaxation channels according to the scheme shown in Fig. 17b were considered:

$$T_0 \rightarrow S \rightarrow T_- \text{ (high-field component) – channel 1;}$$

$$T_+ \rightarrow S \rightarrow T_0 \text{ (low-field component) – channel 2.}$$

For these channels, the distances between the levels S – T_- and S – T_+ are different. In the cases $J \ll g\beta H$ or $J \gg g\beta H$ (J is the distance between the T_0 and S levels), this difference is insignificant, and the rates of relaxation through the channels 1 and 2 are

the same. However, if the magnitudes of J and $g\beta H$ are comparable (Fig. 17), differences in the relaxation $S \rightarrow T_-$ and $T_+ \rightarrow S$ can be expected and, hence, the rates of relaxation through the channels 1 and 2 should differ.

The rates of the spin–lattice relaxation can be represented as:

$$\frac{1}{T_1(B)} = \frac{1}{T_0(B)} + \frac{1}{\tau_1},$$

$$\frac{1}{T_1(B')} = \frac{1}{T_0(B')} + \frac{1}{\tau_2},$$

where $T_0(B)$ and $T_0(B')$ are the times of spin–lattice relaxations through the channels 1 and 2, respectively; τ_1 and τ_2 are the times of relaxation through the channels 1 and 2, respectively. The difference between $1/\tau_1$ and $1/\tau_2$ can explain the effect of abnormal asymmetrical relaxation provided that $1/T_0(B) \leq 1/\tau_1$ and $1/T_0(B') \leq 1/\tau_2$, i.e., where the relaxation channels 1 and 2 under consideration contribute significantly to the relaxation rate.

Thus, the asymmetrical relaxation effect can take place if the singlet–triplet coupling is comparable with the Zeeman coupling, but is still different from the latter. These results can be useful in studies of the effect of a magnetic field on the rates of chemical reactions involving radical pairs as transition states.³⁷

VI. Conclusion

The processes of solid-state hydrogen and electron transfer under photoirradiation considered above provide unique information on the nature of the elementary act in organic matrices which represent potential hydrogen donors. The advantage of studying solid-state systems, particularly single crystals, is that it provided the possibility of ESR in-depth studies of the structural features and kinetic behaviour of radicals which exist as radical pairs as a function of the features of the matrix and its crystal structure.

It was found that solid-state transfer of a hydrogen atom and an electron is possible not only under photoirradiation but also under elastic-wave impact on mechanical mixtures of the corresponding pyrocatechols and quinones or on the same mixtures in the presence of polymeric materials.^{38,39}

The results summarised in this work were obtained with direct participation of Professor Ya S Lebedev, whose top professionalism, authority, and sharp scientific intuition much favoured the development of chemical physics of solid-state processes in general and of the hydrogen atom and electron transfer in particular.

IV. Conclusion	755

Abstract. Published data on the use of cyanoacetamides, cyanothio- and -selenoacetamides in fine organic synthesis and the prospects of application of these compounds in combinatorial synthesis are analysed and generalised. The bibliography includes 653 references.

I. Introduction

Cyanoacetic acid derivatives are important intermediates for preparation of various organic and, especially, heterocyclic compounds possessing diverse biological activities and many other practically useful properties. In this group of compounds, cyanoacetamides and their thio- and selenocarbonyl analogues are of particular interest as very promising reagents for cascade heterocyclisation, which will undoubtedly become one of the main approaches to the targeted synthesis of heterocycles in the near future, and for combinatorial chemistry experiencing nowadays a sharp rise (see, for example, Refs 1–26). This new methodology based on automatic, high-tech synthetic methods enables synthesis of a large number (up to several thousand) of novel organic compounds as subjects for biological screening.

The present review systematises for the first time published data on the reactivity of cyanoacetamides and their thio- and selenocarbonyl analogues (for selected aspects of the chemistry of these compounds, see reviews^{27–34}). The presence of several reactive centres in the molecules of these reagents provides ample opportunities to synthesise a great variety of novel compounds under relatively mild conditions and using rather simple laboratory equipment. Syntheses of many polyfunctional heterocyclic compounds, including those prepared by multicomponent condensations, are based on cyanoacetamides and their S- and Se-containing analogues. The reactions involving these reagents occur, as a rule, with high regioselectivity (often, stereoselectively) and their course can easily be controlled by changing reaction conditions and varying substituents in the molecules of initial compounds. All this makes cyanoacetamides and their S- and Se-analogues very useful reagents for combinatorial synthesis aimed at the design of novel biologically active compounds with a targeted mode of action.

The present review aims to demonstrate the synthetic potential of cyanoacetamides in the synthesis of novel heterocyclic compounds. Primary attention is paid to the methods for preparation of the final products and much less to mechanistic aspects of the reactions surveyed. The structures of the feasible intermediates are considered only in the most synthetically important reactions.

II. Synthesis of cyanoacetamides, their thio- and selenocarbonyl analogues and aryl- and hetarylmethylidene derivatives

Cyanoacetamide (**1a**) can readily be obtained by several methods, viz., using the reactions of cyanoacetates (**2**) with ammonia,³⁵ of cyanoacetic acid (**3**) with NH_4OH ³⁶ and of chloroacetamide (**4**) with NaCN .³⁷

There are several methods for the preparation of cyanothioacetamide (**1b**), viz., treatment of an ethanolic solution of malononitrile with H_2S in the presence of triethylamine^{38–41} or triethanolamine,^{42,43} the reaction of cyanoacetamide (**1a**) with phosphorus pentasulfide in pyridine or ethyl acetate^{44–46} (the yield in the latter reaction does not exceed 36%), and the reaction of 1-ethoxyethylidenemalononitrile (**6**) with H_2S in ethanol.³⁹

B = Et_3N , $(\text{HOCH}_2\text{CH}_2)_3\text{N}$.

Cyanoselenoacetamide (**1c**) was synthesised for the first time in 1985 by the reaction of malononitrile with H_2Se in diethyl ether in the presence of triethylamine at 5 °C under argon in 75% yield.⁴⁷

Aryl- and hetarylmethylidene cyanoacetamides **7** are also promising reagents for the synthesis of functionally substituted heterocycles. These compounds are obtained by the reactions of aromatic or heteroaromatic aldehydes **8** with amides **1a–c** in the presence of organic bases, under argon in the case of cyanoselenoacetamide (**1c**).^{39, 44, 45, 48–56} Thioamides **7b** can also be prepared by the reactions of arylmethylidenemalononitriles **9** with H_2S .⁴⁸ In some cases, amides **7b** ($\text{R} = \text{Ph}$, 4- FC_6H_4 , 4- ClC_6H_4 , 4- BrC_6H_4 , 4- $\text{NO}_2\text{C}_6\text{H}_4$) readily undergo spontaneous [2+4]-cycloaddition to give 3,4-dihydro-2*H*-thiopyrans **10**.⁴⁸

$\text{R} = \text{Ar}$, Het; $\text{X} = \text{O}$ (**a**), S (**b**), Se (**c**).

$\text{Y} = \text{H}$, F , Cl , Br , NO_2 .

1-[(4-Alkoxybenzylidene)pyrrolidin-3-ylidene]cyanothioacetamide (**11**) has been obtained by the reaction of pyrrolidone **12** with cyanothioacetamide (**1b**). The reaction of the same reactants in the presence of β -alanine with azeotropic distillation of water from the reaction mixture results in tetrahydrothieno[2,3-*b*]pyrrole **13**.⁵⁷

Cycloalkylidenecyanothioacetamides **14** were synthesised in a similar way.⁵⁸

$n = 1, 2$.

Some other reactions involving the methylene group of cyanothioacetamide (**1b**) are known. Thus the condensation of this amide with nitroso-arenes affords the corresponding aryliminothioacetamides **15**⁵³ and the reaction with aryldiazonium salts affords compounds **16**.⁵⁹ The latter were used in the synthesis of thiazolidin-3-one and pyrimidine-2-thione derivatives.⁵⁹

Cyanoacetamide **1b** adds unsaturated compounds. Thus its reaction with 3 β -acetoxy pregna-5,16-dien-20-one (**17**) in the presence of sodium ethoxide involves the double bond of the ring *D* yielding (3 β -hydroxy-20-oxopregn-5-en-16 α -yl)cyanothioacetamide (**18**).^{60–62}

$\text{R} = \text{H}$, Ac .

Arylmethylidenecyanothioacetamides **7b** are alkylated with methyl iodide to give the corresponding methyl thioimides **19**, which can be used in the synthesis of heterocyclic systems.^{63, 64}

III. The use of cyanoacetamides and their thio- and selenocarbonyl analogues in the synthesis of heterocyclic compounds

Owing to the presence of several highly reactive centres, first of all, the methylene and carbonyl or thio(seleno)carbonyl groups, cyanoacetamides have found wide use in the synthesis of diverse five- and six-membered heterocycles and their annulated analogues.

All reactions in this Section are systematised in accord with the size of the heterocycle, while each Subsection deals with a certain type of the reacting substrates.

1. Synthesis of five-membered heterocycles

a. Five-membered heterocycles with one heteroatom in the ring

Reactions of the α -mercapto carbonyl compounds **20** with nitriles that contain an active methylene group, including cyanoacetamide (**1a**), in the presence of bases at room temperature afford 2-aminothiophenes **21** in good yields (the Gewald reaction).^{65–74} The first stage of these reactions presumably involves the condensation of a nitrile with the carbonyl group of compounds **20** (the Knoevenagel-like reaction) and formation of 4-mercapto nitriles (path *a*) the structures of which are suitable for intramolecular cyclisation. However, two other possible mechanisms involving the initial nucleophilic attack on the cyano group by thiolate (path *b*) and the concerted cyclocondensation (path *c*) cannot also be excluded from consideration.

$R^1, R^2 = \text{H, Alk, Ar; } Z = \text{CN, CO}_2\text{R}^3, \text{CONH}_2, \text{COAr, 4-NO}_2\text{C}_6\text{H}_4\text{SO}_2\text{R}^4; R^3, R^4 = \text{H, Alk, Ar.}$

The use of dimeric 2,5-dihydroxy-1,4-dithianes ⁷³ instead of the α -mercapto carbonyl compounds **20** in the reactions with amides **1a,b** and other CH acids essentially simplifies the synthesis of substituted 2-aminothiophenes **21**.

A yet more efficient version of the Gewald reaction consists in the use of a mixture of a carbonyl compound **22** (aldehyde, ketone or β -dicarbonyl compound) and sulfur in the presence of an organic base in ethanol or DMF instead of the α -mercapto carbonyl compounds **20**. This method results in higher yields of 2-aminothiophenes **21**.^{66, 68, 69, 73–77}

Treatment of cyanothioacetamide (**1b**) or its *N*-aryl derivatives with sulfur in the presence of bases affords 2,5-diaminothiophenes **23**⁷⁸ or **24**.⁷⁹

Heating of solutions of equimolar amounts of 2-cyanomethylbenzothiazole (**25a**) or 2-cyanomethyl-1*H*-benzimidazole (**25b**) and sulfur in dry DMF in the presence of a base affords 3,5-diamino-4-[benzothiazol(or imidazol)-2-yl]-2-cyanothiophenes **26a,b** in 61%–64% yields.⁸⁰

$X = \text{S (a), NH (b).}$

Treatment of a mixture of cyanothioacetamide (**1b**) and cyclic ketones **27** with sulfur in the presence of a base gives rise to thieno[2,3-*d*]pyrimidine-4-thiones **28**. Compounds **29** are assumed to be the intermediates of this reaction.⁷⁸

$n = 2, 3.$

A series of thiophene derivatives **30–32** has been obtained by the reactions of cyanothioacetamide (**1b**) with ethyl 3-chloro-2,4-dioxopentanoate (**33**)⁸¹ or ethyl bromopyruvate (**34**).⁸² In ethanol in the presence of a base, the reaction of the amide **1b** with compound **33** involves its acetyl group, whereas the reaction of the same compounds in a mixture of pyridine and acetic acid involves

the α -carbonyl group of compound **33** and results in ethyl 5-acetyl-2-amino-3-cyanothiophene-4-carboxylate (**31**).⁸¹

The course of the reaction of the amide **1b** with ethyl bromopyruvate (**34**) also depends on the solvent. Thus the reaction of these compounds in a mixture of pyridine and acetic acid results in ethyl 2-amino-3-cyanothiophene-4-carboxylate (**32**), whereas ethyl 2-cyanomethylthiazole-4-carboxylate (**35**) is formed in DMF.⁸¹

The use of pyridinium ylides in reactions with nitriles containing the activated methylene group has led to the creation, in recent years, of methods of regio- and stereoselective synthesis of partially hydrogenated five-membered heterocycles.^{83–91}

The course of the reactions of pyridinium ylides **36** (prepared *in situ* by treatment of the corresponding pyridinium salts with an equimolar amount of triethylamine) with aryl- or hetarylmethyldene cyanothioacetamides **7b** depends on the temperature. Thus the condensations of these compounds at 20 °C follow the $\text{Ad}_\text{N}\text{-E}_{1,6}$ mechanism to yield stereoselectively substituted 3,4-*trans*-1,2,3,4-tetrahydropyridines **37**, whereas the reactions of these compounds under reflux follow the $\text{Ad}_\text{N}\text{-E}_{1,5}$ mechanism and give rise to 2,3-dihydrothiophenes **38**.^{83–89}

$\text{Ar} = 4\text{-FC}_6\text{H}_4, 4\text{-ClC}_6\text{H}_4, 4\text{-BrC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4, \text{Naph-1-yl};$

$R^1 = \text{Ph, 1-adamantyl}; R^2 = \text{H, Br.}$

Compounds **38** were also obtained by a three-component condensation of pyridinium ylide **36** ($R^1 = 1\text{-adamantyl}$) with aromatic or heteroaromatic aldehydes and cyanothioacetamide (**1b**).^{83, 84, 87, 88}

A novel stereoselective method for the preparation of *trans*-dihydrothiophenes **38** and *trans*-dihydrofurans **39** has been developed based on the three-component condensation of ylides **40** with aldehydes and amides **1a,b** in ethanol in the presence of triethylamine.⁸⁹

R = MeO, Ph; Ar = 2-MeOC₆H₄, 4-FC₆H₄, , ; X = S (**38**), O (**39**).

Functionally substituted *trans*-dihydrothiophenes **38** have also been obtained by the reactions of arylmethylidenecyanothioacetamides **7b** with stabilised sulfonium ylides generated *in situ* from bromides **41**. Cyclopropanethiocarboxamides **42** were found to be the minor products of these reactions.^{92,93}

R = Ph, ; Ar = 2-MeC₆H₄, 2-NO₂C₆H₄, 4-MeOC₆H₄, , .

First publications on the use of the Gewald reaction in the synthesis of sulfur-, selenium- and tellurium-containing five-membered heterocycles have appeared recently.^{65–74} Compounds **43–45** were prepared in 60%–85% yields by treating mixtures of ethyl cyanoacetate (cyanoacetamide, malononitrile) and isothiocyanates, cyclohexanone or camphor with sulfur, selenium or tellurium. It has been found that ultrasound or microwave irradiation considerably accelerate these reactions.^{94,95}

R = Ph, PhCO, CH₂=CHCH₂, Bu^tCO; X = S, Se, Te; Y = CO₂Et, CONH₂, CN.

The addition of cyanoacetamide (**1a**) to 1,1-diphenylethylene in acetic acid in the presence of Mn(OAc)₃ results in a complex mixture of amides **46** and **47**, lactones **48–50**, lactam **51** and benzophenone.⁹⁶

A new approach to the synthesis of substituted pyrrolinone derivatives has been developed using the Knoevenagel condensation of α -hydroxy ketones **52** with substituted cyanoacetamides aimed at comparing biological activities of oxygen- and nitrogen-containing five-membered heterocycles. These reactions occur *via* iminolactams **53**, which are readily converted into the corresponding pyrrolinones **54** under the reaction conditions.⁹⁷

R¹ = Alk, CH₂=CHCH₂, Bn; R² = H, Alk, Bn, Het.

The condensation of cyanothioacetamide (**1b**) with diethyl oxalate results in 4-cyano-5-thioxopyrrolidine-2,3-dione (**55**). The latter reacts with arylmethylidene malonates yielding pyrrolidino[1,2-*b*]-1,3-thiazine-5,6-diones **56**.^{42,43,98}

Z = CN, C(S)NH₂, CO₂Et.

The reactions of amide **1b** with maleic anhydride or *N*-(2-chlorophenyl)maleimide afford pyrrolidine (**57**) or pyrrolo[3,2-*b*]pyrrole (**58**) derivatives.⁹⁹

2,3,6-Trimethylbenzoquinone (**59**) reacts with cyanoacetamide (**1a**) in the presence of sodium methoxide yielding 5-hydroxy-4,6,7-trimethyl-3-cyanoindolin-2-one (**60**).^{100,101}

Polysubstituted phthalimide **61** has been obtained by condensation of methyl acetylenedicarboxylate with the amide **1a** in the presence of Cu₂(OAc)₄ in dioxane.¹⁰²

Cyanoacetamide (**1a**) has been used as the starting material in the synthesis of dye **62**. The cyclocondensation of phthalonitrile with the amide **1a** was carried out in methanol in the presence of NaOMe and then the reaction mixture was treated with barbituric acid at 65 °C.^{103, 104}

(a) **1a**, MeONa, MeOH; (b) $\text{H}_2\text{C}(\text{OC-NH})_2$, 65 °C.

The reaction of enamino ketone of the indoline series **63** with the amide **1a** (refluxing in benzene in the presence of triethylamine) gives rise to 3-amino-2-carbamoyl-9-oxopyrrolo[1,2-*a*]indole **64**.¹⁰⁵

A series of pyrrolothiolates has been synthesised by reaction of the amide **1a** with sulfur in the presence of catalytic amount of diethylamine.¹⁰⁶

b. Five-membered heterocycles with two heteroatoms in the ring

Cyanoacetamides and their chalcogen analogues have been successfully used in syntheses of five-membered heterocycles with two heteroatoms in the ring: thiazoles, isothiazoles, thiazolinones, oxazoles, pyrazoles, imidazoles, dithioles, *etc.*

Thus the condensation of cyanothioacetamide (**1b**) with α -halogeno carbonyl compounds involving their methylene group has been employed in the synthesis of 2-thiazolylacetonitriles **65** as well as thiazolylthiones and other five-membered heterocycles.^{34, 59, 80, 81, 107}

R = Alk, Ar, CO_2Et .

Thiazole derivatives **66** were synthesised by the reaction of 2-acetyl-2-cyanothioacetamide **67** (prepared by the acetylation of the amide **1b**) with ethyl bromoacetate or 1-chloroacetonitrile in good yields.¹⁰⁸

R = OH, NH_2 .

3-(Bromoacetyl)coumarins **68** react with activated thioamides **69** on heating in ethanol to give substituted thiazoles **70** in yields of up to 93%.¹⁰⁹

$\text{R}^1 = \text{R}^2 = \text{H}$; $\text{R}^1 - \text{R}^2 =$; $\text{R}^1 = 7\text{-NEt}_2$, $\text{R}^2 = \text{H}$;

X = CH_2CN , NH_2 , NHNH_2 , $\text{C}(\text{S})\text{NMe}_2$.

The reaction of the pregnenolone derivative **18** containing the cyanothioacetamide fragment with phenacyl bromide was employed for the synthesis of thiazolyl-substituted steroids **71** (yields 85%–97%).^{60, 62, 110}

R = Alk; X = H, Cl, Br.

Cyanothioacetamide (**1b**) reacts with sulfur and isothiocyanates in the presence of bases yielding thiazoline-2-thione derivatives **72**. The latter are cyclised on treatment with formic acid to give thiazolo[4,5-*d*]pyrimidine-2,7-dithiones **73**.⁷⁸ Similar reaction of the amide **1b** with sulfur and hydrogen sulfide affords 1,2-dithiol-3-thione derivative **74**, which is converted into 5-amino-4-cyano-1,2-dithiol-3-thione (**75**) on treatment with formic acid rather than undergoes cyclisation.⁷⁸

R = Me, Ph, $\text{CH}_2 = \text{CHCH}_2$.

Reactions of the amide **1a** and its derivatives with isothiocyanates have also been employed in the synthesis of other substituted thiazoles.^{111, 112}

Thiazolyl-substituted acrylonitriles **76** can be prepared in two ways. The first one is the reaction of phenacyl bromide with salts **77**. The latter are obtained by the reaction of Meldrum's acid (**78**) with aromatic aldehydes and cyanothioacetamide (**1b**) or with arylmethylidenecyanothioacetamides **7b** (ethanol, 20–25 °C, equimolar amount of the secondary amine). The second method of preparation of acrylonitriles **76** is based on the reaction of phenacyl bromide with amides **7b**.^{113–117}

Thiazolinone **79** was obtained by the reaction of cyanoacetamide (**1a**) with mercaptoacetic acid or its ester.^{118,119} This compound can also be synthesised from cyanothioacetamide (**1b**) and ethyl chloroacetate.¹²⁰

R = H, Alk.

Thiazole derivatives **80** and **81** also have been synthesised using the amide (**1b**).^{81,82,109}

4-Thiazoline-2-thione derivatives **82** were obtained by the reaction of cyanoacetamide (**1a**) with isothiocyanates in the presence of elemental sulfur.¹²¹ The reaction of the same amide with 2-mercaptoaniline gives 2-carbamoylmethylbenzothiazole (**83a**).¹²² The latter is employed in light- and waterproof azo-dyes used in polycaprolactam manufacture. Benzoxazole **83b** is obtained in a similar way from the amide **1a** and 2-aminophenol.¹²³

R = Ar, Alk.

X = S (a), O (b).

Reactions of the amide **1a** with phenacyl benzoates in boiling xylene in the presence of BF_3 afford 2-aryl-4-phenyloxazoles in 75%–90% yields.¹²⁴

Isothiazole **84** has been obtained in good yield by bromination of acetyl(cyano)thioacetamide **67**.¹⁰⁸

The condensation of the amide **1a** with CS_2 in the presence of KOH results in 3,5-dimercaptoisothiazole-4-carboxamide **85**.¹²⁵

5-Amino-3-methyl-4-cyanoisothiazole (**87**) has been synthesised by the reaction of the amide **1b** with methyl dithioacetate (**86**).¹²⁶

N-Substituted cyanothioacetamides **88** were prepared from ethyl cyanoacetates and aryl isothiocyanates,¹²⁷ their reactions with hydrazines **89** yielded 5-amino-3-arylaminopyrazoles **90**.¹²⁸ The analogous reaction of the amide **1a** with hydrazonoyl chloride **91** afforded 5-amino-1,3-diphenylpyrazole-4-carboxamide.¹²⁹

$\text{R}^1 = \text{Ar}; \text{R}^2 = \text{H}, \text{Ar}.$

Cyanoacetamide derivatives **92** on heating with hydrazine give pyrazoles **93**, while their reactions with mercaptoacetic acid result in thiazolinones **94**.¹³⁰

Ar = Ph, 4-MeC₆H₄, 4-ClC₆H₄.

The reaction of N-[bis(methylthio)methylidene]toluene-4-sulfonamide (**95**) with the amide **1a** affords compound **96** in 94% yield. The latter gives pyrazoles **97** in yields of up to 98% on treatment with hydrazines.¹³¹

$\text{R} = \text{H}, \text{Ph}, 4\text{-ClC}_6\text{H}_4, 4\text{-NO}_2\text{C}_6\text{H}_4$.

Phenylhydrazone **98** reacts with the amide **1a** in methanol in the presence of sodium methoxide yielding pyrazole **99**.¹³² An analogous reaction of hydrazone **100** with a bulky substituent affords pyrazole **101** in only 6% yield.¹³³ Isooxazole **103** is obtained from hydroximoyl bromide etherate under similar conditions.¹³²

High yields of isoxazoloquinazolines **104** were obtained upon cyclocondensation of 4-methylthioquinazoline 3-oxides **105** with the amide **1a** in the presence of Bu^tOK .¹³⁴

$\text{R} = \text{Ph}, 4\text{-MeC}_6\text{H}_4$.

Reactions of 1-oxa-2-azaspiro[2.5]octane (**106**) with cyanoamides **107** give spiroimidazoline derivatives **108** in high yields.¹³⁵

$\text{R} = \text{cyclo-C}_5\text{H}_9, \text{cyclo-C}_6\text{H}_{11}, \text{Me}(\text{CH}_2)_7, \text{PhCH}_2$.

A four-step synthesis of a xanthine analogue, viz., 5,6,7,8-tetrahydro-4*H*-imidazo[4,5-*c*]-1,4-diazepine-5,8-dione (**109**), has been developed starting from cyanoacetamide (**1a**).¹³⁶

(a) HNO_2 ; (b) $[\text{H}]$; (c) $\text{CH}_2(\text{OEt})_2, \text{BnNH}_2$; (d) KOH ; (e) H_2/Pd .

2-Cyanomethylbenzimidazole (**110**) has been obtained by condensation of cyanoacetamide (**1a**) with *o*-phenylenediamine in good yield.¹³⁷ This reaction, carried out in the presence of concentrated sulfuric acid, was accompanied by hydrolysis of the cyano group resulting in 2-carbamoylmethylbenzimidazole **111**.^{138, 139}

The reaction of *o*-phenylenediamine with substituted cyanoacetamide **112** under similar conditions gives rise to benzimidazole derivative **113**.¹⁴⁰

c. Five-membered heterocycles with three heteroatoms in the ring

The amide (**1a**) and thioamide (**1b**) are widely used in the synthesis of five-membered heterocycles with three heteroatoms in the ring, in particular, of 1,2,3-triazoles possessing a wide range of biological activities. Synthesis of substituted 1,2,3-triazoles by the reactions of cyanoacetamide (**1a**) with alkyl-, aryl- and hetarylazides can be mentioned as an example.^{141–145} It is noteworthy that the preparation of 1,2,3-triazole derivatives from compounds with an activated methylene group and phenyl azide was first reported by Dimroth in 1902.^{146, 147}

1-Azidoglycosides **114** react with the amide **1a** in aqueous DMF in the presence of KOH to give triazolonucleosides **115** in high yields. The reactions proceed with inversion of configuration yielding 1,2-*trans* adducts from 1,2-*cis* azides.¹⁴⁴

The synthesis of 2-substituted 9- β -D-ribofuranosyl-8-azahypoxanthines **116** from β -D-ribofuranosyl azide, sodium salt of the amide **1a** and carboxylic acid esters has also been described.¹⁴⁵

Synthesis of nucleosides with 1,2,3-triazoles and 8-azapurines as aglycones by reactions of azides **117** with the amide **1a** has been undertaken aimed at access to novel potential pharmaceutical preparations. In the presence of KOH in aqueous DMF at 0 °C, these reactions gave rise to 1,2,3-triazole derivatives **118**. The latter were readily converted into 8-azapurine derivatives **119** on treatment with ethyl formate.^{148, 149}

R = PhCH₂O(CH₂)₂, (PhCH₂OCH₂)₂CH; X = O, S.

The reaction of benzyl azide with the amide **1a** in EtOH in the presence of NaOEt followed by treatment of the reaction mixture with carboxylic acid esters affords 3,5-disubstituted 7-hydroxy-3*H*-1,2,3-triazolo[4,5-*d*]pyrimidines **120**. 5-Amino-1-benzyl-1,2,3-triazole-5-carboxamide (**121**) has been postulated as an intermediate.¹⁵⁰

R¹ = H, Me, Et, Pr, CH₂OCH₂Me, CH(OCH₂Me)₂, (CH₂)₂CO₂H, CO₂Et, Ph, PhCO, CH₂NHCOPh; R² = Me, Et.

Many other 1,2,3-triazole derivatives possessing coccidiostatic, anticonvulsive, antiproliferative and other types of biological activities have been synthesised using the reactions of aromatic and aliphatic azides with the amide **1a**.^{151–157}

The reaction of 6-nitroazolo[1,5-*a*]pyrimidines **122** with the amide **1a** in refluxing ethanol involves transformation of the pyrimidine ring into the pyridine ring and affords substituted 2-azolyl-2-pyridylamines **123**. The latter are converted into 7-nitro-9-oxo-4,9-dihydroazolo[1,5-*a*]pyrido[2,3-*d*]pyrimidines **124** on subsequent treatment with sodium carbonate in ethanol and acidification with HCl.^{158, 159}

R = H, Me, SMe, CF₃, Cl, NH₂, NMe₂, Ph; X = N, CH, CNO₂.

Synthesis of 5-amino-4-cyano-1,2,3-thiadiazole (**126**) by the reaction of tosyl azide **125** with cyanothioacetamide (**1b**) has been described.¹⁶⁰

Later,¹⁶¹ 1,2,3-thiadiazolium bromides **127** were obtained by bromination of arylhydrazonocyanothioacetamides **16**.

A group of Japanese scientists¹⁶² have developed a nine-step method of synthesis of a useful chemical modifier of cephalosporin antibiotics, viz., (Z)-2-(5-amino-1,2,4-thiadiazol-3-yl)-2-[(fluoromethoxy)imino]acetic acid (**128**), from cyanoacetamide (**1a**) according to the scheme shown below. The yield of the target product with respect to the initial cyanoacetamide was 17.6%.

(a) HNO₂ (81%); (b) BrCH₂F, Et₃N (75%); (c) POCl₃ (72%); (d) NH₄OH, NH₄Cl (84%); (e) Br₂; (f) KSCN, Et₃N (88%); (g) MeONa, MeOH (92%); (h) H₂SO₄, H₂O (84%); (i) HCO₂H, Ac₂O (84%); (j) NaOH, H₂O (84%).

2. Synthesis of six-membered carbo- and heterocycles

Of six-membered heterocycles synthesised on the basis of cyanoacetamides, pyridin-2-one (-thione and -selenone) derivatives are of major interest (see, for example, reviews^{27, 28, 30–34, 74} and papers^{163–175}). Many of these compounds have been found to be highly effective cardiotonics^{176–251} (e.g., 'amrinone' and 'milrinone'^{242–251}), non-nucleoside inhibitors of HIV reverse transcriptase (potential pharmaceuticals for treatment of

AIDS^{252–265}), tranquilisers,^{266–278} compounds with antiinflammatory, hypoglycemic, anticonvulsant, antiulcerous, fungicidal, bactericidal, pesticidal and many other types of biological activity.^{272–308} Pyridin-2-ones are also very useful starting materials in the design of novel calcium antagonists,^{309,310} CH antioxidants,^{311–315} folic acid analogues,³¹⁶ vitamin B₆,³¹⁷ and other biologically active compounds,^{311, 316–324} as well as models of redox coenzymes NAD and NADP.²⁸⁵ As an example, the use of substituted spiro[cyclopentane-piperidone] in the synthesis of ‘buspirone’, which is an antidepressant and an analgesic, and also prevents an affection to narcotics,²⁶⁹ can be mentioned. The only known natural alkaloid with the cyano group in a molecule is a representative of the class of pyridones (‘ricyan’, 3-cyano-4-methoxy-1-methylpyridin-2-one).³²⁵ Pyridin-2-one derivatives are employed as stabilisers of polymers and lacquers,³²⁶ as pigments and diazo-components in the synthesis of dyes,^{327–334} as acid–base indicators in titrimetric analysis;³³⁵ they possess liquid-crystalline³³⁶ and some other practically useful properties.

The simplest and most convenient methods for the preparation of functionally substituted pyridin-2(1*H*)-ones, -thiones and -selenones are based on the use of cyclisation reactions of carbonyl compounds and their enamines with compounds containing the activated methylene group, first of all, malononitrile and cyanoacetamides. This opens an indirect route to regioselective synthesis of functionally substituted pyridines. Direct functionalisation of the rather inert pyridine ring by electrophilic substitution reactions is quite difficult.

Condensations of symmetrical 1,3-dicarbonyl compounds with cyano(chalcogeno)acetamides **1a–c** occur smoothly in the presence of basic catalysts to give 3-cyanopyridin-2(1*H*)-ones, -thiones and selenones **129** in high yields.^{28, 85, 337–352} Similar reaction of monothiodibenzoylmethane (**130**) with cyanothioacetamide (**1b**) in ethanol in the presence of piperidine gives rise to 3-cyano-4,6-diphenylpyridine-2(1*H*)-thione.³⁵³

R = Alk, Ar, Het; X = O (a), S (b), Se (c).

It is noteworthy that pyridin-2(1*H*)-ones **129a** were obtained by the above method as far back as the end of the past century, while the first thione analogue, *viz.*, 3-cyano-4,6-dimethylpyridine-2(1*H*)-thione, was synthesised by condensation of acetylacetone with the amide **1b** at the end of the 1950's,^{338,341} and the first selenone analogue was prepared in a similar way from the amide **1c** only in 1985.⁴⁷ Reactions of cyanothioacetamide (**1b**) occur under milder conditions and give higher yields of pyridines than with cyanoacetamide (**1a**). The reactions of cyanoselenoacetamide (**1c**) also occur under mild conditions, though an inert atmosphere is required in this case.

The reaction of 1,3-diketones with dimethylformamide dimethyl acetal affords β-enamino carbonyl compounds **131**, which are condensed with amides **1a,b** yielding functionally substituted pyridones and pyridinethiones **132**.^{232, 235, 354–356}

R¹ = Me, Et, CH₂CO₂Et; R² = Me, MeO, EtO; X = O, S.

Synthesis of pyridinethiones **133** by the reaction of ethoxymethylidene diketones **134** with the amide **1b** in ethanol in the presence of piperidine has also been described.³⁵⁷

Condensations of unsymmetrical 1,3-dicarbonyl compounds with cyano(thio, seleno)acetamides **1a–c** leads to two isomeric pyridines with different substituents in positions 4 and 6, which allows one to elucidate the effect of the reactivities of the carbonyl groups on the regioselectivity of reactions. Thus it was shown^{85, 337, 347, 358} that the condensation of benzoylacetone with the amide **1b** gives both isomeric pyridinethiones **135b** and **136b** (Ar = Ph) in the ratio 2 : 1. Earlier, only the isomer **135b** was thought to be the reaction product.³⁴¹ However, the analogous reaction of benzoylacetone with cyanoselenoacetamide (**1c**) occurs with high regioselectivity to give only one isomer, *viz.*, 3-cyano-4-methyl-6-phenylpyridine-2(1*H*)-selenone (**135c**, Ar = Ph).^{358, 359}

Reactions of cyanothioacetamide (**1b**) with other unsymmetrical 1,3-diketones **137** (Ar = 4-MeC₆H₄, 4-MeOC₆H₄, 4-BrC₆H₄, 2-thienyl) also give rise to mixtures of the corresponding isomers **135b** and **136b**.^{360, 361}

Only the isomer **135a** (Ar = Ph) was earlier assumed^{362, 363} to be the reaction product of benzoylacetone with cyanoacetamide (**1a**) or ethyl cyanoacetate in the presence of ammonia or diethylamine. In the condensation of nicotinoylacetone with cyanoacetamide (**1a**), a mixture of isomers **135a** and **136a** (Ar = 3-pyridyl) in the ratio 3 : 2 is formed, while in the reaction of 4-pyridylcarbonylacetone, the isomer **136a** (Ar = 4-pyridyl) is the major product.¹⁶⁷

The regioselectivity of the reaction is the higher the stronger are the electron-withdrawing properties of a substituent at one of the carbonyl groups. Thus 1,3-diketones with the trifluoromethyl group **137** react with cyanoacetamides **1b,c** to give only 3-cyano-6-R-4-trifluoromethylpyridine-2(1*H*)-thiones and -selenones **138** in fairly high yields.^{345, 364–366} The change in the order of operations, *i.e.*, the preliminary generation of a carbanion from the thioamide **1b** by treating it with sodium ethoxide followed by the addition of trifluoroacetylacetone has led to the other isomer, *viz.*, 3-cyano-4-methyl-6-trifluoromethylpyridine-2(1*H*)-thione, in 94% yield.^{365, 367}

R = Alk, Ph, 4-MeC₆H₄, 4-MeOC₆H₄, 4-ClC₆H₄, ; X = S, Se.

Reactions of cyanoacetamide (**1a**) with 1,3-dicarbonyl compounds and their derivatives have successfully been employed in the synthesis of pyrimidines, pyrazines and other heterocycles.^{368–380} Thus the condensation of the amide (**1a**) with methyl 2-acetyl-4-ynoate (**139**) in concentrated aqueous ammonia solution gives rise to pyridone **140**. An analogous reaction of ethyl 2-acetyl-4-enoate (**141**) with the amide **1a** in piperidine yields pyridone **142**.³⁷¹

Substituted dispiro(dipyran[2,4':6,4']bisdithiolo[4,5-*b*:4',5'-*e*])-4,8-benzoquinone **144** was obtained by the reaction of 2,6-bis(diacetylmethylidene)bisdithiolo[4,5-*b*:4',5'-*e*]benzoquinone (**143**) with a twofold excess of the amide **1a** in ethanol in the presence of piperidine.³⁸⁰

The kinetics of condensation of symmetrical and unsymmetrical 1,3-diketones (pentane-2,4-dione, 5-methylhexane-2,4-dione, 5,5-dimethylhexane-2,4-dione) with cyanoacetamide (**1a**) in the presence of piperidine as a catalyst under various reaction conditions has been studied. Judging from the rate constants and activation parameters as well as the structure of unsymmetrical 4,6-disubstituted 3-cyanopyridin-2(1*H*)-ones obtained, a plausible scheme for the reaction mechanism was suggested, which gives a rationale for the regioselectivity of the condensation and the positions of the substituents in the reaction products.³⁸¹

Cyclic 1,3-diketones have been successfully employed as substrates in the reactions with cyanoacetamides **1a-c**, and regioselective syntheses of bicyclic 3-cyanopyridin-2(1*H*)-ones, -thiones and -selenones **146** were proposed.^{85, 346, 382–394}

n = 1, 2; R = Alk, Ar; X = O, S, Se.

This approach has also been applied to the preparation of pyridone **147** having the skeleton of the alkaloid papaverine.³⁸⁶

7-Acetyl-8-aryl-4-cyano-1,6-dimethyl-6-hydroxy-5,6,7,8-tetrahydroisoquinolin-2(1*H*)-ones **149a**, -thiones **149b** and their sodium salts **150a,b** were obtained in high yields in reactions of the amides **1a,b** with 2,4-diacetyl-3-aryl-5-hydroxy-5-methylcyclohexanones **148**.³⁹⁴

Of reactions of cyclic 1,3-diketones with cyanoacetamide (**1a**),^{277, 280, 395–399} the condensations of pyrans or thiopyrans **151** in ethanol in the presence of triethylamine can be noted as the method for preparation of 3-oxopyrano(thiopyrano)[3,4-*c*]pyridines **152**.^{277, 395, 396}

R = Alk, Ar; X = O, S.

It is known that substituted coumarins and their annelated analogues exhibit bactericidal, spasmolytic and hypothermic activities. In order to develop methods of synthesis of substituted coumarins, which could be used in design of novel pharmaceuticals, it was necessary to study reactions of 3-acetylcoumarin

(**153**) with the amides **1a,b** in the presence of bases. This resulted in oxo- and thio-derivatives of benzopyrano[3,4-*c*]pyridines **154**.²⁸⁰

X = O (**a**), S (**b**).

Compared with cyclic 1,3-diketones, cyclic β -oxo aldehydes react with cyanoacetamides more selectively. Thus the condensations of sodium salts of 2-hydroxymethylidenecycloalkanones **155** with amides **1b,c** occur regioselectively to give only one of two possible isomers, viz., 5,6-annulated 3-cyanopyridine-2(1*H*)-thiones **156a** and -selenones **156b**.^{85, 387, 400–406}

$n = 1, 2$; X = S (**a**), Se (**b**).

Yet another example of high regioselectivity is the reaction of sodium salt of 2-formylquinuclidone (**157**) with cyanothioacetamide (**1b**), which affords only bridged 3-cyano-1,5-naphthyridine-2(1*H*)-thione (**158**).⁴⁰⁷

Cyanothioacetamide has been used in the synthesis of steroids annelated with the pyridine ring. Thus pyridinethione **161** was obtained in 80% yield by condensation of the amide **1b** with the sodium enolate of 16-formyl-5 α -androstan-17-one (**159**).^{60, 408} The latter has been prepared by formylation of 5 α -androstan-17-one (**160**) with methyl formate.

An example of recyclisation of (1,2,5-trimethyl-4-oxopiperidin-3-ylmethylidene)cyanothioacetamide (**162**), prepared from the sodium salt of 1,2,5-trimethyl-3-formylpiperidin-4-one (**163**) and the amide **1b**, into 4-cyano-6,7,8a-trimethyl-3-thioxo-1,2,3,5,6,7,8,8a-octahydro-2,7-naphthyridin-1-one (**164**) has been described.^{173, 409}

Similarly to cyclic β -oxo aldehydes, their acyclic analogues also react with high regioselectivity.^{38, 85, 174, 395, 410–422} Thus 6-substituted 3-cyanopyridine-2(1*H*)-thiones and -selenones (**166**) are formed in the reaction of amides **1b,c** with sodium enolates of β -oxo aldehydes (**165**). The regioselectivity of the reaction is independent of the nature of substituents (electron-donating or electron-withdrawing) in the benzene ring of the substrates **165**.^{85, 397–399, 402}

R = Pr, Ph, 4-ClC₆H₄, 4-BrC₆H₄, 3,4-Cl₂C₆H₃, 4-MeOC₆H₄,

2,4-(MeO)₂C₆H₃,  N; X = S, Se.

The key step in the synthesis of 2-pyridinone derivatives **167** possessing high anti-HIV activity^{253, 257} is the condensation of sodium enolate of 2-ethyl-3-oxobutane (**168**) with cyanoacetamide (**1a**) in the presence of piperidinium acetate.

R = , , , , , .

The regioselective reaction of sodium enolates of 2- and 3-thenoylaldehydes **169** with cyanothioacetamide (**1b**) in ethanol in the presence of acetic acid, giving rise to the corresponding 3-cyano-6-thienylpyridine-2(1*H*)-thiones **170**,⁴²¹

presents yet another example of successful synthesis of substituted pyridine-2-chalcogenones using condensations of oxo aldehydes with cyanoacetamides.

The condensations of cyanoacetamides with aliphatic, aromatic and heterocyclic aldehydes also lead to functionalised heterocycles.^{423–436} Among this type of the reactions, cyclocondensations of 5-chloro-3-methyl-1-phenylpyrazole-4-carboxaldehyde (**171**) with amides **1a,b**, giving rise to pyrazolopyridines **172a,b**,⁴²⁶ and of 5-aminopyrazole-4-carboxaldehydes **173** with the amide **1a**, which makes possible the preparation of amino-substituted pyrazolo[3,4-*b*]pyridines **174**,⁴²⁹ are worth mentioning.

X = O (a), S (b).

R = Me, Pr, Ph.

4-Substituted 6-amino-3,5-dicyanopyridine-2(1*H*)-thiones **175** are convenient building blocks in the synthesis of biologically active compounds. It is remarkable that they can be prepared from aliphatic or aromatic aldehydes, cyanothioacetamide (**1b**) and malononitrile in a one-pot preparative step including three consecutive reactions.^{432, 434–442}

R = Alk, Ar.

Analogous reactions of aromatic and heterocyclic aldehydes with cyanoacetamide (**1a**) in the presence of ammonium acetate had earlier been employed for the synthesis of 4-substituted 3,5-dicyano-6-hydroxypyridin-2(1*H*)-ones **176**.⁴³⁷

R = Ar, Het.

The cyclisation of glutaraldehyde with cyanoacetamide (**1a**) occurs in aqueous dioxane in the presence of triethylamine to give 1-cyano-2,6-dihydroxycyclohexane-1-carboxamide (**177**) in 75% yield.⁴²⁵

Reactions of the amide **1a** with 2-nitro- and 2-aminobenzaldehyde have been successfully used in the synthesis of 2-aminoquinoline-3-carboxamide **178**.⁴³⁸

Analogous reactions of amides **1a,b** with hydroxybenzaldehyde and hydroxybenzo[*b*]thiophenecarbaldehyde have led to coumarin derivatives **179a,b** and **180a,b**.^{439–442}

X = O (a), S (b).

β-Enamino carbonyl compounds are widely used in the synthesis of various heterocyclic compounds. They are successfully employed for regioselective synthesis of 3-cyanopyridin-2(1*H*)-ones, -thiones and -selenones **129a–c** (see, for example, reviews^{28, 30, 85} and papers^{443–454}).

R¹ = Alk, Ar, Het; R², R³ = H, Ph;

R²–R³ = (CH₂)₅, (CH₂)₂O(CH₂)₂; X = O (a), S (b), Se (c).

It was found^{47, 85, 341–343, 349, 353, 387} that unlike the condensations of 1,3-dicarbonyl compounds, the reactions of the corresponding symmetrical β-enamines with cyanoacetamides occur under mild conditions (20–40 °C) and in the absence of basic catalysts to give selectively and in higher yields 4,6-disubstituted 3-cyanopyridin-2(1*H*)-ones, -thiones and -selenones **129a–c**.

Synthesis of 5-substituted 3-cyanopyridin-2(1*H*)-ones **181** is based on the use of the reactions of β-enamino aldehydes **182** with cyanoacetamide (**1a**) in the presence of a base.^{272, 455–462}

R = Ar, Het.

Condensations of β -enamines prepared from unsymmetrical 1,3-diketones with amides **1a–c** can afford isomeric 4,6-disubstituted 3-cyanopyridin-2(1*H*)-ones, -thiones and -selenones depending on whether the keto or the amino group of enamines is subjected to the initial nucleophilic attack by amides.^{85, 339, 345, 347, 358, 387, 446, 463–467} Varying the substituents in initial enamines and the reaction conditions, one may control the direction of these reactions leading to one particular isomer or to a mixture of both isomers.

Thus 2-amino-1-benzoylpropene (**183**) reacts with cyanoacetamide (**1a**) in the presence of sodium ethoxide to give 3-cyano-6-methyl-4-phenylpyridin-2(1*H*)-one (**184**),^{339, 464, 466, 467} while the condensation of these compounds at 150 °C for 1 h results in the isomeric 3-cyano-4-methyl-6-phenylpyridin-2(1*H*)-one (**185a**).^{464, 465}

Only 3-cyanopyridine-2(1*H*)-thione **185b** and -selenone **185c** are obtained on brief refluxing of a mixture of β -enamino ketones **186** or **187** and amide **1b** or **1c** in ethanol in the presence of acetic acid.^{85, 347, 358, 446, 463}

X = S (**b**), Se (**c**).

The stronger the electron-withdrawing properties of the substituent at the sp^2 hybridised carbon atom linked with the amino group, the higher the regioselectivity of the reaction. This is true even for those enamines which have the phenyl and 2-thienyl substituents at the carbonyl group. Thus condensations of trifluoromethyl-substituted enamino ketones **188** with amides **1b,c** in ethanol at 25–30 °C in the absence of a catalyst afford 3-cyano-6-phenyl- or -6-(2-thienyl)-4-trifluoromethylpyridine-2(1*H*)-thiones and -selenones **138**.^{85, 345}

R = Ph, ; X = S, Se.

β -Enamino ketones can also be used for the preparation of 5,6-disubstituted 3-cyanopyridin-2(1*H*)-ones. Thus 6-alkyl-5-aryl-3-cyanopyridin-2(1*H*)-ones **189** possessing cardiotoxic activity have been obtained by condensation of enamino ketones **190** ($R^1 = R^2 = \text{Me}$) with cyanoacetamide (**1a**) in the presence of sodium methoxide.^{86, 87, 468–472} 3-Cyano-5-aryl-6-methylpy-

ridine-2(1*H*)-thiones **189** (X = S) were synthesised in a similar way from the enamino ketone **190** [$R^1 - R^2 = (\text{CH}_2)_2\text{O}(\text{CH}_2)_2$].⁴⁷³

Ar = Ph, 4-MeSC₆H₄, 4-SO₂C₆H₄, 3,4-(MeO)₂C₆H₃; $R^1, R^2 = \text{Alk}$;
 $R^1 - R^2 = (\text{CH}_2)_2\text{O}(\text{CH}_2)_2$; $R^3 = \text{Me}, \text{CH}(\text{OMe})_2, \text{cyclo-Alk}$; X = O, S.

The well-known cardiotoxic preparation 'milrinone' (**192**) is obtained by the condensation of the enamine **191** with cyanoacetamide (**1a**) or malononitrile (**5**).⁴⁷⁴

The reaction of enamine **193** with the amide **1a** in isopropyl alcohol in the presence of sodium alkoxides is nonselective and results in a mixture of pyridones **194** and **195**.⁴⁷⁵

5,6-Disubstituted 3-cyanopyridin-2(1*H*)-ones **132** have been obtained by the reactions of 2-aminomethylidene derivatives of 1,3-dicarbonyl compounds **196** with the amide **1a** in the presence of sodium hydride in THF³⁶⁹ or sodium methoxide in DMF.⁴⁷⁶ Both symmetrical^{369, 476} and unsymmetrical^{477–479} β -diketones were used in these reactions. Compounds **196** with substituents $R^1 = \text{Bu}^n$, OEt and $R^2 = \text{Me}$ react regioselectively yielding only one isomer.

$R^1, R^2 = \text{Me}, \text{Pri}, \text{Bu}^t, \text{Bu}^n, \text{OEt}, \text{Ph}$.

3-Cyano-4,4,6-trimethylpyridin-2(1*H*)-one (**197**) has been obtained by the reaction of 4-amino-3-methylpent-3-en-2-one (**198**) with the amide **1a** at 150 °C for 30 min.⁴⁶⁵ This compound was also synthesised by the condensation of the enamine **198** with malononitrile (**5**) in THF in the presence of triethylamine at 20 °C.⁴⁵⁴

The condensations of β -enamino carbonyl compounds **199** with substituted cyanoacetamides **200a,b** occur with the elimination of methanethiol and result in 4-dialkylaminopyridones **201a,b** bearing the β -enamino amide fragment. Compound **201b** reacts with *N*-methylcyanoacetamide **200b** to give naphthyridine-dione **202**.⁴⁸⁰

$\text{R}^1 = \text{Me, Ph, 4-ClC}_6\text{H}_4, 4\text{-MeOC}_6\text{H}_4$; $\text{R}^2 = \text{H}$;
 $\text{R}^3 = \text{Et, Ph, CH}_2\text{CH}(\text{OEt})_2, \text{Bn}$; $\text{R}^4 = \text{H}$;
 $\text{R}^3\text{--R}^4 = (\text{CH}_2)_2\text{O}(\text{CH}_2)_2$; $\text{R}^5 = \text{H}$ (a), Me (b).

Synthesis of fused pyridinones, -thiones and selenones takes advantage of the high reactivity of cyclic β -enamino ketones with respect to cyanoacetamides **1a–c**.^{28, 30, 85, 346, 349, 382, 384–387, 446, 481, 482} Condensations of enamino ketones **203** with amides **1a–c** occur regioselectively to give in each case only one of two possible isomers in the absence of basic catalysts and afford the products in higher yields (on average, by 10%) than those obtained from 1,3-dicarbonyl compounds. Condensations of β -enamino ketones **203** bearing an aryl substituent instead of an alkyl one, demand more drastic reaction conditions. Thus 3-cyano-6-phenyltetrahydroisoquinolin-3-one **146** ($n = 4$, $\text{X} = \text{O}$, $\text{R} = \text{Ph}$) can be obtained on refluxing of the equimolar amounts of the starting compounds in isopropyl alcohol for 1.5 h.³⁸⁴

$n = 1, 2$; $\text{R} = \text{Alk, Ar}$; $\text{X} = \text{O, CH}_2$; $\text{Y} = \text{CN, C(Z)NH}_2$; $\text{Z} = \text{O, S, Se}$.

It has been noted^{369, 481} that condensations of enamines prepared from cyclic oxo aldehydes and secondary amines are more regioselective.

Hydrogenated 3-cyanoquinoline-2(1*H*)-thiones and -selenones **156a,b** were obtained by the condensation of 2-piperidinomethylidenecycloalkanones **204** with amides **1b,c** in ethanol in the presence of acetic acid in high yields.^{85, 352, 387, 402–404, 446}

$n = 2, 3$; $\text{X} = \text{S}$ (a), Se (b).

The reaction of 2-dimethylaminomethylidenecyclohexanediones **205** with cyanoacetamide (**1a**) in THF in the presence of NaOH gives rise to a mixture of cyanopyridones **206** and carbamoylpyrones **207**. When enamines **205** are made to react with the amide **1a** in ethanol under reflux, only carbamoylpyridones **208** are obtained in high yields.³⁶⁹

$\text{R}^1 = \text{H, Me}$; $\text{R}^2 = \text{H, Me, Ph}$.

The reaction of the enamine **209** prepared from dimedone with *N,N*-dimethylacetamide diethyl acetal (**210**) affords diaminodiene **211** in high yield. The latter reacts with amides **1a,b** with the elimination of dimedone to give 3-cyano-6-dimethylamino-pyridin-2(1*H*)-one (**212a**) or -thione **212b**, respectively.⁴⁴⁹

$\text{X} = \text{O}$ (a), S (b).

3-Cyanopyridin-2(1*H*)-ones, -thiones and -selenones can also be synthesised from β -enamino esters. Thus the condensation of the β -enamino ester **214** with the amide **1a** affords 3-cyano-6-hydroxy-4-methylpyridin-2(1*H*)-one (**213**), which is employed in the synthesis of dyes.⁴⁶⁵

It was found^{447, 483, 484} that enamines **215a** and **215b** prepared from ethyl acetoacetate or acetoacetanilide are more reactive toward amides **1a–c** than ethyl acetoacetate itself. Thus the reactions of enamines **215a,b** with amides **1a–c** in ethanol at room temperature afford salts **216** in high yields. The latter are readily converted into the corresponding pyridinones, -thiones or -selenones **217** on treatment with HCl. The pyridone **217** ($\text{X} = \text{O}$) was also prepared by the reaction of the enamine **215a** ($\text{X} = \text{CH}_2$) with the amide **1a** in water followed by acidification of the reaction mixture.

$\text{R} = \text{OEt}$ (**215a**), NHPh (**215b**); $\text{X} = \text{O, CH}_2$; $\text{Y} = \text{O, S, Se}$.

The β -enamino ester **215a** ($X = \text{CH}_2$) reacts with benzylidenecyanoacetamide **218** to give substituted 3,4-dihydropyridone **219**. The latter is transformed into ethyl 3-cyano-6-methyl-4-phenyl-1,2-dihydropyridine-5-carboxylate (**220**) on treatment with dilute nitric acid.⁴⁸⁵

Tetrahydroisoquinolinone **222** has been obtained by the condensation of β -enamino ester **221** with cyanoacetamide (**1a**).⁴⁶⁵

α,β -Unsaturated carbonyl compounds, owing to the substantial difference in reactivities of their nucleophilic centres, react with cyanothioacetamides yet more regioselectively than the corresponding enamino carbonyl compounds. In this case, the synthetic strategy consists in the condensation of unsaturated carbonyl compounds with cyanothioacetamide (**1b**) leading to 5-oxo thioamides **223**. The reason for regioselectivity is that Michael addition occurs preferentially, rather than the Knoevenagel condensation involving the carbonyl group. Further intramolecular cyclisation of the adducts **223** and dehydrogenation of pyridinethiones **224** result in 3-cyanopyridine-2(1*H*)-thiones **225** (see reviews^{28, 41} and papers^{486–500}).

$R^1 = \text{H, Alk, Ph, Bn, } \text{pyridin-2-yl}$; $R^2 = \text{H}$; $R^3 = \text{Ph, 4-ClC}_6\text{H}_4$,
4-MeOC₆H₄, 4-NO₂C₆H₄, 4-MeNC₆H₄; $R^2-R^3 = (\text{CH}_2)_4$.

These reactions were initially used in the synthesis of 4,5-diaryl-3-cyanopyridine-2(1*H*)-thiones.^{343, 486, 488} Later, a series of 4,6-dihetaryl-pyridinethiones was obtained.^{352, 491, 492} α,β -Unsaturated carbonyl compounds were also employed in the synthesis of 4-aryl-6-methyl-^{347, 358} and 4,5,6-trisubstituted 3-cyanopyridine-2(1*H*)-thiones.^{41, 346, 385, 386, 487, 490} The direction of any particular reaction depends on the structure of the initial compounds, reaction conditions and catalyst. Thus reactions with the amide **1b** in boiling ethanol or methanol in the presence of sodium alkoxides result in the formation of substituted 3-cyanopyridine-2(1*H*)-thiones **225**.^{41, 343, 346, 347, 352, 358, 385, 386, 486, 487, 491, 492} However, if the sodium alkoxide catalyst is replaced by an equimolar amount of an organic base and the reaction is carried out at 20 °C, only tetrahydropyridines **224** are formed.^{489, 493–498} In this case, an

organic base acts not only as a catalyst but also as a stabiliser of the partially hydrogenated pyridinethiones, which can be isolated as stable salts. The latter are converted into pyridinethiones **225** on treatment with HCl and oxidation with atmospheric oxygen.

Although the condensations of α,β -unsaturated ketones with cyanothioacetamide (**1b**) afford the final products in somewhat lower yields compared to those obtained from 1,3-dicarbonyl compounds, this is counterbalanced by the selectivity of the reaction. Thus only the corresponding 3,4- or 4,4-bipyridines are formed from 1-(3- or 4-pyridyl)but-1-en-3-ones, respectively.¹⁶⁷

The reactions of 2-arylidene-cyclopentan(or -hexan)ones **226** and of 2,5-dibenzylidenecyclopentanone (**228**) with the amide **1b** give rise to 5,6-annulated 4-aryl-3-cyanopyridine-2(1*H*)-thiones **227**⁴⁹⁹ and **229**,⁵⁰¹ respectively.

Pyridinethiones annulated with steroids were obtained using the reactions of the amide **1b** with α,β -unsaturated ketones **17** and **230**. The condensation of the amide **1b** with the ketone **17** is accompanied by hydrolysis of the acetoxy group and results in pyridinethione **231**. The reaction of the amide **1b** with arylidene-ketone **230** affords 4-arylpyridinethione **232**.^{60, 62}

The condensations of 2-arylmethylidene-3-oxoquinuclidines **233** with the amide **1b** lead to the formation of stable salts **235**, which are converted into partially hydrogenated 4-aryl-3-cyano-1,5-naphthyridine-2(1*H*)-thiones **234** or **236** on treatment with HCl.⁵⁰²

Reactions of cyanoacetamides with aroyl- and hetaroylimino dithioethers have been described.^{273, 503–506} Thus reactions of compounds **237** with cyanoacetamide (**1a**) in methanol in the presence of sodium methoxide afford 2-aryl(hetaryl)-5-cyano-6-methylthio-3,4-dihydropyrimidin-4-ones **238** in 40%–60% yields. However, a vinyllogue of compounds **237**, *viz.*, iminodithioether **239**, gives under similar conditions 5-cyano-6-methylthio-4-phenyl-3,4-dihydropyrimidin-2-one (**240**) in 70% yield.⁵⁰⁴

2-(Diacetylmethylidene)benzooxazole (**241**) prepared from dimethyl dithio acetal **242** and 2-aminophenol reacts with the amide **1a** in boiling methanol in the presence of piperidine to give spiro compound **243** in 58% yield.⁵⁰⁵

O,S-Acetals **244** react with the amide **1a** on heating in ethanol in the presence of sodium alkoxides yielding 4-alkoxy-3-cyanopyridin-2(1*H*)-ones **245**. Similar reactions of cyclic *O,S*-acetals **246** give rise to annelated 4-alkoxy-3-cyanopyridin-2(1*H*)-ones **247**.⁵⁰⁷

Ar = Ph, 4-MeOC₆H₄, 4-ClC₆H₄, , R¹ = Me, Et, Prⁿ; R² = Me, Et.

Salt **248** prepared by the reaction of diacetyl dimethyl ketal **249** with methyl formate in the presence of sodium methoxide reacts with the amide **1a** to give trimethyl orthopicolinate **250**.⁵⁰⁸

The use of α,β -ynones as substrates in the reactions with cyanoacetamides has been described.^{85, 347, 463, 509} 3-Cyano-6-methyl-4-phenylpyridine-2(1*H*)-thione (**136b**) was obtained on stirring a solution of acetylphenylacetylene (**251**) with cyanothioacetamide (**1b**) in ethanol in the presence of morpholine at 25 °C.^{85, 347, 463} However, the reaction of equimolar amounts of the ketone **251** with morpholine followed by the addition of the amide **1b** to the reaction mixture gave isomeric 3-cyano-4-methyl-6-phenylpyridine-2(1*H*)-thione **135b**. It was concluded⁸⁵ that the Michael addition of the amide **1b** to the ketone **251** is realised in the first reaction (path *a*) in which morpholine plays the role of a basic catalyst increasing the nucleophilicity of the methylene group in the amide **1b**. In the latter case (path *b*), β -enamino ketone **252** is initially formed, which then reacts with the amide **1b** in a selective manner to give the isomer **135b**. This mechanism was proved by isolation of intermediate β -enamino ketone **252**.⁸⁵

The use of α,β -unsaturated nitriles in reactions with amides **1b,c** for the preparation of 3-cyanopyridine-2(1*H*)-thiones and selenones is based on the formation of δ -oxothio- and δ -oxoselenoamide intermediates, which easily cyclise into a pyridine ring under the reaction conditions.^{49, 115, 353, 447, 498, 510–521} This is exemplified in the preparation of 6-amino-4-aryl(hetaryl)-3,5-dicyanopyridine-2(1*H*)-thiones and -selenones **253** by the reactions of arylmethylidenecyanothioacetamides **7b** with malononitrile (**5**) or of arylmethylidenemalononitriles **254** with thio- and selenoamides **1b,c**. Pyridinethiones and -selenones **253** can also be prepared by recyclisation of intermediate 2,6-diamino-4-aryl-3,5-dicyanothio(or -seleno)pyranones **255**. The latter were isolated in some cases.^{49, 510, 512, 515–518} 4-Aryl-3,5-dicyano-6-hydroxypyridine-2(1*H*)-thiones and -selenones **257** are synthesised by analogous reactions of arylmethylidenecyanoacetates **256** with amides **1b,c**.^{519–521}

The ambident nature of the thioamide and selenoamide groups in intermediates **258** and **259** is believed to be the reason for the formation of pyridinechalcogenones **253** or thio(seleno)pyrans **255**, the outcome of the reactions depends on the reaction conditions. Thio(seleno)pyrans **255** are formed under kinetically controlled conditions, while pyridinechalcogenones **253** are formed under thermodynamic control. Such a dual chemical behaviour of intermediates **258** and **259** often prevents the unambiguous elucidation of the structure of the reaction products and often leads to misinterpretations. Thus the structure of 5-arylmethylidenepyridinethione has been erroneously attributed to the products of thermodynamically controlled reactions of arylmethylidenemalononitriles **254** with cyanothioacetamide **1b**.^{520, 521} This incorrect structure was then reproduced in reviews.^{34, 166} Another similar mistake has been made with respect to the product obtained in the reaction of (1-amino-2,2,2-trichloroethylidene)malononitrile with the amide **1b**;⁵²² this is not pyridinethione derivative **253** (X = S), but rather the thiopyran derivative **255**.⁵²³ Once again, no evidence in favour of earlier⁵²⁴ postulated formation of 3,4-dihydropyridinethiones has been found later.

One-step condensation of cycloalkylidenemalononitriles **260** with cyanothioacetamide (**1b**) or the corresponding cyanothioamides **261** with malononitrile proceeds *via* intermediates **263** and results in spirodihydropyridines **262**.⁵⁸

The reactions of arylmethylidenecyanothioacetamides **7b** with aldehydes, ketones, esters, amides and the corresponding enamines are also widely used in the synthesis of 4-aryl-3-cyanopyridine-2(1*H*)-thiones. Depending on the structure of the initial carbonyl compound and the reaction conditions, these reactions can stop in the stage of either hydrogenated pyridinethiones or their oxidised forms.^{49, 510–512, 525–530}

Unlike monocarbonyl compounds, acyclic 1,3-dicarbonyl compounds and β -amino carbonyl derivatives react with the amides **7b** in ethanol in the presence of an organic base (piperidine, morpholine, diethylamine, hexamethyleneimine) at 25 °C to give 1,4-dihydropyridine-2-thiolates **264**. The latter are converted into 3-cyano-3,4-dihydropyridine-2(1*H*)-thiones **265** upon treatment with 10% HCl.^{49, 113, 349, 352, 446, 488, 495, 510–512, 529, 531–538}

The reaction of the amide **7b** with a cyclic dicarbonyl compound such as dimedone allowed one to isolate the intermediate Michael adducts **266** as salts.^{113, 512} Acidification of the salts **266** affords compounds **267**. Heating of the latter in ethanol in the presence of a base followed by acidification results in 3,4-dihydropyridinethiones **268**.

4-Aryl-5-arylcarbonyl-3-cyano-6-methylpyridine-2(1*H*)-thiones,⁵³⁹ stable 3-cyano-4-[2-furyl(thienyl)]-3,4-dihydropyridine-2(1*H*)-thiones,⁵⁴⁰ 3-cyano-4-(2-furyl)-6-methyl-5-phenylcarbonyl-1,4-dihydropyridine-2-thiolates and -selenolates⁵⁴ have been synthesised using the reactions of acetoacetanilides with the amides **7b**. This approach was also used for the preparation of 6'-methyl-5'-phenylcarbonyl-3',4'-dihydro-spiro[cyclohexane-1,4'-pyridine]-2'(1'*H*)-thione (**269**) from acetoacetanilide and cyclohexylidenecyanothioacetamide.⁵⁴¹

Synthesis of 3',5'-dicyano-6'-oxo-spiro[cyclopentane-1,4'-1',4',5',6'-tetrahydropyridine]-2'-thiolate **270** by the reaction of ethyl cyclopentylidenecyanoacetate (**271**) with cyanothioacetamide (**1b**) in the presence of *N*-methylmorpholine or by the reaction of cyclopentylidenecyanothioacetamide (**272**) with ethyl cyanoacetate under similar conditions is yet another example of the design of spiro-fused hydrogenated pyridine derivatives.⁵⁴²

All experimental results suggest that reactions of arylmethylidenecyanothioacetamides **7b** and their carbocyclic derivatives with 1,3-dicarbonyl compounds and their enamines always involve the stage of intermediate formation of Michael adducts such as 1,4-dihydropyridine-2-thiolates and 3,4-dihydropyridine-2(1*H*)-thiones. The only exception is the condensation of benzothiazolone **273** with the amides **7b**, which results in the formation of annelated system **274**.⁵⁴³

As to the stereochemical aspects of reactions of cyanoacetamides and their S- and Se-analogues, they remained unexplored until recently. Pyridinium ylides are very convenient model compounds for the study of regio- and stereoselectivity of formation of 3-cyanopyridine-2(1*H*)-thiones.^{58, 71, 83, 85–88, 288, 492, 544–559} It has been shown that condensations of arylmethylidenecyanothioacetamides **7b** with pyridinium ylides **275** generated *in situ* from the corresponding salts result in 3,4-*trans*-1,2,3,4-tetrahydropyridine-6-thiolates **276**. The high selectivity of these reactions is due to the stereoselective addition of the ylides **275** (X = S) to the amides **7b**. Subsequent cyclisation of adducts **277** into betaines **276** occurs with retention of the *trans*-arrangement of the hydrogen atoms.^{549, 554} Betaines **276** were obtained in high yields from pyridinium salts **278** and cyanothioacetamide (**1b**).⁵⁵¹ When malononitrile (**5**) was used in the reaction instead of amide **1b**, *trans*-adducts **279** were obtained from compounds (*E*)-**278**; these were isolated and examined. Treatment of the adducts **279** with H₂S afforded *trans*-tetrahydropyridines **276**. The latter gave 3-cyanopyridine-2(1*H*)-thiones **280** upon boiling in AcOH in the presence of ammonium acetate. The condensations of amides **7b** with pyridinium ylides **275** (X = O, S) give 2-oxo(thio)tetrahydropyridine-6-thiolates **281** in high yields.

Y = Cl, Br.

X = O, S.

A great number of other examples of the use of cyanoacetamides and their S- and Se-derivatives in the synthesis of functionalised 3-cyanopyridine-2(1*H*)-ones, -thiones and -selenones,^{560–604} 3-cyanopyridine-2-olates and -thiolates,^{605–609} pyrimidine-2-ones,^{610–616} tetrahydroquinoline-2-ones,^{617, 618} 5-cyano-3,4-diphenylpyridazine-6-one,⁶¹⁹ 2-aryl-5-cyano-4-methylthio-1,3-oxazine-6-ones⁶²⁰ and other heterocyclic compounds are also documented. Cyanoacetamides **1a, b** have found application in the synthesis of substituted pyridines **282**,⁶²¹ quinolines **178**,⁴³⁸ **283**,⁶²² **284**,^{623, 624} isoquinolines **285**,^{388, 389, 625} **286**,⁶²⁶ pyrazine **287**,⁶²⁷ dihydropyrrolopyrimidines **288**⁶²⁸ and triazines **289**.^{629, 630} Among other heterocyclic systems synthesised with the use of amides **1a–c** and their derivatives, thio- and selenopyrans,^{49, 510, 512, 515–518, 631, 632} coumarins and thiocoumarins,⁴³⁹ ^{442, 633, 634} and thiazines⁶³⁵ are worth mentioning. Apart from that, the preparation of carbocyclic systems of the cyclohexane series from cyanoacetamide (**1a**) has been described.^{425, 636}

In the last decade, many derivatives of pyridin-2(1*H*)-ones, -thiones, -selenones and their salts have successfully been synthesised using a three-component condensation of cyanoacetamides or their derivatives with aliphatic, aromatic or heterocyclic aldehydes and 1,3-dicarbonyl compounds or their derivatives in the presence of an excess of organic base.^{495, 531, 532, 534, 535, 637–653}

$R^1 = \text{Alk, Ar, Het; } R^2 = \text{Alk, 2-MeC}_6\text{H}_4\text{NH; } R^3 = \text{Alk, NHPh;}$

$X = \text{O, S, Se; } B = \text{HN} \begin{smallmatrix} \diagup \diagdown \\ \diagdown \diagup \end{smallmatrix} \text{O, MeN} \begin{smallmatrix} \diagup \diagdown \\ \diagdown \diagup \end{smallmatrix} \text{O, Et}_2\text{NH.}$

Synthesis of 4-(aryl or hetaryl)-3-cyano-6-methyl-5-phenylcarbamoyl-1,4-dihydropyridine-2-thiolates **290** from aromatic or heterocyclic aldehydes, amide **1b** and acetoacetanilide in the presence of an excess of *N*-methylmorpholine may be regarded as an illustration of such an approach.^{642–644}

$R = \text{Ph, 2-ClC}_6\text{H}_4, \text{2-MeC}_6\text{H}_4, \begin{smallmatrix} \diagup \diagdown \\ \diagdown \diagup \end{smallmatrix} \text{S, } \begin{smallmatrix} \diagup \diagdown \\ \diagdown \diagup \end{smallmatrix} \text{N; } B = \text{MeN} \begin{smallmatrix} \diagup \diagdown \\ \diagdown \diagup \end{smallmatrix} \text{O.}$

Cyclic diketones (cyclohexane-1,3-dione, dimedone, Meldrum's acid) were also used as 1,3-dicarbonyl components.^{645–647, 651} Thus 3-cyano-4-[aryl(or hetaryl)]-2-oxo-1,2,3,4-tetrahydropyridine-2-thiolates **291** have been obtained on refluxing an equimolar mixture of the corresponding aldehyde, the amide **1b** and Meldrum's acid in ethanol in the presence of *N*-methylmorpholine. Compounds **291** are converted into 5-amino-4-[aryl (or hetaryl)]-6-mercapto-3,4-dihydropyridin-2(1*H*)-ones **292** on acidification with 10% HCl to pH 5.⁶⁴⁶

$R = 4\text{-MeC}_6\text{H}_4, \begin{smallmatrix} \diagup \diagdown \\ \diagdown \diagup \end{smallmatrix}, \begin{smallmatrix} \diagup \diagdown \\ \diagdown \diagup \end{smallmatrix}, \begin{smallmatrix} \diagup \diagdown \\ \diagdown \diagup \end{smallmatrix}; B = \text{MeN} \begin{smallmatrix} \diagup \diagdown \\ \diagdown \diagup \end{smallmatrix} \text{O.}$

The use of pyridinium ylides **275** ($X = \text{O}$) in the three-component condensations allows one to perform a one-pot synthesis of 3-cyanopyridin-2(1*H*)-ones without preliminary synthesis of arylmethylidenecyanothioacetamides **7b**.^{58, 83, 85, 288, 492, 549, 550}

IV. Conclusion

The data considered here clearly demonstrate the high synthetic potential of cyanoacetamides and their thio- and selenocarbonyl analogues. Many biologically active heterocyclic compounds have been obtained based on these reagents. This suggests that cyanoacetamides and their arylmethylidene and hetarylmethylidene derivatives can be particularly promising starting materials in combinatorial synthesis of functionalised carbo- and heterocyclic compounds used in the design of novel highly effective pharmaceuticals with a broad range of action. The great interest of chemists in these reagents is confirmed by the fact that more than 490 papers of 653 cited in this review are dated to the last 10–15 years and more than 20% of them are patents.

The review was written with financial support of the Russian Foundation for Basic Research (Project No. 99-03-32965).

Synthesis and reactions of mixed halogenobuta-1,3-dienes

R V Kaberdin, V I Potkin, V A Zapol'skii

Contents

I. Introduction	765
II. Synthesis of mixed halogenobuta-1,3-dienes	765
III. Chemical properties of mixed halogenobuta-1,3-dienes	774
IV. Conclusion	778

Abstract. The published data on the methods for the preparation of mixed halogenobuta-1,3-dienes are generalised and systematised with a special emphasis on compounds of high practical value. Chemical transformations of mixed halogenodienes are considered and broad possibilities of the use of these compounds for the synthesis of various valuable, but difficultly accessible polyfunctional products are demonstrated. The bibliography includes 115 references.

I. Introduction

The first representative of halogenobutadienes, *viz.*, hexachlorobuta-1,3-diene, was obtained as early as 1876.¹ However, in the subsequent 50 years studies on the synthesis of halogenobutadienes were episodic and only in the early 1930s did they become purposeful and systematic. The development of preparation methods and the search for possible uses of this class of compounds in organic synthesis were stimulated by the discovery that mono- and dichlorobuta-1,3-dienes easily polymerise.

The first data on the synthesis of halogen derivatives of butadiene were generalised by Petrov in 1944.² Later studies devoted mainly to the synthesis and transformations of chloro and fluoro derivatives of butadiene were systematised in a fundamental Houben–Weyl monograph.³ Particularly intensive studies were carried out in the field of chloro derivatives of butadiene and their results were surveyed in reviews^{4–6} and monographs.^{7–9}

At present, there are numerous publications devoted to the synthesis of mixed halogenobutadienes (MHB) containing atoms of different halogens, *viz.*, fluorine, chlorine, bromine and iodine. Mixed halogenobutadienes possess a broad spectrum of useful properties: they are good dielectrics, refrigerants and heat-transfer agents; they are used as aerosols, lubricants and floatation agents and possess algicidal, bactericidal and fungicidal activities.^{10–15} A number of MHB manifest high antitumour activity.¹⁶ Chlorine–fluorine-containing butadienes are employed as monomers for the preparation of valuable polymers and copolymers resistant to heat, light, chemical corrosion, *etc.*^{13, 17, 18} And, finally, MHB

are promising semi-products in organic synthesis. For example, the preparation of polyfluoromethine compounds is based on MHB, which opens a way to the synthesis of novel polymethine dyes.¹⁹

It should be noted that the introduction of atoms of different halogens into the butadiene molecule leads to a considerable increase in the number of theoretically possible isomers. Thus consideration of structural and geometric isomers shows that dichlorobuta-1,3-diene has nine isomers,⁷ while for butadiene derivatives with two different halogen atoms the number of possible isomers increases tenfold. From a theoretical aspect, mixed halogenobutadienes, like other compounds with the butadiene system, are convenient subjects for studying the *s-cis*–*trans*-isomerism associated with the appearance of conformationally non-equivalent structures resulting from the hindered rotation of the vinyl fragments around the central C–C bond.^{20–22} They are also promising as model substrates for studying regularities of the processes of nucleophilic vinylic substitution (S_NVin). This review surveys the literature data on the chemistry of mixed halogenobuta-1,3-dienes published up to 1999. We presume that such a review will fill the gap in the relevant literature and will contribute to the further development of research into the chemistry of halogen derivatives of alkenes and alkadienes.

II. Synthesis of mixed halogenobuta-1,3-dienes

The basic methods for the preparation of MHB are:

(1) Elimination reactions (dehydrohalogenation and dehalogenation) of polyhalogenobutadienes and -butenes;

(2) halogenation and hydrohalogenation of acetylenic hydrocarbons of the C₄ series;

(1) thermal decomposition of accessible polyhalogenated compounds.

Other methods of the synthesis of individual representatives of MHB are also known.

1. Elimination reactions

Numerous chlorofluoro- and bromochlorobutadienes were obtained by dehydrohalogenation and dehalogenation of polyhalogenobutanes and -butenes).

Dehydrohalogenation of polyhalogenobutenes under the action of various dehydrohalogenation agents proceeds as the 1,4- or 3,4-elimination of a molecule of hydrogen halide depending on the position of the C=C bond. Another conventional way for the synthesis of MHB is dehalogenation of polyhalogenobutanes and -butenes, which is carried out under the action of metals, zinc in most cases.

a. Dihalogenobutadienes

The simplest MHB containing two different halogen atoms can be obtained from trihalogenobut-1- and -2-enes. Thus the dehydrobromination of 1,4-dibromo-2-chlorobut-2-ene (**1**), which is the main product of chloroprene bromination (**2**), resulted in 1-bromo-2-chlorobuta-1,3-diene (**3**) in preparative yield.^{23,24} The diene **3** formed in this reaction is a mixture of geometric isomers with the predominance of the *Z*-isomer **3a**.²⁵

Papazyan *et al.*²⁶ have proposed performing the dehydrobromination of butene **1** in the presence of phase-transfer catalysts (PTC) that considerably simplified the process and made it more economical (the conditions for the synthesis of the diene **3**, its yield and the data related to all subsequent syntheses of MHB by the elimination reaction are presented in Table 1).

Chlorination of bromoprene (**4**) and subsequent dehydrochlorination of 2-bromo-1,4-dichlorobut-2-ene (**5**) leads to a mixture of *E*- and *Z*-isomers of 2- (**6**) and 3-bromo-1-chlorobuta-1,3-diene (**7**).^{27,28}

A more convenient synthesis of *E*- and *Z*-isomers of the diene **7** is based on the dehydrobromination of 3,4-dibromo-1-chlorobut-1-ene (**8**), which is the product of bromination of 1-chlorobuta-1,3-diene (**9**).²⁹

Dehydrohalogenation of the by-products of the chlorine addition to the diene **4**, *viz.*, a mixture of 3- (**10**) and 2-bromo-3,4-dichlorobut-1-enes (**11**), yielded a mixture of 2-bromo-3-chlorobuta-1,3-diene (**12**) and (*E*)-1,2-dichlorobuta-1,3-diene (**13**) (GLC).²⁷

The diene **12** was initially obtained by dehydrobromination of 3,4-dibromo-2-chlorobut-1-ene (**14**), which is a by-product of chloroprene **2** bromination.²⁴

The preparative synthesis of the diene **12** is based on the 1,4-elimination of hydrogen halide from 1,2-dibromo-3-chlorobut-2-ene (**15**) or 2-bromo-1,3-dichlorobut-2-ene (**16**) or a mixture of these butenes with an alkali (KOH or NaOH) in the presence of PTC.³⁰

Of the disubstituted chlorofluorobutadienes, the following three compounds are known: 1-chloro-1-fluoro- (**17**), 1-chloro-2-fluoro- (**18**) and 3-chloro-2-fluoro-buta-1,3-dienes (**19**) (see Table 1).

The diene **17** was obtained as the result of dehydrochlorination of 4,4-dichloro-4-fluorobut-1-ene (**20**),^{31,32} whereas the diene (**18**) resulted from the dechlorination of 3,4,4-trichloro-3-fluorobut-1-ene (**21**).³³ The diene **19** is formed upon dehydrohalogenation of a liquid mixture of mono-, di- and trifluoro compounds which are the products of the reaction of 1,2,3,4-tetrachlorobutane with HF.³⁴ Yet another route to the diene **19** consists in the dehydrohalogenation of 2,4-dichloro-1,3-difluorobutane (**22**), which is the main product of ClF addition to butadiene (see Table 1).^{35,36}

b. Trihalogenobutadienes

The first representative of mixed trihalogenobutadienes, *viz.*, 3-bromo-1,1-dichlorobuta-1,3-diene (**23**), was initially prepared by the thermal dehydrochlorination of 3-bromo-1,1,4-tetrachlorobutane (**24**)³⁷ and later, of 2-bromo-4,4,4-trichlorobut-1-ene (**25**), which is the product of bromotrichloromethane addition to allene.³⁸ (see Table 1).

3-Bromo-1,2-dichlorobuta-1,3-diene (**26**) was obtained by a multistep synthesis the last stage of which was dehydrobromination of 3,4-dibromo-1,2-dichlorobut-1-ene (**27**), which is the main product of 1,2-dichlorobuta-1,3-diene (**13**) bromination. The latter is obtained by the dehydrochlorination of 1,2,4-trichlorobut-2-ene (**28**).³⁹ Papazyan *et al.*²⁶ simplified the synthesis of the diene **26** from the butene **28**. The target product **26** was obtained by direct bromination of the butene **28** and subsequent dehydrohalogenation of the adduct formed, *viz.*, 2,3-dibromo-1,2,4-trichlorobutane (**29**). The by-product of this reaction is 2-bromo-1,3-dichlorobuta-1,3-diene (**30**).

Two methods for the synthesis of 1-bromo-2,3-dichlorobuta-1,3-diene (**31**) are known. It is obtained by dehydrobromination of either 1,4-dibromo-2,3-dichlorobut-2-ene (**32**)³⁹ [the product of 2,3-dichlorobuta-1,3-diene (**33**) bromination]³⁹ or 1,2-dibromo-2,3,4-trichlorobutane (**34**) [the product of bromine addition to the accessible 2,3,4-trichlorobut-1-ene (**35**)].²⁶

Table 1. Synthesis of mixed halogenobuta-1,3-dienes by the elimination from halogenobutanes and -butenes.

^a Triethylbenzylammonium chloride.

1,1-Dibromo-3-chlorobuta-1,3-diene (**36**) is obtained as an insignificant admixture in the synthesis of 1,1,3-tribromobuta-1,3-diene.⁴⁰

Upon dehydrobromination of 1,2,3,4-tetrabromo-2-chlorobutane (**37**) [the product of exhaustive bromination of chloroprene (**2**)], 1,3-dibromo-2-chlorobuta-1,3-diene (**38**) is mainly formed. In addition, a small amount of 1,2-dibromo-3-chlorobuta-1,3-diene (**39**) was detected by GLC.²⁶

2,3-Dibromo-1-chlorobuta-1,3-diene (**40**) was obtained by dehydrochlorination of 2,3-dibromo-1,4-dichlorobut-2-ene (**41**)⁴¹ (see Table 1).

As regards the fluorine-containing trihalogeno derivatives of MHB, 1,1-dichloro-3-fluoro- (**42**), 1,1-dibromo-3-fluoro- (**43**), 2-chloro-1,1-difluoro- (**44**) and 1-chloro-1,2-difluorobuta-1,3-dienes (**45**) were obtained.

The synthesis of the dienes **42** and **43** is based on dehydrohalogenation of 3-bromo-3-fluoro-1,1,1-trihalogenobutanes (**46a,b**).⁴²

X = Cl (**42**, **46a**), Br (**43**, **46b**).

The butadiene **44** was first synthesised from 2-chloro-1,2-difluoro-4-iodobut-1-ene (**47**)⁴³ and later from 1-bromo-1,1-difluoro-2,2-dichloro-2-chlorobut-3-ene (**48**)¹⁶ and 2,4-dichloro-1,1,1-trifluorobut-2-ene (**49**).⁴⁴

The butadiene **45** is formed as a mixture of *E*- and *Z*-isomers upon dehydrobromination of the isomeric forms of 4-bromo-1-chloro-1,2-difluorobut-1-ene (**50**) obtained by dehalogenation of 1,4-dibromo-1,2-dichloro-1,2-difluorobutane (**51**), which is the product of telomerisation of CBrFCICBrFCl with ethylene under the action of benzoyl peroxide. It was shown that the starting butene **50** and the target diene **45** have the same ratio of isomers, *i.e.*, the elimination reaction occurs stereospecifically.⁴⁵

1,1,3-Trihalogenobutadienes are convenient subjects for the elucidation of characteristic features of conformational behaviour. The use of ¹H NMR and UV spectroscopy made it possible to establish that the bulky substituents (Cl, Br) in the 1,3 (or 2,4) positions of the diene chain destabilise the *s-trans*-form, which is characteristic of haloprenes and disubstituted butadienes, hence the 1,1,3-trihalogenobuta-1,3-dienes **23** and **36** exist in a skew conformation in the form of a single conformer.^{40, 46}

According to the ¹H NMR and IR spectroscopic data, the dienes **42** and **43** having a fluorine atom in the position 3 exist as a mixture of two conformers, *viz.*, the skew and *s-trans*-forms.^{42, 47}

c. Tetrahalogenobutadienes

Several examples of the synthesis of tetrasubstituted MHB based on the elimination reaction are given below. Dehydrobromination of 3,4-dibromo-1,1,2-trichlorobut-1-ene (**52**), which is the product of bromine addition to the accessible 1,1,2-trichlorobuta-1,3-diene (**53**),⁴⁸ affords a mixture of 3- (**54**, the main product) and 4-bromo-1,1,2-trichlorobuta-1,3-dienes (**55**, the by-product).²⁶

Two convenient methods have been developed for the synthesis of 1-bromo-1,4,4-trichlorobuta-1,3-diene (**56**). The first method consists in dehydrohalogenation of 1,2-dibromo-1,3,4,4-tetrachlorobutanes (**57**) in the presence of PTC. It was shown that the reaction product is a mixture of geometric isomers with the predominance of the *Z*-form.⁴⁹ The second method of the synthesis of the diene **56** is based on dehydrobromination of 3,4-dibromo-1,1,4-trichlorobut-1-ene (**58**) under the conditions of phase-transfer catalysis in the presence of triethylbenzylammonium chloride (TEBA).⁵⁰

Information about tetra(chloro, fluoro) MHB can be found only in the patent literature. Thus dehalogenation of 4-bromo-2,3-dichloro-3,4,4-trifluorobut-1-ene (**59**) and 1-bromo-2,3,4,4-tetrachloro-1,1,2-trifluorobutane (**60**) result in 3-chloro-1,1,2-trifluoro- (**61**) and 4-chloro-1,1,2-trifluorobuta-1,3-dienes (**62**), respectively.⁵¹

There is only one known representative of the bromine-containing tetrahalogenobutadienes, *viz.*, 3-bromo-1,1,2-trifluorobuta-1,3-diene (**63**), which was obtained in high yield by dehalogenation of 2,4-dibromo-3-chloro-3,4,4-trifluorobut-1-ene (**64**) (see Table 1).³

d. Pentahalogenobutadienes

Some pentasubstituted chlorobromo and chlorofluoro derivatives of butadiene can be obtained by an elimination reaction. Thus dehydrobromination of 3,4-dibromo-1,1,3,4-tetrachlorobut-1-ene (**65**) (the product of bromine addition to the *Z*- or *E*-isomers of 1,1,3,4-tetrachloro-1,3-butadiene) affords a mixture of geometric isomers of 1-bromo-1,2,4,4-tetrachlorobuta-1,3-diene (**66**), the yield of which depends to a considerable extent on the reaction conditions (see Table 1).^{52–54}

Dehydrobromination of 3,4,4-tribromo-1,1,4-trichlorobut-1-ene (**67**) in the presence of PTC leads to a mixture of *E*- and *Z*-isomers of 1,2-dibromo-1,4,4-trichlorobuta-1,3-diene (**68a,b**). Similarly, a mixture of *E*- and *Z*-isomers of 2,4-dibromo-1,1,4-trichlorobuta-1,3-diene (**70a,b**)⁵⁵ was obtained from 1,3,4-tribromo-1,4,4-trichlorobut-1-ene (**69**).

Dehalogenation of 4-bromo-1,2,3-trichloro-3,4,4-trifluoro- (**71**) and 1,3,4-trichloro-1,3,4,4-tetrafluorobut-1-ene (**72**) (see Table 1) yielded 3,4-dichloro-1,1,2-trifluorobuta-1,3-diene (**73**) and 4-chloro-1,1,2,4-tetrafluorobuta-1,3-diene (**74**),⁵⁶ respectively.

e. Hexahalogenobutadienes

The synthesis of hexasubstituted MHB is documented; in particular, the methods for the preparation of some chlorine, fluorine-containing representatives are well developed. Thus 4-chloro-1,1,2,3,4-pentafluorobuta-1,3-diene (**75**) was first obtained by dehalogenation of 1,2,3,4,4-pentachloro-1,1,2,3,4-pentafluorobutane (**76**), which is the reaction product of 1,1,2,3,4,4-hexachloro-1,2,3,4-tetrafluorobutane (**77**) with a slight excess of SbF_3Cl_2 .^{10, 12}

Later,^{57, 58} two new methods for the synthesis of the diene **75** have been proposed. The first method is based on the transformation of a 1 : 1 mixture of *erythro*- and *threo*-forms of 3,4,4-trichloro-1,1,2,3,4-pentafluoro-1-iodobutane (**78**), which is the product of free-radical addition of 1,2,2-trichloro-1,2-difluoro-1-iodoethane to trifluoroethylene (GLC). Dehydrohalogenation of this product and subsequent chlorination of intermediate polyhalogenobutenes yield a mixture of polyhalogenobutenes (**76** and **79**). Dehalogenation of these compounds gives high yield of the diene **75** as a mixture of *E*- and *Z*-isomers.⁵⁷

Another way to the synthesis of the diene **75** is based on the transformation of 1,3,4-trichloro-1,2,3,4,4-pentafluoro-1-iodobutane (**80**), which is the reaction product of 1,2-dichloro-1,2,2-trifluoro-1-iodoethane with 1-chloro-1,2-difluoroethylene.⁵⁸ Successive dehydroiodination, chlorination and dechlorination of polyhalogenobutane (**80**) yields the diene **75**.

The synthesis of 3-chloro-1,1,2,4,4-pentafluorobuta-1,3-diene (**81**) is also based on elimination reactions.^{10, 43}

The synthesis of 1,4-dichloro-1,2,3,4-tetrafluorobuta-1,3-diene (**82**) has attracted much attention. The diene **82** was obtained for the first time by dechlorination of perhalogenobutane **77**,⁵⁹ which in turn was synthesised by fluorination of hexachlorobuta-1,3-diene (**83**),⁶⁰ the reaction of 1,2,3,4-tetrachlorobuta-1,3-diene (**84**) with ClF_3 (see Ref. 61) or chloriodination of 1,2-dichloro-1,2-difluoroethylene (**85**) with subsequent heating of the resulting 1,2,2-trichloro-1,2-difluoro-1-iodoethane (**86**) with acetic anhydride, dichloromethane and granulated zinc at 160 °C (Scheme 1).

Scheme 1

Yet another method for the synthesis of the diene **82** is based on dechlorination of 1,3,4,4-tetrachloro-1,2,3,4-tetrafluorobut-1-ene (**87**), which is the product of thermal dimerisation of the ethylene **85**.^{63,64} The diene **82** is formed in preparative yield upon treatment of 1,2-dibromo-1,3,4,4-tetrachloro-1,2,3,4-tetrafluorobutane (**88**), which is the product of bromine addition to the butene **87**,⁶⁴ with zinc in dioxane (Scheme 1).

And, finally, there are data on the synthesis of diene **82** based on transformations of a mixture of perhalogenobutanes.⁵⁸ Thus dehalogenation of a mixture of telomers $\text{Cl}(\text{CFCl})_3\text{CF}_2\text{I}$ (**79**) and $\text{Cl}(\text{CFCl})_2\text{CF}_2\text{CFCII}$ (**89**) or $\text{F}(\text{CFCl})_4\text{F}$ (**90**), $\text{Cl}(\text{CFCl})_4\text{F}$ (**76**) and $\text{Cl}(\text{CFCl})_4\text{Cl}$ (**77**) affords a 1 : 1 mixture of the dienes **75** and **82** (in the ratio 1 : 1) in the former case or a mixture of dienes **75**, **82** and hexafluorobuta-1,3-diene in the latter case.

Theoretically, the diene **82** can exist in the form of three geometric isomers.

Indeed, as was shown by Kremlev *et al.*,⁶² the diene **82** is an equilibrium mixture of *E,E*-, *E,Z*- and *Z,Z*-isomers in the ratio of 1 : 2.5 : 1.5. The ^{19}F NMR (Ref. 65) and UV (Ref. 21) spectral data and the values of dipole moments⁶⁶ make it possible to conclude that the isomers are in the non-planar *s-cis*-conformation similarly to hexachloro- (**83**)⁶⁷ and hexafluorobutadienes (**91**).⁶⁸

Two methods for the synthesis of 2,3-dichloro-1,1,4,4-tetrafluorobuta-1,3-diene (**92**) are known, *viz.*, dehalogenation of 1,2,2,3,3,4-hexachloro-1,1,4,4-tetrafluorobutane (**93**)¹⁰ and 1,4-dibromo-2,2,3,3-tetrachloro-1,1,4,4-tetrafluorobutane (**94**).^{60,69}

Some other difficultly accessible MHB, *viz.*, 3,4-dichloro-1,1,2,4-tetrafluoro- (**95**), 1,2,3,4-tetrachloro-1,4-difluoro- (**96**) and 2,3,4-trichloro-1,1,4-trifluorobuta-1,3-dienes (**97**), were obtained similarly.^{10,60}

Bromine–chlorine-containing hexahalogenobutadienes were synthesised by an elimination reaction by the authors of this review. Thus dehydrohalogenation of 1,2-dibromo-1,1,3,3,4,4-hexachlorobutane (**98**) with aqueous-ethanolic solutions of alkalis yields two MHB, *viz.*, 2-bromo-1,1,3,4,4-pentachloro- (**99**) and 1,2-dibromo-1,3,4,4-tetrachlorobuta-1,3-diene (**100**), in the ratio of 2 : 1.

The use of an aqueous solution of diethylamine shifted the reaction towards the predominant formation of the diene **99**.⁷⁰

Dehydrohalogenation of (*E*)-1,3,4-tribromo-1,2,4,4-tetrachlorobut-1-ene (**101**) under the conditions of phase-transfer catalysis yielded (*E*)-1,3-dibromo-1,2,4,4-tetrachloro- (**102**) and 1,3,4-tribromo-1,2,4-trichlorobuta-1,3-dienes (**103**) as a mixture of two geometric isomers. Since the β -bromo- α,β -dichlorovinyl group of the butene (**101**) having the *E*-configuration is not directly involved in the reaction, the formation of the two isomeric forms of the diene **103** occurs due to the *E,Z*-isomerisation of the α,β -dibromo- β -chlorovinyl group in the molecule. Consequently, the diene **103** is a mixture of *E,E*- (**103a**) and *E,Z*-isomers (**103b**).⁷¹

2. Halogenation and hydrohalogenation of the acetylenic hydrocarbons of the C₄ series

Acetylenic hydrocarbons, mainly conjugated halogenobutenynes and dihalogenobutadiynes, have served as the starting compounds for the synthesis of the first representatives of MHB.² The syntheses based on acetylene derivatives have not found wide uses because of their poor accessibility and explosiveness. Nonetheless, nowadays procedures for the preparative synthesis of a number of di-, tri- and hexasubstituted MHB have been developed.

It is also noteworthy that a new catalytic reaction of acetylene dimerisation has been recently discovered. This is carried out in methanolic solution of NaI in the presence of Pt(IV); it is accompanied by the addition of an iodine molecule and results in (*E,E*)-1,4-diodobuta-1,3-diene.⁷²

This reaction seems to be promising for the synthesis of certain MHB.

The currently used procedures for the synthesis of MHB by the addition of halogens and hydrogen halides to the carbon–carbon triple bond imply the use of the existing C₄ carbon chain.

a. Dihalogenobutadienes

The first representative of the dihalogenobutadienes, *viz.*, 2-chloro-1-iodobuta-1,3-diene (**104**), was prepared by hydrochlorination of 4-iodobut-1-en-3-yne (**105a**) in the presence of catalysts CuCl + NH₄Cl.⁷³

In the reaction of this butenyne (**105a**) with HBr, the predominant direction is the reductive elimination of the iodine atom at the triple bond with the formation of vinylacetylene (**106**). Among the reaction products, a considerable amount of (*E*)-2-bromo-1-iodobuta-1,3-diene (**107a**) was also found as the addition product of BrI to the enyne (**106**). The yield of (*Z*)-2-bromo-1-iodobuta-1,3-diene (**107b**), which is the addition product of HBr to the initial butenyne **105a**, is insignificant.⁷⁴

The addition of hydrogen halides to the conjugated enynes with a halogen atom at the triple bond in the presence of copper(I) halides is widely used for the synthesis of MHB.⁷⁴ It was established that 4-halogenobut-1-en-3-yne (**105b,c**) add HBr and HI at the triple C≡C bond giving the corresponding dihalogenobutadienes. Thus hydrobromination of 4-chlorobut-1-en-3-yne **105b** proceeds stereospecifically with the formation of the *Z*-form of 2-bromo-1-chlorobuta-1,3-diene (**6b**) in high yield. The reaction of hydroiodination of chloro- (**105b**) and bromo-substituted (**105c**) enynes proceeds similarly and results in the formation of (*Z*)-1-chloro- and 1-bromo-2-iodobuta-1,3-dienes (**108** and **109**), respectively (Table 2).

6: X = Cl, Hal = Br; **108:** X = Cl, Hal = I; **109:** X = Br, Hal = I.

The addition of mixed halogens (CII and BrI) to the conjugated butenyne **106** was studied.^{74,75} It turned out that the 1,4-addition of halogens occurred predominantly. Only with the use of a large excess of enyne and in the presence of CuCl were the 1,2-addition products, *viz.*, the dienes **104** and **107** in the form of *E*-isomers, obtained.^{74,75}

Table 2. Synthesis of mixed halogenobutadienes based on acetylene derivatives.

b. Trihalogenobutadienes

An attempt to obtain mixed trihalogenobutadienes by the addition of halogens to the triple bond of enynes **105a–c** did not give satisfactory results.^{74,75} The reaction of chlorine and bromine with these enynes proceeded mainly as the addition of halogens to the double bond and the 1,4-addition of enynes with the formation of butynes **110** and allenes **111**, respectively. The addition of one mole of a halogen to the triple bond of enynes, which would lead to the corresponding trihalogenobuta-1,3-dienes, is less preferable, the yields of products **53**, **112–116** are low.^{74,75}

X = I; Y = Cl (**112**), Br (**113**);

X = Y = Cl (**53**); X = Cl, Y = Br (**114**);

X = Br, Y = Cl (**115**); X = Y = Br (**116**).

The addition of bromine or iodine to 1,4-dichlorobut-2-yne (**117**) yielded the corresponding halogeno-substituted butenes, which gave (*Z*)-2,3-dibromo-1-chloro- (**40**) and (*Z*)-1-chloro-2,3-diiodobuta-1,3-dienes (**118**) upon catalytic 1,4-dehydrochlorination.^{76,77}

c. Tetra- and pentahalogenobutadienes

The synthesis of tetra- and pentasubstituted buta-1,3-dienes is demonstrated in separate examples. 2,3-Dichloro-1,4-diiodobuta-1,3-diene (**119**) was obtained as a mixture of *Z,Z*-, *Z,E*- and *E,E*-isomers by the reaction of diacetylene with chloriodine.⁷⁸

The reaction of copper(II) bromide with 1,2-dichlorobut-1-en-3-yne gives 1,1,2-tribromo-3,4-dichlorobuta-1,3-diene (**120**) (see Table 2).⁷⁹

d. Mixed perhalogenobutadienes

In 1930, difficultly accessible perhalogenobutadienes (**122–127**), including first representatives of MHB, were obtained by halogenation of dihalogenobuta-1,3-dienes (**121**).^{80,81}

X = Cl (**a**), Br (**b**), I (**c**); Y = Br, I.

Compound	122	123	124	125	126	127
X	Cl	Cl	Br	Br	I	I
Y	Br	I	Br	I	Br	I

According to the patent data,¹¹ 1,4-dichloro-1,2,3,4-tetrabromobuta-1,3-diene (**122**) is formed in quantitative yield upon bromination of dichlorobuta-1,3-diene (**121a**).

Synthesis of some mixed perhalogenobutadienes was carried out based on the accessible perchlorobutenyne (**128**).⁴² Thus direct bromination of the enyne **128** gave 1,3,4,4-tetrachloro-1,2-dibromobuta-1,3-diene (**100**) in high yield, whereas the synthesis of 1,1,2-tribromo- (**130**) and 3,4,4-trichloro-1,1,2-triiodobuta-1,3-dienes (**131**) was carried out using copper trichlorovinyl acetylide **129** (Scheme 2).⁴²

Scheme 2

3. Synthesis of mixed halogenobutadienes by pyrolysis of polyhalogenated compounds

A number of preparative methods for obtaining MHB containing from four to six halogen atoms in the molecule are based on the pyrolysis of cyclic halogen-containing compounds. Thus the passage of 4-chloro-3,3,4-trifluoro- (**132a**) or 4,4-dichloro-3,3-difluoro-tricyclo[4.2.1.0^{2,5}]non-7-enes (**132b**) through a red-hot tube filled with rings of quartz glass yielded 4-chloro-1,1,4-trifluoro- (**133**) and 4,4-dichloro-1,1-difluorobuta-1,3-dienes (**134**), respectively.⁸²

X = F (**132a**, **133**); X = Cl (**132b**, **134**).

A more convenient method for the preparation of the diene **133** is based on the pyrolysis of 1-acetoxy-2-chloro-2,3,3-trifluorocyclobutane (**135**) or 1-acetoxy-3-chloro-2,2,3-trifluorocyclobutane (**136**).⁸³

135: X = Cl, Y = F; **136**: X = F, Y = Cl.

Many MHB were obtained by the pyrolysis of the corresponding halogeno-substituted cyclobutenes. Thus the pyrolysis of 1-chloro-3,3,4,4-tetrafluorocyclobut-1-ene (**137**) gives 2-chloro-1,1,4,4-tetrafluorobuta-1,3-diene (**138**) in preparative yield (Table 3).^{13,83}

The main pyrolysis products of 1,2,3,4-tetrafluoro-3,4-diiodo- and 4-chloro-1,2,3,4-tetrafluoro-3-iodocyclobutenes (**139a,b**) are 1,2,3,4-tetrafluoro-1,4-diiodobuta-1,3-diene (**140**), formed as a

Table 3. Miscellaneous methods for the preparation of mixed halogenobutadienes.

^a A is pyrolysis; B is synthesis of MHB from polyhalogenoacroleins; C is other methods. ^b The starting compounds were obtained by the [2 + 2]-cycloaddition reaction.

mixture of *E,E*-, *E,Z*- and *Z,Z*-isomers, and 4-chloro-1,2,3,4-tetrafluoro-1-iodobuta-1,3-diene (**141**), respectively.⁸⁴

X = I (**139a**), Cl (**139b**).

Mixed halogenobutadienes are also formed by the pyrolysis of some aliphatic compounds. Thus heating of sulfoxide CFCl₂SOCH₂CH=CH₂ or sulfone CFCl₂SO₂CH₂CH=CH₂ yielded 1-chloro-1-fluorobuta-1,3-diene as one of the reaction products (**17**).⁸⁵

Decarboxylation of sodium 5-chloro-2,2,3,3,4-pentafluoropent-4-enoate (**142**) *in vacuo* gives high yield of (*Z*)-4-chloro-1,1,2,3-tetrafluorobuta-1,3-diene (**143**).⁸⁶

The butadiene **81** is present among the pyrolysis products of chlorofluoroethylene. Presumably, this results from thermal dechlorination of butene **144**, which appears in the reaction due to the addition of chlorofluorocarbene to the initial chlorotrifluoroethylene.

4. Synthesis of mixed halogenobutadienes based on polyhalogenoacroleins

An original way of the preparation of some bromine, chlorine-containing MHB is based on the reaction of polyhalogenoacroleins **145–148** with dibromomethylenetriphenylphosphorane.^{88, 89}

Hal = Cl: X = H (**145**, **149**), Cl (**146**, **150**), Br (**147**, **151**);
Hal = I: X = Cl (**148**, **152**).

The first representative of MHB containing three different halogen atoms, *viz.*, 4,4-dibromo-2-chloro-1,1-diiodobuta-1,3-diene (**152**) was obtained in 1970 by the reaction of α -chloro- β,β -diiodoacrolein (**148**) with Ph₃P=CBr₂.^{88, 89}

A method of preparation of (*Z*)-4-bromo-1,1,2-trichlorobuta-1,3-diene (**55**) from the acrolein **146** and phosphorylide Ph₃P=CHCOOEt has been developed.⁸⁹

Yet another method of the synthesis of MHB is based on the reaction of halogenoacroleins with dichloro ketene. Starting from the acrolein **147** and β,β -dibromo- α -chloroacrolein (**153**), 2-bromo-1,1,4,4-tetrachloro- (**154**) and 1,1-dibromo-2,4,4-trichloro-buta-1,3-dienes (**155**) were obtained, respectively.⁴²

147, 154: Hal = Cl, X = Br; **153, 155:** Hal = Br, X = Cl.

This reaction is supposed to proceed through the initial formation of a lactone **156**, which is easily decarboxylated with the formation of the target products **154** and **155**.

The yields of the dienes **55**, **149–152**, **154**, **155** and conditions of their synthesis are listed in Table 3.

5. Miscellaneous reactions for the preparation of mixed halogenobutadienes

It was shown²⁸ that chlorination of bromoprene (**4**) yields, along with different addition products, also 2-bromo-1-chlorobuta-1,3-diene (**6**) as a mixture of *Z*- and *E*-isomers.

The reaction of lithium 1,2,3,4-tetrachlorobuta-1,3-dien-1-ide with iodine yielded 1,2,3,4-tetrachlorobuta-1-iodo-1,3-diene (**157**).⁹⁰

The synthesis of 1,1-dichloro-4,4-difluorobuta-1,3-diene (**134**) in low yield by the reaction of sulfur tetrafluoride with 2,2-dichlorocyclopropanecarboxylic acid (**158**) has been reported.⁹¹

A convenient method for the preparation of 1,4-dichloro-1,2,3,4-tetrafluorobuta-1,3-diene (**82**) is the reductive dimerisation of a mixture of *Z*- and *E*-isomers of 2-chloro-1,2-difluoro-1-iodoethylene in the presence of a copper powder.^{92,93} The diene **82** is formed as a mixture of *E,E*-, *E,Z*- and *Z,Z*-isomers in approximately the same ratio as reported elsewhere⁶² (see Table 3).

Unfortunately, the attempt to extend this reaction for the synthesis of other MHB has been unsuccessful because of inaccessibility of iodine-containing halogenoethylenes.

III. Chemical properties of mixed halogenobuta-1,3-dienes

1. Addition reactions. Halogenation of mixed halogenobutadienes

Despite the fact that MHB possess electrophilic properties, they add, like other diene compounds with conjugated double bonds, halogens to both the terminal positions of the diene system (1,4-addition) and to one of the double bonds (1,2- or 3,4-addition). The direction of this reaction is determined to a considerable extent by the nature of MHB and the halogenation agent; experimental conditions are also highly important. The 1,4-addition is characteristic of the dienes having a small number of bulky substituents (Cl, Br or I) and low asymmetry. In the MHB with a high extent of substitution with bulky substituents, the π,π -conjugation is disturbed so that these dienes react as alkenes. Sometimes, an exhaustive halogenation takes place at both C=C bonds and results in the formation of polyhalogenobutanes.

It was shown that the bromination of a mixture of *E*- and *Z*-isomers of 1-bromo-1,4,4-trichlorobutadienes (**56**) (*E*:*Z* ratio = 1 : 4) occurs at the 1,2- and 3,4-positions and results in a mixture of two products, viz., 3,4,4-tribromo-1,1,4-trichloro- and 1,3,4-tribromo-1,4,4-trichlorobut-1-enes in the ratio 70 : 30 with a total yield of 76 %.^{55,94}

Bromination of the *E*-isomer of the diene **66** (45–50 °C, illumination with an incandescent 60 W lamp, 8 h) occurs exclusively at the β,β -dichlorovinyl group and results in (*E*)-1,3,4-tribromo-1,2,4,4-tetrachlorobut-1-ene in a yield of 93%.⁷¹

Monochloropentafluoro- and dichlorotetrafluorobuta-1,3-dienes (their structure has not been unequivocally established) add one molecule of bromine with the formation of the corresponding butenes of the general formulae $\text{C}_4\text{ClBr}_2\text{F}_5$ and $\text{C}_4\text{Cl}_2\text{Br}_2\text{F}_4$ at 20–150 °C.⁶¹

The diene **81** adds two molecules of bromine at 50 °C and gives 1,2,3,4-tetrabromo-3-chloro-1,1,2,4,4-pentafluorobutane, the structure of which was confirmed by the results of chromatomass spectrometry.⁸⁷ According to Petrov *et al.*,⁹⁵ the chlorination and bromination of the diene **81** occur exclusively as the 1,4-addition and lead to the corresponding but-2-enes. Thus treatment of the diene **81** with a mixture of *N*-bromosuccinimide (NBS) and HF in THF yielded a mixture of *E*- and *Z*-isomers of 3-chloro-1-bromo-1,1,2,4,4,4-hexafluorobut-2-ene (*E*:*Z* = 5 : 1) in a total yield of 82 %. Fluorination of the diene **81** with VF_5 from –20 to –30 °C occurs predominantly as the 1,4-addition and results in 2-chloroheptafluorobut-2-ene as a mixture of *Z*- and *E*-isomers (yields, 20% and 36%, respectively). A small amount (8%) of 2-chlorononafluorobutane is formed as the product of exhaustive fluorination.⁹⁶

According to the patent literature,⁹⁷ the diene **92** reacts with bromine (illumination with a 100 W lamp) to give 1,4-dibromo-2,3-dichloro-1,1,4,4-tetrafluorobut-2-ene (1,4-addition),

whereas with the diene **82** 1,2-addition occurs, which results in 3,4-dibromo-1,4-dichloro-1,2,3,4-tetrafluorobut-1-ene. Its chlorination gives 1,2-dibromo-1,3,4,4-tetrachloro-1,2,3,4-tetrafluorobutane.⁶⁴ Chlorination of the diene **82** affords 1,1,2,3,4,4-hexachloro-1,2,3,4-tetrafluorobutane.⁶⁴

2. Cycloaddition reactions

a. Reaction of mixed halogenobutadienes with difluorocarbene

The addition of carbenes to MHB was studied only for the reaction of difluorocarbene with the diene **81**. Petrov *et al.*⁹⁸ used hexafluoropropylene oxide as the source of difluorocarbene. Heating of an excess of the epoxide with the diene **81** in an autoclave gave the halogeno-substituted cyclopentene **159** in high yield. The cyclopentene **159** is one of the pyrolysis products of chlorotrifluoroethylene.⁸⁷ According to Petrov *et al.*,⁹⁸ the difluorocarbene formed in the course of pyrolysis adds to the diene **81** to give polyhalogenovinylcyclopropanes, whose intramolecular rearrangement yields the cyclopentene **159**.⁸⁷

b. Diels–Alder syntheses involving mixed halogenobutadienes

Chloro-substituted buta-1,3-dienes (mostly, mono- and dichloro-derivatives) are convenient subjects for studying the Diels–Alder reaction and preparation of practically valuable compounds.⁷ Some MHB were also studied in the [4 + 2]-cycloaddition. Thus upon prolonged boiling of an excess of the dienes **40** and **118** with methyl vinyl ketone in the presence of Na₂CO₃, the corresponding 1-acetyl-3,4-dihalogenocyclohexa-1,3-dienes **160** (X = Br) and **161** (X = I) were obtained. Upon treatment of the cyclohexadienes **160** and **161** with 1,8-diazabicyclo[5.4.0]undec-7-ene, they are readily aromatised into the corresponding halogenoacetophenones **162** and **163**.^{77, 99}

The [4 + 2]-cycloaddition of (ClSN)₃ and FSN to the butadiene **81** yielded the difficultly accessible and highly reactive 6-membered heterocycles **164** and **165**, respectively, which are the derivatives of 1,2-thiazines (Scheme 3). Treatment of the 1,2-thiazine **164** with water yields the 1,2-thiazin-3-one-1-oxide **166**. The reaction of methanol with the 1,2-thiazine **165** results in the

Scheme 3

substitution of the methoxy group for the sulfur-bound fluorine atom by the methoxy group with the formation of the product **167**. Thiazine **164** is easily fluorinated with KF and gives a high yield of the thiazine **165**.¹⁰⁰

3. Elimination reactions

As has been shown above (see Section II.2), butenyne is widely used in the synthesis of MHB. In turn, the accessible MHB can be used in the synthesis of some highly reactive halogen-containing butenyne. Thus the preparation of 4-bromo-1,1,2-trichlorobut-1-en-3-yne (**168**) has been developed based on dehydrobromination of the dienes **55** and **150**. The synthesis of the butenyne **168** (yield 60 %) from the diene **55** (Z-isomer) includes two stages: the elimination of HBr under the action of the methanolic solution of potassium carbonate and the substitution of bromine for a hydrogen atom in the 1,1,2-trichlorobut-1-en-3-yne obtained under the action of sodium hypobromite. The second method of the synthesis of the butenyne **168** consists in the dehydrobromination of the diene **150**. It was established that the yield of the target product depends to a considerable extent on the nature of the dehydrohalogenation agent. When the methanolic solution of potassium carbonate is used, the yield of butenyne **168** is 57.5 %; this amounts to 70% with the use of benzyltrimethylammonium hydroxide (Triton B).^{89, 101, 102}

It was shown that the dehydrobromination of the diene **40** under the action of finely ground KOH at 100 °C results in 2-bromo-4-chlorobut-1-en-3-yne in 51 % yield.⁴²

Dehydrochlorination of some pentahalogenosubstituted MHB yielded the previously inaccessible tetrahalogenobutenynes.

Hal = Cl, X = Br; Hal = Br, X = Cl.

4. Substitution reactions

a. Interaction of mixed halogenobutadienes with organometallic compounds

Organolithium and -magnesium reagents found rather limited uses in the chemistry of MHB. The pronounced 'affinity' of these compounds to halogens, on the one hand, and the presence of a large number of halogen atoms in the MHB molecules, on the

other hand, largely prevent selective nucleophilic substitution in these substrates, though such reactions are known (see below). The metal-halogen exchange is more characteristic of MHB. Thus starting from 1,2,3,4-tetrachlorobuta-1,3-diene **84** and butyllithium, mono- and dilithium derivatives were obtained, based on which a number of fine syntheses were carried out.^{103, 104}

Syntheses involving MHB were studied in the example of 1,4-dichloro-1,2,3,4-tetrafluoro-1,3-butadiene (**82**).⁶² Treatment of an isomeric mixture of the diene **82** (*E,E*:*E,Z*:*Z,Z* = 1:2.5:1.5) with butyllithium and then with CO₂ gave (*E,Z*)-5-chloro-2,3,4,5-tetrafluoropenta-2,4-dienoic acid (**169**) in 25% yield. Comparison of the ratio of isomeric forms of this diene and the yield of the acid shows that it is the *Z,Z*-isomer of the diene **82** that reacts. This reaction proceeds through the stage of exchange of an *exo*-chlorine atom for lithium (according to Kremlev *et al.*,⁶² the starting diene exists in a non-planar *s-cis*-conformation).

The reaction of organomagnesium compounds with MHB occurs in a different way. The reaction of 1-chloroperfluorobuta-1,3-diene (**75**) (*E*:*Z* = 1:1) with phenylmagnesium bromide (**170**) includes the nucleophilic substitution of the phenyl radical for the terminal fluorine atom of the trifluorovinyl fragment, which results in the formation of 4-chloro-1,2,3,4-tetrafluoro-1-phenylbuta-1,3-diene (**171**) as a mixture of *E,E*-, *E,Z*- and *Z,Z*-isomers in the ratio 2:1:2 and in a total yield of 77%.⁵⁷

Various *para*-substituted arylmagnesium bromides (**172**–**175**) were used in this reaction, and this extended appreciably the synthetic possibilities of this method.¹⁰⁵ It was shown that the resulting 1-aryl-4-chloro-1,2,3,4-tetrafluorobuta-1,3-dienes (**176**–**179**) (yields of 40%–49%) represent mixtures of *E,E*-, *E,Z*- and *Z,Z*-isomers in the ratio 1:1:1 (NMR data). The crystalline *E,E*-isomer of compound **176** was isolated in individual form. Metallation of products **171**, **176**–**179** with butyllithium and subsequent carbonisation yielded a series of (*E,E*)-5-aryl-2,3,4,5-tetrafluoropenta-2,4-dienoic acids (**180**–**184**).

R = H (**170**, **171**, **180**), Me₂N (**172**, **176**, **181**), MeO (**173**, **177**, **182**), Me (**174**, **178**, **183**), CF₃ (**175**, **179**, **184**).

¹⁹F NMR studies of the electronic effect of substituents and determination of the acidity have shown that the 1,2,3,4-tetrafluorobuta-1,3-diene system is involved in the transfer of the electronic influence from a substituent in the aromatic ring to the corresponding reaction centre, *viz.*, the carboxyl group or a fluorine atom.¹⁰⁵

Compounds **171**, **176**–**179** served as the basis for the synthesis of symmetrical α,ω -diarylperfluoropolyenes (**185**).¹⁹

Compounds of the type **185** with the (CF=CF)_{*n*} groups are good conductors of the conjugation effect because the fluorine atoms do not create any steric hindrance to its transfer. This opens up a broad perspective for the synthesis of a novel type of polymethine dyes with a totally or partially fluorinated chain.^{19, 105}

b. Nitration reactions

Of all the principal methods for the preparation of nitrobutadienes, the leading part belongs to the nitration of dienes with nitric acid or nitration mixtures.

Nitro- and especially polychloronitrobutadienes are widely employed in organic synthesis.¹⁰⁶ For example, pentachloro-2-nitrobuta-1,3-diene, which was obtained by the reaction of pentachloro-2*H*-buta-1,3-diene with nitric acid, proved to be a versatile starting material for numerous syntheses of compounds belonging to different classes.^{107–109}

The first representative of nitroderivatives of MHB [4-bromo-1,1,3,4-tetrachloro-2-nitrobuta-1,3-diene (**186**)] was obtained by the reaction of 60% nitric acid with a 1:1 mixture of *Z*- and *E*-isomers of 1-bromo-1,2,4,4-tetrachlorobuta-1,3-diene **66** at 80–85 °C. The nitrodiene **186** is a mixture of two isomers (GLC).

Along with the nitration of the initial diene **66** at the β,β -dichlorovinyl group, competitive oxidative destruction takes place, which leads to the formation of 3-bromo-2,3-dichloroacrylic acid (**187**) as a by-product.¹¹⁰

Recently,⁵⁴ the nitration of the diene **66** with nitrating mixtures HNO₃–H₃PO₄ and HNO₃–H₂SO₄ has been studied over a broad range of concentrations and temperatures. It was found that the optimum conditions for the nitration process are as follows: the temperature 95–100 °C, the ratio of the components of the nitration mixture HNO₃:H₃PO₄ (or HNO₃:H₂SO₄) equal to 10:1 and the ratio of diene:nitration mixture equal to 1:3 or 1:4. Under these conditions, the reaction is completed in 23 h; the yield of the nitrodiene **186** reaches 56% upon nitration with the HNO₃–H₂SO₄ mixture and 58% upon nitration with the HNO₃–H₃PO₄ mixture.

The nitration of the diene **66** (as a mixture of *Z*- and *E*-forms in the ratio 1:3) yields an isomeric mixture of the nitrodiene **186** in virtually the same ratio. Among by-products of this reaction, β -bromo- α,β -dichloroacrolein (yield 8%) and 3-bromo-2,3-dichloroacrylic acid (**187**) were detected.

The nitration of other pentasubstituted MHB, *viz.*, 1,2-dibromo-1,4,4-trichloro- (**68**) and 1,3-dibromo-1,4,4-trichlorobuta-1,3-dienes (**70**) with nitric acid or nitration mixtures occurs similarly. Thus nitration of the *E*-isomer of the diene **68** with the 55%–60% nitric acid, fuming nitric acid or a nitration mixture HNO₃–H₃PO₄ yielded (*E*)-3,4-dibromo-1,1,4-trichloro-2-nitrobuta-1,3-diene (**188**).

The nitration of the diene **70** with the above-cited reagents under similar conditions gives 1,3-dibromo-1,4,4-trichloro-2-nitrobuta-1,3-diene in yields of 35%, 43% and 48%, respectively.

1-Bromo-1,4,4-trichlorobuta-1,3-diene (**56**) reacts differently with nitric acid and with nitration mixtures. In this case, the nitration proceeds in the two directions: (1) substitution of a hydrogen atom in the β,β -dichlorovinyl group and (2) substitution of a bromine atom in the β,β -bromochlorovinyl group resulting in the formation of 1,1,4-trichloro-1,3-dinitrobuta-1,3-diene (**189**). Another reaction product is 4-bromo-1,1,4-trichloro-3-nitrobut-1-ene (**190**). Under the optimum conditions [the nitration mixture HNO₃–H₃PO₄ (10 : 1), 90–95 °C, 2 h], the yields of 1,4-dinitrobuta-1,3-diene **189** and nitrobutene **190** are 18% and 40%, respectively.⁴⁹

According to the IR spectroscopy and the X-ray diffraction analysis, the diene **189** is the *Z*-isomer and has a virtually planar *s-trans*-configuration.^{111, 112}

5. Isomerisation reactions

It was shown above (see Section II.3) that the accessible polyhalogenocyclobutenes are convenient starting compounds for the synthesis of some MHB. As early as 1949, the thermal cyclisation of hexafluorobuta-1,3-diene (**91**) at 150–180 °C was carried out and resulted in hexafluorocyclobutene (**191**) and a mixture of dimers C₈F₁₂ and trimers C₁₂F₁₈.¹¹³ Later, these transformations were also performed for hexachlorobuta-1,3-diene (**83**), and hexachlorocyclobutene (**192**) was isolated by distillation.⁷ The isomerisation of halogenobutadienes into the corresponding cyclobutenes is a reversible reaction.

The isomerisation of MHB was studied in the example of 1,4-dichloro-1,2,3,4-tetrafluorobuta-1,3-diene (**82**) and 2,3-dichloro-1,1,4,4-tetrafluorobuta-1,3-diene (**92**). It was shown that heating of the diene **82** at 250 °C in a sealed glass tube results in 3,4-dichlorotetrafluorocyclobutene (**193**) in 56% yield. Upon heating of this diene in a platinum crucible over activated carbon to 320 °C, the yield of the butene **193** reaches 74%. The reverse process (transformation of cyclobutene into diene) occurs at 380 °C at a lower rate, therefore, the content of butadiene in the thermolysis products of the cyclobutene **193** is only 14%.⁶⁴

Heating of a mixture of *E,E*-, *E,Z*- and *Z,Z*-isomers of the diene **82** in a nickel tube at 330 °C yielded three products, viz, 3,4-dichloro- (**193**), 1,4-dichloro- (**194**) and 1,2-dichlorotetrafluorocyclobutenes (**195**). Presumably, the cyclobutenes **194** and **195** are formed due to the double bond migration catalysed by the fluoride ion.¹¹⁴

The diene **92** undergoes only partial transformation when heated in a sealed steel tube at 170 °C for 44 h. The unreacted diene **92** was recovered, 1,2-dichlorotetrafluorocyclobutene (**195**) and a small amount of unsaturated dimers and a dimer **196**⁹⁷ were isolated from the reaction mixture. The total conversion of the diene **92** into the cyclobutene **195** occurs after 89 h.⁹⁷

It was supposed⁶⁴ that the reaction diene $\rightleftharpoons$ cyclobutene is a general characteristic of the polyhalogenobutadienes.

6. Miscellaneous reactions

The reduction of MHB was studied only in the example of (*Z*)-1-bromo-2-chlorobuta-1,3-diene (**3**). It was shown that the reduction of *Z*-diene (**3a**) with LiAlD₄ in diethyl ether occurs with high stereoselectivity and leads to the formation of a mixture of (*E*)- (**197a**), (*Z*)-2-chloro-1-deuteriobuta-1,3-diene (**197b**) and 2-chlorobutadiene (**2**) in the ratio 94.2 : 2.2 : 3.6, respectively.²⁵

In example of the reaction of pentachloro-2*H*-buta-1,3-diene (**198**) with fuming nitric acid it was shown that the reaction product is 3,4,4-trichloro-2-nitrobut-3-enoic acid (**199**), i.e., the β,β -dichlorovinyl group of the diene **198** is involved in the reaction and an earlier transformation into the CH(NO₂)COOH group occurs.¹¹⁵ An analogous reaction giving 4-bromo-3,4-dichloro-2-nitrobut-3-enoic acid (**200**) in high yield also occurs upon interaction of fuming nitric acid with 1-bromo-1,2,4,4-tetrachlorobuta-1,3-diene (**66**).¹¹⁰

X = Cl (**198**, **199**), Br (**66**, **200**).

The reaction of the *E*-isomer of the diene **66** with chlorosulfonic acid proceeds in an unusual manner. Under the optimum conditions (70–80 °C, the diene : acid ratio equal to 1 : 2; 5 h), the reaction gives (*E*)-1,3-dibromo-1,2,4,4-tetrachlorobuta-1,3-diene **102** in 31% yield as the main product.

In addition, bromochloromaleic acid **201** (yield 6%) and hexachlorobuta-1,3-diene **83** (yield ~ 2%) were also found among the reaction products. Dienes **102** and **83** are apparently

formed upon halogenation of the starting compound **66** with chlorine and bromine, which appear in the reaction mixture upon destruction and resinification of the substances involved. Acid **201** is the hydrolysis product of the diene **102**.

When the diene **66** is used in the reaction in the form of *E*- and *Z*-isomers (1 : 1), the diene **102** is also formed as a mixture of two isomers in the ratio 1 : 1.⁷¹

IV. Conclusion

Analysis of the published data shows that constant attention is paid to the synthesis of mixed halogenobuta-1,3-dienes. Nowadays, there are rather well developed methods for the synthesis of hexasubstituted chloro-, fluoro- and chlorobromobutadienes, while the methods for the synthesis of MHB containing from 2 to 5 atoms of halogens are somewhat less developed.

Most of the methods for the preparation of MHB are based on the elimination reactions of accessible polyhalogenobutenes and -butanes, *i.e.* they rely on the use and transformations of the existing C_4 carbon chain. At present, novel methods have been proposed for the synthesis of MHB under the conditions of phase-transfer catalysis, which makes their preparation simpler and more efficient.

Virtually all of the synthesised MHB contain two kinds of the halogen atoms. At present, there is a convenient procedure for the synthesis of only one MHB representative containing three kinds of the halogen atoms. Unfortunately, until now no MHB have been prepared with four different halogen atoms (F, Cl, Br, I) which could be used as convenient models for studying regularities of competitive processes of nucleophilic vinylic substitution ($\text{S}_\text{N}\text{Vin}$) of different halogen atoms.

Transformations of MHB are represented in the relevant literature to a lesser extent; nonetheless, the available data show that MHB possess broad possibilities for the development of new methods for the synthesis of polyfunctional compounds which are difficultly accessible or totally inaccessible by other ways.

We hope that a stimulus for the further development of studies in this field will be the fact that many MHB possess a broad spectrum of useful properties.

Abstract. Data on the synthesis, polymerisation and copolymerisation of aryl (meth)acrylates are generalised and systematised. Chemical and photochemical properties of the polymers and copolymers are considered. Basic directions of practical application of poly[aryl (meth)acrylates] and copolymers are demonstrated. The bibliography includes 449 references.

I. Introduction

Aryl (meth)acrylates $\text{H}_2\text{C}=\text{C}(\text{R})\text{CO}_2\text{Ar}$ (hereinafter $\text{R} = \text{H}, \text{Me}$) occupy a special place in the series of (meth)acrylates due, first of all, to the diversity of functional groups which may be introduced into the aromatic ring of these monomers and the derived polymers. Specificity of physical properties of poly[aryl (meth)acrylates] is determined by the enhanced rigidity of the polymeric chains (because of the presence of aromatic rings). Aryl (meth)acrylates are easily copolymerised with most of the known monomers, which opens broad prospects for their application.

Until recently, the results of numerous studies on the synthesis and properties of aryl (meth)acrylates have not been generalised. The present review is intended to fill this gap.

II. Methods for the synthesis of aryl (meth)acrylates

Earlier methods for the synthesis of aryl (meth)acrylates were rather complicated and were not of a general character. Thus phenyl acrylate (PA) was prepared by direct esterification of phenol with acrylic acid in the presence of trifluoroacetic anhydride¹ and also by the Reppe reaction, *i.e.*, by the reaction of acetylene and carbon monoxide with phenol.² Phenyl³ and naphthyl acrylates⁴ were obtained by pyrolysis of 2-acetoxypromates $\text{MeCH}_2(\text{OAc})\text{CO}_2\text{Ar}$. The systematic studies of the methods for the preparation of aryl acrylates were initiated by Magagnini and Pizzirani⁵ who investigated the reactions of

acryloyl chloride with phenols. In addition to PA, these authors described acrylates of isomeric cresols, chlorophenols, thymol, hydroxybiphenyl and 4-methoxyphenol. It should be noted that the reactions were carried out under conditions precluding the addition of hydrogen chloride to the double bond. In earlier attempts of the synthesis of acrylates by this method, this addition took place; therefore, β -chloropropionates were the major products. Conducting of these reactions in the presence of triethylamine allowed a considerable increase in the yields of methacrylates of substituted phenols. This method was successfully used to prepare isomeric phenol di(meth)acrylates,⁶ 2-biphenyl acrylate⁷ and 4-biphenyl (meth)acrylate⁸ and mono- and di(meth)acrylates of substituted 2,2'-methylenebisphenols.⁹

Aryl (meth)acrylates are usually synthesised by the reaction of phenols with (meth)acryloyl chloride in the presence of hydrogen chloride acceptors. This process may be carried out in inert solvents in the presence of Na_2CO_3 ,¹⁰ in pyridine,¹¹ in ethanolic solution of KOH ¹² or triethylamine.⁷ It is also convenient to use the Schotten–Baumann reaction, which involves the acylation of phenolates with (meth)acryloyl chloride in aqueous solutions at reduced temperature in the presence of an excess of alkali.¹³ This reaction occurs efficiently at the interface of the aqueous and organic phases.¹⁴ Monomers based on halogenated 2,2-di(4-hydroxyphenyl)propanes¹⁵ and hydroxyphenyl derivatives of 2*H*-benzotriazole¹⁶ were prepared in this manner.

The methods described above have allowed the preparation of numerous alkyl- (see Refs 4, 6, 13, 17, 18), halogeno- (see Refs 4, 6, 11, 14) and nitro-substituted^{4,10,19} phenyl (meth)acrylates (PMA). At the same duration and temperature of the reaction, the yields of esters decreased in the following order: *meta*-isomer > *para*-isomer > *ortho*-isomer > disubstituted phenol.¹⁰ Optimum conditions were found for the preparation of 2,6-dimethylphenyl acrylate, 2,4,6-trichloro-, 2,4,6-tribromo-, 2,4,6-trimethyl-, 2,6-diisopropyl- and 2,6-di(*tert*-butyl)-phenyl methacrylates, 2,4,5-trichlorophenyl acrylate²¹ and methacrylate.²²

PMA with substituents in the aromatic ring containing the aldehyde and ketone,²³ carboxy,^{24,25} benzyl,²⁶ tetracyanocyclobutyl²⁷ and dioxolane²⁸ groups have been described. Special mention should be made of (meth)acrylates of hydroxyphenylacetic²⁹ and hydroxybenzoic^{24,25} acids as well as of surfactant salts³⁰ of the general formula $\text{CH}_2=\text{CMeC}(\text{O})\text{OC}_6\text{H}_4(\text{CH}_2)_n\text{X}$ [$n = 3, 7$; $\text{X} = \text{CO}_2\text{Na}, \text{N}^+(\text{C}_n\text{H}_{2n+1})_3\text{Z}^-$; $\text{Z} = \text{Cl}, \text{Br}, \text{I}, \text{MeSO}_4$].

4-(Meth)acryloyloxybenzoic acids form liquid-crystalline polymers upon polymerisation and give birth to a large number of mesomorphic monomers and polymers.³¹ Of all monomers of this type, the best studied are the esters of the general formula $\text{CH}_2=\text{C}(\text{R}')\text{C}(\text{O})\text{OYCR}''$ ($\text{R}' = \text{H},^{32} \text{Me},^{33} \text{OR}''$; $\text{R}'' = \text{Me},^{32-35} \text{Pr},^{34} \text{Bu}^n,^{32-34,36} \text{n-C}_6\text{H}_{13},^{37}$ and $\text{Alk}(\text{C}_8-\text{C}_{16})^{36}$ (hereinafter $\text{Y} = 1,4\text{-C}_6\text{H}_4$). Monomers with more complex structures have been also described, *e.g.*, methacrylates with the mesogenic side groups $\text{YC}(\text{O})\text{OYOC}(\text{O})\text{YOR}'$ ($\text{R}' = \text{H}, \text{Alk}$);³⁸ or thermotropic bisacrylates $\text{R}'\text{XR}'$ ($\text{X} = (\text{CH}_2)_n$; $n = 6-10, 12$; $\text{R}' = \text{CH}_2=\text{CHC}(\text{O})\text{O}.$ $\text{YC}(\text{O})\text{OYCR}''$).³⁹ It should be noted that mesomorphic monomers are also found among aryl (meth)acrylates with a different character of substitution. These are acrylates and methacrylates of hydroxybiphenyl with alkyl⁴⁰ and alkoxy^{41,42} substituents or the CN group⁴³ at the position 4'. It is noteworthy that poly(4,4'-biphenylene diacrylate) does not possess liquid-crystalline properties.⁴⁴

The group of mesomorphic monomers also includes easily polymerisable acrylates of azomethines derived from 4-hydroxybenzaldehyde. Polymers with Schiff's bases as the pendent groups can be obtained by polymer-analogous transformations from polyacryloyl chloride and the corresponding hydroxybenzylideneaniline.⁴⁵ A large group of this type of monomers of the general formula $\text{CH}_2=\text{C}(\text{R}')\text{C}(\text{O})\text{OYCH}=\text{NX}$ [$\text{X} = \text{Alk}(\text{C}_1-\text{C}_4), \text{C}_6\text{H}_4\text{Z}$; $\text{Z} = \text{OH}, \text{OMe}, \text{OEt}, \text{NMe}_2, \text{NEt}_2, \text{NHPh}, \text{naphthyl}, \text{pyridyl}$] has been proposed⁴⁶ for the preparation of non-aqueous dispersions of polymers used in polygraphy.

4-(4-Acryloyloxybenzylideneamino)phenyl acrylate⁴⁴ and *N*-(4-cyanobenzylidene)-4-acryloyloxyaniline are azomethines based on 4-aminophenol.⁴⁷ Mesomorphic monomers (as well as the derived polymers) are rarely found among methacryloylazomethines.⁴⁸

(Meth)acrylates of hydroxyazobenzenes⁴⁹⁻⁵¹ and hydroxyazoxybenzenes⁵² were used to prepare liquid-crystalline polymers. Azo-monomers possess, as a rule, alkyl, alkoxy or aryl substituents in the *para*-position relative to the azo group. The respective polymers are lyotropic or thermotropic liquid crystals, which undergo reversible changes under the action of UV radiation.⁵³ Liquid-crystalline polymers based on 4,4'-(bisacryloyloxy)azoxybenzene⁴⁴ are also obtained by the reaction of 4-hydroxyazobenzene with poly(acryloyl chloride).⁵⁴ Comb-like polymers with liquid-crystalline properties were obtained by polymerisation of hydroquinone mono(meth)acrylates esterified at the second OH group with 4-*n*-alkoxybenzoic acids.⁵⁵⁻⁵⁸

The results of studies on liquid-crystalline polymers derived from aryl (meth)acrylates have been described rather comprehensively in monographs.^{59,60}

Syntheses of (meth)acrylates of derivatives of condensed aromatic systems (naphthalene, anthracene, phenanthrene) have been described.⁶¹ Syntheses of α - and β -naphthyl esters of some α, β -unsaturated acids,⁶² 2-(β -substituted acryloyl)-1-methacryloyloxynaphthalenes, which are cross-linking agents,⁶³ and 4-benzoylamino- α -naphthyl methacrylate,⁶⁴ which is an efficient thermostabiliser, are documented. Monomeric dyes of the anthraquinone series were obtained by the reaction of unsaturated acid chlorides with 4-amino-1,5-dihydroxy-2,6-diisobutyl-, 5-(3-aminophenylthio)-1,5-dihydroxy-2,6-diisobutyl- and 4,5-diamino-1,8-dihydroxy-2,7-diisobutylanthraquinones.⁶⁵ Copolymerisation of these dyes with styrene and butyl methacrylate yields polymers self-coloured in yellow, red and blue. Kimura *et al.*⁶⁶ have described 2- and 9-fluorenyl methacrylates. Upon their polymerisation in the presence of a telogen, the degree of telomerisation of the second monomer is lower. A number of monomers based on fluoranthene, including 3-fluoranthenyl methacrylate, produce polymers of the donor type, which form charge-transfer complexes possessing electrical properties with tetracyanoquinodimethane and tetracyanoethylene.⁶⁷

Methacrylates of the 8-hydroxyquinoline series⁶⁸ of the general formula

$\text{X} = \text{H}, \text{Br}, \text{Cl}, \text{I};$

$\text{R}' = \text{C}(\text{O})\text{CMe}=\text{CH}_2;$

$\text{R}'' = \text{H}, \text{Br}, \text{Cl}, \text{CH}_2\text{OMe}, \text{CH}_2\text{OEt}$

were synthesised in order to obtain subsequently medicinal preparations with prolonged action.^{69,70} Halogens were shown to favour polymerisation. Methacrylates of hydroxyphenyl derivatives of other nitrogen-containing heterocycles are also known, *e.g.*, 1,3-diphenyl-5-(4-methacryloyloxyphenyl)-2-pyrazoline.⁷¹ Of these, the most complex are acrylate and methacrylate of 5-(4-hydroxyphenyl)-10,15,20-triphenylporphyrin⁷² (the respective polymers possess semiconducting properties and adsorb oxygen at temperatures below 200 K) and of 5-(4-acryloyloxyphenyl)-15-phenyl-2,8,12,18-tetraethyl-3,7,13,17-tetramethylporphyrin.⁷³

Some monomers contain the methacryloyloxy group bound directly to the heterocyclic ring, *e.g.*, 2-pyridyl methacrylate.⁷⁴ Aryl (meth)acrylates with the nitrogen-containing heterocyclic substituents in the *para*- and *meta*-positions of the benzene ring have been described.⁷⁵ The initial *N*-(hydroxyphenyl)imides were obtained by condensation of aminophenols with the corresponding anhydrides. Monomers were synthesised by acylation with unsaturated acid chlorides.

As regards aryl (meth)acrylates with nitrogen-containing substituents in the phenyl group, monomers with the nitro (see Refs 4, 10, 19) and cyano⁷⁶ groups have been described; a number of monomers with the azo (see Refs 77, 78), azoxy and azomethine groups⁷⁹⁻⁸² are also known. 4-Azidophenyl methacrylate,⁸³ salicinide,⁸⁴ *N*-benzyl- and *N*-phenyl-4-hydroxybenzamide acrylates and methacrylates⁸⁵ were synthesised.

4-Aminophenyl methacrylate proved to be sensitive to oxidation, which reduces the possibility of its practical application.⁸⁶ However, 3-(*N,N*-dimethylamino)phenyl methacrylate is fairly stable,⁷⁶ it forms charge-transfer complexes with electron acceptors and is promising for the synthesis of polymeric photoconductors.

Many reactive monomers, *e.g.*, acylaminophenyl methacrylates of the general formula $\text{R}'\text{C}(\text{O})\text{NHC}_6\text{H}_4\text{OC}(\text{O})\text{CR}=\text{CH}_2$ ($\text{R}' = \text{H}, \text{Me}, \text{Et}, \text{Pr}, \text{Bu}, \text{C}_5\text{H}_{11}, \text{PhCH}=\text{CH}, \text{O}_2\text{NC}_6\text{H}_4$ and BrC_6H_4) were obtained by *N*-acylation of isomeric aminophenols with equimolecular amounts of carboxylic acid chlorides (in anhydrous acetone, methanol or DMF) with subsequent esterification by the Schotten-Baumann reaction with acryloyl or methacryloyl chlorides.⁸⁷⁻⁹⁰ If 4-, 3- or 2-aminophenols are esterified with methacrylic acid, both functional groups react to give 4-, 3- or 2-(meth)acryloylaminophenyl (meth)acrylates. These reactive monomers undergo cross-linking in the polymerisation.^{14, 91, 92} Di- and tri(meth)acryloyl derivatives of 2,4-diaminophenol (amidol) were synthesised by successive acylation.⁹²

Diacryloyl and di(meth)acryloyl derivatives of nitroaminophenols

were prepared⁹³ by acylation of 2-amino-4-nitro- and -5-nitrophenols with unsaturated acid chlorides in tetrahydrofuran in the presence of triethylamine.

Based on 4-amino- α -naphthol, azonaphthyl methacrylates,^{94,95}

$\text{R}' = \text{H}, \text{OMe}, \text{Br}, \text{NO}_2,$

imidonaphthyl methacrylates⁹⁴ and 4-benzoylamino- α -naphthyl methacrylate⁹⁵ were synthesised.

Thus, aryl (meth)acrylates with diverse functional groups in the aryl residue have been prepared to date.

III. Polymerisation of aryl (meth)acrylates

Aryl (meth)acrylates are relatively easily polymerised by a radical mechanism, the polymerisation rate being mainly determined by steric effects of substituents.⁹⁶ Thus *ortho*-substituted PMA are appreciably less reactive than the *para*-isomers, the chemical nature of the substituent does not play any substantial role, which has been confirmed by the results of polymerisation of nitro- and methoxyphenyl methacrylates.^{13, 97, 98} Polymerisation was carried out in block and in different solvents in the presence of benzoyl peroxide. Since the electronic effect of the nitro and methoxy groups is opposite, one could expect that the rates of polymerisation of *o*- and *p*-nitrophenyl methacrylates and *o*- and *p*-methoxyphenyl methacrylates would be different; however, polymerisation of *para*-derivatives occurred faster in both cases. The EPR spectra of radicals devoid of *ortho*-substituents, e.g., poly(phenyl methacrylate) (PPMA) and poly(4-methylphenyl methacrylate), are identical, whereas the spectra of radicals of 2,6-diisopropylphenyl methacrylate and 2,6-di-*tert*-butylphenyl methacrylate revealed differences related to the shielding of the growing end of the polymeric chain by the *ortho*-substituents and the α -methyl group.⁹⁹

The overall rate constant of the bulk polymerisation of alkylphenyl methacrylates (alkyl = Et, Prⁱ, Bu^t) is higher for the *para*-substituted monomers than for the *ortho*-substituted ones and is virtually independent of the substituent size, whereas for the *ortho*-isomers this constant decreases with the increase in the substituent size.¹⁰⁰ The reaction order with regard to the initiator (dilauryl peroxide) is 0.5 for non-substituted PMA, while it is 0.64–0.94 for the sterically hindered monomers. The presence of methyl groups in the *ortho*-position (e.g., in 2,6-dimethylphenyl methacrylate) decreases appreciably the ceiling temperature of polymerisation (down to 73 °C) compared to that of non-substituted PMA (140 °C).¹⁰¹ The overall activation energy (kJ mol⁻¹) increases in the following order: 2,6-diisopropylphenyl methacrylate (45.7) < 4-*tert*-butylphenyl methacrylate (49.9) < 4-(1,1,3,3-tetramethylbutyl)phenyl methacrylate (59.6) < 4-methyl-, 4-ethyl- and 4-isopropylphenyl methacrylates (70–76).^{102, 103}

Substitution of the cyclohexyl radical for the phenyl radical in the molecule of aryl methacrylate affects the polymerisation rate. For example, methacrylate of thymol, which contains a bulky isopropyl residue, is polymerised with difficulty, while methacrylate of menthol (hydrogenated thymol) analogous to the preceding monomer is polymerised easily under the same conditions.¹³ This is rationalised by the non-planarity of the cyclohexane ring and, consequently, by a lower rigidity of this monomer molecule compared to the methacrylate of thymol.

Block polymerisation of substituted PMA is accompanied by gel-effect, which is observed in 2,4,6-tribromophenyl, 4-tolyl, 4-cyclohexylphenyl and 4-methoxyphenyl methacrylates at 35%, 35%, 15% and 2% conversions of the monomer, respectively [the concentration of the polymerisation initiator, viz., azobisisobutyronitrile (AIBN) is 0.4%].¹⁰⁴ The kinetic parameters of PMA polymerisation in block and in solvent (60 °C, AIBN) were compared with those for alkyl methacrylates.¹⁰⁵ The overall polymerisation rate has an order of 0.5 with respect to the initiator and 1 with respect to the monomer, i.e., it is described by the usual equation of radical polymerisation. The ratio of the chain termination constant (k_t) to the squared chain propagation constant (k_p) increases in the following order: (phenyl < isobutyl $\approx$ *n*-butyl < ethyl < methyl) methacrylate. According to the radiometric analysis of the initiator fragments, the share of disproportionation in PMA is 89% [72% in methyl methacrylate (MMA)]. The initiation rate of radical polymerisation of PMA by

AIBN depends slightly on the nature of the solvent, while k_p (litre mol⁻¹ s⁻¹) increases in the following series of solvents: benzene (176) < fluorobenzene (180) < chlorobenzene (223) < anisole (230) < bromobenzene (235) < benzonitrile (243).¹⁰⁶ The magnitude of k_p was found to correlate with the difference in chemical shifts of β -alkene protons of monomers depending on the solvent.

The MO LCAO method was used to calculate the stabilisation energy in the formation of complexes of a radical with a solvent; k_p was found to decrease with the increase in the complexation energy. It was shown later that this trend holds for MMA¹⁰⁷ and PMA.¹⁰⁸ The rate of radiation-induced polymerisation of PMA is proportional to the radiation dose to the power 0.65;¹⁰⁹ in the temperature range 20–34 °C, the activation energy of the process is equal to 14.15 kJ mol⁻¹, $k_p/k_t^{0.5} = 0.0198$. At high degrees of conversion, a three-dimensional network is formed owing to the involvement of the terminal double bonds.

Investigation of the influence of substituents on the radical polymerisation of PA has shown that the rate of this process increases in the order: methyl acrylate < 2-chlorophenyl acrylate < PA < 4-chlorophenyl acrylate.¹¹⁰ This is rationalised by changes in the flexibility of the propagating polymer chains. The increase in the overall polymerisation rate (toluene, 60 °C, lauryl peroxide) was found to increase in the following series:¹¹¹ (2-*tert*-butyl- < 2-isopropyl- $\approx$ 2-propyl- < 2-ethyl- < 2-methyl- < PMA < 4-methyl- < 4-isopropyl- < 4-*tert*-butyl- < 4-propylphenyl) methacrylate. The reaction order with regard to lauryl peroxide is 0.51–0.87 depending on the monomer concentration.

In the radical polymerisation of 2,4,5-trichlorophenyl methacrylate¹¹² in dioxane ($k_p = 2.73 \times 10^3$, $k_t = 7.22 \times 10^7$ litre mol⁻¹ s⁻¹), the polymerisation rate is proportional to the monomer concentration to the power 1.5, which is explained by the possible formation of complexes of the monomer with the solvent molecules. In the case of radical polymerisation of nitrophenyl methacrylates, at a low monomer concentration (0.01 mol litre⁻¹) one observes an inhibitory effect of the intra- and intermolecular chain transfer, the former being prevalent.^{113–115} For this reason, 2,6-dinitrophenyl, 2-methyl-4,6-dinitrophenyl and picryl methacrylates are not polymerised under these conditions, and the conversion of 2,4-dinitrophenyl methacrylate hardly reaches 2.6% in 2 h. The reaction orders of 4-biphenyl methacrylate polymerisation (in DMF with AIBN) are 0.55 and 1.1 with respect to the initiator and monomer respectively; the total activation energy is 58 kJ mol⁻¹ (see Ref. 8).

Replacement of an alkyl substituent by the electron-withdrawing acyl substituent in the benzene ring leads to an increase in the polymerisation rate of substituted phenyl (meth)acrylates because of the lower activation energy of the C=C bond cleavage.¹⁷ DTA studies of thermal bulk polymerisation of 4-acetylphenyl acrylate and methacrylate have shown¹¹⁶ that this process is the first-order reaction with respect to the monomer, the activation energies are equal to 228.1 and 120.5 kJ mol⁻¹, respectively. High polymerisation rates were observed for acylaminophenyl (meth)acrylates;^{87, 88} however, the rate of polymerisation decreased with increase in the length of the acyl radical. On the other hand, 4-diethylaminophenyl acrylate and methacrylate polymerised at a lower rate than non-substituted PMA.⁸⁹

Radical polymerisation of mixed diesters of 2,2'-methylene-diphenols with methacrylic and crotonic acids¹¹⁷

where R' and/or R'' are methacrylic and crotonic acid residues and R''' = H, Me, Bu^t, resulted in soluble polymers where R' = R'' (polymerisation involved the methacryloyl group alone),

insoluble dimethacrylates where R' and R'' were the methacrylic acid residues and no polymerisation occurred where R' and R'' were the crotonic acid residues.

(Meth)acryloyl derivatives of *N*-hydroxyphenyl-substituted phthalimide¹¹⁸ $R'C_6H_4OC(O)CR=CH_2$ (R' = phthalimido)

Monomer	I	II	III	IV
R	H	H	Me	Me
Position of R'	<i>para</i>	<i>meta</i>	<i>para</i>	<i>meta</i>

and alicyclic diacylamines^{118, 119} polymerise at high rates and are more reactive than PMA, which seems to be due to the electron-withdrawing character of the imide fragment. The reactivity of monomers decreases in the following order: I > III > II > IV > *p*-acetylaminophenyl methacrylate (*p*-AAPMA), acrylates being more reactive than the corresponding methacrylates and the *para*-isomers more reactive than the *meta*-isomers.¹¹⁸

The reactivity of *m*-phthalimidophenyl (meth)acrylates¹²⁰

Monomer	R'	R''	R'''
I	H	H	H
II	Me	H	H
III	H	Cl	Cl
IV	Me	Cl	Cl
V	Me	Br	Br
VI	Me	NO ₂	H

decreases with in the series: IV > V > II > *m*-AAPMA > VI, i.e., with the weakening of the electron-withdrawing character of the phthalimido group. The reduced reactivity of the monomer with the nitro group in the phthalimide cycle may be explained by its inhibitory action.

The polymerisation rate of imidonaphthyl (meth)acrylates is lower than that of analogous imidophenyl methacrylates, and, according to Vretik *et al.*,⁹⁴ this is due to the reduced reactivity of radicals because of a stronger electronic conjugation in the naphthyl-containing system. The most reactive of all the naphthyl (meth)acrylates studied proved to be bismethacrylate with an additional cycloalkene double bond. This compound was obtained by the reaction of endic dianhydride with 1-amino-4-methacryloyloxynaphthalene.⁹⁴

Irrespective of the initiation mode (thermal or photo-initiation), *m*-(succinimido)phenyl methacrylate (*m*-SIPMA) and acrylate (*m*-SIPA) occupy an intermediate position with regard to their reactivity between *m*-phthalimidophenyl methacrylate (*m*-PTIPMA) and acrylate (*m*-PTIPA), and acetylaminophenyl methacrylate (*m*-AAPMA) and acrylate (*m*-AAPA): *m*-PTIPMA > *m*-SIPMA > *m*-AAPMA > PMA; *m*-PTIPA > *m*-SIPA > *m*-AAPA > PA, i.e., there is correlation between the electron-withdrawing properties of the substituent and polymerisability of substituted phenyl (meth)acrylates.¹²¹ High reactivity of these aryl (meth)acrylates allows the introduction of the above-mentioned heterocyclic fragments into the side chains of macromolecules in order to impart definite photochemical, biological and other properties to the polymeric materials.

Based on imidoaryl (meth)acrylates,^{122, 123}

$X = OC(O)CR=CH_2$; $R', R'' = NO_2, NH_2$; $n = 1, 2$;

$X = NH_2, OC(O)CR=CH_2$; $R' = NO_2$; $n = 1, 2$

homopolymers were obtained with the controllable intramolecular energy transfer. In such polymers, movement of singlet or triplet excitons from one part of the macromolecule to another or from one unit chain to another is observed. The prerequisite for such a transfer is the presence of isolated aromatic systems with different excitation energies in each of the neighbouring units; the initial excitation should be generated in a definite element of the system. Such compounds are promising for the design of micro-electronic devices in which advantage is taken of photophysical processes at the molecular level.¹²⁴

Polymerisability of bifunctional monomers deserves special mention. Cross-linked polymers are formed upon polymerisation of *p*- and *m*-phenylene di(meth)acrylates; *o*-phenylene diacrylate can undergo cyclopolymerisation⁷ with the formation of ladder polymers; the extent of cyclisation increases with the decrease in the monomer concentration and the increase in the polymerisation temperature.¹²⁵ At a monomer concentration above 0.5 mol litre⁻¹, an insoluble polymer is formed. The intramolecular chain growth in the cyclopolymerisation follows mostly the 'head-to-tail' mechanism, and a small number of units are formed by the 'head-to-head' mechanism.

Radical polymerisation of 2-allylphenyl (meth)acrylates is a two-step process:¹²⁶ at an 18%–30% monomer conversion, a soluble low-molecular-mass polymer is formed, which is then cross-linked. The low molecular mass of the product and the absence of the gel-effect are associated probably with the ability of the allyl group to undergo chain transfer. A detailed study of the polymerisation of 2-allylphenyl acrylate in toluene at 60 °C in the presence of AIBN revealed high content of the residual double bonds in the pendent allyl groups of the polymer.¹²⁷ Subsequent cyclopolymerisation occurs due to the reaction of the C=C bonds of the acryloyl and allyl groups. Cyclopolymerisation of 2-allylphenyl, 2-(*o*-allylphenoxy)ethyl and 4-(*o*-allylphenoxy)butyl acrylates catalysed by alkylaluminium chlorides^{127–129} yields 8-, 11- and 13-membered rings; however, the catalyst's activity is insignificant for the formation of the 15-membered ring from 6-(*o*-allylphenoxy)hexyl acrylate.

Polymerisation of *ortho*-, *meta*- and *para*-(meth)acryloylaminophenyl (meth)acrylates initiated by AIBN occurs with the formation of cross-linked polymers.⁹² A decrease in the reactivity in the order *meta*- > *ortho*- > *para*-aminophenol di(meth)acrylates is associated with the character of conjugation in these monomers. Tri(meth)acryloyl derivatives of 2,4-diaminophenol (amidol) are more reactive than the corresponding (meth)acryloylaminophenyl (meth)acrylates, whereas di(meth)acryl derivatives of amidol (with a free OH group) do not polymerise. Upon polymerisation of monomers based on 2-amino-4- and -5-nitrophenols, no formation of cross-linked polymer is observed even at a 60% conversion,⁹³ as is the case of polymerisation of di(meth)acryloyl derivatives of 2-aminophenol. The presence of the nitro group decreases the number of active centres in the system resulting in the higher probability of chain transmission and formation of cycloliner structures in macromolecules.

Cinnamoylaminophenyl (meth)acrylates⁹⁰

polymerise at a lower rate than di(meth)acryloyl derivatives of isomeric aminophenols; the early chain termination at low conversions appears to be due to the inability of the cinnamoyl C=C bond, which acts as a trap for free radicals, to polymerise. This conclusion is prompted by comparison of the IR spectra of

the monomer and the polymer. Photosensitivity of such monomers (photoinitiator, benzoin), like that of 4-cinnamoylamino-phenol, confirms the non-reactivity of the cinnamoyl double bond in radical polymerisation and its capability of photoaggregation.¹³⁰ The nitro group in 4-nitrophenyl cinnamate or in 4-nitro-1-naphthyl cinnamate exerts a photosensitising effect. These monomers are light-sensitive and belong to the group of self-sensitised ones.¹³¹ Poly(4-cinnamoylphenyl methacrylate) obtained in the presence of benzoyl peroxide as an initiator with a degree of conversion of 78% is insoluble in common organic solvents.¹³²

In contrast to MMA, radical telomerisation of aryl (meth)acrylates with the use of bromotrichloromethane as the telogen is not accompanied by the formation of lactones;¹³³ however, the distribution with regard to the degree of polymerisation and tacticity are analogous. Pyrolysis of telomers at 150–200 °C leads to the formation of unsaturated compounds and in part lactones.

The behaviour of 4-methacryloyl- and 4-acryloyloxybenzoic acids is highly specific under thermal treatment.¹³⁴ At 250 °C (above the upper limit of polymerisation temperature), the former undergoes polycondensation with the elimination of methacrylic acid and formation of a rigid-chain polymer, *viz.*, poly(4-hydroxybenzoate). The latter undergoes simultaneous polymerisation and polycondensation. In the polymerised state, both acids undergo polycondensation upon thermal treatment.

Methacrylic monomers with the azo group based on aminophenols^{77, 135}, and 4-amino- α -naphthol¹³⁶

R' = H, Me, NO₂;

R' = H, Br, OMe, NO₂

attract attention because of the possibility of using them for the preparation of 'self-coloured' polymers containing dye residues incorporated into the polymeric chain. Of the monomers based on azo compounds of 3-aminophenol, only the azo-coupling products at the *para*-position relative to the methacryloyl group can polymerise. The monomers based on 4-amino- α -naphthol are incapable of radical homopolymerisation because of a decreased reactivity of their radicals due to high electronic conjugation in the azo system. However, they copolymerise with styrene forming coloured polymers. Copolymers of *trans*-4-(phenylazo)-1-naphthyl acrylate and *trans*-4-(phenylazo)phenyl acrylate with (–)-menthyl acrylate are optically active.¹³⁷

The data on ionic polymerisation of aryl (meth)acrylates are scarce. They are known to polymerise by an anionic mechanism. Polymerisation of PMA on organolithium catalysts proceeds more slowly than that of alkyl methacrylates;¹³⁸ this process is characterised by the existence of a 'limit' of monomer conversion and the fact that the degree of polymerisation does not increase as the process proceeds further. Anionic polymerisation of PMA, cresyl acrylate^{139, 140} and 4-(α , α -dimethylbenzyl)phenyl methacrylate¹⁴¹ in the presence of *n*-butyllithium, as well as anionic polymerisation of *p*-cresyl methacrylate¹⁴² with naphthyllithium, butyllithium and LiAlH₄ in the hydrogen atmosphere are documented. Reduction of the polymers thus obtained with lithium aluminium hydride yields poly(α -methylalcohol) (in the case of *p*-cresyl methacrylate) and polyallylic alcohol (in the case of *p*-cresyl acrylate). Phenyl (meth)acrylate also polymerises readily with alkylaluminium chlorides by an anionic mechanism.¹⁴³ Some PA, *e.g.*, 4-nitrophenyl acrylate, do not polymerise by an anionic mechanism.¹⁴⁰

Comparative studies of radical and anionic polymerisation of 9-fluorenyl and 9-phenylfluorenyl methacrylates¹⁴⁴ in THF or toluene at temperatures from –78 to –60 °C in the presence of AIBN or butyllithium revealed substantial differences in the reaction course. Upon initiation with AIBN, the yield of polymers amounted to 60%–95%, the degree of polymerisation ranged from 9 to 37 with $M_w/M_n = 1.8$ –3.6, while upon initiation with butyllithium, the yield of polymers ranged from 3% to 40%, and $M_w/M_n = 1.9$ –2.0.

IV. Aryl (meth)acrylates in copolymerisation reactions

Aryl (meth)acrylates copolymerise easily with most monomers. For example, copolymers of PMA with ethylene¹⁴⁵ and butadiene¹⁴⁶ have been described. But of greatest interest are numerous data^{147, 148} on copolymerisation of substituted phenyl (meth)acrylates with styrene, acrylonitrile and MMA. Parameters of copolymerisation (AIBN, in bulk or in benzene at 60 °C) of PMA and its derivatives with substitutions in the ring with styrene are presented in Table 1.

It was noted that the reactivity of monomers towards styrene radical ($1/r_1$) is determined by the polar (σ) and resonance (E_r) effects of substituents and is satisfactorily described by the modified Hammett equation¹⁴⁹

$$\log \frac{1}{r_1} = \rho\sigma + \gamma E_r$$

for $\rho = 0.21$ and $\gamma = 1$. Low values of the copolymerisation constants r_1 and r_2 point to the tendency of aryl methacrylates for the alternation with styrene in the copolymerisation. The electron-donor substituents in PMA decrease polarity (e_2), while the electron-withdrawing substituents, especially those in the *para*-position, increase polarity. This is accompanied by a decrease in the frequencies of stretching vibrations of the $-\text{C}=\text{C}-$ and $>\text{C}=\text{O}$ groups.¹⁵⁰ Linear correlation is observed between the Hammett constants and the e_2 criteria as well as between $\log Q_2$ (Q_2 is the criterion of the monomer reactivity) and E_r .¹⁴⁷ In the case of *p*- and *m*-nitrophenyl methacrylates, the linear dependences are distorted because of the inhibitory effect of the nitro group. Introduction of several functional groups enhances the effect, as is observed for the criteria Q_2 and e_2 in 2,4,6-tribromophenyl and pentabromophenyl methacrylates.^{151, 152} The azo group manifests rather strong acceptor properties ($e_2 = 1.0$).¹⁵³ *ortho*-Substituents, *e.g.*, the carboxy group, strongly increase the values of Q_2 but virtually do not affect the e_2 values, which is well explained by considering the increased steric hindrances.^{154, 155}

In copolymerisation with styrene, 2-naphthyl methacrylate (2-NMA) manifests a weaker (compared to PMA) trend for alternation, which is, however, enhanced in polar solvents (*e.g.*, in acetonitrile).^{156–158} Irrespective of the solvent nature, the polydispersity and molecular mass increase with the increase in the content of 2-NMA. In complex aromatic systems, the methacryloyloxyphenyl group behaves in the usual manner, as it does in PMA.¹⁵⁹

Parameters of copolymerisation of substituted PA with styrene are presented in Table 2. Comparison of the data presented in Tables 1 and 2 shows that the values of the parameters Q and e are higher for PA than for the corresponding MA, which is associated with the absence of the effect of the α -methyl group.¹⁶⁰ For example, e_2 is equal to 1.32 for 2,4,6-tribromophenyl acrylate^{161–163} and to 0.91 for the corresponding methacrylate.

Copolymers of PA with MMA¹⁶⁴ are characterised by the predominance of MMA units ($r > 1$) in the macromolecule. In this case, the reactivity of substituted PA¹⁶⁵ is determined by their ability to form π -complexes with the double bond of MMA, which decreases in the series: PA > 2-chlorophenyl acrylate > 4-chlorophenyl acrylate. The values of parameter e increase in the same order (up to 1.46 for the latter member).

Table 1. Parameters of copolymerisation of substituted PMA with styrene.

Note. The subscripts 1 and 2 in the parameters refer to the first (styrene) and the second (PA) monomer, respectively.

It was noted¹⁶⁵ that the presence of aromatic substituents in copolymers of MMA with phenyl (meth)acrylates increases the number of hetero- and isotactic sequences in macromolecules. As in the case of 4-phenylazophenyl methacrylate,¹⁵³ copolymers of MMA with 2-methacryloyloxybenzoic acid are enriched in the units of the latter ($r_1 = 0.74$, $r_2 = 1.22$). The rate of copolymerisation decreases with the increase in the content of the second component.¹⁶⁶ For 4-acetylphenyl methacrylate, the influence of the penultimate unit¹⁶⁷ was observed, which is due to strong steric hindrances and high polarisability of the aromatic oxo group.

Constants of copolymerisation of a number of substituted phenyl (meth)acrylates with acrylonitrile are presented in Table 3; their reactivity towards the acrylonitrile radical varies depending on the nature of the substituent group and its position in the ring.¹⁶⁸ The trend for alternation is not strong, the values of r_1 fit well the dependence

$$\log \frac{1}{r_1} = -0.98(\sigma + 1.66\Delta\sigma),$$

where σ is the Hammett polar constant, $\Delta\sigma$ is the difference between the Brown and Hammett constants for substituents. Accumulation of substituents in the ring of phenyl acrylates decreases even more strongly the trend for alternation, as is seen in the example of 2,4,6-tribromophenyl acrylate.¹⁶⁹ However, the

Note. The subscripts 1 and 2 in the parameters refer to the first (acrylonitrile) and the second (PMA) monomer, respectively. ^a For acrylonitrile $e_1 = 1.2$, $Q_1 = 0.6$.

trend for alternation was observed for 2,4,6-tribromophenyl and pentabromophenyl methacrylates.¹⁷⁰

Copolymerisation of 2-NMA with acrylonitrile in chloroform or benzene proceeds with the formation of donor–acceptor complexes between the monomers; therefore, the values of r_1 and r_2 differ in different solvents.^{171, 172} Complexation was also found to occur in the copolymerisation of 2-NMA with monomethylitaconate,^{173, 174} thus the alternation of monomers of this pair is different in different solvents: in chloroform, $r_1 = 2.44 \pm 0.19$, $r_2 = 1.20 \pm 0.28$; in dioxane, $r_1 = 0.49 \pm 0.04$, $r_2 = 0.97 \pm 0.29$; in acetone, $r_1 = 0.15 \pm 0.01$, $r_2 = 0.28 \pm 0.03$ and in acetonitrile, $r_1 = 0.10 \pm 0.01$, $r_2 = 0.35 \pm 0.14$. Such changes in the copolymerisation constants reflect interactions between the monomer molecules and the corresponding solvent.

The constants of copolymerisation of PMA with methacrylic acid (MAA) are as follows: $r_1 = 0.40$ and $r_2 = 0.52$ (benzene), $r_1 = 0.21$ and $r_2 = 1.52$ (DMF/benzene), which points to a lower reactivity of MAA and higher reactivity of PMA in the presence of DMF, which appears to act as a complexation agent.¹⁷⁵ Copolymers of pentachlorophenyl acrylate with acrylic acid (AA) are enriched in the AA units.¹⁶³ In 2-butanone, PMA and glycidyl methacrylate give a copolymer enriched in PMA ($r_1 = 0.84 \pm 0.51$, $r_2 = 1.57 \pm 0.56$).¹⁷⁶ Optically active copolymers were obtained upon copolymerisation of phenyl, benzyl and 1-naphthyl methacrylates with maleic anhydride in the presence of β -cyclodextrin.¹⁷⁷ Copolymerisation of *N*-vinylpyrrolidone with 2-carboxyphenyl acrylate¹⁶⁰ and 2,4,5-trichlorophenyl acrylate¹⁷⁸ was also studied; in the latter case, copolymers with a high degree of alternation were obtained.

In copolymerisation of *p*- and *m*-phenylene diacrylates with styrene, a copolymer with acrylate pendent groups is formed in the initial stages; these groups then react with styrene to form a cross-linked copolymer, which precipitates from the reaction mixture in the form of a gel. *o*-Phenylene diacrylate forms a non-cross-linked ladder copolymer with styrene due to cyclopolymerisation. The smallest values of the polarity criterion e were obtained for the *ortho*-isomer.⁶ The values of the copolymerisation constants for isomeric phenylene diacrylates (PDA) are presented in Table 4.

Table 4. The values of copolymerisation constants for phenylene diacrylates (FDA) and styrene.

FDA isomer	Solvent	r_1	r_2	Q_2	e_2
<i>ortho</i> -	THF	0.55 ± 0.15	0.48 ± 0.19	0.74	0.37
	benzene	0.42 ± 0.28	0.45 ± 0.19	0.83	0.49
<i>meta</i> -	THF	0.33 ± 0.06	0.17 ± 0.02	0.78	0.90
	benzene	0.67 ± 0.11	0.15 ± 0.04	0.46	0.72
<i>para</i> -	THF	0.35 ± 0.06	0.21 ± 0.07	0.79	0.82
	benzene	0.30 ± 0.08	0.35 ± 0.09	1.00	0.70

Note. The subscripts 1 and 2 in the parameters refer to the first (styrene) and the second (FDA) monomer, respectively.

In radical copolymerisation of *p*-chlorophenyl methacrylate with ethylene glycol, 2,2-di(4-hydroxydiphenyl)propane and hydroquinone dimethacrylates,^{179, 180} the most reactive is ethylene glycol dimethacrylate as the second monomer, which is devoid of the mesomeric effect. The copolymer produced both upon catalytic and photochemical initiation is enriched in this compound ($r_1 = 0.29 \pm 0.03$ and $r_2 = 1.31 \pm 0.06$).

Methacrylamide¹⁸¹ and peroxide monomers can be used for subsequent cross-linking in copolymerisation with PMA. The constants of copolymerisation of PMA with *tert*-butyl *p*-vinylperbenzoate are as follows: $r_1 = 1.35$, $r_2 = 0.32$.¹⁸²

Copolymerisation of aryl methacrylates in donor–acceptor complexes bears a special character. For example, complexes of monomers and polymers of carbazoyl methacrylates with dinitrophenyl-containing monomers and polymers were obtained.¹⁸³ Charge-transfer complexes (CTC) are formed in copolymerisation of the donor monomers, *viz.*, *N*-(2-hydroxyethyl)carbazoyl acrylate (**1**) and -methacrylate (**2**) with the acceptor monomers, *viz.*, 2,4-dinitrophenyl acrylate (**3**) and methacrylate (**4**).^{114, 183, 184} The extent of intramolecular charge transfer in copolymers (according to the chemical shift values of aromatic protons in the ¹H NMR spectra of **3** and **4**) increases as the content of **4** in the alternating diads with **1** is increased and is larger in the **2–3** copolymer than in the **1–3** copolymer. In copolymers containing only methacrylate units, no intramolecular CTC are revealed, the most stable CTC are formed in copolymers having only acrylate units. In copolymerisation of **1** with **4**, the intermonomeric CTC are not added as a whole,¹⁸⁴ and the relative reactivity is determined solely by the sequence of distribution of units rather than by the configuration factors. With the increase in the temperature, the CTC present in the copolymer disintegrate due to the higher segmental mobility. Intramolecular CTC are also formed in the copolymerisation of picryl (meth)acrylate (incapable of homopolymerisation) with *N*-(2-hydroxyethyl)carbazoyl (meth)acrylate. The copolymerisation constants indicate that the most stable CTC are formed in dioxane.^{185–187} Photoconductivity of poly(*N*-vinylcarbazole) increases when electron-acceptor comonomers forming CTC are used, *e.g.*, isomeric 2,2-dicyanovinylphenyl (meth)acrylates (NC)₂C=CHC₆H₄OC(O)CR=CH₂ (see Ref. 188). Mixing of poly(*N*-vinylcarbazole) with the same amount of the low-molecular-weight acceptor leads to a less pronounced effect.

Directed intramolecular transfer of electronic triplet excitations was studied in a copolymer of 1-naphthyl acrylate (1-NA) and 4-acetylphenyl methacrylate.¹⁸⁹ The copolymer contains two π -electronic systems in which unidirectional transfer of electronic excitation is brought about. Upon selective excitation of the singlet level of 4-acetylphenyl methacrylate units, phosphorescence of only 1-NA units is observed. Such a molecular structure can function as a specific exciton gate.^{190–192}

In a ternary styrene–acrylonitrile–2,4,6-tribromophenyl (meth)acrylate system, the third component decreases the molecular mass and thermal stability of the terpolymers formed.^{193–195} In copolymerisation of phenyl, 4-butylphenyl, 4-nitrophenyl and

1-naphthyl acrylates with SO₂ and also in three-component copolymerisation of these monomers with hept-1-ene (see Ref. 196), the maximum content of sulfonyl monomeric units in copolymers ranges from 13% to 24% depending on the inductive steric effects. The composition of terpolymers varies within a wide range depending on the molar ratio of reagents and conversion. It is also possible to copolymerise PMA one with another.¹⁹⁷ Changes in the enthalpy and parameters of PMA copolymerisation with 2-methylphenyl and 2-ethylphenyl methacrylates were studied in the temperature range 80–100 °C.

The problems of the relationship between the structure of polymeric carriers based on cross-linked PA polymers and their copolymers with styrene and the reactivity of such carriers were reviewed.¹⁹⁸

V. Structure and properties of poly[aryl (meth)acrylates]

Esterification of atactic, syndiotactic and isotactic polyacrylic acids with phenols yields only atactic polymers. This points to the spatial isomerisation of the tertiary carbon atom in the course of esterification and the impossibility of obtaining stereoregular poly(aryl methacrylates) by polymer-analogous transformations.

Radical polymerisation of PMA yields an atactic polymer which contains nonetheless more syndiotactic structural blocks than the structurally similar poly(benzyl methacrylate) and poly(2-phenylethyl methacrylate).¹⁹⁹ This is related to the higher polarity ($\sigma = 0.6$) of the phenyl groups than that of the alkyl groups (σ varies from -0.3 to 0.215) rather than to their higher rigidity or small volume. Jimmy *et al.*²⁰⁰ studied the influence of the side groups and the size of the polymer coil of poly(benzyl methacrylate), poly(triphenylmethyl methacrylate) and poly(diphenylmethyl methacrylate). The overall activation energy of radical polymerisation of PMA is equal to 69.0 kJ mol^{-1} , which is somewhat lower than that for poly(methyl methacrylate) (PMMA).²⁰¹ In polymerisation with AIBN in the temperature range 30–100 °C, a Bernoulli distribution of stereochemical structures in the PPMA chains is observed. The content of iso- and syndiotactic triads in them decreases as the temperature increases, which is characteristic of α, α -disubstituted monomers. The triads are disposed in the chain in an isolated manner. The phenyl radical is oriented with its maximum polarisability axis along the direction of the main *trans*-chain.²⁰² In poly(aryl methacrylates), the content of isotactic, atactic and syndiotactic triads is 15%, 40% and 45%, respectively.²⁰³ The use of high-frequency NMR spectroscopy (500 MHz for ¹H and 125 MHz for ¹³C) allowed calculation of isotactic parameters for poly(phenyl acrylate) (PPA) ($P_m = 0.44$) and poly(4-fluorophenyl acrylate) ($P_m = 0.48$)²⁰⁴ obtained by radical polymerisation. Isotactic PPA can be obtained by anionic polymerisation in the presence of butyllithium.¹⁴⁰ Kempf and Harwood²⁰⁵ have shown that PPMA of a predetermined configuration can nonetheless be obtained from polymethacrylic acid if certain conditions are met.

Studies of the influence of solvents on the microstructure of poly(1-naphthyl methacrylate) and poly(2-naphthyl methacrylate) (1-PNMA and 2-PNMA, respectively) in comparison with poly[cumylphenyl methacrylate] and PMMA have shown^{206–208} that the polymerisation of 2-NMA in methanol, acetonitrile and nitromethane occurs heterogeneously. Even in the presence of non-polar solvents, the percentage of isotactic triads in 1-PNMA and 2-PNMA is higher and the percentage of syndiotactic triads is lower than in PMMA. Syndiotacticity of 2-PNMA is higher than that of 1-PNMA. In solvents with higher dielectric constants, PNMA with a still higher content of isotactic triads is obtained. Poly(1-naphthyl methacrylate) possesses a higher heterotacticity than 2-PNMA. In copolymerisation of 2-NMA with MMA ($r_1 = 1.93 \pm 0.16$, $r_2 = 0.33 \pm 0.08$), syndiotactic addition proved to be preferential.²⁰⁹ The behaviour of PA is analogous.²¹⁰ However, PPMA, poly(*p*-cresyl methacrylate), 2- and 4-methoxyphenyl methacrylates, obtained by polymerisation in the presence

of butyllithium at low temperatures in toluene, have an isotactic structure with 90% of isotriads,²¹¹ while syndiotactic polymers are formed in THF.²¹²

The temperature characteristics of poly[aryl (meth)acrylates] are determined by their structural peculiarities. As was indicated above,⁴ the thermostability is determined by the character of the substitution: in the *para*-substituted poly[aryl (meth)acrylates] the glass transition temperature (T_g) is always lower than in the *ortho*-substituted ones. This is explained by the shielding effect of *ortho*-substituents on the ester bond. T_g increases with the increase in the size of substituents and their polarity. Thus PPA, poly(*o*-tolyl acrylate) and its *para*-isomer have T_g values of 56.5, 51.5 and 24.5 °C, respectively. For 1-PNMA and 2-PNMA, T_g values are 135 and 119 °C, respectively.²¹⁴ The relationship between T_g and molecular mass (M) of poly(*o*-alkylphenyl methacrylates) is non-linear and may be described by the following equation:²¹⁵

$$T_g = T_g(0) + k \ln P,$$

where $T_g(0)$ is the temperature characteristic of the monomeric unit and P is the degree of polymerisation. For the infinitely large PPMA molecules, $T_g = 118$ °C, while for poly(2,6-dimethylphenyl methacrylate) (PMPMA) $T_g = 177$ °C. In copolymers of phenyl, 2-chlorophenyl and 4-chlorophenyl acrylates with MMA, T_g decreases with the increase in the concentration of MMA.²¹⁶ In this case, the concentration dependence of T_g obeys Johnson's equation, which considers the contribution of diads in the polymer chain to the glass transition effect. A comparative calorimetric study of substituted PPA²¹⁷ and poly(vinyl benzoates) made it possible to establish that the dependence of specific heat capacity (C_p) on temperature in the range of glassy state is described by the equation

$$C_p = A + BT + CT^2 + DT^2.$$

The increase in C_p in the glassy state was observed for all substituted polymers with increase in the volume of substituents. For a number of alkyl- and alkoxy-substituted PPA the values of T_g were found and the heat capacity jumps in the glass transition region and coefficients A , B , C and D in the proposed equation were determined.

Thermal stability of poly(aryl methacrylates) was studied by the TGA method;²¹⁸ the curves for poly(tolyl methacrylates) (PTMA) and poly(benzyl methacrylate) are S-shaped and similar to the curves for PMMA. For PPMA, the process was characterised by several ranges of decomposition. *ortho*-PTMA proved to be the most stable isomer. Effective activation energies of thermal destruction for the polymers studied vary from 81 to 159 kJ mol^{-1} (210 kJ mol^{-1} for PMMA).

Thermal destruction of poly(2-methacryloyloxybenzoic acid)²¹⁹ occurs in three steps in temperature ranges of 140–220, 250–330 and 350–450 °C with mass losses (according to TGA data) of 33%–35%, 30% and 30%, respectively, which corresponds to the stoichiometric content of salicylic acid in the polymer in the first two stages. The effective activation energy in the first stage is 79 kJ mol^{-1} . Upon destruction, fragments of the glutaric anhydride type accumulate first in the polymer (up to 330 °C); after this, the macrochains undergo disintegration.

Copolymers of PMA with MMA are more thermostable than the homopolymers;²²⁰ monomers are the main degradation products. At a low content of PMA, oligomers containing anhydride groups are also formed; with the increase in the PMA content the ability to form anhydrides drops. In contrast to homopolymers, the destruction of copolymers is characterised by relatively short kinetic chains of depolymerisation and the cleavage of the principal bonds in the macrochain. Among the copolymers of acrylonitrile with 2,3-dibromopropyl, pentabromophenyl and 2,4,6-tribromophenyl acrylates, the highest thermostability was observed for copolymers with the latter.²²¹

In studies of poly[aryl (meth)acrylates], a prominent place is occupied by the investigations of properties of their dilute solutions. By measuring the swelling degree, solubility para-

meters (δ) were determined and their dependence on the character of forces of interaction of polymer with solvent was confirmed.²²² Chloroform, tetrachloroethane, chlorobenzene and ethyl acetate are the best solvents for poly(aryl methacrylates). The values of δ for poly(alkylphenyl methacrylates) were determined in 20 solvents of different nature, considerably differing in their polarities (the contribution of δ_p) and ability to form hydrogen bonds (the contribution of δ_H), and in the widest possible range of the chain flexibility parameter σ . The magnitude of δ_H decreases slightly with the enhancement of the 'paraffinic character' of the solvent.²²³ The influence of alkyl residues is weakly manifested and the values of δ_H found differ somewhat from the calculated ones. Investigation of properties of dilute solutions by the osmometry and viscosimetry methods showed that the *ortho*-substituents in the benzene ring of the side chain increase appreciably the rigidity of the polymer. For PMPMA, the solubility parameter in toluene is equal to $9.6 \text{ cal}^{-1/2} \text{ cm}^{3/2}$ (see Ref. 224). The power index α in the dependence

$$[\eta] \approx M_w^\alpha,$$

where $[\eta]$ is the specific viscosity, increases as the thermodynamic quality of the solvent is enhanced (α is equal to 0.5 in toluene, 0.59 in THF and 0.69 in chlorobenzene). It was established that $\langle r_0^2 \rangle^{1/2}$ (characteristic chain ratio) and T_g increase upon transition from PPMA to PMPMA. For poly(2,6-diisopropylphenyl methacrylate), the solubility parameter in toluene is also equal to $9.6 \text{ cal}^{-1/2} \text{ cm}^{3/2}$ (see Ref. 225), while the Mark–Hauwink equation ($[\eta] = KM_n^\alpha$) (25 °C) has the following form for THF

$$[\eta] = 1.02 \times 10^{-4} M_n^{0.71},$$

for toluene

$$[\eta] = 1.22 \times 10^{-4} M_n^{0.69},$$

and the THF : water mixture (90.9 : 9.1)

$$[\eta] = 8.51 \times 10^{-4} M_n^{0.50},$$

for the ratio of the mean squared distance between the ends of the polymer coil and the molecular mass of the polymer (see Ref. 225)

$$\langle r_0^2 \rangle = 0.677 M^{1/2}.$$

For *p*-AAPMA²²⁶ in DMF at 25 °C

$$[\eta] = 1.40 \times 10^{-3} M_n^{0.85}.$$

Investigation of the influence of temperature on the thermodynamic properties and undisturbed dimensions of PPMA macromolecules in isobutyl methyl ketone showed²²⁷ that for all fractions an anomalous dependence of $[\eta]$ on temperature takes place at 20–35 °C, which becomes more pronounced with the increase in the molecular mass. The value of the coefficient K in the Mark–Hauwink equation is maximum at 25 °C, which implies changes in the character of hydrodynamic interactions inside the macromolecular coil, whereas the value of α is a minimum at the same temperature, which means drastic deterioration of the solvent quality. These phenomena point to a conformational transition associated with the increased chain flexibility resulting from the changes in specific interactions between the phenyl groups. The side chains in PMMA, poly(isobutyl acrylate) and poly(cyclohexyl methacrylate) have a strong influence on the temperature of the conformational transition and changes in the undisturbed dimensions of the chains, which is accompanied by the appearance of a jump in the temperature dependence of viscosity, refraction index and partial specific volume of polymers.²²⁸ Gargallo *et al.*²²⁹ analysed the influence of the size and the nature of the side groups in poly(alkylphenyl methacrylates) on the magnitude of partial volumes. The intramolecular character of the conformational transition is confirmed in the example of poly(4-*tert*-octylphenyl methacrylate).²³⁰ It was established for PPMA solutions that the conformational transition occurs owing to the changes in specific near-order interactions between the phenyl rings in the pendent

groups of the polymer studied.²³¹ Comparison of magnitudes and orientation of dipole moments related to the pendent groups of poly(chlorophenyl acrylates) revealed their strong dependence on the position of the substituent in the benzene ring.²³² The example of PPMA with the phenyl benzoate side groups showed²³³ that the influence of thermodynamic quality of the solvent on the dipole moment is characteristic of polymers with highly rigid polymeric chains and strong intramolecular interactions of the side groups.

For poly(2-biphenyl methacrylate), rather insignificant (5%–18%) variation of $[\eta]$ in different organic solvents was observed,²³⁴ whereas in other poly(aryl methacrylates) the variation of $[\eta]$ is 21%–61%, which is due to the presence of the bulky *o*-biphenyl group localised close to the basic chain. In poly(4-biphenyl methacrylate),²³⁵ the undisturbed dimensions of the chain calculated by the Stockmayer–Fixman method with consideration of the dependence of $[\eta]$ on M proved to be three times as large as those in the case of free rotation in the main valent chain, which is indicative of an appreciable inhibition of rotation in poly(aryl methacrylates). For this polymer, the temperature coefficient of undisturbed dimensions of the chain was determined (2.3×10^{-3} at 13–40 °C and 1.2×10^{-3} at 40–60 °C);²³⁶ similar calculations were performed for the *ortho*-isomer and for poly(2,4,5-trichlorophenyl methacrylate).²³⁷ In the case of poly(2-biphenyl methacrylate), the value of the chain flexibility parameter σ (2.8) was larger than that for poly(4-biphenyl methacrylate) ($\sigma = 2.7$), which points to a larger flexibility of the former due to a close position of the *o*-diphenyl groups to the basic chain.²³⁸ Studies of the mobility in poly(2-biphenyl methacrylate) by the DSC method pointed to the occurrence of four relaxation processes with the temperature increase, *viz.*, γ , β , α and ρ . The processes of α - and β -relaxation are related to vitrification and subvitrification, respectively.²³⁹

For PPA, it was found that the values of temperature coefficients of the undisturbed dimensions range from -3.4×10^{-3} to -4.7×10^{-3} , the upper critical temperature of dissolution Θ in ethyl lactate is 14 °C and the values of $[\eta]$ increase with the temperature increase within the range 7–77 °C.²⁴⁰ As for PMMA, the constants of the Mark–Hauwink equation for PPMA fit the van Krevelen equation.²⁴¹ The use of the light scattering method in ethyl lactate for PPA allowed determination of values of M_w , second virial coefficients A_2 , mean squared radii of inertia $\langle S^2 \rangle$ and coefficients of swelling at different temperatures.²⁴² This method was also applied to study PNMA solutions^{243,244} in comparison with polystyrene. The ratios of the threshold concentration c_0 in light scattering measurement to the second virial coefficient A_2 for these polymers were the same and equal (in non-polar solvents) to 0.93. For dilute solutions of homopolymers with the main methacrylate chain and methoxy-biphenyl mesogenic groups and their copolymers,²⁴⁵ the constants in the Mark–Hauwink equation, parameters of Flory–Huggins interaction and the mean squared distances between the chain ends $\langle r^2 \rangle$ were determined. The latter parameter is greater than that in PMMA, which indicates an appreciable increase in the rigidity of the polymethacrylate chain upon introduction of the mesogenic side groups. As regards PMA copolymers²⁴⁶ and substituted PMA,²⁴⁷ for them, too, the values of K , α and Θ were found in certain solvents, and the undisturbed dimensions of the polymer coils and parameters of the chain rigidity were calculated.

The data on electrical properties of poly(aryl (meth)acrylates) are scanty. The spectra of dielectric losses at different temperatures were studied for specimens of PPMA and polymers of *o*-, *m*- and *p*-PTMA²⁴⁸ and for polymethoxy-substituted PMA.²⁴⁹ Three relaxation processes were found to occur. The high-temperature process (α -relaxation) occurs in the glass transition range and is related to the micro-Brownian mobility in the basic chain of the polymer. The maximum temperature of this process increases in the following order: *m*-PTMA < *o*-PTMA < PPMA < *p*-PTMA; the crystallinity of polymers increases in the same order. In the middle-temperature range, β -relaxation is observed due to the micro-Brownian mobility of the side groups, which is particularly

manifested in *o*-PTMA. Increased activation energies of this process were observed for specimens of higher crystallinity (PPMA and *p*-PTMA). The low-temperature γ -relaxation is associated with the motion of the tolyl and methoxyphenyl pendent groups. Investigation of the dielectric relaxation of poly(phenyl and chlorophenyl acrylates) revealed that the intensity of the β -process in PPA and poly(4-chlorophenyl acrylate) is lower than in poly(2-chlorophenyl acrylate) and poly(3-chlorophenyl acrylate); in the last two polymers the intensity of β -process is higher than that of α -process. α -Relaxation is determined by the free volume and is well described by the binding model;²⁵⁰ in polymers the time of dielectric relaxation is always shorter than the time of mechanical relaxation.²⁵¹

Noticeable changes in the electrical characteristics of polyethylene in strong fields (electrical strength and I – V characteristics in the pre-breakdown voltage range) are observed when small amounts (1%–2%) of comonomers, such as pentabromophenyl and 2,4,6-tribromophenyl methacrylates, were introduced.²⁵² The maximum value of breakdown voltage is observed at the content of the former additive of 0.1%–0.2%, the doping action is produced by units of the above-mentioned PMA. Such an effect is not exerted by benzyl methacrylate.

In a magnetic field, a noticeable effect of the increase in spontaneous orientation of PPMA may be observed only in mesomorphic polymers, in particular in those with the phenyl benzoate pendent groups.²⁵³

Poly[aryl (meth)acrylates] are very transparent (transmission coefficient > 90%) and possess good mechanical properties.²⁵⁴ Therefore, copolymers containing up to 99% of these monomers are used as materials for manufacturing lenses.²⁵⁵ Some of them, in particular 1- and 2-NMA, determine the high refraction index of copolymers.²⁵⁶

Some aryl (meth)acrylates and their polymers may exist in the liquid-crystalline state with characteristic anisotropy of optical properties.^{31, 257} Their polymeric nature is manifested in considerable enhancement of thermal stability of the mesophase, its temperature range is restricted by the glass-transition and clarification temperatures and is determined to a considerable extent by the nature of the basic chain and its flexibility.²⁵⁸ In such polymers, structures of various mesophases and different variants of the packing of mesogenic groups can be realised. Most polymers can form lamellar structures of the smectic type. Nematic structures arise in polymers with shorter substituents and flexible hinges. In particular, all polymers with the lateral mesogenic groups possess nematic mesomorphism.²⁵⁹ Clarification temperatures of polymers with the same mesogenic groups but different chemical composition of the basic chain coincide, whereas in these cases the T_g values decrease with the increase in flexibility of the basic chain or the length of the terminal fragments of the mesogenic pendent groups.

For all the polymers having one mesogenic side unit per elementary unit of the chain, it was established that the global anisotropy is independent of steric inhibition of the α -methyl groups. A decrease in temperature results in a basic polymer chain extension normally to its mesogenic units, which thus acquires an elongated shape.²⁶⁰ According to the results of X-ray diffraction analysis, the macromolecules of polymers of phenyl and 4-alkoxyphenyl esters of acryloyloxybenzoates,²⁶¹ which form anisotropic systems on cooling of melts or concentrated solutions, represent cylinders 8–10 nm long and 2.5–3.9 nm in diameter formed by aperiodic helices.

Acrylic polymers that contain mesogenic phenyl benzoate groups with short alkyl substituents form only nematic mesophases.^{262, 263} In studies of the comb-like liquid-crystalline polymers, which differ in the nature of the basic chain (acrylate or methacrylate) but contain identical phenyl benzoate groups,^{264, 265} the low- and high-temperature smectic phases of polyacrylate are referred to the smectic types B and A, respectively. For polymethacrylates, the following scheme of polymorphic transformation was proposed: smectic F $\rightarrow$ smec-

tic C $\rightarrow$ smectic A $\rightarrow$ isotropic liquid. Investigation of conformational changes in poly(methacryloyloxyphenyl 4-*n*-alkoxybenzoates)²⁶⁶ in the temperature range including the glassy, liquid-crystalline and isotropic states revealed that the conformational changes are observed in the glassy state 40–80 °C before the transition to the liquid-crystalline state depending on the alkyl chain length and that they are accompanied by the homeotropic orientation in the polymeric films. Poly(biphenyl acrylate) prepared by the reaction of polyacryloyl chloride with 4-hydroxybiphenyl forms a smectic mesophase A at 144 °C, which is totally destroyed at 250 °C. The mesophase–isotropic transition is nearly fully reproduced in repeated cycles of heating.²⁶⁷ Poly(4-acryloyloxyazobenzene) is in turn in the mesomorphic state at 100–240 °C. Polyacrylates and polymethacrylates that contain the cyano-substituted aromatic azomethine and cyanobiphenyl mesogenic groups form liquid-crystalline phases of the nematic type and also of the smectic type A and C.^{268, 269} In polymethacrylate with the biphenyl fragments as mesogens in the side chains, a poorly ordered smectic phase exists at 136–157 °C and above these temperature, the isotropic phase.²⁷⁰

Thus, among poly[aryl (meth)acrylates] it is possible to find polymers that have mesophases in different temperature ranges. Such polymers are capable of reflecting selectively light in the IR, UV and visible parts of the spectrum, manifesting transitions induced by electric and magnetic fields, and in some cases they even possess ferroelectrical properties.²⁵⁸ Owing to such electrical and other effects, the field of application of these polymers in modern technology is extended.

VI. Chemical and photochemical properties of poly[aryl (meth)acrylates] and their copolymers

Chemical properties of poly[aryl (meth)acrylates] and their monomers are determined primarily by the presence of the ester group, the aromatic ring and its substituents. The rate of hydrolysis of the pendent groups in PPMA at different temperatures in aqueous DMSO is described by three different constants corresponding to the hydrolysis of the ester groups of the polymer with the adjacent 0, 1 and 2 hydrolysed ester groups.²⁷¹ The activation energies that correspond to these constants are equal to 40.6, 58.2 and 74.0 kJ mol^{–1}, respectively. Alkaline hydrolysis of PPMA with *p*-Cl, *p*-OMe, *p*-Me and *m*-NO₂ substituents in the aromatic ring is of the pseudo-first order;²⁷² the first two constants increase with the higher KOH concentration, whereas the third constant remains virtually unchanged. The values of these constants correlate well with the values of the Hammett constants for substituents.

Enzymatic hydrolysis of the side ester groups in copolymers of 4-nitrophenyl methacrylate with acrylamide²⁷³ in the presence of lipase did not take place, whereas esterase and α -chymotrypsin acted very slowly. The rate of alkaline hydrolysis increased with the higher content of acrylamide in the copolymer, which was due to the influence of acrylamide units on the reactivity of ester groups in the 4-nitrophenyl fragments. The action of α -chymotrypsin on 2-biphenyl methacrylate (BPMA) and its copolymers induced hydrolytic liberation of hydroxybiphenyl; the Michaelis constant for the copolymers was lower than for the homopolymer and decreased in the following series of comonomers: methacryloylglycine > vinyl acetate > methacryloylalanine > styrene.²⁷⁴ The catalytic effect of α -chymotrypsin was weaker in the case of poly(2-biphenyl acrylate).²⁷⁵ The possibility of modifying polymers and copolymers of 2,4,5-trichlorophenyl acrylate²⁷⁶ and 4-nitrophenyl methacrylate^{277–279} through their aminolysis has been demonstrated.

Optimisation of the reaction conditions makes it possible to introduce various substituents, for example, perfluoroalkyl groups,²⁸⁰ into the phenyl groups of PPMA. Reactive functional groups can be subjected to further transformations²⁸¹ and be used for the chelate formation.^{282, 283}

Chemical transformations of poly[aryl (meth)acrylates] under the action of different types of radiation are rather diverse. Investigation of the photobehaviour of phenyl-containing methacrylate polymers showed²⁸⁴ that the lifetime of the singlet state in polymers is shorter than in model small molecules, which is related to the higher sensitivity of this parameter to steric hindrances. A high yield of long-living triplet states was observed in the presence of naphthalene rings.²⁸⁵ The acetyl groups favour quenching of the triplet. 2,4-Diacetyl-1-naphthyl methacrylate units induce quenching even at their content ~ 1 mol. % with a quantum yield of 0.4.²⁸⁶ In poly(2-naphthyl methacrylate), insignificant migration of the singlet energy occurs.²⁸⁷ Because of a large difference in the energies of the excited singlet and triplet states, the singlet energy transfer to the ketone traps in a copolymer of 2-NMA with arylvinyl aromatic ketones and the triplet energy is transferred from these traps again to the naphthalene chromophores. The fluorescence (FL) spectrum of 2-PNMA²⁸⁸ is characterised by the presence of two bands which are attributed to monomeric (340 nm) and excimeric (400 nm) luminescence. The luminescence spectrum of copolymers strongly depends on the amount of a comonomer. In copolymers with MMA, the correlation between the excimeric and monomeric fluorescences is determined basically by the molar fraction of naphthyl methacrylate units.²⁸⁹ The ratio of intensities of excimeric and monomeric fluorescences is taken as the compatibility parameter of copolymers of naphthyl and anthryl methacrylates with MMA and *n*-butyl methacrylate (BMA).^{290,291} In copolymers of PMA,²⁹² the band of excimeric FL is at 355 nm. The FL spectra of copolymers of vinyl 3-(1- and 2-naphthyl)acrylate with vinyl hexanoate and vinyl acetate were analysed in order to reveal the monomeric and excimeric FL of the naphthalene groups at 340 and 390 nm, respectively. It was shown²⁹³ that the excimer is formed by two naphthalene groups bound to cyclobutane in the 1,2 or 1,3 positions *cis*-arranged relative to the cyclobutane ring. The curves of FL decay are well described by three exponents attributed to three fluorescence centres: excimers, monomeric chromophores capable of transition to the excimer form and isolated monomeric chromophores incapable of excimer formation.

Copolymers of 2-[(2,4,6-tricyanophenyl)thio]ethyl methacrylate with 3,5-bis(*N,N*-dimethylamino)phenyl methacrylate which are obtained in bulk phase and form rigid films possess photoconductivity. The photocurrent in such films was observed upon illumination with light with wavelengths of 200–700 nm.²⁹⁴

Photodestruction of PPMA in vacuum and in air occurs with the random scission of macrochains and is intensified under short-wave UV irradiation.²⁹⁵ The presence of chlorine atoms in the phenyl radical accelerates photodestruction. For 1-PNMA and its copolymers with BMA it was established that in contrast to thermodestruction leading to depolymerisation, the photo- and radiation destructions involve processes of the basic chain scission, the photodestruction rate depending on the intramolecular excimer formation.²⁹⁶ For this reason, the quantum yield of the chain scission decreases monotonically (down to 0.015) with the increase in the content of 1-NMA units. Excimers are not formed for the BMA–NMA–BMA sequences.^{297,298} Upon irradiation with electrons (20 keV) and UV light, the perfluoroalkylated PPA is cross-linked in contrast to the non-perfluoroalkylated one which is destroyed under these conditions.²⁹⁹

In the presence of oxygen, photooxidation of poly[aryl (meth)acrylates] occurs with the formation of carbonyl groups. Investigation of the photooxidation of 2-NMA copolymers with styrene, MMA and acrylonitrile revealed³⁰⁰ that where the content of 2-NMA was 7 mass %, the concentration of carbonyl groups was considerably higher than in polystyrene (0% of NMA) or in copolymers with 13% or 26% of 2-NMA. The number-average molecular mass is also most strongly decreased in copolymers with 7% of 2-NMA.

On the whole, poly[phenyl (meth)acrylates] are regarded as radiation-resistant materials,³⁰¹ however, their resistance is

sharply decreased upon introduction of halogens into the aromatic rings. Upon irradiation of poly(4-chlorophenyl methacrylate) with ionic beams,^{302,303} the primary process is the elimination of the chlorine atom with the formation of reactive centres in the basic chain under the action of atomic chlorine. Recombination of these two types of polymeric radicals leads to the cross-linking of the polymer. The radiation yield of the basic chain scission in the radiolysis of MMA copolymers with trichloro- and tetrabromophenyl methacrylates³⁰⁴ is strongly enhanced by small amounts of the latter, which is related to the important role of the processes of dissociative electron capture. The yield drops dramatically with the increase in the concentration of chlorine-containing monomer to 17% when the processes of cross-linking become noticeable. An analogous behaviour is displayed by halogen-substituted PPMA upon irradiation with a beam of electrons.³⁰⁵

Homopolymers of 4-acryloyloxyazobenzene and 4-methacryloyloxyazobenzene copolymers with methyl acrylate³⁰⁶ and MMA,³⁰⁷ respectively, possess photochromic properties. The azo group in their units undergoes *trans*–*cis*-isomerisation under UV irradiation ($\lambda = 370$ nm). The increase in absorption is observed at $\lambda < 280$ nm and $\lambda > 400$ nm. Photoisomerisation occurs as the first-order reaction and is reversible, the rate constant for this reaction is independent of temperature. The reverse dark reaction (thermal *cis*–*trans*-isomerisation) is also of the first order. In homopolymers, the kinetics of photoisomerisation is of a more complex character. For them, this is an energetically more favourable process than for copolymers, which may be explained by the interaction of pendent groups. The absorption band of the azobenzene group corresponds to the π – π^* -transition and is shifted from 321.5 to 324 nm with the decrease in the content of the *trans*-isomer.³⁰⁷

Like other phenyl esters, PA and PMA as well as their polymers and copolymers undergo the photochemical Fries rearrangement under the action of UV light^{308–313}

$R^1 = CR = CH_2$.

The rearrangement is inhibited after transformation of certain amount of phenyl esters into *o*- and *p*-hydroxyphenyl ketones (a 2:1 mixture). The ketones were identified by the appearance of absorption maxima at 265–270 and 294 nm in the UV spectra of irradiated monomers or new absorption bands at 1620 and 1660 cm^{-1} in the IR spectra of UV-irradiated poly[phenyl (meth)acrylates]. The stability of the polymer with respect to further UV irradiation is associated with the formation of hydroxy ketones on its surface and their photoshielding effect due to higher extinction coefficients. It is known³¹⁴ that 2-hydroxybenzophenones are good light stabilisers. It is presumed that their light-stabilising effect is related to the fast tautomerism of excited states. Spectral measurements showed³¹⁵ that under prolonged action of the UV light the molecules of *m*- and *p*-(*N*-acylamino)phenyl (meth)acrylates undergo the Fries rearrangement involving mainly the ester groups rather than the acylamino groups and resulting in the appearance of the hydroxy and amino groups, respectively.

R' = Me, Et, Pr.

Poly(1- and 2-naphthyl methacrylates) also undergo photochemical transformations by the Fries reaction upon UV irradiation.^{316,317} This reaction may be of practical value for the modification of polymeric materials. Yet another type of light-sensitive polymers, *viz.*, poly(methacryloyloxybenzylideneacetophenones)^{318,319} and copolymers of 4-methacryloyloxybenzylideneacetophenone with BMA,³²⁰ have been described. Upon UV irradiation, they become insoluble in organic solvents because of photodimerisation resulting in the formation of cyclobutane structures. Spectral sensitisation of such copolymers is possible with triplet sensitisers, *viz.*, 5-nitroacenaphthene, picramide, *N*-acetyl-4-nitronaphthylamine and some quinones. Evidently, this process is similar to the photoaggregation of cinnamates.

The polymers containing 4-acryloyloxybenzophenone units are highly efficient photoinitiators of polymerisation.^{321–323} After light absorption, the units of this monomer pass into the singlet-excited state with subsequent intercombinational conversion into π, π -triplet state and transition to n, π -triplet state, which may be quenched by oxygen molecules or be deactivated in the presence of a hydrogen donor with the formation of ketyl radicals.³²³ Homopolymer is the most efficient as the polymeric photoinitiator and its copolymers with 4-dimethylaminostyrene are also highly active.³²¹

Some PMA copolymers possess unusual photoluminescent properties, whereas the corresponding low-molecular-mass compounds and homopolymers do not luminesce under experimental conditions.³²⁴ The large diversity of properties opens wide possibilities for the application of poly[phenyl (meth)acrylates].

The data on liquid-crystalline aryl (meth)acrylates were generalised in a number of monographs (see, *e.g.*, Refs 59, 60), and this allows us not to go into details of this information.

VII. Practical application of aryl (meth)acrylates

At present, several types of phenyl (meth)acrylates are produced in small quantities and their variety increases continually. An analysis of most recent scientific and patent publications shows that these monomers and polymers, novel for modern industries, will find wide uses basically as modifiers of properties of polymers produced on a large scale.

In order to manufacture lenses with high refractive indices (up to 1.67), thermal stability, resistance to shock and solvents and surface hardness, use is made of copolymers of the known monomers (MMA, styrene, *etc.*) with 3%–40% of PMA,^{325–328} halogenoaryl methacrylates,^{329–332} tribromophenyl methacrylate,^{333–337} brominated phenyl acrylates,³³⁸ as well as 1- and 2-naphthyl (meth)acrylates and benzylphenyl methacrylate.^{339,340} Pentachlorophenyl (meth)acrylates may be used as comonomers in the manufacture of light-conducting fibres.³⁴¹ PMA and PA may be the components of oxygen-permeable plastics intended for manufacturing contact lenses.³⁴² Poly(fluorophenyl acrylates) are used for manufacturing glass for aircraft port-holes.³⁴³

Halogen-containing phenyl (meth)acrylates [*e.g.*, 2,4,6-tribromophenyl (meth)acrylate] were recommended as components of rubbers³⁴⁴ and plastics³⁴⁵ in order to increase their fire resistance. For the same purpose, pentabromophenyl (meth)acrylates are incorporated as the third component into a styrene–acrylonitrile copolymer.^{346,347}

Aryl (meth)acrylates are introduced into plastics to improve their service properties, *e.g.*, shock resistance.³⁴⁸ Poly[3-pentadecylphenyl (meth)acrylates] are used as pressure-sensitive adhesives for binding various porous materials.³⁴⁹ 2,2-Di(4-hydroxyphenyl)propane di(meth)acrylates exert a particularly noticeable effect on general properties of plastics.^{350–352}

It is proposed to use di(meth)acryloyl derivatives of dihydroxybiphenyl oxides as cross-linking agents for polymeric materials. Fluoro-substituted diacrylates, for example, 1,3-bis(hydroxy-hexafluoropropan-2-yl)benzene diacrylate, are used for making coatings.³⁵³ It is proposed to use alkoxyated dimethacrylates of bisphenol-A,^{354–356} xylene dimethacrylates³⁵⁷ and aryl or naphthyl (meth)acrylates^{358,359} in compositions for photo-solidified coatings and glues. High-strength solidifying compositions may be prepared using hydroxyaryl (meth)acrylates that can form urethanes with diisocyanates or isocyanatoethyl methacrylate.³⁶⁰

PMA and its derivatives and 2-NMA ($\geq 10\%$) are incorporated into copolymers used in the production of precision optical devices and video discs for recording information.^{361–364} Low-hygroscopic methacrylic polymers with the water absorption $\leq 0.58\%$ at 50 °C have been patented.³⁶⁵ Polymeric surfactants based on copolymers of hydrophilic and hydrophobic monomers are highly effective.³⁶⁶ These include di(meth)acrylates of hydroquinone containing in its ring such substituents as halogens, alkyls (C₁–C₂₀) and biphenyl. Copolymers which are components of hydrosol compositions with improved adhesive capacity and cohesive strength may contain 2-acryloyloxynaphthalene-2-sulfonic acid along with other monomeric acids.³⁶⁷ Emulsifying monomers of the general formula

accelerate polymerisation and increase the yield of the target polymer.³⁶⁸

The adhesively strong coatings resistant to the action of water and ethanol were obtained based on film-forming aryl (meth)acrylate copolymers.^{369,370} Aqueous dispersions of such copolymers applied onto the polymer surface prevent sweating of plasticising agents from them.

Phenyl (meth)acrylates are used for the modification of well-known polymeric products. In order to prepare self-coloured polypropylene, polycaprolactam or polyethylene terephthalate fibres³⁷¹ and films,³⁷² these are grafted (with the aid of UV light) to azo monomers, for example,

Azo monomers are also used in the synthesis of polymeric luminophores.³⁷³ Units of tribromophenyl methacrylate are incorporated into polystyrene in order to improve its colourability.³⁷⁴ Coloured polymeric films were prepared by dispersing dyes based on 3,3'-diethoxydicarbocyanine iodide in PPMA.³⁷⁵

Phenyl (meth)acrylates containing groups with antioxidant or UV-stabilising activities may be introduced into macromolecules as intrachain stabilisers.^{376,377} This method of stabilisation is more efficient than the conventional introduction of antioxidants because it prevents their losses from polymers due to volatilisation during processing or diffusion in the course of their service. *p*-Anilinophenyl methacrylate³⁷⁸ may be regarded as one of the efficient thermostabilisers of this type for polyethylene.³⁷⁶ Copolymers of dienes and vinylarenes (styrene) are stabilised by introducing up to 1.5% of a complex acrylate³⁷⁹

$R', R'', R''' = \text{H, Alk}(C_1-C_{16}), \text{Ar, cyclo-Alk}(C_5-C_9), \text{AlkAr}(C_7-C_{12})$.

Monomeric amines of the type of 4-hydroxydiphenylamine (meth)acrylate belong to the group of non-sweating and non-washed off antioxidants for rubbers.³⁸⁰ 2-*tert*-Butyl-6-(3-*tert*-butyl-2-hydroxy-5-methylbenzyl)-4-methylphenyl acrylate is a high-temperature thermostabiliser belonging to the group of polymer-bound antioxidants of the phenol type.^{381, 382}

Aminophenyl (meth)acrylate derivatives have been used as antioxidants³⁸³

$R' = \text{H, Me, OMe}; R'' = \text{H, Me, Ph}; X = \text{NH, O}$.

Such antioxidants are not washed off from rubbers by solvents, are not evaporated and do not cause their bleaching, which is highly important in the technology of rubber processing.

Acylaminophenyl (meth)acrylates, imidophenyl (meth)acrylates and imidonaphthyl (meth)acrylates^{384, 385} are efficient light stabilisers for styrene. The mechanism of stabilisation is associated with the intramolecular energy transfer in molecules under the action of UV light. Aryl methacrylates introduced into the polystyrene macromolecule in the amount of 5 mass % undergo the Fries photorearrangement, which is accelerated owing to the intramolecular energy transfer of triplet excitations from the phenyl to the naphthalene moieties of the molecule. The photorearrangement rate is an order of magnitude higher in naphthyl (meth)acrylates than in phenyl (meth)acrylates.

The use of monomers providing for self-stabilisation upon exposure to natural conditions is rather promising for the preparation of copolymers.³¹⁶ Under the action of light, the Fries rearrangement occurs in films, for example, of copolymers of 1-NMA or 2-NMA with styrene or MMA, with the formation of structures of the type of 2-acetyl-1-naphthol with absorption at 320–400 nm. Even at a degree of conversion of $\sim 5\%$, one observes a substantial decrease in the photorearrangement rate, which leads to the increased light-resistance of NMA units situated at a distance of ~ 2.6 nm from the photoproduct.³⁸⁶ The application of such light stabilisers is advisable for coatings and fibres. Polymeric absorbers can also be obtained by copolymerisation of monomers which contain light-stabilising fragments or groups, *e.g.*, of phenyl 5-(meth)acryloyloxysalicylate with vinyl acetate, vinylidene chloride and vinyl chloride and of 2-hydroxy-4-(meth)acryloyloxybenzophenone with MMA.^{387, 388} The effect of light stabilisation is also achieved by grafting these monomers to polystyrene, polypropylene and polyethylene; the activity of methacrylate is higher and this is explained by additional stabilisation of the radical owing to hyperconjugation with the methyl group.³⁸⁹ An analogous effect is also observed for di(meth)acryloyl derivatives of 2,4-dihydroxybenzophenone.³⁹⁰

To prepare transparent articles with improved UV absorption and weather resistance, it is proposed to introduce phenyl (meth)acrylates with benzotriazole substituents into copolymers.^{391, 392}

$X', X'' = \text{H, Hal, Alk, Ar}$.

The photochemical behaviour of numerous monomers and polymers with benzotriazole fragments has been described in

several publications.^{393–395} It was shown that the light-protective effect of polymeric UV absorbers depends on the nature of the groups which determine the nearest environment of the fragment and their influence on the strength of the intramolecular hydrogen bond in the benzotriazole fragment. Polyethylene used for manufacturing a packing material containing 4-acryloyloxybenzophenone units (from 0.1% to 40%), which is destroyed under the action of light in 120 h, has been patented.³⁹⁶

Monomers with the nitro groups, for example, 4-nitrophenyl methacrylate³⁹⁷ or 4-nitro-1-naphthyl methacrylate can be used as photosensitisers. Monomers with 4-dialkylaminobenzylidenacetophenone residues, *e.g.*, 4-(4-dimethylaminobenzylidenecarbonyl)phenyl methacrylate can be used as³⁹⁸ photoinitiators, including the intrachain ones,^{399, 400} sensitive to light with a wavelength of 488 nm.

Aryl (meth)acrylates undergo photopolymerisation, which makes them promising components of photopolymerisable compositions (PPC) for printed circuit boards and photoresists. Di(meth)acrylates of the general formula $\text{H}_2\text{C} = \text{CRC}(\text{O})\text{NH} - \text{C}_6\text{H}_4\text{OC}(\text{O})\text{CR} = \text{CH}_2$ are introduced into PPC for improving the technology of manufacturing offset type forms,⁴⁰¹ upgrading printing-technical properties of compositions for obtaining thin copying layers.⁴⁰² It was proposed to introduce 3-acetylaminophenyl acrylate into PPC for the same purpose.⁴⁰³ Dimethacrylates of isomeric aminophenols are also used as light-sensitive compounds in compositions for ideally transparent planographic printed circuit boards.⁴⁰⁴ Two preparative methods for obtaining light-sensitive polymers containing *p*-phenylene diacrylate groups (PDAG) have been described. Under the action of radiation from an argon laser, PDAG is photodimerised with a quantum yield of 0.44, which allows one to use these polymers as resists.⁴⁰⁵ Comparison of the reactivities of PA in UV-compositions with alicyclic and aliphatic analogues (including diacrylates) showed its highest efficiency.⁴⁰⁶ A copolymer of 4-nitrophenyl methacrylate with 2-cinnamoyloxyethyl methacrylate is an efficient negative photoresist with a sensitivity of $17-34 \text{ mJ cm}^{-2}$ and a resolution of $1.5-3 \mu\text{m}$ for a layer $0.5-1 \mu\text{m}$ thick.⁴⁰⁷ Homo- and copolymers of 4- or 2-*tert*-butoxycarbonyloxyphenyl (meth)acrylates are used as binding agents in irradiation-sensitive polymer mixtures and depending on the development technique of the irradiated photoresists, negatives or positives are obtained.⁴⁰⁸ The use of phenyl acrylates in resists for X-ray microlithography with the plasma-based development makes it possible to attain submicron resolution ($\sim 0.5 \mu\text{m}$) at a sensitivity of 2.5 mJ cm^{-2} (see Ref. 409). The content of aryl (meth)acrylate in X-ray resists reaches 30%.⁴¹⁰ Positive photoresists with high sensitivity and resolution are obtained by polymerisation of esters of 2-cyanoacrylic acid in the presence of sulfur-containing compounds.⁴¹¹

Irradiation of poly(halogenophenyl methacrylates) with electrons induces their cross-linking;⁴¹² therefore, such polymers may be used as negative electron resists. Poly(4-chlorophenyl methacrylate) is an example. However, the increase in the number of chlorine atoms in the ring makes destructive processes more pronounced and the resist may become negative. Poly(phenyl methacrylates) with the perfluoroalkyl groups are also regarded as negative electron resists. The sensitivities of C_3F_7 - and $\text{n-C}_6\text{F}_{13}$ -containing polymers are 20 and $7 \mu\text{C cm}^{-2}$, respectively.⁴¹³ In the case of copolymers, the fluorine atoms may be present in comonomer units. For example, a copolymer of PMA containing up to 50% of α -trifluoromethylacrylic acid is an electron resist with a sensitivity of $10 \mu\text{C cm}^{-2}$ at a zero residual thickness.^{414, 415} The halogen-free poly[aryl (meth)acrylates] are positive electron resists with an insufficiently high electron sensitivity. It is $50 \mu\text{C cm}^{-2}$ for PPMA, $200 \mu\text{C cm}^{-2}$ for PNMA, $65 \mu\text{C cm}^{-2}$ for poly(fluorenyl methacrylate), $550 \mu\text{C cm}^{-2}$ for poly(anthryl methacrylate) and differs considerably from that for PMMA ($10 \mu\text{C cm}^{-2}$).⁴¹⁶ Introduction of halogen, *e.g.*, by chloromethylation, changes drastically the situation.⁴¹⁷ Electron-ray resists become negative with a sensitivity of $3.7-11.0 \mu\text{C cm}^{-2}$; their sensitivity increases up to a 20%

content of chloromethyl groups. The crucial role in the cross-linking process is played by recombination of free radicals formed as the result of cleavage of the carbon – halogen bond. In contrast to vinyl and epoxide polymers, virtually no postirradiation chain polymerisation, which decreases the resolution obtained, occurs in 2-PNMA. In this particular case it reaches 0.5 μm . This polymer may be sensitised to the action of light with $\lambda = 365\text{ nm}$ (3% of Michler's ketone), the resultant sensitivity is $\sim 100\text{ mJ cm}^{-2}$. The above-considered polymers may be used in the so-called hybrid lithography, where relatively large details of microrelief are obtained under the action of UV light, while fine details are obtained with the aid of a well-focused electron beam.

Copolymers of ethylene with halogenoalkyl-substituted PMA are excellent dielectrics.^{418, 419} Polymers of 4-hydroxystyrene or its halogen derivatives esterified with methacryloyl chloride,⁴²⁰ exhibit good dielectric properties, heat and fire resistance. These are also suitable for manufacturing bases for semiconductor devices. As in the case of copolymers of styrene with 2,4,5-trichlorophenyl acrylate,⁴²¹ modification of functional groups makes it possible to prepare electron-conducting metallocomplexes. Polymethacrylates, containing aromatic amino groups in the side chain, were found to possess the hole-type photoconductivity with rather high mobility of charges comparable to that in polyvinylcarbazole.⁴²²

There are data on piezoelectrical⁴²³ and magnetic⁴²⁴ properties of poly[aryl (meth)acrylates]. Specific behaviour of such polymers with liquid-crystalline properties in electric and light fields allows prediction of their wide use in electronics and optics, in particular, in birefringent and colour displays using the 'guest – host' effect, phase lenses and high-resolution laser devices.^{425, 426}

Like phenols, phenyl (meth)acrylates are antiseptics. Introduction of chlorine atoms into the aromatic rings increases biocidal activity; however, the low rate of the ester bond hydrolysis⁴²⁷ of poly[aryl (meth)acrylates], e.g., 2,4,5-trichlorophenyl methacrylate, may lead to the total loss of this activity. Nonetheless, materials based on copolymers of styrene with pentachlorophenyl acrylate,^{428, 429} *p*-chloro-, *p*-cresyl or biphenyl acrylate and analogous copolymers with MMA and acrylates⁴²⁹ possess noticeable antimicrobial activities. Homo- and copolymers of pentachlorophenyl methacrylate⁴³⁰ and 2-carboxyphenyl methacrylate⁴³¹ are analogous in this respect. It is proposed to use polymers of 2- and 4-(meth)acryloyloxyphenylacetic acids^{432, 433} and their alkyl esters as bactericidal agents for the purification of sewage.

High fungicidal activity is displayed by copolymers of pentachlorophenyl (meth)acrylate⁴³⁴ with vinyl acetate, ethyl and butyl acrylates, MMA and MAA. Their emulsions possess good film-forming properties and may be used as components of fungus-resistant dyes⁴³⁴ for indoor and outdoor work, while copolymers with acrylamide⁴³⁵ are applied for impregnation of paper.

It is proposed to use 2,2-bis(4-methacryloyloxyphenyl)propane in compositions for fillings in dentistry.^{436–438} Dentists also make use of solidified compositions which possess enhanced adhesion to metals and the dental tissue and contain from 0.5% to 10% of hydroxybenzoic (meth)acrylate⁴³⁹ or aromatic di(meth)acrylates.⁴⁴⁰ A hemocompatible polymeric material for coating blood-contacting surfaces was obtained from dimethyl (2-hydroxyethyl)ammonium salt of poly(2-acryloyloxybenzoic acid).⁴⁴¹ Some phenyl methacrylates, e.g., 4-azidophenyl methacrylate, are components of copolymers possessing hemoglobin function.⁴⁴² Others, e.g., 4-nitrophenyl acrylate, are introduced into polymeric carriers for the isolation of biologically specific molecules such as proteins, which may be used for radiodiagnostics of thrombi, antigens and tumours⁴⁴³ or for immobilisation of enzymes, amino acids, proteins^{444, 445}, e.g., serum albumin.^{446, 447} Polymers based on 2,4,5-trichlorophenyl, 4-nitrophenyl or 2,4-dinitrophenyl (meth)acrylates are X-ray contrasting preparations.⁴⁴⁸

Introduction of residues of unsaturated acids into medicinal substances and subsequent polymerisation yield drugs with prolonged action.^{69–70} Resorption of polymers of acrylic acid

with β -naphthyl acrylate as potential coatings of such medicinal preparations was studied by liquid chromatography by monitoring the liberation of the β -naphthol upon hydrolysis of the copolymer.⁴⁴⁹

Thus, aryl (meth)acrylates possess a very broad spectrum of useful properties and their further studies are highly advisable.

Abstract. Methods of synthesis, molecular and electronic structures and electrophysical, optical and magnetic properties of ternary and quaternary chalcogenides based on copper, silver and gold are considered. The possibility of the synthesis of chalcogenide analogues of high-temperature superconductors is discussed. The prospects of searching for new high-temperature superconductors in $Ln-Cu-X$ systems, where Ln is a rare-earth element and X is S, Se or Te, are shown. The bibliography includes 148 references.

I. Introduction

The discovery of the high-temperature superconductivity in 1986¹ has given powerful impetus to the development of solid-state chemistry. This has awakened great interest in metal oxide systems with the perovskite-like structures. High-temperature superconductors (HTSCs) with the superconducting transition temperatures (T_c) of up to 150 K (see Ref. 2) were synthesised (the data, while unconfirmed, on the synthesis of HTSCs with T_c of up to 250 K are also available in the literature^{3,4}). It has since become clear that the properties of new superconducting materials cannot be explained within the framework of the BCS theory (Bardeen–Cooper–Schrieffer). Apparently, the RVB (resonance valence bond) model proposed by Anderson⁵ is most realistic.^{5–9} This model assumes the occurrence of mixed-valence states in the system of chemically bonded atoms as an essential prerequisite for the high-temperature superconductivity. The mixed valence is necessary not only for the provision of the required carrier concentration and the equivalent positions for the carrier motion but also provides the basis for the coupling mechanism. In this connection, it becomes apparent that solid-state chemistry is of paramount importance in the solution of both theoretical and applied problems of physics of superconductivity.

In spite of the ten-year history of HTSCs, much in the chemistry of these materials remains unclear. Suffice it to mention that the problem associated with the estimation of the degree of oxidation of copper in metal-oxide samples, which is of importance for constructing the theory of HTSCs, is still debated. Leaving aside the details of this problem, let us mention a study,¹⁰

in which the authors used X-ray emission spectroscopy for estimating the degree of oxidation of copper atoms in HTSCs. This method is free from the drawbacks of X-ray photoelectron spectroscopy (XPS), which is most often used for these purposes.

The role of oxygen atoms in HTSCs also remains unclear. In the available chemical models of superconductivity of HTSCs, which are based on Anderson's ideas,^{11–13} the possibility of formation of weakly bound O_4 complexes upon transformation of HTSCs into the superconducting state is considered. The bond strength in these complexes is determined, on the one hand, by the sizes of the cations and, on the other hand, by the concentration of holes, which disturb the antiferromagnetic order in the initial dielectric system. Taking into account the greater ability of sulfur and selenium atoms to form polychalcogenide ions, chalcogenide analogues of HTSCs would be expected to possess stronger electrophysical characteristics compared to those of oxide HTSCs. This idea was proposed, for example, in the study;¹⁴ simultaneously, it was assumed that the structural characteristics remain unchanged. The prospects for synthesising HTSCs based on thio-, seleno- and tellurocuprates are very attractive because chalcogenides of transition metals, in particular, copper chalcogenides, provide substantially greater possibilities for the preparation of compounds possessing various physicochemical properties compared to those of the corresponding oxides. The most essential differences consist in the higher covalence of the metal–chalcogen bonds, the ability of chalcogen atoms to form bonds with each other resulting in molecular anions and the higher ability of metal atoms to form metal–metal bonds (due to the lower formal charge). Owing to these facts, chalcogenides of Group IB metals can exhibit a broad spectrum of electrical (from dielectric to superconducting¹⁵) and magnetic properties (from diamagnetism to temperature-independent paramagnetism).

Table 1 gives the structural and electrophysical characteristics of selected superconductors based on chalcogenides of transition metals, *viz.*, chalcogenides of copper and rare-earth elements, which are structural elements of HTSCs, as well on some ternary chalcogenides characterised by high T_c values. Analysis of these data suggests that a search for HTSCs in $M-Ln-X$ systems, where M is IB Group metal, Ln is a rare-earth element and X is chalcogen, may have promise. Thus, in the studies of the $Cu_2S-La_2S_3$ system performed in 1968–1972,^{19–21} ternary sulfides, *viz.*, the hexagonal $Cu_2La_4S_7$ and monoclinic $CuLaS_2$ phases, were detected. However, Andreev²² studied the same system in 1988 and found only the $CuLaS_2$ phase. Later on, Andreev published the paper entitled 'The Cu_2S-BaS system as a possible HTSC',²³ where he demonstrated that two phases, *viz.*, the tetragonal $BaCu_2S_2$ and orthorhombic $BaCu_4S_3$ phases, exist

in this system. In 1994, Chinese researchers²⁴ at the National Laboratory of Superconductivity synthesised a series of oxyselenides LnCuSeO ($\text{Ln} = \text{La}, \text{Sm}, \text{Gd}$ or Y). The structures of the latter contain the alternating $[\text{Ln}_2\text{O}_2]$ and $[\text{Cu}_2\text{Se}_2]$ layers. Analogous layers have been found previously by Popovkin²⁵ in oxyselenide BiCuSeO . Attempts were undertaken to perform partial replacement of oxygen atoms in HTSCs by halogen or chalcogen atoms. These attempts often cast doubt from the chemical standpoint^{14, 26, 27} and do not solve the problem because they allow only an insignificant amount of oxygen to be replaced by chalcogen. The effect of the latter in these systems can be considered only as a weak perturbation, which was in essence found in the above-mentioned studies.

As early as 1991, we attempted to synthesise chalcogenide analogues of HTSCs, in particular, $\text{La}_2\text{CuS}_{4+\delta}$ and $\text{YBa}_2\text{Cu}_3\text{S}_{6+\delta}$.²⁸ However, because of difficulties associated with the preparation of a single phase and the lack of data on simpler systems (for example, $\text{Ba}-\text{Cu}-\text{S}$ and $\text{Cu}-\text{Ln}-\text{S}$), we turned our attention primarily to ternary systems consisting of chalcogenides of Group IB metals and chalcogenides of alkali, alkaline-earth or rare-earth metals.

Nevertheless, even regardless of the problem of HTSCs, the success achieved in the chemistry of ternary and quaternary chalcogenides based on Group IB elements within the last decade is so impressive that it makes sense to expose not only chemists and physicist involved in studies of HTSCs but also researchers working in other fields to the results obtained. The present review is devoted to analysis of methods of synthesis and molecular and electronic structures of chalcogenides in relation to their magnetic and electrophysical properties.

Molecular polychalcogenides are considered first because it is in this class of compounds that sulfides and selenides differ most sharply from the corresponding oxides. We next consider the coordination polymers based on polychalcogenides of Group IB metals. Finally chalcogenides containing only X^{2-} and/or X_2^{2-} ions, i.e., the structural elements identical to those in oxide HTSCs, are considered. Tellurides are considered at the end of each chapter for two reasons. First, tellurium has peculiarities and the properties of tellurides differ from those of the corresponding

sulfides and selenides and second, these compounds are poorly known.

II. Molecular copper, silver and gold polychalcogenides

Molecular polychalcogenides of Group IB metals containing isolated $[\text{M}_n\text{X}_m]^{q-}$ clusters ($\text{M} = \text{Cu}, \text{Ag}$ or Au ; $\text{X} = \text{S}, \text{Se}$ or Te) were virtually unknown up to the early 1980s.²⁹ (The synthesis of polynuclear copper sulfide complexes was reported for the first time in 1983.)

The $(\text{Et}_4\text{N})_3[\text{Cu}_3(\text{S}_6)_3]$ complex was prepared by the reaction of copper(II) acetate with an ethanolic solution of polysulfides.³⁰ The complex contains the complex $[\text{Cu}_3(\text{S}_6)_3]^{3-}$ ion in which the Cu^+ ions are chelated by the hexasulfide ions (Fig. 1). One of the terminal sulfur atoms of each S_6^{2-} ion acts as a bridge and is involved in formation of the central six-membered Cu_3S_3 ring. In the following year,³¹ researchers succeeded in isolating salts, which contain $[\text{Cu}_3(\text{S}_4)_3]^{3-}$ ions and are structurally similar to $[\text{Cu}_3(\text{S}_6)_3]^{3-}$. In this study, the $(\text{Ph}_4\text{P})_4[\text{Cu}_2\text{S}_{20}]$ salt containing the $[\text{S}_6\text{CuS}_8\text{CuS}_6]^{4-}$ ions in which two CuS_6 rings are bound to each other through the bridging S_8^{2-} anion was also described. Analogous silver salts containing the $[\text{Ag}_2\text{S}_{20}]^{4-}$ ions were also obtained.³² Note that in all these salts, the copper and silver atoms adopt the coordination number of 3, which is rarely observed in the chemistry of coordination compounds.

**Figure 1.** Structure of the $[\text{Cu}_3(\text{S}_6)_3]^{3-}$ anion.²⁹

Müller and coworkers synthesised a series of four-nuclear clusters of the general formula $[\text{Cu}_4(\text{S}_4)_{3-x}(\text{S}_5)_x]^{2-}$. These clusters contain the tetrahedral Cu_4 core in which the copper atoms are chelated by the bridging S_4^{2-} and/or S_5^{2-} ions. All members of this series were isolated, viz., salts with $x = 0,^{31} 1, 2^{33}$ and $3.^{34}$ The structure of the $[\text{Cu}_4\text{S}_4(\text{S}_5)_2]^{2-}$ cluster is shown in Fig. 2. It should be noted that these clusters provide rare examples of coexistence of the MS_4 and MS_5 chelates.

**Figure 2.** Structure of the $[\text{Cu}_4\text{S}_4(\text{S}_5)_2]^{2-}$ anion.³³

In 1984, the $(\text{Ph}_4\text{P})_2[\text{Cu}_6(\text{S}_4)_3\text{S}_5]$ salt was synthesised virtually simultaneously at the laboratories headed by Henkel³⁵ and Müller.³⁶ This salt can be prepared either by the reaction of $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$ with a threefold excess of NaSR ($\text{R} = \text{Et}$ or CH_2Ph) in methanol³⁵ or by the reaction of $\text{Cu}(\text{acac})_2$ with an ethanolic solution of polysulfides.³⁶ In both cases, the salt was isolated as orange-red crystals upon addition of a solution of Ph_4PBr to the

Figure 3. Structure of the $[\text{Cu}_6(\text{S}_4)_3\text{S}_5]^{2-}$ anion.³⁶

reaction mixture. In this complex, a new coordination mode was found (Fig. 3). Six copper atoms form two distorted tetrahedra, whose vertices are occupied by the Cu(1), Cu(2), Cu(3), Cu(1'), Cu(2') and Cu(3') atoms. These tetrahedra are linked *via* the shared Cu(3)–Cu(3') edge. The metal atom is coordinated by the tetrasulfide ions only through the terminal atoms, while the pentasulfide ions are coordinated to the metal atoms through four sulfur atoms [S(2), S(2'), S(3) and S(3')].

In the laboratory headed by Henkel,³⁷ the $(\text{Ph}_4\text{P})_4[\text{Cu}_{12}\text{S}_8]$ salt containing the $[\text{Cu}_{12}\text{S}_8]^{4-}$ cluster ions was synthesised. This salt was prepared as wine-red needles by the reaction of $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$ with a threefold excess of NaSEt in methanol ($\sim -78^\circ\text{C}$) followed by addition of Li_2S and (after completion of the reaction) of a solution of Ph_4PBr . The $[\text{Cu}_{12}\text{S}_8]^{4-}$ anion has the ideal O_h symmetry. The sulfur atoms occupy the vertices of the cube and the copper atoms occupy the centres of the edges.

Later on, Marbach and Strähle³⁸ isolated an analogous gold complex as the tetraphenylarsonium $(\text{Ph}_4\text{As})_4[\text{Au}_{12}\text{S}_8]$ salt. The $[\text{Au}_{12}\text{S}_8]^{4-}$ and $[\text{Cu}_{12}\text{S}_8]^{4-}$ anions have identical structures. In 1992, Kanatzidis and Huang³⁹ prepared the $(\text{Et}_4\text{N})_3[\text{NaAu}_{12}\text{Se}_8]$ complex, which is the selenium analogue of the $(\text{Ph}_4\text{As})_4[\text{Au}_{12}\text{S}_8]$ salt. The larger size of the selenium atom compared to that of the sulfur atom allows Na^+ ions to occupy the centres of the $[\text{Au}_{12}\text{Se}_8]^{4-}$ cuboctahedra. Hence, this complex is one of a few examples of inorganic cryptands. The Na^+ ion occupies the inversion centre. The distances from the sodium ion to the gold ions are shorter than those to the selenium atoms. Apparently, the interactions between the sodium ion and the twelve Au^+ ions are stronger. The authors³⁹ believed that this fact reflects the general tendency of the Au^+ ions to interact with alkali-metal ions. Note that the Au^+ or Cu^+ ions in the $[\text{M}_{12}\text{X}_8]^{4-}$ complexes ($\text{M} = \text{Au}$ or Cu) have a typical linear coordination.

An example of a supposedly extremely large copper chalcogenide cluster was described in the study.⁴⁰ The authors succeeded not only in isolating the $[\text{Cu}_{146}\text{Se}_{73}(\text{Ph}_3\text{P})_{30}]$ cluster but also in characterising it structurally. Although this compound is not a purely chalcogenide cluster because it contains the triphenylphosphine group, it corresponds to the subject of this review because this compound is formally a derivative of copper selenide $\text{Cu}_2\text{Se} - \{[\text{Cu}_{146}\text{Se}_{73} \cdot 30(\text{Ph}_3\text{P})]\}$. This cluster is also of interest because it is a semiconductor with the conductivity $\sigma_{RT} = 1.5 \times 10^{-2} \Omega^{-1} \text{cm}^{-1}$. The selenium atoms in this cluster form three planar layers consisting of 21, 31 and 21 atoms (*ABA* packing) arranged in a close packed fashion. The copper atoms occupy the cavities in this packing. In the crystal, the clusters are arranged in such a way as to form cavities (channels) with a diameter of 1.6 nm. When crystallisation is performed from organic solvents, channels are occupied by the solvent molecules, which can be, however, removed under mild conditions without destruction of the crystal lattice. For example, 42 tetrahydrofuran molecules can add per formula unit of the cluster.

In the above-considered examples, the specificity of the Cu^+ , Ag^+ and Au^+ ions is not manifested. Let us consider examples of chalcogenides, in which this specificity is apparent. The Au^+ ion, like the Cu^+ ion, forms a complex with the tetrasulfide ion with

Figure 4. Structure of the $[\text{Au}_2(\text{S}_4)_2]^{2-}$ anion.³⁴

composition $[\text{Au}_2(\text{S}_4)_2]^{2-}$.³⁴ Unlike analogous copper complexes, the gold(I) tetrasulfide complex can be described as a ten-membered ring, in which the Au^+ ion has a nearly linear coordination (Fig. 4).

The gold(I) pentaselenide complex was isolated as the $[(\text{Ph}_2\text{P})_2\text{NPh}_2]_2[\text{Au}_2\text{Se}_{10}]$ salt. However, according to the data of X-ray diffraction analysis,⁴¹ this complex is in fact an Au^{3+} derivative and contains coordinated selenide and tetraselenide ions. It was suggested that the Au^+ complex with the Se_5^{2-} ions in which the Au^+ ion has linear coordination, was actually formed at the initial stage. However, the subsequent intramolecular two-electron transfer from the Au^+ ion to the terminal Se–Se bond afforded the Au^{3+} and Se^{2-} ions and the Se_4^{2-} ions were formed from the Se_5^{2-} ions. The complex $[\text{Se}_4\text{AuSe}_2\text{AuSe}_4]^{2-}$ ion is planar, like the majority of $\text{Au}(\text{III})$ complexes.

Oxidation of $\text{Au}(\text{I})$ with the pentaselenide ion proceeded unusually. The reaction of AuCl_3 with Na_2Se_5 upon addition of a Ph_4PBr solution to the reaction mixture afforded gold and the product of oxidation of the pentaselenide ion, *viz.*, $(\text{Ph}_4\text{P})_2\text{Se}_{11}$, *i.e.*, Au^{3+} was reduced with the pentaselenide ion. Apparently, the only analogous reaction is the reaction in the $\text{Ti}^+ - \text{I}_3^-$ system in which Ti^{3+} ions were completely reduced with I^- ions to Ti^+ . However, Ti^+ ions reacted with an excess of I_3^- ions to form the Ti^{3+} complex with composition $[\text{TiI}_4]^-$.⁴¹

Polyselenide $\text{Au}(\text{I})$ complexes were prepared with the use of polyselenides Se_n^{2-} with $n = 1-4$.⁴² Thus, the reaction of AuCN with a Na_2Se_2 or Na_2Se_3 solution in the presence of Ph_4PCl yielded the $(\text{Ph}_4\text{P})_2[\text{Au}_2\text{Se}_2\text{Se}_3]$ salt containing the seven-membered cyclic $[\text{Au}_2\text{Se}_2\text{Se}_3]^{2-}$ anions (Fig. 5). The complex anion adopts an envelope conformation with the linear coordination of the Au^+ ions. The reaction performed under analogous conditions with the use of K_2Se_4 instead of Na_2Se_2 or Na_2Se_3 gave the $(\text{Ph}_4\text{P})_2[\text{Au}_2\text{Se}_2\text{Se}_4]$ salt. This salt contains the eight-membered cyclic anion in which two Au^+ ions are symmetrically coordinated by the diselenide and tetraselenide ions.

Figure 5. Structure of the $[\text{Au}_2\text{Se}_2\text{Se}_3]^{2-}$ anion.⁴²

Finally, the reaction with the use of pentaselenide K_2Se_5 gave the $\text{K}_2[\text{Au}_2\text{Se}_2(\text{Se}_4)_2]$ complex. Unlike the two above-described complexes, the latter complex contains the Au^{3+} ion as a result of the higher oxidising capacity of the Se_5^{2-} ion compared to those of the Se_4^{2-} and Se_3^{2-} ions.⁴³

In addition to the above-mentioned $[\text{Ag}_2\text{S}_{20}]^{4-}$ anion, the Ag^+ complex with hexasulfide ions with composition $[\text{Ag}_2(\text{S}_6)_2]^{2-}$ is known. In this complex, the coordination of the S_6^{2-} ligands is analogous to that observed in the $[\text{Cu}_3(\text{S}_6)_3]^{3-}$ anion, with the only difference that the binuclear $[\text{Ag}_2(\text{S}_6)_2]^{2-}$ anion contains the four-membered Ag_2S_2 rings.⁴⁴

The coordination of the tetraselenide anions by the Ag^+ cations is also very similar to that observed in Cu^+ salts. Thus, four-nuclear silver tetraselenides $(\text{Et}_4\text{N})_4[\text{Ag}_4(\text{Se}_4)_4]$ and $(\text{Pr}_4\text{N})_2[\text{Ag}_4(\text{Se}_4)_3]^{2-}$ were isolated.⁴⁵ The $[\text{Ag}_4(\text{Se}_4)_4]^{4-}$ anion is formed by four Ag^+ ions, which occupy the vertices of the planar rhombus and which are linked *via* the bridging Se_4^{2-} ligands (Fig. 6). The silver atoms in this cluster are nonequivalent. The coordination environment about two of them $[\text{Ag}(1)$ and $\text{Ag}(1')]$, see Fig. 6) is a tetrahedron, while two other atoms $[\text{Ag}(2)$ and $\text{Ag}(2')]$ have a planar-trigonal coordination. Analogously, the Se_4^{2-} ions are also nonequivalent. Two of them link three silver ions each and the remaining two complex ions link two silver ions each.

Figure 6. Structure of the $[\text{Ag}_4(\text{Se}_4)_4]^{4-}$ cluster.⁴⁵

The structure of the cluster $[\text{Ag}_4(\text{Se}_4)_3]^{2-}$ ion (Fig. 7) is based on the tetrahedral cage formed by the Ag^+ ions, which are linked *via* three Se_4^{2-} ligands. This cage, in turn, forms the distorted adamantane-like central Ag_4Se_6 core in which all silver atoms adopt a planar-trigonal coordination.

Figure 7. Structure of the $[\text{Ag}_4(\text{Se}_4)_3]^{2-}$ cluster.⁴⁵

The complex copper and silver selenides, *viz.*, $[\text{Cu}_2\text{Se}_4(\text{Se}_5)_2]^{4-}$, $[\text{Cu}_4(\text{Se}_4)_{2.4}(\text{Se}_5)_{0.6}]^{2-}$ and $(\text{Ph}_4\text{P})_2. [\text{Ag}_4(\text{Se}_4)_{3-x}(\text{Se}_5)_x]$, which are related to the above-described copper sulfides $[\text{Cu}_4(\text{S}_4)_{3-x}(\text{S}_5)_x]^{2-}$, were also described.^{46, 47} These salts were prepared by the reaction of CuCl with a melt of polyselenide Li_2Se_n or by fusing a mixture of CuCl_2 , sodium and selenium. Their structures are similar to those of the corresponding sulfides.

The mononuclear complexes with the nonasulfide ion are known only for gold and silver. Marbach and Strähle isolated cyclic nonasulfidoaurate(I) $(\text{Ph}_4\text{As})[\text{AuS}_9]$.⁴⁸ Its structure is shown in Fig. 8. The Au^+ ion binds the terminal sulfur atoms of the ligand and has a nearly linear coordination [the $\text{S}(1)\text{AuS}(9)$ angle is 176°]. The analogous silver salt $(\text{Ph}_4\text{P})[\text{AgS}_9]$ is also

Figure 8. Structure of the $[\text{AuS}_9]^{9-}$ anion.⁴⁸

known.²⁹ However, the anions in the crystal of this salt are substantially disordered.

Finally, let us consider a few examples of molecular polytellurides, which are presently known only for gold. In 1985, the first gold polytelluride $(\text{Ph}_4\text{P})_4[\text{KAu}_9\text{Te}_7]$ containing isolated cluster ions was described.⁴⁹ The reaction of a methanolic solution of K_2AuTe_2 with a solution of Ph_4PBr afforded an orange precipitate. Additional treatment of the latter with DMF and a solution of Ph_4PBr in MeOH gave two products. One of them, which was isolated as triangular red platelet-like crystals, has the composition $(\text{Ph}_4\text{P})_4[\text{KAu}_9\text{Te}_7]$. The structure of the $[\text{KAu}_9\text{Te}_7]^{4-}$ anion (Fig. 9) can be considered as that derived from the cubic structure of the above-described $[\text{M}_{12}\text{S}_8]^{4-}$ ions ($\text{M} = \text{Cu}$ or Au) in which one vertex and three edges are removed. The ideal cubic structure is distorted due to the contraction along the threefold axis passing through the absent vertex and the centre of the ion. This contraction is responsible for the pronounced $\text{Au}-\text{Au}$ interaction. The $\text{Au}-\text{Au}$ distances in the triangles (see Fig. 9) vary from 0.3039 to 0.3221 nm. The average distance (0.313 nm) is close to the $\text{Au}-\text{Au}$ distance in metallic gold (0.288 nm) and is substantially shorter than that in the hypothetical $[\text{Au}_{12}\text{Te}_8]^{4-}$ ion (0.363 nm). Like $[\text{NaAu}_{12}\text{Se}_8]^{3-}$, the $[\text{Au}_9\text{Te}_7]$ framework incorporates the encapsulated potassium ion, the $\text{Au}-\text{K}$ distances being shorter than the $\text{Au}-\text{Te}$ distances, which reflects the higher electronegativity of gold compared to that of tellurium (2.4 and 2.1, respectively). It is believed that the above-described encapsulation is responsible for the formation of a cryptand with this composition because the K^+ ion is too large to be encapsulated into the hypothetical $[\text{Au}_{12}\text{Te}_8]^{4-}$ ion.

Figure 9. Structure of the $[\text{KAu}_9\text{Te}_7]^{4-}$ anion.⁴⁹

The electrochemical preparation of the $(\text{Ph}_4\text{P})_2[\text{Au}_2\text{Te}_4]$ and $(\text{Bu}_4\text{N})_3[\text{Au}_3\text{Te}_4]$ salts with the use of AuTe_2 as the electrode was reported in a study.⁵⁰ The $[\text{Au}_3\text{Te}_4]^{3-}$ anion is gold(I) telluroditelluride (Fig. 10a) and the $[\text{Au}_2\text{Te}_4]^{2-}$ anion is gold(I) bistelluride (Fig. 10b). In both cases, the gold atoms have a linear coordination typical of Au^+ ions. However, the tendency for the trigonal coordination through the $\text{Au}-\text{Au}$ bonds is also pronounced. The lengths of these bonds (see Fig. 10a, b) are only slightly larger than the $\text{Au}-\text{Au}$ distances in metallic gold.

Treatment of gold tellurides KAuTe and K_3AuTe_2 with ethylenediamine or DMF afforded salts containing the $[\text{Au}_2(\text{Te}_2)_2]^{2-}$ and $[\text{KAu}_9\text{Te}_7]^{4-}$ anions and the $[\text{K}_2\text{Au}_4\text{Te}_4]^{2-}$ anion in which the $[\text{Au}_4\text{Te}_4]^{4-}$ rhombi are linked in infinite stacks through the K^+ ions.^{49, 51}

Figure 10. Structures of the $[\text{Au}_3\text{Te}_4]^{3-}$ (a) and $[\text{Au}_2\text{Te}_4]^{2-}$ (b) anions.⁵⁰

The reaction of AuCN with polytellurides Te_n^{2-} in DMF in the presence of PET_3 and NET_4Cl yielded the $(\text{NET}_4)_3[\text{AuTe}_7]$ salt.⁵² The $[\text{AuTe}_7]^{3-}$ anion is planar, which is typical of Au(III) complexes (Fig. 11 a). The fact that the degree of oxidation of gold is equal to +3 is indirectly supported by the Au–Te bond lengths (0.2638–0.2664 nm), which are comparable with those in the known Au(III) compounds, for example, in AuTeI (0.2642–0.2684 nm), and is also confirmed by the data of Mössbauer spectroscopy on ^{197}Au nuclei. Hence, the anion under consideration is bisditelluridotritelluridoaurate(III).

Figure 11. Structures of the $[\text{AuTe}_7]^{3-}$ (see Ref. 52) (a) and $[\text{AgTe}_7]^{3-}$ (b) anions.⁵⁴

The structure of the analogous silver complex $[\text{AgTe}_7]^{3-}$ isolated as the $(\text{Ph}_4\text{P})_2(\text{Et}_4\text{N})[\text{AgTe}_7]$ salt (Fig. 11 b)^{53,54} differs from that of the $[\text{AuTe}_7]^{3-}$ anion. In this silver complex, the Ag^+ ion adopts a trigonal coordination. Based on the charge of the $[\text{AgTe}_7]^{3-}$ anion, the charge of –4 should be assigned to the ligand and the ligand can be considered as $\eta^3\text{-Te}_7^{4-}$. The $\text{Te}(4)\text{--Te}(5)$ and $\text{Te}(4)\text{--Te}(3)$ bond lengths (0.2866 and 0.3230 nm, respectively) are substantially different, whereas this difference in the corresponding bonds in the analogous $[\text{HgTe}_7]^{2-}$ complex is insignificant (0.3050 and 0.2997 nm, respectively⁵³). Therefore, the nature of the bonds in the new polytelluride $\eta^3\text{-Te}_7^{4-}$ ligand is still unknown. Polyhalide ions, in particular, such as I_8^{3-} , are the closest analogues of this ligand. The concept of hypervalence is used for describing the nature of bonds in these compounds, in particular, in S_2N_2 , S_4N_4 , polyhalides, xenon halides, etc.⁵⁵ In accordance with this concept, the $\text{Te}(3)\text{--Te}(4)\text{--Te}(5)$ bond can be considered as a three-centre four-electron bond, whereas the $\text{Te}(2)\text{--Te}(3)$ and $\text{Te}(5)\text{--Te}(6)$ bonds are usual two-centre two-electron bonds.

Copper and silver tetratellurides containing the $[\text{Te}_4\text{M}(\mu\text{-Te}_4)\text{MTe}_4]^{4-}$ ions ($\text{M} = \text{Cu}$ or Ag) were also prepared.⁵⁶ The structures of these ions are similar to that of the $[\text{S}_6\text{Cu}(\mu\text{-S}_8)\text{CuS}_6]^{4-}$ ion. In these tellurides, the copper(I) and silver(I) atoms are trigonally coordinated through the chelating and bridging Te_4^{2-} ions.

III. Coordination polymers based on polychalcogenides of Group IB elements

Coordination polymeric polychalcogenides are intermediate between low-molecular-weight polychalcogenides and chalcogenides containing only X^{2-} and/or X_2^{2-} ions. These ions are bound to metal ions through substantially covalent bonds due to which these compounds are virtually insoluble in the usual organic solvents.

Polymeric polychalcogenides containing the $[\text{CuS}_4]^-$ anion have been known since the early 20th century.⁵⁷ However, their structures were established only late in the 1980s. Generally, polymeric polychalcogenides were prepared from solutions. However, the procedure for the synthesis of these compounds from melts of alkali metal polychalcogenides, which act simultaneously as the solvent and the reagent, was proposed in 1989.⁵⁸ This method appears to be more promising and allows one to prepare more perfect single crystals suitable for X-ray diffraction study. Coordination polymeric polychalcogenides can be synthesised in the temperature range of 150–350 °C. At lower temperatures, molecular polychalcogenides are obtained. At higher temperatures, mono- and dichalcogenides of Group IB metals are formed.

Oxidation of copper in a melt of K_2S_4 at 215 and 250 °C affords two modifications (α and β , respectively) of the $\text{K}[\text{CuS}_4]$ salt. These modifications are insoluble in usual organic solvents and stable to hydrolysis and oxidation with atmospheric oxygen. Both phases have quasi-one-dimensional structures (Fig. 12).

Figure 12. Infinite $\alpha\text{-}[\text{Cu}(\text{S}_4)]_n^-$ (a) and $\beta\text{-}[\text{Cu}(\text{S}_4)]_n^-$ (b) chains.⁵⁸

The $\alpha\text{-K}[\text{CuS}_4]$ salt is isostructural to the $(\text{NH}_4)[\text{CuS}_4]$ salt described previously⁵⁹ and contains the tetrasulfide ligands chelating the copper(I) ions (Fig. 12 a). The $[\text{CuS}_4]^-$ ions form infinite noncentrosymmetrical chains extended along the a axis. These chains can be considered as a sequence of fused five-membered CuS_4 and Cu_2S_3 rings. Therefore, the S_4^{2-} ion in this structure plays the unprecedented role of a bridge that links three Cu^+ ions.

The structure of $\beta\text{-K}[\text{CuS}_4]$ contains centrosymmetrical one-dimensional $\beta\text{-}[\text{CuS}_4]_n^-$ chains with a nearly linear (the CuCuCu angle is 173.5°) arrangement of the copper atoms linked through the bridging S_4^{2-} ligands (Fig. 12 b). Unlike the α -phase, the $\beta\text{-}[\text{CuS}_4]_n^-$ chains consist of the five-membered (CuS_4) and four-membered (Cu_2S_2) rings. Since the β -modification is formed at higher temperature, it can be suggested that this phase is thermodynamically more stable. Heating of crystals of $\alpha\text{-K}[\text{CuS}_4]$ above 250 °C results in transition to the β -phase. However, cooling of crystals of the β -phase do not lead to the reverse transition. The K_2S_4 solvent is of considerable importance in the $\alpha \rightarrow \beta$ -transition. Heating of crystals of $\alpha\text{-K}[\text{CuS}_4]$ in the absence of the solvent *in vacuo* resulted in their decomposition to CuS and K_2S_x .⁵⁸

Treatment of an alkaline solution of the $(\text{NH}_4)[\text{CuS}_4]$ salt with solutions of salts containing bulky cations afforded low-molecular-weight polysulfides, for example, $(\text{NMe}_4)_2[\text{Cu}_4(\text{S}_6)_3] \cdot 4\text{H}_2\text{O}$, $(\text{Et}_3\text{NBn})_2[\text{Cu}_4(\text{S}_4)(\text{S}_5)_2] \cdot 4\text{H}_2\text{O}$ and $(\text{Ph}_3\text{PBN})_2[\text{Cu}_6(\text{S}_6)_4] \cdot 12\text{H}_2\text{O}$.⁶⁰ The authors failed to prepare single crystals suitable for X-ray diffraction study and hence, the formulas were proposed by analogy with the known $[\text{Cu}_4(\text{S}_4)_x(\text{S}_5)_{3-x}]^{2-}$ and $[\text{Cu}_6(\text{S}_4)_3(\text{S}_5)_3]^{2-}$ salts.^{31,35,36} Metal cations bulkier than alkali

metal cations were used, apparently, with the aim of achieving more complete isolation of depolymerisation products from solutions.

The $[(\text{NH}_3)_2\text{C}_2\text{H}_4][\text{CuS}_5]_n \cdot 4\text{H}_2\text{O}$ salt was synthesised as orange-red single crystals.⁶¹ In the $[\text{CuS}_5]_n^{n-}$ anion formed as an infinite sequence of the $-\text{Cu}-\text{S}-\text{Cu}-\text{S}-$ bonds, each S_5^{2-} ion links three Cu^+ ions (Fig. 13). Therefore, the $[\text{CuS}_5]_n^{n-}$ chains consist of the five-membered CuS_4 and Cu_2S_3 rings. Analogous anionic chains were also observed in the crystals of the $(\text{NMe}_4)[\text{AgS}_5]$ ⁶² and $(\text{NMe}_4)[\text{AgSe}_5]$ salts.⁶³

These examples demonstrate that the properties of the above-described polysulfides are relatively independent of the nature of the outer-sphere cations.

Figure 13. Infinite $[\text{CuS}_5]_n^{n-}$ chains.⁶¹

Treatment of copper with a melt of cesium polysulfide with composition Cs_2S_{11} at 270°C afforded the $\text{Cs}[\text{CuS}_6]$ salt.⁶⁴ In the crystal, the $[\text{CuS}_6]_n^{n-}$ anions form one-dimensional centrosymmetrical $[\text{CuS}_6]_n^{n-}$ chains (Fig. 14) separated by Cs^+ ions. The Cu^+ ions are chelated by the terminal sulfur atoms of the S_6^{2-} ions to form the seven-membered CuS_6 rings. In this case, the terminal sulfur atoms of the S_6^{2-} ion each act also as a bridge between the adjacent copper atoms resulting in the formation of the four-membered Cu_2S_2 rings. The $\text{Cs}[\text{CuS}_6]$ salt is one of a few examples of coordination polymers containing such long polychalcogenide ions.

Figure 14. Infinite $[\text{CuS}_6]_n^{n-}$ chains.⁶⁴

In the crystals of the $\{(\text{Ph}_4\text{P})[\text{AgSe}_4]\}_n$ salt, the trigonal coordination about the silver(I) atom is formed by the Se_4^{2-} ions. However, only five-membered rings occur in this case (Fig. 15). Only one of the terminal selenium atoms of the Se_4^{2-} ion acts as a bridge.⁶⁵

Polymeric silver selenides with stack structures were prepared with the use of ethylenediamine in the supercritical state as the solvent.^{66, 67}

Figure 15. Infinite $[\text{Ag}(\text{Se}_4)]_n^{n-}$ chains.⁶⁵

The crystals of $\text{K}_2\text{Ag}_{12}\text{Se}_7$ contain the 18-membered $\text{Ag}_{12}\text{Se}_6$ rings. The seventh Se^{2-} ion occupies the centre of this ring. In the crystal structure, the rings are packed in stacks resulting in the formation of channels. These channels are occupied by K^+ ions. The sulfide with the same composition, which was prepared under analogous conditions, has quite a different structure.⁶⁸

Oxidation of gold with a melt of potassium polyselenides at 250°C afforded polymeric gold polyselenides KAuSe_5 and $\text{K}_3\text{AuSe}_{13}$ containing the $[\text{AuSe}_5]_n^{n-}$ and $[\text{AuSe}_{13}]_n^{3n-}$ ions, respectively.⁶⁹

Unlike the analogous copper and silver pentachalcogenides, the Au^+ ions in the $[\text{AuSe}_5]_n^{n-}$ anions are linearly coordinated (the SeAuSe angle is 179°) by the bridging Se_5^{2-} ions (Fig. 16a), the latter being coordinated only through the terminal selenium atoms. The structure of the $[\text{AuSe}_5]_n^{n-}$ ions is analogous to that of the $[\text{AuSe}]_n^{n-}$ ions with the formal replacement of the Se^{2-} ions by the Se_5^{2-} ions. The $[\text{AuSe}_5]_n^{n-}$ chains are linked through $\text{Au}-\text{Au}$ interactions. The $\text{Au}-\text{Au}$ distance (0.295 nm) is close to that in metallic gold (0.288 nm) and is substantially shorter than the corresponding distances in KAuSe^{70} and in α - and β - AuSe^{69} . Therefore, the presence of $\text{Au}-\text{Au}$ contacts leads to dimerisation of polymeric $[\text{AuSe}_5]_n^{n-}$ ions. In this case, the gold atom has the d^{10} configuration and this dimerisation is one of a few examples of $d^{10}-d^{10}$ interactions. Formally, a combination of two filled d -orbitals of the gold atom gives bonding and antibonding orbitals resulting in the absence of a bond. However, it is known that the relativistic effects are essential in the case of heavy elements, such as gold,⁷¹ and the reasoning regarding the electronic structures of silver complexes, which is based on the nonrelativistic approach, is incorrect. Pekka⁷¹ examined the role of relativistic effects in studies of the structural molecular characteristics. If these effects are taken into account, the bond lengths are decreased, the value of this decrease being proportional to the square of the charge on the atomic nucleus and varying from 0.250–0.300 nm for AuH to 0.450–0.500 nm for Au_2 . Correspondingly, the force constant and the dissociation energy of the Au_2 molecule increase by factors of more than four and two, respectively. The role of the relativistic effects decreases as the bond ionicity increases. Therefore, this role should be noticeable in gold chalcogenides in which the degree of covalence of the $\text{Au}-\text{X}$ bonds is large. Dimerisation of the $[\text{AuSe}_5]_n^{n-}$ ions is a prominent example of this phenomenon.

The presence of these bonds between ions with closed shells was also described for other gold compounds, in particular, for the complex $[\text{Au}_2\text{Se}_5]^{2-}$ and $[\text{Au}_2\text{Se}_6]^{2-}$ anions,⁷² and for the sulfide $\text{Ti}_2\text{Au}_4\text{S}_3$.⁷³ Since this phenomenon is unknown in the chemistry of other elements, it was suggested⁷² that the term 'aurophilic attraction' to be used for the $\text{Au}^+ - \text{Au}^+$ interaction. The authors believed⁷² that the aurophilic attraction is a result of correlation effects, which are ignored in the Hartree–Fock approximation.

Figure 16. Structure of the $[\text{AuSe}_5]_n^{n-}$ (a) and $[\text{AuSe}_{13}]_n^{3n-}$ chains (b).⁶⁹

However, the authors restricted themselves only to nonrelativistic calculations. Hence, the above-considered interpretation, in which the importance of the relativistic effects in chemistry was emphasised, is, admittedly, more reliable (see also the study⁷⁴).

The $[\text{AuSe}_{13}]_n^{3n-}$ ion also has an unusual structure. This ion can be described as the catenabis(pentaseleido- μ -triseleido-aurate)(III) ion $[\text{Se}_5\text{Au}(\mu\text{-Se}_3)\text{AuSe}_5]_n^{3n-}$. This is the only known complex containing simultaneously the monodentate Se_5^{2-} ions and the bridging Se_3^{2-} ions coordinated to the Au^{3+} ions (Fig. 16 b).

The reaction performed under the same conditions (ethylenediamine in the supercritical state) with the use of sodium polyselenides instead of potassium polyselenides afforded Na_3AuSe_8 .⁷⁵ The crystals of this complex contain polymeric chains formed by the planar-square Au^{3+} complexes. Two Se_3^{2-} ions are coordinated in a monodentate fashion.

The polymeric complexes $(\text{Me}_4\text{N})[\text{MTe}_4]$ ($\text{M} = \text{Cu}$ or Ag) containing tetratelluride ions were prepared for the first time in 1993.⁴³ These complexes, unlike the analogous tetrasulfides and tetraselenides, have layered structures (see Fig. 17). The layers consist of the five-membered MTe_4 rings. Each Te_4^{2-} ligand links three copper atoms. An interesting feature of this structure is the presence of cavities formed by 14-membered rings (see Fig. 17). The size of the cavity is determined by the shortest distances between the opposite tellurium atoms (0.6034 and 0.6195 nm). The $(\text{Me}_4\text{N})[\text{MTe}_4]$ salts are diamagnetic semiconductors with the width of the forbidden band of 0.80 and 0.90 eV for $\text{M} = \text{Cu}$ and Ag , respectively.

In attempting to prepare mixed copper sulfidotelluride complexes from melts of $\text{Cs}_2\text{S}_x\text{Te}_y$, the authors⁶⁴ isolated the $\text{Cs}_6\text{Cu}_2(\text{S}_6)_2(\text{TeS}_3)_2$ complex containing the dimeric $[\text{Cu}_2(\text{S}_6)_2(\text{TeS}_3)_2]^{6-}$ anion (Fig. 18). In this anion, two Cu^+ ions are chelated by two Se_6^{2-} ions (the seven-membered CuS_6 rings) and are linked to each other through two bridging TeS_3^{2-} ions. Only one sulfur atom of each TeS_3^{2-} ion is involved in coordination, i.e., the four-membered Cu_2S_2 rings are formed. The trithiotellurite ion differs sharply in this property from the isoelectronic SO_3^{2-} ion.

Figure 17. Structure of the $[\text{CuTe}_4]^-$ layers.⁴³ One of the 14-membered rings is hatched.

Figure 18. Structure of the $[\text{Cu}_2(\text{S}_6)_2(\text{TeS}_3)_2]^{6-}$ ion.⁶⁴

Unfortunately, successful attempts to prepare mixed selenidotelluride complexes are as yet unknown although their syntheses are quite possible because selenium and tellurium differ in properties to a lesser degree than sulfur and tellurium. For example, mixed sulfidoselenide complexes were formed in the $\alpha\text{-CsCu}(\text{S}_x\text{Se}_{4-x})$ and $\text{CsCu}(\text{S}_x\text{Se}_{6-x})$ systems.⁷⁶

IV. Chalcogenides containing only X^{2-} and/or X_2^{2-} ions

The majority of compounds of this type give crystals with essentially covalent $\text{M}-\text{X}$ bonds. Many of these compounds possess metallic properties and exhibit superconducting properties at low temperatures (Table 1). According to the RVB theory,⁵⁻⁹ the metallic state in these crystals can occur on condition that the metal atoms exhibit a mixed valence.

It is well known that the simplicity of the electronic structures of chalcogenides, such, for example, as CuS or CuS_2 , is more apparent than real. Thus, according to the X-ray diffraction data, the formula $\text{Cu}_4^+\text{Cu}_2^+(\text{S}_2^{2-})_2(\text{S}^{2-})_2$ should be assigned to covellite CuS , i.e., both the metal and chalcogen atoms in this compound exhibit mixed valences.¹⁷ However, after the results of the study performed by Jellinek were reported,⁷⁷ the question about the electronic structures of copper chalcogenides became a matter of discussion. Based on the results of X-ray photoelectron spectroscopy, Jellinek assigned the degree of oxidation of +1 to the copper atoms in all chalcogenides (for example, in CuS , CuSe , CuTe , CuS_2 , KCu_4S_3 , etc.). To satisfy the principle of electronegativity of the salts, Jellinek had to represent the structures of the copper chalcogenides by formulas, which are absurd from the chemical standpoint, such as, for example, Cu^+Te^- for CuTe , $\text{Cu}_3^+(\text{S}_2^{2-})\text{S}^-$ for CuS or $\text{K}^+\text{Cu}_4^+\text{S}_2^{2-}\text{S}^-$, where S^- and Te^- are nothing but radical ions, which should be dimerised to the S_2^{2-} and Te_2^{2-} ions, respectively. I do not share the opinion of Jellinek and believe that one of the reasons for the absence of lines from the Cu^{2+} ions in the X-ray photoelectron spectra⁷⁷ is a mistake in the procedure for the preparation of samples. Thus, ground samples of the dichalcogenides were applied to the freshly purified surface of indium. In this case, it is quite possible that the chalcogenide reacted with indium as a result of which Cu^{2+} was reduced to Cu^+ on the surface:

The authors⁷⁷ did not perform subsequent treatment of the surface of the samples under study with Ar^+ ions (to remove the surface layer containing the adsorbed molecules) until this treatment ceased to affect the spectral patterns. Note also that the formulas proposed by Jellinek do not allow one to explain the fact that the above-mentioned chalcogenides possess the metallic conductivity. Since both the Cu^+ and S_2^{2-} ions have filled electron shells, only the S^- ions (actually, these ions are the S^{2-} radical anions) can be responsible for the charge transfer. Interactions between the orbitals of the adjacent S^- species would necessarily lead to the formation of the covalent bond

and hence, the formulas proposed by Jellinek would be more properly written as $\text{Cu}_2^+(\text{Te}_2^{2-})$ or $\text{Cu}_6^+(\text{S}_2^{2-})_3$. However, in this

case, the copper chalcogenides would exhibit dielectric properties and, moreover, the above-considered formulas are contradictory to the structural data.¹⁷

The fact that the approach proposed by Jellinek is inadequate gave impetus to the more accurate determination of the structure of CuS. Thus, Gotsis *et al.*⁷⁸ attempted to redetermine the structure of CuS by the high-resolution X-ray powder diffraction method and calculated the electronic structure using density functional theory. Based on the results obtained, the authors reasoned that the $\text{Cu}^+ - \text{S}_2^{2-} - \text{Cu}^+$ formula is more realistic for CuS (the authors believed that this formula is also appropriate for CuSe). However, this interpretation of the charge state of CuS suffers from drawbacks analogous to those of Jellinek's interpretation. Liang and Whangbo⁷⁹ believed that the $\text{Cu}_3^+(\text{S}_2)\text{S}^{2-}$ formula is more adequate than the formula suggested by Jellinek [$\text{Cu}_3^+(\text{S}_2^+)\text{S}^-$]. Although the authors noted the substantially covalent character of the Cu–S bond, they concluded that holes in the valence band are associated with oxidation of only sulfur, *i.e.*, the authors did not assume the mixed-valence state for copper.

A study⁸⁰ was devoted to the electronic structures of copper chalcogenides and their relationship with the conductivity. The authors calculated the electronic structures of copper sulfides with the use of the extended Hückel method and demonstrated that holes are approximately equally distributed over copper and sulfur atoms due to substantial overlap between the $3p$ orbitals of the sulfur atoms and the $3d$ orbitals of the copper atoms. This indicates that the classical formula for CuS is more realistic and, as will be seen from the data given below, agrees with the existence of charge density waves (CDWs) in conducting chalcogenides based on copper.

The X-ray photoelectron spectra of samples of highly pure CuS, which was synthesised according to a procedure reported in the handbook,⁸¹ have lines at 932.2 and 933.7 eV with the intensity ratio of 1.3 : 1.¹⁰ These lines correspond to the energies of the $2p_{3/2}$ levels of copper [$\text{ECu}(2p_{3/2})$]. The first and second lines can be assigned to the Cu^+ and Cu^{2+} ions, respectively. Note that the $\text{ECu}(2p_{3/2})$ value given for CuS (932.8 eV) in the handbook⁸² is the average of the values determined in the study.¹⁰ Jellinek⁷⁷ reported an obviously unrealistic value of 931.4 eV, which is even smaller than that for Cu_2S (*cf.* 932.0 eV⁷⁷ and 932.9 eV⁸²).

To summarise, it can be noted that the problem of the determination of the charge state of copper in chalcogenides is in essence identical to that for oxide HTSCs based on copper. However, in the case of chalcogenides the situation is more complex because the Cu–X bonds in these compounds are more covalent than those in the corresponding oxides.

Taking into account the complexity and ambiguity of the determination of charge states of the copper and chalcogen atoms in chalcogenides, hereinafter the following approach will be used.

Chalcogenides are considered to be compounds of monovalent copper if the sum of the degrees of oxidation of the cations is equal to twice the number of the chalcogen atoms (*i.e.*, on the assumption that the degrees of oxidation of the chalcogen and copper atoms are -2 and $+1$, respectively). If this sum is smaller than twice the number of the chalcogen atoms, chalcogenides are considered as mixed-valence compounds in which the degree of oxidation of copper is larger than $+1$ and the degree of oxidation of chalcogen is larger than -2 . Thus, according to this approach, sulfide NaCu_5S_3 contains the Cu^+ and S^{2-} ions, whereas sulfide NaCu_4S_3 is a mixed-valence compound. This approach is known in the literature as Zintl's concept (according to Ref. 83).

Ternary copper chalcogenides can be divided into two groups: compounds with chain structures and compounds with layered structures. At the same time, according to the above-proposed approach, these compounds can be separated into copper(I) chalcogenides and mixed-valence copper chalcogenides (the degree of oxidation of copper is larger than unity). The fruitfulness of this approach is apparent. Thus, virtually all copper(I) chalcogenides are semiconductors, whereas mixed-valence copper chalcogenides possess the metallic conductivity.

All chalcogenides of the general formula $\text{MCu}_2\text{X}_{n+1}$ (where M is alkali metal, X is chalcogen, $n = 1-3$) have layered structures. The following layered ternary copper chalcogenides are known: TlCu_2Te_2 ,⁸⁰ TlCu_2Se_2 ,⁸⁴ TlCu_2S_2 , TlCu_2SeS ,⁸⁵ TlCu_4S_3 , TlCu_4Se_3 ,^{80,86} KCu_4S_3 ,⁸⁷ KCu_4Se_3 ,⁸⁶ RbCu_4S_3 ,⁸⁸ RbCu_4Se_3 , CsCu_4S_3 , CsCu_4Se_3 ⁸⁶ and TlCu_6S_4 .⁸⁹ Since the total charge of the cations in the compounds of this series is one less than twice the number of the chalcogen atoms, these chalcogenides should be considered as mixed-valence compounds. It is therefore concluded that the valence band contains holes. Hence, these chalcogenides should exhibit metallic properties.

Selenide TlCu_2Se_2 was prepared⁸⁴ by heating ($< 1050^\circ\text{C}$) stoichiometric amounts of TlSe, copper and selenium *in vacuo* followed by slow cooling. The crystals of TlCu_2Se_2 consist of the Cu–Se layers. The Tl^+ ions are located above and below the layers. The Cu–Se bonds within the layers are substantially covalent. The copper atoms are located inside the tetrahedra formed by the selenium atoms, only three-fourths of positions being occupied (the ThCr_2Si_2 structural type) (Fig. 19).

Figure 19. Crystal structure of TlCu_2Se_2 .⁹⁰

It was found⁹⁰ that the TlCu_2Se_2 salt exhibits metallic properties. To account for this fact, Brun *et al.*⁹⁰ assumed the coexistence of Tl(I) and Tl(III) selenides in the lattice. However, this assumption is contrary to the structural data and the results of electrophysical measurements.⁹¹ Selenide TlCu_2Se_2 possesses the rather high conductivity ($\rho_{RT} = 5 \times 10^{-5} \Omega \text{ cm}$). The temperature dependence of the conductivity, which was measured down to liquid helium temperature, is typical of metals. No substantial difference between the conductivities measured for single crystals and for pressed powders of TlCu_2Se_2 was observed, which is indicative of the weak anisotropy of the resistance of crystals. For TlCu_2Se_2 , the Hall effect was measured and it was demonstrated that this selenide is a metal with hole conductivity (one hole per formula unit, like in the isostructural TlCu_2Te_2 compound⁹¹). This fact rules out the existence of two forms of thallium suggested in the study⁹⁰ because if this were the case, electrons, which fill the conduction band, would act as carriers.

Isostructural sulfide TlCu_2S_2 was prepared by Berger.⁸⁵ Thus, heating a one-phase sample of Tl_4S_3 , which has been synthesised beforehand, with powdered copper and sulfur afforded TlCu_3S_2 the subsequent treatment of which with a concentrated ammonia solution and a 30% H_2O_2 solution yielded TlCu_2S_2 . This compound is unstable⁸⁵ and reversibly decomposes to three phases, *viz.*, to TlCuS , TlCuS_2 and TlCu_4S_3 , on heating to 330 K.

Sulfide TlCu_2S_2 , like the selenide and telluride, exhibits metallic properties.

Later on, chalcogenides TlCu_2X_2 ($\text{X} = \text{S}$ or Se) and mixed chalcogenide TlCu_2SSe were prepared⁹² and studied by X-ray photoelectron spectroscopy. According to Jellinek's concept, the authors⁹² assigned the degree of oxidation of $+1$ to the thallium and copper atoms in TlCu_2SSe . The X-ray photoelectron spectrum of this compound has two lines in the $\text{ECu}(2p_{3/2})$ region. The authors attributed these lines to the difference in the environment about the copper atoms and suggested that one line belongs to the copper atom bound to the selenium atom and the second line belongs to the copper atom bound to the sulfur atom. However, this assignment of the lines implies the structural ordering in the

crystals of the mixed chalcogenide and the equality of the two lines, which was not observed experimentally.

The metal–nonmetal transition should occur on addition of one electron to the valence band of chalcogenide MCu_2X_2 (M is alkali metal) because the valence band becomes completely filled. Actually, the replacement of alkali metal by alkaline-earth metal causes this transition and chalcogenides BaCu_2S_2 and BaCu_2Se_2 exhibit dielectric properties.^{83, 93–95}

Single crystals of BaCu_2X_2 develop an orange colour in transmitted light and a metallic-black colour in reflected light, which is characteristic of semiconductors. In the study,⁹³ chalcogenides BaCu_2X_2 were prepared by heating stoichiometric amounts of barium and copper chalcogenides with metallic copper. In this case, orthorhombic crystals with a chain structure were formed.

Sulfide BaCu_2S_2 was prepared by the reaction of BaCO_3 and CuO with sulfur at 700 °C under a stream of CS_2 .⁹⁴ However, this procedure afforded the tetragonal phase of BaCu_2S_2 ,⁹⁵ which has the layered structure^{83, 95} analogous to the structure of TiCu_2X_2 (the ThCr_2Si_2 structural type).

The conductivity of sulfide BaCu_2S_2 was measured⁹⁶ and this compound was found to exhibit metallic properties in the range of 40–293 K. This result is difficult to explain on the basis of the accepted notion of the electronic structure of chalcogenides because sulfide BaCu_2S_2 does not contain holes in the valence band and can be represented by the formula $\text{Ba}^{2+}\text{Cu}_2^+\text{S}_2^{2-}$. At the same time, it was demonstrated⁸³ that this compound exhibits semiconducting properties at 77–293 K. This discrepancy in the results was accounted⁸³ for by the procedure for the synthesis used in the study,⁹⁶ which afforded a mixture of $\text{Ba}_{0.96}\text{Cu}_{2.01}\text{S}_{1.94}$ and $\text{Ba}_{0.95}\text{Cu}_{3.91}\text{S}_{2.97}$ in a ratio of 17:3. The resistance of the sulfide increases insignificantly (by a factor of ~ 2.7) as the temperature decreases from 300 to 77 K, from which an approximate estimate of the activation energy can be obtained ($E_a \sim 0.01$ eV). This estimate was not made in the study.⁸³ For BaCu_2S_2 , the magnetic susceptibility was measured and the superconductivity was found to be absent to 2 K. The temperature dependence of the magnetic susceptibility is described by the following equation

$$\chi_{\text{exp}} = \frac{C}{T} + \chi_{\text{dia}} + \chi_0,$$

where C is the Curie constant, χ_{dia} is the diamagnetism of the core and χ_0 is the temperature-independent paramagnetism. Judging from the value of the Curie constant ($C = 5.83 \times 10^{-3}$ emu K mol⁻¹), the paramagnetic contribution results from admixtures whose concentration was $\sim 1.5\%$ and BaCu_2S_2 possesses diamagnetic properties. Hence, Zintl's concept appears to be true for both polymorphous modifications of BaCu_2S_2 , which justifies its use in the present review.

Chalcogenides NaCuSe , NaCuTe , KCuSe , KCuTe ⁹⁷ and KCuS ⁹⁸ in which the degrees of oxidation of the copper and chalcogen atoms are +1 and -2, respectively, are similar in electronic properties to BaCu_2X_2 . In spite of the formal similarity, these compounds have different structures. Thus, chalcogenides NaCuSe and NaCuTe belong to the PbFCl structural type, whereas KCuS , KCuSe and KCuTe belong to the Ni_2In structural type (contain zigzag Cu–S chains). The authors related this change in the structural type caused by the replacement of sodium by potassium to the difference in the ionic radii and noted that this change is unusual because only intermetallic compounds rather than salts belong to the Ni_2In structural type. These chalcogenides, judging from their colour, are narrow-band semiconductors. All these compounds were isolated as bright black crystals.

Chalcogenides of the general formula MCu_4X_3 (M is alkali metal and X = S or Se) were described for the first time by Rüdorff.⁹⁹ He isolated the KCu_4S_3 and RbCu_4S_3 salts. The CsCu_4S_3 ⁸⁸ and TiCu_4S_3 ⁸⁶ salts and the selenium analogues MCu_4Se_3 (M = Tl, K, Rb or Cs)⁸⁶ were described. The majority of these compounds were synthesised according to Rüdorff's

carbonate method. Copper and chalcogen were mixed with carbonate of the corresponding metal and the mixture was heated to 650–700 °C. The resulting product was isolated as platelet-like black crystals. The thallium salts were synthesised with the use of Ti_2S or TiSe . Unlike the sulfide, the selenide CsCu_4Se_3 , which was prepared according to the carbonate method, was not a one-phase compound.⁸⁶ The KCu_4Se_3 salt was prepared⁸⁶ also by fusing stoichiometric amounts of K_2Se , Cu and Se in a sealed evacuated quartz tube at 800 °C.

All the above-mentioned chalcogenides have layered structures. The double layers consist of sulfur atoms, which form tetrahedra linked *via* shared edges. The copper atoms are located inside the tetrahedra and the alkali metal or thallium atoms are located between layers. Due to mutual repulsions between the like-charged $[\text{Cu}_4\text{X}_3]_n^{n-}$ layers, it is required by the sizes of the M^+ ions that the M–X distances will be larger than the sum of their ionic radii. Thus, the Na^+ ion is too small to screen mutual repulsions between the layers and hence, NaCu_4X_3 salts do not exist.

Goodenough (according to Ref. 86) suggested the $D_0(n, l)$ criterion, which depends on the electronic configuration of the metal atom and the nature of the bridging ligand. This criterion determines the possibility of the nonmetal–metal transition. According to this criterion, Cu^{2+} sulfide complexes with the d^9 configuration can exhibit metallic properties if the internuclear distances Cu–Cu < 0.31 nm. In sulfide KCu_4S_3 , four Cu–Cu distances are 0.276 nm and one Cu–Cu distance is 0.297 nm. These data satisfy Goodenough's criterion well and, consequently, KCu_4S_3 can exist in the metallic state. Hence, taking into account also the mixed-valence state of the copper and chalcogen atoms (the formal degree of oxidation of copper is +1.25), it can be suggested that chalcogenides MCu_4X_3 are metals. Actually, as early as 1952 Rüdorff found⁹⁹ that KCu_4S_3 and RbCu_4S_3 exhibit metallic properties. According to Rüdorff, the specific resistance ρ_{RT} of KCu_4S_3 and RbCu_4S_3 at ~ 20 °C is 2.5×10^{-2} and 1.67×10^{-2} Ω cm, respectively.

Later on, the major metallic state of KCu_4S_3 was confirmed:⁸⁷ $\rho = 2.5 \times 10^{-4}$ and 1.67×10^{-5} Ω cm at 293 and 20 K, respectively. The specific resistance changes linearly with temperature throughout the temperature range. Sulfide KCu_4S_3 exhibits temperature-independent paramagnetism (Pauli paramagnetism) and shows metallic reflection in the visible and near UV regions. Rüdorff obtained higher values of the electrical resistance because he performed measurements with the use of the double-contact method, which ignored the thermoelectromotive force.

In 1983, it was established¹⁰⁰ that other alkali thiocuprates MCu_4S_3 also exhibit metallic properties. Their electrical resistance changes linearly with temperature in the range of 150–300 K. At ~ 293 K, the resistance is 6.25×10^{-4} , 7.14×10^{-4} and 8×10^{-4} Ω cm for KCu_4S_3 , RbCu_4S_3 and CsCu_4S_3 , respectively. All three salts show temperature-independent paramagnetism.

Selenide CsCu_4Se_3 was prepared¹⁰¹ by the hydrothermal synthesis. Alkali metal polyselenide M_2Se_x (M = Na or K; $x = 2, 4$ or 5), CsCl and copper were placed in a tube with water. The tube was evacuated, sealed and heated at ~ 120 °C for five days. Needle-like crystals of α - CsCu_4Se_4 and platelet-like crystals of CsCu_4Se_3 were isolated from the reaction mixture. The increase in the temperature to 170 °C resulted in an increase in the yield of CsCu_4Se_3 to 80% but the compound was formed as polycrystals. The Cu–Cu distances in selenides MCu_4Se_3 (0.2895 and 0.3071 nm¹⁰¹) satisfy Goodenough's criterion. Hence, taking into account also the mixed-valence states of the copper and selenium atoms, these selenides can be considered as metals.

The crystal structures of the MCu_4X_3 salts¹⁰² are characterised by the presence of octahedral cavities (one cavity per formula unit) between the $[\text{Cu}_4\text{X}_3]_n^{n-}$ layers. The size of the cavity is large enough for an additional copper atom to occupy this cavity. The insertion of copper atoms into the octahedral cavities should lead to annihilation of holes in the valence band and, consequently, should cause the metal–nonmetal transition. According to Zintl's

criterion, chalcogenide MCu_5X_3 contains the $\text{M}^+\text{Cu}_5^+\text{X}_3^{2-}$ ions with the closed shells. The electrochemical reaction

metal
(Pauli paramagnetism)

semiconductor
(diamagnetic)

afforded¹⁰³ chalcogenide KCu_5S_3 (Cu_1 and Cu_0 are the copper atoms occupying the tetrahedral and octahedral positions, respectively); the back reaction, *viz.*, anodic oxidation of KCu_5S_3 , gave the initial sulfide KCu_4S_3 . According to the X-ray diffraction data,¹⁰³ the tetragonal symmetry of the crystals is retained in the course of the reaction. The unit-cell volume decreases from $140.4 \times 10^9 \text{ nm}^3$ for KCu_4S_3 to $129.6 \times 10^9 \text{ nm}^3$ for KCu_5S_3 due to additional attractions between the charged layers caused by the copper ions occupying the octahedral cavities between the layers. The specific resistance increases from $7.34 \times 10^{-4} \Omega \text{ cm}$ for KCu_4S_3 to $1.90 \times 10^{-3} \Omega \text{ cm}$ for KCu_5S_3 , the sign of the temperature resistance coefficient changing to minus, *i.e.*, KCu_5S_3 is a semiconductor.

As mentioned above, the NaCu_4S_3 salt does not exist. However, the $\text{Na}_2\text{Cu}_4\text{S}_3$ and NaCu_5S_3 salts are known.^{104,105} Both these salts can be considered as analogues of the KCu_5S_3 salt, in which octahedral cavities are occupied either by Na^+ or by Cu^+ ions. The NaCu_5S_3 salt was prepared by the hydrothermal synthesis and the $\text{Na}_2\text{Cu}_4\text{S}_3$ salt was synthesised from a carbonate melt.

Crystals of NaCu_5S_3 belong to the hexagonal system (unlike tetragonal crystals of KCu_5S_3) (Fig. 20). There are two crystallographically nonequivalent copper atoms per asymmetric unit. The $\text{Cu}(1)$ atoms are almost linearly coordinated by two sulfur atoms. The $\text{Cu}(2)$ atoms are coordinated by three sulfur atoms (as in $\text{Na}_2\text{Cu}_4\text{S}_3$) to form a trigonal pyramid. The $\text{Cu}(1)$ atoms each have four $\text{Cu}(2)$ neighbouring atoms, whereas the $\text{Cu}(2)$ atoms each are surrounded by six $\text{Cu}(1)$ atoms. The $\text{Cu}-\text{Cu}$ distances (0.27 nm) satisfy Goodenough's criterion. However, according to Zintl's criterion, both salts contain ions with closed shells and, consequently, the NaCu_5S_3 and $\text{Na}_2\text{Cu}_4\text{S}_3$ salts are, apparently, semiconductors. This is also true for selenide TiCu_5Se_3 .⁸⁵

Annihilation of holes in the valence band of MCu_4X_3 can be also induced by the replacement of alkali metal by alkaline-earth metal. Sulfide BaCu_4S_3 was prepared¹⁰⁶ by heating a mixture of BaS , copper and sulfur in a sealed evacuated tube at 800°C as crystals, which develop a red colour in transmitted light and exhibit metallic lustre in reflected light. According to the X-ray diffraction data, these are two different phases, *viz.*, the α and β phases. The α phase, which is stable at room temperature, is transformed into the β phase at 640°C . Both phases belong to the

Figure 20. Crystal structure of NaCu_5S_3 projected onto (001). The NaS_6 octahedra (the Na atoms at $z/c = 1/4$ and $3/4$), the linear coordination in $\text{Cu}(1)\text{S}_2$ (the Cu(1) atoms at $z/c = 1/4$ and $3/4$) and the $\text{Cu}(2)\text{S}_3$ pyramids [the Cu(2) atoms at $z/c \sim 0$ and $1/2$].

orthorhombic system. Their structures are similar and consist of chains formed by the BaS_6 trigonal prisms linked to each other *via* shared triangular faces. The copper atoms form infinite zigzag chains in the α phase ($\text{Cu}-\text{Cu}$, 0.275 nm) and infinite linear chains in the β phase ($\text{Cu}-\text{Cu}$, 0.29 nm). In spite of the filled valence band (as follows from the formula $\text{Ba}^{2+}\text{Cu}_4^+\text{S}_3^{2-}$), the short $\text{Cu}-\text{Cu}$ contacts are responsible for the noticeable conductivity ($\rho_{RT} = 0.2 \Omega \text{ cm}$) of the crystals of BaCu_4S_3 , which is virtually independent of the temperature.

Only one salt belonging to the $\text{MCu}_{2n}\text{X}_{n+1}$ series with $n = 3$ is known, *viz.*, TiCu_6S_4 .⁸⁹ This salt was prepared by fusing a mixture of TiS_2 , copper and sulfur in a quartz tube. Its structure is similar to those of the preceding members of the series with $n = 1$ or 2. The crystal contains layers consisting of the CuS_4 tetrahedra alternating with layers of the thallium atoms. The TiCu_6S_4 salt should exhibit metallic properties because it is a mixed-valence compound with the $\text{Cu}-\text{Cu}$ distances of 0.2783 and 0.2917 nm. Actually, the electrical resistance of single crystals of TiCu_6S_4 varies (although not quite linearly) proportional with temperature. The crystals are characterised by a plus sign of the Hall constant. The concentration of holes was determined from this constant (+1.29 per formula unit). Berger and Eriksson⁸⁹ noted that the effective radius of sulfur increases in the series $\text{TiCu}_{2n}\text{S}_{n+1}$ as n increases and related this effect to a change in the concentration of holes in the valence band per sulfur atom. A decrease in the ratio from +0.5 at $n = 1$ to +0.25 at $n = 3$ correlates with an increase in the radius (the closer the charge of sulfur to -2 , the larger the radius). This interpretation is reasonable. However, from this interpretation it does not follow that holes are localised exclusively on the sulfur atoms.

In chalcogenides TiCu_7X_4 ($\text{X} = \text{S}$ or Se), which are derivatives of the TiCu_6S_4 salts, additional copper atoms occupy cavities, which leads to filling of the valence band and causes the metal–nonmetal transition.⁸⁵ The mineral crookesite with composition $\text{TiCu}_{6.8}\text{Se}_4$, in which 80% of vacancies are occupied, possesses metallic properties⁸⁹ because the valence band is only partially filled (there are +0.2 holes per formula unit in the crystal).

The members of the MCu_6X_4 series are represented only by thallium salts. However, the ammonium analogue of TiCu_7X_4 , *viz.*, the $\text{NH}_4\text{Cu}_7\text{S}_4$ salt, is known. This salt satisfies Zintl's criterion and, consequently, has a filled valence band.⁸⁷ Judging from the $\text{Cu}-\text{Cu}$ bond lengths (0.283 and 0.294 nm), this salt possesses semiconducting properties.

Since no salts of the $\text{MCu}_{2n}\text{X}_{n+1}$ series with $n > 3$ are available, the question of whether these salts can exist was considered theoretically.⁸⁰ The formal analogy of the reactions of the type

was drawn to the so-called isodesmic reactions, which are well known in theoretical organic chemistry. In these reactions, the number of bonds of a particular type remains invariant, but their relative arrangement changes. For example,

It was demonstrated that this concept is applicable to two layers of the $\text{Cu}_{2n}\text{X}_{n+1}^{q-}$ anions ($q = 1$ or 2) and the energy effects of the isodesmic reactions with the participation of these anions were calculated (the extended Hückel method).⁸⁰

Reaction	(2)	(3)	(4)
$\Delta E/\text{eV}$ ($q = 1$)	−0.320	−0.159	−0.061
$\Delta E/\text{eV}$ ($q = 2$)	−0.023	−0.002	0.000

The results of calculations are in complete agreement with the experimental data. Thus, these reactions are most favourable for compounds with $q = 1$, viz.,

where M is a single-charged ion (alkali metal or thallium). These reactions are less favourable for analogous barium salts ($q = 2$). Thus, the absence of the BaCu_6S_4 salt is attributable to fact that the gain in energy is virtually absent for the reaction

Judging from the very low energy of reaction (4), MCu_8S_5 salts, most probably, do not exist.

The absence of compounds of the $\text{MAG}_{2n}\text{X}_{n+1}$ series lends support to the validity of the approach, which we applied to the determination of the electronic structures of ternary copper chalcogenides. In these compounds, silver should possess mixed valence because the oxidation state of this element in chalcogenides is no greater than +1. However, when hydrogen sulfide was passed through a melt of $\text{Ba}[\text{Ag}(\text{CN})_2]$ in a mixture with KNCS (500 °C, 30 min), the sulfide BaAg_2S_2 (CaAl_2Si_2 structural type), which meets Zintl's concept, was obtained.¹⁰⁷ The structure of CaAl_2Si_2 is characterised by the presence of the $[\text{Al}_2\text{Si}_2]^{2-}$ structural elements in which three crystallographically equivalent Si–Al bonds are shorter than the fourth bond directed along the c axis. An analogous situation was observed in the crystals of BaAg_2S_2 , with the only difference that three equivalent S–Ag bonds (0.2686 nm) are longer than the fourth bond (0.2659 nm). The data on the conductivity were not reported in the study.¹⁰⁷ However, based on Zintl's concept and taking into account the dark-red colour of the crystals, it is believed that sulfide BaAg_2S_2 is a semiconductor.

Chalcogenides $\text{K}_2\text{Ag}_4\text{S}_3$ ^{87, 110} (Fig. 21 *a*) and KAg_4Se_3 ¹⁰⁹ (analogues of $\text{Na}_2\text{Cu}_4\text{S}_3$) as well as RbAg_5S_3 ¹⁰⁸ (an analogue of NaCu_5S_3) and CsAg_7S_4 ¹⁰⁸ (an analogue of TlCu_7S_4) satisfy Zintl's criterion. The $\text{M}_2\text{Ag}_6\text{S}_4$ salts ($\text{M} = \text{Na}$ or K) containing an alkali metal atom instead of the seventh silver atom were reported.⁶⁶ These chalcogenides were prepared according to the carbonate procedure by heating a mixture of powdered silver, chalcogen and the corresponding alkali metal carbonate to 1000 °C for ~ 6 h. Since the resulting anthracite-like bright crystals are unstable in air, the authors¹⁰⁹ failed to isolate the $\text{K}_2\text{Ag}_4\text{Se}_3$ salt as single crystals suitable for X-ray diffraction analysis.

Figure 21. Projections of the structures $\text{K}_2\text{Ag}_4\text{S}_3$ (*a*) and CsAg_3S_2 (*b*) along the b axis.

The RbAg_5S_3 and CsAg_7S_4 salts were prepared as dark-red needle-like crystals according to the carbonate procedure by heating in an autoclave (~ 300 °C, 84 h) with the use of ethylenediamine in the supercritical state as the solvent.

The hexagonal crystals of RbAg_5S_3 contain the Ag_6S_6 twelve-membered rings in which the silver and sulfur atoms adopt the coordination number of 3. The rings are linked to each other through the silver atoms (the coordination number is 2) with the nearly linear coordination and are packed in stacks. The structure contains channels with a diameter of ~ 0.7 nm. These channels are occupied by the Rb^+ ions (Fig. 22). The Ag–Ag distances vary from 0.296 to 0.307 nm, which may indicate the presence of covalent interactions between the Ag^+ ions with the d^{10} configuration. It was noted¹⁰⁸ that the potassium analogue KAg_5S_3 has an analogous structure.

Figure 22. Projection of the structure of RbAg_5S_3 along the c axis;¹⁰⁸ columns containing Rb^+ ions are shown.

The structure of the cesium salt CsAg_7S_4 is unique. The crystals contain the eight-membered Ag_4S_4 rings in which the silver and sulfur atoms adopt the coordination numbers of 2 and 3, respectively. These rings, as in the structure of RbAg_5S_3 , are linked to each other through the silver atoms, which have a nearly linear coordination. The $\text{Ag}^+ - \text{Ag}^+$ contacts, as in the rubidium salt, are in the range of 0.2961–0.3087 nm.⁹⁹ The rings are packed in infinite stacks. The channels (with a diameter of ~ 0.6 nm) formed in the structure are occupied by the cesium ions (Fig. 23).

Analysis of these structures allows the conclusion to be drawn about the similarity of the structural motifs of ternary copper and silver chalcogenides satisfying Zintl's concept. The ions with the d^{10} configuration have the linear or trigonal coordination, whereas the copper ions, which exist in a formal oxidation state greater than +1, are tetrahedrally coordinated.

The compounds of the series of chalcogenides of the general formula MB_3X_2 (M is alkali metal or thallium; $\text{B} = \text{Cu}$ or Ag ; $\text{X} = \text{S}$ or Se) can be considered as chalcogenide derivatives MCu_2X_2

As in the case of reaction (1), the insertion of an additional copper atom leads to annihilation of holes in the valence band and causes the metal–semiconductor transition. Since the compounds of the MB_3X_2 series meet Zintl's criterion, i.e., contain only B^+ ions, these compounds may be thought to possess a structural motif identical to that of the above-considered silver salts.

The first compounds of this series to be prepared by the carbonate procedure were the silver salts RbAg_3S_2 and CsAg_3S_2 .¹¹¹ Their structures are isotypic and are in many respects similar to the structure of $\text{K}_2\text{Ag}_4\text{S}_3$. In both cases, the sulfur and silver atoms form layers between which the alkali metal atoms are

Figure 23. Projection of the structure of CsAg_7S_4 along the c axis;¹⁰⁸ channels formed by eight-membered rings are shown.

located, with the only difference that these layers in MAg_3S_2 are parallel to the (001) plane, whereas these layers in $\text{K}_2\text{Ag}_4\text{S}_3$ are parallel to the (100) plane (see Fig. 21 *a, b*). However, the structures of the layers are different. Thus in the structure of $\text{K}_2\text{Ag}_4\text{S}_3$, the eight-membered Ag_4S_4 rings are linked to each other *via* shared vertices through the bridging sulfur atoms, whereas the analogous rings in MAg_3S_2 are linked *via* shared edges. In Fig. 21 *a, b*, the fused Ag_4S_4 rings, which are similar in appearance but crystallographically nonequivalent, are hatched.

The first compound of the series of copper chalcogenides to be synthesised was sulfide KCu_3S_2 , which was prepared by heating a mixture of K_2CO_3 , copper and sulfur to 850 °C under an Ar atmosphere.¹¹² When the reaction was performed at a temperature lower than 780 °C, sulfides KCu_4S_3 and $\text{K}_3\text{Cu}_8\text{S}_6$ were obtained⁹⁹ (see below). The KCu_3S_2 salt exists as bright black needle-like crystals insoluble in water. These crystals as well as the crystals of MAg_3S_2 ($\text{M} = \text{Rb}$ or Cs) belong to the same structural type (X-ray diffraction data).

Later on,⁸⁸ the cesium salt CsCu_3S_2 was prepared by the carbonate procedure. It was found that brief heating (up to 1.5 h) at 700 °C afforded CsCu_4S_3 . However, an increase in the duration of annealing and in the temperature (4 h, 800 °C) resulted in the CsCu_3S_2 salt, which was free from admixtures. Unlike the blue-black crystals of CsCu_4S_3 , the crystals of CsCu_3S_2 are transparent and almost colourless. Since these crystals are oxidised in air and develop a dark-brown colour, they are stored under an inert atmosphere. From the colour of the crystals and their composition, which satisfies Zintl's criterion, CsCu_3S_2 can be unambiguously assigned to compounds possessing dielectric properties.

In spite of the formal similarity to KCu_3S_2 , the crystal structure of CsCu_3S_2 is quite different (the CdI_2 structural type). The sulfur atoms form hexagonal close packing. Half of octahedral positions are occupied by layers of Cs^+ ions. The layers with unoccupied octahedral positions, which remain unoccupied in the structure of CdI_2 , are filled with copper atoms located at the centres of the edges of the octahedra (Fig. 24). The sulfur (the coordination number is 3) and copper (the coordination number is 2) atoms form layers perpendicular to the c axis. The copper ions have a linear coordination, which is uncommon in the chemistry of alkali chalcogenides of copper. It is evident from the above-considered examples of chalcogenides, which meet Zintl's criterion, that trigonal coordination or trigonal coordination combined with the linear coordination is more typical of these compounds.

Figure 24. Projection of the structure of CsCu_3S_2 along the c axis.⁸⁸

In the above-considered sulfide KCuS , the copper atoms have a linear coordination (the SCuS angle is 179 °). However, the crystal structure consists only of chains, which impart the quasi-one-dimensional structure to this salt. The $\text{Cu}-\text{S}$ distances in KCuS (0.213 and 0.216 nm) and in CsCu_3S_2 (0.217 nm) are virtually identical and are typical of copper sulfides with covalent bonds.

The thallium chalcogenides TlCu_3X_2 ($\text{X} = \text{S}$ or Se) described previously^{85, 113–117} were synthesised in two stages. Initially, Tl_4S_3 was prepared from the elements. Then, the fusion of the latter with copper and sulfur afforded sulfide TlCu_3S_2 .

These chalcogenides are very sensitive to oxidising agents. Thus, the selenide is oxidised in air, whereas active oxygen formed upon decomposition of hydrogen peroxide is required to oxidise the sulfide. The reaction

can be performed by oxidation (including electrochemical oxidation^{116, 117}). Berger called this reaction 'extraction' of copper from TlCu_3X_2 . This reaction is analogous to the above-described process (1) for the $\text{KCu}_5\text{S}_3-\text{KCu}_4\text{S}_3$ system and can be formally represented by Scheme (5). To perform chemical oxidation, powdered TlCu_3S_2 was deposited on a glass filter (with the aim of performing the process in a dynamic mode) and an ammonia solution of hydrogen peroxide, which decomposed under the action of the sulfide, was added dropwise. Ammonia that was released coordinated the Cu^{2+} ions, which were formed as result of oxidation, thus facilitating their extraction into a solution.

Selenide KCu_3Se_2 was synthesised by heating (910 °C, 3 h) a mixture of powdered copper, potassium and copper selenide in a quartz tube.¹¹⁸ The KCu_3Se_2 salt was obtained as well-faceted black platelet-like crystals. Its crystal structure is analogous to that of TlCu_3S_2 (X-ray diffraction data).

The data on other copper selenides MCu_3Se_2 are unavailable in the literature. However, analogous silver selenides RbAg_3Se_2 and CsAg_3Se_2 were reported.¹⁰⁹ Both salts crystallise as dark anthracite-like crystals and are readily oxidised in air. Their structures are similar to those of the analogous sulfides. The selenium and silver atoms form layers separated by layers of the M^+ ions.

Sulfide $\text{Na}_2\text{Cu}_3\text{S}_3$, which crystallised as needles, was described in a pioneering study.⁹⁹ More recently, it was demonstrated¹¹⁹ that this sulfide has in fact the composition $\text{Na}_3\text{Cu}_4\text{S}_4$ and its structure contains the $[\text{Cu}_4\text{S}_4]^{3n-}$ stacks. Below is schematically shown the formation of these stacks from the *cis*- CuS chains. The coordination about the copper atoms is planar-trigonal.

The stacks are separated by the Na^+ ions, thus imparting the quasi-one-dimensional electronic structure to the crystals. The shortest $\text{Cu}-\text{Cu}$ distances (0.2619–0.306 nm) satisfy Goode-nough's criterion. Besides, the $\text{Na}_3\text{Cu}_4\text{S}_4$ salt is a mixed-valence compound. As was noted in the study,¹¹⁹ all copper atoms in the

structure are equivalent, which is typical of metallic bonds (electrons delocalised along the $[\text{Cu}_4\text{S}_4]_n^{3n-}$ stacks), and sulfide $\text{Na}_3\text{Cu}_4\text{S}_4$ should exhibit metallic properties.

The electrophysical properties of this sulfide were examined.^{100,120} The electrical resistance of single crystals of $\text{Na}_3\text{Cu}_4\text{S}_4$ was found¹²⁰ to change linearly as the temperature decreased over the range from 300 to 150 K. Below 150 K, the $\rho(T)$ dependence becomes weaker, tends to saturation and reaches $3.3 \times 10^{-6} \Omega \text{ cm}$ at 15 K.¹⁰⁰

The electrical resistances for tableted samples at 293 K ($\rho_{RT} = 3.3 \times 10^{-3} \Omega \text{ cm}$) and 15 K ($\rho_{15} = 6.7 \times 10^{-4} \Omega \text{ cm}$) were reported.¹⁰⁰ For single crystals, the electrical resistance along the crystal axis, *i.e.*, along the stacks, was measured ($\rho_{RT} = 6.5 \times 10^{-5} \Omega \text{ cm}$). This $\rho(T)$ dependence is characteristic of metals.

Although Ghosh and Chaudhury¹⁰⁰ failed to measure $\rho_{\perp}$ (the resistance perpendicular to the stacks), the noticeable difference (by a factor of ~ 50) in the resistance of tableted samples and single crystals is indicative of the substantial anisotropy of the electrical resistance. The temperature-independent paramagnetism, which was found in the studies^{100,120} (150×10^{-6} and $170 \times 10^{-6} \text{ emu mol}^{-1}$, respectively), is also evidence in favour of the metallic state of $\text{Na}_3\text{Cu}_4\text{S}_4$.

It should be noted that the change in the specific electrical resistance according to the law

$$\rho = \rho_0 + \rho' T \quad (7)$$

is typical of normal metals, unlike quasi-one-dimensional molecular metals, whose specific resistance changes quadratically. The authors^{100,120} used the approach proposed by Jellinek in studies of sulfide $\text{Na}_3\text{Cu}_4\text{S}_4$ as a salt containing only Cu^+ ions and mentioned that the oxidation state of +2 for copper atoms was not revealed by X-ray photoelectron spectroscopy. Curiously, the authors¹²⁰ considered all sulfur atoms as being also identical, whereas Jellinek's concept requires the presence of S^{2-} and S^- ions in the structure. However, this is quite reasonable when it is considered that the compound under study is a metal and the electrons are delocalised along the stacks. In this case, the valence fluctuations $\text{Cu}^{2+} \rightarrow \text{Cu}^+$ within the stack occurred in $\sim 10^{-16} \text{ s}$.

The absence of the metal–nonmetal transition up to 13 K and the peculiarities in the $\rho(T)$ dependence associated with the formation of charge density waves (CDWs) are not understood. It is known¹²¹ that the so-called Peierls instability, which is manifested in the structural distortion of the one-dimensional chain associated with the increase in its period, is characteristic of quasi-one-dimensional metals. If the degree of filling of the band with electrons or holes is n^{-1} , a decrease in the temperature leads to n -merisation of the chain accompanied by splitting of the conduction band in such a way that the metal–nonmetal transition occurs. In this case, the larger is n , the smaller the gain in energy.

The reasons for the absence of the Peierls transition in the crystals of $\text{Na}_3\text{Cu}_4\text{S}_4$ up to 13 K were theoretically examined.¹²² In particular, it was noted that $\text{Na}_3\text{Cu}_4\text{S}_4$ is a one-dimensional metal because the shortest distance between the adjacent one-dimensional $[\text{Cu}_4\text{S}_4]_n^{3n-}$ stacks (0.423 nm) in this salt is substantially larger than the sum of the van der Waals radii of sulfur atoms (0.360 nm). Calculations within the framework of the extended Hückel method demonstrated that the Fermi level intersects two bands, each being formed half by the 3d orbitals of the copper atoms and half by the 3p orbitals of the sulfur atoms. Hence, Whangbo and Canadell¹²² believed that the hybrid formula including both the Cu^{2+} and S^- ions, *viz.*, $\text{Cu}_3^+\text{Cu}^{2+}\text{S}_4^{2-}$ and $\text{Cu}_4^+\text{S}_3^{2-}\text{S}^-$, is more adequate than Jellinek's formalism. This view is similar to our approach to the interpretation of the electronic structures of copper chalcogenides, which do not meet Zintl's concept.

Whangbo and Canadell¹²² believed that the state with CDWs preceding the Peierls transition is not formed due, probably, to the fact that the stabilisation of the electronic energy is exactly

compensated by the deformation energy of the stack. In the case of one-dimensional metals in the absence of states with CDWs, an alternative possibility consists in the formation of spin density waves (SDWs), which is generally observed at lower temperatures. In a review,¹²¹ we noted that the spin–lattice interaction responsible for the spin-Peierls transition is more efficient than the electron–lattice interaction at $t \approx U$, where t is the integral of the electron transition between the nearest electronic states and U is the interaction energy of two electrons located at one node. In one-dimensional conductors $[\text{MS}_4\text{C}_4(\text{CF}_3)_4]\text{TTF}$ ($\text{M} = \text{Cu}$ or Au ; TTF is tetrathiafulvalene), the spin-Peierls transition is observed at 12 (Cu) and 2.1 K (Au). I believe that the deviation of the $\rho(T)$ dependence from the linearity for $\text{Na}_3\text{Cu}_4\text{S}_4$ at $T < 80 \text{ K}$ is, probably, caused by fluctuations preceding the spin-Peierls transition at $T < 13 \text{ K}$.

A series of ternary copper sulfides M_nCuS with the Cu : S ratio of 1 : 1 can be distinguished based on formal attributes. In this series, all members with n from 0 (CuS) to 1 (KCuS) are known, the n value varying with a step of 0.25. Thus, the above-considered sulfide $\text{Na}_3\text{Cu}_4\text{S}_4$ corresponds to $n = 0.75$, whereas the above-considered layered sulfides MCu_2S_2 (the first members of the $\text{MCu}_{2n}\text{X}_{n+1}$ series) are characterised by $n = 0.5$. Finally, sulfide NaCu_4S_4 synthesised in 1996¹²³ corresponds to $n = 0.25$. It should be noted that the M_nCuS series can be distinguished only formally because the insertion of alkali metal into the lattice of CuS leads not only to a change in the electronic properties but also to a change in the structure. Thus, unlike $\text{Na}_3\text{Cu}_4\text{S}_4$, which has a quasi-one-dimensional stack structure, NaCu_4S_4 has a layered structure, though formally contains the same Cu_4S_4 structural elements.

Heating of a mixture of copper, Na_2S and BaS with sulfur (taken in a ratio of 1 : 3 : 0.5 : 6, respectively) in an evacuated glass tube (500 °C, 4 days) followed by cooling at a rate of 4 °C/h afforded a melt, which was freed off from polysulfides with water and DMF under a nitrogen atmosphere. As a result, platelet-like black crystals of NaCu_4S_4 were obtained in 79% yield.

The crystals consist of trigonal-symmetrical layers of CuS alternating with layers of Na^+ ions (Fig. 25). The structure of $\text{Na}_{0.25}\text{CuS}$, like CuS, contains both sulfide and disulfide ions. The $[\text{Cu}_4\text{S}_2(\text{S}_2)]^-$ layers have the sandwich structure: the Cu_2S_2 layers (the *anti*-GaS structural type) are located between two CuS layers (the BN structural type). These layers are linked through the copper atoms from the *anti*-GaS layer and through the sulfur atoms from the BN layer to form the Cu–S bond resulting in four-coordinate S^{2-} ions with the unusual inverted tetrahedral geometry. Unlike the structurally similar CuS salt in which the Cu_2S_2 layers of the *anti*-GaS type alternate with the CuS layers of the BN type, half of the *anti*-GaS layers in NaCu_4S_4 are replaced by layers of Na^+ ions. Therefore, the structure of NaCu_4S_4 contains two crystallographically nonequivalent copper atoms,

Figure 25. Packings of the atoms in NaCu_4S_4 (a) and in the $[\text{Cu}_4\text{S}_4]^-$ ions (b) along the c axis (large and small empty circles denote S atoms from two different layers).

viz., the copper atom tetrahedrally coordinated by one S^{2-} ion and three S_2^{2-} ions and the trigonally coordinated copper atom.

Sulfide $NaCu_4S_4$ is a metal with the hole conductivity. Its electrical resistance increases linearly with temperature in the range from 4.2 to 250 K. From measurements of the thermoelectromotive force it follows that holes act as charge carriers. This salt possesses the Pauli paramagnetism, $\chi_M = 6.2 \times 10^{-5} \text{ emu mol}^{-1}$.

Sulfide $BaCuS_3$, which we prepared¹²⁴ by heating a mixture of BaS , CuS and sulfur taken in stoichiometric amounts (800 °C, 2 h), has no analogues. This sulfide was formed as black bright platelet-like crystals belonging to the monoclinic system. Since the composition of this sulfide does not satisfy Zintl's criterion, it is believed that this compound is a metal. Actually, the specific resistance ($\rho_{RT} = 9.4 \times 10^{-2} \Omega \text{ cm}$) of the samples, though large, decreases as the temperature decreases and reaches $0.037 \Omega \text{ cm}$ at 15 K. Unlike other ternary copper sulfides, the $\rho(T)$ dependence is described by a fractional-rational rather than by a linear function

$$\rho(T) = \frac{1 + \alpha T}{\beta + \gamma T}, \quad (8)$$

where $\beta^{-1} = \rho(0)$, *i.e.*, $\beta = \sigma(0)$, $\alpha/\gamma = \rho(\infty)$.

Equation (8) can be rewritten in a more customary form

$$\rho(T) = \rho_\infty + \frac{a}{b + T} \quad (9)$$

with the 'Curie-like' second term. The magnetic susceptibility of metals containing paramagnetic centres is described by this formula. In the case of $BaCuS_3$, the following parameters were obtained for Eqn (9): $\rho_\infty = 0.136 \Omega \text{ cm}$, $a = -18.98 \Omega \text{ cm K}^{-1}$ and $b = 178.3 \text{ K}$.

Note that the temperature dependence of the electrical resistance described by Eqn (9) is untypical of all conducting materials, and not just of ternary sulfides. Analysis of the published data makes it possible to reveal analogous $\rho(T)$ dependences for $Cu_{1.5}Co_{1.5}S_4$,¹²⁵ which has the spinel structure, for $Rb_4Mo_{18}Se_{20}$ ¹²⁶ consisting of Mo_6Se_8 clusters and for spinel-like $CuRh_2S_4$ and $CuRh_2Se_4$.¹²⁷ The dependences reported in these studies are well described by Eqn (9). Apparently, the authors¹²⁷ failed to approximate the $\rho(T)$ dependence throughout the temperature range because the high-temperature region was described by the linear function (7), the temperature range with $T < 20 \text{ K}$ was described by the function

$$\rho(T) = \rho_0 + AT^n \quad (10)$$

with $n = 3$, whereas the temperature range from 20 to 250 K was not interpreted. The authors considered this dependence as the supporting evidence for the applicability of the Wilson model. However, the $\rho(T)$ dependence for single crystals of $BaCuS_3$ as well as that for chalcogenides studied in Refs 125–127 are described by Eqn (9) throughout the temperature range (from 300 K up to the superconducting transition). This result should give impetus to theoretical studies in the field of solid-state physics.

Sulfide $K_3Cu_8S_6$, which was the first representative of ternary copper chalcogenides of the general formula $M_3Cu_8X_6$ (M is alkali metal and $X = S$ or Se), was synthesised as early as the mid-nineteenth century.¹²⁸ Later on, this sulfide, along with other salts described above, was prepared according to the carbonate procedure and studied by the X-ray diffraction method.⁹⁹ However, the structure of this compounds remained unknown. In 1979, structural studies demonstrated¹²⁹ that this sulfide as well as the rubidium analogue $Rb_3Cu_8S_6$ have layered structures analogous to that of KCu_3S_2 . The structures of three sulfides, *viz.*, KCu_3S_2 ($K_3Cu_9S_6$), $K_3Cu_8S_6$ and KCu_4S_3 ($K_2Cu_8S_6$), are shown in Fig. 26 *a–c*. This comparison, which is not just formal, confirms that $K_3Cu_8S_6$ is intermediate between sulfides KCu_3S_2 and KCu_4S_3 . It was demonstrated¹³⁰ that KCu_4S_3 occurs as a low-temperature phase, which is stable up to 820 °C. At higher temperatures, the KCu_3S_2 phase is stable. Sulfide $K_3Cu_8S_6$ occurs as a metastable phase. The optimum conditions for the synthesis of the latter consist in annealing at 875 °C for 1–2 h.

As can be seen from Fig. 26 *a*, the low-temperature KCu_4S_3 phase contains close-packed layers in which all copper atoms are tetrahedrally coordinated. In the high-temperature KCu_3S_2 phase (Fig. 26 *c*), the layers are corrugated because the copper atoms adopt both the tetrahedral and trigonal coordinations. The structure of $K_3Cu_8S_6$ is intermediate between the above-described structures. The $[Cu_4S_4]^{n-}$ chains are linked in layers *via* shared edges of the tetrahedra so that the semisegment of the double layer, which is observed in KCu_4S_3 , is formed. The $Rb_3Cu_8S_6$ salt has the analogous structure.¹²⁹

In the same year, selenides $Rb_3Cu_8Se_6$ and $Cs_3Cu_8Se_6$ were synthesised by the carbonate procedure from powdered copper and selenium sulfide.¹³¹ After annealing at 900–1050 °C (3–4 h), the melt was slowly cooled and washed with water and alcohol to obtain dark anthracite-like crystals. The structure of $Rb_3Cu_8Se_6$ is similar to those of sulfides $K_3Cu_8S_6$ and $Rb_3Cu_8S_6$. Apparently, the cesium salt crystallises in two modifications one of which is analogous to $Rb_3Cu_8Se_6$, whereas the second modification was not identified. The results of electrophysical measurements for selenides are unavailable in the literature. However, based on their compositions and on the shortest Cu–Cu distances (0.2488–0.2893 nm) in these compounds, it can be said with assurance that these compounds are metals.

The electrophysical and magnetic studies of the crystals of $K_3Cu_8S_6$ were performed.¹³⁰ The magnetic susceptibility depends only slightly on the temperature at $T > 180 \text{ K}$. However, this dependence becomes pronounced at temperatures lower than 180 K, which is indicative of a phase transition of the second kind. This transition is reversible. The transition temperature can be determined more accurately from the temperature dependence of the $(\partial\chi/\partial T)$ derivative (150 K). At approximately 50 K, the second transition (of the first kind) with the noticeable hysteresis was observed.

The electrical resistance of single crystals of $K_3Cu_8S_6$ is $5 \times 10^{-4} \Omega \text{ cm}$; the $\rho(T)$ dependence was measured in the range of 350–5 K.¹³¹ The resistance decreases linearly as the temperature decreases, which is indicative of the metallic behaviour of

Figure 26. Structures of sulfides KCu_4S_3 (a), $K_3Cu_8S_6$ (b) and KCu_3S_2 (c).¹³⁰ In all the structures, the K^+ ions separate layers.

single crystals of $\text{K}_3\text{Cu}_8\text{S}_6$ down to 160 K. At about 150 K, a reversible phase transition occurs, which is manifested in an increase in the resistance in the course of subsequent cooling to 63 K. At this temperature, the resistance decreases sharply and from this point on the $\rho(T)$ dependence again corresponds to the metallic behaviour in the region of 50–5 K. The anomaly at about 160 K is also present in the temperature dependence of the thermoelectromotive force. Its plus sign confirms that $\text{K}_3\text{Cu}_8\text{S}_6$ is a metal with hole conductivity. In a study,¹³¹ all these anomalies were attributed to the occurrence of the state with CDWs, which is typical of low-dimensional metals, *viz.*, of quasi-one-dimensional salts {for example, of $\text{K}_2[\text{Pt}(\text{CN})_4]\text{Cl}_{0.3} \cdot x\text{H}_2\text{O}$ and NbSe_3 } and of quasi-two-dimensional salts (TaSe_2). However, this state can also occur in three-dimensional metals (for example, in CuV_2S_4). Sulfide $\text{K}_3\text{Cu}_8\text{S}_6$ can be considered (as is evident from its structure) as a quasi-two-dimensional metal. However, unlike quasi-two-dimensional metals, such as, for example, NbSe_2 or TaS_2 , the layers in $\text{K}_3\text{Cu}_8\text{S}_6$ are noticeably anisotropic, as is evident from the mode of linkage of the Cu_4S_4 columns in layers. The fact that the metallic properties are retained at temperatures lower than the phase transition temperature indicates that this anisotropy is yet inadequate to consider the crystals of $\text{K}_3\text{Cu}_8\text{S}_6$ as quasi-one-dimensional. An analogous anisotropy of the layers occurs, for example, in molybdenum bronze $\text{K}_{0.3}\text{MoO}_3$, which is a structurally two-dimensional metal with a essentially monomeric CDWs.

X-Ray scattering was studied at different temperatures¹³² and it was found that the phase transition at 153 K generates states, which are incommensurate with the lattice period, with the wave vector

$$q = \frac{(1 - \delta)b^*}{2},$$

where δ is the temperature-dependent variable ($\delta \approx 0.1$ at 150 K) and b^* is the reciprocal lattice vector. At 55 K, the wave vector of CDW becomes commensurate with the lattice period, which leads to a structural phase transition resulting in the superstructure with the commensurate period at $q = (\frac{1}{5}, \frac{1}{5}, 0)$. Sulfide $\text{K}_3\text{Cu}_8\text{S}_6$ is the first example of a metal with the hole conductivity in which CDWs with pronounced p character appear.

In conclusion, let us consider a few available examples of tellurides of Group IB elements containing discrete Te^{2-} or Te_2^{2-} ions.

Thus, ternary copper tellurides with compositions MCuTe^{97} and MCu_3Te_2 ^{104, 133} ($\text{M} = \text{Na}$ or K) satisfying Zintl's criterion were described. In 1976, telluride TiCu_2Te_2 was synthesised from the elements (600 °C, 48 h).¹³⁴ This telluride can be assigned to the series of $\text{MCu}_{2n}\text{X}_{n+1}$ chalcogenides. According to the data of X-ray diffraction analysis, this telluride is isostructural to selenide TiCu_2Se_2 . The electrophysical properties of the telluride under consideration were studied in Ref. 90. The electrical resistance (293 K) of single crystals of TiCu_2Te_2 is $2.3 \times 10^{-5} \Omega \text{ cm}$. The $\rho(T)$ dependence is analogous to that corresponding to metals, *viz.*, the resistance decreases linearly (by a factor of 3.5) as the temperature decreases and reaches $6.5 \times 10^{-6} \Omega \text{ cm}$ at 77 K. Holes act as charge carriers (the results of measurements of the Hall effect). Although the electrical resistance decreases as the samples are cooled, the ρ_{300}/ρ_{77} ratio is rather small. This is attributable to the fact that the concentration of the carriers in the sample decreases substantially (by a factor of 21) in the range of 300–77 K simultaneously with an increase (by a factor of 76) in the carrier mobility (from $34 \text{ cm}^2 \text{ V}^{-1}$ at 300 K to $2600 \text{ cm}^2 \text{ V}^{-1}$ at 77 K), *i.e.*, the effect of an increase in the carrier mobility is more pronounced than the effect of a decrease in their concentration. This leads to an increase in the conductivity upon cooling. To put it differently, TiCu_2Te_2 would be more properly characterised as a semimetal.

Layered mixed-valence telluride $\text{K}_2\text{Cu}_5\text{Te}_5$ was synthesised¹³⁵ by heating the telluride K_2Te with copper and tellurium in an evacuated tube (350 °C, 3 days). The telluride was obtained as black parallelepiped-shaped crystals. The structure of this salt

consists of the corrugated $[\text{Cu}_5\text{Te}_5]_n^{2n-}$ layers alternating with the layers of the potassium ions. The $[\text{Cu}_5\text{Te}_5]_n^{2n-}$ layers are formed by the Cu_2Te_2 rhombi linked *via* shared edges so that their structure corresponds to the distorted *anti*- PbO type. A comparison with the structure of CuTe demonstrates that the addition of 0.4 e per CuTe molecule leads to the cleavage of some of $\text{Te}-\text{Te}$ bonds in $\text{K}_2\text{Cu}_5\text{Te}_5$, whereas the addition of one electron (as in NaCuTe) leads to the cleavage of all $\text{Te}-\text{Te}$ bonds and generates the ideal structure of the *anti*- PbO type. Therefore, $\text{K}_2\text{Cu}_5\text{Te}_5$ is intermediate between CuTe and NaCuTe .

The electrical resistance and the thermoelectromotive force were measured for $\text{K}_2\text{Cu}_5\text{Te}_5$ and it was revealed that this telluride is a p -type metal in the range of 300–5 K. The electrical resistance is $6.67 \times 10^{-5} \Omega \text{ cm}$ at 293 K and reaches $3.1 \times 10^{-6} \Omega \text{ cm}$ at 5 K. The telluride possesses temperature-independent paramagnetism ($2.56 \times 10^{-4} \text{ emu mol}^{-1}$).¹³⁵

The electronic structure of the $\text{K}_2\text{Cu}_5\text{Te}_5$ salt was studied by quantum-chemical calculations using the extended Hückel method.¹³⁶ Since the conductivity increases only insignificantly as the temperature decreases in the range of 293–5 K, the nature of the ground state remains unclear, *i.e.*, the question of whether this telluride is a metal or a semimetal remains open. Another problem studied in Ref. 136 is associated with the possibility of the synthesis of tellurides $\text{K}_3\text{Cu}_5\text{Te}_5$ and KCu_5Te_5 . In particular, the question was studied of whether the addition of one electron to the $[\text{Cu}_5\text{Te}_5]_n^{2n-}$ layer or removal of one electron from this layer can lead to the metal–nonmetal transition.

According to the data obtained, the pre-Fermi region ($\varepsilon_F = -10.5 \text{ eV}$) from -10.1 to -12.6 eV is formed predominantly by the $5p$ orbitals of tellurium atoms, whereas the region from -12.6 to -16 eV is formed by the $3d$ orbitals of copper atoms. A broad gap extends from -10.1 to -7.5 eV . However, a narrow peak corresponding to σ^* antibonding orbitals of the $\text{Te}(2)-\text{Te}(2)$ bond is present at -8.3 eV (Fig. 27). The scheme of the structure of the $[\text{Cu}_5\text{Te}_5]_n^{2n-}$ layer is shown in Fig. 27. It can be seen that this layer contains three types of tellurium atoms. Only the $\text{Te}(2)$ atoms are involved in formation of the $\text{Te}-\text{Te}$ bonds. The populations of the $5p_y$ states of the tellurium atoms are approximately equal [1.43, 1.45 and 1.49 e for $\text{Te}(1)$, $\text{Te}(2)$ and $\text{Te}(3)$, respectively], *i.e.*, holes are to a large extent delocalised in the layer. This fact as well as the approximately equal $\text{Cu}(2)-\text{Te}(1)$ and $\text{Cu}(3)-\text{Te}(3)$ distances allows one to consider $\text{K}_2\text{Cu}_5\text{Te}_5$ as a metal. From the results of calculations it follows that the crystals of this telluride should exhibit the noticeable anisotropic conductivity. Unfortunately, it was impossible to measure this anisotropy because of small dimensions of the crystals.

The addition of one electron to the $[\text{Cu}_5\text{Te}_5]_n^{2n-}$ layer, which corresponds to the transformation to $\text{K}_3\text{Cu}_5\text{Te}_5$, leads to filling of the p band formed by the $5p$ orbitals of the tellurium atoms. One would expect that this will result in the metal–nonmetal transition. However, it was demonstrated¹³⁶ that the insertion of potassium leads not only to an increase in the degree of filling of the p band but also to structural changes. The structure of $\text{K}_2\text{Cu}_5\text{Te}_5$ contains vacancies sufficient for location of potassium ions above the $\text{Te}(2)-\text{Te}(2)$ bonds. The insertion of potassium leads to the cleavage of the bonds. In this case, the peak localised at -8.3 eV is broadened and merges with the p band. As a result, $\text{K}_3\text{Cu}_5\text{Te}_5$ retains the metallic properties, possesses two holes per formula unit and is a structural analogue of the NaCuTe salt.

Figure 27. Scheme of the $[\text{Cu}_5\text{Te}_5]_n^{2n-}$ layer.¹³⁶

Upon the removal of one electron, which corresponds to the transformation to KCu_5Te_5 , the $\text{Te}(1)–\text{Te}(3)$ bond could be formed, *i.e.*, the Te_2^{2-} ion could be formed if the potassium atoms located above this bond are removed. This would result in the formation of the energy gap, *i.e.*, in the metal–nonmetal transition. However, according to the results of the study,¹³⁶ the metallic state is retained in this case because there are three $\text{Te}–\text{Te}$ bonds per two holes with respect to $\text{K}_2\text{Cu}_{10}\text{Te}_{10}$.

As part of continuing studies of reactions proceeding in melts of polytellurides, Zhang *et al.*¹³⁷ prepared a new class of polytellurides containing dodecahedral $[\text{Cu}_8\text{Te}_{12}]$ clusters, *viz.*, $\text{K}_4\text{Cu}_8\text{Te}_{11}$, $\text{M}_3\text{Cu}_8\text{Te}_{10}$ ($\text{M} = \text{Rb}$ or Cs), $\text{M}_1\text{M}'_2\text{Cu}_8\text{Te}_{10}$ ($\text{M}, \text{M}' = \text{K}, \text{Rb}$ or Cs) and $\text{M}_2\text{BaCu}_8\text{Te}_{10}$ ($\text{M} = \text{K}, \text{Rb}$ or Cs). Telluride $\text{K}_4\text{Cu}_8\text{Te}_{11}$ has a three-dimensional framework structure formed by the $[\text{Cu}_8\text{Te}_{12}]$ clusters linked to each other. Each layer contains an encapsulated K^+ ion (Fig. 28). The structure contains channels parallel to the b axis. These channels are occupied by potassium ions. The $[\text{KCu}_8\text{Te}_{12}]^{3-}$ clusters are ideal platonic bodies (the point symmetry group T_h) formed by the Cu_2Te_3 planar pentagons linked to each other. Each tellurium atom belongs to a Te_2^{2-} ion so that the clusters are in fact formed by the copper and ditelluride ions $[\text{Cu}_8(\text{Te}_2)_6]$.

Figure 28. Structure of the $[\text{Cu}_8\text{Te}_{12}]$ cluster inside which the K^+ ion is located.¹³⁷

Unlike the $\text{K}_4\text{Cu}_8\text{Te}_{11}$ salt containing three-dimensional networks of the clusters, the $\text{Rb}_3\text{Cu}_8\text{Te}_{10}$ and $\text{Cs}_3\text{Cu}_8\text{Te}_{10}$ compounds have layered structures. The $\text{Rb}_3\text{Cu}_8\text{Te}_{10}$ salt consists of $[\text{RbCu}_8\text{Te}_{10}]_n^{2n-}$ layers alternating with the layers of Rb^+ ions. In spite of a substantial structural difference, the major structural blocks in the latter salt are identical to those observed in $\text{K}_4\text{Cu}_8\text{Te}_{11}$. The layers are formed by the $[\text{Cu}_8\text{Te}_{12}]$ pentagonal dodecahedra linked to each other. The Rb^+ ions are encapsulated into these layers. The structure of the cesium salt is analogous to that of the rubidium salt.

The structural studies of the salts with the mixed composition demonstrated that encapsulation is favourable for ions of smaller radii. Thus, in the $\text{KCs}_2\text{Cu}_8\text{Te}_{10}$ and $\text{KRb}_2\text{Cu}_8\text{Te}_{10}$ salts, the potassium ions are located inside the dodecahedra.

The $\text{K}_2\text{BaCu}_8\text{Te}_{10}$ and $\text{Rb}_2\text{BaCu}_8\text{Te}_{10}$ salts are isomorphous with the $\text{Rb}_3\text{Cu}_8\text{Te}_{10}$ salt. The centre of the dodecahedral cavity is occupied by the Ba^{2+} ion, whose ionic radius is close to that of the K^+ ion. In the case of the potassium salt, the K^+ ions are located between the layers, which implies that encapsulation of the ion with the larger charge is more favourable in the case of the equal ionic radii.

Zhang *et al.*¹³⁷ studied the electrophysical and optical properties of the tellurides synthesised. According to the structural data, the formula of the $\text{K}_4\text{Cu}_8\text{Te}_{11}$ salt can be written as $\text{K}_4\text{Cu}_8(\text{Te}_2)_5\text{Te}$. Taking the charges of the ditelluride and telluride ions to be equal to -2 and the charge of the copper ions to be equal to $+1$, it can be concluded that this salt satisfies Zintl's criterion and, consequently, should exhibit semiconducting properties. This suggestion is also confirmed by the fact that the electrical resistance of the crystals of $\text{K}_4\text{Cu}_8\text{Te}_{11}$ (293 K) is rather small ($6.25 \times 10^{-3} \Omega \text{ cm}$) but it increases according to the activation law as the temperature decreases.

The $\text{M}_3\text{Cu}_8\text{Te}_{10}$ and $\text{MM}'_2\text{Cu}_8\text{Te}_{10}$ salts (which do not meet Zintl's criterion) contain the $[\text{Cu}_8(\text{Te}_2)_4\text{Te}_2]^{3-}$ anions and, consequently, these salts are mixed-valence compounds. According to

the results of quantum-chemical calculations,¹³⁷ the degree of oxidation of copper in these compounds is equal to $+1$ (the $3d$ orbitals of the copper atoms are located substantially lower than the $5p$ orbitals of the tellurium atoms). Therefore, the p band formed by the orbitals of the tellurium atoms contains one hole per formula unit. It is believed that these salts exhibit metallic properties. The data of electrophysical measurements confirmed that the $\text{Rb}_3\text{Cu}_8\text{Te}_{10}$, $\text{Cs}_3\text{Cu}_8\text{Te}_{10}$ and $\text{KRb}_2\text{Cu}_8\text{Te}_{10}$ salts exhibit metallic properties in the range of $5–300 \text{ K}$. Thus, the specific resistance of the samples of $\text{Cs}_3\text{Cu}_8\text{Te}_{10}$ decreases by almost three orders of magnitude from $1.1 \times 10^{-3} \Omega \text{ cm}$ at 293 K to $1.2 \times 10^{-6} \Omega \text{ cm}$ at 5 K . The ρ_5 value for this salt is the smallest among all chalcogenides based on copper.

The thermoelectromotive forces of the $\text{M}_3\text{Cu}_8\text{Te}_{10}$ salts are positive and increase linearly with temperature in the range of $90–300 \text{ K}$, which indicates that these compounds are metals with hole conductivity. The magnetic properties of these salts are also typical of metals. These salts exhibit temperature-independent paramagnetism.

The $\text{M}_2\text{BaCu}_8\text{Te}_{10}$ salts satisfying Zintl's criterion should be analogous to $\text{K}_4\text{Cu}_8\text{Te}_{11}$. It was found that $\text{K}_2\text{BaCu}_8\text{Te}_{10}$ and $\text{Rb}_2\text{BaCu}_8\text{Te}_{10}$ possess the low electrical resistances at 293 K . Their resistances increase only slightly as the temperature decreases down to $\sim 150 \text{ K}$. Below 150 K , the electrical resistance increases more rapidly. This means that either these salts are degenerate semiconductors or they have a very narrow forbidden band. The optical measurements in the visible and UV regions revealed no gaps. However, the gap is observed in the IR region and it corresponds to 0.1 eV for the $\text{Rb}_2\text{BaCu}_8\text{Te}_{10}$ salt. The barium salts exhibit the temperature-independent paramagnetism typical of dielectrics.

The scarce data on copper tellurides allow one to make definite conclusions. Thus, the $\text{Te}\cdots\text{Te}$ contacts, which are shortened compared to the sum of the van der Waals radii, were found in tellurides $\text{Na}_6\text{Te}(\text{Te}_5)$, Na_2Te_6 , M_2Te_3 ($\text{M} = \text{K}, \text{Rb}$ or Cs), M_2Te_5 ($\text{M} = \text{Rb}$ or Cs) and CsTe_4 .¹³⁸ However, these contacts are absent in tellurides containing bulky cations, for example, in $(\text{Ph}_4\text{P})_2\text{Te}_4 \cdot 2\text{MeOH}$ and Me_4NMTe_4 ($\text{M} = \text{Cu}$ or Ag). Apparently, cations characterised by a high charge to radius ratio assist in decreasing Coulomb repulsions between polytelluride ions and in reducing the possibility of $\text{Te}\cdots\text{Te}$ interactions. In this connection, melts of polytellurides containing barium ions along with alkali metal cations were studied further. Thus, isomorphous polytellurides $\text{NaBa}_6\text{Cu}_3\text{Te}_{14}$ and $(\text{K}_{0.60}\text{Ba}_{0.40}) \cdot \text{Ba}_6\text{Cu}_{2.58}\text{Te}_{14}$ were isolated.¹³⁸ The structure of the $\text{NaBa}_6\text{Cu}_3\text{Te}_{14}$ salt is based on the $[\text{Cu}_3\text{Te}_3(\text{Te}_3)_3]^{9-}$ clusters of a new type. These clusters are six-membered rings formed by three copper atoms and three tellurium atoms. Each copper atom is coordinated in a bidentate fashion to the Te_3^{2-} ion, thus acquiring trigonal coordination (Fig. 29). Hence, the cluster ions each contain one six-membered ring and three four-membered rings. The $[\text{Cu}_3\text{Te}_3(\text{Te}_3)_3]^{9-}$ clusters are packed in stacks. The Na^+ ions are encapsulated into the cavities between these stacks. The composition of the stacks can be represented by the formula $[\text{NaCu}_3\text{Te}_3(\text{Te}_3)_3]_n^{8n-}$. Each stack is surrounded by six stacks formed by the Ba^{2+} ions. Each telluride ion is surrounded by six Ba^{2+} ions, thus adopting a trigonal-prismatic coordination environment. Therefore, the structure of this telluride is best described by the formula $\text{Ba}_6[\text{NaCu}_3\text{Te}_3(\text{Te}_3)_3]\text{Te}_2$, which satisfies Zintl's criterion. Because of this and taking into account the existence of ionic $\text{Te}\cdots\text{Te}$ contacts, which are shortened compared to the sum of the van der Waals radii, this telluride would be expected to be a narrow-band semiconductor or a semimetal.

This conclusion was confirmed by both electrophysical and optical measurements. Thus, ρ_{RT} is $\sim 10 \Omega \text{ cm}$, increases according to the activation law as the temperature decreases and reaches $2.5 \times 10^3 \Omega \text{ cm}$ at 20 K , which corresponds to the width of the forbidden band of about 0.01 eV and to the absorption in the far-IR region (at about 40 cm^{-1}). According to the data of measure-

Figure 29. Packing of $\text{NaBa}_6\text{Cu}_3\text{Te}_{14}$ along the c axis.

ments of the thermoelectromotive force, telluride $\text{NaBa}_6\text{Cu}_3\text{Te}_{14}$ is a p -type semimetal (the Seebeck coefficient is $\sim 100 \mu\text{V K}^{-1}$).

The structure of telluride $(\text{K}_{0.60}\text{Ba}_{0.40})\text{Ba}_6\text{Cu}_{2.58}\text{Te}_{14}$ is very similar to that described above, with the difference that the cavities in the $[\text{Cu}_3\text{Te}_3(\text{Te}_3)_3]^{9-}$ stacks are statistically occupied by the K^+ and Ba^{2+} ions. The retention of the electroneutrality is provided by the presence of an equivalent number of vacancies in positions occupied by the copper atoms. This telluride is a p -type semiconductor. Its ρ_{RT} is $10^5 \Omega \text{ cm}$, increases as the temperature decreases and reaches $10^{12} \Omega \text{ cm}$ at 130 K, which corresponds to the width of the forbidden band of 0.69 eV. Both tellurides possess diamagnetic properties.

Telluride $\text{K}_{0.33}\text{Ba}_{0.67}\text{AgTe}_2$ was described.¹³⁹ Unlike analogous tellurides based on copper, this telluride has a layered structure (Fig. 30), which is characterised by the presence of two type of monolayers separated by the K^+ and Ba^{2+} ions. One of the monolayers is a corrugated $[\text{Ag}_2\text{Te}_2]^{2-}$ layer and the second monolayer is a planar-square layer formed by the tellurium atoms. The degree of oxidation of the tellurium ions in the $[\text{Te}_2]^{4/3-}$ monolayer is $-2/3$ on the assumption that the degrees of oxidation of the silver and tellurium ions in the $[\text{Ag}_2\text{Te}_2]^{2-}$ layer are $+1$ and -2 , respectively.

It should be noted that the existence of the ideal planar-square layers formed only by the tellurium atoms is the unique peculiarity of telluride $\text{KBa}_2[\text{Ag}_3\text{Te}_3]\text{Te}_3$. The crystals of the RbTe_6 and $\text{Cs}_3\text{Te}_{22}$ salts¹⁴⁰ also contain planar layers of tellurium atoms. However, these layers can be considered as derivatives of the structure shown in Fig. 30 in which $2/5$ of all tellurium atoms are removed. The double planar layers of tellurium atoms were found in the unusual $(\text{Te}_2)_2(\text{I}_2)$ compound,¹⁴¹ which can be considered as a product of intercalation of tellurium by iodine.

Figure 30. Structure of $\text{K}_{0.33}\text{Ba}_{0.67}\text{AgTe}_2$; (a) the unit cell; (b) the $[\text{Ag}_2\text{Te}_2]^{2n-}$ layers; (c) the $[\text{Te}_2]^{4n-/3}$ layers.¹³⁹

The covalent interactions between the $[\text{Ag}_2\text{Te}_2]$ and $[\text{Te}_2]$ layers are negligible. According to the quantum-chemical calculations within the framework of the extended Hückel method, the Fermi level is located within the band formed by atomic orbitals of the tellurium atoms of the $[\text{Te}_2]$ layer. This corresponds to a gap in the band structure of the $[\text{Ag}_2\text{Te}_2]$ layers. Consequently, this compound can exhibit metallic properties due to the planar-square $[\text{Te}_2]$ layers.

The measurements of the electrical resistance and the thermoelectromotive force demonstrated that this telluride exhibits semiconducting properties. Thus, ρ_{RT} is $\sim 5 \Omega \text{ cm}$ and increases according to the activation law as the temperature decreases. The width of the forbidden band, which was determined from the temperature dependence of ρ , is 0.06 eV to which the optical absorption at energies lower than 0.15 eV corresponds. The semiconducting properties of $\text{K}_{0.33}\text{Ba}_{0.67}\text{AgTe}_2$ are also confirmed by the results of measurements of the thermoelectromotive force. It has a positive value and the Seebeck coefficient is $200 - 300 \mu\text{V K}^{-1}$.

This discrepancy between theory and experiment may be accounted for by different reasons. Thus, it is quite apparent that nonrelativistic calculations for a salt containing the heavy atom, such as tellurium, are inadequate. Another possible reason is that the mixed-valence state of the silver ions in the telluride is absent because silver, unlike copper, obviously cannot exist in chalcogenides in the form of Ag^{2+} . The structural distortion of the $[\text{Te}_2]^{4/3-}$ layers due to the appearance of CDWs may be also responsible for the manifestation of semiconducting properties. The latter possibility was considered in Ref. 139. Since X-ray diffraction studies did not reveal structural distortions resulting in the deviation from the ideal I_4/mmm symmetry, the authors used the electron diffraction method, which is more sensitive to weak structural distortions of the $[\text{Te}_2]^{4/3-}$ layers. The electron diffraction data are unambiguously indicative of the presence of two superlattices. In one type of domain, distortions generate an incommensurate superlattice with $a_{\text{super}}^* = 0.352a_{\text{sub}}^*$; $b_{\text{super}}^* = b_{\text{sub}}^*$, $c_{\text{super}}^* = c_{\text{sub}}^*$. The domains of the second type contain a commensurate superstructure with $a_{\text{super}} = 3a_{\text{sub}}$; $b_{\text{super}} = 3b_{\text{sub}}$, $c_{\text{super}} = c_{\text{sub}}$. The results obtained confirm the suggestion that CDWs are responsible for localisation of electrons in the $[\text{Te}_2]^{4/3-}$ layers. The formal charge of the tellurium ions in the layers is equal to $-2/3$. Hence, the appearance of CDWs is associated with the formation of the Te_3^{2-} ions in the $[\text{Te}_2]$ layers in the case of the occurrence of the superstructures 3×3 and 3×1 because the charge, which fluctuates in the ideal square lattice, is localised on going to the tritelluride ion.

However, the available data on mixed copper tellurides, while rather scarce, demonstrate that tellurides differ substantially from sulfides and selenides. Although simple tellurides with compositions identical to those of sulfides and selenides exist, the majority of tellurides have no analogues among the corresponding sulfides and selenides. The same is true for their structures. Thus, the structures of CuS and CuSe are identical, whereas the CuTe structure is quite different. Unlike the widespread copper polysulfides, examples of the presence of polytelluride ions in copper salts are few in number. Thus, the isostructural $\alpha\text{-KCuX}_4$ and $\text{M}_3\text{Cu}_8\text{X}_6$ salts ($\text{X} = \text{S}$ or Se) are known, whereas the corresponding tellurides do not exist. At the same time, there are no sulfide analogues of $\text{K}_2\text{Cu}_5\text{Te}_5$ or $\text{K}_4\text{Cu}_8\text{Te}_{11}$.

As was mentioned in Chapter III, attempts to prepare mixed sulfide–telluride copper complexes from a melt of $\text{M}_2\text{S}_x\text{Te}_{1-x}$ afforded salts containing sulfide and trithiotelluride ions. Later on, the $\text{MM}'\text{TeS}_3$ salts ($\text{M} = \text{K}, \text{Rb}$ or Cs ; $\text{M}' = \text{Cu}$ or Ag) containing only TeS_3^{2-} ions, viz., CsCuTeS_3 , α - and β - KAgTeS_3 , RbCuTeS_3 , RbAgTeS_3 and CsAgTeS_3 , were isolated.¹⁴² The last-mentioned four salts are quasi-two-dimensional and isomorphous. These salts contain the anionic $[\text{M}'\text{TeS}_3]^{2-}$ layers between which the alkali metal ions are located (Fig. 31). The Cu^+ ions are coordinated by four sulfur atoms of the TeS_3^{2-} ions, thus adopting a distorted tetrahedral coordination. Each TeS_3^{2-} ion acts as a

Figure 31. Two-dimensional structure of RbCuTeS_3 along the c axis. The rubidium ions form monoatomic layers between the $[\text{CuTeS}_3]_n^-$ layers.¹⁴²

bridge and links four Cu^+ ions. Two sulfur atoms each link one Cu^+ ion and the third sulfur atom acts as a bridge between two Cu^+ ions.

The α - KAgTeS_3 compound has a centrosymmetrical layered structure. The most substantial difference in the structures of the α and β phases consists in the difference in the arrangement of the pyramidal TeS_3^{2-} ions. In the structure of α - KAgTeS_3 , the tellurium atoms are located on the surface of the layers so that their lone electron pairs are directed away from the layer. Neither silver ions nor alkali metals interact with these lone pairs. On the contrary, the K^+ ions are surrounded by seven sulfur atoms.

The crystals of CsCuTeS_3 belong to the cubic system. In the crystal structure, the CuTeS_3^- ions are linked to each other to form a three-dimensional non-centrosymmetrical chain. The Cu^+ ions have a planar-trigonal coordination. Each CuS_3 triangle is linked to three adjacent TeS_3^{2-} pyramids *via* shared vertices and *vice versa*. The crystallographically equivalent sulfur atoms are linked through the copper and tellurium atoms at an angle of $\sim 90^\circ$.

All compounds of the trithiotellurides series satisfy Zintl's criterion, which accounts for their dielectric properties. The optical measurements revealed the presence of the forbidden band in the region from 1.95 eV (RbCuTeS_3) to 2.2 eV (α - KAgTeS_3).

Kanatzidis¹⁴⁰ summarised a rare experience in the field of inorganic chemistry of tellurium and noted that this division of synthetic and structural chemistry of chalcogenides is characterised by the fact that both the compositions and structures of tellurides are unpredictable. However, even from the available data it is clear that ternary copper and silver tellurides are very promising material because they show diverse physical properties (from dielectric to semiconducting), possess interesting magnetic properties and exhibit transitions to states with CDWs. These transitions, which attracted the attention of chemists only early in the 1970s, comprise a new exciting field of solid-state chemistry because they are closely associated with the problem of the variable valence and charge ordering in crystals. The detailed consideration of this problem is beyond the scope of this review. Let us only mention the small but rather informative review devoted to this problem.¹⁴³

V. Conclusion

As is evident from the present review, the chemistry of ternary copper chalcogenides, which has progressed in the last decade, shows promise from the viewpoint of the development of new materials with a broad spectrum of electrophysical properties, including new high-temperature superconductors. In essence, only ternary copper and silver chalcogenides containing ions of alkali or alkaline-earth metals as well as thallium have been systematically studied. Data on physicochemical properties of ternary $\text{Ln}-\text{Cu}-\text{X}$ chalcogenides (Ln is a rare-earth element), which are analogues of high-temperature superconductors, are scarce. This field of research is in its infancy. In 1994, the first mixed copper chalcogenides containing cerium, *viz.*, KCuCe_2S_6 and

KCu_2CeS_4 , were synthesised.^{144, 145} Both sulfides were prepared from $\text{K}_2\text{S}-\text{Cu}-\text{Ce}-\text{S}$ melts and have layered structures. Their compositions do not satisfy Zintl's criterion (it is highly improbable that cerium in sulfides has the degree of oxidation of +4). However, both salts exhibit dielectric properties; the width of the forbidden band in KCuCe_2S_6 is 1.8 eV. In $\text{K}_2\text{Cu}_2\text{CeS}_4$, the gap was not found in the range of 250–2500 nm. The conductivity of this salt at 293 K ($\sigma_{RT} \sim 10^{-3} \Omega^{-1} \text{cm}^{-1}$) is five orders of magnitude larger than that of the KCuCe_2S_6 salt. However, the temperature dependence of the electrical resistance is typical of semiconductors. The thermoelectromotive force of crystals of the $\text{K}_2\text{Cu}_2\text{CeS}_4$ salt has a plus sign and the thermoelectromotive force decreases as the temperature decreases, which may be indicative of the metallic state. However, the thermoelectromotive force is much larger than the expected value for a metal.

Based on these facts as well as on the results of magnetic measurements, the authors¹⁴⁴ proposed the following formulas for mixed sulfides: $\text{K}^+\text{Cu}^+(\text{Ce}^{3+})_2(\text{S}^{2-})_2(\text{S}_2^{2-})_2$ for KCuCe_2S_6 and $\text{K}_2^+(\text{Cu}^+)_2\text{Ce}^{3+}(\text{S}^{2-})_3(\text{S}^-)$ for $\text{K}_2\text{Cu}_2\text{CeS}_4$. The magnetic susceptibility of the KCuCe_2S_6 salt obeys the Curie–Weiss law (the Weiss constant $\theta = -67 \text{ K}$), $\mu_{\text{eff}} = 3.1 \mu_B$, which is close to the purely spin value of $2.83 \mu_B$ for two unpaired electrons (one electron from each Ce^{3+} ions). A more complex situation arises with sulfide $\text{K}_2\text{Cu}_2\text{CeS}_4$. For this compound, either the $\text{K}_2^+\text{Cu}^+\text{Cu}^{2+}\text{Ce}^{3+}\text{S}_4^{2-}$ structure with the mixed-valence state for copper or the above-mentioned structure containing 'holes' in the p band formed by the $3p$ orbitals of the sulfur atoms has to be postulated. According to the approach accepted in our works, the mixed-valence states both of sulfur and copper atoms should be considered, as in the case of the above-considered chalcogenides, taking into account substantially covalent interactions between copper and sulfur atoms.

However, the absence of metallic properties in sulfide $\text{K}_2\text{Cu}_2\text{CeS}_4$ seems to be strange. Sutorik *et al.*¹⁴⁴ attributed this situation to the fact that the peculiarities of the crystal structure of this compound lead to the formation of a very narrow band, which, in turn, results in the formation of low-lability polarons in the presence of highly charged ions, such as Ce^{3+} ions in the case under consideration.

In the case of sulfides KCuCe_2S_6 and $\text{K}_2\text{Cu}_2\text{CeS}_4$, the combination of rare-earth elements and the alkali metal does not lead to an increase in the degree of oxidation of copper, unlike high-temperature superconductors. The reason is that the electronegativity decreases in going from oxygen to sulfur. Besides, as is evident from the present review, no copper sulfides (neither binary nor mixed) containing only Cu^{2+} ions are known.

Two years later,¹⁴⁶ sulfide KCuEu_2S_6 was synthesised. This salt contains double layers formed by the EuS_8 polyhedra (bicapped trigonal prisms) and the CuS_4 polyhedra (tetrahedra) linked to each other. The authors did not perform electrophysical measurements. However, judging from the dark-brown colour of the crystals, it is believed that this sulfide is a narrow-band semiconductor.

The manifestation of the effect of the chalcogen content on the physical properties of mixed copper oxides and sulfides is also different. It is known¹⁰ that in oxides, such as, for example, $\text{La}_2\text{CuO}_{4-x}$ or $\text{YBa}_2\text{Cu}_3\text{O}_{6.5+x}$, the degree of oxidation of copper increases as the oxygen content increases. Sulfide analogues of oxides $\text{La}_2\text{CuO}_{4-x}$ and $\text{Y}_2\text{Cu}_2\text{O}_5$ were synthesised¹⁴⁷ with the aim of elucidating the effect of the anionic subsystem on the electrophysical properties of chalcogenides based on copper. Sulfides $\text{La}_2\text{CuS}_{4+x}$ and $\text{Y}_2\text{Cu}_2\text{S}_{5+x}$ were prepared by fusing a mixture of Ln_2S_3 , CuS and S at 800–900 °C. Their individuality was confirmed by X-ray diffraction studies. The X-ray photoelectron spectra have doublets in the region of the $ES(2p)$ values. One of these doublets at 161.8 eV corresponds to the S^{2-} ions⁸² and the second doublet at 162.8 eV can be assigned to the S_2^{2-} ions. In the $ECu(2p_{3/2})$ region, the lines at 932.6 eV correspond to the Cu^+ ions. According to the data of X-ray photoelectron spectroscopy, a decrease in the sulfur content in samples upon annealing

in vacuo occurs as follows: lines at 934.5 eV, which correspond to the Cu^{2+} ions, appear and intensities of the lines corresponding to the disulfide ions decrease.

Samples of $\text{La}_2\text{CuS}_{4+x}$ saturated with sulfur have the composition La_2CuS_5 . Based on the results of X-ray photoelectron spectroscopy, their structures can be represented by the formula $\text{La}_2^{3+}\text{Cu}^+(\text{S}_2^{2-})_{1.5}(\text{S}_2^{2-})_2$. Sulfide La_2CuS_5 exhibits dielectric properties. When sulfur is removed until the sample acquires the composition La_2CuS_4 , the degree of oxidation of copper increases and the content of disulfide ions decreases. The appearance of the mixed-valence state of copper leads to the nonmetal–metal transition. The temperature dependence of the electrical resistance of samples of La_2CuS_4 is typical of metals. Below 100 K, the temperature dependence of the resistance is nonlinear.

Sulfide $\text{Y}_2\text{Cu}_2\text{S}_{5+x}$, which is maximum saturated with sulfur, has the composition $\text{Y}_2\text{Cu}_2\text{S}_5$. Its X-ray photoelectron spectrum has lines at 932.8 and 934.5 eV belonging to the Cu^+ and Cu^{2+} ions.⁸² Sulfur is present as the S^{2-} and S_2^{2-} ions [$ES(2p) = 161.8$ and 162.8 eV, respectively]. The $\rho(T)$ dependence is typical of metals (Fig. 32). When sulfur is removed until the compound acquires the composition $\text{Y}_2\text{Cu}_2\text{S}_4$, this dependence becomes more complex and goes through a weak maximum at $T \sim 240$ K. According to the results of X-ray photoelectron spectroscopy, this sample contains sulfur only as sulfide ions and the $\text{Cu}^+:\text{Cu}^{2+}$ ratio decreases from 3:1 in the initial sample to 1:1 in the final product.¹⁴⁸

Figure 32. Temperature dependence of the electrical resistance of samples of $\text{Y}_2\text{Cu}_2\text{S}_4$ (1) and $\text{Y}_2\text{Cu}_2\text{S}_5$ (2).¹⁴⁸

Hence, in the case of sulfides, the situation is opposite to that observed in oxides. The possible reasons for this fact are the lower electronegativity of sulfur responsible for reducing properties of the sulfide ion,

as well as the reaction

in the course of which excess sulfur is bound by sulfide ions rather than oxidises Cu^+ ions.

Apparently, these processes are hindered when the sulfur content is decreased and, as a consequence, the degree of oxidation of sulfur decreases as its content decreases.

The review was written with the financial support of the ISSEP Foundation (Grant No APU073103).

- IX. Conclusion

Abstract. Characteristics of the ferroelectricity in polyvinylidene fluoride (PVDF) and copolymers based on vinylidene fluoride (VDF) with different previous thermomechanical histories are analysed. Switching of polarisation and the fluctuation mechanism of formation of new nuclei upon the appearance of conformation defects such as kink bonds are considered. The role of the space charge, which stabilises the new polarisation position, is noted. It is shown that the Curie transition can be either a first- or second-order phase transition depending on the copolymer composition. The influence of the morphology of PVDF on some ferroelectric characteristics is found. In particular, the morphology of thick lamellar crystals is favourable for enhanced spontaneous polarisation. It is shown that a ferroelectric structure approaching the texture of an ideal single crystal can be created in Langmuir–Blodgett films. As the number of unimolecular layers decreases, the concentration of conformational defects in these films increases and the crystallographic order in the lattice is violated. This intensifies the low-temperature Curie transition. The bibliography includes 247 references.

I. Introduction

Poly(vinylidene fluoride) (PVDF) and copolymers based on vinylidene fluoride (VDF) present interest for both fundamental science and applied research. This is due to the fact that these materials were found to exhibit ferroelectric properties normally atypical of polymers. Owing to the high piezo- and pyro-electric activities found in PVDF films,¹ this polymer has been recommended in some cases as a competitive material for energy converters of various types.^{2,3} The results of experimental and theoretical studies in this field need to be surveyed at intervals for two reasons. Firstly, this could prompt the ways for optimisation of characteristics of the materials studied, which is significant for the solution of applied problems. Secondly, this would help to

elucidate the influence of the polymeric state of substance on its electrophysical characteristics and would thus provide the understanding of the fundamental features of the formation of ferroelectricity and piezo- and pyroelectric properties in other polymers, for example, in poly(vinylidene cyanide),^{4–13} odd nylons,^{4–16} polyacrylonitrile,^{17,18} polyurethanes,^{19,20} liquid-crystal polymers^{21–26} and biopolymers.²⁷

PVDF is known to exhibit clear-cut polymorphism.²⁸ Three of the four crystallographic modifications of PVDF usually have non-zero cell dipole moments; therefore, there are prerequisites for the formation of a ferroelectric structure. Crystallites (or their sections) can be compared with domains characterised by a particular value of spontaneous polarisation.

II. General characteristics

The ferroelectric character of PVDF and VDF copolymers is confirmed, among other facts, by the occurrence of dielectric hysteresis for these materials. Figure 1 presents the variation of the electric displacement (D) as a function of the electric field strength E for a uniaxially stretched PVDF film.²⁹ It can be seen that hysteresis is displayed only in fields with a strength greater

Figure 1. Electric displacement in a uniaxially stretched PVDF film at 20 °C vs strength of the external electric field.²⁹ Frequency of the electric field 10^{-3} Hz; strength / MV m $^{-1}$: (1) 40, (2) 80, (3) 100, (4) 120.

Figure 2. Temperature dependences of the electric displacement (a) and the polarisation current density (b) vs the electric field strength in the initial non-polarised PVDF film.²⁹

T /°C: 20 (1), -20 (2), -60 (3), -100 (4) (a); 20 (1), 0 (2), -20 (3), -40 (4), -60 (5), -80 (6), -100 (7) (b); t is the current time.

than 40 MV m^{-1} and that an increase in the field strength results in an increase in both the remanent (for $E = 0$) and spontaneous polarisation, P_r and P_s , respectively. In relatively low fields (80 MV m^{-1}), the curve shows double hysteresis. This can be seen in more detail in Fig. 2, which shows the variation of properties of a non-polarised film placed in a 240 MV m^{-1} field for temperatures varying over wide limits.

Temperature plays an important role for the manifestation of ferroelectricity in PVDF and in crystallisable VDF copolymers. Only a fraction of the sample bulk is occupied by crystals; the rest (which makes 50% to 60% in PVDF) is filled by a disordered phase. The role of this phase in the formation of ferroelectricity is not entirely clear. The dynamics of chains in the disordered phase can have a substantial influence on the characteristics of the electric hysteresis (see Fig. 2). In temperature regions below the glass transition temperature of PVDF ($T_g \approx -40$ °C), large-amplitude motions of chain sections are frozen. Some researchers (e.g., Tamura *et al.*³⁰) have observed even the disappearance of the hysteresis in low fields. However, in high fields, disappearance was not noted but the $D-E$ dependences were characterised by double hysteresis (see Fig. 2a). This can be seen more clearly in the field dependences of the polarisation current density (see Fig. 2b), which have two peaks at low temperatures. The position of one (lower-field) peak remains virtually unchanged, while the other peak shifts to lower fields as the temperature rises. The low-field peak may be related to the response of polar crystals to the application of the field and the peak at higher fields may be due to the response of dipoles in the disordered phase. Evidently, an increase in the temperature is favourable for the activation of the latter process because the second peak markedly shifts to lower fields. In the region below -40 °C, this shift can occur due to a

decrease in the relaxation times of the local forms of mobility upon an increase in temperature; above -40 °C, this can be due to the generation of cooperative forms of mobility with high amplitudes.²⁸

Thus, the amorphous phase makes a certain contribution to the formation of ferroelectricity and cannot be regarded as an 'inert matrix'. This conclusion appears sufficiently justified because the double hysteresis has been noted both for PVDF³¹ and for VDF copolymers with tetrafluoroethylene (TFE)^{32,33} or trifluoroethylene (TrFE).³⁴ It has been shown for the latter copolymer³⁴ that the probability of double hysteresis depends on the method used to prepare the sample. In particular, double hysteresis in the VDF copolymer with TrFE of the 52.8/47.2 composition is manifested only for samples crystallised by slow cooling of the melt. In the several initial polarisation cycles, these samples exhibit a typical double hysteresis, which is transformed into a single hysteresis in the subsequent cycles (Fig. 3). A similar result has been obtained for uniaxially stretched PVDF samples (Fig. 4a); no double hysteresis is observed for polarised samples at any temperature. This transformation in the pattern of the $D-E$ hysteresis should point to fundamental changes in the material structure after the generation of non-zero remanent polarisation.

One process which might result in structural changes is the irreversible increase in the degree of crystallinity after polarisation.³⁵ The kinetics of transition of the film subjected to polarisation into a new structural state depends on the frequency of the electric field applied. Thus at room temperature and a frequency of $\sim 10^{-3}$ Hz, this requires several poling cycles;^{29,34} when the frequency is 50 Hz, the double hysteresis passes into single hysteresis in one cycle of the increase in the intensity of the polarising field.^{31,32} Analysis of the time dependences of the polarisation current and thermodepolarisation curves for the 75/25 VDF/TrFE copolymer suggests that polarisation involves two types of dipoles (in the crystal and in the amorphous phase).³⁶

It can be seen from comparison of Figs. 2 and 4 that the structural changes in the film induced by poling have a substantial effect on the temperature dependences of both the coercive field and the remanent polarisation. Whereas in the initial sample, E_c changes slightly with the temperature, in the polarised state, this value markedly increases as the temperature diminishes. The state of chain dynamics in the disordered phase affects precisely the magnitude of the coercive field; it can be seen that the E_c-T plot is broken at about the glass transition temperature (see Fig. 4b). The sharper growth in the E_c in the region of T_g indicates that freezing of the high-amplitude cooperative motion of chain segments retards substantially the processes of polarisation switching. The remanent polarisation depends on the temperature to a lesser extent, although an increase in P_r has been noted below 50 °C.

Figure 3. Reversible polarisation current vs the intensity and voltage (U) of the electric field (5×10^{-3} Hz/ 27 °C) in the several initial (1) and subsequent (2) cycles of poling of VDF/TrFE samples.³⁴

Figure 4. Influence of the temperature on the D – E hysteresis curves (a) and on the hysteresis parameters (coercive field E_c and the remanent polarisation P_r) (b) in uniaxially stretched polarised PVDF films.²⁹ T / °C: –100 (1), –60 (2), –20 (3), 20 (4).

Measurements of the hysteresis during the variation of the polarising field frequency from 10^{-2} to 10^{-4} Hz demonstrated that neither P_r nor the piezoelectric constant e_{31} depend on the frequency. This finding permitted the conclusion²⁹ that the ferroelectricity in PVDF has a purely dipole origin. A similar conclusion has been drawn for the 73/27 VDF/TFE copolymer, for which experimental P_r and P_s values are in good agreement with those calculated using a simple dipole model.³⁷

It has been assumed³⁸ that free charge carriers in the polymer get frozen in deep traps and this compensates to an extent the intrinsic polarisation of crystals. This hypothesis was confirmed³⁸ by the data on the influence of annealing of a polarised PVDF film on the shape of the D – E hysteresis curve. The curve obtained in the first cycle of measurements after annealing was distorted. This was explained by assuming that immediately after the annealing, the charge carriers are characterised by a non-equilibrium distribution, which changes during the subsequent poling cycles.

The dipole nature of the ferroelectricity is also confirmed by the hysteresis type of variation of the intensities of some absorption bands in the IR spectra.^{28, 39, 40} This conclusion is also supported by the qualitatively consistent results of studies^{41, 42} devoted to X-ray recording of the change in the distribution of the b axes (direction of the dipole moment) of the β -phase lattice after polarisation. It was shown that the intensity of the 110, 200 reflections of the crystalline β -phase changes by more than 20% following polarisation along particular directions. When developing the model of polarisation switching, Kepler and Andersen⁴² proceeded from the fact that the orthorhombic cell of the β -phase can be transformed into a hexagonal cell upon 1% distortion. The chains in the planar zigzag conformation can occupy one of six equivalent positions (Fig. 5). When a field E is applied, the b axis of the cell occupies one of these positions with the probability⁴²

Figure 5. Packing of the PVDF chains in the crystal lattice of the β -phase. The dashed line denotes the boundary between the domains.⁴³

$$f(\psi) = \exp(a \cos \psi) \left[\sum_{i=1}^6 \exp(a \cos \psi_i) \right]^{-1}, \quad (1)$$

where ψ is the angle between the domain dipole moment (μ) and the direction of the field (E); in addition, $\psi_i = \psi + (1/3)(i-1)\pi$; $a = \mu E/kT$.

After polarisation, the orientation of the dipole moments can be described by the normalised distribution function

$$\begin{aligned} \frac{n(\psi)}{n_0} &= f(\psi) \left[\int_0^{2\pi} f(\psi) d\psi \right]^{-1} = \\ &= \frac{3}{\pi} \left[\exp(a \cos \psi) \right] \left[\sum_{i=1}^6 \exp(a \cos \psi_i) \right]^{-1} \end{aligned} \quad (2)$$

(n is the number of oriented axes, n_0 is the total number of axes), and polarisation is described by the equation

$$P = \frac{3P_0}{\pi} \int_0^{2\pi} \left[\exp(a \cos \psi) \cos \psi \right] \left[\sum_{i=1}^6 \exp(a \cos \psi_i) \right]^{-1} d\psi, \quad (3)$$

where P_0 is the overall polarisation under the assumption that all dipoles are completely oriented.

The intensity of X-ray diffraction for the case of variation of the angle between the direction of incidence of the beam and the perpendicular to the film surface has been calculated.⁴² The intensity curves for various values of the parameter $\exp(2\mu E/kT)$ were constructed. The experimental points obtained by averaging over seven samples are in the best agreement with the calculation based on the assumption that $\exp(2\mu E/kT) \simeq 10^3$.

Similar experiments have been carried out in another study.⁴⁴ The researchers monitored the variation in the intensity of the 110, 200 reflections after poling of a PVDF film shaped like a cylinder rotating around its axis, which coincided with the stretching direction. These experiments also confirmed the hypothesis that the dipole orientation can change by 60° steps during polarisation (see Fig. 5). This polarisation model is also confirmed by calculations of the potential energy for the chain rotation, which show that two neighbouring equilibrium positions of the CF_2 group are separated by 60°.⁴² Finally, the data on the hysteresis of the IR bands upon application of a field also point to 60-degree reorientations. Indeed, in terms of the model assuming 180-degree steps of rotation, no changes in the IR absorption intensity should be expected because the intensity is proportional to $\cos^2\theta$ (see Ref. 40).

The values of polarisation calculated from Eqn (3) are presented in Table 1. The most probable $\exp(2\mu E/kT)$ value for PVDF amounts to 10^3 ; it is matched by $P \simeq 111 \text{ mC m}^{-2}$. The crystallinity of the sample is normally $\sim 50\%$; hence, polarisation should be 50 mC m^{-2} , which is consistent with the PVDF remanent polarisation found experimentally. The known $\exp(2\mu E/kT)$ value can be used to determine the dipole moment of the domain.⁴² For the field $E = 600 \text{ kV cm}^{-1}$ at 100°C , it amounts to $3 \times 10^{-28} \text{ C m}$. If the dipole moment of a monomer

Table 1. Polarisation of crystalline PVDF calculated for various magnitudes of the $\mu E/kT$ parameter.⁴²

$\mu E/kT$	$\exp(2\mu E/kT)$	$P/\text{mC m}^{-2}$

6.91	10^6	121

unit in a planar zigzag chain is taken to be $\mu_0 = 7 \times 10^{-30}$ C m, then a domain should comprise ~ 40 monomer units. The polar β -phase crystals with normal sizes (~ 100 Å) contain many more monomer units. This means that field-induced orientation occurs in an area the size of which is much smaller than the size of the β -phase crystal. This conclusion is probably confirmed by the data of analysis of the ferroelectric and pyroelectric characteristics of thin films of the 70/30 VDF/TrFE copolymer prepared by the Langmuir–Blodgett method.⁴⁵ In the films containing several monolayers, the formation of a domain structure was noted; hysteresis of the pyroelectric current and a first-order Curie transition of the ferroelectric–paraelectric type was clearly observed for these films.

The regions of spontaneous polarisation, typical of ferroelectrics, can be probed using the electrochromism of optical labels. The optical labels used are normally azo dyes that efficiently absorb in the visible region. For instance, 4-dimethyl-amino-4'-nitrostilbene (DANS), for which the dipole moment in the ground state and the difference between the dipole moments in the ground and excited states are known, has been used as the optical label for PVDF and systems based on it.^{46, 47} To estimate the strength of the local (internal) field E_l which had appeared in the sample after polarisation, the researchers made use of the fact that the absorption spectra of DANS in the perturbed ($E \neq 0$) and non-perturbed ($E = 0$) states differ in the absorbance and in the frequency of the main absorption band.⁴⁸

The local field strength in polarised samples of a blend of PVDF and poly(methyl methacrylate) (PMMA) proved to be more than twice as high as the strength of the external field during poling.⁴⁷ A similar result has been obtained for the VDF/TrFE copolymer.⁴⁶ Apparently, for these polymers, the influence of the charge carriers injected from the electrode material should be taken into account. This hypothesis is supported by the results of analysis of the polarisation profile in these samples by the thermal pulse method.^{49, 50} The polarisation profile is formed not only by dipoles but also by the space charge. The role of the latter is to stabilise the areas of oriented dipoles, which ensures the invariability of E_l in the temperature range of annealing (60–90 °C).⁴⁷ Some decrease in E_l near 60 °C (glass transition region) implies, apparently, that the fields of the disordered phase areas should also make a contribution to E_l . This contribution is relatively low because the most pronounced decrease in E_l occurs at about ~ 120 °C, where annealing is accompanied by depolarisation processes due to disorientation of the β -phase crystals.

Jimbo *et al.*⁵¹ have attempted to determine the above-noted substantial changes in the coercive field observed in the polarised PVDF upon the temperature variation (see Fig. 4) using a simple phenomenological relaxation theory. In accordance with this theory, they calculated the E_c values, which corresponded to the experimental data in the temperature range chosen.

As noted above, PVDF and VDF-based copolymers contain at least two phases (ordered crystalline phase and disordered amorphous phase) having substantially different electric parameters, in particular, dielectric permittivity. This is attributable to the fact that the disordered phase occurs at room temperature in the liquid-like state and its chains execute cooperative motion with

large amplitudes.²⁸ Therefore, depolarisation field E_d , the direction of which is opposite to that of the applied field E , can arise at the boundaries of ferroelectric crystals.

The field E_l which really acts on the crystal can be described by the equation⁵²

$$E_l = E - E_d = f \left[\left(E - \frac{L}{\varepsilon \varepsilon_0} \right) (P_c - P) \right] = f \left[\left(E - \frac{L}{\varepsilon \varepsilon_0} \right) \left(\frac{1}{\alpha f} - 1 \right) P \right], \quad (4)$$

where f is a parameter related to the depolarisation factor L and to the difference between the dielectric constant of the sample as a whole ε and that of the crystalline region ε_c (their polarisations are P and P_c , respectively), ε_0 is the vacuum dielectric constant and α is the degree of crystallinity.

The fact that E_l is lower than E means that the experimental hysteresis curves do not reflect characteristics of polar crystals. By processing experimental P – E curves, Ikeda *et al.*⁵² elucidated the dependences for the crystallites, *i.e.*, those in the P_c – E_l coordinates. The theoretical P_c – E_l curves were constructed for $L = 0.04$ and 0.08 ; provided that $\varepsilon = 12$ and $\varepsilon_c = 3$, this is matched by $f = 1.031$ and 1.064 and the draw ratios for an ellipsoidal crystal are 6.5 and 3.8. Since f differs insignificantly from unity, then, taking into account that $E_l = fE_c$ (see Ref. 51), the coercive field values for the calculated and experimental curves are virtually identical.

Spontaneous polarisation of the crystal P_{sc} and that for a sample with the degree of crystallinity α are related as follows:⁵¹

$$P_{sc} = \frac{P}{f\alpha}.$$

When $\alpha = 0.45$, spontaneous polarisation is substantially higher than the overall polarisation. The value $P_{sc} \simeq 170$ mC m^{−2} obtained by Ikeda *et al.*⁵² is consistent in order of magnitude with the spontaneous polarisation (130 mC m^{−2}) calculated for a perfect crystal of the β -phase.

III. Characteristic features of the polarisation switching processes

The analysis of the features of polarisation switching processes is conveniently started with the data on PVDF; this homopolymer has been studied in the uniaxially stretched state, in which the crystalline phase occurred in the ferroelectric β -modification. Switching experiments usually consist in the application to the film of a stepwise field and recording of the time dependence of the electric displacement or polarisation current. The latter operation is often replaced by differentiation of the $D(t)$ curve (t is the current time) with respect to time. These curves are shown in Fig. 6. It can be seen that, as the electric field strength increases, the inflection point in the $D(t)$ curve and, correspondingly, the

Figure 6. Time dependences of the electric displacement (a) and its derivative with respect to time (b) for the ferroelectric switching in a polarised PVDF film at 20 °C and at various external electric field strengths.⁵³ $E/\text{MV m}^{-1}$: 20 (1), 40 (2), 60 (3), 80 (4), 100 (5), 120 (6), 140 (7), 160 (8), 180 (9), 200 (10).

maximum of the derivative shift to shorter times. This type of behaviour has also been noted for classical inorganic ferroelectrics and is usually described by the relations

$$\tau_s = \tau_0 \exp\left(\frac{E_a}{E}\right) \quad (5)$$

or

$$\tau_s = \tau_0 \left(\frac{E}{E_0}\right)^{-n}, \quad (6)$$

where τ_s is the time of polarisation switching [corresponding to the maximum of the derivative of $D(t)$ or to the switching point], τ_0 is the pre-exponential factor, E_a is the activation field, and E_0 and n are constants. The $D(t)$ function can be represented as follows

$$D = D_0 + 2P_s \left[1 - \exp\left(-\frac{t}{\tau_s}\right)\right]^n, \quad (7)$$

where D_0 is the instant electric displacement and $2P_s$ is the reversible polarisation. The exponent n corresponds approximately to the half-width of the $\partial D/\partial \log t$ peak. When the field strength is 60 MV m^{-1} , the exponent n for the 65/35 VDF/TrFE copolymer is greater than 5.

It has been noted above that the specific character of the polymeric state is due, on the one hand, to the strong anisotropy of bonds along and across the chain and, on the other hand, to the presence of an amorphous phase in addition to the crystalline phase. The chain dynamics of the amorphous phase below and above glass transition temperature are substantially different;²⁸ therefore, to understand the mechanism of generation of ferroelectricity in polymers, it is important to find out how this can influence the switching characteristics. Furukawa *et al.*⁵³ have studied the processes of switching in a polarised PVDF film in which the amorphous phase occurred in the liquid-like or vitrified state (Fig. 7). It can be seen that, when the field is so high (200 MV m^{-1}), switching can also take place below T_g (-40°C). Below the glass transition temperature, the equilibrium electric displacement regularly decreases, the maximum switching rate D diminishes, and the peaks themselves become markedly broader as the temperature decreases. Figure 8 presents the field dependences of the switching times in a polarised PVDF film at various temperatures. These plots are linear both above and below the glass transition temperature, indicating that relations (5) and (6) hold. Transition of the amorphous phase into the glassy state noticeably changes the switching parameters (Table 2). In fact, as the temperature diminishes from room temperature to T_g , the exponent n and the constant τ_0 in Eqn (6) substantially increase (see Table 2). If the field dependences are represented as Eqn (5), then, in accordance with the results obtained by Furukawa and Johnson,⁵⁴ the transition of the disordered phase in the glassy state is also accompanied by a substantial increase in the activation field; E_a is 1.1 GV m^{-1} at 20°C and 1.9 GV m^{-1} at -60°C .

PVDF is characterised by higher activation fields and by higher exponents n in relations (6) or (7) than inorganic ferro-

electrics. This fact was explained⁵³ in terms of the model of nucleation and growth of domains. Within the framework of this model, the switching curve $D(t)$ is described by the expression

$$D = 2P_s \left\{ 1 - \exp \left[- \int_0^t N_0 R e^{-Rs} F(v(t-s)^m) ds \right] \right\}, \quad (8)$$

where N_0 is the number of nucleation sites, R is the probability of nucleation, s is the current time, F is a factor depending on the shape of the growing domain, v is the growth rate, t is the total time, and m is the growth dimensionality. If switching is assumed to occur in very thin lamellae, consideration can be restricted to two-dimensional growth, *i.e.* $m = 2$. In this case, it follows from Eqn (8) that

$$D = 2P_s \left\{ 1 - \exp \left[- \frac{2FN_0v^2}{R^2} \left(\frac{R^2t^2}{2} - Rt + 1 - e^{-Rt} \right) \right] \right\}. \quad (9)$$

If $Rt \gg 1$, then

$$D = 2P_s [1 - \exp(FN_0v^2t^2)], \quad (10)$$

if $Rt \ll 1$, then

$$D = 2P_s \left[1 - \exp \left(- \frac{FN_0v^2R}{3} t^3 \right) \right]. \quad (11)$$

In both cases, the n values found by the calculations are smaller than those found experimentally. Agreement with experimental results can be attained by assuming that the domain growth is self-accelerated.

The influence of the state of the disordered phase on the switching parameters has also been studied by Matsushige *et al.*,⁵⁵ who derived switching characteristics from the time variation of the transpolarisation current at the same field strength

(200 MV m⁻¹). Three temperature regions of variation of τ_s characterised by different activation energies of the switching process can be distinguished. The first region lies below T_g and has an activation energy of 2.3 kcal mol⁻¹. Here, the dynamics of molecular motion is characterised by only local types of motion, which can occur in both the amorphous and crystalline phases.²⁸ The activation energy of switching increases somewhat when cooperative forms of motion are excited in the amorphous phase ($60^\circ\text{C} > T > T_g$). Finally, the third region falls to temperatures above 60°C , when motion in crystalline lamellae begins.²⁸ This motion decreases the activation barrier to switching.

Thus, switching is sensitive not only to crystalline domains but also to the surrounding disordered areas.

A complex pattern of the curves of reversible polarisation has also been found for the VDF/TrFE copolymer. Specific features of switching near the Curie point, in which a ferroelectric–paraelectric transition occurs, have been studied.⁵⁶ In the vicinity of this point (68°C), the plot for D at low fields has two steps (Fig. 9).

Figure 9. Time dependences of the electric displacement (a) and its derivative with respect to time (b) for polarisation switching in 65/35 VDF/TrFE at 63°C and various field strengths.⁵⁶ E /MV m⁻¹: 75 (1), 90 (2), 135 (3), 200 (4), 300 (5).

The shape of experimental curves is described adequately by an equation with two switching times, one (τ) being independent on the field intensity and the other (τ_s) depending on it according to the law normal for ferroelectrics (Fig. 10). The switching time (τ) varies in the same way as that for an ordinary relaxation process; therefore, the expression for D can be written as follows:⁵⁶

Figure 10. Field dependences of the switching times τ_s (1) and τ (2) in the 65/35 VDF/TrFE copolymers at 63°C .⁵⁶

$$D = \varepsilon_0 E + \Delta \varepsilon E \left[1 - \exp\left(-\frac{t}{\tau}\right)^\beta \right] + 2P_r \left[1 - \exp\left(-\frac{t}{\tau_s}\right)^n \right], \quad (12)$$

where $\Delta \varepsilon$ is the relaxation force, β is a parameter determining the distribution of the relaxation time, and n is a parameter determining the shape of the switching curve. This expression is suitable (provided that τ does not depend on E) for describing the experimental switching curves shown in Fig. 9. In particular, it also accounts for the shape of the curve at high fields. The straight lines shown in Fig. 10 intersect at a certain field strength. At the point of intersection, $\tau = \tau_s$; therefore, switching curves for such field strength attest to a one-step process.

The changes in the field dependence of τ_s with an increase in the temperature in the copolymer considered and in PVDF are similar. However, as the Curie point is approached, the slope of this plot markedly decreases. According to Eqn (5), this is equivalent to the decrease in the activation field E_a . Taking into account the probable generation of great fluctuations of the motion near the Curie point, a hypothetical mechanism for the nucleation of domains during polarisation switching was proposed.⁵⁶ The scheme of this mechanism is presented in Fig. 11. The authors proceeded from the real conformational structure found in the chains of PVDF and VDF copolymers.

Figure 11. Scheme for the fluctuation motion (a), nucleation (b) and the growth of the nucleus (c) in the switching processes in 65/35 VDF/TrFE.⁵⁶

The ordered areas in the VDF copolymers with TrFE or TFE are known to crystallise as the ferroelectric β -phase with the planar zigzag conformation. The polarisation of a domain in a polarised film is stipulated by the external field. The results of X-ray and IR-spectroscopy studies demonstrate that, in addition to the planar zigzag conformation, chain sections occurring in a mixed conformation, TT, TG, or TG⁻, are also present.²⁸ They should be located either in the amorphous phase or in the crystals of the paraelectric phase, which can coexist with the ferroelectric phase. These sections should be the first to respond to a field because the relaxation times τ for them are shorter than τ_s (if the fields are not extremely high) (see Fig. 10). If the chains are mainly located in the film plane (this is the case for the uniaxially oriented state), a chain section having, for example, the TGTG⁻ conformation should pass into a different position upon the interaction of the field with the transverse component of the dipole moment. In a high field, a conformational transition of the TGTG⁻ $\rightarrow$ TTTT type is possible;²⁸ therefore, the second stage in the nucleation process is the appearance of chain sections in the

planar zigzag conformation with a new orientation of the dipole moment. Evidently, these processes involve simultaneously a certain rearranging region rather than individual sections of the chain because above T_g , the micro-Brownian motion in the amorphous phase is to some extent cooperative.²⁸ After a nucleus has formed by the above mechanism, it starts to grow in both the longitudinal and transverse directions.

Certainly, the mechanism described above merits attention because it is underlain by the real structure of the chains in PVDF and VDF copolymers. The validity of this mechanism is confirmed by the presence of tie chains, characteristic only of crystallisable polymers, in the compounds considered. As a result of spontaneous nucleation during crystallisation, the same chain can be incorporated in both the crystal and the neighbouring disordered phase. If the chain section adjacent to the crystal occurs in the TGTG⁻ conformation, the orientation and conformational changes described above would create internal stresses in the section of the same chain contained in the crystal because the direction of its dipole moment would be opposite to the new direction of the field. This fact as well as the influence of an external electric field are additional factors inducing transpolarisation of a region of the crystalline phase. The time τ (like the normal relaxation time) decreases as the temperature increases, which can also affect the temperature dependence of the switching time τ_s .⁵⁵

The above mechanism for the generation and development of domains in the switching processes does not take into account the effect of the space charge formed by both the inherent charge carriers and those injected from the electrodes during poling. However, experimental results imply that this effect cannot be neglected. For example, in a study⁵⁷ dealing with switching in the 73/27 VDF/TrFE copolymer on exposure to 1-second rectangular pulses, an unusual phenomenon was discovered, which can be described as follows. As the delay period t_0 between the preceding and the subsequent pulses (having opposite polarities) increases, the switching curves regularly shift to longer switching times. The same trend is observed if the strength of the external field decreases (see, for example, Figs. 6, 8). This correlation led the researchers to the conclusion that the decrease in the switching time following an increase in the duration of leaving the sample after a high-voltage pulse has been applied is due to field effects. Since the external field strength was maintained constant (80 MV m⁻¹), all the foregoing was explained by variation of the local field acting on the domain. The period the sample is left and the final concentration of charge carriers in the sample bulk create real prerequisites for the processes described above.

Free charge carriers are present both in non-polarised (remaining catalyst, ionic side products of the synthesis, *etc.*) and polarised PVDF. In the latter case, there are also charge carriers injected from the electrode. It is assumed that charge carriers are captured into deep traps located along the boundaries between the ordered and amorphous regions. If these regions occur in the liquid-like state, in which the segments execute cooperative motion with large amplitudes,²⁸ there are conditions for the charge to be liberated and re-captured by another trap. From energy reasons, it is more favourable for these carriers to be located on polar surfaces of crystallites, which should result in partial compensation of their polarisation. The local polarisation P_l would differ from the macroscopic value P ; in accordance with Eqn (4), this should change the field E_l acting on the crystal. These effects have been considered quantitatively.⁵⁸ The expression proposed for E_l has the form

$$E_l = -\frac{n'(1-\alpha)P_0}{\varepsilon_a - (\varepsilon_a - \varepsilon_c)n'(1-\alpha)} \exp\left(-\frac{t_0}{\tau}\right), \quad (13)$$

where n' is the depolarisation factor for ellipsoidal crystals with dielectric constant ε_c immersed in an amorphous matrix with dielectric constant ε_a , and α is the volume fraction of these crystals. The exponential term (kinetic factor) includes the characteristic

relaxation time of the space charge τ , which is related to the conductivity of the amorphous phase g by the equation

$$\tau = \frac{\varepsilon_a - (\varepsilon_a - \varepsilon_c)(1-\alpha)n'}{g[1 - (1-\alpha)n']}. \quad (14)$$

The overall expression for the polarisation switching time with allowance for the foregoing has the following form:

$$\log \tau_s = \log \tau_0 + \frac{0.4343E_a}{E + A \exp(-t_0/\tau) - E_l}, \quad (15)$$

where E_a and A are constants for a given polymer, E_l reflects the correction of the external field E due to the effect of the depolarising field.

Figure 12a shows experimental points for τ_s at various t_0 for samples of the 73/27 VDF/TrFE copolymer obtained by quenching and by slow cooling. It can be seen that τ_s increases with an increase in t_0 in accordance with Eqn (15). The τ_s value is always greater for a quenched sample, all other factors being the same. This can be explained qualitatively by the following fact, which has been confirmed experimentally. The volume fraction of the ferroelectric phase is always lower in a quenched sample; therefore, the conductivity of the amorphous phase g should be greater. In conformity with Eqn (14), this results in a lower τ and, according to relation (15), this increases τ_s . Yet another way for increasing the conductivity in the copolymer considered is an increase in the concentration of charge carriers by doping with, for example, iodine.⁵⁹ For a doped sample, the τ_s values are greater and the shape of the curves calculated from Eqn (15) is described adequately by experimental data (Fig. 12b).

Figure 12. Plots for the polarisation switching time in 73/27 VDF/TrFE films prepared either by slow cooling or by quenching (a) and either non-doped or doped with iodine (b) in a 80 MV m⁻¹ field (see Refs 57–59); (a): (1) cooling, (2) quenching; (b): (1) without doping, (2) doping for a week, (3) doping for a month; the solid line corresponds to the calculation by Eqn (15).

The experiments carried out by Bihler *et al.*^{60,61} were devoted to the non-trivial role of the space charge in the polarisation switching in PVDF and VDF copolymers. In the study of polarisation of the initial films and transpolarisation of polarised films in pulsed electric fields, the attention was concentrated on the comparison of the time dependences of the electric displacement D and the resulting remanent polarisation P_r . The D value was measured using a capacity divider circuit and P_r was measured by generation of a pressure pulse in the short circuit mode. The investigation objects were PVDF films crystallised as mixtures of α - and β -phases⁶⁰ and 75/25 VDF/TrFE copolymer films.⁶¹ Figure 13 presents the time dependences of D and P_r for isotropic films of 75/25 VDF/TrFE to which a primary high-voltage pulse has been applied. Both characteristics vary according to similar patterns but the positions of the characteristic points on the $D(t)$ and $P_r(t)$ curves are substantially different. For example, the time it takes for P_r to reach half its equilibrium value (this is marked by the vertical line) in a 160 MV m⁻¹ field amounts to ~ 100 μ s, whereas the electric displacement virtually reaches its maximum over this period. More detailed data for this

Figure 13. Time dependences of the electric displacement (*a*) and the remanent polarisation (*b*) upon application of a pulse electric field with various strengths in the initial non-polarised films of the 75/25 VDF/TrFE copolymer.⁶¹
E /MV m⁻¹: 80 (1), 120 (2), 160 (3).

Figure 14. Time dependences of *D* (*a*) and *P_r* (*b*) for pulse transpolarisation in various fields of preliminarily polarised films of the 75/25 VDF/TrFE.⁶¹
E /MV m⁻¹: 80 (1), 120 (2), 160 (3).

copolymer and also for PVDF are presented in Table 3. It can be seen that for both compounds, the points where the slope begins and when half the equilibrium *P_r* value is attained on the *P_r*(*t*) curve are substantially displaced to longer times with respect to the corresponding points on the *D*(*t*) curves. Qualitatively similar data have also been obtained for preliminarily polarised films upon application of a high-voltage pulse with the opposite polarity (Fig. 14). The *D*(*t*) curves follow the same pattern as those for initial (non-polarised) films but the *P_r*(*t*) plots have a minimum which separates two branches reflecting antiparallel variation. The descending branch of *P_r* evidently corresponds to the removal of the polarisation which had existed before the pulse with the opposite polarity was applied. The increase in *P_r* is apparently due to the formation of a remanent polarisation in the new direction. As in the previous case, the time it takes for *D* to reach half its equilibrium value (marked by vertical lines) proves

even shorter than the time required for the initial polarisation to diminish to zero (a vertical line is also drawn through the minimum point). This led the researchers^{60,61} to the conclusion that the processes responsible for the increase in *D* and *P_r* are not equivalent. It is believed that an increase in *D* reflects the rotation of dipoles, which respond to a high field almost instantaneously. The delay of the formation of the remanent polarisation is due to the fact that this process involves the carriers forming the space charge. If dipoles of the ferroelectric β-phase have occupied a new position in the field, then, due to the finite mobility of charge carriers, the space charge would occupy a new equilibrium position within some period after the dipoles have rotated, which is actually observed in the experiment. The influence of the space charge is not limited to the retarded kinetics of equilibration of *P_r* with respect to *D*. The space charge also plays an important role in the stabilisation of the remanent polarisation, resulting in the retention of piezo- and pyro-electric properties in polarised films of PVDF and VDF copolymers over long periods of time.

Table 3. Parameters of the characteristic points in the time dependences for 75/25 VDF/TrFE and PVDF recorded during poling of films by high-voltage pulses of various durations.

<i>E</i> / MV m ⁻¹	Beginning of the slope /μs		The time it takes to reach half the maximum value /μs	
	I	II	I	II
VDF/TrFE ⁶¹				
80	400	3 000	1 000	17 000
120	30	100	50	2 000
200	1	10	< 10	80
PVDF ⁶⁰				
120	200	2 000	20 000	40 000
200	< 10	80	10	3 000

Note. I are characteristic points on the *D*(*t*) curves; II are characteristic points on the *P_r*(*t*) curves.

Thus, polarisation switching in PVDF films and films of VDF copolymers with a ferroelectric β-phase occurs most likely in two stages. The first (fast) stage involves reorientation of domains due to the rotation of dipoles *via* 60-degree rotations of the chains (see Fig. 5). This conclusion is confirmed by numerous structural data and also by calculations of the activation energy of switching in terms of this model.⁶² According to these calculations, the activation barrier should not exceed several tens of kilocalories per mole, which agrees with the experimental values. For example, it has been reported⁵⁵ that the activation barrier does not exceed 10 kcal mol⁻¹ and, according to another publication,⁶³ it is not higher than 18 kcal mol⁻¹. The latter value is much lower than would be required by the model which implies 180-degree rotations of the chain.⁶² The stage of formation (nucleation) of new domains is apparently a fluctuation type process.^{56,64} For this stage, it is necessary to take into account the possibility that the same chain can be incorporated both in the crystal and in the disordered phase adjacent to it. If the relaxation processes in the latter are taken into account in the nucleation of a new domain,

the chains in the crystal acquire an additional rotational moment, which facilitates the growth of new domains.⁶²

The structural heterogeneity of PVDF creates prerequisites for the influence of fine features of the phase boundary; the disordered phase is characterised by a higher dielectric constant, which may result in the appearance of a depolarising field.^{57,59,65} When free charge carriers are present, the structural heterogeneity induces the second stage of the resultant switching process. In this stage, due to the migration of the carriers over the disordered interfacial regions, the space charge relaxes to a state matching the newly formed domains.

IV. Curie transition

The ferroelectricity of the polymer systems in question should be described by general phenomenological relations. For example, in the absence of mechanical stress ($X = 0$), the variation of free energy G as a function of polarisation P is described by the expression

$$G = \frac{1}{2}\beta(T - T_0)P^2 + \frac{1}{4}\gamma P^4 + \frac{1}{6}\delta P^6, \quad (16)$$

where T_0 is the characteristic temperature; the β and δ constants are positive, and the sign of constant γ depends on the type of transition (it is negative for first-order transitions and positive for second-order transitions). The first derivative of G with respect to polarisation gives an equation which describes the electric field

$$E = \beta(T - T_0)P + \gamma P^3 + \delta P^5. \quad (17)$$

For a second-order phase transition, $\beta > 0$, $\gamma > 0$, and δ can be regarded as being equal to zero. In this case, the equation for the dielectric susceptibility χ has the form

$$\chi = [\beta(T - T_0) + 3\gamma P_s^2]^{-1}. \quad (18)$$

By differentiating this expression, one finds the second- (ϵ_2) and third-order (ϵ_3) dielectric constants⁶⁵

$$\epsilon_2 = -3\gamma P_s \chi^3, \quad (19)$$

$$\epsilon_3 = (-\gamma + 18\gamma^2 P_s^2 \chi) \chi^4. \quad (20)$$

At temperatures below the Curie point T_C ,

$$P_s^2 = \frac{\beta(T_0 - T)}{\gamma} \quad (21)$$

and

$$\epsilon_3 = 8\gamma \chi^4. \quad (22)$$

Since $\gamma > 0$, the ϵ_3 value is positive and ϵ_2 is negative. Above the Curie point, $P_s = 0$; hence, $\epsilon_2 = 0$. With allowance for Eqn (20), we have

$$\epsilon_3 = -\gamma \chi^4.$$

Thus, for a second-order phase transition, the second-order dielectric constant ϵ_2 is always negative below the Curie point and at T_C , it becomes equal to zero. The sign of the third-order dielectric constant ϵ_3 changes from positive to negative at the Curie point.

As noted above, for a first-order phase transition, $\gamma < 0$, and $\delta > 0$. In this case,

$$\chi = [\beta(T - T_0) + 3\gamma P_s^2 + 5\delta P_s^4]^{-1}, \quad (23)$$

$$\epsilon_2 = -(3\gamma + 10\delta P_s^2) P_s \chi^3, \quad (24)$$

$$\epsilon_3 = -[\gamma P_s^2(10\delta - 18\gamma^2 - 120\chi\gamma\delta P_s^2 - 200\chi\delta^2 P_s^4)] \chi^4. \quad (25)$$

The Curie point is determined by the temperature at which the energies of the polar and nonpolar phases become identical. This means [with allowance for Eqn (16)] that

$$T_C = T_0 + \frac{3\gamma^2}{16\beta\delta}. \quad (26)$$

During heating, the first-order phase transition ($\gamma < 0$) will be observed above T_C , whereas during cooling, it will occur below T_C . Thus, in practice, to determine the type of Curie transition, one should record the temperature dependences of ϵ_2 and ϵ_3 or establish the presence (or the absence) of a hysteresis of one or another characteristics during heating or cooling.

Strong piezoelectricity was first detected in a textured PVDF film;¹ therefore, it is this homopolymer that was used to verify the hypothesis about the ferroelectric nature of this phenomenon. However, the homopolymer is an inconvenient object for the study of the temperature anomalies which accompany the hypothetical ferroelectric–paraelectric transition. The temperature region of the Curie transition coincides in this case with the melting region; therefore, it is difficult to separate them in the experiment.

The presence of piezo- and pyro-electric properties in PVDF has stimulated the search for ways of modifying the chemical structure of this polymer. Copolymerisation of VDF with TFE and TrFE proved to be the most suitable method. The introduction of even small amounts of these co-monomers results in the formation of the polar (ferroelectric) β -phase directly during crystallisation from the melt, which is not characteristic of the homopolymer.²⁸ This type of chemical modification of PVDF also influences the parameters of the unit cell being formed. The tendency of variation of the interplanar spacings in VDF/TFE copolymers upon the variation of the proportion of TFE can be followed by looking at Table 4. It can be seen that an increase in the TFE proportion is accompanied by an increase in the interplanar spacing corresponding to the intermolecular 200, 110 reflections. Hence, the cell packing becomes less dense along the direction perpendicular to the c axis.

Table 4. Interplanar spacings ($\text{\AA}$) in oriented VDF/TFE copolymers with various co-monomer ratios.⁶⁶

54	4.82 ^a	2.58	2.27

^a Non-resolved doublet.

This fact is, apparently, the main reason why the Curie transition and the melting point in these copolymers occur in different temperature ranges, which permits recording of the pure Curie transition by, for example, the X-ray diffraction method.⁶⁶ The influence of the temperature on the interplanar spacing and on the unit cell dimension along the a axis in the 76/24 VDF/TFE copolymer is illustrated by Fig. 15. It can be seen that hysteresis phenomena are observed not only for the reflection intensities but also for the interplanar spacings. The transition to the paraelectric phase is accompanied by a discontinuous increase in the unit cell parameter a . The temperature range in which both reflections coexist is attributed to the presence of both the ferroelectric and paraelectric phases. Yet another interpretation of this fact assumes the formation of some single phase with a symmetry lower than the hexagonal symmetry.^{67,68}

The changes in the 200 and 110 reflections for VDF/TFE copolymers with compositions 76/24 and 75/25 are qualitatively similar,⁶⁸ although the hysteresis phenomena are less pronounced

Figure 15. Temperature dependences of the interplanar spacings and the unit cell parameter a for the ferroelectric (1, 2) and paraelectric (3, 4) phases of the 76/24 VDF/TFE prepared in the heating (1, 3) and cooling (2, 4) regimes.⁶⁶

in the latter case. In view of the high information content of IR spectroscopy, it would be of interest to follow the variation of the conformational state of PVDF chains in the vicinity of the Curie transition by this method. These data are presented in Fig. 16 for the 75/25 VDF/TFE copolymer.⁶⁸ It can be seen that the bands at 842 and 1325 cm^{-1} , arising from the planar zigzag conformation in the chains of the VDF copolymer, become much less intense in the temperature region of this transition. Simultaneously, the proportion of chain units occurring in the helical *gauche*-conformation increases in the same temperature range. It is significant that the sharp decrease in the content of *trans*-conformers observed in the vicinity of the Curie transition involves not only VDF sections in the copolymer but also TFE sequences (a band at 620 cm^{-1}), a certain fraction of which (*e.g.*, for the 71/29 composition) can occur as dyads.⁶⁹

Figure 16. Temperature dependences of the relative variation of the intensities of the bands and 620 (1), 842 (2), 1325 (3), and 926 cm^{-1} (4) in the IR spectra of the ferroelectric 75/25 VDF/TFE copolymer.⁶⁸ (1) TFE groups in the *trans*-conformation, (2, 3) VDF groups in the *trans*-conformation, (4) VDF groups in the *gauche*-conformation.

Thus, the ferroelectric–paraelectric transition in VDF/TFE copolymers is accompanied, apart from the change in the lattice parameters, by the substantial change in the conformational state of the chains, the equilibrium of the *trans*- and *gauche*-isomers being displaced towards the latter.

Figure 17. Melting and Curie points as functions of the VDF content in VDF/TFE copolymers⁷⁰ (a) and phase diagram of VDF/TrFE (b).⁶⁷ HT is the paraelectric phase, LT and QL are the ferroelectric phases; (1–3) are boundaries between the phases.

As the proportion of TFE in the copolymer increases, a regular decrease in the Curie point should be expected in addition to the monotonic ‘loosening’ of the crystal along the a axis of the unit cell. This is confirmed by the results of X-ray diffraction^{67, 70} and spectroscopic⁶⁸ studies. According to X-ray diffraction data,⁷⁰ an increase in the fraction of TFE to 40 mol.% is accompanied by a linear decrease in the Curie point (Fig. 17a). The dependence of the melting point on the monomer ratio has a minimum; when the VDF fraction in the copolymer is below 80 mol.%, the Curie transition and melting temperatures are different, and these processes can be observed separately. With the assumption that the linear dependence of T_c on the VDF fraction still holds when this fraction is above 80 mol.% (dashed line in Fig. 17a), the Curie point for pure PVDF (in the β -phase) should be 198 °C, which is higher than the melting point (175 °C).

Copolymers of VDF with TrFE, which possess higher piezoelectric characteristics, have been studied more comprehensively in this respect. In several studies of the thermal properties of these copolymers by differential scanning calorimetry (DSC), in addition to the melting endotherm, typical of crystallisable polymers, one more peak, attributed to the Curie transition, was observed at lower temperatures (Table 5).^{67, 71–73} As the proportion of TrFE in the copolymer increases, the Curie point is displaced to lower temperatures. The enthalpy of this transition in the heating regime is always greater than that in the cooling regime. When the content of VDF is more than 70 mol.%, the Curie point exhibits a clear-cut hysteresis, pointing to a first-order phase transition. However, for the copolymer with 52.8 mol.% of VDF, the temperature hysteresis is hardly visible, which indicates the possibility of a second-order phase transition. In this case, the enthalpy is much lower.

Structural studies of VDF/TrFE copolymers showed⁶⁷ that their unit cell parameters, like those of VDF/TFE copolymers (see Fig. 15), change in the region of the Curie transition, which is due to the rearrangement of the polar cell into a nonpolar one. However, this transition is not so unambiguous, as was first suggested. Detailed analysis of the line contour of the intermolecular reflection near the Curie transition showed that two types of ferroelectric phases, QL and LT, can, in principle, exist.^{28, 67} This conclusion has also been drawn in several other studies. For example, the presence of two heat evolution peaks below the melting region on the DSC curves has been explained⁷⁴ by the presence of two types of lattice of the ferroelectric phase differing in their degree of defectiveness. These peaks are matched by two maxima on thermal depolarisation curve for 75/25 and 70/30 VDF/TrFE copolymers. Experiments on the observance of dielectric hysteresis in these copolymers showed two peaks for the transpolarisation current, the characteristics of which depend on

the previous thermal history³⁴ and poling conditions of the samples.⁷⁵

The appearance of dielectric anomalies points to the ferroelectric–paraelectric transition. Therefore, if there exist two types of ferroelectric phases with different degrees of crystallographic order, the temperature dependences for the real (ϵ') and imaginary (ϵ'') components of the complex dielectric constant should have two maxima. This is actually the case for the 65/35 VDF/TrFE copolymer (Fig. 18). The phase diagrams of VDF/TrFE copolymers show these two ferroelectric phases (see Fig. 17b, QL and LT

Figure 18. Temperature dependences of the real (a) and imaginary (b) components of the complex dielectric constant recorded during heating of the 65/35 VDF/TrFE copolymers.⁷⁶ Frequency /MHz: 0.5 (1), 2.5 (2), 10 (3).

phases). According to the diagram, the more defective ferroelectric phase QL is formed only in copolymers with low concentrations of VDF, whereas in copolymers enriched in VDF, the ferroelectric transition follows the LT → HT pattern. Having agreed with the qualitative character of this diagram, Ogura *et al.*⁷⁶ reported data that made it more precise. Figure 19 shows the diffraction curves in the region of the principal intermolecular reflection for the 65/35 VDF/TrFE copolymer. At room temperature (below the Curie point), the copolymer with this composition should contain only the LT type ferroelectric phase (see

Figure 19. Variation of the shape of the diffraction curve for the intermolecular reflection near the Curie transition in the 65/35 VDF/TrFE copolymer at various temperatures.⁷⁶ $T/^\circ\text{C}$: 30 (a), 70 (b), 80 (c).

Fig. 17b). However, two components of the reflection (see Fig. 19a, b) point to the presence of both phases, QL and LT. In addition, as the temperature is raised, the LT → HT transition and then the HT → melt transition should occur. However, the paraelectric phase HT starts to appear in the presence of both the QL and LT phases (Fig. 20). In the vicinity of a certain temperature T_a , the proportions of the ferroelectric phases QL and LT start to decrease and the pattern of the temperature dependences of the corresponding interplanar spacings changes. In the same region, the paraelectric phase HT appears; in the range between T_a and T_C it coexists with the ferroelectric phases.

Figure 20. Temperature dependences of the reflection intensities (a) and interplanar spacings (b) for the paraelectric and ferroelectric phases in the region of the Curie transition for the 65/35 VDF/TrFE copolymer.⁷⁶

The QL phase has greater interplanar spacings than LT. According to Tashiro *et al.*,⁶⁷ the less dense packing of the QL phase can be described by two structure models (Fig. 21). The first model implies the formation of crystals in which chains with planar zigzag conformations arranged in the (130) planes are bent with respect to c axis through an angle of 18° (Fig. 21a). Bends of this type can also arise in the crystals of the LT phase but in this case, the angle is $\sim 3^\circ$. The other model assumes the occurrence of 60° domains (Fig. 21b). These defects preclude the possibility of a denser packing, as in the LT phase. For example, the LT phase is characterised by the following monoclinic unit cell parameters: $a = 9.12 \text{ \AA}$, $b = 5.25 \text{ \AA}$, c (chain axis) $= 2.55 \text{ \AA}$, $\beta = 93^\circ$. The QL phase has the same lattice symmetry but contains a portion ($\sim 30\%$) of crystals with the above-noted defects. The crystal parameters are as follows: $a = 9.16 \text{ \AA}$, $b = 5.43 \text{ \AA}$, c (chain

Figure 21. Schematic pattern of the disordered structure of the QL phase in the model of bent chains with the planar zigzag conformation (a) and in the model of the 60-degree domains (b).⁶⁷

axis) = 2.53 Å, $\beta = 93^\circ$. It can be seen that the lattice distortions arising on passing from the LT phase to the QL phase are accompanied by a noticeable decrease in the packing density in the polar direction (*b* axis).

As the Curie point is approached (in the rising temperature regime), conformational changes start to occur in the chains of the copolymers considered, as in the VDF/TFE copolymer (see Fig. 16). This is illustrated by Fig. 22 for 72/28 VDF/TrFE. It can be seen that near T_C , the intensity of the band at 1290 cm^{-1} , corresponding to the long sequences of VDF chains in the planar zigzag conformation (*trans*), sharply decreases.²⁸ Conversely, the intensity of the band at 612 cm^{-1} , due to the TGTG[−] conformation (*gauche*),²⁸ starts to increase substantially. Apparently, this is due to the fact that, as the Curie point is approached, bonds with 'defective' conformations, TG, T₃G, TG[−] and T₃G[−], begin to appear in the VDF chains in the planar zigzag conformation. This fact may account for the decrease in the intensities of reflections of the LT and QL phases and the increase in the intensity of the reflection due to the paraelectric HT phase (see Fig. 20a). The same assumption can explain the change in the interplanar spacing and the decrease in the intensity of the 001 reflection of the β -phase (see Fig. 22a,b). The pronounced hysteresis of the above-mentioned characteristics indicates that the Curie transition in this copolymer is a first-order phase transition.

In view of the appearance of conformations corresponding to the α - and γ -modifications in the PVDF chains,²⁸ a dense packing of chains in the paraelectric HT phase should not be expected. In fact, this phase is characterised by the following unit cell

Figure 22. Temperature variations of the relative change in the interplanar spacing (a), the intensity of the 001 reflection (b), the intensity of the bands at 1290 (c) and 612 cm^{-1} (d) in the IR spectra of the 72/28 VDF/TrFE copolymer.⁸⁶

parameters: $a = 9.75$ Å, $b = 5.63$ Å, c (chain axis) = 4.60 Å and $a/b = \sqrt{3}$. Several questions concerning the structure of paraelectric phase remain to be solved because calculation of the statistical chain packing does not provide agreement with experimental results.⁶⁷ This was attributed to the intense thermal motion in the HT phase, which can be recorded by dielectric measurements^{77, 78} and NMR.^{79, 80}

It should be noted that the presence of the QL and LT phases can account for the appearance of the 'anomalous' double hysteresis patterns in VDF/TrFE copolymers with high contents of a second co-monomer.^{75, 81, 82}

The type of Curie transition in VDF copolymers is usually identified based on the presence or absence of hysteresis on the temperature dependence of one or another parameter sensitive to phase transformations. These parameters are found in the studies of thermal, electric and spectroscopic properties of objects. The NMR method and measurements of ultrasound⁸³ and crystal microhardness⁸⁴ are used more rarely for this purpose. Analysis of the temperature dependences of structural and spectroscopic characteristics of both VDF/TFE and VDF/TrFE containing more than 65 mol.% of VDF shows that temperature hysteresis is always observed in heating–cooling cycles (see Figs. 15, 16, 22). However, for VDF/TrFE copolymers of the compositions 60/40 and 52/48, this hysteresis becomes slightly visible.⁸⁵ This behaviour is typical of a second-order phase transition.

This conclusion was confirmed in another study⁶⁵ using a more appropriate method based on the measurement of non-linear dielectric properties, in particular, second- (ϵ_2) and third-order (ϵ_3) dielectric constants. These characteristics behave in different ways in first- and second-order phase transitions. Figure 23 shows the temperature variation of ϵ_2 and ϵ_3 for 52/48 and 73/27 VDF/TrFE copolymers. It can be seen that these characteristics behave differently for the two copolymers. Indeed, ϵ_2 and ϵ_3 of the 73/27 copolymer remain finite and positive over the whole temperature range up to the Curie point, whereas for 52/48 copolymer, ϵ_2 drops to zero, and ϵ_3 changes its sign at the Curie point. In accordance with relations (20) and (25), the criterion for a second-order phase transition is clearly fulfilled for the 52/48 copolymer (see Fig. 23a,c). Conversely, for the 73/27 composition (and for 65/35, which is not shown in the Figure), the condition for a first-order phase transition is complied with. Thus, the hypothesis that the character of phase transition in

Figure 23. Temperature dependences of the second- and third-order dielectric constants in VDF/TrFE copolymers with compositions 52/48 (a, c), 73/27 (b, d) obtained in the heating (1) and cooling (2) regimes.⁶⁵

VDF/TrFE copolymers changes at a composition of 52/48 (or near it) is confirmed not only by the specific features of the temperature hysteresis.

The VDF/TrFE copolymers are convenient as model compounds for predicting the behaviour of the LT–HT phase boundary. If the copolymer is considered to be ideally statistical, *i.e.* containing no composition fluctuations, the T_C value should be proportional to the concentration of ferroelectric groups in VDF.⁸⁸ This, however, is not confirmed by experiments (see Fig. 17b). This inconsistency can be due to the following reasons. Firstly, the appearance of ferroelectricity in the blocks of TrFE chains cannot be ruled out.^{81,87} Secondly, the real copolymers cannot be regarded as ideally statistical. In fact, VDF/TrFE copolymers (as well as PVDF) contain a certain number of defects caused by the ‘head-to-head’ attachment.^{28,69} In addition, for instance, in VDF/TFE copolymers, about 5% of TFE units occur as dyads even when the TFE proportion is 29 mol.%.⁶⁹

Both reasons can, on the one hand, be responsible for the non-linear course for the LT–HT phase boundary (see Fig. 17b) and, on the other hand, account for the formation of two ferroelectric phase modifications, LT and QL. The question why the Curie point in VDF/TrFE copolymers corresponds to a first-order phase transition for VDF contents of more than 60 mol.% and to a second-order phase transition for lower VDF concentrations has been tackled by Odajima⁸⁷ from the viewpoint of statistical theory. For this purpose, the investigator analysed the dielectric anomalies near the transition, characterised by the inverted dielectric absorption $\Delta\epsilon$. Finite (non-zero) $1/\Delta\epsilon$ values at the Curie point are inconsistent with the classical views [see, for example, relation (18)]. Evidently, this is due to the specific character of crystallisable polymeric systems, namely, to the presence of disordered areas, which are taken into account by using a constant in the theoretical description of the temperature dependence of $1/\Delta\epsilon$ near the Curie transition.⁷⁷ The structural heterogeneity of VDF/TrFE copolymers and the possibility of composition fluctuations in their chains are responsible for the fact that the region of dielectric anomaly covers a fairly broad temperature range; the Curie transition can thus be attributed to diffuse phase transitions.⁸⁷ This is also confirmed by the fact that the Curie points found by DSC and NMR are lower than those found from dielectric measurements.^{89–91}

The types of the phase transition at the Curie point have been predicted using the temperature dependences of the absorbances at two wavelengths (850 and 610 cm^{-1}) in the paraelectric phase of the copolymers considered. The former band corresponds to the bonds in the *trans*-conformation and the latter corresponds to the bonds in the *gauche*-conformation.²⁸ The D_{850}/D_{610} ratio was regarded as being equivalent to the ratio of populations of these states. In the case of the 72/28 VDF/TrFE copolymer, the D_{850}/D_{610} ratio for the paraelectric phase was found to increase on raising the temperature, while for the composition 52/48 it was found to decrease.⁹² If the energies of the *trans*- and *gauche*-isomers are denoted by U_t and U_g , respectively, then for the 72/28 VDF/TrFE,

$$J = U_t - U_g < 0,$$

and for the composition 52/48,

$$J = U_t - U_g > 0.$$

In other words, *gauche*-isomers are found to be more stable in the former copolymer, and *trans*-isomers are more stable in the latter copolymer.

Resorting to these experimental facts, Odajima⁸⁷ developed a statistical theory of ferroelectric transitions in the copolymers in question for two models of pair interactions in the linear lattice formed by bonds in *trans*- and *gauche*-conformations with invoking combinatorial formulae.⁹³ The calculated reduced spontaneous polarisation as a function of reduced temperature in the region of ferroelectric transition is presented in Fig. 24a. Accord-

Figure 24. Temperature dependences of the reduced spontaneous polarisation in the region of the Curie transition for two models characterised by the parameter $B = J/kT_0$.⁸⁷

B : -2.0 (1), -1.0 (2), 0 (3), 2.0 (4) (a); -0.3 (1), -0.2 (2), 0 (3), 0.5 (4), 2.0 (5) (b). N_0 is the concentration of dipoles, μ is the dipole moment of the CF_2 group.

ing to both models, a first-order phase transition is manifested only for $J < 0$ because only in this case, do metastable states arise at temperatures $T > T_0$ (T_0 is the characteristic temperature). In the case where $J > 0$, a second-order phase transition occurs and no hysteresis is displayed. The latter situation ($J > 0$) occurs in 52/48 VDF/TrFE, for which almost no temperature hysteresis is observed in the region of transition.⁹²

Thus, the theory developed in the study cited⁸⁷ provides results which coincide qualitatively with experimental data. If a copolymer with a composition of 72/28 has $J < 0$,⁹² then $P \neq 0$ can also be fulfilled at $T > T_C$ (see Fig. 24), *i.e.* prerequisites for temperature hysteresis appear, which is consistent with the data of Table 5. For the 65/35 VDF/TrFE copolymer, hysteresis is also observed but the situation is more complicated. For this copolymer, $J \approx 0$ (see Ref. 92) and temperature hysteresis is possible only in terms of model II (Fig. 24b), which uses more complex combinatorics of bonds in the linear lattice than model I. It remains to be seen whether the calculated character of phase transition in 52/48 VDF/TrFE copolymer coincides with that observed in the experiment. The calculation⁸⁷ was based on the fact that free energy does not depend on lattice parameters. Practically, this could be the case only if the measurements are carried out in the ‘constricted’ state. The majority of experiments are carried out under free conditions under which the sample lattice should deform under the action of polarisation. Thus, the electrostriction effect can influence the free energy and, as a consequence, a second-order phase transition should be transformed into a first-order transition.⁹⁴

The 52/48 VDF/TrFE copolymer has a low Curie point; therefore, it can be used to monitor the influence of an external static field on the position of the Curie point. This task has been accomplished by Date.⁹⁵ The Curie transition was detected in the temperature dependences of the pyroelectric coefficient p_y based on the point where $p_y = 0$. This is exemplified in Fig. 25, which presents the experimental temperature dependences of the pyroelectric coefficient for this copolymer under the action of fields with various polarities. If the external field coincides in direction with the remanent polarisation, it shifts the Curie point to higher temperatures. If the field has the opposite sign, the Curie point shifts to lower temperatures. This shift is linear and has the slope

$$\frac{dT_C}{dE} = \Delta P \frac{T_C}{L}. \quad (27)$$

Here ΔP is the change in the polarisation near the Curie transition and L is the latent heat. By increasing the amplitude of the negative bias field, the Curie point can be appreciably decreased; in this particular copolymer, it can be brought close to room temperature. If the temperature in some region is raised (*e.g.*, by use of a laser), the direction of spontaneous polarisation in this region will be reversed due to the bias field. This enables optical

Figure 25. Temperature dependences of the pyroelectric constant in the 52/48 VDF/TrFE copolymer upon the application of electric fields with various strengths.⁹⁵

$E/\text{MV m}^{-1}$: -10 (1), -5 (2), 0 (3), 5 (4), 10 (5), 15 (6).

recording of information with the aid of ferroelectric polymer films, which was actually demonstrated in practice.⁹⁵

For recording, it is important to ensure efficient transfer of a thermal pulse to the ferroelectric matrix. Evidently, this can be attained by introduction into the films of dye molecules with an absorption band in the range of laser radiation. In this respect, studies of the behaviour of dyes carried out by Verkhovskaya *et al.*^{96–98} appear significant. In particular, it was found that doping of 70/30 VDF/TrFE copolymer by merocyanines makes it possible to observe photoelectric sensitivity in the visible and UV regions of the spectrum. Analysis of the fluorescence⁹⁸ and absorption⁹⁶ spectra showed intense interaction of the rhodamine 6G molecule with the ferroelectric phase of the copolymer. The appearance of temperature hysteresis in the region of the Curie transition indicates that it is a first-order phase transition. The so-called structure-chromic effect was established; this means that spectral characteristics of the dye molecules change depending on whether the crystalline phase occurs in the ferroelectric or in the paraelectric state. Thus, the principal band of merocyanines shifts to the blue region and becomes less intense above the Curie point.^{96,97} The optical recording in doped copolymers was performed using the dye spiropyran, which exhibits a photochromic effect. The possibility of observing the photorefractive effect using these systems has been demonstrated.⁹⁷

V. The mechanism of the generation of ferroelectricity based on NMR studies

The nature of ferroelectricity in the polymers in question can be elucidated more precisely on the basis of the molecular dynamics characteristics. Quasielastic neutron scattering is sometimes used for this purpose;⁹⁹ various modifications of NMR are employed more often. VDF/TrFE copolymers with various ratios of the components have served as the objects of NMR studies. For example, copolymer with the composition 70/30 has been studied.¹⁰⁰ The researchers attempted to answer a number of fundamental questions. In particular, they tried to find out whether or not passing from the low-temperature ferroelectric phase to the high-temperature paraelectric phase gives rise to specific mobility. If this mobility does appear, whether it results in a higher symmetry in the disordered phase. The point group of symmetry in this phase, which can vary from $6/mmm$ (centrosymmetrical lattice) to $6/2m$ (non-centrosymmetrical lattice), also presents interest.

The signal of free induction at temperatures above 80 °C can be represented as a superposition of two components.¹⁰¹ One component (for short times t) refers to the ^{19}F nuclei in the crystal and is described by the Gaussian function¹⁰⁰

$$M(t) = \Delta M(0) \exp\left(-\frac{M_{2c} t^2}{2}\right), \quad (28)$$

where M_{2c} is the second moment of the line for the crystalline phase.

The second component is associated with the amorphous phase: at $T > 80$ °C, this component is described by a Lorentzian dependence, typical of viscous liquids. The temperature dependence of the free induction signal from the NMR data can be used to estimate the change in the dynamic degree of crystallinity (in addition to the static degree of crystallinity, which can be estimated, for example, based on X-ray data). Figure 26 shows the temperature dependences of the dynamic degree of crystallinity and the rate of transverse relaxation as well as the DSC curves for 70/30 VDF/TrFE copolymer. In the region of the Curie transition, the dynamic degree of crystallinity markedly changes and hysteresis in the heating and cooling regimes is observed. The temperature plots for the transverse relaxation rate for the crystal also change markedly in the transition region and exhibit a clear-cut hysteresis. The chain dynamics in the amorphous phase also proves to be sensitive to the phase transition because the corresponding line in this region does not vary monotonically, although hysteresis is barely visible in this case.

Figure 26. Temperature dependences of the dynamic degree of crystallinity (α_d) (a), the transverse relaxation rate (ω_r) (b) and heat evolution (Q) (c) in the 70/30 VDF/TrFE copolymer;¹⁰⁰ (I) heating, (2) cooling; I is the crystal, II is the amorphous phase.

Thus, the Curie transition in this copolymer is of dynamic origin and can be likened to the plastic phase transitions observed in some low-molecular-mass crystals.¹⁰⁰

By using different modulation frequencies (9.14 and 20 MHz), the researchers separated the contributions of the amorphous and crystalline phases to the spin–lattice relaxation times (T_1). The contribution of the amorphous phase (T_{1a}) varies nearly monotonically exhibiting no hysteresis in the transition region, whereas the contribution of the crystalline phase (T_{1c}) passes through a minimum in this region and exhibits a typical hysteresis in the heating–cooling cycles. Below the Curie point, the absolute values of T_{1a} and T_{1c} differ by more than an order of magnitude, whereas above the Curie point, they differ only by a factor of 2. Thus the parameters characterising the dynamics in the paraelectric phase are similar to those for the disordered phase. The chains forming the paraelectric phase can have several equilibrium positions, which should result in a higher symmetry compared to that in the ferroelectric phase.¹⁰²

The character of the Curie transitions in VDF/TrFE copolymers of various compositions can be judged from the data that are given in Table 6 and include results obtained by the NMR method. It can be seen that the Curie transition temperatures determined by different methods are somewhat different; however, in some cases, the tendency for hysteresis in the cooling and

Table 6. Temperatures T_C (°C) found by various methods for VDF/TrFE copolymers of various compositions in the heating (I) and cooling (II) regimes.^{104, 106}

Com-position	NMR ^a		NMR ^b		DSC		DM ^c	
	I	II	I	II	I	II	I	II
52/48	63	63	65	65	60	62	79	73

^a Based on the variation of the line width; ^b based on the variation of T_1 ; ^c dielectric method (measurement of $\Delta\epsilon^{-1}$).

heating regimes can be followed. It is confirmed once again that in 52/48 copolymers, a second-order phase transition occurs, which is replaced by a first-order phase transition for higher VDF concentrations.

Ishii and Odajima¹⁰³ used the Ising model^{104, 105} to calculate some parameters of the fluctuation transition, in particular, the effective distance (d) between the fluctuating ordered units connected by short-range forces and the correlation length of the fluctuation region of polarisation (ξ). The d and ξ values were found to be somewhat greater for 52/48 and 65/35 copolymers than for copolymers with other compositions. Apparently, the ferroelectric–paraelectric transformation in these copolymers is better interpreted as a second-order phase transition.

Later, the same researchers studied the molecular dynamics in the region of the Curie transition using a different NMR technique, namely, analysis of the shape of the absorption peaks.^{106–109} Textured films of the copolymers were used as the samples; the angle between the external field and the stretching direction was varied. At room temperature, the absorption line consists of three components, which are interpreted in terms of nonequivalence of the local fields for the fluorine nuclei occurring in the bulk of the ferroelectric phase, at its boundaries, and in the amorphous phase. For 52/48 copolymer, the absorption line at 30 °C contains only two components.^{106, 109} The temperatures of transition to the paraelectric phase, found from the narrowing of the widest component of the signal for various copolymers, are listed in Table 6. These temperatures are very close to the spin–lattice relaxation temperatures (T_1), their variation fitting in the general regularity of hysteresis in these copolymers. In fact, hysteresis is not displayed in the 52/48 copolymer but appears at higher VDF proportions.

Lovinger *et al.*¹¹⁰ used ¹H and ¹⁹F NMR spectroscopy to analyse the molecular dynamics in the VDF/TrFE copolymers containing 10 mol.% to 70 mol.% of VDF. When the composition was 70/30, the ¹H NMR free induction signal in the 15–60 °C temperature range consisted of three components. The narrowest and the medium components were attributed to the motion in the normal and ‘stressed’ amorphous phase, respectively. In the temperature range 60 °C < T < T_C , the medium component becomes more intense; this was interpreted as being due to the ferroelectric–paraelectric transition. The calculation of the second moment ΔH_2^2 for the medium and broad components, which are assigned to the paraelectric and ferroelectric phases, respectively, shows that these phases coexist in a broad temperature range, from 60 to 120 °C. The data on the second moment for the crystals of the paraelectric phase in the 70/30 VDF/TrFE copolymer indicate the possibility of substantial dynamic disorder in this phase. In fact, the ΔH_2^2 value for the rigid lattice of the paraelectric phase calculated based on the X-ray diffraction data should be 11.6 G², while the experimental value is only 2.5 G². This appreciable difference cannot be explained only by the changes in the type of packing in the crystal and in the chain conformations upon the Curie transition. Evidently, vigorous molecular motion, whose type is yet unknown, should be expected in the paraelectric phase. In particular, if the chains in the paraelectric phase are

assumed to rotate about the macromolecule axes, the calculated ΔH_2^2 value decreases to 3.5 G² (see Ref. 110).

The difference in the dynamic degree of crystallinity found from ¹H and ¹⁹F experiments for copolymers with VDF contents not higher than 70 mol.% is attributed to the difference in the compound compositions in the regions with slow and fast dynamics. The difference may be due to the segregation of phases enriched in VDF and TrFE groups; this is not at variance with the conclusion about the existence of two crystalline modifications in these copolymers¹¹¹ or with the conclusion concerning the presence of LT and QL phases. If segregation does occur, it should also influence characteristics of the disordered phase. Indeed, since the glass transition temperatures of PVDF and polytrifluoroethylene (PTrFE) are appreciably different (–40 and +40 °C, respectively), the regions enriched in VDF and TrFE should also be characterised by different glass transition temperatures. This can account for the specific features of the dynamics of these copolymers near 40 °C^{71, 112} and for the data of ultrasonic¹¹³ and NMR studies.¹¹⁴

A fairly unusual conclusion has been drawn¹¹⁴ in a study of copolymers with various previous thermal histories. In particular, samples obtained by quenching and isothermal crystallisation were studied, the perfection and the volume fraction of crystals being higher in the latter case. The Curie point for samples obtained by quenching was found to be higher than that for isothermally crystallised ones. Similar results were obtained by the DSC method.¹¹⁵ The second moment of the absorption line, ΔH_2^2 , scarcely changes above the Curie point.¹¹⁴ The interplanar spacing behaves in a similar way, while the intensities of the absorption bands corresponding to the planar zigzag conformation continue to change in the $T > T_C$ region.^{116, 117} This means that the conformational changes in the vicinity of the Curie transition ‘lag behind’ the changes in the lattice type.

Unlike ΔH_2^2 , the correlation time τ_c is determined by the movement of domain boundaries and, hence, the pattern of its temperature variation near T_C should be symmetrical. In reality, experiments showed slight asymmetry of this dependence.¹¹⁴ Rigamonti¹¹⁸ has attributed this asymmetry to the order–disorder transition.

Comparison of the anomalies in the temperature dependences of spin–lattice relaxation times in an ordinary and in a rotating system of coordinates near the Curie transition¹¹⁴ shows that they resemble most closely the dielectric anomalies considered, for example, by Davis *et al.*¹¹⁹ When comparing the spin–lattice relaxation times in copolymer samples obtained by quenching and isothermal crystallisation above the Curie point, the researchers noted that the samples are more perfect in the former case. This contradicts the known properties of crystallisable polymers. This contradiction can be explained by the presence in the copolymers of two crystalline phases, ferro- and paraelectric phases, which differ in both the lattice parameters and chain conformations. Crystallisation at $T > T_C$ should be accompanied by an increase in the proportion of chains in the helical conformations in the crystal; after cooling the sample to room temperature (*i.e.* below T_C), these chains will be perceived as conformational defects. This may be the reason for the lower Curie temperature observed for these samples. This hypothesis is confirmed by NMR data for samples of the 70/30 VDF/TrFE copolymer annealed above the Curie point.¹²⁰ Local mobility in the ferroelectric crystals was found; this can be attributed to the presence of the conformational defects mentioned above. These defects are ‘weak points’ in the ferroelectric phase (with chains in the planar zigzag conformation) but they can play an important role in the initiation of the Curie transition; specifically, they shift the transition to lower temperatures, which has been observed in a study.¹¹⁴

The chain dynamics in the disordered phase also influence the Curie transition. This phase has been reported¹²⁰ to have high-frequency mobility modes similar to those in the paraelectric phase. The parameters of these modes can also have an influence

on the characteristics of the ferroelectric transition because crystallisable polymers have no clear-cut phase boundaries.

At the crystal boundary, regions with tie-tough chains (TTC) are located, in which the same chains can be incorporated simultaneously in the disordered (in the strict crystallographic sense) phase and in the adjacent crystal. Since the neighbouring monomer units in a chain are linked by covalent bonds, the high-frequency motion modes in the disordered phase should at certain amplitudes generate conformational defects in the ferroelectric phase through the TTC sections. Evidently, this stage precedes the Curie transition. This is confirmed by the correlation between the variation of the interplanar spacing in the ferroelectric phase lattice and the intensity of the absorption band corresponding to the planar zigzag conformation. The change in the packing density of chains in the crystal is, apparently, the main reason for the generation of the high-frequency motion mode because high-frequency motions of the same nature were noted¹²⁰ in the amorphous phase below the Curie point and in the paraelectric crystal.

The views on the chain dynamics in the paraelectric phase have been detailed to a degree by varying the field frequency for resonance at the ¹H and ¹⁹F nuclei and analysing the data on the anisotropy of the second moment for textured samples.¹²¹ The researchers admit that rotation of the chain in the TGTG[−] conformation as a whole, which they proposed previously,¹¹⁰ appears unlikely, because a similar ΔH_2^2 value is found for this type of motion for chains in a planar zigzag conformation.¹²¹ The hypothesis of motion through propagation of kink bonds along the chain was also verified. For example, motion of the flip-flop type (a 180-degree kink) should result in the minimum of ΔH_2^2 being observed at an angle of 45° between the axis of tension and the direction of the magnetic field but this is not confirmed experimentally. This fact together with the fact that the calculated ΔH_2^2 value is several times greater than the experimental one prompted the researchers¹²¹ to conclude that this motion is impossible in the paraelectric phase. Motions as 120- or 60-degree kinks (between three or six symmetrical positions) are more probable because they provide reasonable agreement with experimental results. The possibility of the 'crankshaft' type motion involving three neighbouring bonds was also considered in the study cited.

VI. The influence of pressure on the characteristics of the ferroelectric transition

The mechanism of the formation of ferroelectricity in polymers can be elucidated more precisely by investigating the specific influence of various external factors, in particular, pressure and uniaxial stretching, on the ferroelectric–paraelectric transition parameters. The results of a study,¹²² dealing with the influence of pressure (up to ~1 GPa) on the components of the complex dielectric constant of PVDF and 70/30 VDF/TrFE can be considered as an example. The character of variation of the real dielectric constant ϵ' in the region of transitions upon variation of the external pressure can be followed from the temperature dependences shown in Fig. 27a. It can be seen that the $\epsilon'(T)$ curve for atmospheric pressure has two characteristic points. The low-temperature maximum is attributed to the dielectric anomalies in the vicinity of the Curie transition (T_C) and the inflection at higher temperatures is ascribed to the dynamic melting process (T_m). At higher pressures, both transitions are displaced to higher temperatures. This shift is non-linear (Fig. 27b). If the relative change in the volume ($\Delta V/V_0$) is taken as the variable, the temperature dependences for the Curie transition and for melting become straight lines (Fig. 27c). The slope regularly increases as the transition temperature rises; this also applies to the region of the transition associated with freezing of the micro-Brownian motion in the disordered phase.¹²²

In the case of the 52.8/47.2 VDF/TrFE copolymer, in which, as noted above, the Curie transition is a second-order phase

Figure 27. Temperature dependences of the real dielectric constant (100 kHz) at various pressures (a); transition temperatures vs pressure (b) and vs the relative change in the volume (c) for 70/30 VDF/TrFE copolymers;¹²² (a): P /MPa: 0.1 (1), 150 (2), 300 (3), 450 (4); (b, c): (1) T_m , (2) T_C .

transition, an increase in pressure influences the Curie transition temperature in a similar way.⁷³ If the Curie point is characterised by a maximum of ϵ' , the Curie–Weiss equations for this copolymer have the following form:

for $T < T_C$,

$$\frac{1}{\epsilon'} \approx \frac{T_C - T}{C_1}, \quad (29)$$

and for $T > T_C$,

$$\frac{1}{\epsilon'} \approx \frac{T - T_C}{C_2}. \quad (30)$$

The C_1 and C_2 constants for the standard pressure are 123 and 140 °C and $T_C = 67$ °C.

Similar relations have been obtained for the dependence of ϵ' on the pressure p for $p < p_C$,

$$\frac{1}{\epsilon'} \approx \frac{p_C - p}{C_3}, \quad (31)$$

and for $p > p_C$,

$$\frac{1}{\epsilon'} \approx \frac{p - p_C}{C_4}, \quad (32)$$

where $C_3 = 10.8$ GPa, $C_4 = 2.37$ GPa, and $p_C = 134$ MPa at 110 °C.

The displacement of the transition point under the action of external pressure for the copolymer with the 52.8/47.2 composition can be described by the following relation:⁷³

$$T_C = 76 \text{ °C} + 0.314p. \quad (33)$$

When the VDF content in the copolymer is 64.6 mol.%, two equations are needed to describe these dependences due to the hysteresis phenomena:

for heating,

$$T_C = 80 \text{ °C} + 0.383p \quad (34)$$

and for cooling,

$$T_C = 60 \text{ °C} + 0.401p. \quad (35)$$

The influence of pressure on the ferroelectric transition in these two copolymers can be followed from the data presented in Table 7. The experimental coefficients for the displacement of the Curie point as a function of pressure found by dielectric measurements and by the thermal expansion method are in good agreement with one another. The theoretical values of these coefficients were calculated using the Clausius–Clapeyron equation

Table 7. Curie temperatures, experimental and calculated coefficients of the displacement of the Curie temperatures (dT_C/dp /deg MPa), relative volume changes ($\Delta V/V_0$) and enthalpies (ΔH) for VDF/TrFE copolymers.^{73, 123}

Regime	$T_C / ^\circ\text{C}$	dT_C/dp		$\frac{\Delta V}{V_0} \times 10^2$	$\frac{\Delta H \times 10^{-7}}{\text{J m}^{-3}}$
		experiment	calculation		
Composition 52.8/47.2					
Heating	67	0.314 ^a 0.318 ^b	0.487	1.56	1.09
Composition 64.6/35.4					
Heating	86	0.383 ^a 0.381 ^b	0.206	1.51	2.63
Cooling	60	0.401 ^a 0.394 ^b	0.170	−1.05	−2.06

^a Dielectric measurements; ^b thermal expansion.

$$\frac{dT_C}{dp} = \frac{T_C(\Delta V/V_0)}{\Delta H} \quad (36)$$

It can be seen from the Table that the experimental and theoretical coefficients for the transition displacement can differ by a factor of more than two. Comparison of the presented dT_C/dp values with those for a similar copolymer containing 70 mol.% of VDF shows¹²² that the previous thermal history of samples can affect substantially the pattern of the influence of pressure on the transition considered.

The effect of pressure on the 54/46 VDF/TrFE copolymer has been studied.^{124, 125} This was done using a set of methods including DSC, X-ray diffraction, $D-E$ hysteresis, and ultrasonic studies. The temperature dependences of a number of parameters determined by these methods are shown in Fig. 28. It can be seen that at a pressure of 350 MPa the Curie transition becomes a two-stage process. In fact, according to DSC, two endotherms appear instead of one. The interplanar spacings for the 110 and 200 reflections also change in two stages. Two characteristic points are present in the temperature dependences

**Figure 28.** Temperature dependences of heat evolution (I , I'), interplanar spacing (2 , $2'$, 3 , $3'$), absorbance (4 , $4'$), sound velocity (5 , $5'$) and remanent polarisation (6 , $6'$) at a pressure of 0.1 (a) and 350 MPa (b) for the 54/46 VDF/TrFE copolymer.¹²⁴

of the absorbance, the sound velocity and the remanent polarisation.

This unusual phenomenon can be interpreted based on the above hypothesis concerning the formation of two types of ferroelectric phase, LT and QL, in the copolymers considered.^{124, 126} It is assumed that under normal pressure, crystallisation proceeds in the QL phase, whereas at the Curie point, the QL phase transforms in one step into the paraelectric phase. As the pressure increases to 350 MPa at room temperature, the QL ferroelectric phase transforms into a more perfect phase, LT. This can be judged from the decrease in the interplanar spacings for the 110 and 200 reflections (see Fig. 28, curves 2, 2' and 3, 3'). Heating under increased pressure is accompanied by transformation of the LT phase into the less perfect QL phase, which is subsequently transformed into the paraelectric phase. This scheme is consistent with a two-stage mechanism of the Curie transition, which is confirmed experimentally.

The influence of mechanical loading on the characteristics of the ferroelectric transition will be considered separately. Studies have been performed with textured films of VDF/TrFE copolymers to which mechanical stress X has been applied along¹²⁵ or across¹²⁷ the axis of tension. The Curie transition was monitored based on the characteristics of thermal shrinkage on heating (cooling) of uniaxially stretched films. It was found that the relative decrease in the size of the film (x) is most pronounced near the Curie transition. This characteristic temperature range was found to be well correlated with the range of specific changes in the structural parameters determined by X-ray diffraction and IR spectroscopy.¹²⁶

Figure 29 presents the displacement of the Curie point as a function of external stress. These plots allow one to follow the shift of the Curie transition. (The negative ΔT values imply displacement of T_C to lower temperatures). It can be seen that slight stress both along and across the axis of tension shifts the transition in both the heating and cooling regimes to lower temperatures. Thus, the shifts in the Curie temperature induced in the copolymers studied by an increase in the external stress are opposite to the pressure-induced shifts.

**Figure 29.** Influence of the external mechanical stress in isotropic (I) and uniaxially stretched (2 , 3) films of the 65/35 VDF/TrFE copolymer on the displacement of the Curie point during cooling (a) and heating (b).¹²⁷ The stress was applied along (2) and across (3) the stretching axis.

If we assume that the free energies of the ferroelectric (LT) and paraelectric (HT) phases are equal at the Curie point, then the shift of the Curie point caused by transverse stress X is described by the equation¹²⁷

$$\frac{dT_C}{dX} = -\frac{k' \Delta x_C}{\Delta S} \quad (37)$$

where k' is a constant, Δx_C is the change in the transverse dimension of the crystallite at the transition point, and ΔS is the difference between the entropies of the LT and HT phases. The sign of dT_C/dX in relation (37) is determined only by the sign of the constant k' . The negative sign is mainly due to high Poisson coefficient ($\mu_P = 4.5$), which is typical of textured crystallisable polymers.

It is very important to find out whether characteristics of the amorphous phase remain invariate during mechanical loading in the above experiments. Unfortunately, this point has been considered only in passing,^{125, 127, 128} although it deserves more comprehensive study. In fact, it has been found^{28, 129, 130} that loading of textured films of crystallisable polymers may bring about complex conformational transitions in amorphous regions (especially in those adjacent to the crystal).

This is confirmed by a study¹³¹ dealing with the variation of the longitudinal velocity of sound v_s and birefringence upon loading along the axis of tension of textured films of VDF/TFE. The increase in these values (for films with relatively low texturing temperatures T_d) points to conformational rearrangements, $TGTG^- \rightarrow (TT)_n$ and $T_3GT_3G^- \rightarrow (TT)_n$, for chain sections in disordered regions, which are highly pliable. The probability of these rearrangements depends substantially on the temperature of texturing (uniaxial stretching), which influences the number of conformational defects. Indeed, in the case of high T_d , the v_s and birefringence values change only slightly. The data of low-angle X-ray scattering indicate that the structure formed at these T_d is characterised by a greater difference between the densities (in the draw direction) of the crystal and the amorphous phase.^{131, 132}

External mechanical stress should apparently influence yet another ferroelectric characteristic of textured films — the time of polarisation switching τ_s in an electric field. For uniaxially stretched films, it would be pertinent to consider the influence of mechanical stress in the film plane applied at an angle normal to the axis of tension. This problem was solved in terms of the 60-degree switching model, according to which the nuclei of the new (switched) phase are formed at the crystal–amorphous phase boundary.¹³³ This model was substantiated by experimental facts pointing to a special role of the boundaries between the crystal and the amorphous phase and the TTC sections in them, which can act as the nuclei for new domains. Proceeding from this model, Jishi¹³⁴ considered the influence of the external stress X on τ_s with allowance for the Gaussian shape of stress distribution at the crystal–amorphous phase interface. By specifying particular values for the characteristic effective stress found from the experimental plots for the piezoelectric constant d_{32} vs mechanical stress,¹³⁵ the researcher cited showed that τ_s should diminish substantially under the action of stress. For example, at room temperature, the mechanical stress $X = 12$ MPa for a field with a strength of 200 MV m^{-1} should decrease τ_s by more than three orders of magnitude.¹³⁴ Unfortunately, this was not confirmed experimentally.

The role of pressure in the switching processes has been studied experimentally.¹³⁶ Figure 30 shows the characteristics of the switching process in PVDF with the ferroelectric β -phase as a function of the applied pressure. It can be seen that an increase in pressure increases the average switching time (τ_s) and regularly decreases the maximum current (Fig. 30a). The full transpolarisation charge, found by integrating the experimental curves, changes almost linearly starting from 200–300 MPa (Fig. 30b). The maximum current and τ_s vary nonlinearly as functions of pressure. To interpret the data obtained, the changes in the volume of the films with various degrees of crystallinity have been studied. This made it possible to estimate the compressibility of the crystalline and amorphous phases in a bulk sample.

The crystal was found to be the least compressible and the disordered phase was the most compressible; the real bulk specimen was found to have a medium compressibility. Since τ_s increases with pressure (when the specific volume decreases), it was assumed that the switching time should depend on the fraction of free volume f . This relationship can be described by an equation of the type of the Doolittle equation,¹³⁷ which is often used when studying the relaxation processes in polymers

$$\tau \approx \exp\left(\frac{1}{f}\right). \quad (38)$$

Figure 30. Switching current density in PVDF films with the β -phase at various pressures vs time (a); surface charge density for the maximum current and switching time vs pressure (b); and switching time vs relative change in the volume (c).¹³⁶ (a): p /MPa: 0.1 (1), 150 (2), 300 (3), 500 (4); (b): (1) $q(p)$, (2) $j_{\text{max}}(p)$, (3) $\tau(p)$; (c): (1) is the amorphous phase with a fraction of free volume of 0.054, (2) is the crystal with a fraction of free volume of 0.034.

The f value is expressed via the relative change of the volume¹³⁶

$$f(p) = \frac{f_0 V(p)}{V_0}, \quad (39)$$

where f_0 is the relative free volume at atmospheric pressure and room temperature, i.e. when $V(p) = V_0$. It follows from relations (38) and (39) that

$$\ln \tau(p) = \frac{A + V_0}{f_0}. \quad (40)$$

If this concept is valid, the variation of $\tau(p)$ as a function of $V_0/V(p)$ should follow a linear pattern in semilogarithmic coordinates (Fig. 30c). The slope of the plots for $\ln \tau_s$ vs V_0/V determines the f_0 value. The f_0 values were calculated for both the crystalline and amorphous phases based on the data on compressibility of samples with various crystallinity degrees. It was found that for the amorphous phase, $f_0 = 0.054$, which is close to the values 0.05–0.07, typical of standard amorphous polymers.¹³⁸

Thus, experimental plots for the switching time vs pressure imply that the state of the amorphous phase plays a very important role in the mechanism of polarisation switching in crystallites. This is consistent with the above-stated hypothesis that nuclei of new domains can arise in the amorphous phase (or at its boundary with the crystal), TTC sections playing a special role. Evidently, the dynamic characteristics of TTC should be the first to be taken into account, which is confirmed by the parameters of switching in samples with various previous thermal history and in samples exposed to γ -rays.¹³⁶

VII. The influence of the structural features of polymers on their ferroelectric characteristics

As the crystalline phase becomes more perfect, the ferroelectric parameters in crystallisable polymers are improved. An original method for decreasing the imperfection of the crystal lattice has been found.¹³⁹ A deuterated PVDF sample with the crystals of the β -phase was compared with a similar non-deuterated sample. The degree of perfection of the crystal lattice was estimated indirectly relying on the parameters of the D – E hysteresis dependences, obtained under the same poling conditions. For the non-deuterated sample (field strength $> 200 \text{ MV m}^{-1}$), the remanent

polarisation was 56 mC m^{-2} , which is consistent with the results of other researchers. The P_r value for the deuterated film proved to be almost twice as great ($\sim 100 \text{ mC m}^{-2}$), which was explained by a more perfect structure of the ordered regions. The reasons for this phenomenon are still not entirely clear, because a mere increase in the degree of crystallinity α could cause a similar increase in P_r .

The influence of the parameter α on P_r has been specially studied for 80/20 VDF/TFE samples with different previous thermal histories.¹⁴⁰ Three modes of crystallisation from the melt were considered, namely: quenching, crystallisation at 120°C and a pressure of 0.1 MPa , and crystallisation at 250°C and a pressure of 500 MPa . The melting points T_m were estimated from DSC data, and the degrees of crystallinity α were calculated from the density (Table 8). The α values varied from 43% to 80%. An increase in α was accompanied by an increase in not only the melting point but also the piezoelectric constant e (upon poling for 30 min in a field of 20 MV m^{-1}). The electrostriction constant k changed especially sharply (by an order of magnitude). The changes in the dielectric constant ϵ' confirmed the character of the variation of α (the crystalline phase has lower ϵ').

Table 8. Physical properties of the 80/20 VDF/TFE copolymer samples crystallised under various conditions.¹⁴⁰

ϵ' (10 Hz)	k (10 Hz)	$e \times 10^{-3}/\text{C m}^{-2}$	$T_m/^\circ\text{C}$	α (%)
10.3	-0.2	3.7	128	43
9.5	-1.0	4.6	140	60
7.6	-2.0	10.2	142	80

Figure 31a shows the curves for the polarisation current in the samples studied. It can be seen that, as α increases, the curve narrows down and shifts to lower fields. This points to a decrease in the coercive field. These curves were used to calculate the remanent polarisation. Both values are presented as functions of the degree of crystallinity in Fig. 31b. It can be seen that the plots are linear but variations of the two values are antiparallel; as α increases, P_r increases and E_c decreases. The former finding appears quite natural if ferroelectric properties are considered to originate from the crystalline phase. By extrapolating $P_r(\alpha)$ to $\alpha = 1$, one can find the P_r value for the crystals. It is equal to 84 mC m^{-2} . The relationship between P_r and the spontaneous polarisation P_s for isotropic samples can be represented as^{140, 141}

$$P_r = P_s[1 - \langle \cos^2\theta \rangle], \quad (41)$$

where θ is the angle between the field direction and the chain axis. In this particular case, $\langle \cos^2\theta \rangle = 1/3$; hence, the P_s value for the crystal is 126 mC m^{-2} . This is close to the value (140 mC m^{-2}) calculated from the relation¹⁴⁰

$$P_s = \left(\frac{\epsilon + 2}{3} \right) \langle \mu \rangle N \alpha F, \quad (42)$$

where $\epsilon = 3$ is the dielectric constant of the crystal, $\langle \mu \rangle = 2.1 \text{ D}$ is the dipole moment of the CF_2 group, $N = 1.4 \times 10^{28} \text{ m}^{-3}$ is the concentration of dipoles calculated based on the lattice parameters, $F = 0.9$ is the fraction of bonds formed in the normal ('head-to-tail'²⁸) fashion.

The decrease in the coercive field with an increase in the degree of crystallinity can be accounted for qualitatively by the high dielectric constant of the amorphous phase. This diminishes the field which really acts on the crystals, if they are assumed to be immersed into a disordered phase matrix. As the degree of crystallinity increases, the matrix should be reversed; thus, the crystals become located in an external field, which decreases the observed E_c .

A relationship has been found between the E_c value and some characteristics of the morphology of crystals of the ferroelectric phase.¹⁴⁰ It was found by scanning electron microscopy that in samples crystallised at 500 MPa , $150\text{--}250\text{-nm}$ thick lamellae, typical of extended-chain crystals (ECC), are formed. The low-angle X-ray scattering technique showed that the values for the long period L are also correlated with the α values; for samples with $\alpha = 0.43$ and 0.60 , the L values are $8\text{--}12$ and 30 nm , respectively. The variation of E_c as a function of $1/L$ was found to be linear (Fig. 31c); therefore, the magnitude of the coercive field for a hypothetical sample with an infinitely thick lamella can be calculated. This correlation can also be helpful in elucidating the role of specific defects of polymeric crystal folds in the mechanism of generation of ferroelectricity. It is assumed that the proportion of the folded areas in the crystal decreases as the large period increases; this creates more favourable conditions for the rearrangement of the dipole structure under the influence of an external field. This assumption is substantiated because near folds, the directions of the bond dipole moments vary continuously. This fact, together with the fact that specific defects of the 'entanglement' type can arise in these regions, hamper cooperative rearrangements in an electric field.

The dependence of the remanent polarisation on the volume fraction of crystals and the details of morphology can be followed by examining the data on the influence of annealing on the structural and ferroelectric characteristics of PVDF films.^{142, 143} For this purpose, uniaxially stretched films were used in which crystals occurred in the ferroelectric β -phase. The annealing was carried out under isometric conditions in order to prevent film shrinkage and crystal disorientation. Annealing at a temperature above 100°C causes substantial changes in the crystal structure. The decrease in the half-width ($\beta_{0.5}$) of the principal intermolecular reflections of the β -phase, 200 and 110, indicates a substantial increase in the transverse dimension of the crystal and/or its perfection. The shift of these reflections to greater angles points to an increased density of packing of the chains in the crystal. The remanent polarisation virtually does not depend on the above structural parameters because it does not change up to $T_0 = 160^\circ\text{C}$. A sharp increase in P_r (from 56 to 85 mC m^{-2}) is observed only upon annealing in the temperature range $170\text{--}180^\circ\text{C}$, i.e. in the range of pre-melting of the PVDF crystals. The appreciable increase in P_r observed under these conditions can be attributed to an increase in the degree of crystallinity (from 45 to 68%).¹⁴² Unfortunately, this has not been verified by direct methods. It can only be noted that the observed increase in P_r does not contradict the hypothesis¹⁴⁰ concerning the role of crystal folds. In fact, high-temperature annealing should be accompanied by melting of small (imperfect)

Figure 31. Polarisation current density in samples of the 80/20 VDF/TFE copolymer with various degrees of crystallinity vs external field strength (a); remanent polarisation and coercive field vs degree of crystallinity (b); and coercive field vs long period (c).¹⁴⁰ α (%): (1) 43, (2) 60, (3) 80.

crystals. Since annealing proceeds under conditions of external stress, recrystallisation processes can be accompanied by the formation of new crystals including extended-chain crystals, *i.e.* the concentration of specific defects of lamellar crystal folds can diminish, which is favourable for the P_r values.

The increase in the perfection of the crystal structure upon annealing at 100–160 °C, established by the X-ray diffraction method,¹⁴² does not influence the P_r value but limits the dynamics of the polarisation switching process. Thus the time of switching τ_s at –20 °C (in a field of 200 MV m^{–1}) amounts to 67.0 μ s for the initial sample and becomes 52.4 or 41.3 μ s after annealing at 120 or 160 °C, respectively.¹⁴³ A more detailed analysis shows that better packing of chains in the crystal results mainly in an increase in the rate of growth of the domain boundaries.¹⁴³

One of the approaches used to modify the polymer structure and molecular dynamics is plasticisation of polymers.^{144–146} In the case of crystallisable polymers, the introduced plasticiser (low-molecular-mass compound) is accumulated in amorphous regions, *i.e.* in sites characterised by an increased fraction of the free volume and decreased intermolecular interaction. It is of interest to follow the role of a plasticiser in the variation of the ferroelectricity characteristics. Tricresyl phosphate (TCP) was used as the plasticiser; it was introduced into a finished PVDF film at 130 °C in an amount of 5.5 mass % (see Ref. 145) or 1 mass % (see Ref. 146). The former study was devoted to the influence of the plasticiser on the field-induced $\alpha \rightarrow \beta$ transformation in isotropic PVDF films crystallised in a nonpolar α -phase.²⁸ The proportion of the polar β -modification arising was found to be much higher in the plasticised films under the same poling conditions.¹⁴⁵ The variation of the chain packing density in the ferroelectric phase was followed in relation to textured films with the β -phase oriented after treatment in a strong field. Comparison of the data on plasticised and non-plasticised films showed that in the former case, the polarisation-induced shifts of the principal intermolecular reflections, 200 and 110, of the β -phase to higher angles proved to be greater than those for the non-plasticised film. This was unambiguously attributed to the presence of the plasticiser because an increase in its concentration caused a regular shift of this reflection.¹⁴⁵

The effect of the same plasticiser on the remanent polarisation has been studied using characteristics of D – E hysteresis and thermodepolarisation currents. Even upon slight doping of PVDF films (the TCP content was 1 mass %), an increase in P_r was noted. This influence was more pronounced at low polarisation fields; at 60 mV m^{–1} and 20 °C, the addition of TCP resulted in an increase in P_r from 1 to 6 mC m^{–2}. The role of the plasticiser at high fields is less significant: at 200 MV m^{–1}, the P_r value increases upon doping from 57 to 66 mC m^{–2}.¹⁴⁶ These data demonstrate that the disordered phase plays a special role in the mechanism of formation of ferroelectricity in PVDF. The plasticiser most probably affects characteristics of the chain dynamics in the amorphous phase, especially at the boundaries with the crystals. The weakening of the interchain interaction in the sections with TTC should enhance the micro-Brownian mobility of chain segments. In this case, the crystal growth can be completed by some of the chains from the disordered phase; this must occur by an epitaxial mechanism. The increase in the proportion of the crystalline phase results in higher P_r values.

When considering the important role of the degree of crystallinity in the formation of ferroelectric characteristics of PVDF and VDF copolymers, one should not ignore other, equally significant, structural factors. When P_s remains constant, P_r can increase due to variation of $\langle \cos^2\theta \rangle$ [see relation (41)]. An increase in P_s can formally be attained by texturing an isotropic sample ($\langle \cos^2\theta \rangle = 1/3$) by uniaxial or biaxial stretching. According to X-ray diffraction data, the axes of macromolecules are arranged predominantly along the axis of tension within the plane of the film. The field is always directed at a right angle to the film plane, which implies a decrease in $\langle \cos^2\theta \rangle$ and an increase in P_r .

The validity of the foregoing is confirmed, for example, by comparing the characteristics of the D – E hysteresis in isotropic and textured films of VDF/TFE and VDF/TrFE copolymers, which always crystallise from the melt as the ferroelectric β -phase. The transition from the isotropic state to the textured state should be accompanied only by variation of the θ angle and should not be complicated by polymorphic transitions of the $\alpha \rightarrow \beta$ type as in the homopolymer.²⁸ This idea was verified for 94/6³² and 71/29 VDF/TFE.²⁸ It was found that the texturing process is really accompanied by an increase in P_r and also by a decrease in the coercive field.²⁸ The parameters of the D – E hysteresis in the films of VDF/TrFE copolymers with compositions 52/48, 65/35 and 73/27 have been compared.¹⁴⁷ The films were obtained by extrusion followed by rolling. The extruded films are characterised by slight crystal orientation; therefore, $\langle \cos^2\theta \rangle$ for these films would be close to that for isotropic samples. Rolling of the films between rolls is equivalent to a sort of uniaxial or biaxial stretching and brings about a clear-cut texture, which should substantially change the $\langle \cos^2\theta \rangle$ value. The ferroelectric characteristics of these films are listed in Table 9.

Table 9. Remanent polarisation, coercive field and piezoelectric constant e_{31} in rolled (I) and extruded (II) films of VDF/TrFE copolymers with a crystalline phase fraction of 41%.¹⁴⁷

Compo- sition	P_r /mC m ^{–2} (see ^a)		E_c /MV m ^{–1}		P_r /mC m ^{–2} (see ^b)		e_{31} /mC m ^{–2} (see ^b)	
	I	II	I	II	I	II	I	II
52/48	76	57	32	36	102	66	51	25
65/35	44	81	39	47	—	—	—	—
73/24	25	62	34	43	—	—	—	—

Note. The P_r and E_c values were found from characteristics of the D – E hysteresis.

^a Poling in the corona discharge at room temperature.

^b Contact poling at elevated temperatures.

It can be seen that the behaviour of the 52/48 copolymer is qualitatively similar to that of VDF/TFE copolymers, *i.e.* rolling results in higher P_r values and somewhat lower coercive fields compared to those before rolling. This is manifested especially clearly in the case of films prepared by contact poling at elevated temperatures, for which P_r (and, consequently, e_{31}) differ by a factor of ~ 2 . The data obtained for copolymers with higher VDF contents are contradictory; on passing from an extruded film to a rolled film, E_c changes as in the previous case but the variation of P_r shows an abnormal pattern. Unfortunately, the researchers cited¹⁴⁷ offer no explanation for this finding. This abnormal variation is surprising because the influence of the degree of crystallinity on P_r should not work in this case (the samples had equal proportions of the crystalline phase).

The relationship between the type of texture in the materials in question and the parameters of ferroelectricity has not been adequately studied. This can be illustrated, for example, by the data on D – E hysteresis of biaxially and uniaxially stretched PVDF films.¹⁴⁸ The former film contained crystals of both polar (β) and nonpolar (α) phases and the latter film contained only crystals of the ferroelectric phase. An increase in the number of cycles of D – E hysteresis for the former film was accompanied by an increase in both P_r and P_s , which is observed most frequently for polarisation of PVDF films. This can be caused to some extent by field-induced polymorphic transformations of the $\alpha \rightarrow \alpha_p$ and $\alpha \rightarrow \beta$ types.²⁸ The P_r and P_s values of the latter film decreased as the number of polarisation cycles increased. This finding was explained¹⁴⁸ by the somewhat speculative assumption that the field induces additional crystallisation of chains of the amorphous phase and this changes the ratio of the characteristic sizes of crystals and, hence, also changes the depolarisation factor.

The previous thermal history of texturing is a very important circumstance influencing the ferroelectric characteristics.¹⁴⁹ An increase in the temperature of uniaxial stretching is accompanied by a regular increase in the large period. The interlamellar layers are packed less densely due to a higher content of defective conformations, TGTG[−] and T₃GT₃G[−].^{28, 131, 149} The remanent polarisation in these films is several times lower.³³ The important role of the amorphous phase in the generation of ferroelectricity in VDF/TrFE copolymers has been pointed out in a series of studies,^{150–153} in which the Curie transition has been studied by Brillouin^{150, 151} and non-coherent neutron scattering.¹⁵² The attention is focussed on the dynamics of chains in this phase because near the Curie transition, the cooperative mobility with great amplitudes is characterised by reorientation frequencies of more than 10⁵ Hz.^{28, 153} It has been shown in relation to the 65/35 VDF/TrFE copolymers¹⁵⁴ that it is in oriented films that the parameters of several reflections of the ferroelectric crystals change markedly in the switching processes, whereas no changes are observed in isotropic films. Orientation is known to increase substantially the probability of formation of TTC.¹⁵⁵ The dynamics of the latter should be characterised by low relaxation times. As a consequence, the response of polar segments in such chains to an external electric field should initiate switching of the dipole moments of domains in the crystal. Therefore, the microstructure of the amorphous regions, especially at the boundaries with the crystal, should be taken into account in the mechanism of formation of ferroelectricity.

Identification of defects in ferroelectric crystals and elucidation of their influence on the ferroelectric characteristics of the polymers studied is an important problem. Some of the defects are entirely due to the character of macromolecules and generally cannot be eliminated. These defects can be represented, for example, by chain ends, which are located inside the crystal, and folds, typical of lamellar crystals of polymers. Some features of polymerisation of the compounds in question account for the appearance of the chemical defect caused by the 'head-to-head' attachment, which can be incorporated in the crystal bulk.²⁸ For crystals of the nonpolar α -phase, specific defects are also possible, consisting in different arrangements of chains in the lattice according to the 'up' and 'down' type.²⁸ In the interchain interactions, this can result in conformational rearrangements according to the TGTG[−] → GTG[−]T pattern. When the temperature increases, the equilibrium between these isomers shifts and, hence, the ordered phase passes into the 'condis' crystal state.¹⁵⁶ This transition is detected in the 47–77 °C range as a weak endothermic peak (with an enthalpy of 150–200 J mol^{−1}) in the heating cycle in DSC experiments.¹⁵⁶ This type of interaction is believed to be also responsible for dielectric relaxation,²⁸ which occurs in the crystalline phase of PVDF with α -modification.¹⁵⁷ At higher temperatures, this type of defect initiates conformational transitions of the TGTG[−] → T₃GT₃G[−] type and promotes the high-temperature α → γ phase transition.^{28, 158, 159} On exposure to strong electric fields of PVDF films crystallised as the α -phase, several new reflections were found,¹⁶⁰ which could not be assigned to any of the known polymorphic modifications (α , β , γ or α_p).²⁸ The appearance of a new superlattice for a conformationally non-commensurate form of PVDF is attributed to the interaction of the field with conformational defects of the type considered above.¹⁶⁰

Some details of the ferroelectric–paraelectric transition can be followed by comparing X-ray and spectroscopy data. In the case of oriented PVDF crystallised as the ferroelectric β -phase, the appearance of an additional blurred reflection near the identified 001 reflection is interpreted as being due to the conformational defect of the kink-bond type,¹⁶¹ i.e. local bonds in the TGTG[−] conformation appear in the crystal, while the majority of chains occur in the planar zigzag conformation.¹⁶² Defects of this type can be found in both VDF/TFE^{131, 163, 164} and VDF/TrFE copolymers.⁶⁷ These defects can be especially significant for the Curie transition, which is really confirmed by the temperature

Table 10. Values of the long period L , the transverse dimension of the crystal l_c , the size of amorphous layers l_a and the degree of crystallinity α for 70/30 VDF/TrFE films at various temperatures.¹⁶⁵

$T/^\circ\text{C}$	L/nm	l_c/nm	l_a/nm	$\alpha(\%)$
115	26.9	13.4	13.5	50
117	27.2	13.7	13.3	51
120	27.2	14.4	12.8	53
125	29.0	16.0	13.0	55
130	31.0	18.0	13.0	58
135	35.0	20.0	15.0	58

dependences shown in Fig. 16 and in Table 10. It can be seen that the transverse dimension of the crystal l_c remains virtually unchanged up to a temperature of 120 °C. However, the decrease in the concentration of bonds occurring in the *trans*-conformation starts well before 120 °C.

Thus, the lattice rearrangement at the Curie point ($\sim 120^\circ\text{C}$) is preceded by smooth accumulation of conformational defects, which occurs most likely as a thermally induced fluctuation process. The smooth changes in the microhardness of this copolymer can be due to the same process.¹⁶⁵ The rearrangement of the polar phase lattice into the lattice of the nonpolar phase might take place at a certain critical concentration of kink bonds (conformational defects) in the ferroelectric crystal. Above the Curie point, the crystals of the paraelectric phase start to grow noticeably and, simultaneously, the degree of crystallinity increases (see Table 10). The latter is due to the fact that some chains of the disordered phase are incorporated in the crystal by the mechanism of diffusion movement of defective bonds, which are laid on the surface of a new crystal. This process is expected to be facilitated by the similarity of the conformations in the amorphous phase and in the paraelectric crystal.

The 'memory' effects have been studied in relation to the 75/25 VDF/TrFE copolymer in the vicinity of the Curie transition.^{166–168} Analysis of the plots presented in Fig. 32 helps us to understand the essence of this effect. It can be seen that the ferroelectric phase (the reflection on the side of greater angles) and the paraelectric phase (the reflection on the side of smaller angles) coexist near the Curie point.

Figure 32. Character of the variation of the diffraction maxima in the vicinity of the Curie transition (a) and temperature dependences of the degree of the ferroelectric transition (α_f) (b) in 75/25 VDF/TrFE films.¹⁶⁸ $T/^\circ\text{C}$: (1) 120 (point A), (2) 120 (point A'), (3) 123, (4) 126, (5) 129.

Isotropic films prepared by quenching from the melt were studied. The rate of heating in the experiment was 2 K min^{−1}, the isothermal maintenance at each point was 30 min, and the maintenance at 120 °C (annealing) was carried out for 19 h and after that, the X-ray diffraction patterns were recorded. The annealing was accompanied by a marked decrease in the intensity of the reflection for the ferroelectric phase (see Fig. 32a). The

fraction of the ferroelectric phase remaining near the transition can be estimated from the intensity ratio of the two reflections (Fig. 32b). The change in the content of the ferroelectric phase upon annealing is marked by points *A* and *A'*. It can be seen that prolonged storage at 120 °C is accompanied by a change in the shape of the phase diagram curve; point *A* passes into *A'* instead of the movement along the trajectory shown by the dashed line. The subsequent temperature variation does not change the fraction of the ferroelectric phase (*A'B* section). Only at point *C*, is the character of the phase diagram restored. When the curve is recorded in the cooling regime, in addition to the hysteresis noted previously, the shape of the curve changes at point *D* (which corresponds to point *A'* regarding the phase ratio). The initial shape is restored at point *E*, reflecting the 'memory' effect in the system. Similar effects are also observed in inorganic ferroelectrics with incommensurate crystal structures; they are explained by interaction of mobile defects with the domain walls.¹⁶⁹

In the case of the polymer systems considered here, the incommensurability is determined by different chain conformations in the two phases; therefore, there are prerequisites for the memory effect. Judging by sections *AA'* and *BC* of the phase diagram, some relaxation processes occur in the crystalline phase and ensure transition of the system into an equilibrium state. These processes (which are described, in all probability, by an exponential law¹⁶⁸) might also be responsible for the unusual influence of the heating rate on the temperature of the Curie transition in VDF/TrFE copolymers.^{170, 171} The presence of these processes is confirmed by the study of the longitudinal acoustic mode (LAM), discovered in the crystals of VDF/TrFE copolymers in the frequency region of 10–20 cm⁻¹ (see Ref. 172). The characteristics of the LAM show that, as the proportion of TrFE in its copolymers with VDF increases, the libration frequency in the ferroelectric crystal decreases virtually linearly as a function of the average interchain distance.

The LAM bands for the copolymers considered here are poorly observable compared, for example, to those for polyethylene (PE).¹⁷³ This was attributed to the low degree of orientation in the copolymers, where the draw ratio was only 4, whereas in PE it reached 20. The poor orientation accounts for a broad distribution of the lamellae over thicknesses, resulting in appreciably broadened LAM bands.

The LAM characteristics were used to determine the sound velocity and the elastic constant c_{33} for a ferroelectric PVDF crystal. This polymer contains ~50 Å-thick lamellae; hence, based on the LAM frequency found and with the assumption of the half-wave resonance, the sound velocity in the crystal of the PVDF β -phase is $v_c = 7500$ m s⁻¹. If we assume that the crystal density $\rho_c = 1.97$ g cm⁻³ (see Ref. 28), then $c_{33} = \rho v_s^2 = 110$ GPa, which is comparable with this constant for the polyethylene crystal.

The elastic constants of the disordered phase have been estimated in terms of the two-phase model.¹⁷² They were 3.6 and 2.6 GPa for temperatures 27 and 87 °C; these values correspond to sound velocities of 1450 (27 °C) and 1250 m s⁻¹ (87 °C).

As the Curie point is approached, both phases (crystalline and amorphous) are 'softened' in similar ways: $\Delta v_{s\text{cr}}/v_{s\text{cr}} = -22\%$ and $\Delta v_{s\text{a}}/v_{s\text{a}} = -14\%$. This can serve as one more piece of evidence supporting the hypothesis of the strong connection between the chain dynamics in the disordered phase and characteristics of the Curie transition in the crystal.

The higher the temperature of crystallisation, the larger and the more perfect the crystals formed. When the crystals are formed in the paraelectric phase, they are less perfect. If crystallisation occurs at temperatures below T_C , the resulting ferroelectric crystals should be smaller and more perfect than those formed in the paraelectric phase. Hence T_C is determined by two factors acting in the opposite directions. A study has been devoted to verification of this hypothesis.¹⁷¹ It was shown that an increase in the crystallisation temperature is accompanied by an increase in the melting point (indicating the formation of larger crystals) but

in this case, the Curie point in the cooling regime decreases abnormally.

Similar conclusions have been drawn from the analysis of the Curie transition characteristics in the heating regime. The DSC curves for two copolymer samples obtained by fast quenching and by slow cooling of the melt were compared. The latter crystallisation mode in polymers is normally accompanied by a decrease in the fraction of the disordered phase and by crystal growth. Simultaneously, the melting point regularly shifts to higher temperatures. However, the Curie transition (in the heating regime) again shifts abnormally to lower temperatures. It was shown¹⁷¹ that crystals of the ferroelectric phase in samples with different previous thermal history are almost identical in size. This means that displacement of the Curie point in these samples cannot be explained by the change in the crystal geometry alone.

A similar variation of T_C observed for VDF/TrFE films prepared by crystallisation from solutions in solvents having different affinities to the TrFE groups is due to different concentrations of these groups in ferroelectric crystals.¹⁷⁴ The same might be responsible for this phenomenon observed in the above experiments. The co-monomer TrFE can be regarded as a defect in the PVDF chain. It is known that 'head-to-head' type defects can occur in PVDF crystals;²⁸ therefore, TrFE sections should also be incorporated in the ferroelectric phase. Since the thermodynamic flexibility of TrFE chains is lower than that of PVDF chains, it takes a long period of time for the former to be incorporated in the crystal. When the cooling rate is high (or the crystallisation temperature is low), it may happen that diffusion processes do not ensure, for kinetic reasons, the equilibrium number of TrFE groups in the crystal. Therefore, their concentration in the crystal may prove to be lower than the average concentration along the chain. Thus, the crystal becomes enriched in the VDF groups, which are responsible for the ferroelectricity. A decrease in the proportion of TrFE in the copolymer is known to result in all cases in higher Curie points. Thus, the Curie transition in the ferroelectric crystals obtained by fast quenching (or by crystallisation at lower temperatures), which are depleted of the TrFE groups, should be shifted to higher temperatures, which is actually observed in the experiments.

To understand the mechanism of ferroelectricity, it is significant to elucidate the role of crystal defectiveness. This problem was considered in relation to the 65/35 VDF/TrFE copolymer.¹⁵⁴ The data listed in Table 11 demonstrate how the transverse dimension and the second-kind defectiveness of the crystal, estimated from known relations (see, for example, Ref. 175), change upon polarisation. An increase in the polarising field leads mainly to an increase in the coherence length of the crystal and to a slight increase in the degree of its perfection.

Table 11. Coherence length of the crystal (l_{110}) in the ferroelectric (LT) and paraelectric (HT) phases and the second-kind defectiveness (g) in the LT phase upon polarisation of 65/35 VDF/TrFE films.¹⁵⁴

$E/\text{MV m}^{-1}$	l_{110}/nm		g
	LT phase	HT phase	
0	13	57	—
60	19	—	0.034
90	33	—	0.032
200	39	—	0.030

These processes are equivalent to an increase in the degree of crystallinity. The mechanism of this phenomenon assumes conformational rearrangements of the TGTG⁻ → (TT)_n and T₃GT₃G⁻ → (TT)_n types in the amorphous phase of the polymer. The additional incorporation in the crystal of sections with the planar zigzag conformation can be responsible for the increase in the coherence length after polarisation noted above.

This is confirmed to a degree by the results of a study by Latour and Moreira,¹⁷⁶ who found that polarisation of similar VDF/TrFE copolymers results in an increase in the intensity of the libration mode ($\sim 70 \text{ cm}^{-1}$) for the crystal in which the chains occur in a planar zigzag conformation.

Structural changes occurring during polarisation switching have also been studied for non-oriented films of the same copolymers.¹⁵⁴ The researchers noted that the extreme points are located in the regions where electric induction D reaches a virtually equilibrium value rather than in the regions characterised by the maximum rate of its variation. In experiments, an increase in the polarising field shifts the $D(t)$ curve to shorter times. The position of the minimum on the time dependence of the peak intensity varied in a similar way; however, in all cases, the minimum fell within the final stage of the switching process.²⁸ The resulting correlations were interpreted taking account of various ways of formation of new (switched) domains. If the old and the switched domains are coherent (and the fraction of switched domains is χ), the intensity of a reflection is determined by the expression

$$I = (1 - \chi)|F|^2 + \chi|F^*|^2 \approx |F|^2,$$

where F and F^* are structural factors of the old and new domains, respectively, which should be close because the type of the lattice remains the same. If the domains are non-coherent, then

$$I = |(17w)F + wF^*|^2 \leq |F|^2.$$

Thus, the assumption that the originating domain is not coherent with respect to the old one accounts for the decrease in the intensity of the 110 reflection observed experimentally. This decrease takes place if the new domain is rotated with respect to the old one (see Fig. 5). In all probability, the model with 120- or 180-degree rotation of the chain is realised. The latter is preferable because it requires that the boundary between the domains be located at the 100 planes, whereas for the 120-degree rotation, the 310 planes should be involved.¹⁵⁵

When the chain rotates through 180° , the hydrogen atoms go into the places of fluorines. The stress arising in the lattice can be diminished if the chain is translated by $c/2$ along the axis. Nevertheless, the 001 and 002 planes are distorted at the site of contact of the old and new domains. If the chains in two adjacent nascent domains are translated by $c/2$ in the opposite directions, the distortions are appreciably diminished. Thus, joining of two domains does not require translational motion of the chain in the arising new lattice with a new position with respect to the field.

It has been noted above that polarisation results in a threefold increase in the transverse dimension of the β -phase crystal in the VDF/TrFE copolymer (see Table 11). For a similar copolymer with the composition 75/25, this fact has also been confirmed by DSC.¹⁷⁷ The intensity of the low-temperature peak, which is attributed to the Curie transition, increases markedly after polarisation. Upon annealing at a temperature above 128°C after polarisation, the intensity of this peak decreases. The electron diffraction and IR spectroscopy data¹⁷⁸ do not show any changes in the lattice parameters or chain conformations, while changes in the domains do occur. After repeated annealing, a disproportion occurs in the narrow temperature range, $127\text{--}129^\circ\text{C}$, namely the remanent polarisation or electromechanical coupling coefficient (K_t) is already equal to zero,¹⁷⁹ whereas ferroelectric crystals are still present (the enthalpy of the Curie transition, $\Delta H \neq 0$). To eliminate this contradiction, it has been assumed¹⁷⁷ that rearrangements take place in ferroelectric crystals in this narrow temperature range (before transition to the paraelectric phase). As a result of chain rotation, in some domains, sub-domains are formed (without changes in the lattice parameters and chain conformations), in which spontaneous polarisation points to the opposite direction. Generally, this gives a zero remanent polarisation when ferroelectric crystals are still retained.

It has been shown in relation to the VDF/TFE copolymer¹⁴⁰ that crystallisation at elevated pressures is accompanied by the

formation of thick ($150\text{--}250 \text{ nm}$) lamellar crystals. These samples are also characterised by high remanent polarisation. Thus, it is clear that the P_r value is correlated with the morphology of the ferroelectric crystals formed. These correlations for VDF/TrFE copolymers have been considered in a series of studies.^{180–186} In one study,¹⁸¹ the problem of structuring in copolymers with high VDF contents, 86.88 mol.% and 94 mol.%, has been considered. These objects are of interest because, on the one hand, high temperatures of the Curie transition should be expected for these VDF proportions (this is important for the practical implementation of energy converters), and, on the other hand, crystallisation as the nonpolar α -phase is possible in this case.²⁸ This brought about the need to establish the details of the structuring of the copolymers in question and to identify their role in the variation of ferroelectric characteristics.

The films were prepared from a solution in dimethylformamide and annealed at a temperature (T_h) somewhat below the melting point. The structural characteristics were analysed using X-ray diffraction methods, IR spectroscopy, and electron diffraction. The morphology of the resulting crystals was studied by optical and electron microscopy. The copolymers under study can be described by the general formula $(\text{VDF})_x(\text{TrFE})_{1-x}$; the type of the morphology depends substantially on the x value. For $0.82 \leq x \leq 0.9$, this preparation technique always yielded thick lamellar crystals with dimensions $\sim 0.1 \mu\text{m}$, which has been noted previously for copolymers with $0.6 \leq x \leq 0.82$.¹⁷⁸ In the case of copolymers with $x = 0.94$, thick lamellae are formed only upon high-pressure crystallisation ($\sim 100\text{--}500 \text{ MPa}$); crystallisation under standard conditions results in spherulite morphology, typical of the PVDF α -phase.²⁸ Analysis of X-ray diffraction data shows that thick lamellae are formed by crystals of the α -, β - and, perhaps, even γ -phase. For copolymers with $x \geq 0.9$, the

(a): (1) β -phase, the coinciding 200 and 110 reflections; (2) α -phase, the 101 reflection; (3) rotator phase; (b, c): (1) β -phase, the 200 and 110 reflections; (2) β -phase, 001, 310, 020; (3) rotator phase; (d): transitions: (1) β -phase $\rightarrow$ liquid, rotator phase $\rightarrow$ liquid; (2) γ -phase $\rightarrow$ rotator phase; (3) α -phase $\rightarrow$ rotator phase; I — β -phase, thick lamellae; II — a mixture of α -, β -, and γ -phases, thick lamellae; III — α -phase, spherulites; IV — rotator phase.

spherulites are formed by the crystals of the α -phase (Fig. 33). The morphology is very significant for the stability of the crystals formed from copolymers of the same composition. This is demonstrated by the comparison of the temperature dependences of the intensities of the X-ray reflections of films incorporating lamellar crystals and thin fibrils, obtained by annealing and uniaxial stretching (Fig. 33a, b). It can be seen that in the former case, noticeable decrease in the intensity of the principal intermolecular reflections of the β -phase, 200 and 110, starts only at $\sim 100^\circ\text{C}$, while in the latter case (oriented films), it starts nearly at room temperature. A special role in this stability is played by film polarisation processes. After polarisation, the intensity of the 200 and 110 reflections does not change up to 150°C (Fig. 33b). Detailed analysis shows that a polymorphic transition of the $\alpha \rightarrow \beta$ type occurs in the polarisation cycles; this was detected relying on the typical change in the intensity ratio of reflections of the α - and β -phases and characteristic absorption bands in the IR spectra.¹⁸¹

The presence of a rotator phase is an important feature of thick lamellar crystals, which manifests itself at elevated temperatures (see Fig. 33a, b). This phase is responsible for a reflection with the angle position $2\theta \simeq 18^\circ$; therefore, it may be a modification of the paraelectric phase. The region in which the rotator phase is displayed depends on the structural features of the sample. This becomes clear upon comparison of the curves shown in Fig. 33a, b. In the initial sample, the lamellae contain a mixture of crystals of α - and β -modifications, which is confirmed by X-ray diffraction and spectroscopic data. In this case, the rotator phase starts to appear even at 100°C and is retained up to the melting point. After polarisation, this phase appears only at $\sim 150^\circ\text{C}$, the region of its existence being markedly narrower. After polarisation, the α -phase transforms into the polar β -modification and the intensity of bands responsible for the TGTG⁻ conformation in the IR spectra substantially decreases.¹⁸¹ Thus, the presence of α -phase regions (mixed with the β -phase) and the presence of conformational defects as sections of a helical conformation, with the planar zigzag being the major conformation, facilitate the appearance of the rotator phase.

High contents of VDF in copolymers with TrFE cause a number of structural features (Fig. 33d). If $x \leq 0.82$, a standard phase diagram is observed, *i.e.* on heating, the ferroelectric phase is converted into the paraelectric phase and then into the melt. For the $0.82 \leq x \leq 0.90$ region, in which thick lamellae are formed by crystals of α -, β - and γ -modifications, a multiplet character of transitions should be expected. As the temperature increases, the α -modification crystals are the first to pass into the rotator phase; they are followed by the γ -phase and then by the β -phase. The validity of this scheme is supported by the fact that endotherms for three transitions can be seen in the thermograms of the 88/12 copolymer.¹⁸¹ Some additional electrophysical data for the copolymers in question are listed in Table 12. It can be seen that all the samples with the morphology of thick lamellae are characterised by very high remanent polarisations, and, correspondingly, the electromechanical coupling coefficient. The increase in the VDF proportion in the copolymer is accompanied by a regular increase in the coercive field, as has been noted above. By comparing the E_c values for samples with $x = 0.81$, one can elucidate the influence of the texturing factor on E_c . Orientation of the film decreases E_c , which has also been noted in analysis of the results of other studies.²⁸ The piezoelectric constant d_{31} in textured films is, on average, more than twice as high as that for isotropic samples. However, the sound velocity is somewhat greater in the latter case. If the sound velocity is determined from the relation

$$v_s = \sqrt{\frac{c}{\rho}},$$

(c is the elasticity modulus, ρ is the substance density), it turns out that isotropic samples possess lower compliance ($1/c$) than

oriented ones. This circumstance may be reflected in the features of the piezoelectric response of textured films.

Some details of structural transformations in the same copolymers with high proportions of VDF were elucidated in a study,¹⁸² in which crystallisation was carried out at high pressures and thus the morphology of thick lamellar crystals was ensured. The results of studies of ferro- and piezo-electric properties of these copolymers are presented in Table 13. For comparison, data for one copolymer crystallised at normal pressure are also given in the Table. It can be seen that for copolymers with VDF contents of at least 86 mol.%, the Curie point (T_C) proves to be higher than the melting temperature (T_m). On the one hand, this can be interpreted as being due to the large thickness of lamellar crystals. On the other hand, it can be seen that the morphology of ferroelectric crystals has no influence on the pattern of dependence of the coercive field on the copolymer composition. As in the case of other crystallisation methods, an increase in the proportion of TrFE regularly shifts E_c to lower values. However, some facts cannot be explained. For example, the P_r and, hence, the K_t values for all films crystallised at elevated pressures prove to be lower than those for samples crystallised at a pressure of 0.1 MPa. The reason for this fact is not entirely clear. To interpret this abnormal feature, Ohigashi *et al.*¹⁸² assumed, without adequate substantiation, that high-pressure crystallisation affords less perfect crystals. A practically valuable conclusion was drawn in this study, namely, the morphology of thick lamellar crystals can be used to produce energy converters based on the copolymers considered here with an extended temperature range of operation. This was confirmed by the data on the pulse echo signals from the 86/14 copolymer at 165°C .

^a Crystallisation at 0.1 MPa and 140°C .

As noted above, thick lamellae are typical of ECC. Folded-chain crystals (FCC) are more often formed in polymers; however, ECC can also appear under specific conditions. This problem has been studied in detail for crystallisation of PE.¹⁸⁷ It was found that crystallisation from the orthorhombic phase yields FCC and crystallisation from the mobile hexagonal phase affords ECC.¹⁸⁸ For less dense packing of chains in the hexagonal phase, diffusion sliding processes are possible, which underlies the theory of thickening of lamellar crystals.^{189,190} In addition to PE, the formation of ECC has been noted for other crystallisable polymers, for example, polychlorotrifluoroethylene (PCTrFE), *trans*-1,4-polybutadiene,¹⁹¹ and in VDF/TrFE copolymers. If the composition of these copolymers is below the triple point ($x \approx 0.82$) (see Fig. 33d), they can crystallise (like PE) as orthorhombic (ferroelectric) and mobile hexagonal (paraelectric) phases. The mobile hexagonal phase can occur even under atmospheric pressure (a similar behaviour has been noted for PCTrFE and *trans*-1,4-polybutadiene); in the case of PE, this phase appears only at elevated pressures.¹⁸³

The first data on the formation of thick lamellae in PVDF were reported for crystallisation at elevated pressures.^{28,192,193} Subsequently, the possibility of the formation of ECC under atmospheric pressure has been verified. VDF/TrFE copolymers with VDF proportions (x) of 0.75 and 0.78 were chosen for this purpose. These values are lower than the x value in the triple point (0.82); therefore, in accordance with the phase diagram (see Fig. 33d), crystallisation can be carried out as the mobile hexagonal paraelectric HT phase. The data from scanning electron microscopy of samples crystallised at various degrees of supercooling show that the morphology of thick lamellar crystals is actually observed. At early stages of crystallisation, single lamellae were $\sim 0.3\text{-}\mu\text{m}$ thick. At later stages, stacking of lamellae into $\sim 0.8\text{-}\mu\text{m}$ thick stacks was noted. This aggregation in VDF/TrFE copolymers is observed more commonly than in PE, which is attributed to the greater role of screw dislocations in the former case. The particles arising are cigar-shaped and $20\text{--}30\text{-}\mu\text{m}$ long. Crystallisation of the same copolymers at high pressures (80 MPa) hardly changes the morphology arising. The thickness of single lamellae remains the same and the particle length is $10\text{--}20\text{ }\mu\text{m}$.¹⁸³ For copolymers with a known molecular mass, the full extended length was estimated to be $\sim 0.7\text{ }\mu\text{m}$. This means that chains fit almost entirely into the lamellae.

The theoretical possibility of the formation of thick lamellae, *i.e.* ECC, in the VDF/TrFE copolymer (see Fig. 33d) exists also when x is greater than that corresponding to the triple point. In fact, in the range of $0.82 \leq x \leq 0.9$, the mobile hexagonal (rotator) phase can exist.¹⁸¹ This hypothesis has been verified in a study.¹⁸⁵ VDF/TrFE copolymers with VDF proportions of 0.88 and 0.89 were studied. When conducting crystallisation from the melt under atmospheric pressure and with various degrees of supercooling, the researchers found cigar-shaped particles with dimensions approximately equal to those obtained upon crystallisation of copolymers with $x < 0.82$. Thus, it was confirmed experimentally that ECC can form even above the triple point in the phase diagram.

Nevertheless, in the study cited,¹⁸⁵ this finding was explained without assuming the existence of some rotator phase but proceeding from the Ostwald 'threshold' rule. The temperature dependences of the free energy for the three phases were derived, under certain assumptions,¹⁹⁴ as straight lines with different slopes. This results in two melting points, one for the hexagonal phase (T_m^h) and one for the orthorhombic phase (T_m^o). According to this diagram, crystallisation at a certain temperature T_{cr} converts the liquid in the supercooled state.

Specific defects referred to as 'entanglements' occur in the melt between the macromolecules. 'Untangling' of these defects on cooling the melt to T_{cr} takes some time; therefore, the liquid remains in the supercooled state for some period. After it has passed into the hexagonal phase, this phase occurs in the metastable state for some period of time. Its transition into the

more equilibrated orthorhombic phase also takes some time, because, in addition to the change in the type of lattice, this requires conformational rearrangements in the copolymer chains. The equilibrium in the hexagonal phase–orthorhombic phase (paraelectric–ferroelectric) system shifts with time towards the latter. Due to the enhanced molecular mobility, some of the crystals remaining in the metastable hexagonal phase form thick lamellar crystals as ECC.

The possibility of formation of thick lamellar crystals in the uniaxially stretched VDF homopolymer crystallised as the β -phase has been verified.¹⁸⁶ Two crystallisation modes were employed (Fig. 34a).

Figure 34. Melting thermograms of stretched PVDF films after high-pressure crystallisation in various regimes (a) and the T - p phase diagram (b).¹⁸⁶

(b): (1) T_m (hexagonal phase); (2) T_{cr} (hexagonal phase); (3) T_C for the orthorhombic–hexagonal phase transitions; (4) T_m for a uniaxially stretched film with the β -phase; (5) T_m for the β -phase ECC; (6) T_C for the hexagonal–orthorhombic phase transition during cooling. The region of regimes favourable for the formation of ECC is hatched. Points A–F correspond to the conditions of the crystallisation of samples (1–6) in (a).

Samples 1–3 were crystallised in the constant-pressure mode (200, 400 and 500 MPa, respectively), the temperature being increased to the maximum value (280, 300 and 300 °C, respectively). Samples 4–6 were crystallised under isothermal conditions (217, 262 and 282 °C, respectively), the pressure being increased from the initial value to the maximum value (100 $\rightarrow$ 500, 200 $\rightarrow$ 500, and 200 $\rightarrow$ 500 MPa, respectively). According to DSC data, the characters of melting endotherms observed for different samples are substantially different. The thermograms of samples 2, 5 and 6 with intense high-temperature peaks (maximum temperature 205 °C) can be distinguished. Analysis of the data of optical and electron microscopy for crystallised films demonstrated that it is in these samples that thick lamellar crystals are formed, *i.e.* the ECC morphology is realised. The transition enthalpies for samples 5 and 6 are 19.5 and 20.5 cal g⁻¹, respectively. These values are roughly equal to the sum of the enthalpies of the Curie transition and melting in the 74/26 VDF/TrFE copolymer.¹⁷⁹ This means that the Curie and melting points in PVDF films coincide; therefore, only one process is recorded.

The T - p phase diagram for PVDF shown in Fig. 34b helps in formulating the conditions for crystallisation yielding the ECC morphology. Since the Curie point in PVDF is very high, its crystallisation as the mobile hexagonal phase can be accompanied by thermal destruction processes. Certainly, they deteriorate the structural characteristics of ECC. Due to the large hysteresis in the Curie transition during heating and cooling, it is better to cool the melt and transform it into the hexagonal phase (metastable state); in this case, crystallisation can be carried out at markedly lower temperatures. Above the hatched region, thermal destruction exerts unfavourable influence, while below straight line 6 the system occurs as the orthorhombic phase, in which thick lamellar crystals do not form. The thickness of these crystals in samples 5 and 6 (see Fig. 34a) is 0.1–0.2 μm , which is comparable with the crystal thickness in 79/21 and 75/25 VDF/TrFE copolymers, although interplanar spacings of the 110 or 200 reflections (4.25 Å) in the samples under consideration are 5%–7% lower than those in these copolymers.^{178, 179}

Analysis of the X-ray diffraction data shows that even in sample 6 the lamellae consist of mixed crystals of the β - and γ -phases. On high-temperature polarisation of the films, the latter is transformed into the pure β -phase. Thus, the assumption that the morphology of thick lamellar crystals improves ferroelectric characteristics was confirmed once again. Comparison of the D - E hysteresis curves for the initial (oriented) film and sample 6 shows that the P_r value is greater in the latter case. More detailed data are presented in Table 14. The Curie point is found above the melting region (as in the case of copolymers with higher VDF contents). The highest sound velocities in these films and the minimum dielectric constants point indirectly to the highest degree of crystallinity in these polymers. However, this conclusion contradicts the reported data,¹⁴⁰ according to which an increase in the degree of crystallinity resulted in a decrease in the coercive field (see Fig. 31c), which was then found to be maximum for PVDF with ECC (see Table 14). In the opinion of Hattori *et al.*,¹⁸⁶ this can be attributed to the fact that the latter material does not form a pseudo-hexagonal lattice with $a/b = \sqrt{3}$. For PVDF with ECC, the a and b values are 8.66 and 4.25 Å, respectively, which do not yield this ratio.

The data on the structure of VDF/TrFE copolymers with critical compositions $0.82 \leq x \leq 0.90$ are the most contradictory. As noted above, thick lamellae have been detected in these copolymers.¹⁸¹ They should incorporate both ferroelectric β -phase crystals and nonpolar crystals of the α -phase (and, perhaps, even γ -phase) (see Fig. 33d). This assumption made it possible to explain why the Curie point and the melting point coincide. Thick lamellae with a size of $\sim 0.1 \mu\text{m}$ have also been detected¹⁹⁶ on slow cooling of copolymers with the composition 86/14. A low-angle X-ray scattering study showed the presence of

thin crystals ($l \approx 8.5 \text{ nm}$) apart from thick lamellae. If the hypothetical crystals of the α -, β - and γ -phases are assumed to coexist in both types of lamellae, two melting points and two Curie transitions should be expected, because thin lamellae disappear at 147–155 °C, whereas thick ones are retained up to 165–170 °C.¹⁹⁶ The α -phase melts more readily;²⁸ therefore, thin lamellae are likely to be formed by crystals of the α -phase, and thick lamellae are mainly formed by crystals of the β -phase.

In all probability, the morphology of thin lamellae is metastable because their content sharply diminishes at about ~ 150 °C.¹⁹⁷ The increase in the proportion of thick lamellae indicates that recrystallisation processes in this temperature region can be accompanied by solid-phase transformations of the $\alpha \rightarrow \beta$ type.²⁸ This assumption is not without reason because such a transition has actually been detected by the X-ray diffraction method in, for instance, the 94/6 VDF/TFE copolymer crystallised in the metastable state,^{28, 197} and in the case of the 86/14 VDF/TrFE copolymer, a decrease in the degree of crystallinity has been noted well before melting.¹⁹⁷ If the Curie transition occurs in this temperature range, it could be initiated to some extent by the dynamical changes in the disordered regions, as has been noted above.

VIII. Ferroelectricity of ultrathin films

Due to the pronounced influence of the morphology of thick lamellar crystals on the ferroelectric characteristics of PVDF and VDF copolymers, it is of interest to consider the results of studies of these characteristics in thin and ultrathin films. The electro-physical characteristics of the three-layer metal–dielectric–semiconductor system have been analysed.¹⁹⁸ The system contained a 32- or 150-nm thick dielectric film of the 73/27 VDF/TrFE copolymer deposited from a solution onto a silicon substrate with the hole type of conductivity. After the copolymer film had been coated by a protective SiO_2 layer (50–70 nm), the breakdown field intensity for this film was 230 MV m^{-1} , which is comparable with the values typical of films with a standard thickness. Analysis of the dependence of the capacity (at a frequency of 1 MHz) on the voltage applied on the metal–dielectric–semiconductor structure made it possible to estimate the remanent polarisation in the copolymer films after poling ($\sim 100 \text{ MV m}^{-1}$). For a 32-nm thick film, P_r amounts to 5.9 mC m^{-2} ; for a thickness of 150 nm, this value is 4.1 mC m^{-2} . These values are approximately an order of magnitude lower than the P_r values for ordinary films. The reason for this is obscure because the coercive fields in these films, like those in ordinary films, are about 40–33 MV m^{-1} (see Ref. 198).

In other studies,^{199, 200} copolymer films have been deposited by the vacuum vaporisation technique. In the case of 80/20

VDF/TrFE, a KBr crystal served as the substrate. Study of films of various thicknesses (~ 10 to 60 nm) by IR spectroscopy resulted in the conclusion that deposition is accompanied by thermal destruction of macromolecules. The destruction yields fragments retaining the initial chain conformation rather than the monomers.

The change in the substrate temperature leads to a changed orientation of chains with respect to the surface. At 35°C (cold substrate), the axes of macromolecules are arranged at right angles to the surface and at 80°C (hot substrate) they are parallel to the surface. Similar effects have also been described in other studies,^{201,202} which have also noted that the orientation of copolymer chains on the substrate also depends on the film thickness. The temperature effects on the formation of films on the substrates can be regarded as general because they are also manifested for the same films deposited by epitaxial growth from solutions.²⁸

It seems attractive to combine polarisation with deposition of thin films on the substrate. This attempt was made in a study,²⁰⁰ in which the 54/46 and 73/27 VDF/TrFE copolymers were sprayed onto quartz at a rate of 0.02 nm s^{-1} in a field of up to 30 MV m^{-1} . The 400-nm thick films of the copolymer with 54 mol.% of VDF displayed dielectric anomalies in the Curie transition region only in those cases where spraying was carried out in a field (30 MV m^{-1}); when deposition was performed without a field, no dielectric anomalies were observed. As in ordinary films, the Curie transition had signs of a second-order phase transition (without hysteresis). These facts confirm the significant role of electric field in the formation of a ferroelectric structure. The fact that no ferroelectricity was found in films that had not been exposed to an external electric field points indirectly to the occurrence of irregular sections, most probably, of a chemical nature, which hamper the formation of the ferroelectric phase.

This assumption is supported by the data obtained by the same researchers for 73/27 VDF/TrFE. Films prepared by spraying in a field displayed no dielectric anomalies near the Curie transition ($\sim 120^\circ\text{C}$) because the sample melted at 105°C . Melting could be due to chain rupture reactions, which efficiently proceed during deposition; they should markedly decrease the average molecular mass of the chain and, hence, the melting point. Thermal destruction should increase the concentration (and mobility) of ionic impurities. Indeed, the shape of the D – E hysteresis curves implies an enhanced role of free charge carriers.²⁰⁰ This can increase the probability of electric break-down of the films. The coercive fields were found to be lower (by two orders of magnitude). This can be explained qualitatively by assuming that the films thus obtained possess higher degrees of crystallinity (see Fig. 31). This situation can be a consequence of the substantial decrease in the average molecular mass upon thermal destruction, which apparently gives a low-molecular-mass product.

Thus, thin films deposited by spraying exhibit ferroelectric properties; however, the chain structure in these materials is transformed in such a way that ferroelectric characteristics prove most often to be poorer than those for thick films. The formation of thin films from solutions, which allows one to control the conformational characteristics of the chain and the phase state of the crystals formed due to the specific influence of a particular solvent, appears more promising.²⁸ This method brought the studies at a new level after Russian scientists had proved the possibility of producing monomolecular films of the polymers in question using the Langmuir–Blodgett technique.^{45,203–210}

These films are promising for the use in optical memory cells provided that ferroelectric switching has been detected in them. Films of the 70/30 VDF/TrFE copolymer, deposited from solutions in dimethyl sulfoxide with a copolymer concentration of 0.01 mass % have been studied.^{45,203–210} The Langmuir–Blodgett films were formed on the surface of doubly distilled water using a setup described in the literature.²¹¹ After the films had been transferred onto a metallic substrate and the upper electrode

Figure 35. Pyroelectric response (a) and transpolarisation current density (b) vs electric voltage in a 15-nm thick Langmuir–Blodgett film of the 70/30 VDF/TrFE copolymer.²⁰⁶

had been deposited, it was possible to study electrophysical characteristics of the films. Analysis of surface tension isotherms showed that the thickness of a monomolecular film is ~ 0.5 nm.⁴⁵ Films composed of 5 to 40 monolayers were mostly used. Ferroelectric characteristics, in particular, spontaneous polarisation, were measured using the pyroeffect, namely, by recording the current arising on exposure of the film to a $100\text{-}\mu\text{s}$ pulse of the Nd-laser radiation ($\lambda = 1.06\text{ }\mu\text{m}$). Figure 35 shows the field dependences of the pyroelectric response and the transpolarisation current density in a Langmuir–Blodgett film composed of 30 monolayers. The presence of pyroactivity in the initial (non-polarised) film points to a non-zero residual (spontaneous) polarisation, which may be due to the specific conditions of the film formation.

The presence of switching effects indicates unambiguously that these films possess ferroelectricity, which is manifested in a special way. Firstly, the coercive field strengths, $E_c = 300\text{ MV m}^{-1}$, are almost an order of magnitude greater than those observed in ordinary films (see Fig. 35 and Table 9). Secondly, analysis of the scanning tunnelling microscopy data (STM) shows a two-dimensional lattice with two identity periods on the film surface. One of the periods ($2.6\text{ }\text{\AA}$) is virtually constant for all samples and is related to the lattice constant $c = 2.56\text{ }\text{\AA}$ (see Table 4) along the macromolecule axis. The other identity period varies from sample to sample from 2.2 to $4\text{ }\text{\AA}$ and characterises the intermolecular packing. Langmuir–Blodgett films are expected to have very high break-down fields (at least, 600 MV m^{-1}). These films are characterised by higher pyroelectric coefficients than ordinary films — $400\text{ }\mu\text{C m}^{-2}\text{ K}^{-1}$ against $\sim 30\text{ }\mu\text{C m}^{-2}\text{ K}^{-1}$.

If a denser, on the average, packing of chains is assumed for Langmuir–Blodgett films, the Curie point in these films may be expected to shift to higher temperatures relative to that in thick (block) films. It can be seen from Fig. 36 that the Curie transition in the Langmuir–Blodgett films is displaced to lower temperatures relative to that for ordinary films ($\sim 15\text{ }\mu\text{m}$).

Figure 36. Temperature dependences of the pyroelectric voltage, polarisation (a) and capacity (b) in the Langmuir–Blodgett films (1) and ordinary films (2) of the 70/30 VDF/TrFE copolymer.^{206,212}

Thus, the shift of the Curie point observed experimentally is opposite to that suggested beforehand. In all probability, the reason for this anomaly is the same as for the unusual behaviour of the spontaneous polarisation, which starts to diminish well before the Curie point. These abnormal features are apparently due to different energy states of macromolecules on the film surface and in its bulk. Macroscopic ferroelectric characteristics in thick films should be determined by parameters of chains in the bulk, whereas in the case of Langmuir–Blodgett films, the chains located on the surface can contribute more significantly to the properties.

The appearance of ferroelectricity in 100–200 Å thick films implies that this layer permits the formation of a three-dimensional crystal of the ferroelectric phase. Chains in the planar zigzag conformation are packed in such a way that polar axis *b* becomes the predominant direction. The polarisation component directed at right angles to the film surface is usually measured; therefore, the transverse dimension of the crystal should be not less than the film thickness. The transverse dimension of the crystal can be estimated based on the width of the 200 and 110 intermolecular reflections of the ferroelectric phase. In the case of the thin lamellar morphology, this dimension for block films is ~100–200 Å (see, for example, Table 11). This means that only one crystal is formed in the perpendicular direction in a Langmuir–Blodgett film consisting of 30 monolayers, *i.e.* in this direction, the degree of crystallinity is 100%. This is confirmed indirectly by values of spontaneous polarisation equal to 0.1–0.15 C m⁻²,²⁰⁶ which are comparable with the values calculated for the crystal of the β -phase (0.13 C m⁻²).

More evidence for the advanced hypothesis could be provided by the magnitude of the component of the dielectric constant ϵ' along the perpendicular to the film. By using the dependences presented in Fig. 36, Palto *et al.*²¹² found that for room temperature, $\epsilon' = 4$, which is substantially lower than this value for a 15- μ m film ($\epsilon' = 12$). The high ϵ' value for ordinary films is due to the contribution of amorphous areas with developed cooperative mobility, in which the dielectric constant is much greater than in the crystal.²⁸ Therefore, the low ϵ values may point to the formation of single lamellar crystals across the Langmuir–Blodgett films. This assumption appears more natural than, for example, the hypothesis of Zhong *et al.*²¹³ concerning thin ferroelectric inorganic films.

The formation of the threshold thickness of the crystal (~150 Å) in the case of Langmuir–Blodgett films is an important point. Indeed, the electric resistance of these films containing 12 or 7 layers is markedly lower than that of ordinary films.²⁰³ Moreover, the coercitive field was found to increase regularly upon a decrease in the number of monomolecular layers in the film; for a film with 30 monolayers, $E_c \approx 300$, for a 12-monolayer film it is 400–700, and for a 7-monolayer films it is 1000–1200 MV m⁻¹.

Conduction by the tunnelling mechanism may arise in the Langmuir–Blodgett films under the action of a strong electric field. This phenomenon was actually observed in a study,²⁰³ in which the curves of pyroelectric hysteresis were measured (Fig. 37a). In addition to recording of the pyroelectric response, the conductance of the Langmuir–Blodgett films was estimated. Upon pyroelectric switching, the conductance changed by more than three orders of magnitude (from 10⁻⁶ to 10⁻⁹ Ω^{-1}).

One more difference between the characteristics of the Curie transition in ordinary films and in Langmuir–Blodgett films can be noted. It can be seen from Fig. 36b that in the latter case, the maximum capacity is only 1.6 times as high as that at room temperature. In the former case, it increases more than fivefold. The dielectric constants of the Langmuir–Blodgett film at room temperature is 4 (that for an ordinary film is ~12), and its maximum value is ~8.5 (that for an ordinary film is ~60). Assuming that one crystallite fits across the Langmuir–Blodgett film, this pronounced differences of the maximum ϵ' values for block films should be attributed to the presence of sections of the disordered phase. This proves once again the non-trivial role of

Figure 37. Temperature dependences of the dielectric constant (*a*, *b*), density of states at the Fermi level (*c*), conductivity (*d*), pyroelectric current (*e*) and capacity (*f*) in the Langmuir–Blodgett films of the 70/30 VDF/TrFE copolymer with a number of monolayers of 30 (*a*), 2 (*b*) and 5 (*c–f*).

this phase in the transition, although according to the classical views, it is expected to be associated with the crystalline phase.

The presence of amorphous regions with excess free space in ordinary films permits one to estimate the local field of ferroelectric crystals. This can be done by doping ferroelectric copolymers by particular dyes, which create admixture colour centres. The molecules of the doping additive are located in the regions with more free space, *i.e.* in the disordered phase. Dye molecules are usually characterised by high dipole moments; therefore, they should be captured by polar planes adjacent to amorphous areas. Thus, the dye molecules would be located in the ferroelectric crystal field and their optical characteristics would carry information about local crystal fields. This fact underlies the method for the estimation of these characteristics developed by Blinov *et al.*²⁰⁸.

The local field E_{loc} at some point of a dielectric polarised in external field E can be represented as the sum²⁰⁸

$$E_{loc} = E + E_1 + E_2 + E_3, \quad (43)$$

where E_1 is the depolarising field caused by the bound surface charge; E_2 is the Lorentzian field induced by the charge of the internal surface of the imaginary spherical cavity about the chosen point, and E_3 is the field of the charges inside this cavity. The last term is equal to zero for isotropic media and for crystals with cubic symmetry. In the short-circuited state after polarisation $E + E_1 = 0$; therefore, in the case of isotropic distribution of atoms

$$E_{loc} = E_2 = \frac{P}{3\epsilon_0}, \quad (44)$$

where P is the sum of the induced P_i and spontaneous P_s polarisations. Since for ferroelectrics $P_s > 100$ mC m⁻² and $P_s \gg P_i$,

$$E_{\text{loc}} = \frac{P_s}{3\epsilon_0}. \quad (45)$$

If one proceeds from the value $P_s = 100 \text{ mC m}^{-2}$, in conformity with Eqn (45), $E_{\text{loc}} \approx 4 \text{ GV m}^{-1}$. To verify this value experimentally, three dyes, rhodamine 6G (R6G), 4-diethylamino-4'-nitroazobenzene (DEANAB) and 4-diethylamino-4'-nitrostilbene (DEANS), parameters of the excited states for which are well known, were introduced into the VDF/TrFE copolymer.^{214–217} Absorption of a light quantum by a dye molecule is accompanied by a change in its static dipole moment μ and polarisability α .^{217,218} Therefore, the electric field E decreases the energies of the ground (denoted by subscript g) and excited (denoted by e) states to different extents

$$\Delta W_g = -\mu_g E - \frac{\alpha_g E^2}{2}, \quad (46)$$

and

$$\Delta W_e = -\mu_e E - \frac{\alpha_e E^2}{2}. \quad (47)$$

As a consequence, under the action of an electric field, the optical transition frequency (ν) shifts by²¹⁹

$$\Delta \nu = \frac{1}{hc} \left(\Delta \mu E + \frac{1}{2} \Delta \alpha E^2 \right), \quad (48)$$

where $\Delta \mu = \mu_e - \mu_0$ and $\Delta \alpha = \alpha_e - \alpha_0$ are the changes in the dipole moment and the average polarisability in the excited state.

The frequency shift consists of two components, linear and quadratic with respect to the field [see Eqn (48)]. The validity of this equation for doped VDF/TrFE copolymers was verified for the copolymer containing DEANAB in a concentration of 0.5 mass %. The films were not polarised; therefore, only the local field for the initial ferroelectric crystal E_l should be considered. In accordance with Eqn (45), below the Curie point $E_l \neq 0$, and in the paraelectric phase $E_l = 0$ because $P_s = 0$. Thus, on passing through the Curie point (~ 370 – 380 K), the absorption band should shift, which is actually observed by experiment.²⁰⁸ The absorption bands of the dyes DEANAB and R6G change in different ways near the Curie transition; in the former case, they shift to shorter wavelengths, and in the latter case, conversely, they shift to longer wavelengths. In addition, the magnitudes of these shifts for these dyes are also substantially different.²⁰⁸ These facts can also be explained in terms of the proposed model. In fact, it has been reported^{216,220} that for DEANAB, $\Delta \mu = 8$ – 10 D and $\Delta \alpha = +45 \text{ \AA}^3$, and for R6G these values are markedly lower — $\Delta \mu = 1.5 \text{ D}$ and $\Delta \alpha = -1.2 \text{ \AA}^3$. According to Eqn (48), this should result in a smaller shift of the band for R6G, which was actually observed in the experiments.

The model considered here makes it possible to estimate the local field after poling of a doped film. As noted above, polarisation can be accompanied by substantial structural changes, which influence E_l . Polarisation is attained using high-strength fields; therefore, charge carriers are injected from the electrode into the film and they also influence E_l . The local field can be calculated from the frequency shift of the absorption band after polarisation. This calculation was performed^{46,47} in relation to mixtures of PVDF with PMMA doped with a dye. Other researches tackled this problem more rigorously.²⁰⁸ They believed that direct recording of the shift of the bands is complicated because the bands are broad. Therefore, they proposed recording the degree of light modulation by an alternating field applied to the sample.^{218,220–222} Practically, the task was to measure the gain in the optical density ΔD at frequency ν corresponding to the chosen band following the imposition of an electric field on the sample. This value should be proportional to the first and second derivatives of the optical density with respect to frequency²¹⁸

$$\Delta D(\nu) = A_1 \nu \frac{\partial D(\nu)}{\partial \nu} + A_2 \frac{\partial^2 D(\nu)}{\partial \nu^2}. \quad (49)$$

Assuming a particular symmetry of the molecular distribution over the factors A_1 and A_2 for measurements at the first and second harmonics of the modulating field, one can find E_l .

Poling of a Langmuir–Blodgett film of PVDF in a $\pm 40 \text{ MV m}^{-1}$ field induces a substantial Stark effect, proportional to the first derivative $\partial D/\partial \nu$. When the direction of the polarising field changes, the sign of the linear Stark effect changes. This means that the dipole moments of the dye are also re-oriented in the opposite direction. If a constant field E_n is applied together with the modulating field, variation of the former induces the variation of the amplitude of the linear Stark effect in accordance with a pattern having a hysteresis. The hysteresis may arise due to the interaction of the dye dipoles with the internal field of the ferroelectric. The E_l value was found to be 300 MV m^{-1} . Thus, as in the studies cited above,^{46,47} the internal field was found to be much more intense than the polarising field.

The structures of Langmuir–Blodgett films have been considered²²³ in relation to the homopolymer PVDF, which usually crystallises as a nonpolar α -phase.²⁸ Primary attention was devoted to conformational characteristics of films prepared from a solution in DMSO.²²³ Analysis of the IR spectra showed that crystallisation in the thickest film (30 monolayers) gives a ferroelectric β -phase with planar zigzag conformations of chains.²⁸ This is confirmed by the presence of specific absorption bands at 470 , 509 , 840 and 1275 cm^{-1} . The formation of this conformation is apparently facilitated by the substrate on which the film is formed. This substrate is water, the molecules of which have a high dipole moment. Under these conditions, the minimum free energy can be attained by decreasing electrostatic interactions. The decrease is most pronounced if a chain in the planar zigzag conformation is parallel to the water surface.²²³

This role of water in the establishment of the conformation of PVDF chains is supported by the fact that polymerisation of VDF in aqueous media always results in a polymer crystallised as the polar β -phase.²²⁴ In addition, if the foregoing is true, the Langmuir–Blodgett film being formed (provided that the transfer on a solid substrate does not change the situation) should possess a non-zero spontaneous polarisation P_s . Indeed, a finite value of pyroelectric response has been noted experimentally for a non-polarised film.²²³

As the number of monomolecular layers n in the Langmuir–Blodgett films decreases, the conformations of macromolecules may change, due to the enhancement of the role of surface states differing in energy characteristics from those in the bulk. In order to verify this hypothesis, the IR spectra of films containing different numbers of monomolecular layers have been compared.²²³

A decrease in the number of monolayers in a Langmuir–Blodgett film ($n = 15$ and 10) brings about the appearance of conformational defects as the TGTG[−] and T₃GT₃G[−] isomers, which can be detected from the increase in the intensity of the absorption bands corresponding to them (Table 15). Apparently, these changes occur as accumulation of conformational defects as the above-mentioned isomers in the ferroelectric β -phase. The defects originate within long sequences of planar zigzag conformations (see Table 15). This is confirmed by the character of variation of the intensities of bands at 1275 and 840 cm^{-1} , sensitive to these sequences.^{28,225} The longest sequences are the first to be affected because the decrease in n from 30 to 10 results in the intensity of the band at 1275 cm^{-1} decreasing by 30% and that of the band at 840 cm^{-1} decreasing by only 10% .

The structural changes following a decrease in the thickness of a Langmuir–Blodgett film deteriorate the three-dimensional ordering in the ferroelectric crystal. This is indicated by the increase in the intensities of the two bands associated with the amorphous structure, 600 and 905 cm^{-1} . This conclusion is also supported by the variation of the intensity of the band at 470 cm^{-1} , which is attributed to *trans*-isomers in disordered areas in PVDF.²⁸ The increase in the intensity of this band

Table 15. Relative variation of the normalised intensities of several bands in the IR spectra of the Langmuir–Blodgett films of PVDF with various numbers of monolayers.²²³

^a Amorphous (a) and crystalline (c) phases.

following a decrease in *n*, points to the tendency for disordering of chains in the planar zigzag conformation.

The above structural changes in the studied films can also influence their electrophysical characteristics. If the structural changes in the Langmuir–Blodgett films of PVDF and VDF/TrFE copolymer are assumed to be similar, then regular features can be found for the latter, for example, in the parameters of the Curie transition.

The dielectric anomalies (the maximum of the dielectric constant) near the Curie transition in the Langmuir–Blodgett films of the 70/30 VDF/TrFE copolymer have been considered.²²⁶ Two anomalous regions (a low-temperature and a high-temperature region), were found in all films (*n* varied from 30 to 2). Since the first anomaly becomes more pronounced as *n* decreases (see Fig. 37*a,b*), it was regarded as being due to the surface ferroelectric transition. The assumption that the structural changes in very thin Langmuir–Blodgett films formed from the copolymer and the homopolymer are similar entails an interesting conclusion. The low-temperature Curie transition can be ascribed to the crystals of the ferroelectric β-phase with high concentration of conformational defects and with the tendency for disruption of the three-dimensional ordering in the bulk.

The pyroelectric response curves for the switching of polarisation in the Langmuir–Blodgett films based on PVDF²²³ exhibit hysteresis similar to that observed in the Langmuir–Blodgett films based on the VDF/TrFE copolymer (see Fig. 35).²²³ For a PVDF film with *n* = 30, the calculated coercive field strength was 500 MV m^{−1}. This coincides in order of magnitude with that for the film based on the VDF/TrFE copolymer. Tentative experiments with the Langmuir–Blodgett films having *n* = 15 show that the switching voltage remains the same (8–10 V), *i.e.* the coercive field is enhanced by a factor of nearly two. As noted above, similar results have been observed for VDF/TrFE copolymer films. Thus, a decrease in the number of monomolecular layers in the Langmuir–Blodgett films of the polymers in question increases the coercive field. This fact together with the data on the structural changes in the PVDF film entail the following interesting conclusion. The increase in the intensity of the band at 600 cm^{−1} following the decrease in the number of monolayers formally implies a decrease in the degree of crystallinity; therefore, the enhancement of the coercive field is due to an increase in the

proportion of the disordered phase. This conclusion is confirmed by the results obtained for block PVDF films, in which a decrease in the degree of crystallinity also results in a linear increase in the coercive field, although these fields in block films are substantially lower in magnitude.¹⁴⁰

Analysis of the hysteresis curves for the pyroelectric response (see Fig. 35) displayed yet another specific feature of the Langmuir–Blodgett films. Judging by the voltage applied for measurement of the pyroelectric response, the intensity of the break-down field should be at least 1 GV m^{−1}. This value is much greater than the corresponding values for block films. The above-noted specific structural features of the Langmuir–Blodgett films may be responsible for this. This film can be regarded as a material with 100% degree of crystallinity in the direction perpendicular to its surface. The mobility of free charge carriers in this material is much lower than that in a material containing the amorphous phase, in which chains execute cooperative motions with large amplitudes.²⁸ The break-down in the Langmuir–Blodgett films under study is limited most likely by a thermal mechanism, which requires a particular free path length of the carriers. The free path length can happen to be longer than the film thickness. In this case, there are no prerequisites for an avalanche-like movement of charge carriers, which limits the currents for the thermal break-down mechanism.

The local fields created by ferroelectric crystals have been studied in detail²²⁷ by Stark spectroscopy. The optical probe used was a multilayer of the anthraquinone dye KD-78, having a principal absorption band at about 15700 cm^{−1}. The ferroelectric moiety of the film contained 70 monomolecular layers of PVDF and the probing moiety incorporated six bimolecular layers of KD-78. A symmetrical set of aluminium electrodes was used in the experiments. The change in the absorbance (Δ*A*) was measured at the principal frequency (*f*) and the second harmonic (2*f*). The relations derived by Palto²²⁷ were used to calculate two characteristics, namely, the amplitude of the local alternating field (*E*_i) and the static local field (*E*_{dc}). Figure 38 presents the experimental Stark spectra for the PVDF Langmuir–Blodgett

**Figure 38.** Spectra of the Stark effect at the first (1) and second (2) harmonics demonstrating bistable switching of the static local field in the initial nonpolarised (a) and polarised (b–e) Langmuir–Blodgett PVDF films;²²⁶

(b) a bias voltage, $U_{dc} = +10$ V, was applied to the sample; (c) $U_{dc} = 0$ after poling by a voltage of +10 V; (d) a bias voltage, $U_{dc} = -10$ V, was applied to the sample; (e) $U_{dc} = 0$ after poling by a voltage of -10 V. The spectra were measured at the alternating voltage amplitude $U = 5$ V, basic frequency $f = 1000$ Hz.

films; it is using this spectra that these characteristics were calculated. A clear-cut quadratic Stark effect of the probing layer measured at the second harmonic is observed in the initial non-polarised film. With allowance for the electrooptical constant for KD-78, $C_b = 5.7 \times 10^{-22} \text{ m}^2$, and the amplitude ΔA of the quadratic Stark effect, the local field was found to be 270 MV m^{-1} .

The Stark effect at the first harmonics for the initial sample is 20 times weaker ($\Delta A_1 \approx 1.2 \times 10^{-5}$); this corresponds to a static local field strength of -13 MV m^{-1} (see Ref. 227), which is due to the remanent polarisation in the initial film. After a constant bias voltage ($+10 \text{ V}$ with respect to the electrode) has been imposed on the substrate, the remanent polarisation sharply increases because the amplitude of the Stark effect at the first harmonics increases by more than two orders of magnitude (see Fig. 38b). The ΔA_2 also increases approximately twofold, and the above-mentioned local fields become $E_1 \approx 380 \text{ MV m}^{-1}$ and $E_{dc} \approx -1.4 \text{ GV m}^{-1}$. The ratio $E_{dc}/E_1 \approx -3.7$, which is much greater in magnitude than the ratio of the constant voltage to the alternating voltage amplitude, which is equal to two. Thus, the local field factor at zero frequencies is ~ 1.9 times greater than at a modulation frequency, equal to 1 kHz , *i.e.* dispersion of the local field factor is observed.

An unusual result was obtained after removal of the $+10 \text{ V}$ voltage (see Fig. 38c). It can be seen that the sign of the effect at the first harmonic changes, which indicates unambiguously the change in the local field direction with respect to that in the initial (non-polarised) sample. The static local field becomes $+170 \text{ MV m}^{-1}$, *i.e.* it is higher than that in the initial film by more than an order of magnitude. This may be due to substantial structural rearrangements (for instance, a sharp decrease in the number of conformational defects) in the Langmuir–Blodgett film after polarisation. A voltage with the opposite sign (-10 V , see Fig. 38d) does not change the Stark effect at the second harmonic, *i.e.* E_1 remains unchanged. However, the effect at the first harmonic does change. If the electric displacement is subsequently diminished to zero, the static field would be retained but its sign would be reversed, -170 MV m^{-1} . This field does not relax over a plausible period of time but it can be switched to the opposite one.

Thus, two directions of the local static field correspond to the two directions of the polarisation vector in the ferroelectric crystal. However, one contradiction has been noted.²²⁷ In fact, the direction of the local static field should coincide with the direction of the remanent polarisation. The opposite situation occurs in the experiment: the sign of the Stark effect at the first harmonic in the presence of a polarising field is opposite to the sign of the Stark effect after the removal of the bias field (see Fig. 38d, e).

A model has been developed²²⁷ which assumed full symmetry of the near-electrode areas with identical space charge distribution. Analysis of the situation in the absence of this symmetry shows that the direction of the local static field can be opposite to that of the polarisation. In this case, the question arises of whether the assumption of the asymmetry of the space charge on the sides of near-cathode and near-anode regions is physically substantiated.²²⁸ This question can be answered by using the results of some studies dealing with the behaviour of PVDF in strong electric fields. The pyroelectric characteristics of polarised samples on application of thermal pulses on the sides of the cathode and the anode has been studied.²²⁹ The pyroelectric effect was found to be higher in the latter case. This was interpreted as being indicative of an asymmetry of the space charge on the sides of the cathode and the anode.

Another independent group of experiments included elucidation of the possibility of the appearance of a bending moment in polarised films upon imposing an electric field.²³⁰ It was shown that in the case of a non-shielded electrode (*i.e.* when there were prerequisites for the injection of charge carriers from the electrode in the polymer) and not very high polarisation fields, bending

actually arose in the film when working in the mode of the inverse piezoelectric effect. This fact was unambiguously ascribed to the asymmetry of the arising space charge on the cathode and anode sides.²³⁰ This asymmetry can appear if the conditions for the injection of electrons and holes into the polymer are non-equivalent. Analysis of the voltammetric characteristics of PVDF films obtained in studies of the conduction in strong electric fields also confirms this assumption.²³¹ The authors of two studies cited^{229,230} arrived at the same conclusion, namely, that in the case of contact poling of PVDF, the injection of holes into the material is preferred over the injection of electrons. Thus, the interpretation of the abnormal behaviour of the local field direction after removal of the polarising voltage proposed by Palto²²⁷ is confirmed by independent experiments.

Apart from the electrophysical characteristics of thin Langmuir–Blodgett films ($n = 5$), the change in the direct and inverse photoemission spectra (DPES and IPES, respectively) was considered to be additional substantiation of the presence of surface ferroelectricity.²³² The methods of electronic spectroscopy, which are extremely sensitive to the state of the surface, can provide useful and independent information on this problem. Analysis of the temperature dependences of these spectra shows substantial changes in the electronic structure of the films near the low-temperature transition (20°C) (Fig. 37a, b, f), similar to those found in the surface layers of germanium^{233,234} and silicon.²³⁵ The density of states at the Fermi level in the low-temperature transition region changes markedly (see Fig. 37). This was interpreted as pointing to strong electron–phonon interactions near this transition. Assuming that the copolymer compositions at the surface and in the bulk are identical, Choi *et al.*²³² concluded that the difference between the electronic structures in the bulk and near the surface may be due to the lower coordination of atoms in the latter case. The presence of characteristic points on the temperature dependences of the conductivity, pyroelectric current, dielectric permittivity or electric capacity was also interpreted as being due to the presence of two types of transition — those on the surface and in the bulk.

The whole set of these data makes it possible to elucidate the mechanism of formation of the ferroelectric phase following a decrease in the thickness of Langmuir–Blodgett films somewhat more precisely. Indeed, the interpretation of experimental data^{226,232} does not account for some details of the experimental curves. For example, two dielectric anomalies of the temperature dependences of the dielectric permittivity are observed as well for the block films of the 65/35 VDF/TrFE copolymer (see Fig. 18 and 27). According to X-ray diffraction data, two types of ferroelectric phase, QL and LT, should be present in these compounds.²⁸ The less perfect QL phase may be responsible for the low-temperature transition.

Some indirect data supporting the interpretation of the anomalies observed^{226,232} which assumes the existence of ferroelectric QL and LT phases can also be found in earlier publications by the same authors. Indeed, no low-temperature transition was noted in a similar Langmuir–Blodgett film (see Fig. 36), *i.e.* this transition is not always reproducible. The low-temperature ‘anomaly’ of the dielectric permittivity is more clear-cut in the heating regime, whereas in the cooling regime it is weak and the high-temperature anomaly is more pronounced (see Fig. 37). Since this film is formed by only two copolymer monolayers (*i.e.* there is actually no bulk), it can be assumed that the film structures in the heating and cooling regimes should be different. A similar behaviour is also typical of thicker films ($n = 5$). Thus the conduction ‘anomaly’ observed in the region of the low-temperature transition is also more pronounced during heating (see Fig. 37d). Moreover, the electronic spectroscopy data indicate that the transition ascribed to the bulk is observed only in the cooling regime (see Fig. 37c).

These facts can be interpreted more simply taking into account the existence of the QL and LT phases. In this case, the different ratios of the ‘anomalies’ at 20 and 80°C are obviously

due to interconversion of these phases. In particular, during heating (to fairly high temperatures), annealing can occur, which is always accompanied by enhancement of the lattice ordering for crystallisable polymers. In this particular case, this is the QL $\rightarrow$ LT type transition. Apparently, an increase in the proportion of the latter (more perfect) phase accounts for the ‘anomalies’ noted for several characteristics of the transition in the heating–cooling cycles.

According to STM, Langmuir–Blodgett films of the copolymer²²⁶ contain chains with bent skeleton, which is consistent with one of the models of the QL phase structure (see Fig. 21a).²⁸ STM studies show²²⁷ that the identity period across the chain ranges from 2.7 to 5 Å for different regions of the film. This may be because areas of either phase differing in packing density across the chain can be present in the scanning area.^{28, 67}

Thus, it can be assumed that Langmuir–Blodgett films incorporate two types of ferroelectric phase with different degrees of perfection. The ratio of these phases can change upon a decrease in the film thickness towards a higher content of the less perfect ferroelectric phase. This is confirmed by IR spectroscopy (see Table 15).

The concept assuming the existence of two types of ferroelectric phase in PVDF and VDF copolymers can also help in the interpretation of yet another phenomenon observed in the Langmuir–Blodgett films of the VDF/TrFE copolymer. Ducharme *et al.*²³⁶ verified the hypothesis of Devonshire²³⁷ about the presence of a critical temperature (T_c) and a critical electric field (E_c) in ferroelectrics with a first-order phase transition (at the Curie point). Practically, the task was to follow the hysteresis curves of the dielectric permittivity ϵ' upon application of an alternating electric field on the Langmuir–Blodgett film. It was found that below 70 °C the field dependences of ϵ' display a single peak (although it is asymmetrical) falling on the region of the coercive field. In the temperature range from 90 to 140 °C, the $\epsilon'(E)$ curves have two maxima, the positions of which depend on the temperature.²³⁶ It was suggested to represent the E – T phase diagram for this temperature range (at 1 atm) as the linear plot for the Curie point *vs* the field strength (see Fig. 39b) similar to the plot that can be obtained for the block films of the 52/48 VDF/TrFE copolymer (see, e.g., Fig. 25).⁹⁵ By processing the experimental data,²³⁶ critical parameters of the films were determined. Data for these films and for other ferroelectrics are listed in Table 16. It can be seen that the critical field for the Langmuir–Blodgett film is higher by several orders of magnitude than the fields for other ferroelectrics. This fact is predictable for VDF copolymers because the coercive fields for them are also much higher. The difference between the T_c values for the Langmuir–Blodgett film and a block copolymer film raises more questions. Some of them can be answered upon examination of Fig. 39. When measurements are performed during heating in the absence of a field (curve 1), two types of transition

Table 16. Parameters of the ferroelectric phase transitions in the Langmuir–Blodgett ($n = 30$)²³⁶ and block²³⁸ films of the 70/30 VDF/TrFE copolymer, in BaTiO₃ (see²³⁹), in the crystals of deuterated potassium dihydrogen phosphate (DPDP)²⁴⁰ and in a liquid-crystal ferroelectric (LCF).²⁴¹

Parameter	Langmuir–Blodgett–film	Block film	BaTiO ₃	DPDP	LCF
$T_c / ^\circ\text{C}$	80 ± 10	102	108	–61	55.0
$T_{cr} / ^\circ\text{C}$	145.5	–	116	–60	55.8
$10^6 E_{cr} / \text{V m}^{-1}$	$(0.93 \pm 0.1) \times 10^3$	–	0.6	0.83	5.0
$\frac{dT_c}{dE} / \text{m (}^\circ\text{C)} \text{V}^{-1}$	$(7 \pm 2) \times 10^{-8}$	12×10^{-8}	6.5×10^{-4}	1.25×10^{-6}	1.6×10^{-7}

with temperatures of ~ 80 and ~ 110 °C are recorded, while in the cooling regime (curve 2) only one transition is detected taking into account the temperature hysteresis. This points to the presence of two types of ferroelectric phases, the ratio of which changes on passing from the heating regime to the cooling regime due to the QT $\rightarrow$ LT transition on annealing (heating). This transition can also be induced by an electric bias field because only one transition is observed in this case even during heating (see curve 3).

One circumstance which has not received adequate attention²³⁶ should be noted, namely, the exceptionally broad temperature range in which the double hysteresis loops of ϵ' are observed. For Langmuir–Blodgett films, this range is 65 °C, whereas for BaTiO₃ it covers only 8 °C (and even less for other ferroelectrics). This can also be interpreted with the aid of the assumed existence of two types of ferroelectric phase, QL and LT. If these phases differ in the degree of lattice perfection, their coercive fields should also differ, which is reflected as twin hysteresis loops on the $\epsilon'(E)$ curves.²³⁶ If this assumption is used to explain the broad range of critical temperatures (see Table 16, Fig. 39), an equally broad temperature range of coexistence of these phases should be expected. In fact, in the VDF/TrFE copolymer with the composition 65/35 (*i.e.* approximately the same as that of the copolymer studied in the publication under discussion²³⁶), the QL and LT phases coexist in a temperature range of not less than 70 °C (see Fig. 20). This value is close to that indicated by Fig. 39, which confirms once again the validity of this hypothesis.

Evidence that the ferroelectric QL phase can occur not only in VDF/TrFE copolymers but in the homopolymer and in other copolymers (for example, with TFE) can be found in the literature. If the low-temperature transition is assumed to be due to the QL $\rightarrow$ paraelectric transformation, it should also be expected in the Langmuir–Blodgett films based on PVDF. Tentative results show that this is actually the case.

In all probability, the QL phase reflects the existence of so-called quasi-domains, characterised by a particular type of long-range order, in the disordered phase of the objects considered. The presence of quasi-domains was judged relying on the ‘anomalies’ of the low-temperature dielectric relaxation processes in PVDF.²⁴² These processes are attributed to the mobility in the disordered phase.²⁸ The static dielectric permittivity in the temperature range studied has been found to increase with temperature, which is an atypical type of behaviour for most polymers. The general thermodynamic expression for the entropy of a dielectric in field E has the form²⁴³

$$S = S_0 + \frac{\partial \epsilon_0}{\partial T} \frac{E^2}{8\pi},$$

where S_0 is the entropy without a field. When a field is applied, the entropy increases. This can be interpreted only as an indication of

Figure 39. Temperature dependences of the capacity in the heating–cooling cycles in the absence of a field and with a bias field (a) and the E – T phase diagram ($p = 1$ atm) for the Langmuir–Blodgett films of the 70/30 VDF/TrFE copolymer with $n = 30$;²³⁶ (1, 2) without a bias field; (3, 4) with a bias field, $U = 5$ V.

existence of correlated chain sections with a definite long-range order in the disordered areas.²⁴³

The quasi-domains in question (like classical domains) should undergo a transition into a disordered (paraelectric) state. This is indicated by the dielectric anomalies (in particular, a maximum of the dielectric absorption $\Delta\epsilon$) found for the β -relaxation in PVDF.²⁴⁴ In the homopolymer, this maximum is often masked by the α_c -relaxation region.²⁸ The intensity of α_c -relaxation substantially decreases with a decrease in the degree of crystallinity. Therefore, the dielectric anomalies in the region of the hypothetical transition should be detected more easily in amorphised polymers of this class.

An efficient way of amorphisation of PVDF is its copolymerisation with comonomers having bulky substituents. In particular, hexafluoropropylene (HFP) can be used for these purpose. Indeed, the crystallinity of the 86/14 VDF/HFP copolymer proves to be markedly lower.²⁴⁵ The temperature dependences of the dielectric permittivity in the region of 40–50 °C has an anomaly, which was attributed to a smeared transition of quasi-domains into a disordered state.

The low-temperature dielectric anomaly in the Langmuir–Blodgett film of the 70/30 VDF/TrFE copolymer²²⁶ can be identified by a more detailed comparison of the dielectric data for samples obtained by the standard method (block films) and by the Langmuir–Blodgett method. It has been noted above that two transitions are detected for both types of films (see Fig. 18*a* and 37*a*, *b*, *f*). Some researchers separated the contributions of the dielectric constant components by the amorphous and crystalline phases to the overall curves.²⁴⁶ It was found that the amorphous phase in all the VDF/TrFE copolymers considered (73/27, 65/35 and 54/46) is characterised by a blurred maximum in the 0–40 °C range. The maxima of the dielectric constant of the Langmuir–Blodgett films derived from the VDF/TrFE copolymer,²²⁶ PVDF^{242, 244} and the VDF/HFP copolymer²⁴⁵ are located in about the same temperature range. Thus, these maxima can be considered to be of the same origin; in the case of block films, this is the transition of quasi-domains occurring in the disordered regions into the disordered state and for the Langmuir–Blodgett films, this is a similar transition occurring in the near-surface macromolecules, the conformational state of which is close to that in the amorphous phase of block films.²²³

Evidently, the reason for the formation of the quasi-domains (in other words, the QL phase) lies in the fact that the chains of the amorphous phase in the vicinity of the crystals of the ferroelectric β -phase occur under the influence of strong local fields. According to theoretical estimates,²⁴⁷ they can be as high as 9.28 GV m⁻¹ in PVDF (with crystals of the β -form) at room temperature. They are of the same order of magnitude (4 GV m⁻¹) for 70/30 VDF/TrFE copolymer, although the experimental values are somewhat lower. Such high fields in the area of localisation of chains of the disordered phase create conditions for them to be arranged in quasi-domains. In fact, in such a field, the potential energy of the CF₂ bond dipole in PVDF at room temperature is very high (11.7 kcal mol⁻¹).²⁴⁷ However, the formation of quasi-domains (QL phase) in the disordered phase is possible in this case only when the fluctuations are high-amplitude cooperative motions in this phase. A peculiar feature of PVDF and VDF copolymers is that, due to the low glass transition temperature, these motions really occur in the amorphous phase at room temperature (with relaxation times of $\sim 10^{-7}$ s);^{28, 242} therefore, it is quite likely that prerequisites for the formation of sections with an intermediate form of ordering would arise in the areas adjacent to the crystals.

Once the above-described nature of the formation of quasi-domains (QL phase) has been accepted, one reason for the transition of these fluctuation structures into the disordered state (low-temperature transition) can be explained as follows. The allowance made for the contribution of dipole oscillations in the ferroelectric crystal of the β -phase²⁴⁷ shows that an increase in the temperature diminishes the spontaneous polarisation and, correspondingly, the local field at the boundaries with the disordered

phase. Therefore, at a particular temperature, the quasi-domains would be destroyed, which is actually detected as the presence of the low-temperature dielectric anomaly.

One more piece of evidence for the existence of quasi-domains in the amorphous phase can be derived from the chain dynamics characteristics found by NMR. For example, the spin–lattice relaxation times T_1 for the amorphous (T_{1a}) and crystalline (T_{1c}) phases of VDF/TrFE copolymer have been compared.¹⁰⁰ These characteristics were found to differ by more than an order of magnitude below the Curie point and by a factor of only two above this point. Thus, the chain dynamics in the disordered phase is characterised by approximately the same parameters as that in the paraelectric phase. This fact can be regarded as indirect evidence for the existence in the amorphous phase of these quasi-domains with imperfect long-range order similar to that occurring in the paraelectric phase.

The results obtained by the broad-line technique, a modification of the NMR method, also point to the presence of quasi-domains in the amorphous phase. If the quasi-domains actually do exist, the dynamics in them should differ from the dynamics in the proper disordered (isotropic) phase and in the crystal. Information on this point can be derived by strict analysis of the line contours in the NMR spectra of the compounds in question. This was demonstrated in relation to the VDF/TrFE copolymers.¹¹⁰ In particular, if the composition is 70/30, the free induction signal (for ¹H nuclei) at 15–60 °C is described by three components. The widest component refers to the ferroelectric phase, and the narrowest one corresponds to the isotropic amorphous phase. The intermediate component is attributed to so-called stressed amorphous phase. This might imply the quasi-domains mentioned above, in which the dynamics should be more hindered than that in the isotropic amorphous phase due to the presence of a certain long-range order. Furthermore, the reported¹¹⁰ data on the temperature dependence of the intensity of the intermediate component can be interpreted in a different way. In the region of 60–120 °C (below the Curie point), the intensity of the intermediate component increases appreciably. This was attributed to partial transition of the ferroelectric phase into the paraelectric phase. However, this hypothesis provokes serious objections. The researchers cited noted themselves that the experimental value of the second moment ΔH_2^2 for this component is 2.5 G², which is substantially lower than the value calculated for the lattice of the paraelectric phase (11.6 G²).

To explain this contradiction, a definite type of motion in the paraelectric lattice, namely, rotation of the chains about their axes, had to be assumed. If the intermediate component is related to quasi-domains, this fact can be explained. In the 60–120 °C region, some of the domains (in small crystals with less perfect packing) can pass into a state with higher symmetry (quasi-domains). The packing in them is less perfect than in the paraelectric phase; therefore, the dynamics is less hindered, which accounts for the low experimental value of ΔH_2^2 .

The assumption that the ferroelectric QL phase is identical to the quasi-domains, found in the amorphous phase in some experiments, is supported to some extent by the temperature dependences of the X-ray diffraction parameters for isotropic and textured samples of the 94/6 VDF/TrFE copolymer.¹⁹⁶ At a temperature of 160 °C (below the melting point), two reflections are observed, one of them corresponding to the β -phase and the other diffuse halo reflection being due to the paraelectric phase (Fig. 40). This can be judged relying on the interplanar spacings, which coincide with those in the same phase of the VDF/TrFE copolymer (see Fig. 20).

In the 170–180 °C temperature range, the interplanar spacing in the paraelectric phase sharply increases (see Fig. 40*b*). This may imply that the ferroelectric and paraelectric phases coexist up to the melting point. If the Curie point is considered to overlap with the melting region (due to the very high proportion of VDF in the copolymer), melting should be accompanied by the ferroelectric–paraelectric transition. Actually, melting of paraelectric

Figure 40. Temperature dependences of the X-ray diffraction curves for isotropic (a) and uniaxially stretched (equatorial region) (c) samples of the 94/6 VDF/TFE copolymer and the average interchain distance in the paraelectric phase and in the 'melt' of the same copolymer (b).¹⁹⁶ T /°C: 160 (1), 184 (2), 260 (3), 315 (4) (a); 20 (1), 95 (2), 145 (3) (c).

crystals can also be involved because the interplanar spacing in the lattice of the paraelectric phase sharply changes (see Fig. 40b). The halo reflection remaining for the melt ($T > 184$ °C) has a complex structure, *i.e.* in addition to the principal line, its asymmetry on the low-angle side is clearly observed. It can be seen that the half-width of the reflection (see Fig. 40a) is fairly small, which is unusual for isotropic systems with short-range order. Therefore, it was assumed¹⁹⁶ that the amorphous phase of the melt consists of two components. One component corresponds to the isotropic constituent, matched by the low-angle asymmetry of the halo reflection in the melt. The principal line characterises the presence of regions with anisotropic distribution of polymer segments. These regions can be characterised by a certain long-range order similar to that observed in the nematic phase of liquid crystals. These structures should be fairly stable to heating because the halo reflex is retained up to 315 °C (Fig. 40a).

If the energy of interatomic interaction is estimated based on the average interchain distance, this conclusion is also confirmed by Fig. 40b; extrapolation of the high-temperature straight line to room temperature gives $d = 4.92$ Å, whereas for the paraelectric phase $d = 4.76$ Å.

Upon texturing the copolymer samples (for example, by uniaxial stretching), the two components of the amorphous phase can be readily separated from one another. The isotropic component would be manifested as an azimuth-independent halo, and the anisotropic component would cause scattering only in the equatorial region.¹⁹⁶ The interaction energy in the areas described by the anisotropic component should be much lower than that in the ferroelectric crystal (see Fig. 40c). This can be judged by the temperature dependences of the average interchain distance for both phases. When measurements are carried out under isometric conditions (when disorientation of the β -phase crystallites is excluded), the anisotropic component of the X-ray diffraction patterns in the equatorial direction (see Fig. 40c) is better resolved from the principal intermolecular reflection of the ferroelectric phase at high temperatures.

Thus, analysis of the data listed above provides general characteristics of the nuances of the phase states of VDF-based polymeric ferroelectrics. The densest packing is found in the ferroelectric crystal lattices. If the density is characterised by the average interchain distance, it can be estimated based on the identity period d for the 200, 110 planes of the β -phase. In the 94/6 VDF/TFE copolymer at room temperature, this d value is

4.30 Å.¹⁹⁶ Transition from the ferroelectric phase to the paraelectric phase is accompanied by a substantial decrease in the packing density in the crystal — at room temperature d increases from 4.30 to 4.76 Å (see Fig. 40b). It is significant that in VDF/TrFE copolymers with high contents of the former component, the two phases can coexist up to the melting point. The Curie transition, in which the crystals in the ferroelectric phase pass into a non-polar form, occurs in the same region.

The amorphous phase of these polymers should incorporate two types of structure, one of them being typical of isotropic liquids. The anisotropic constituent of the amorphous phase should contain areas with a particular type of long-range order. The chain segments can be packed in these areas in such a way that the directions of their moments in particular regions are identical. Thus, so-called quasi-domains localised in the amorphous phase are formed; they can be classified as the imperfect ferroelectric QL phase. As noted above in analysing the NMR data, the energy of interaction in these quasi-domains should be close to that in the paraelectric phase.¹¹⁰

Thus, in quasi-domains, chains are packed more loosely than in the domains of the proper crystal phase (for the 94/6 VDF/TFE copolymer this difference is $\sim 15\%$). Therefore, two Curie transitions should occur in these compounds; they have been detected in both block films and Langmuir–Blodgett films. The specifics of the latter is that a decrease in the number of monolayers results in a higher proportion of chains in which three-dimensional order is lost and conformational defects are accumulated. Thus, the equilibrium in a domain–quasi-domain mixture (or a mixture of LT and QL phases) shifts towards higher contents of the latter component. Experimentally, this manifests itself as enhancement of the low-temperature transition.

IX. Conclusion

The analysis of the published data on the ferroelectricity in PVDF and VDF-based copolymers carried out in this review leads to the following main conclusions.

In the crystallisable polymers considered here, the amorphous phase is more than merely an inert matrix. The cooperative mobility in the disordered phase contributes to the switching of ferroelectric domains.

Polarisation is accompanied by an irreversible increase in the degree of crystallinity. This can be attained *via* an increase in the transverse dimension of crystallites of the β -phase due to incorporation of some chains of the disordered phase.

Unfreezing of the cooperative mobility in the amorphous phase facilitates field-induced structural rearrangements in it. The type and the degree of mobility in the disordered regions surrounding the ferroelectric crystals has a substantial effect on the coercive field.

The high dynamic heterogeneity of PVDF at room temperature can account for the stability of the ferroelectric characteristics, in particular, remanent polarisation. On exposure to a strong field, the new position of domains is stabilised upon 'shielding' by the space charge. The effective mobility of charge carriers is limited by the relaxation times of segments in the disordered phase, which are ~ 100 ns at room temperature. Under these conditions, a new equilibrium state of the space charge is attained over short periods, thus ensuring the above-noted stability of the switched domains.

The type of supermolecular structure was found to influence some ferroelectric characteristics. Specifically, the morphology of thick lamellar crystals proves to promote high spontaneous polarisation. If there are conditions for crystallisation of the chains in textured PVDF as ECC, the Curie point becomes markedly higher.

Two types of ferroelectric phase differing in the degree of perfection are characteristic of PVDF and VDF copolymers. The dielectric anomalies observed in the relaxation region ascribed to

glass transition imply that the QL phase can be localised in disordered regions of the polymer.

The Langmuir–Blodgett films derived from PVDF and VDF/TrFE copolymer possess single crystal textures because they display finite values of the pyroelectric response in the nonpolarised state. As the number of monolayers in these films decreases, conformational defects are accumulated and the crystallographic order tends to be violated.

Methods for the synthesis of tritium-labelled fatty acids and their derivatives, oxylipins and steroids

V P Shevchenko, I Yu Nagaev, N F Myasoedov

Contents

I. Introduction	859
II. Synthesis of tritium-labelled fatty acids and their derivatives	860
III. Oxylipins	868
IV. Steroids	874
V. Conclusion	877

Abstract. The achievements in the field of synthesis and application of tritium-labelled oxylipins, steroids, fatty acids, phospho-, sphingo- and other lipids are reviewed. The importance of these studies for the solution of current problems of biochemistry, biology and pharmacology is exemplified in the application of labelled compounds. The bibliography includes 148 references.

I. Introduction

Methods used for the synthesis of tritium-labelled classical representatives of lipids and oxylipins (fatty acids, steroids, prostaglandins, sphingo- and phospholipids, *etc.*) and their biologically active analogues close in physicochemical properties to lipids have gained considerable popularity. The choice of lipids for investigation is based on the fact that apart from the ability of these compounds to accumulate metabolic fuel, which for many decades was considered to be their sole function,¹ two other important functions have been recently assigned to them. First, they are the principal structural components of cell membranes and, second, they are bioeffectors, which control intracellular biochemical reactions, intercellular interactions and other physiological processes occurring in the organism. Evidently, the interaction of bioeffectors with their targets and, consequently, the specificity of their action are largely determined by their structure.¹

The advantages of tritium as a radioactive label, *viz.*, low radiotoxicity, long half-life (12.26 years), high molar radioactivity (1.08 PBq g-atom⁻¹), *etc.*, are universally known.^{2–5} The methods used for the synthesis of tritium-labelled compounds include different versions of reactions of isotope exchange, chemical and enzymic methods. The mechanisms of labelling by isotope exchange[†] have been considered.^{5–15}

The labelling by a liquid-phase method is accompanied by reactions of isotope exchange; migration, isomerisation and hydrogenation of double bonds; selective hydrogenation of one of several double or triple bonds; dehalogenation and reduction of

the corresponding functional groups. Only a careful choice of reaction conditions can result in satisfactory yields of labelled target products. An important role is ascribed to the choice of a catalyst and a solvent and determination of optimum experimental parameters (the pressure of gaseous tritium, the reaction time, the catalyst : substrate : modifying additives ratio, *etc.*).

Classical methods have limited application, since only milligram and submilligram quantities of precursors are normally used in the synthesis of tritium-labelled compounds. As a result, the catalyst : precursor ratio should markedly exceed that prescribed for selective hydrogenation using classical procedures on purely technological grounds. In contrast, the proportional increase in catalyst-modifying additives (quinoline, pyridine, *etc.*) significantly decreases the yield of the labelled target product and considerably increases the total radioactivity of the reaction mass due to incorporation of the label into side products and modifying additives, which complicates the isolation and purification of the target compound.

If the components used in biological studies are sufficiently stable at elevated temperatures, a solid-phase method where the substance applied onto the catalyst is heated in the atmosphere of gaseous tritium is the most promising approach.^{9, 12, 13}

The method of isotope exchange with tritiated water in inert solvents is used for labelling compounds that are labile in hydrogenation conditions; the use of inert solvents prevents self-radiolysis of highly enriched tritiated water.² The latter is usually obtained by reduction of PdO with gaseous tritium. Palladium black and palladium catalysts immobilised on inert supports initiate the isotope exchange. Obviously, the more active the catalyst the higher the degree of isotope exchange with tritiated water, but the probability of degradation of the labile compound increases also.

As a rule, chemical syntheses of tritium-labelled lipids are preceded by the synthesis of the corresponding precursors^{4, 5, 16–22} containing triple or additional double bonds, halogen-substituted fragments, *etc.* Treatment of these compounds with gaseous tritium in the presence of a catalyst results in the formation of a labelled product. In some cases, tritium-labelled

[†] Modern methods of isotope exchange can be conventionally divided into three main groups, *viz.*, heterogenous catalytic isotope exchange of gaseous tritium with an organic compound dissolved in a solvent (liquid-phase methods), heterogenous catalytic isotope exchange of gaseous tritium with a solid organic compound at elevated temperatures (solid-phase methods) and heterogenous catalytic isotope exchange of an organic compound dissolved in an aprotic solvent with tritiated water.

lipids are obtained by a multistep synthesis which utilises a labelled preparation as a starting compound. This approach requires the use of methods which not only ensure high yields of target products but also make the process technologically safe.

II. Synthesis of tritium-labelled fatty acids and their derivatives

1. Fatty acids

Fatty acids differ in the structure of the carbon backbone and the number of double bonds as well as in the presence and number of other functional groups. They are present in natural subjects, predominantly as esters. Fatty acids are constituents of phospholipids, sphingolipids, glycolipids, gangliosides, glycerides, steroid esters and vitamins. It had long been thought that the sole function of fatty acids was to provide membrane integrity and the optimum level of unsaturation of tissue lipids;²³ however, it has recently been established that these compounds also regulate the enzyme activity, modulate binding of steroid hormones to their specific receptors and control gene transcription.^{24–26} Indeed, a change in the fatty acid composition of membrane lipids changes the activity of membrane-bound enzymes and expression of receptors.²⁷

Isotopically labelled fatty acids can be synthesised by isotope exchange, selective hydrogenation of the corresponding acetylenic precursors with gaseous tritium as well as by chemical, microbiological and other methods.⁵

The liquid-phase method of isotope exchange is the simplest procedure for obtaining unsaturated fatty acids, since it allows direct labelling of the target compound. Besides, this procedure is devoid of many drawbacks of microbiological methods, *e.g.*, difficulties in isolation of labelled preparations from homogenates, isotopic dilution of the labelled target product with endogenous products derived from microbial cultures and the loss of the label in the course of biological conversions.^{4,5} For example, the molar radioactivity of labelled (5Z,8Z,11Z,14Z,17Z)-eicosapentaenoic (thymnodonic) acid synthesised from [8-³H]stearic acid⁵ using a culture of *Saprolegnia parasitica* (ATC 22284) decreased 250–400-fold in comparison with that of the original fatty acid.

The lability of alkenes in liquid-phase isotope exchange is the main property which restricts the application of this method for introducing the label into unsaturated fatty acids. It is known^{3–5} that hydrogenation, *cis-trans*-isomerisation and double bond migration occur extensively even with the Lindlar catalyst. The isomerisation reactions are equally probable, while the double bond migrates by 85%–88% towards the carboxy group. However, these restrictions did not prevent the labelling of both monoenoic and polyenoic acids by varying the reaction conditions (Table 1). Some data on the distribution of the label in molecules of these compounds will be given below.

Despite the relative simplicity of the liquid-phase isotope exchange, it is of limited use, since the molar radioactivity of target products seldom exceeds 0.1 PBq mol^{–1}. Molar radioactivities of polyenoic fatty acids are much higher, if chemical methods are used. Acetylenic precursors can be prepared either from the corresponding fatty acids or by total chemical synthesis. The former method was used in the synthesis of 5-acetylenic analogues of methyl arachidonate, methyl thymnodonate, the 14-acetylenic analogue of methyl arachidonate and the 4-acetylenic analogue of methyl (4Z,7Z,10Z,13Z,26Z,19Z)docosahexaenoate (methyl docosahexaenoate). This type of synthesis is illustrated in the example of 5-acetylenic analogues of eicosapolyenoic acids and the 14-acetylenic analogue of methyl arachidonate (Schemes 1 and 2).^{16, 17, 30}

The major difference in these schemes is that in the latter the epoxy acid is formed upon treatment of the starting compound with *m*-chloroperbenzoic acid in dichloromethane in the presence

Table 1. The values of molar radioactivities (α) of labelled unsaturated fatty acids.^a

Starting compound	α /PBq mol ^{–1}	Ref.
Liquid phase isotope exchange		
Methyl oleate	0.146	28
Methyl linoleate	0.025	28
Methyl dihomo- γ -linolenate	0.034	28
Methyl arachidonate	0.092	28
Selective hydrogenation with gaseous tritium		
8,11,14-Triyne analogue of methyl dihomo- γ -linolenate	5.6	29
5,8,11,14-Tetrayne analogue of methyl arachidonate	7.4	29
5,8,11,14,17-Pentayne analogue of methyl thymnodonate	9.2	29
5-Acetylenic analogue of methyl arachidonate	1.3	16
14-Acetylenic analogue of methyl arachidonate	1.2	16
5-Acetylenic analogue of methyl thymnodonate	1.9	16
4-Acetylenic analogue of methyl docosahexaenoate	1.8	17

Note: In liquid-phase isotope exchange, the label is incorporated by isotope exchange of hydrogen atoms for tritium atoms; in hydrogenation with gaseous tritium, the label is incorporated owing to the reduction of triple bonds to double bonds.

^a Free fatty acids were obtained by alkaline hydrolysis of their methyl esters.

Scheme 1

of KHCO₃.¹⁶ It is known that the use of nonpolar solvents for epoxidation results in the formation of substantial amounts of diepoxides due to the high reactivity of the peroxy acid under the given experimental conditions; therefore, ethanol was used to increase the yield of monoepoxides.³⁰ This procedure was applied

Scheme 3

The figures in parentheses indicate the percentage of the monoepoxide with respect to the total monoepoxide content in the reaction mixture.

for the preparation of monoepoxides from arachidonic (AA), thymnodonic (TA) and docosahexaenoic acids (DA) (Scheme 3).

Acetylenic analogues of eicosapolyenoic acids, *viz.*, the 8,11,14-triayne analogue of methyl homo- γ -linolenate, the 5,8,11,14-tetrayne analogue of methyl arachidonate and the 5,8,11,14,17-pentayne analogue of methyl thymnodonate were synthesised by purely chemical methods (Scheme 4).

The reduction of triple bonds to double bonds in the atmosphere of gaseous tritium was used to prepare highly labelled polyenoic fatty acids (see Table 1). In order to increase the selectivity of hydrogenation of the corresponding acetylenic analogues, one had to modify palladium catalysts with lead diacetate, pyridine and quinoline. However, the yield of tritium-labelled alkenes did not exceed 10%–40% even when the hydrogenation of one triple bond was performed according to the previously described procedures (*cf.* Ref. 5). Satisfactory yields

were obtained with palladium on barium sulfate as a catalyst, which had been treated consecutively with methanolic solutions of lead diacetate [$\text{Pd}:\text{Pb} = 1:(0.5-1.0) \text{ mg mg}^{-1}$] and sodium borohydride [$\text{Pd}:\text{NaBH}_4 = 50:(0.4-4.0) \text{ mg mg}^{-1}$]. A 4:1 heptane–dioxane mixture was used as a solvent. The catalyst:substrate ratio was (2–6):1.²⁹ Under these conditions, the yield of the target products with a molar radioactivity of 1.2–1.8 PBq mol^{−1} per selectively reduced triple bond was 89%–99% after 25–35 min (see Table 1).

It is necessary to emphasise that the reaction conditions were optimised not only for the labelling of unsaturated fatty acids, but also for pheromones, attractants and lipid hormones the complete chemical synthesis of which includes selective hydrogenation of acetylenic precursors in the final stage.³¹ This can be exemplified in the use of acetylenic precursors in the synthesis of the *Lepidoptera* pheromones (Table 2).

Thus, bombykol (molar radioactivity 1.85 PBq mol^{−1}) was synthesised from hexadec-(10*E*)-en-12-yn-1-ol (see Ref. 29); the abscisic acid analogue (molar radioactivity 1.21 PBq mol^{−1}) (see Ref. 29) was prepared from (2*Z*)-5-(4-*tert*-butyl-*trans*-1-hydroxycyclohexyl)-3-methylpent-2-en-4-ynoic acid; retinoic acid (molar radioactivity 1.75 PBq mol^{−1}) (see Ref. 20) was obtained from 11,12-dehydroretinoic acid. (Z)-[11,12-³H]Hexadeca-1,11-dien-3-one, (Z)-[6,7-³H]eicos-6-en-11-one and some other labelled pheromones³² with a molar radioactivity of $\sim 1.5 \text{ PBq mol}^{-1}$ were obtained by selective hydrogenation of the acetylene bonds.

The use of the liquid-phase isotope exchange for labelling saturated fatty acids is not promising, since molar radioactivities of reaction products were of the order of several hundredths of PBq mol^{−1} (Table 3). However, in contrast with alkenes, the isotope exchange in saturated compounds is not accompanied by side reactions; therefore, investigations into the use of this method were carried out and some regularities were established. Thus it was found that the kinetic curves of the isotope exchange reaction reach the plateau rather rapidly. In this case, the degree of substitution of tritium for hydrogen is much smaller than could

be expected from the equilibrium distribution of the tritium label. Besides, the kinetic curves of molar radioactivity have a complex shape, which is attributed to the different saturation of palladium with the hydrogen isotopes during the formation of the α -phase of palladium hydride and its subsequent transition into the β -phase.²⁸

The high thermal stability of alkanes has made it possible to use solid-phase isotope exchange for introducing the label into saturated compounds (see Table 3).

Studies of solid-phase isotope exchange with stearic acid as a model compound in the presence of palladium and platinum catalysts supported on different carriers showed that this reaction proceeded with the greatest efficiency on 5% Pt/C at 210 °C (the catalyst : substrate ratio = 10 : 1) (Figs 1–4).[‡]

Similar investigations were carried out with stearic acid homologues. It was demonstrated that in this case, too, the optimal conditions for a solid-phase isotope exchange were as follows: 5% Pt/C, the catalyst : substrate ratio = 10 : 1, reaction time = 15 min. Other regularities were also established. First, the dependence of changes in the molar radioactivities of fatty acid homologues on the length of the carbon chain was practically linear, which points to the random labelling by this method. Second, the temperature at which the degree of isotope substitution was a maximum ($T_{\max}$), was different for different analogues.

Acid	Lauric	Myristic	Palmitic	Stearic
M.p. /°C	44.3	58	64	70
$T_{\max}$ /°C	190	200	205–210	210

In all probability, this temperature depends on the phase transition temperature for representatives of the same homologous series (*e.g.*, fatty acids).

[‡] In the study aimed at establishing the relative degree of the label incorporation, α_{rel} , the maximum molar radioactivity of the preparation was taken as 100%.

**Figure 1.** The dependence of the relative degree of the label incorporation into stearic acid on the nature of the catalyst.

Catalyst: (1) 5% Pt/C, (2) 10% Pd/C, (3) 10% Pd/BaSO₄, (4) 5% Pd/C, (5) 5% Pd/BaSO₄, (6) 5% Rh/C.

**Figure 2.** The dependence of the relative degree of the label incorporation into stearic acid on the catalyst : substrate (5% Pt/C) ratio.**Figure 3.** The dependence of the relative degree of the label incorporation into stearic acid on temperature (the catalyst is 5% Pt/C, the catalyst : substrate ratio is 10 : 1).**Figure 4.** The kinetics of the label incorporation into stearic acid (the catalyst is 5% Pt/C, the catalyst : substrate ratio is 10 : 1, 210 °C).

It is evident that at certain temperatures the diffusion of these lipid molecules increases to such an extent that the rate of diffusion of the spill-over hydrogen no longer affects the rate of the overall reaction of isotope exchange. The efficiency of the isotope exchange decreases drastically after 10–15 min. The latter

circumstance can be rationalised as follows. The study of the valence state of hydrogen in hydrides of intermetallic compounds carried out by Semenenko *et al.*³⁷ has offered a new outlook on the problem of the valence state of hydrogen in systems of the Pd–H₂ type. Debates on this problem, which is of particular importance for hydride chemistry, have begun since the appearance of classical works of Ubbelohde,³⁸ who put forward a concept of a positively charged hydrogen atom on palladium, and of Gibb,³⁹ who proposed a model with a negatively charged hydride ion. Semenenko *et al.*³⁷ proposed and rationalised the concept according to which hydride dispersion is a result of a redox reaction associated with the formation of hydride ions, H^{δ−}, at a hydrogen concentration (*c*_H) in the solid hydride exceeding a critical concentration (*c*_{Hcrit}), which, in turn, depends on the redox potential of the reaction:

where M is the metal template of the catalyst. According to this model, the hydrogen chemisorbed on the active centres on the catalyst surface donates some of its *s*-electrons to the metal conduction band. In this context, at low values of *c*_H the behaviour of the absorbed hydrogen is well described in terms of the Ubbelohde model³⁸ which entails high diffusion mobility of the H^{δ+} ions and an increase (or, at least, the lack of a decrease) in electric conductivity of the hydride phase in comparison with the original metal. The value of *c*_{Hcrit} corresponds to the concentration of the oxidising agent (H^{δ+} species) at which the latter oxidise the metal template and become electron density acceptors being converted into bulky, practically immobile H^{δ−} ions. As a result, the metal conduction band is depleted in electrons. Obviously, at higher degrees of filling of cavities with H^{δ−} ions having a fairly large effective volume, the electron deficiency on the metal ions forming a metal sublattice in the crystalline structure of the catalyst should increase which probably restricts its ability for reversible hydrogen absorption. In this connection, the concentration of the species (*e.g.*, of tritium in the case of labelled preparations) which can enter into exchange reactions drops drastically, eventually resulting in a practically complete cessation of the isotope exchange.

Approaches to the synthesis of fatty acids with high molar radioactivity were successfully used for the preparation of other highly labelled saturated lipids, *viz.*, fatty acid derivatives, fatty alcohols and alkanes (*e.g.*, methyl stearate, 3-hydroxypalmitic, 6-ketopalmitic and chloroundecanoic acids, cetyl alcohol and hexadecane) (Tables 4–6).³⁴ It was found that the isotope exchange in halogen-containing saturated acids occurs much easier than dehalogenation. The experimental values of molar radioactivities reached tens of PBq mol^{−1}, which makes it possible to conduct biological experiments of any kind including ligand–receptor binding studies. The nonspecific label distribu-

tion in the products obtained upon the isotope exchange is the only disadvantage of this method.

Hydrogenation of double bonds (see Table 3) is used in the synthesis of saturated fatty acids with a definite position of the label (its precursor is an accessible unsaturated acid).^{4, 29, 35} Studies with [10,11-³H]undecanoic acid obtained by this method, which is a component of a termite pheromone, have shown that it comes to the pheromone glands with food or is biosynthesised.

Among other methods used for the synthesis of labelled fatty acids, thermal activation of tritium deserves special mention. The use of this procedure for labelling of methyl 12-hydroxystearate (0.56 TBq mol^{−1}) was described by Shevchenko and Myasoe-dov.⁴ The method consists in the application of a substance as a thin film onto the inner surface of a cylindrical vessel containing a tungsten filament placed along its axis. The system is evacuated, filled with tritium up to 0.67 Pa, cooled with liquid nitrogen and the tungsten filament is heated to 2000 K for 30 s. Tritium molecules dissociate, which significantly increases the degree of the isotope exchange.

[8L-³H]- and [8D-³H]Stearic acids⁵ were obtained by conversion of methyl 8D(8L)-hydroxystearate into the corresponding tosylate, which was further reduced with lithium aluminium tritide (6.6 TBq mol^{−1}). Stearic alcohols formed were oxidised with CrO₃ to yield the target product (3.3 TBq mol^{−1}).

Labelled fatty acids find application in biological studies and in the synthesis of various derivatives and labelled oxylipins based on them. Thus, they can be used in studies of cholesterol esters biosynthesis⁴⁰ or in the synthesis of monoepoxides (see Schemes 1–3), which are the products of the epoxigenase pathway of the arachidonic acid cascade or other polyunsaturated fatty acids. The biological activity of these epoxides is widely known. They stimulate the *in vitro* release of somatostatin from

the median tubercle of hypothalamus and the secretion of insulin and glucagon from pancreatic islets, inhibit the vasopressin-stimulated release of H₂O in bladder tumours, suppress aggregation of platelets and neutrophils, enhance the release of calcium from dog aortic smooth muscle microsomes and increase the cytosolic levels of free calcium. Under the action of various enzymes, these epoxides are converted into other, more oxidised products, *e.g.*, vicinal diols, 20- and 19-hydroxy derivatives.

2. Fatty acid derivatives

a. Fatty acid esters

Glycerides. The high biological activity of glycerides can be exemplified in the properties of 2-arachidonoylglycerol, which is an intermediate in tri- and diglyceride metabolism and an alternative precursor of arachidonic acid manifesting cannabimimetic activity.⁴¹ The use of a tritium-labelled analogue of this glyceride provided additional information about its pharmacological activity.

Labelled glycerides are usually obtained by condensation of the corresponding labelled fatty acids with glycerol.⁴ Different approaches to the synthesis of triglycerides (TG) have been considered.⁴² These lipids are formed upon heating of a mixture of glycerol and a fatty acid to 160–190 °C; the reaction proceeds more efficiently in the presence of toluenesulfonic acid with removal of water formed by distillation with xylene. Higher yields of TG are obtained in reactions of silver salts of fatty acids with 1,2,3-tribromopropane in boiling xylene and of acid chlorides or mixed anhydrides with glycerol. TG can also be synthesised under very mild conditions in the presence of dicyclohexylcarbodiimide and 4-dimethylaminopyridine. This procedure can also be used in the synthesis of the corresponding steroid esters. The use of this approach (the reaction was carried out in 1,2-dichloroethane; a solution of dicyclohexylcarbodiimide in benzene was added in several portions) resulted in labelled TG in more than 90% yield. Di- and monoglycerides can be prepared from triglycerides under the action of the corresponding lipases.⁴³ Thus 2-arachidonoylglycerol was prepared from triarachidonoylglycerol by treating it with *Rhizopus delemar* ('Seikagaku Kogyo', Japan) in 0.05 M AcONa–AcOH buffer (pH 5.6) containing 0.1 mmol litre^{−1} NaCl and 10 mmol litre^{−1} CaCl₂ with vigorous stirring for 60 min.⁴⁴

Among other methods used for glyceride synthesis, special mention should be made of the reduction of dihydroxyacetone 1,3-derivatives with sodium borotritide and the isotope exchange with tritiated water. Molar radioactivities of TG obtained by this method were by one order of magnitude lower than those of the tritiated water employed.⁴

Studies with 2-[³H]arachidonoylglycerol revealed that neuroblastoma N18TG2 cells contain nonspecific esterases. Hydrolysis of this monoglyceride was only partly (by less than 40%) inhibited by an excess of the unlabelled substrate, whereas the degree of selectivity of the esterase isolated from peripheral cells of the basophilic rat leukemia RBL-2H3 was much higher (74%). It was shown also that in contrast with 2-palmitoylglycerol, 2-linoleoylglycerol inhibited hydrolysis of 2-arachidonoylglycerol by intact cells as a result of which the concentration of 2-arachidonoylglycerol capable to activate the cannabinoid receptor increased considerably. The experimental results described by different authors^{41,45–49} suggest that non-cannabimimetic monoglycerides enhance the effect of 2-arachidonoylglycerol by increasing the half-time of its conversion and increase binding of 2-arachidonoylglycerol to the cannabinoid receptor (4–8-fold).

Phospholipids. Formerly, phospholipids were considered exclusively as structural components of biological membranes which fulfilled the barrier function in respect of electrolytes and served as a matrix for membrane-bound enzymes and receptors. However, it has presently been recognised that phospholipids and the products of their enzymic and free-radical conversions also perform important cell regulatory functions, being substantial for the manifestation of catalytic activities of many enzymes. Besides,

some phospholipids are endowed with hormone-like activities, play the role of platelet activation factors (PAF) (1-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine), accelerate wound healing (lyso-phosphatidic acid), *etc.* Hydrolysis of phosphoinositides and methylation of phosphatidylethanolamine are the key reactions in the transmission of intercellular signals.^{50–52}

As a rule, the tritium label is introduced into phospholipids by hydrogenation of natural or synthetic unsaturated precursors (Table 7). The synthesis of tritium-labelled phosphatidylinositol and diphosphoinositide is shown in Scheme 5. Isotope exchange (Tables 7 and 8) and condensation of labelled fatty acids with the corresponding precursors as well as biological and enzymic methods and their combination are the most promising approaches.^{4,55}

Unsaturated precursors were synthesised in order to prepare labelled phosphatidylinositol and diphosphoinositide.⁵⁶ Several steps of their synthesis including deacetylation with hydrazine hydrate, were identical. If the phosphatidylinositol was the target product, the protective groups were removed by anionic debenzoylation and treatment with a cation-exchange resin (H⁺-form). In

the synthesis of diphosphoinositide, inositol was phosphorylated at position 4 with an excess of phosphorus oxychloride in pyridine with subsequent deprotection. Hydrogenation of the unsaturated fatty acid residues in the *myo*-inositol derivatives in an atmosphere of gaseous tritium in the presence of a catalyst has led to highly labelled phospholipids.²⁹

These conditions proved to be versatile and can be used in the synthesis of labelled sterol esters. Thus, the hydrogenation of cholesteryl oleate was used to prepare cholesteryl [9,10-³H]-stearate²⁹ with a molar radioactivity of 1.98 PBq mol⁻¹. Condensation of [9,10-³H]oleic acid (0.07 PBq mol⁻¹) with lysophosphatidylcholine in the presence of dicyclohexylcarbodiimide and *N*-dimethylaminopyridine (1 : 1 : 1 : 100) in ether (stirring for 20 h at room temperature) affords lecithin (yield 35%–40%).⁴

The synthesis of phosphatidyl[³H]inositol can serve as an example of a synthesis of tritium-labelled fatty acid derivatives by biological methods.⁴ The starting compound, [2-³H]inositol, was synthesised by solid-phase reduction³⁵ of a commercially available *scillo*-inosose (2,4,6,3,5-pentahydroxycyclohexanone).³⁵ In a search for optimum conditions for *scillo*-inosose reduction, 5% Pd/CaCO₃, 5% Rh/Al₂O₃, 5% Pd/BaSO₄, 5% Pt/C, 5% Pd/C were tested as catalysts. The best results were obtained on a

rhodium catalyst (the catalyst : substrate ratio = 10 : 1) with heating to 150 °C for 15 min (the molar radioactivity of the labelled preparation was 0.56 PBq mol⁻¹, the yield was 25%). In addition, *scillo*-inosose with a molar radioactivity of 0.11 PBq mol⁻¹ was isolated from the reaction mixture in ~ 10% yield.

The biosynthesis of the labelled phospholipid was performed by incubation of [2-³H]inositol with a culture of *Kloeckera brevis* (ATCC 9774) (7 days, 25 °C). Subsequent extraction, chromatographic purification and desalting resulted in phosphatidyl[³H]inositol, which contained 54% of the original label and had a molar radioactivity ~ 2 times as low as that of the original [2-³H]inositol.

A combination of chemical and enzymic methods was used in the synthesis of 1,2-dioleoyl-*sn*-[2-³H]glycero-3-phosphoserine.⁵⁵ The first step included the chemical synthesis of [2-³H]glycerol; its incubation with glycerol kinase in the presence of ATP gave *sn*-[2-³H]glycerol-3-phosphate (yield 98%–99%). Boiling of the monotetraethylammonium *sn*-[2-³H]glycerol-3-phosphate tetraethylammonium oleate and oleic acid anhydride (1 : 10 : 10) in dry carbon tetrachloride (3 h, 80 °C) afforded 1,2-dioleoyl-*sn*-[2-³H]glycerol-3-phosphate in ~ 56% yield. The pyridinium salt of the latter was condensed with the benzhydryl ester of *N*-Boc-

serine in the presence of 2,4,6-triisopropylbenzenesulfonyl chloride (1 : 3.2 : 6.4) in dry pyridine (24 h, 30 °C). Deprotection under acidic conditions and chromatographic purification yielded 1,2-dioleoyl-*sn*-[2-³H]glycero-3-phosphoserine (total yield 12%, molar radioactivity 0.93 PBq mol⁻¹).

Labelled phospholipids play an important role in present-day biological studies. Thus in a study of the role of PAF in the regulation of cellular activity and cell-to-cell contacts, its labelled analogue was used in order to establish the effect of different antagonists blocking PAF activity at the level of PAF receptors on cell activation.⁵¹ A synthetic lipid antagonist CV-3988 inhibited the binding of the labelled phospholipid to platelets and suppressed the secretion and aggregation of platelets (0.1–0.15 µmol litre⁻¹).⁵⁷ The binding of this phospholipid to PAF receptors is known to trigger a cascade of biological reactions which result in the signal transfer into the cell and its subsequent activation.⁵¹ It has been shown⁵⁸ that 5 s after treatment of platelets with PAF, phosphatidylinositol-4,5-diphosphate undergoes hydrolysis to inositol-1,4,5-triphosphate. This hydrolysis is catalysed by membrane-bound phospholipase C. It was found also that the antagonists inhibit both the binding of labelled PAF to platelets and the formation of inositoltriphosphate in platelets.⁵⁹ The role of inositoltriphosphates in the regulation of the Ca²⁺ level in cell cytoplasm is immense, which may account for the pronounced effect of phospholipids on vital activity of cells in general.⁵⁰

b. Fatty acid amides

Ethanolamides of fatty acids represent highly active endogenous bioregulators. Arachidonic acid ethanolamides, which has been named later anandamide, was isolated from porcine brain in the early 1990's.⁶⁰ This compound proved to be an endogenous ligand of cannabinoid receptors, *viz.*, it competitively inhibited the specific binding of cannabinoids to receptors and mimicked their biological effects.^{60–67} Ethanolamides of other polyenoic fatty acids were isolated from mammalian brain more recently.^{68,69} These compounds also bind specifically to cannabinoid receptors. It is established now that mammalian tissues manifest synthase and amidase activities responsible for the synthesis and inactivation of anandamide.^{70–77} Tritium-labelled ethanolamides of fatty acids were used in studies of their metabolism, the activity of enzymes of the arachidonic acid cascade in the oxidation of these fatty acid derivatives and the effects of these labelled compounds on functioning of the arachidonic acid cascade in different animal and plant cells.

Ethanolamides can be labelled at both the acyl and ethanolamide fragments. Highly labelled fatty acids can be synthesised by selective hydrogenation in an atmosphere of gaseous tritium, while labelling of ethanolamine can only be done by solid-phase methods.^{78,79} Glycolic acid nitrile proved to be a promising starting compound, and 5% Pt/C, 5% Rh/C, 5% Pd/C, 5% Rh/Al₂O₃ and 5% Rh/CaCO₃ are effective catalysts. The highest yields were obtained with palladium catalysts; the molar radioactivity was higher on rhodium catalysts. The latter were used in the synthesis of labelled ethanolamine with a molar radioactivity of 1.04–1.48 PBq mol⁻¹, but the yields of target products were so insignificant that preparative syntheses of the labelled compound could be carried out only in the presence of 5% Pd/C. On platinum catalysts, dehydrogenation predominantly occurs.

The data summarised in Table 9 suggest that *T* = 100–120 °C is the optimum temperature. Under these conditions, the labelled product was obtained in 10%–20% yield and had a molar radioactivity of 0.15–0.22 PBq mol⁻¹.⁷⁸ Isobutyl chloroformate⁷⁸ or *N,N'*-diisopropylcarbodiimide⁷⁹ were used for condensation of fatty acids with ethanolamine (Table 10).

Studies on kinetics of oxidation of labelled anandamide and thymnodonic acid ethanolamide with soybean 15-lipoxygenase and on their possible oxidation in mouse splenocytes can serve as examples of application of these labelled compounds in biological studies.⁸⁰ It was found that the values of Michaelis constants (*K_m*)

and *V_{max}* for these compounds were equal to 3.2 and 4.9 µmol litre⁻¹ and to 0.11 and 0.15 µmol l⁻¹ s⁻¹, respectively. These values are of the same order of magnitude as those for arachidonic acid.^{79,81} Experiments have shown that mouse splenocytes contain an anandamide-metabolising system. Splenocytes are related to cells continuously secreting 12-HETE and other eicosanoids. Anandamide-induced changes in the concentration of these products modulate functions of lymphocytes and other eicosanoid-controlled immune cells.

Sphingolipids pertain to the class of lipid molecules with different chemical structures and functional activities. Sphingene (sphingosine) is the most common sphingosine base of human and animal cell sphingolipids. The sphingene molecule contains two chiral carbon atoms and can exist in four stereoisomeric forms. Natural sphingene represents a *D-erythro*-isomer. *N*-Acylation of the amino group of sphingene with fatty acids results in ceramides, the precursors of more complex sphingolipids (sphingomyelin and glycosphingolipids).

Until the 1980's, the effect of the structure of the acyl residues of these lipids on their biological activity had been virtually neglected.⁸² However, studies carried out in the late 1980's provided evidence that sphingene inhibited cell differentiation,⁸³ while ceramides activated it.^{84–87} More recent studies have shown that the biological properties of the fatty acid residues of ceramides depend on their lengths. Thus it was found that C₁₈-ceramide does not inhibit lymphocyte proliferation (in contrast to the short-chain ceramides C₂ and C₆),⁸⁸ whereas hydroxy acids present in natural ceramides strongly suppressed the induction of apoptosis.⁸⁹ The activation of protein phosphatase with ceramides also depends on the length of the acyl chain.⁹⁰ This can be ascribed to the hydrophobic interactions between the hydrocarbon chains of sphingosine and the fatty acid which depend on the structure of both the sphingosine chain (length, the presence (sphingene) or the absence (sphinganine) of a double bond) and the fatty acid residue (length, the presence or the

absence of double bonds, their number, position, the presence of hydroxy groups, *etc.*). Such interactions may attenuate the differences in the effector activities of ceramides and dihydroceramides. Thus investigations into the mechanism of action of ceramides on target cells revealed that dihydroceramides, unlike the corresponding ceramides, inhibited (rather than stimulated) the activity of protein phosphatases,^{90,91} but had no effect on the activity of the protein kinase C isoform⁹² and phospholipase D,⁹³ which are inhibited by ceramides. However, in certain tests *N*-acetyl-sphingenin and *N*-acetyl-sphinganine manifested identical activities.

Radioactive labelling of sphingolipids can be performed in different ways, such as by condensation of the corresponding aminodiol with labelled fatty acids, by enzymic or chemical oxidation of hydroxy groups of sphingolipids with subsequent reduction with sodium or potassium borotritides, biosynthesis of labelled gangliosides starting from labelled *N*-acetyl-D-mannosamine and hydrogenation of the corresponding unsaturated precursors with gaseous tritium (Table 11).

The latter method was used for the synthesis of labelled gangliosides, sphingomyelin and ceramides. It was found^{4,5} that the ³H-label adds preferentially to the carbon atoms of multiple bonds. If liquid-phase isotope exchange is used for the labelling of unsaturated fatty acids, the label is predominantly incorporated into the allylic positions and into the double bonds. In phospholipids, the greater part of the label is localised in the fatty acid residues, whereas in the case of sphingolipids it is detected in both fatty acid and sphingosine moieties (Table 12).

Labelling of cerebrosides on the Lindlar catalyst results in the label incorporation into the fatty acid moiety, while on 5% Pd/BaSO₄ as a catalyst, it incorporates into the sphingosine moiety. This can be explained by the fact that the molecules of these compounds contain several polar groups (carboxy, hydroxy, amino, *etc.*), which compete with one another for the active centres on the catalyst's surface.²⁸ Presumably, the adsorption of the fatty acid residue on the Lindlar catalyst is more preferential than the adsorption of sphingosine bases. This fact determines the distribution of the tritium label.

It should be noted that chemical methods can be used for the synthesis of compounds with a predetermined position of the label.^{95,96} Complete chemical synthesis was used to obtain labelled *D*-erythro- and *L*-threo-sphingosines (Scheme 6).

Starting from galactose, azidosphingosines were prepared; the allylic hydroxy group was oxidised with 2,3-dichloro-5,6-dicyanobenzoquinone with subsequent reduction of the resulting ketone with sodium borotritide.⁹⁵

An attractive approach was proposed by Toyokuni *et al.*⁹⁶ Natural sphingenin was used as the starting compound; its primary hydroxy group was oxidised with CrO₃ (the Collins reagent) after protection of the amino group and the allylic

Note: The percentage of the activity of a given moiety relative to the activity of the original molecule is given in parentheses.

case, Ehrlich ascites carcinoma cells, which are efficient receptors of the influenza virus, were employed. The viral adsorption decreased drastically after treatment of cells with *Vibrio cholerae* neuraminidase which points to the fact that sialo-containing compounds (gangliosides) are specific receptors of the virus on the cell surface. Indeed, gangliosides GM_1 , $\text{GD}_{1\alpha}$ and $\text{GT}_{1\beta}$ restored the viral adsorption by cells. Based on the experimental data, it was concluded that: (1) the oligosaccharide chain of the ganglioside, $\text{Gal}\beta 1 \rightarrow 3 \text{GalNAc}\beta 1 \rightarrow 4(\text{NeuAc}\alpha 2 \rightarrow 3)\text{Gal}\beta 1 \rightarrow 4 \text{Glc}$, is the 'minimum' structural element providing the adsorption

of the influenza virus by the gangliosides; (2) the gangliosides probably take part in both binding and penetration of the virus into the cell; one receptor site binds ~ 100 ganglioside molecules involved in the reception.

III. Oxylipins

Oxylipins comprise eicosanoids and eicosanoid-like compounds with shortened or lengthened carbon chains, which are synthesised, for the most part, by cyclooxygenase, lipoxygenase and cytochrome P450 pathways.^{5,99} The main pathways of arachidonic acid metabolism resulting in oxylipins, *e.g.*, prostaglandins (PG), thromboxanes (TX), leukotrienes (LT), hydroxyeicosatetraenoic acids (HETE), hydroperoxyeicosatetraenoic acids (HPETE), lipoxins (LX), heptoxylins (HX), epoxytrieneoic acids (EET), *etc.*, are depicted in Scheme 7. It is of note that the scheme demonstrates exclusively transformations of arachidonic acid and its derivatives; however, other eicosapolyenoic acids can also be used as substrates in this reaction.

Scheme 8

Scheme 9

Under the action of enzymes, arachidonic acid yields: (1) PG, TX and prostacyclins (PGI), (2) hydroxy acids (LT, HX, LX); (3) epoxy and ω -hydroxy derivatives of fatty acids. Scheme 8 depicts preparation of PG and TX from prostaglandin G₂, Schemes 9 and 10, of hydroxy acids and LT from 5-HPETE, Schemes 11 and 12, of hydroxy acids, LX and HX from 12- and 15-HPETE. The synthesis of ω -hydroxy acids and epoxides is exemplified in oxidation of arachidonic acid in the presence of cytochromes P450 (Scheme 13).

The biological and pharmacological effects of these compounds are extremely diverse. Thus lipoxins control the activity of killer cells and manifest spasmogenic activity;¹⁰⁰ heptoxylins are the releasing factors in insulin secretion by pancreatic cells and regulate the transmembrane transfer of calcium;¹⁰¹ leukotrienes

are mediators of hypersensitivity (allergy, anaphylaxis).¹⁰² Prostaglandins have a wide application as medicinal drugs.¹⁰³ However, despite the diversity of oxylipins and the broad spectrum of their biological activities, it is the continuous interaction of these compounds with one another that provides for the normal course of vitally important reactions occurring in the organism. The validity of this concept was confirmed in the studies of the role of arachidonic acid metabolites in the maintenance of the normal functioning of hemostasis in mammals.¹⁰⁴ There exist at least two ways of maintaining the necessary level of arachidonic acid in a hemostatic system, viz., from cell phospholipids and from plasma low density lipoproteins. The metabolites of polyunsaturated fatty acids (prostacyclin, 13-hydroxyoctadecadienoic acid, 6-keto-PGE₁, PGE₁, HETE and HPETE, TXA₂, PGE₂, PGF_{2 α} ,

Scheme 10

Scheme 11

PGD₂, LTA₄, LTB₄) participate in the regulation of practically all units of the blood coagulating system as well as in reactions of the plasma component of hemostasis by influencing the fibrinolytic potential of blood and hemodynamic conditions. Thus, the urgency of investigations of these compounds is dictated by the fact that their effect on enzymic oxidation of polyenoic fatty acids is the central link in the mechanism of action of the majority of bioeffector lipids.

The main investigations in the field of oxylin with established structure are aimed at the study of their biosynthesis and metabolism. Labelled oxylin have played a prominent role in these studies. For this reason, a part of the present review which is devoted to the synthesis of labelled oxylin by enzymic methods can be regarded as an illustrative example of their application in

biological studies. In addition, studies of metabolic conversions of oxylin also consider their properties, *e.g.*, solubility, penetrability through biological membranes, *etc.* Labelled analogues turned out to be a helpful tool in pharmacokinetic studies of the first medicinal drugs (as a rule, natural prostaglandins and their synthetic analogues). Besides, they are indispensable components in the elaboration of highly sensitive methods for determination of oxylin in biological samples and in reception studies (interaction with protein molecules).

Radioactive labels can be introduced into eicosanoids by several routes. Isotope exchange or chemical methods are used for labelling synthetic derivatives of oxylin, where non-labelled prostaglandins are used as precursors or where the yields of the target products obtained by biological methods are negligibly

Scheme 12

Scheme 13

small (*e.g.*, the synthesis of epoxy compounds, prostacyclin, *etc.*), as well as for interconversion of labelled compounds.

The isotope exchange and chemical methods are indispensable tools in the synthesis of labelled eicosanoids having a non-natural structure, *e.g.*, (17*S*)-17-methyl-20-[11-³H]homoisocarbacycline,¹⁰⁵ fluoro prostaglandins,¹⁰⁶ *etc.* These methods were used to obtain fluorinated compounds with molar radioactivities varying from 0.09 to 1.1 PBq mol⁻¹ (Table 13).

Selective hydrogenation of prostaglandins of series 2 and 3 (*e.g.*, of PGE₃ to PGE₂ and PGE₁, Scheme 14) with gaseous tritium¹⁰⁷ afforded labelled preparations with molar radioactivities of 1.5–2.9 PBq mol⁻¹ (see Table 13).

Scheme 14

In the latter method, the results of calculations in assumption that the rates of all reactions are described by first-order equations showed good agreement with experimental results. In this case, the ratio of hydrogenation rate constants (k_1 , k_2 , k_3) were 2:1:4 for the reaction in acetone and 2:1:8 for the reaction in a benzene:acetone mixture. Obviously, for the synthesis of labelled

PGE₂ from PGE₃ the benzene:acetone mixture is more preferable; under these conditions, the yields of [17,18-³H]PGE₂ and [5,6,17,18-³H]PGE₁ were 40%–45% and 10%–15%, respectively.

The use of chemical methods for the synthesis of labelled compounds requires a detailed analysis of their chemical properties. Thus it is known⁵ that prostaglandins E are converted into PGA in acidic media, into PGB in alkaline media and into PGF after treatment with borohydrides. The latter in turn can serve as a precursor in the synthesis of prostacyclin or 6-keto-PGF_{1α} (see Table 13). Chemical methods can also be used for the synthesis of labelled methyl esters, *e.g.*, LTA₄ and 8-epi-PGF_{2α} (Scheme 15).^{108, 109, 110}

The choice of catalysts for selective hydrogenation with gaseous tritium was carried out as described in Section II.1. The best results were obtained with palladium catalysts poisoned with lead diacetate. In the case of more labile compounds, triethylamine was added to a solvent in order to minimise the formation of side products.

Selective hydrogenation with gaseous tritium can be used in the synthesis of other oxylipins, *e.g.*, [5,6,8,9,14,15-³H]hepoxylins B₃ (Scheme 16).¹⁹

Enzymic methods with the use of labelled eicosapolyenoic acids as the starting substrates (see Scheme 7) are the most popular methods for the synthesis of labelled eicosanoids. It is impossible to mention all of the currently known data concerning this problem in a single review; therefore, we shall confine our description to the consideration of a few examples illustrating the versatility of this approach.¹¹¹ Thus the use of only one enzyme, *e.g.*, PG synthase, which catalyses the transformation of eicosa-

polyenoic acids into PGH (its half-life in aqueous media is ~ 5 min), made it possible to obtain a variety of labelled products, such as PDG, PGE, PGF _{α} and 12-hydroxyheptadecatrienoic acid (HHT) (see Scheme 8). The yield of labelled PGH and, consequently, of its degradation products depends on the concentrations of the eicosapolyenoic acid and PG synthase. Under optimum conditions, the yield of [5,6,8,9,11,12,14,15-³H]PGH₂ was 70%; those of [5,6,8,9,11,12,14,15,17,18-³H]PGH₃, [5,6,8,9,11,12-³H]HHT, [5,6,8,9,11,12,14,15-³H]PGF_{2 α} , [5,6,8,9,11,12,14,15,17,18-³H]PGF_{3 α} and [5,6,8,9,12,14,15,17,18-³H]PGD₃ were 45%, 35%, 63%, 27% and 25%, respectively. The ratio of products of non-enzymic degradation of PGH₂ in different buffer systems is variable (Table 14).

The use of two-enzyme systems has made it possible to find conditions for the predominant formation of only one reaction product and to synthesise compounds which cannot be obtained by spontaneous degradation of PGH. In this case, PG synthase was supplemented with the enzymes specifically converting labile [³H]PGH into [³H]PGE, [³H]PGD, labelled thromboxane and [³H]HHT, viz., PGE synthase for the synthesis of [³H]PGE, PGD synthase for the synthesis of [³H]PGD and TX synthase for the synthesis of [³H]TXB and [³H]HHT. In a study with individual enzymes, conditions for eicosanoid biosynthesis were optimised by varying the concentrations of each enzyme and their ratios.¹¹² All the preparations used in this study retained their activities

upon storage (6 months at -60 °C). Even highly labile PGE synthase retained up to 80% of activity for 12 days at -60 °C. Inactivation of enzymes (PG synthase, 12-lipoxygenase, TX synthase) in the course of biosynthesis was taken into consideration using the following kinetic equation:

$$\frac{de}{ds} = \frac{1}{V},$$

where e is the concentration of the active enzyme species, s is the substrate concentration and V is the dimensionless parameter reflecting the number of the enzyme turnovers up to complete inactivation and depending on the chemical nature of the

^a After 30-s incubation, hydrochloric acid was added to the reaction mixture to pH 3.0 and the incubation was continued (1 h, 25 °C).

substrate. The experimental values of *V* for the PG synthase-catalysed conversions of arachidonic and thymnodonic acids¹¹⁰ differed more than 10-fold.

Quantitative calculations carried out with the use of a mathematical model and experiments with two-enzyme systems have shown¹¹² that the maximum yields of target products can only be obtained if the substrate is gradually added to the reaction mixture containing both enzymes. Under these conditions, the yields of target eicosanoids are restricted by enzyme inactivation in the course of the reaction. It was also found that the efficiency of a two-enzyme system can be significantly increased if some specified initial concentrations of the enzymes and the substrate are used.

Thus, the strategy of enzymic synthesis of labelled eicosanoids is based on the use of artificial two-enzyme systems and can be formulated as follows.¹¹² First, enzyme preparations must be purified to the maximum degree, since ballast proteins cause strong adsorption of the original labelled eicosapolyenoic acids, make them inaccessible for PG synthase and provoke undesirable conversions of PGH (Table 15).

Second, the enzyme:substrate ratio should be an optimum, *e.g.*, 747 and 63 nmoles of arachidonic and thymnodonic acids, respectively, should be taken per unit of PG synthase activity.

Third, high yields of target products can be obtained at high concentrations of PGH-converting enzymes. Thus in the case of PGE₂, a fourfold increase in the concentration of PGE synthase caused a 1.9-fold increase in the eicosanoid yield; in the case of PGD₂, a threefold increase in the concentration of PGD synthase increased the eicosanoid yield twofold, whereas in the case of TXB₂, a fivefold increase in the concentration of TX synthase

Eicosanoid	Yield (%)	
	I	II
PGD ₂	23	33
PGD ₃	17	25
TXB ₂	13	24
TXB ₃	10	18

increased the yield of the target product 2.4-fold. Probably, this is associated with the necessity for creation of conditions where the rates of enzymic conversions of PGH will markedly exceed the rate of its spontaneous degradation.

Fourth, the procedure of conducting the biosynthesis plays a very important role. The yield of the target product can be increased 1.5–2-fold by separate addition of the enzymes to the reaction mixture (Table 16). The optimum time of incubation of an eicosapolyenoic acid with PG synthase prior to the addition of the second enzyme is 1.5–2 min. Within this period, the accumulation of PGH is a maximum, *i.e.*, the rate of its formation by the PG synthase reaction coincides with the rate of its nonenzymic degradation.

Fifth, the temperature dependence of the yields of these eicosanoids in two-enzyme synthesis has a broad optimum (20–25 °C). This implies that the optimal yields of labelled eicosanoids can be attained at room temperature.

This strategy was successfully used in the synthesis of various highly labelled oxylipids (Table 17).

Considerable interest recently arose in the studies of functioning of various enzymic subsystems under heterophasic conditions.¹¹² This interest is due to the fact that the catalytic activity and stability of many enzymes under reaction conditions can be significantly increased. Thus a search for the ways aimed at increasing the 'productivity' of enzymes involved in prostaglandin synthesis, which undergo irreversible inactivation in the course of the reaction, has demonstrated high efficiency of macroheterogenous systems (water-in-octane and octane-in-water). It was found that the activities of the enzymes of eicosanoid synthesis (PG synthase, PGE synthase, TX synthase, 12-lipoxygenase) were retained in all heterophasic systems under study. The highest values of activity, *V*, for the PG synthase

reaction were observed with octane-in-water emulsions stabilised with native microsomal membranes. It was also found that if water:octane:lyophilised membranes ratios were close to those at which the system is stratified, the catalytic activity of PG synthase increased nearly 10-fold in comparison with systems containing no organic solvents. Moreover, the main advantage of this approach to the synthesis of labelled preparations is that in stabilised emulsions the labelled eicosapolyenoic acid is predominantly accumulated in the organic solvent, whereas the oxidation products (*e.g.*, PGE₂) are detected only in the aqueous phase. As a result, the negative effect of radiolysis on the formation of target labelled eicosanoids is reduced and the reaction products, the enzyme and the nonconsumed substrate are readily separated by centrifugation.

In addition to these methods for the synthesis of labelled oxylipins, special mention should be made of the possibility of synthesis of certain labelled prostaglandins by enzymic modification of other labelled prostaglandins. The use of chemical methods is coupled with the formation of stereoisomers and the necessity to perform additional steps for protection of functional groups with similar reactivities. Enzymic syntheses of prostaglandins starting from other prostaglandins as substrates are devoid of these drawbacks. Thus 15-keto-PGF_{2α}, 13,14-dihydro-15-keto-PGF_{2α}, PGE₂, 15-keto-PGE₂, 13,14-dihydro-15-keto-PGE₂ and 9α,11β-PGF₂ were synthesised from [³H]PGF_{2α} and [³H]PGD₂ using 9- and 15-hydroxyprostaglandin dehydrogenases, PGF synthase, *etc.*, isolated from various sources (see Table 17).^{111–113}

Labelled 15-HETE, 5,15-DHETE, 8,15-DHETE and 12-HETE were synthesised in up to 60%–65%, 20%–25%, 10%–15% and 21%–51% yields, respectively, using enzymes of the lipoxygenase pathway of eicosapolyenoic acid metabolism (*e.g.*, 15- and 12-lipoxygenase) (see Schemes 11 and 12).

The optimum conditions for these reactions were selected in the studies of the dependence of the yields of target products on the presence of appropriate additives in the reaction mixture as well as on the substrate:enzyme ratio, substrate and enzyme concentrations, degree of enzyme purification, *etc.*^{111, 114, 115}

An analysis of the data presented in Table 18 suggests that if the 12-lipoxygenase reaction is conducted in the presence of certain reducing agents, the yield of 12-HETE increases considerably. However, the use of enzymes is not always successful. Thus labelled leukotriene B₄ was synthesised in but 0.1% yield using enzymes of the lipoxygenase pathway of eicosapolyenoic acid metabolism,²⁹ whereas the yields of lipoxins¹¹⁶ were negligibly small. These examples demonstrate that the use of enzymic methods demands a careful selection of reaction conditions and a thorough analysis of factors decreasing the yield of target products.

IV. Steroids

The fundamental problem of a relationship between the structure of biologically active compounds and their activities is still very

urgent. Its solution would make it possible to use both natural and modified steroids as medicinal drugs. It is known that steroid hormones fulfil several functions in the organism, each being mediated by a specific receptor. Studies of the mechanism of steroid–receptor interaction shed light on what fragments of the steroid molecule are responsible for one or another of its biological function. This knowledge will allow the minimising of potential side effects of natural steroids used as medicinal drugs, on the one hand, and influencing their particular biological function by modifying natural steroid molecules, on the other hand.²²

Tritium-labelled steroids possessing estrogenic, androgenic and anabolic activities are necessary for estimating the biological characteristics of pharmacological preparations used in studies on reproduction and increase of the productivity of animals. Labelled analogues of steroid hormones are used in investigation of various metabolic processes in normal and pathological states, in diagnostics of diseases and quantitation of steroids in various biological fluids.¹¹⁷ The topicality of synthesis of labelled steroids is connected with the application of their natural precursors in the treatment of various diseases, such as atherosclerosis, asthma, rheumatism, eczemas, allergies, polyarthritis, gout, radiation disease, diabetes mellitus, *etc.*

The label is introduced into steroids by various routes. Let us consider the methods used in the synthesis of labelled cholesterol as an example.

The data presented in Tables 19–21 suggest that dehalogenation, solid-phase isotope exchange and isotope exchange with

Methylandrosta-1,4-dien-17 α -ol	0.200
Methylandrosta-5-ene-3 β ,17 α -diol	0.226

tritiated water are the most promising methods.^{118–122} The label can successfully be introduced into androstanes, pregnanes and some other steroids by a modified Wiltzbach procedure (see Ref. 123). Labelled steroids can also be prepared by biological methods,¹²⁰ hydrogenation and selective hydrogenation of the corresponding precursors^{124–127} in combination with other chemical methods (Table 22).^{129–133}

Dehalogenation allows one to prepare stereospecifically labelled steroids. Molar radioactivities of the thus synthesised [³H]cholesterol, [³H]pregnenolone and [³H]dehydroepiandrosterone amount to 0.37 PBq mol⁻¹, and those of aromatic 2,4-dibromosteroids, to 1.1 PBq mol⁻¹.^{118–120}

Biological methods entail the conversion of labelled steroids into other steroids. Thus [16-³H]aldosterone (molar radioactivity 0.08 PBq mol⁻¹) was prepared from [16-³H]progesterone (0.5 PBq mol⁻¹) using bovine adrenal cortex enzymes, and [16-³H]cortisol (molar radioactivity 0.07 PBq mol⁻¹) was obtained from [16-³H]corticosterone with a molar radioactivity of 0.14 PBq mol⁻¹.¹²⁰

It is known that the reactivity of double bonds of unsaturated steroid hormones decreases in the following order: 1,2 > 6,7 > 16,17 > 4,5. By changing the reaction conditions (solvents, catalysts, *etc.*), one can perform selective hydrogenation of a definite bond and obtain the target steroid with high molar radioactivity.^{118,120} This method seems to be the most versatile for radioactive labelling of steroids; this results in steroids with high molar radioactivities.^{130,133} The syntheses of 17 α -ethynyl-19-nor[9,11-³H]testosterone and 18-methyl-17 α -ethynyl-17 β -hydroxyl[14 α ,15 α -³H]estr-4-en-3-one are shown in Schemes 17 and 18.

These schemes provide illustrative examples of the potentialities of chemical approaches to the synthesis of complex labelled compounds which are very labile under conditions of treatment with gaseous tritium in the presence of catalysts. If biological studies require labelled saturated steroids, solid-phase hydrogenation is the method of choice. In this case, the molar activity of steroids increases owing to the isotope exchange (Table 23).¹²⁰

Selective hydrogenation is indispensable for the synthesis of labelled derivatives of natural steroids.^{22,129,134} As can be seen from Scheme 19, several tritium-labelled, biologically active progesterone analogues can be prepared from the same precursor (see Table 22).¹²⁹

18-Methyl-3-methoxy-[14 α ,15 α - ³ H]estra-1,3,5(10),8-tetraen-17 β -ol acetate	2.1	133

The selectivity of the process is achieved through the use of homogenous catalysts. Kinetic studies have shown that hydrogenation of the C(1)=C(2) bond occurs 1.5–2 times more easily than that of the C(3')=C(4') bond. However, reduction of the C(3')=C(4') bond is still the fast reaction, and after 1–1.5 h the reaction mixture did not contain even more stable 16 α ,17 α -[1,2-³H]cyclohex-3'-enopregn-4-ene-3,20-dione. Under optimum conditions (40 min), the reaction mixture contained 10%–15% of 16 α ,17 α -[3',4'-³H]cyclohexanopregna-1,4-diene-3,20-dione, 20%–25% of 16 α ,17 α -[1,2-³H]cyclohex-3'-enopregn-4-ene-3,20-dione {[³H]CHE} and 60%–70% of 16 α ,17 α -[1,2,3',4'-³H]cyclohexanopregn-4-ene-3,20-dione. Hydrogenation of the latter in the presence of heterogenous catalysts yielded two

additional labelled steroids, *viz.*, 5 α ,16 α ,17 α -[1,2,3,4'-³H]cyclohexanopregnane-3,20-dione and 5 β ,16 α ,17 α -[1,2,3',4'-³H]cyclohexanopregnane-3,20-dione.

The use of labelled reagents, *e.g.*, metal borotritides, has been mentioned above (see Table 19). Reactions with these reagents

and tritium-labelled methyl iodide and its derivatives afforded labelled steroids, such as [4-³H]- and [16-³H]cholesterols, 1 α ,3 β -dihydroxy-(20*S*)-[4-³H]-(3-hydroxy-3-methylbutyloxy)pregna-5,7-diene, 1 α ,25-dihydroxy-22-oxavitamin D₃ and some other compounds.^{3, 4, 118, 120, 135} The main disadvantage of this method is that the molar radioactivities of the resulting products depend on those of the labelled reagents, which are sometimes too low for conducting biological experiments. Presumably, syntheses of labelled preparations can be based on the use of non-labelled reagents and labelled steroidal precursors and reactions of condensation, oxidation, hydrolysis, acetylation or reduction.^{3, 136}

Several labelled 16 α ,17 α -cycloalkano- and 16 α ,17 α -cycloalkeno-substituted progesterones with different sizes of the additional ring *D'* were synthesised,^{22, 129} and their interactions with the progesterone receptor were studied for the first time in direct experiments. The steroid–receptor binding was studied using labelled 16 α ,17 α -cyclohexanopregn-4-ene-3,20-dione {[³H]CHA}, 16 α ,17 α -cyclopropanopregn-4-ene-3,20-dione {[³H]CPA} and proteins from the soluble fraction of rat uterus homogenates responsible for progesterone reception. The interaction of CPA and CHA with the progesterone receptor and other rat uterus proteins was assayed by cross-inhibitory analysis, which is based on the displacement of a labelled ligand from complexes of proteins with non-labelled steroids. The values of relative com-

Table 24. The values of relative competitive activity (RCA) of natural progesterone calculated from the displacement of labelled ligands from complexes with the progesterone receptor from the soluble fraction of pregnant rat uterus.

^a The progesterone activity was taken as unity.

petitive activity (RCA) were calculated from the concentration ratios of non-labelled compounds inducing 50% inhibition of specific binding of the labelled ligand (Table 24).

It was shown that a progesterone receptor in the soluble fraction of a rat uterus homogenate is a protein that specifically binds CHA and CPA and manifests almost identical parameters of competitive binding. The same regularity was observed with [³H]CHE. This compound binds by the protein which is identical with the progesterone receptor, no other specific binding species in the soluble fraction of rat uterus were detected. This conclusion was confirmed by analysis of CHE inhibitory effect on [³H]progesterone binding. During biological experiments, no metabolic conversions of labelled steroids occur. No significant differences were found in the mode of interaction of [³H]CHE and [³H]progesterone with a receptor isolated from the cells of different animals either. It is interesting to note that CHE as a representative of this class of steroids manifested higher activity in a pregnancy preservation test and a relatively low activity in an endometrium proliferation test upon systemic administration than progesterone.¹³⁷ These examples illustrate the possibility of the synthesis of steroid hormones with separated biological functions as regards progestagenic activity.

V. Conclusion

This review describes various methods for introducing tritium labels into biologically active compounds. Recent advances in radiochemistry have made it possible to solve numerous problems concerning the study of processes determining the vital activity of cells and the whole organism. There is no doubt, however, that further progress in medicine and biology will demand elaboration of novel and the development of existing methods of synthesis of labelled compounds. Studies on effects of micromodifications of molecules of various steroids are currently under way. These studies are necessary for the design of a new generation of medicinal drugs possessing strictly specific activity and having no adverse side effects.¹³⁸ New approaches to modification of oxylipins and polyenoic fatty acids are being developed in order to elucidate the relationship between the structure and function of these compounds, since the use of natural oxylipins as medicinal drugs is strongly restricted by the wide range of their pharmacological action and rapid metabolism.¹⁰⁶ The synthesis of some derivatives of polyunsaturated acids (e.g., dicarboxylic acids) required for the analysis of enzyme-substrate binding of mammalian 15-lipoxygenases has been carried out. This is important for continuing investigations in the field of gastroenterology, cardiology, angiology, oncology, etc.^{139,140} A vast variety of compounds (fungicides, immunodepressants, medicinal drugs influencing the central nervous system, pheromones, etc.), sometimes having an exotic structure, are being synthesised.¹⁴¹⁻¹⁴³

Considerable effort is devoted to a search for novel approaches to the synthesis of tritium-containing preparations. These investigations include an elaboration of original procedures for the synthesis of new catalysts and labelled reagents which

represent fragments of biologically active compounds or sources of radioactive labels, methods of enzymic synthesis of labelled oxylipins using organic solvents are being developed, etc.¹⁴⁴⁻¹⁴⁷ Thus data were obtained showing that enzymes functioning within micelles possess higher stability which increases the efficiency of synthesis of these labelled preparations.¹⁴⁸

Abstract. Physicochemical factors influencing the catalytic activities of hemoproteins (of cytochrome P450, in particular) that find use in biosensors and bioreactors are considered. The authors' data on the preparation of semisynthetic hemoproteins based on cytochrome P450 2B4 and NADPH-dependent cytochrome P450 reductase are presented. The use of alternative electron sources (electrochemical reduction and photoreduction) for the redox cycle of hemoproteins is discussed. The effects of temperature, pressure, chemical modification of proteins and organic solvents on the efficiency of hemoprotein-catalysed enzymic reactions are analysed. The bibliography includes 86 references.

I. Introduction

Cytochromes P450 are unique enzymes in that they are able to hydroxylate substrates with nonactivated C–H bonds. Cytochromes metabolise up to 200 000 compounds and catalyse about 60 types of chemical reactions, such as hydroxylation, N-, O- or S-demethylation, dealkylation, epoxidation, *etc.*¹ This feature of cytochromes P450 can be employed for quantification of medicinals and/or their metabolites and xenobiotics in different media as well as for stereodirected synthesis of steroids and other classes of biologically active compounds. The increase in the efficiency of catalysis by cytochromes P450 is a problem of considerable practical importance. The principles of bioelectrocatalysis have been discussed in detail.^{2,3}

The present review is devoted to the analysis of effects of various physicochemical factors on different stages of enzymic reactions with special emphasis on the advantages of alternative electron sources (electrochemical and photoreduction) over traditional reducing agents, such as NADH or NADPH. Reduction with the use of pyridine nucleotides is not a continuous process due to rapid exhaustion of NADH or NADPH. NADPH-

regenerating enzymes are normally introduced into a biochemical system to maintain the required concentration of reducing agents, which makes the system more complicated. The use of cathodic current instead of NADH or NADPH allows the reduction process to become more long-lasting and controllable by means of physicochemical factors, such as voltage and electric current. In the case of photoreduction, this process is monitored by recording the generated photocurrent and can be controlled by changing the excitation wavelength. The published data obtained in the past decade on cytochromes P450 are surveyed.

II. The use of electrochemical methods in the study of hemoproteins

1. The use of electrolysis for reduction of hemoproteins

Electron transport in biological systems normally occurs in the presence of electron donors (*e.g.*, NADH and NADPH) and an electron mediator, such as flavin nucleotides. In recent years, electrical systems are finding increasing use in the study of redox conversions of enzymes (of metalloenzymes, in particular).⁴ Electrons can be transferred to the electrode either directly, by electrochemical transport from the protein redox centre, or in the presence of mediator molecules.⁵ Different types of electrodes, such as graphite (glassy carbon, pyrolytic graphite), gold, platinum, semiconducting (indium oxide, tin oxide) and chemically modified graphite electrodes combined with redox catalysts (*e.g.*, rhodium catalysing oxygen reduction to hydrogen peroxide or water, metal complexes which efficiently mediate electron transport, *etc.*).^{6–8}

The electron transfer in enzyme systems containing cytochrome P450 occurs according to the scheme:

Here, NADPH is the electron donor and the microsomal flavo-protein (NADPH-dependent cytochrome P450 reductase) or a mitochondrial system consisting of a flavoprotein and a protein containing a Fe–S cluster is the electron carrier from NADPH to the hemoprotein (cytochrome P450).

The use of cathodic current instead of NADPH for electroreduction of flavins as mediators in oxygenase reactions has made it possible to obtain highly efficient electrochemical systems (Table 1).⁹ The hydroxylation of lauric acid in the presence of an

electrochemical system consisting of a gold or platinum electrode and a purified fused protein containing P450 4A1 and NADPH-dependent cytochrome P450 reductase has been studied.^{6, 9, 10} In addition to the fused protein, the electrochemical system contained a coordination compound of Co(III), *viz.*, [(S)-1,3,6,8,10,13,16,19-octaazabicyclo[6.6.6]eicosanocobalt(III)] as a mediator. The standard redox potential, *U*, of this compound is -350 mV (*vs.* standard hydrogen electrode). Presumably, the reduction of the Co(III) ion on the cathode occurs within the coordination compound according to the scheme: $\text{Co}^{3+} + e \rightarrow \text{Co}^{2+}$. If the electrolysis is carried out in a system containing only the flavoprotein (reductase) or a hemoprotein (cytochrome P450) no hydroxylation of lauric acid occurs, which suggests that the Co^{2+} ion plays the role of an activator. This reduces flavin nucleotides of the reductase, which, in turn, reduce the heme iron of cytochrome P450. Oxygen activation occurs on the reduced heme iron within the triple complex 'substrate- Fe^{2+} - O_2 '; in this case, the oxidation of various substrates under physiological conditions occurs at high rates.¹ Electrochemical reduction of the fusion protein generates hydrogen peroxide, which destroys the enzyme system. The addition of catalase increases the efficiency of the system in the hydroxylation reaction. It was shown that the highest rate of lauric acid hydroxylation is observed at -450 mV (*vs.* standard hydrogen electrode).^{6, 9, 10}

A semiartificial flavohemoprotein (flavocytochrome P450 2B4) possessing reductase and oxygenase activities was obtained earlier in our laboratory.^{11, 12} Using an electrochemical system consisting of flavocytochrome 2B4 or 1A2 and rhodium-graphite microelectrodes, we performed successful aniline *p*-hydroxylation, aminopyrine N-demethylation and 7-ethoxy- and 7-pentoxoresorufin O-dealkylation. The reduction was carried out at *U* = -450 mV (*vs.* AgCl electrode).¹³ The catalytic constants of NADPH-dependent and electrochemical reactions catalysed by flavocytochromes 1A2 and 2B4 were comparable.

Several factors have plagued direct electron transfer between electrodes and proteins. These include: (i) electroactive prosthetic groups deep within the protein structure, (ii) adsorptive denaturation of proteins onto electrodes, and (iii) unfavourable orientations at electrodes. Remarkable recent progress provides several strategies for achieving direct electron exchange between electrodes and proteins.

Immobilisation of enzymes on the electrode surface is used to increase the efficiency of the electron transfer from the electrode to the electroactive prosthetic group of the protein¹⁴⁻¹⁶ by means of adsorption, covalent binding and incorporation of enzymes into polymeric films coating the electrodes. For example, positively charged proteins are immobilised by adsorption on electrodes of pyrolytic graphite containing negatively charged carboxy groups, whereas immobilisation of hemoproteins on graphite electrodes involves covalent binding in the presence of a cross-linking bifunctional reagent (glutaraldehyde) and albumin.¹⁷ In the latter case, albumin is strongly adsorbed on the surface of graphite electrodes, while glutaraldehyde cross-links the redox protein with

albumin through the amino groups thereby binding the former to the electrode.

Yet another approach consists of the use of promoter molecules which favour the electron transport through proper orientation of the proteins on the electrode, which thus blocks their adsorptive denaturation. The role of promoters can be played by alkanethiols containing terminal functional groups (*e.g.*, mercaptoundecanoic acid).¹⁸ The chemisorption of mercaptoundecanoic acid on the surface of gold electrodes is accompanied by the formation of a stable monolayer, which facilitates subsequent binding (both covalent and ionic) of proteins to the electrode surface.

Double-stranded DNA, which is strongly adsorbed on electrodes of pyrolytic graphite, can also be used as a promoter molecule.¹⁹ Such DNA-containing electrodes can readily extract hemoproteins from the solution.

The rate of the electron transfer from the electrode to the redox protein, can be increased if the electrodes containing covalently bound or adsorbed electron transport mediators, such as riboflavin or methylviologen, are chemically modified;^{20, 21} the stability of hemoproteins in electrochemical systems is increased if they are incorporated into phospholipid films which coat the electrodes.²²⁻²⁴ Surfactants containing charged or polar head groups and a hydrophobic tail (didodecyldimethylammonium bromide, polystyrenesulfonate, dihexadecyl phosphate, dimyristoylphosphatidylcholine) are used as films mimicking natural biomembranes.

It is of note that electrochemical processes involving redox proteins are reversible only in liquid-crystalline films.²² If cytochrome P450_{cam} is incorporated into liquid-crystalline films formed by dimyristoyl-L- α -phosphatidylcholine or didodecyldimethylammonium bromide, direct reversible electron transfer occurs from the electrode to the heme iron of the enzyme as is judged by direct current cyclic voltammograms.²²⁻²⁴ Thus myoglobin reduction in liquid-crystalline didodecyldimethyldiammonium bromide films coating the pyrolytic graphite electrodes is reversible in contrast with its reduction on electrodes without biomembrane-like surfactant films.²⁴ On addition of a substrate (*e.g.*, trichloroacetic acid), this is reduced, as follows from the increase in the cathodic current. The incorporation of cytochrome P450_{cam} into DNA films adsorbed onto gold electrodes has made it possible to perform direct reduction of the heme iron and catalytic epoxidation of styrene.²⁵

Electrochemical reduction of metmyoglobin ($\text{X-MbFe}^{\text{III}}$), which is a perfect functional model of cytochrome P450 (the catalytic activity of myoglobin is close to that of cytochrome P450), was studied by Onuoha *et al.*²⁴ The electroreduction was carried out on electrodes of pyrolytic graphite at the potential, *U* = -400 mV (*vs.* SCE) in aqueous buffers or microemulsions of

hydrocarbons, water and cationic detergents. Under these conditions metmyoglobin is reduced on the electrode [Scheme 1, reaction (1)]. The reduced metmyoglobin rapidly reacts with oxygen to yield an $X-MbFe^{II}-O_2$ complex, which is reduced with the liberation of hydrogen peroxide on the electrode. The hydrogen peroxide evolved effects stepwise oxidation of metmyoglobin ($X-MbFe^{III}$) to ferrylmyoglobin ($HX-MbFe^{IV}=O_2$), an active oxidised form of myoglobin [Scheme 1, reactions (4) and (5)].

Scheme 1

where X is an amino acid residue, *e.g.*, tyrosine-130. Styrene added to the reaction system is oxidised by hydrogen peroxide to give styrene oxide and benzaldehyde.

The efficiency of electrolysis used for the reduction of hemoproteins is comparable with the traditional reduction with pyridine nucleotides. The results obtained in the study of electrochemical and NADPH-dependent reactions of several isoforms of cytochrome P450 are presented in Table 1.

At present, attempts are being undertaken aimed at designing cytochrome P450-containing bioreactors and biosensors based on electrochemical systems.^{9, 22, 26}

2. The use of inorganic semiconductors in redox systems

The effectiveness of inorganic semiconductors (TiO_2 , ZnO , CdS) in combination with enzymes (hydrogenases, dehydrogenases) in photoproduction of hydrogen, photoreduction of $NADP^+$ and photosynthesis of organic acids and amino acids has been demonstrated in a number of studies.^{27–31} The system 'inorganic semiconductor–enzyme' can transform light energy by semiconductor-photosensitised oxidation of organic electron donors and by enzyme-catalysed reduction of substrates (H^+ , $NADP^+$, organic acids and amino acids) with electrons photogenerated in the semiconductor. Coupling of an inorganic semiconductor with an enzyme is usually attained with the help of electron carriers (mediators), *e.g.*, methylviologen, a rhodium bipyridyl complex and other compounds subject to reversible oxidation–reduction. Direct mediator-free transfer of electrons photogenerated in the conduction band of the semiconductor to the enzyme reaction centre has been described by Nikandrov *et al.*²⁸ A prerequisite for the conjugate effect of a semiconductor and an enzyme in the absence of an electron carrier is the sorption of the enzyme on the semiconductor surface.

3. The construction of an enzymic 'galvanic couple' for redox reactions

The operating principle of a galvanic element is based on the difference in the electrode potentials of the oxidant and the reducing agent. Active metals (*e.g.*, zinc) are most commonly used as reducing agents, while hemoproteins are used as oxidants. Normally, hemoproteins have a more positive standard electrode potential than zinc [$E_0(Zn^0/Zn^{2+}) = -763$ mV]; therefore zinc serves as a reducing agent in a zinc–hemoprotein couple. We used metallic zinc as an electron donor and a hemin–human serum albumin complex as an artificial hemoprotein and succeeded in effecting N-demethylation of aromatic amines.³² The rates of these reactions were comparable with those of NADH-dependent reactions carried out in the presence of flavin nucleotides or riboflavin as electron transfer mediators.

Metallic cadmium [$E_0(Cd^0/Cd^{2+}) = -403$ mV, $E_0(NAD^+/NADH) = -340$ mV] was used as a reducing agent in a system

containing NAD^+ -dehydrogenase.³³ In this case, too, the 'galvanic couple' principle is realised.

III. Photoinduced electron transport

Light energy is utilised not only in traditional photosynthetic reactions or in photoinduction of semiconductors, it also triggers electron transport in redox systems. Direct photoreduction of hemoproteins in the absence of electron donors has been described by Gu *et al.*³⁴ Metmyoglobin, cytochromes *c* and *b₅* and heme complexes with octapeptides and cytochrome P450 were photo-reduced upon laser irradiation at wavelengths of 430–254 nm. UV irradiation resulted in photooxidation. This study has shown that the heme ligands play a crucial role in photoreduction. The photoreduction products were characterised by UV and visible absorption spectra and Raman spectra and compared with the products formed upon chemical reduction.

Heme photoreduction in hemoproteins can be utilised for 'triggering' redox reactions, such as oxygen activation by cytochrome P450 or binding of ligands (*e.g.*, O_2) with myoglobin or hemoglobin. Studies of model complexes (hemin–octapeptides) corroborated the viewpoint that aromatic amino acids are not the primary electron donors, since the model peptides were devoid of aromatic amino acid residues. In the presence of organic solvents (glycerol and other alcohols), the rate of photoreduction increased.³⁴ Irradiation with a nonfocused laser ($\lambda = 457.9$ nm, power 40 mV) of a 'riboflavin–hemin–albumin' complex resulted in riboflavin photoreduction as could be evidenced from changes in the absorption spectrum of the complex. Amine demethylation and aniline hydroxylation products were formed in the presence of *N*-substituted amines or aniline; the rate constants (k_{cat}) for dimethylaniline N-demethylation and aniline hydroxylation are equal to 0.5 min^{-1} and 0.13 min^{-1} , respectively, *i.e.*, they are comparable with those of NADPH-dependent reactions.³²

The photooxidation of the reduced flavocytochrome b_2^+ from *Saccharomyces cerevisiae* (lactate dehydrogenase) upon irradiation with a laser ($\lambda = 400$ nm) has been described by Hazzard *et al.*³⁵ At this wavelength, the oxidised form of 5-deazariboflavin passes into an excited triplet state; it is this state that is involved in the oxidation of the reduced heme. The rate of intermolecular electron transport was 2200 s^{-1} .

A series of investigations^{36–40} have been devoted to the study of electron transport in hemoproteins (in cytochromes *c* and *b₅*, in particular) modified with ruthenium or cobalt complexes. A characteristic feature of ruthenium complexes is their ability to undergo reversible photoreduction and to transfer electrons to other acceptors. Thus a ruthenium complex covalently bound to cysteine-65 of cytochrome *b₅* effected rapid reduction of cytochrome *c* according to the scheme.³⁶

The electron transfer in these systems was studied in direct photoreduction of ruthenium complexes and using a flash-photolysis technique. The photoreduction of the flavoprotein cytochrome P450 reductase in the presence of electron acceptors (ferricyanide, Tetrazolium Nitro Blue) could be carried out in the absence of NADPH.⁴⁰

† Reduced flavocytochrome was obtained by titration of the oxidised enzyme with a 1.5-fold excess of L-lactate.

Thus, photoinduced electron transport can serve as an alternative source of electrons in redox reactions provided the proteins contain photosensitive prosthetic groups or their analogues.

IV. Changes in the microenvironment of the protein and its active centre

1. Modelling of the membrane environment

The environment, especially the cell membrane, strongly influences the enzyme activity in living organisms. The construction of an artificial membrane-like environment may significantly enhance the enzyme activity. Among various synthetic membranes studied, synthetic membrane-like phospholipid bilayers were shown to possess an activating effect.⁴¹ Cytochrome *c* incorporated into such membranes increases the rate of H₂O₂-induced *N,N*-dimethylaniline *N*-demethylation 10.6-fold. A 20-fold decrease in the Michaelis constant for H₂O₂ is observed, which suggests increased affinity of the enzyme towards hydrogen peroxide. Changes in the spectral characteristics of cytochrome *c* incorporated into the phospholipid bilayer suggest significant structural and functional changes. The oxidised form of the protein is characterised by a short-wave shift of the optical density maximum (from 408 to 406 nm) upon incorporation, the absorption maximum of the reduced form is shifted from 416 to 426 nm and one maximum at 550 nm is observed instead of two maxima at 520 and 550 nm.

The incorporation of myoglobin into membrane-like films results in a decrease in the activation energy of electrochemical reduction of dibromoethylene and trichloroacetic acid, the rate of electron transport increases 1000-fold.¹⁶ Acetylcholinesterase, cholinesterase and horseradish peroxidase incorporated into polymeric films prepared from polyvinylpyridine and polyethylene glycol can be used as amperometric sensors for detecting acetylcholine, choline and hydrogen peroxide.⁸

2. Enzymatic catalysis in reversed micelles and organic solvents

Many properties of biological membranes are efficiently mimicked by reversed micelles of surfactants in organic solvents, which can be regarded as biomembrane models.

In 1977, Martinek *et al.*⁴² showed that enzymes solubilised in organic solvents with the aid of reversed micelles of synthetic surfactants retain their catalytic activities. Some hemoproteins, *e.g.*, cytochrome *c* and methemoglobin, induce the formation of reversed micelles by incorporating into bilayer membranes with simultaneous preservation of their enzymic activities.^{43–45} Horseradish peroxidase solubilised in a sodium diisooctyl sulfosuccinate–water–octane system catalyses pyrogallol oxidation by hydrogen peroxide much more efficiently than the water-soluble enzyme.⁴⁶

Efficient catalysis of redox reactions by hemoproteins incorporated into reversed micelles of surfactants was used for increasing the operational stability of catalase, superoxide dismutase and glutathione peroxidase.⁴⁷ Systems mimicking hemoproteins (albumin–hemin complexes and ferritin) were also incorporated into reversed micelles.⁴⁸

Cytochrome P450 1B1 and cytochrome P450 reductase as a fusion protein was incorporated into oil-in-water macroemulsion, termed polyaphron, (the internal organic phase content was more than 0.74). The efficiency of such immobilisation exceeded 85%; the enzyme preparation remained active towards substrates (erythromycin, chlorotolurone) for 24 h at 15 °C.⁴⁹

In order to decrease the water content in colloidal media, the substitution of a water-organic mixture for the water surrounding the enzyme in reversed micelles of surfactants was suggested.⁵⁰ The hemoglobin-catalysed oxidation of dibenzothiophene in various water-organic mixtures was studied by Klyachko and Klivanov.⁵¹ The preparation of suspensions of lyophilised enzymes in organic solvents is an alternative procedure for

excluding water. The enzymes suspended in organic solvents acquire new properties, which affects virtually all the aspects of their functioning, *viz.*, catalytic activity, substrate specificity, stereoselectivity, thermal stability, *etc.*^{52, 53}

In addition to ordinary enzymic reactions, the reactions nonspecific for enzyme behaviour in aqueous media may occur either in nonaqueous organic solvents or in organic solvents with the H₂O content of 0.01 vol.%. The reasons for the alteration of the substrate specificities are different for individual enzymes. Nevertheless, enzymatic catalysis in organic solvents obeys the Michaelis–Menten kinetics, which suggests the formation of a classical enzyme–substrate complex in nonaqueous solutions.

The phenomenon of ‘enzyme memory’ has been discovered in experiments with enzyme suspensions in organic solvents. An enzyme lyophilised from an aqueous solution containing a specific ligand and then suspended in an organic solvent binds the ligand several tens of times more efficiently. This property disappears after repeated dissolution in water. A possible explanation of this phenomenon is that the enzyme retains an ‘imprint’ of the ligand even after its removal upon lyophilisation. In nonaqueous media where the conformation of the protein molecule becomes more rigid, the enzyme manifests higher affinity for the ligand.^{54, 55} The ability of enzymes to retain the ‘imprints’ of ligands has a certain practical significance for the synthesis of chiral pharmacologically useful intermediates.

The effects of organic solvents on the properties of cytochrome P450 have been studied to a lesser degree. It was found that organic solvents favour the transition of cytochrome P450 into the inactive form, P420.⁵⁶ This transition is due to the changes in the nearest coordination sphere (sulfur atoms) around the iron atom. A similar transition is observed in the case of chloroperoxidase.⁵⁶ However, cytochrome *c* suspended in tetrahydrofuran containing 1% D₂O fully preserves its tertiary structure.⁵⁷ These conclusions were made on the basis of analysis of the tertiary structure of cytochrome *c* by two-dimensional NMR spectroscopy.

V. Chemical modification of proteins for triggering new catalytic functions

This section considers the methods used for enhancement of the enzymatic activity by introducing new catalytically active groups into the enzyme molecule.

Thus cytochrome P450 manifests monooxygenase activity only within a complex with the flavoprotein reductase. Here flavin nucleotides represent electron carriers which reduce the heme iron of cytochrome P450. The introduction of flavin nucleotides or their analogues into cytochrome P450 converts the latter into a self-competent enzyme which does not require the involvement of partner proteins in the catalytic cycle.

Semisynthetic flavohemoglobin was prepared by attachment of activated flavin derivatives⁵⁸ to the β -subunit of hemoglobin used in a 2:1 ratio.^{59, 60} Hemoglobin catalyses monooxygenase reactions occurring in a system containing a hemoprotein, oxygen, NADPH and a flavoprotein (NADPH-dependent cytochrome P450 reductase). Covalent binding of flavin to hemoglobin makes it possible to conduct similar reactions in the absence of reductase. The rates of the catalytic reaction of aniline hydroxylation in the presence of flavohemoglobin and the microsomal monooxygenase system are comparable. The rate of aniline hydroxylation in the presence of semisynthetic flavohemoglobin increased in comparison with hydroxylation rates in the presence of hemoglobin and the hemoglobin–reductase system (7.7- and 1.3-fold, respectively).

The catalytic activity of the covalent complexes ‘cytochrome P450–flavin adenine dinucleotide’ (FAD) and ‘cytochrome P450–flavin mononucleotide’ (FMN) has been studied by Uvarov *et al.*⁶¹ The complex in which cytochrome P450 is covalently bound to FMN (1:3) turned out to be more active. The catalytic rate constants for dimethylaniline and aminopyrine

N-demethylation and aniline hydroxylation were about 2 times lower than those of the analogous reactions catalysed by microsomes, which represent natural complexes of cytochrome P450 and reductase. The rates of reactions catalysed by covalent and noncovalent P450–FAD complexes are 10 times lower than those of microsome-catalysed reactions.

A monomolecular monooxygenase system formed by covalent binding of the electron-accepting antibiotic bleomycin to a flavoprotein (NADPH-dependent cytochrome P450 reductase) has been described by the same authors.⁶¹ The rates of reactions involving the reductase–bleomycin complex are 10 times lower than those of microsome-catalysed reactions.

Reductase does not possess its own catalytic activity in monooxygenase reactions; however, after incorporation of 1 to 10 heme residues into the reductase molecule the semi-artificial hemoreductase manifested activity in NADPH-dependent N-demethylation of amidopyrine ($k_{\text{cat}} = 0.7 \text{ min}^{-1}$). The k_{cat} values for the analogous reactions catalysed by the microsomal monooxygenase system and the semi-artificial flavocytochrome 2B4 are 2.4 and 0.98 min^{-1} , respectively.^{11,12} A semi-artificial hemoreductase⁶² which represents a covalent complex of heme and NADPH-dependent cytochrome P450 reductase manifested reductase activity with respect to electron acceptors, such as potassium ferricyanide, cytochrome *c* and hemein.

The covalent binding of flavodoxin to ferredoxin–NADP⁺ reductase⁶³ (1:1) gave an artificial enzyme which catalyses the reduction of cytochrome *c* with high efficiency. The transfer of electrons in this system occurs according to the same scheme as in NADPH-dependent cytochrome P450 reductase.

Ferredoxin–NADP⁺ reductase modified with viologen in the presence of carbodiimide manifests oxidase activity, which is absent in the native enzyme.⁶⁴ In the absence of ferredoxin, the reductase does not reduce cytochrome *c*, whereas the modified enzyme displays high activity. In the presence of electron acceptors such as 2,6-dichloroindophenol and ferricyanide, the activity of the modified enzyme decreases twofold, whereas the rate of the cytochrome *c* reductase reactions increases 30-fold. The scheme of electron transport in a system with the nature enzyme appears as:

When the reactions are carried out in the presence of superoxide dismutase, the viologen–reductase systems utilise the oxygen molecule reduced to the superoxide radical anion as the final electron acceptor. It is the presence of active oxygen species that accounts for the appearance of oxidase activity in the modified enzyme. Titration of the reduced viologen–reductase system revealed that the electron transfer to viologen occurs through the flavin group of FAD present in the reductase. The standard electrode potential of viologen covalently bound to ferredoxin–NADP⁺ reductase is -365 mV , while that of soluble viologen is -420 mV . The electrode potentials of other reaction participants are -320 mV (NADPH), -344 mV (reductase) and -420 mV (ferredoxin). The electrochemical preparation of NADPH using the native enzyme requires an electron donor capable of reduction of ferredoxin, since in this case the scheme of electron transport appears as:

The electric current generated by the electrochemical system ‘viologen–reductase’ in the presence of NADP⁺ points to the electron transfer between the electrodes and the system. The latter can therefore be used for regeneration of NADPH.

Ferrocene and its derivatives are known to be efficient electron carriers. Modification of glucose oxidase (GOx) with ferrocene-carboxylic acids (FCA) has been described by Badia *et al.*⁶⁵ Covalent derivatisation of the GOx molecule containing two

FAD molecules with additional electron carrier groups imparts the ability to be involved in the electrochemical reaction. The optimum number of FCA groups is 13 residues per GOx molecule. In native glucose oxidase, reduced FADH₂ is oxidised with atmospheric oxygen, whereas the role of oxygen in ferroceneglucose oxidase is played by FCA responsible for ‘internal’ electron transport. Ferroceneglucose oxidase undergoes electrochemical conversions on the electrodes according to the scheme:

The arrangement of bound FCA residues relative to the FAD molecule is more important for electron transport than their number. The electrode potential of the FADH₂/FADH[•] couple is -219 mV , that of the FCA⁺/FCA couple is $+773 \text{ mV}$. Hence, the motive force of the electron transport in the given system is about 1 V.

Modification of cytochrome P450_{cam} and β-lactamase with a new electron-active reagent, *N*-(2-ferrocenylethyl)maleimide, was described by Gleria *et al.*^{66–68} who showed that modified enzymes are electrochemically active. These authors suggest using *N*-(2-ferrocenylethyl)maleimide as a promising reagent for the conversion of electropassive enzymes into electroactive ones as well as for the design of electrochemical sensors and for studies of mechanisms of intraprotein electron transport.

The covalent binding of glutathione reductase to the photosensitive dye eosin (1:2) was used to obtain a photoactivated system which can be used for glutathione reduction.⁶⁹ Eosin-modified glutathione reductase retains 50% of activity of the native enzyme in a NADPH-dependent reaction. However, the photosystem thus obtained was 1000 times less active in glutathione reduction than the glutathione reductase with NADPH as the electron source.

VI. Effect of temperature on hemoprotein-catalysed reactions

Studies of reactions catalysed by cytochrome P450 2B4 have shown that an increase in temperature causes an increase in the rate of substrate hydroxylation. For example, with a rise in temperature from 20 to 37 °C, the catalytic constant, k_{cat} , for peroxide-dependent O-dealkylation of *p*-nitroanisole increases twofold.⁷⁰

The catalytic cycle of cytochrome P450 is rather complex and comprises at least seven steps.^{1,71} The effect of temperature on the binding of various substrates (*e.g.*, benzphetamine) to cytochrome P450 and on the spin equilibrium between low- and high-spin forms of the hemoprotein was studied in most detail. It was shown⁷² that a change in temperature from 12 to 27 °C has no effect on the absorption spectra of cytochrome P450 2B4. The spectra are not changed after addition of benzphetamine ($0.8 \text{ mol litre}^{-1}$) either. The dissociation constants (K_d) and concentration $[\text{ES}]_{\text{max}}$ of enzyme–substrate complexes show the following temperature dependence:

Temperature / °C	$K_d / \mu\text{mol litre}^{-1}$	$[\text{ES}]_{\text{max}} / \mu\text{mol litre}^{-1}$
13.8	189 ± 5	0.085 ± 0.002
23.8	86 ± 5	0.087 ± 0.004

As can be seen, the concentration of enzyme–substrate complexes is practically constant at different temperatures. However, the use of the ‘temperature jump’ technique, which consists of instantaneous increase in the temperature in the reaction cell upon high-power electric discharge revealed enhanced binding of the substrate to the enzyme.⁷²

The substrate-induced spin equilibrium obeys a bimolecular mechanism:

where l.s. and h.s. are the concentrations of the low-spin and high-spin forms of the enzyme, respectively. The catalytic constant of this reaction can be written as:

$$k_{\text{cat}} = \frac{1}{\tau_f} = k_1([E]_{\text{eq}} + [S]_{\text{eq}}) + k_{-1},$$

where τ_f is the fast relaxation time, *i.e.*, the time during which the system passes into a new state and $[E]_{\text{eq}}$ and $[S]_{\text{eq}}$ are the equilibrium concentrations of the enzyme and the substrate, respectively. In the absence of the substrate, the relaxation does not occur, which is consistent with the experimental data concerning the effect of temperature on the absorption spectra of cytochrome P450 not bound to the substrate.

A study of temperature-dependent electrochemical reduction of the fusion protein[‡] (within the temperature range of 4–36 °C) revealed that the rate of reduction is a maximum at 22 °C.⁶ The reason should be sought in the simultaneous occurrence of several parallel reactions in electrochemical systems that are differently affected by temperature.

VII. Effect of high pressure on the catalytic activity of hemoproteins

The effect of high pressure on the kinetics and dynamics of conformational conversions of proteins has been studied by Morild.⁷³ High pressures are used for shifting chemical and biochemical equilibria as well as for changing the rates of individual steps of enzymatic reactions.

The changes in the reaction and activation (ΔV^* and ΔV^{**}) volumes calculated from the experimental data on the effect of high pressure can be utilised in the study of molecular mechanisms of different enzymes and their transition states during the formation of new bonds. If ΔV^* and ΔV^{**} values are negative, an increase in pressure will shift the equilibrium towards the formation of enzymatic reaction products in accordance with the Le Châtelier principle.^{74, 75}

The effect of high pressure on bacterial camphor-metabolising cytochrome P450_{cam} was extensively studied by several authors.^{76–79} It was found that the pressure affects the equilibrium between low-spin and high-spin states. An increase in pressure to 2.2 kbar induces the transition of cytochrome P450_{cam} into the inactive form, P420. Chloroperoxidase is also converted into C420 at high pressure.⁷⁵ The effect of high pressure on the redox potential of cytochrome *c* was studied by Tschirret-Guth *et al.*⁸⁰ By measuring changes in the standard potential (E^0) as the function of pressure (P), one can calculate the reaction volume, ΔV^0 :

$$\left(\frac{\partial E^0}{\partial P}\right)_T = \frac{\Delta V^0}{nF},$$

where F is the Faraday constant, $\Delta V^0 = \sum V_p^0 - \sum V_r^0$ ($\sum V_p^0$ and $\sum V_r^0$ are the sums of standard molar volumes of the products and reactants, respectively). As the pressure is increased, the reaction accompanied by a decrease in the molar volume will be preferred. In the case of a redox process, this will induce a positive shift of the redox potential. According to Tschirret-Guth *et al.*,⁸⁰ the increase in pressure to 5 kbar results in the changes of the potential from –5 mV to +76 mV; the molar volume also changes upon transition from the oxidised to the reduced form of cytochrome *c*:

$$V[\text{cyt } c(\text{Fe}^{2+})] - V[\text{cyt } c(\text{Fe}^{3+})] = -24 \text{ ml mol}^{-1}.$$

These findings are consistent with the results of structural and physicochemical studies, *viz.*, ferrocycytochrome *c* has a more compact structure than ferricytochrome *c*. By changing the pressure on the enzymic system, one can shift the chemical

equilibrium in redox hemoproteins towards the formation of the reduced form.

VIII. Conclusion

Most enzymes, including hemoproteins, are rather sensitive to physical and chemical influences which can induce complete or partial loss of their activities. This necessitates the design of artificial enzymes based on proteins with higher resistance to such influences. In some studies, artificial hemoproteins were prepared as a result of the formation of noncovalent specific complexes of hemin^{32, 81} or its analogues (cobalt octaethylbis-porphyrinate, cobalt octapyridinemethylphthalocyanine and lute-cium diphthalocyanine)⁸² with human or bovine serum albumin and synthetic peptides.^{83, 84} These complexes manifest oxygenase-like catalytic activity in aminopyrine N-demethylation and aniline hydroxylation. Yet another trend, *viz.*, the design and *de novo* synthesis of artificial proteins with predetermined structure and functional properties by gene engineering methods is also in progress.^{85, 86}

This review summarises the data on targeted action of various physicochemical factors on individual steps of enzymic reactions catalysed by hemoproteins. A rational combination of physicochemical approaches to the study of natural, semi-artificial and artificial enzymic systems can be useful in the design of new effective biosensors, test systems and bioreactors.

VIII. Conclusion	904

Abstract. Published data on the functionalisation of fullerenes (mainly, C_{60}) including those using addition reactions (cyclo addition, hydrogenation, oxidation, etc.) are surveyed. The participation of fullerenes in catalysis and fullerene-containing polymers are considered and the prospects for the practical use of fullerene derivatives are discussed. The bibliography includes 191 references.

I. Introduction

Synthesis of polyhedral carbon clusters, fullerenes C_{60} , C_{70} and so on,¹ from hot carbon plasma has initiated and triggered vigorous development of a new line of research in the chemistry of cage compounds, namely, study of the reactivity of fullerenes. In 1996, Kroto, Curl and Smalley were awarded the Nobel Prize in chemistry for the discovery of fullerenes, a new allotropic modification of carbon. In this respect, it is pertinent to consider the essence of this discovery, the history of which is presented in detail in the Nobel lectures of the authors.^{2–4}

A necessary condition of the success was the original apparatus designed by Smalley for the preparation and investigation of clusters formed on heating of high-melting compounds. This was a supersonic source of cluster beams with laser vaporisation. In this setup, a slowly rotating graphite disc was exposed to the radiation of a pulsed laser. The carbon vapour was treated with a helium flow in the supersonic flash regime and cooled to a temperature of several Kelvins by adiabatic expansion. The cluster beams were directed into a time-of-flight mass spectrometer with photoionisation of the molecular beam.

By varying the conditions of clustering and the time of cooling, the researchers attained the predominance of the stable C_{60} cluster in the mixture. The researchers^{2–4} proposed and substantiated the structure of C_{60} fullerene as a spherical hollow molecule shaped like a truncated icosahedron (Fig. 1). To verify the presence of a cavity inside the C_{60} spheroid, the graphite disc of

the setup was impregnated with an aqueous solution of lanthanum chloride; in this case, laser vaporisation gave a stable complex with the metal located inside the fullerene cage.

Figure 1. C_{60} fullerene (see Ref. 3).

Calculations for the C_{60} molecule, which gave rise to the suggestion that this molecule should be stable, had been performed^{5,6} fifteen years ahead of the experiments of Smalley *et al.*¹ (according to Kroto's assertion,³ they were not acquainted with these data).

Vigorous development of the physics and chemistry of fullerene became possible only when Krätschmer, Lamb, Fostiropoulos and Huffman⁷ had developed a method for the preparation of macroscopic quantities of fullerenes. The fact that fullerenes are formed during vaporisation of graphite electrodes in an electric arc in a helium atmosphere, discovered by these investigators, served as the basis for this method. The researchers⁷ prepared and studied crystals of the C_{60} cluster.

The development of the preparative-scale method for the synthesis of fullerenes brought about an avalanche-like increase in the number of publications devoted to this topic. Osawa, who had predicted the stability of icosahedral fullerenes in 1970,⁵ composed a computer database (fullerene literature data base, FLDB), based on reprinting from *Current Contents*.⁸

The journal *Fullerene Science and Technology* was founded in 1993, the to-be Nobel Prize winners being among its editors.

Reviews on fullerenes are published routinely (see, for example Refs 9–17). A widely cited monograph by Hirsch¹⁸ on fullerene chemistry appeared in Germany in 1994 (a year later it was re-edited in the USA).

In the present review, we cover the most important recent achievements in the functionalisation of fullerenes, mainly C_{60}

fullerene, and new prospects for the use of fullerenes including participation in polymerisation and in catalysis.

II. General aspects, synthesis and separation

Fullerenes constitute a subclass of polyhedranes, closed cage structures consisting of tricoordinated carbon atoms and having 12 pentagonal and $n/2 - 10$ hexagonal faces ($n \geq 20$), each pentagon adjoining only hexagons.

The nomenclature and atom numbering in fullerene systems were proposed in 1993 by Taylor.¹⁹ In 1995 Diederich *et al.*²⁰ introduced a system of numbering for chiral fullerene derivatives. The chemical and electronic structures of fullerene have been considered comprehensively in the report by Sokolov and Stankevich.⁹ An algorithm for the bond designation based on the spiral pattern of numbering generally accepted for fullerene derivatives⁹ has been proposed;²¹ it permits unambiguous assignment of the [6-6] and [5-6] bonds in addition products (compatible with the rules proposed in another publication²⁰). In 1997, the Commission on Nomenclature of the IUPAC, having Taylor as a member, accepted a terminology and a tentative nomenclature of fullerenes (see Refs 22 and 23 and the Atlas of Fullerenes²⁴).

A system of numbering for fullerenes based on the Schlegel diagrams⁹ (Fig. 2) is described in detail in a special appendix to a study by Wudl *et al.*²² In this review, we mainly adhere to the nomenclature used in the publications cited.

Carbon clusters, *i.e.* chains of carbon atoms, were discovered by astrophysicists in the spectra of some extraterrestrial objects (carbon stars, comet tails and interstellar dust),²⁵ but the hypothesis that these include C_{60} , C_{70} or C_{60}^+ clusters has not been confirmed.² Corannulene $C_{20}H_{10}$, a possible hydrocarbon precursor of C_{60} , which could be formed upon condensation of corannulene with carbon vapour, has been detected in meteorites.²⁶

Natural fullerenes have been found in some minerals. The $C_{70}:C_{60}$ ratio in them varies from 0.21 to 0.36.²⁵ Fullerenes are assumed to favour migration and accumulation of some elements, in particular, they presumably influence the formation of diamond deposits.²⁵ Kinetic measurements and mathematical simulation of the fullerene synthesis in an arc reactor led researchers to the conclusion^{27,28} that the $C_{60}:C_{70}$ ratio remains invariant over a broad range of the arc process parameters and amounts to $\sim 85:15$.

One of the preparative methods for the synthesis of higher fullerenes (up to C_{108}) is combustion of benzene in a mixture of oxygen and argon.²⁹ To increase the yield of higher fullerenes in

the arc synthesis, carbon electrodes are doped with hafnium, zirconium or titanium.³⁰ The lower limit of the temperature of fullerene formation is 1200–1500 °C. Recently, a pyrogenetic process for the production of fullerene soot has been developed.³¹ According to this method, a hot mixture of H_2 and a carbon-containing compound is fed through a nozzle into a water-cooled spherical reactor; the best results are attained with C_2Cl_4 as the carbon precursor. At the outlet of the nozzle, plasma is formed. The yield is 0.2 g of fullerenes per kV, which corresponds to the conversion of 2.1% of the carbon from the C_2Cl_4 introduced. The $C_{60}:C_{70}$ ratio depends on the cooling conditions.

Several mechanisms have been proposed for the formation of fullerenes from the precursor nuclei. Thus it has been assumed³² that the first stage of this process is a gas–liquid transition in the expanding flow of supersaturated carbon vapour and this is followed by the formation of small clusters with a dendrite³² or corannulene (curled sheet) structure.³³ It has been found³⁴ that on heating, pure C_{60} crystals are transformed into amorphous carbon. Based on this finding, the researchers conclude that the C_{60} liquid phase, described previously, does not actually exist.

Mixtures of C_{60} with 5%–15% of C_{70} are often used for the functionalisation of C_{60} because C_{70} usually does not enter into reactions. However, in some cases, especially in the measurements of physical characteristics of processes, it is required that C_{60} should have a purity of $\geq 99\%$. Nowadays, C_{60} and C_{70} are normally separated by HPLC, which sharply increases the cost of the product; therefore, the interest in the optimisation of methods for fullerene isolation does not abate. The sorbents currently used for this purpose consist of polyaromatic compounds, π -acids, porphyrins and phthalocyanines immobilised on silica gel.³⁵ The commercially available Buckyclutcher, which is 3,3,3-tris(dinitrobenzene)propyl silica gel, is commonly used. The use of tetraphenylporphyrin immobilised on silica gel ensures the preparation of C_{60} with 98.5% purity and C_{70} with a $> 99\%$ purity for a 5-mg batch.³⁶ Preparative quantities of C_{60} and C_{70} have been successfully separated using the chromotropic acid tetramer with formaldehyde bound to γ -aminopropyl silica gel as the sorbent.³⁵ A sorbent based on Al(X) tetraphenylporphyrin fixed on hydroxydimethylsilyl silica gel has been proposed for the separation of large amounts of fullerenes.³⁷

Recently it has been found³⁸ that the solubility of C_{60} exhibits an abnormal temperature dependence: the maximum of the fullerene solubility in toluene and carbon disulfide falls down to 0 °C, and that in *o*-xylene is observed at 30 °C. In the case of C_{70} , the temperature variation of the solubility follows a standard pattern. This fact might prove useful for the separation of mixtures of C_{60} and C_{70} .

The main distinctive features of the C_{60} fullerene molecule permitting its functionalisation are the 'pseudo-aromaticity',⁹ which governs the reactions with nucleophiles, carbenes and free-radical species to give various adducts, and the presence of the spherical cavity within the cage.²

III. Complexes and inclusion compounds

A unique chemical feature of fullerenes is the formation of metallofullerenes, endohedral complexes, in which one or several metal atoms reside inside the carbon cage.[†] A metal atom occurring as a cation cannot be extracted from the fullerene polyhedron without complete destruction of the cage, which can take place, for example, in the presence of oxygen.

Fullerenes are capable of forming charge transfer complexes (CTC).³⁹ Strictly speaking, the formation of CTC and endometallofullerenes cannot be regarded as functionalisation of fullerenes; nevertheless, we present here some novel data concern-

Figure 2. Numbering of carbon atoms in C_{60} fullerene (Schlegel diagram).¹⁹

[†] Endohedral complexes of fullerenes are designated using the character @. The metal atoms occurring inside the cage are written to the left of this character, *e.g.*, La@ C_{82} .

ing this type of reaction in order to characterise the properties of fullerenes more fully and because these compounds are highly promising.

Even a weak nucleophile such as iodine forms a CTC with fullerene of the composition $C_{60} \cdot I_2$. This complex is unstable, its stability constant is $< 0.1 \text{ litre mol}^{-1}$ (see Ref. 40). In an earlier study,⁹ it was reported that this complex was not formed.

A new method for the synthesis of CTC of fullerenes, in particular the complex with iodine, has been proposed;⁴¹ the method involves doping with iodine of other CTC prepared beforehand (for example, complexes with substituted tetrathiafulvalenes).

In the syntheses of potential precursors of new superconductors, special attention is paid to CTC of C_{60} fullerene having layered structures. For example, a complex of this type with tetramethyltetraselenofulvalene has been synthesised.⁴² Doping of the octamethylenetetrafulvalene $\cdot C_{60}$ benzene complex with potassium resulted in the detection of superconductivity with $T_c = 17\text{--}18.8 \text{ K}$, while doping with rubidium produced superconductivity with $T_c = 23\text{--}26 \text{ K}$.⁴³

A new type of superconductor has been obtained by the inclusion of potassium into non-superconducting Ba_3C_{60} .⁴⁴ The compound KBa_3C_{60} , which possesses block superconductivity at 5.6 K , is synthesised by heating a mixture of K and Ba_3C_{60} powders in a sealed glass tube for three days in a high vacuum at 260°C .

Endohedral fullerene complexes $M@C_n$ are usually prepared in an arc discharge with a metal–graphite composite as the positive electrode. These complexes were isolated in a pure state only in 1994,⁴⁵ and since 1996 they have been studied successfully using scanning tunnelling microscopy.⁴⁵

The C_{82} fullerene forms complexes with Sc, La, Y, Ce, Pr and Gd; they are most stable in air. The data obtained by electron paramagnetic resonance showed the occurrence of ‘intrafullerene’ transfer of electrons from the endohedral atom to the carbon cage. According to X-ray diffraction data,⁴⁵ the metal atom does not reside in the centre of the cage but, perhaps, wanders inside the spheroid; strong metal–cage interaction takes place in this system. Endohedral complexes are mixtures of isomers with different arrangements of five- and six-membered rings in the cage with respect to the metal.⁴⁵ The cages of some higher fullerenes can accommodate two or three metal atoms.⁴⁶ For instance, the complexes $Sc_2@C_{84}$, $Sc_3@C_{82}$ and $La_2@C_{80}$ have been isolated. It was established for the latter complex that the La atoms execute a circular motion inside the spheroid.⁴⁵

The data from high-energy spectroscopy provided the basis for the conclusion that the lanthanide ion in $Tm@C_{82}$ is in the divalent state.⁴⁷ The synthesis, isolation, and, what is the most important, purification of the compound $Dy@C_{82}$ have been described in detail.⁴⁸

Endometallofullerenes with calcium were synthesised for the first time by evaporation of a graphite anode filled with calcium carbide particles in an arc discharge.⁴⁹ Extraction with carbon disulfide gave a reaction product in which the majority of $C_{58}\text{--}C_{100}$ fullerenes contained one calcium atom but some held two calcium atoms inside the cage.

Endohedral complexes of fullerenes find use in studies of cells in molecular biology.⁴⁵ The variation of the EPR spectra of solutions of the endohedral metallofullerenes $La@C_{82}$ and $Y@C_{82}$ (their preparative synthesis has been reported⁵⁰) as functions of the oxygen concentration can be employed for the monitoring of oxygen in biological, physical and chemical processes.^{51, 52}

IV. Addition reactions

The most important line in functionalisation of C_{60} is exohedral addition to the fullerene cage. The exohedral covalent attachment

to the fullerene cage is possible for many classes of compounds. From 1990 to 1995, cycloaddition, radical and nucleophilic addition, hydrogenation, oxidation and halogenation as well as complex formation with transition metals had been studied. The features of the fullerene reactivity have been considered in detail in reviews by Diederich and Thilgen^{12, 17} and Hirsch,¹³ which cover publications up to the end of 1995.

The C_{60} molecule is constructed of 12 five-membered rings, each being surrounded by six-membered rings (20 altogether). It has thirty bonds between six-membered rings ([6-6] bonds) and sixty bonds between six- and five-membered rings ([6-5] bonds). The fact that [6-6] bonds are shorter ($1.38 \text{ \AA}$) than the [6-5] bonds ($1.45 \text{ \AA}$) influences the chemical behaviour of C_{60} .

The conjugated π -system in C_{60} is not completely delocalised, the reactivity of this cluster being similar to that of an electron-deficient polyolefin. The electrophilic double [6-6] bonds readily add nucleophiles and radicals. The addition of 34 methyl radicals to C_{60} has been detected by mass spectrometry.¹⁰ Therefore, C_{60} fullerene is referred to as a ‘radical sponge’.

In the adducts, some of the carbon atoms in the functionalised fullerene cage have changed the hybridisation from sp^2 to sp^3 . Nucleophilic and carbene attacks, cycloaddition and hydrogenation usually occur as 1,2-addition, while radical reactions, for example, halogenation, follow the 1,4-addition pattern. However, the latter type of addition is also possible for nucleophilic reactions if they involve bulky fragments. Thus adducts **A** and **B** have been described¹² (Fig. 3).

Figure 3. Addition to the C_{60} molecule. **A** is 1,2-adduct, **B** is 1,4-adduct.

When porphyrins or phthalocyanines contain fullerene fragments, the photoinitiated electrical conductivity of their solutions increases. In this case, photoinitiated electron transfer with participation of C_{60}^* and C_{70}^* takes place to give $C_{60}^{\cdot-}/C_{70}^{\cdot-}$ (see Ref. 53). The unpaired electron in the $RC_{60}^{\cdot}$ radicals is mainly delocalised over the atoms of the two six-membered rings adjacent to the $C\text{--}CR$ bond.¹⁰ The molecule of C_{70} , unlike C_{60} , contains five types of nonequivalent atoms; therefore, free-radical addition to C_{70} can yield five isomeric $RC_{70}^{\cdot}$ radicals.¹⁰

1. Cycloaddition reactions

Cycloaddition to fullerenes gives mainly products of monoaddition, commonly, 1,2-addition to a [6-6] bond, which is energetically more favourable than addition to a [6-5] bond.¹³ The reaction products are used as the initial compounds for further functionalisation. The $[m+2]$ cycloaddition reactions with C_{60} ($m = 1\text{--}4$) have found wide use, because they are facilitated by the low LUMO energy; $[4+2]$ cycloaddition and, in particular, Diels–Alder reactions, proceed especially easily; [6-6] bond is always dienophilic. The addition of various alkenes has been considered in a review.¹³

In recent years, quinodimethanes are successfully used as dienes in reactions with fullerenes. These compounds are either synthesised beforehand or formed *in situ* upon thermally induced elimination of SO_2 from heterocyclic sulfones or sultines

This reaction underlies the so-called 'reactive extraction' method, which permits recovery of higher fullerenes from fullerene soot.⁵⁴ The soot is first extracted with toluene and 1,2,4-trichlorobenzene and the residue is heated with quinodimethane precursor **1**.

This gives rise to a product soluble in conventional solvents and containing C_{60} – C_{400} clusters including multisubstituted ones. The ordinary extraction from commercial soot recovers 8.4% of fullerenes, whereas reactive extraction gives additionally 11.8%. Derivatives **2a,b** and **3a,b** result from reactions of C_{60} with sulfones **4**, **5**, which act as precursors of pyrimidine- and pyrimidonequinodimethanes.⁵⁵

X = OMe (**a**, 77%), N(CH₂)₂NH (**b**, 95%).

R = H (**a**, 82%), Me (**b**, 52%).

The biological activities of these derivatives can be assayed, if they have been transformed into water-soluble products, for example, into acetyl derivatives **6**.⁵⁵

Fullerene derivatives **7–9** have been prepared by [4+2] cycloaddition to C_{60} of six-membered heterocyclic analogues of *o*-quinodimethane generated *in situ* from the corresponding thiophenes, furans and thiazoles.⁵⁶

$R^1 = R^2 = H$; $R^1 = H, R^2 = CO_2Me$; $R^1 - R^2 = (CH=CH)_2$.

When the reactants are exposed to microwave radiation, the reaction time becomes shorter and the product yields increase. Thus microwave irradiation was used to synthesise compound **10** by the reaction of C_{60} with quinodimethanes prepared *in situ* from the corresponding *o*-bis(bromomethylated) quinoxaline and pyridine derivatives on treatment with NaI in the presence of a crown ether.⁵⁶ The use of microwave radiation for other Diels–Alder reactions and for 1,3-dipolar cycloaddition to C_{60} has also been proposed.⁵⁷ The reaction time decreases to several minutes, which makes it possible to avoid decomposition to the initial components.

$R^1 - R^2 = (CH=CH)_2$, ; $R^1 = R^2 = CN$.

The redox potentials for all newly synthesised organofullerenes were determined by voltammetry in solution.⁵⁶ The first reduction potentials for these compounds were found to undergo slight cathodic shifts with respect to that for C_{60} .

In another study,⁵⁸ sultines (prepared from commercially available ronalite) were used as the precursors of quinodimethanes. On heating in toluene in the presence of C_{60} , sultines eliminate SO_2 ; the resulting adducts are converted into quinones **11** on further modification.

$R^1 = H, R^2 = C_6H_{13}, Me$; $R^1 = Br, R^2 = Me$; $R^1 - R^1 = (CH=CH)_2$, $R^2 = Me$; DDQ is 2,3-dichloro-5,6-dicyano-1,4-benzoquinone.

Quinodimethanes have also been used to prepare adducts of C_{60} with phthalocyanines and hemiporphyrins; electrochemical characteristics of these compounds have been determined.⁵⁹ In particular, triad **12**, containing two fullerene fragments was synthesised for the first time in the 1-chloronaphthalene medium (Scheme 1).

Scheme 1

R = $CH_2OC_5H_{11}$.

Yet another example of functionalisation of C_{60} via [4+2] cycloaddition is its reaction with indene, which isomerises into isoidene under the reaction conditions. The yield of the reaction product **13** was 30%, while about 35% of the C_{60} recovered unchanged. The electron-withdrawing capacity of the adduct was somewhat lower than that of C_{60} (see Ref. 60).

The researchers cited⁶⁰ believe that the indene adducts might be useful for the development of new materials for optics and electronics.

The new method for the synthesis of 1,3-diazines fused to fullerene, described by Torres-Garcia *et al.*,⁶¹ can be extended to a large number of diamines. It should be noted that the last stage is carried out in an acid medium in order to prevent nucleophilic addition to fullerenes.

(a) C_{60} , 1,2- $Cl_2C_6H_4$, 180 °C, > 50%; (b) Br_2 , -77 °C; (c) $Et_3N \cdot 3HF$;

(d) R^1 , R^2 , 1,2- $Cl_2C_6H_4$, AcOH;

$R^1 = R^2 = H$ (**a**, 37%); $R^1 = H$; $R^2 = OMe$ (**b**, 29%);

$R^1 - R^2 = (CH=CH)_2$ (**c**, 32%), (**d**, 10%).

1,3-Bis(*tert*-butyldimethylsilyloxy)-2-azabuta-1,3-diene (**15**) adds to C_{60} fullerene at room temperature.⁶² Hydrolysis, replacement of the silyloxy group by an alkoxy group (in order to avoid the retro-reaction) and dealkoxylation yield a fullerene derivative of δ -valerolactam **16**, which is a very interesting starting compound for the synthesis of amino acids and polyamides containing a fullerene fragment. These derivatives can be prepared after opening the six-membered ring.

(a) C_{60} , PhH, 20 °C, Ar, 4 h; (b) 10% HCl (77%);

(c) conc. HCl, R^2OH , $CHCl_3$, Δ , 12 h; $R^2 = Et$ (100%), $(CH_2)_3OH$ (62%); (d) Et_3SiH , CF_3CO_2H , $CHCl_3$, Δ , 12 h (88%).

On prolonged heating, C_{60} adds 7-substituted 4-hydroxytropone.⁶³ The tropone moiety exists as two tautomeric forms, **A** and **B**. Since the reactivity of the sterically more hindered form **B** increases at elevated pressures, in most cases, the yields of reaction products **17a–c** increase when the reaction is carried out under a pressure of 300 MPa.

X = H (**a**), OMe (**b**), Cl (**c**).

γ -(9-Anthryl)-7-oxaoctanoic acid **18** adds to C_{60} in a similar way.⁶⁴ Adduct **19** forms true Langmuir films on an aqueous phase; they can be transferred as monolayer and multilayer films onto substrates, quartz, Si[111] or calcium fluoride plates.⁶⁴

X = $CH_2O(CH_2)_5CO_2H$.

At 160–180 °C, fullerene C_{60} reacts with norbornadiene and its 7-spirocyclopropane derivatives (a 200- to 300-fold excess of the diene is used in the reaction) to give, depending on the substituent in the cyclopropane ring, [1+3]-, [1+4]- or [2+2]-type adducts, including polyaddition products.⁶⁵

The fullerene analogue of thiochroman **20** was obtained by the hetero-Diels–Alder reaction with thioquinonemethide (**21**),⁶⁶ formed *in situ* from benzothietane (**22**).

The bulky fullerene fragment does not prevent oxidation of compound **20** at the sulfur atom by *m*-chloroperbenzoic acid. This reaction at 20 °C gave a sulfoxide (yield 89%) and sulfone (yield 45%). At room temperature, C_{60} readily reacts with 2,5-dimethylthiophene *S*-oxide and with 2,5-dimethylthiophene *S,S*-dioxide; the reaction with the sulfoxide affords monoadduct **23**, and the reaction with the sulfone gives tetraadduct **24**.⁶⁷

The goals of the synthesis of the adducts **23** and **24** were firstly, to carry out further functionalisation at the SO and SO_2 groups and, secondly, to study their biological activities, because cycloadducts with thiophene oxide fragments are used as biologically important reactive metabolites.

Llacay *et al.*⁶⁸ were the first to synthesise the fullerene adducts with organosulfur compounds containing a sulfonyl group capable of being eliminated, for example, with tetrathiofulvalene **25**.

Thione **26** was isolated in 41% yield as a highly stable clathrate including 0.5 molecules of CS₂.

Fulleropyrrolidines, which are fairly promising compounds for the preparation of stationary phases for liquid chromatography of biological objects, have been synthesised by stereospecific thermal 1,3-dipolar cycloaddition of C₆₀ to *cis*- and *trans*-*N*-benzyl-1,2-diphenylaziridines.^{69, 70} Thermally induced cleavage of the aziridine ring in *N*-[3-(triethoxysilyl)propyl]-2-methoxycarbonylaziridine (**27**) in the presence of C₆₀ gives rise to fulleropyrrolidine **28**, which can be attached by a covalent bond to silica gel used for HPLC.

This new adsorbent with the immobilised fullerene-containing group displays an exceptionally high separating capacity with respect to cyclic oligomeric compounds, calixarenes or cyclodextrins in both organic and mixed aqueous-organic media.⁷⁰ Optically pure fulleropyrrolidines have also been synthesised.⁷¹ Stationary phases modified with chiral fullerenes can be used for separation of enantiomers.

When a mixture of α -amino acid, a carbonyl compound and C₆₀ fullerene is heated in chlorobenzene, fullerene undergoes a [2 + 3]-type cycloaddition to the intermediate azomethine ylide **29**, giving rise to oligoadducts containing one to three pyrrolidine fragments, depending on the reaction conditions.^{72–77}

$n = 1-3$.

The reaction with methyl nonyl ketone follows a similar route.⁷² Heating of sarcosine, terephthalic aldehyde and C₆₀ in toluene (in this case, the intermediate ylide is stabilised by the phenyl group) gave compound **30**, which was converted into the amphiphilic 1-methyl-2-(4-dimethoxymethylphenyl)fulleropyrrolidine (**31**).⁷⁴

Compound **31** forms Langmuir–Blodgett films and monolayers on an air/water interface; these films are also formed when 22-tricosenoic acid is added. They possess good transparency and thermal stability.^{73, 74}

Fluorescence of aryl-substituted fulleropyrrolidines has an interesting feature, namely, its intensity is much higher than that of C₆₀, which is due to the decrease in the symmetry of the molecule. At the same time, the electron-withdrawing ability of the C₆₀ spheroid in these adducts is markedly lower than that of fullerene.⁷⁷

Silylamines can be used in this type of synthesis instead of the amino acid; the compound **32** obtained in this way has been oxidised to a quinone.⁷⁸

By varying the amino acid and the aldehyde used, one can prepare biologically active compounds. For example, a fullerene analogue of natural nicotine **33** has been prepared in order to estimate the influence of the fullerene fragment on the toxicity of nicotine.⁷⁹ However, the solubility of compound **33** in solvents miscible with water was found to be too low.

The amino acid was modified by an efficient solubilisation agent, triethylene glycol; this gave compound **34**, which reacted with aldehydes and C₆₀ fullerene to give fulleropyrrolidones **35** (including those containing a nicotine fragment) soluble in an H₂O–DMSO mixture.⁷⁹

R = 3-Py (**a**), 4-Py (**b**), CH₂O(CH₂)₂O(CH₂)OMe (**c**).

Compound **35c** exhibits an antimicrobial activity including that with respect to a large number of pathogenic microorganisms.⁷⁹

On oxidation with *m*-chloroperbenzoic acid, fulleropyrrolidines are converted into stable nitroxides possessing ferromagnetic properties.^{75, 76}

Paramagnetic nitroxide **36** with a spirocyclohexane fragment has been synthesised from C₇₀ fullerene.⁷⁶

Nitrile oxides generated from oximes or in another way add to C₆₀ giving rise to fullerenoisoxazolines.^{77–84} Thus fulminic acid (**37**) is converted into fullerenoisoxazoline **38**, while its esters **39a–c** afford derivatives **40a–c** with retention of the alkoxy-carbonyl group.⁸⁰

The readily available fullerenoisoxazoline **38** is a convenient starting compound for the synthesis of diverse functional derivatives of fullerene.⁸¹

Fullerenoisoxazolines decompose under relatively mild conditions with quantitative regeneration of C₆₀. This process occurs on refluxing in chlorobenzene in the presence of Mo(CO)₆ or on treatment with excess diisobutylaluminium hydride in toluene at 20 °C.⁸² The decomposition of the isoxazoline fragment can be used either to control fullerene functionalisation or to perform further functionalisation. Thus treatment of substituted fullerenoisoxazoline **41** with formaldehyde yields tricyclic derivative **42**. When the latter compound is made to react with Mo(CO)₆, *N*-substituted fulleropyrrolidine **43** is produced.⁸²

(a) CH₂O, PhMe, Δ, 67%; (b) Mo(CO)₆, PhCl, Δ.

The method for the synthesis of cyclopentenes based on cycloaddition of 2,3-dienoates or 2-ynoates to electron-deficient alkenes in the presence of phosphine has been employed successfully for the synthesis of fullerencyclopentenes. The driving force of this reaction is nucleophilic attack by a tertiary phosphine on a β-allene or acetylene carbon atom. A series of successive prototropic shifts is followed by β-elimination of phosphine giving rise to fullerencyclopentene **44**.^{85, 86}

The first example of cycloaddition of ylide **45**, prepared from *N*-benzyl-1-(4-nitrophenyl)chloromethylideneamine (**46**), to C₆₀ fullerene was reported.⁸⁷

However, based on the ¹³C and ¹H NMR data, the authors suggest that, in addition to the normal [6-6]-adduct **47**, the reaction yields an approximately equal amount of a [5-6]-adduct with an open annulene structure as a mixture of two diastereoisomers.

It is known that photoexcited C₆₀ fullerene in the triplet state has stronger electron-withdrawing capacity than that in the ground state. Thus it is able to react with moderately electron-releasing reagents according to the [2+2]-cycloaddition pattern.^{88–90} For example, anthracene adds to C₆₀ on exposure to a laser radiation with λ ≥ 500 nm giving rise to adduct **48**.⁹¹

4-Propenylanisole does not react with C_{60} fullerene without light. On exposure to the light of a xenon lamp ($\lambda > 500$ nm) at 20 °C, both *cis*- and *trans*-isomers are converted into monoadducts (yield 40%, the *trans*-compound being the major product), which, however, decompose to the initial components under conditions of mass spectroscopy.⁸⁸ Studies of the isotope effects and the ^1H NMR spectra of the adducts formed in the reaction of C_{60} fullerene with *cis*-2-deuterio-1-(4-methoxyphenyl)propene made it possible to propose a two-step reaction mechanism involving a bipolar or biradical intermediate.⁸⁹

Jensen *et al.*⁹⁰ have studied the behaviour of C_{60} fullerene in the De Mayo reaction, *i.e.* [2 + 2] photocycloaddition of enolizable 1,3-diketones and 1,2-diketones to alkenes followed by opening of the cyclobutane ring giving rise to cyclooctadienones. The reactions of C_{60} with compounds **49** resulted in the synthesis of fused fullerene-furans, both chiral (**50a,b**) and achiral (**51a,b**).

$R^1 = \text{H}, \text{Me}_3\text{Si}; R^2 = \text{H}$ (**a**), Me (**b**).

Presumably, the reaction involves either intermolecular oxidation by singlet oxygen of the cyclobutane intermediates formed initially or intramolecular oxidation of these intermediates by a triplet fullerene fragment.

Synthesis of methanofullerenes using cycloaddition reactions is especially significant. Methanofullerenes can serve as the initial compounds for the preparation of functional derivatives of fullerene by introducing substituents into the side chains of the adducts. Routes to methanofullerenes are diverse. They include thermal addition of diazo compounds followed by thermolysis or photolysis, addition of carbenes, and reactions with ylides, which follow an addition–elimination mechanism. Cyclopropanation by diethyl bromomalonate (Bingel reaction⁹²) is among the best and most widely used cyclopropanation methods. Recently this reaction has been modified⁹³ in such a way that bromomalonates (which are difficult to prepare) are formed *in situ* during the cyclopropanation of fullerene. Fullerene is made to react with malonates in the presence of CBr_4 and diazabicyclo[5.4.1]undec-7-ene (DBU) at 20 °C in toluene; the reagents are taken in a 10-fold excess (DBU in a 20-fold excess) with respect to fullerene.

$R = 3,5\text{-(3-BnOC}_6\text{H}_4\text{CH}_2\text{O)}_2\text{C}_6\text{H}_3\text{CH}_2$ (29%), Et (57%), $\text{C}_{18}\text{H}_{37}$ (65%),

The reaction of monoesters of malonic acid, I_2 and DBU with C_{60} resulted unexpectedly in iodinated derivatives **52a–c**.⁹⁴

$R = \text{Bn}$ (**a**), $3,5\text{-(C}_{12}\text{H}_{25}\text{O)}_2\text{C}_6\text{H}_3\text{CH}_2$ (**b**), $(\text{CH}_2)_2\text{O}(\text{CH}_2)_2\text{OEt}$ (**c**).

Presumably, the carbanion arising at the first stage is not sufficiently nucleophilic to be converted into diiodomalonate; instead, it is decarboxylated to give $\text{RO}_2\text{CCH}_2\text{I}$, which adds to fullerene. The reaction with diester **53** yielded fullerene-cyclopropanedicarboxylate **54** and monoester **55**.

$R = 3,5\text{-(C}_{12}\text{H}_{25}\text{O)}_2\text{C}_6\text{H}_3\text{CH}_2$.

Amphiphilic C_{60} derivatives, **56** and **57**, containing an undecanoic acid fragment, have been synthesised (in 45% total yield); the purpose of the synthesis was to study the properties of thin films prepared from these compounds. The monoadduct **56** was resolved into isomers **A–C** using column elution chromatography.⁹⁵

$X = (\text{CH}_2)_9\text{CO}_2\text{Et}$.

The side chain in methanofullerenes is often modified in order to obtain biologically active compounds. Mono- and di-carboxylic acids, especially 1,2-methanofullerene[60]-61-carboxylic (fulleromalonic) acid, are used most frequently as the starting compounds. Thus *N*-phenyl(1,2-methanofullerene[60])-61-formohydroxamic acid has been prepared from this acid.⁹⁶

When 1,2-methanofullerene[60]-61,61-dicarboxylic acid (**58**) reacts with *N*-hydroxysuccinimide (NHS) and chloro-*N,N*-dicyclohexylcarbodiimide (DCC), it eliminates water and CO_2 being thus converted into compound **59**, which reacts with primary and secondary amines, 1-aza-12-crown-4 and 1,6-aza-homo[60]fullerene.⁹⁷

of a stoichiometric amount of dirhodium tetraacetate to give normal methanofullerenes, mainly, at a [6-6] bond.¹⁰¹ A mechanism including the formation of metallacycle **66** was proposed for the reaction.

$$\text{C}_{60} + \text{Me}_2\text{S}^+\text{CH}_2\text{R} \xrightarrow[\text{Bu}_4^+\text{NBr, PhMe, H}_2\text{O}]{\text{K}_2\text{CO}_3} \text{C}_{60}(\text{S}^+\text{CH}_2\text{R}) \quad \mathbf{67}$$

The reaction of C₆₀ with *tert*-butyl diazoacetate in benzene or toluene in the presence of dirhodium tetraacetate affords a new type of cycloadducts, tricyclic compounds **62a,b**, instead of the expected methanofullerenes. It is assumed that initially, cyclopropanation of the solvent gives norcaradiene **63**, and it is this product that reacts with fullerene.¹⁰⁰ Hydrolysis of the ester group yields acids **64a,b**, which are then converted into derivatives **65a,b** at the amino group of leucine.

Spiro derivative of C₆₀ fullerene, adduct **69**, containing an ‘open’ [5-6] bond has formed unexpectedly in the reaction of C₆₀ with 4,4,5,5-tetramethyl-1,3-diazolidine-2-thione (**70**) and DL-valine.¹⁰⁴

The mechanism assumed for this reaction includes the reaction of thione **70** with amino acid to give a carbene, which adds to fullerene.

Shen *et al.*¹⁰⁵ were the first to demonstrate that the reaction of C₆₀ fullerene with chiral 1,4-di-*tert*-alkoxy-2,3-bisazidobutanes gives rise to chiral bisazafulleroids. Enantiomeric pairs with the

R = H (**a**), Me (**b**); DCC is dicyclohexylcarbodiimide.

However, when 1-methylnaphthalene is used as the solvent, fullerene smoothly reacts with ethyl diazoacetate in the presence

(2*R*,3*R*) and (2*S*,3*S*) symmetry were obtained in ~51% yields. The enantiomers exhibit mirror image circular dichroism curves.

Apparently, removal of the *tert*-alkyl groups from compounds **71** would provide a route to water-soluble chiral fullerene derivatives, which is important for the investigation of their biological activities.

A bisazafulleroid fragment has been inserted in a crown-ether chain.¹⁰⁶

According to NMR data, the bisadduct **72** has a structure with 'open' [5-6] bonds. The fullerene-crowns are excellent agents for binding metals. Perhaps, new superconducting substances would be found among these complexes.¹⁰⁶

The reaction of fullerene with tetrabromides **73a-d** has resulted in selective multifunctionalisation of fullerene, the goal of which was to prepare disubstituted bisphenols with substituents located at particular rings in the cage.¹⁰⁷

n = 2 (**a**), 3 (**b**), 4 (**c**), 5 (**d**).

The reaction is carried out under conditions of high dilution (10^{-4} mol litre⁻¹) and the guiding (CH₂)_{*n*} chain is subsequently split off.¹⁰⁷ When *n* = 2–5, the addition occurs selectively within one hemisphere of the C₆₀ cage. When *n* = 2, 3, only *cis*-2- and *cis*-3-isomers are formed and for *n* = 5, bisaddition yields the *e*-adduct. When *n* = 4, the reaction gives a complex mixture of bisadducts. For both the cyclic precursors and acyclic bisadducts, types of symmetry and the relationship between the symmetry and chirality were established by analysing the data of mass, NMR, UV and visible spectra (all adducts with *C*₁ and *C*₂ symmetry are chiral and those with *C*_s symmetry are achiral). The chiral *cis*-3- and *e*-adducts were resolved into enantiomers using HPLC with a chiral phase [cellulose tris(3,5-dimethylphenyl carbamate)-coated silica gel (CHIRAL CEL OD), hexane–isopropyl alcohol]. For example, for *n* = 2, the bisphenol **74a** was obtained.

Both the precursor **75a** and the final diol **74a** are *cis*-2 isomers (this was observed for the first time for fullerene bisadducts) and are achiral; the compound **75a** corresponds to *C*_s symmetry.

The cyclic precursor **75d** and the bisphenol **74d** for *n* = 5 are *e*-isomers with *C*₁ symmetry; they are chiral and optically active. The total yield of the isomers at the final stage is 100%. The [α]_D values for the ethers **75a,d** (5.7×10^2 and -5.2×10^2) and the diols **74a,d** (4.4×10 and -7.4×10) were determined. The structures of optical isomers of the bisphenol **74d** are presented below.

The compounds **74a-d** belong to the few examples of chiral derivatives with achiral substituents known in the chemistry of cage compounds, in particular, in the fullerene chemistry.

The reaction of C₆₀ fullerene with diazo compound **76** has resulted in the synthesis of spirane methanofullerenes **77** with quinone type addends.¹⁰⁸

R = H, Me, Bu^t.

Spiro[10-anthrone-9,61']methanofullerene (**78**) and spiro[cyclohexanone-4,61']methanofullerene (the latter as a mixture of [6-6] and [5-6] isomers) were prepared in a similar way. The conjugated dienone **78** exhibits stronger electron-withdrawing capacity than the initial C₆₀ fullerene. The anthrone **78** was converted into compounds **79** and **80**.¹⁰⁸

(a) Me₃SiN=C=NSiMe₃, TiCl₄, CHCl₃, Δ, 5 days (60%);

(b) CH₂(CN)₂, TiCl₄, Py, CHCl₃ (26%).

Chemical modification of more than two double bonds in the C_{60} molecule gives, as a rule, a mixture of regio- and stereo-isomers. Therefore, study of the possibility of synthesising a single isomer by multifunctionalisation of C_{60} is of interest. These molecules could serve as useful tools in the studies of functional catalysis and in the materials science; they could find application in bioorganic chemistry (for example, for reactions with DNA, enzyme inhibition, design of compounds for drug transport, and for other purposes¹⁰⁹).

Hirsch has studied the regiochemistry and stereochemistry of multiple addition to the double bonds in C_{60} and has developed a theoretical substantiation of these reactions.^{13, 21}

Double (and multiple) cyclopropanation with dialkyl bromo-malonates according to the Bingel reaction pathway is used most often to prepare polysubstituted fullerenes.⁹² Thus C_{60} has been made to react⁹³ with the malonate and CBr_4 in the presence of DBU on the addition of 10 equiv. of 9,10-dimethylanthracene and at longer reaction times; under these conditions, symmetrical hexakis(adducts) **81** were obtained in good yields.

$R = CO_2CH_2Me, CO_2(CH_2)_{16}Me$.

When pentakis(adducts) **82** with C_{2v} symmetry are again treated with diazomethane, heptakis- and octakis-adducts with C_s symmetry, pyrazoline derivatives, are formed with high regioselectivity. These products are converted into methanofullerenes by thermally induced abstraction of nitrogen. The direction of nitrogen abstraction was assumed to be controlled by orbital symmetry.¹¹⁰

$X = C(CO_2Et)_2, C(CO_2CH_2CO_2Et)_2$.

The tetrakis(adduct) **83** contains a fulvene π -subsystem located on the spheroid surface. This compound is prepared from a mixture of C_{60} , fluorenylpotassium and fluorene in THF. The mixture is kept under an argon atmosphere in the presence of traces of oxygen for 72 h and the adduct is then isolated by preparative chromatography.¹¹¹

The tetrakis(adduct) **83** adds nucleophiles, which is typical of a fulvene π -system. Thus it reacts with 1-octynyllithium in THF or with NaCN in a DMF–chlorobenzene mixture to give pentakis(adducts) **84a,b** in 63% and 68% yields, respectively.

$RM = C_6H_{13}C\equiv CLi$ (**a**, 63%), $NaCN$ (**b**, 68%).

Long-term heating of C_{60} with compounds **85** in anhydrous 1,2-dichlorobenzene in the presence of 4 Å molecular sieves results in double cycloaddition giving rise to tricyclic compounds **86**.¹⁰⁹

$R-R = OCM_2O$; $n = 3, 4, 6$.

Acid hydrolysis affords quantitatively the corresponding diketones **87**.

A [2]catenane containing the C_{60} bishomofullerene fragment was synthesised for the first time using a sequence of two modified Bingel reactions (yield 18%).¹¹²

2. Nucleophilic, electrophilic and radical addition

Nucleophilic addition to C_{60} fullerene gives, as a rule, mono-adducts; for example, C_{60} adds one amino acid molecule.¹¹³ Dipeptides react in a similar way.¹¹⁴

R is an amino acid or dipeptide residue.

Fullerene dipeptide derivatives are soluble in water owing to association with amino acid residues.¹¹⁴ These adducts penetrate

inside the liposomes, they exhibit adjuvant[‡] properties and antiviral activity.^{113, 115, 116}

The reaction of C₆₀ in 1,2-dichlorobenzene with NaCN in DMF affords not only the [C₆₀(CN)][−] anion but also the [C₆₀(CN)]^{2−} and [C₆₀(CN)]^{3−} anions, although the monoion predominates (as shown by negative-ion mass spectrometry).¹¹⁷

Mechanochemical activation (mixing of solid reactants in a vibratory mill¹¹⁸) can be used for functionalisation of fullerenes. The reaction of C₆₀ with NaCN carried out in this way gave the dimer C₁₂₀ **88**, in which two spheroids are linked *via* a cyclobutane ring. The fact that the reaction pathway differs from that observed in solutions is due to the unique ability of the cyanide ion to serve as both a nucleophile and a leaving group.

The reactivity of the dimer **88** does not differ much from that of C₆₀. For instance, it enters into the Bingel reaction with diethyl bromomalonate and DBU (in equimolar amounts) to give a mixture of isomeric monoadducts (at least, three compounds) in 44% total yield.¹¹⁸

Tanaka *et al.*¹¹⁹ made use of the fact that the fullerene spheroid readily forms anions and synthesised an unusual class of compounds, hydrocarbon salts.

R⁺ is tris[1-(5-isopropyl-3,8-dimethylazulenyl)]cyclopropenylum.

Vinyl ethers add to the stable 2-(1-octynyl)-1,2-dihydrofulleren[60]-1-ide ion (**89**) in the presence of HCl; this affords [6-6] bisadducts **90**, which are promising monomers for cationic polymerisation.¹²⁰

R = CH₂Prⁱ, (CH₂)₂OAc.

The fullerene C₆₀ adds Grignard reagents ClMgCH₂SiR₃ (R = Alk, Ar, AlkO) yielding mainly compounds C₆₀(H)CH₂SiR₃ in THF and only products of the formula C₆₀(CH₂SiR₃)₂ in toluene.¹²¹

Fullerenylmethylsilanes such as C₆₀(H)CH₂SiMe₂Cl, C₆₀(H)CH₂SiMe_n(OR)_{3−n} and C₆₀[CH₂SiMe_n(OR)_{3−n}]₂, where R = Alk, n = 0, 1, are used to modify silica gel. The products thus formed are used as sorbents for HPLC, as heterogeneous photosensitisers and in catalysis.¹²¹

Irradiation of C₆₀ and allylstannanes in a benzene or toluene solution results in the regioselective formation of fullerene mono-allylation products. The process is inhibited by oxygen or benzonitrile.¹²² Fullerene derivatives **91** have been synthesised in this way. This reaction occurs by a mechanism involving triplet C₆₀ and single-electron transfer.¹²²

R¹, R², R³ = H, Me.

Mixed adducts **92–94** were directly synthesised for the first time from C₆₀ and 2,2-dibenzyl-1,3-diazidopropane¹²³ by refluxing the reactants in chlorobenzene.

Bistriazolines are precursors of bisdiazolines and can be converted into the latter by thermolysis in chlorobenzene. Thermolysis of the bistriazoline **92** afforded the compound **94**. The formation of the adducts **93** and **94** was interpreted¹²³ in terms of a radical mechanism, similar to the mechanism of triazoline thermolysis.

3. The addition of hydrogen and the properties of hydrides

All attempts to prepare completely hydrogenated fullerene C₆₀H₆₀ failed. This compound appears to be highly unstable due to the enormous strain which arises upon the formation of twenty planar cyclohexane rings and numerous shielding H–H interactions.¹³ By 1997, hydrides with the compositions C₆₀H_x (x = 2, 4, 18, 32, 36, 36–50, 42–44) and C₇₀H_x (x = 2, 4, 8, 10, 34–36, 36–38, 36–44) were known.^{124, 125}

The methods used to prepare fullerene hydrides have all been considered in detail;^{11, 125} they include Birch reduction, hydroboration, hydrozirconation, solid-phase and liquid-phase hydrogenation with hydrogen, electrochemical reduction, reduction with diimide or with chromium acetate, photoinitiated electron transfer and reduction with metal hydrides.

Despite the fact that fullerenes could be promising catalysts for activation of the C–H bonds in hydrocarbons *via* the formation of fullerene hydrides, as was convincingly demonstrated in a comprehensive review,¹¹ this aspect has not yet received adequate attention. Studies are mainly concerned with the structure^{124, 125} and spectral and photophysical properties of fullerene hydrides.^{124–128} It is assumed that the solid hydride C₆₀H₃₆ corresponds to *T* symmetry and contains four isolated

[‡] Adjuvants are compounds stimulating an increase in the number of antibodies.

benzenoid rings, located in tetrahedral positions on the surface of the closed shell of the molecule.

A preparative synthesis of fullerene hydrides was carried out by treatment of fullerenes with metals and water serving as a source of protons;¹²⁵ although the number of possible isomers is enormous, only a few of them are formed. For instance, heating of a solution of C₆₀ fullerene in toluene with a Zn(Cu) mixture (freshly prepared Zn dust is employed) gives rise to a mixture of hydrides, which are isolated by preparative liquid chromatography. Depending on the temperature, reaction time and the ratio of the metals, the compounds C₆₀H₂, C₆₀H₄ and C₆₀H₆ (two isomers) can be obtained in 66%, 45% and 38% yields, respectively. Reduction of C₇₀ fullerene afforded C₇₀H₈ and C₇₀H₁₀ (three isomers) in a total yield of 62%. The hydrides C₇₀H_n are all unstable in air and during storage.

Fullerene hydrides and deuterides containing up to 24 hydrogen atoms per fullerene molecule have been obtained upon hydrogenation (with either hydrogen or deuterium) at 1–2.5 MPa and 573–673 K of a mixture of fullerite (83% of C₆₀, 15% of C₇₀ and 2% of higher fullerenes) and powdered intermetallic compounds LaNi₅, LaNi_{14.65} and CeO₃.¹²⁹ At 800 K, fullerene hydrides (deuterides) decompose with evolution of gaseous hydrogen (or deuterium); at 1000 K, the reaction of fullerite with intermetallic compounds is accompanied by evolution of the corresponding 3d metal.¹²⁹ The hydrides prepared in this way can serve as sources of high-purity hydrogen. When fullerite (78% of C₆₀ and 22% of C₇₀) is deuterated in the presence of Pd clusters (Pd powder and Pd/C), the maximum content of deuterium corresponds to [C₆₀ + C₇₀]D₂₆ and is attained after ten repetitions of the heating–cooling cycle (673–293 K) at 2.5 MPa.¹³⁰

Fullerene dihydride C₆₀H₂ has been synthesised by ultrasonic treatment of C₆₀ fullerene in decalin for 2–4 h in a sealed vessel under argon.¹³¹ The hydrogen needed to hydrogenate fullerene is formed upon sonolysis of the solvent.

The dehydrating capacity of C₆₀ fullerene may be useful in the studies of biological objects. Thus C₆₀ dehydrates the Hantsch ester (the reaction simulates the action of dihydronicotinamide-adeninedinucleotide) at 100 °C under anaerobic conditions to give diethyl 2,6-dimethylpyridine-3,5-dicarboxylate; in this reaction, fullerene is converted into mixed hydrides C₆₀H_n (*n* = 2, 4, 6).¹³² It is of interest that this dehydrogenation can be carried out by leaving the reaction mixture in the light at 20 °C; in this case, C₆₀ acts as a catalyst because it is recovered unchanged.¹³²

On irradiation in the presence of sensitisers such as 9,10-dicyanoanthracene (and diphenyl as a co-sensitiser), the radical cation C₆₀^{•+} is generated from C₆₀. The radical cation reacts with hydrogen donors, for example, with *tert*-butyl methyl ether, propionaldehyde and alcohols giving rise to 1-substituted 1,2-dihydro[60]fullerenes.¹³³

The hydride 1,2-C₆₀H₂ has been prepared in 70% yield by the reaction of photoexcited C₆₀ fullerene with 10-methyl-9,10-dihydroacridine.¹³⁴

The proton at the 4-position of stable 1-*tert*-butyl-1,4-dihydro[60]fullerene undergoes base-catalysed migration to give a thermodynamically more favoured isomer, 1-*tert*-butyl-1,2-dihydro[60]fullerene.¹³⁵

4. Oxidation

The electronegative fullerene molecules can be easily reduced but cannot be readily oxidised; however, the reaction of fullerene with oxygen on exposure to UV light (in hexane) or heating of fullerene in the presence of oxygen results in vigorous oxidation accompanied by fragmentation, *i.e.* rupture of the C=C bonds in the cage.¹³ Upon irradiation, C₆₀ passes initially into the triplet state; the transfer of energy from this species affords singlet oxygen, which oxidises the fullerene.⁹

Oxygen derivatives of fullerenes receive little attention yet. The monoxide, namely, 1,2-epoxy[60]fullerene (**95**), is prepared by reactions with various oxidants including systems with cyto-

chrome P450;¹³⁶ however, the yields are relatively low. A preparative pathway to 1,2-epoxy[60]fullerene (**95**) has been described¹³⁷ in which fullerene is treated with the system 'methyltrioxorhenium–hydrogen peroxide (as a complex with urea)'.

Interestingly, either component of this oxidative system taken alone give virtually no target product.

The epoxide C₇₀O, which is fairly difficult to obtain, has been isolated in ~0.5% yield upon the use of an arc-discharge reactor with a rotating cathode and an anode made of carbon plates (the reactor operation time was 24 h).¹³⁸ Study by ¹³C NMR spectroscopy showed the presence of two isomers, 1,2-epoxy-C₇₀ and 5,6-epoxy-C₇₀ in 47:57 ratio. The predominance of the [5-6] isomer was interpreted¹³⁸ as being due to the lower strain in its molecule.

The compound C₁₂₀O (its synthesis has been reported¹³⁹) disproportionates at 400 °C to give 60% of C₆₀, 15% of C₁₂₀O₂, and a mixture containing oligomeric (C₆₀)_nO_m oxides (*n* = 3, 5; *m* = 3–9).¹⁴⁰

The dioxide C₁₂₀O₂ is stable at room temperature both in a pure state and in solutions. After thermolysis of C₁₂₀O at 550–560 °C, product C₁₁₉ containing two C₅₈ cages was isolated from the reaction mixture in 2% yield. The cages are connected by a bridge comprising three *sp*³-hybridised carbons, two of which are equivalent.¹⁴¹

Oxidation of C₆₀[−] permits the preparation of an aqueous colloidal solution of C₆₀ fullerene.¹⁴² The C₆₀[−] anion is formed when a solution of C₆₀ in THF is treated successively with an Ni–Al alloy and an aqueous solution of sodium hydroxide; C₆₀^{2−} can be prepared in a similar way except that DMSO is used in place of THF. The anions are inert with respect to water but highly sensitive to oxygen. Oxidation occurs *via* consecutive steps

the overall reaction being written as

If the oxidation is performed in an aqueous medium, C₆₀ forms a colloidal solution containing non-crystalline and quite homogeneous particles with a dimension of ~10 nm (as established by electron microscopy); in an anhydrous organic solvent, C₆₀ precipitates as a black powder.

Electrochemical reduction of C₆₀O affords an electrochemically active film; a different active film is formed upon the reduction of C₆₀ to the dianion in the presence of O₂.¹⁴³ Films of conducting polymers, which are deposited on the electrodes upon electrochemical reduction of C₆₀O, are promising for the design of important materials for engineering (*e.g.*, for microelectronics).¹⁴⁴

An interesting feature of pentaphenyl-substituted fullerenes has been discovered.¹⁴⁵ The compound C₆₀Ph₅Cl was kept for two weeks in air and in the light, and C₆₀Ph₅H was stored for a year. Both substances were spontaneously oxidised yielding complex mixtures of products. In both cases, a compound with the composition C₆₀Ph₄C₆H₄O₂ was isolated from the mixture in 60% yield. Relying on NMR and mass spectroscopy, it was established that elimination of hydrogen or chlorine atoms linked to the cage and an *ortho*-hydrogen atom of the neighbouring phenyl group followed by oxidation gives rise to fullereno-benzo[*b*]furan **96**. The mechanism of this reaction is not yet entirely clear.

The radicals generated in the reaction of fullerene with *tert*-butyl peroxide on irradiation are highly stable under a nitrogen atmosphere and react only slowly with oxygen, water and with radical traps such as nitrobenzene.¹⁴⁶

$n \geq 1$.

Fullerenols eliminate active oxygen radicals including superacidic radical anions formed in biological systems,¹⁴⁷ which opens up the way for using them in biochemistry and pharmacology.

No compounds containing the C_{60}^+ cation have been obtained. However, the salt **97**, containing the C_{76}^+ cation, which has a much lower electrochemical oxidation potential, has been synthesised.¹⁴⁸

$\text{R} = 2,4\text{-Br}_2\text{C}_6\text{H}_3$.

The salt **97** can be stored for several weeks under a nitrogen atmosphere. Apparently, this is the first compound with a carbocation consisting only of carbon.

5. Halogenation

It was shown back in 1991–1992 that C_{60} fullerene reacts with gaseous chlorine and fluorine and with liquid bromine giving complex mixtures of addition products.¹³ Subsequently, these studies have not progressed greatly due to the difficulties in the isolation of individual compounds and in controlling halogenation reactions.

It had been considered⁹ that iodine does not react with fullerene; however, later,^{40,41} CTC involving iodine and C_{60} were prepared.

The C_{60} fullerene readily reacts with chlorine under free radical reaction conditions to give $\text{C}_{60}\text{Cl}_{40}$ (see Ref. 149). This compound can be used as an intermediate in the further fullerene functionalisation, namely, synthesis of polyfullerol and polyfluorofullerene.

The reaction of C_{60} with excess iodine chloride (toluene, 20 °C) gives rise to an individual compound, C_{60}Cl_6 ; the reaction with liquid bromine affords C_{60}Br_2 , while the reaction in CS_2 solvent results in C_{60}Br_5 (see Ref. 9).

Fluorination of fullerenes is receiving somewhat more attention because fluorinated derivatives might be of interest for materials science.¹⁵⁰

Thus fluorofullerenes containing up to 60 fluorine atoms per molecule, including $\text{C}_{60}\text{F}_{48}$,¹⁵¹ can be prepared by fluorination with fluorine gas, while hyperfluorofullerenes $\text{C}_{60}\text{F}_{76}$ can be synthesised on treatment with fluorine with exposure to UV radiation; this reaction is accompanied by cleavage of the spheroidal cage.¹⁴⁹ When C_{60} is treated with MnF_3 at 330 °C (24 h), $\text{C}_{60}\text{F}_{36}$ is formed.¹⁵² Judging by the mass spectrometric data, the mixture of fluorinated derivatives resulting from the reaction of C_{60} with KrF_2 in anhydrous HF contains mainly

$\text{C}_{60}\text{F}_{44}$ and $\text{C}_{60}\text{F}_{46}$ (see Ref. 150). Treatment of $\text{C}_{60}/\text{C}_{70}$ with vapours of the fluorides WF_6 , TaF_5 , NbF_5 and TiF_4 results in the preparation of fluorides $\text{MF}_n \cdot \text{C}_{60}$ (the $\text{MF}_n:\text{C}_{60}$ ratio is $< 1:2$).¹⁵³

A preparative route to fullerene derivatives with organofluorine substituents (for instance, derivative **98**) involves the reaction of C_{60} with haloalkanes and tributyltin hydride under free-radical reaction conditions.¹⁵⁴

When $n\text{-C}_6\text{F}_{13}\text{I}$, BrCF_2Br , $n\text{-C}_{12}\text{F}_{25}\text{I}$ and $\text{I}(\text{CF}_2)_6\text{I}$ are used, initiation of the reaction requires the addition of azoisobutyronitrile. The hydrogen atom in the C_{60} ring in the resulting compounds is highly acidic and can be replaced by other functional groups in a weakly alkaline medium.¹⁵⁴

V. Fullerenes in polymerisation reactions

When C_{60} fullerene pellets are exposed to a pressure of 1.2 GPa at 600 K for 5 h, $[2+2]$ cycloaddition occurs to give polymers including linear polymers in which the C_{60} fragments are linked by cyclobutane rings.¹⁵⁵ The C_{70} fullerene is more difficult to polymerise,¹⁵⁶ which has been explained by steric hindrance to the $[2+2]$ cycloaddition involving the double bonds in the equatorial region of the ellipsoidal cage. Judging by spectroscopic data,¹⁵⁶ heating solid C_{70} fullerene at 750 °C under a pressure of at least 7.5 GPa affords dimers.

Shvartsburg *et al.*¹⁵⁷ have designed a setup permitting generation of the $\text{C}_{120}^{+/-}$, $\text{C}_{130}^{+/-}$ and $\text{C}_{140}^{+/-}$ ions, which are formed upon laser-induced desorption of crude C_{60} films, and measured their mobility and the trajectories. The trajectories of these ions were in satisfactory agreement with those calculated for the dimers produced upon $[2+2]$ cycloaddition. This study is the first experimental proof of the structure of fullerene dimers.¹⁵⁷

Simultaneous laser-induced vaporisation of C_{60} and graphite at a low helium pressure and a temperature of 400–500 °C or 1900–2400 °C gives rise to polymers of the composition $\text{C}_{60}(\text{CC}_{60})_{n-1}$ ($n = 2\text{--}7$), the dimer C_{121} being the predominant species.¹⁵⁸ When the laser radiation intensity is low, polymers dissociate to give the monomeric components, whereas high radiation intensity results in the elimination of C_2 .

During polymerisation of ordinary monomers, C_{60} can be introduced both in the backbone and in the side chain of the polymer formed.

The chain growth reaction during polymerisation of polystyrene in the presence of C_{60} yields stable free radical (polystyrene) C_{60} (see Ref. 159). The C_{60} and C_{70} fullerenes copolymerise with styrene by a standard free radical mechanism both in block and in aromatic solvents;¹⁶⁰ this affords dark-brown polymers soluble in the same solvents as polystyrene and fluorescing more intensely than polystyrene (fluorescence is shifted to the blue region).

High-pressure (0.1 to 1.5 GPa) polymerisation of styrene in the presence of C_{60} gives rise to a mixture containing products both soluble and insoluble in chloroform.¹⁶¹ An insoluble polystyrene with the chains cross-linked by fullerene molecules was isolated from this mixture.

Modification of polymers by C_{60} fullerene fragments changes markedly their physicochemical properties and, in some cases, substantially increases the solubility. A new method for the synthesis of soluble fullerenedated polymers by the reaction of carbanionic polymeric intermediates with C_{60} has been developed.¹⁶²

Poly-4-bromostyrene **99** with pendant fullerenes is readily soluble in most common organic solvents (CCl_4 , CHCl_3 , PhH, THF). Poly(vinylbenzyl chloride) modified with C_{60} fullerene and soluble in organic solvents has been prepared in a similar way.¹⁶³ It was found^{164, 165} that C_{60} fullerene substantially inhibits free-radical polymerisation of vinyl monomers in the presence of AIBN by reacting with the initiator and/or by terminating the chain growth.^{164, 165} This is true for copolymerisation with methyl acrylate, methyl methacrylate, acrylonitrile, vinyl acetate and *N*-vinylpyrrolidine.¹⁶⁴ Only with highly reactive monomers such as cyanoethyl acrylate and cyanovinyl acetate, does C_{60} give copolymers (yields 53% and 65%, respectively). Free-radical copolymerisation of 4-vinylbenzoic acid and 2- or 4-vinylpyridine with C_{60} results in polyelectrolytes.¹⁶⁶ Apparently, in addition to non-linear copolymers, the process yields homopolymers and microparticles, which can be separated from copolymers only using microporous filters.

When styrene or methyl methacrylate is subjected to radical polymerisation in the presence of C_{60} (1 mass % in the reaction mixture), fullerene reacts at early steps of the process. This gives rise to branched structures; the proportion of the linear polymer increases with time. Physicochemical properties of these polymers have been characterised in detail.¹⁶⁷

As noted above, the synthesis of water-soluble fullerene derivatives, in particular water-soluble polymers, is important regarding the investigation of the biological properties of fullerenes. Derivatives of this type have been prepared by covalent attachment of hydrophilic linear polymers to the fullerene fragment.¹⁶⁸ Thus the poly(propionylethyleneimine–ethyleneimine) copolymer is added to methano[60]fullerenedicarboxylic acid in the presence of 1-ethyl-3-(dimethylaminopropionyl)carbodiimide. The reaction is carried out in chloroform at 0 °C. This gives water-soluble polymer **100** with pendant C_{60} groups (molecular mass 49 000) in about 15% yield.

The high solubility of this polymer is due to the presence of the *N,N*-diethylenepropioamide fragment, which is structurally

related to *N,N*-dimethylformamide and *N,N*-dimethylacetamide, miscible with water.

New copolyamides containing dimethanofullerene fragments in the backbone have been synthesised¹⁶⁹ using [60]fullerene-bismethanocarboxylic acid (**101**) (Scheme 2). The polymer forms a brown brittle film capable of coating glass.

Cationic polymerisation involving C_{60} fullerene has been studied.¹⁷⁰ Multicharged cations derived from C_{60} (they are generated¹⁷¹ using a special ion source) are highly reactive in the gas phase. Dications and trications initiate cyclochain polymerisation of allene or propyne under these conditions.¹⁷⁰ More than sixteen allene molecules add to the C_{60}^{2+} dication, odd-numbered adducts reacting approximately 10 times faster than even-numbered ones. It is assumed that multiaddition occurs during the chain growth; the alternation of the reaction rates is attributed to the difference between charge distribution and stability due to the formation of either acyclic or cyclic cation, for example, **102** or **103**.

Studies dealing with the development of conducting and semiconducting polymeric systems involving C_{60} are in progress. One method for the synthesis of conducting polymeric composites is polymerisation on a supporting template.¹⁷² The template is a cross-linked fullerenol–polyurethane elastomer. It is impregnated with aniline; this gives a film, which is brought in contact with an oxidising aqueous solution containing LiCl , $(\text{NH}_4)_2\text{S}_2\text{O}_8$ and HCl at -15 °C and is thus converted into a new elastomer with inserted polyaniline. This product is characterised by much higher conductance than the initial ‘prepolymer’ without losing the elasticity and tensile properties. The presence of the template hampers migration of the conducting species, which is a significant reason for deterioration of the physical properties of the material.

The bisthiophene derivative **104**, functionalised with fullerene, polymerises at the electrode during voltammetry in CH_2Cl_2 in the presence of $\text{Bu}_4^+\text{NPF}_6^-$.¹⁷³

An electrically conducting polymer of the ‘necklace with a pendant’ type was prepared for the first time by anodic oxidation of the bisthiophene derivative containing a fullerene fragment **105**.¹⁷⁴

The change in the photophysical and optical properties of conducting polymers upon the formation of composites with C_{60} fullerene is due to complex formation (resulting in the change in

Scheme 2

the polymer conformation¹⁷⁵) and, what is more important, to the transfer of electrons from the polymer to C₆₀ (see Ref. 176). The spectrum of the film prepared from a mixture of C₆₀ with poly(3-hexylthiophene) exhibits a substantial shift in the UV and visible region.¹⁷⁵ Doping of poly(3-octadecylthiophene) with C₆₀ causes quenching of the polymer photoluminescence.¹⁷⁶ The poly-2-methoxy-5-(2'-ethylhexyloxy)-1,4-phenylvinylene film doped with C₆₀ fullerene is promising for the manufacture of holographic recording materials.¹⁷⁷

VI. Fullerenes in catalysis

Fullerene C₆₀ participates in catalysed processes as either a part of the catalyst and/or a substrate which modifies the action of the catalyst.

The complex $\eta^2\text{-C}_{60}\text{Pd}(\text{PPh}_3)_2$ has been used as the catalyst in the homogeneous (in toluene) and heterogeneous (supported on Sibunit) hydrogenation of 3,7-dimethyloct-6-en-1-yn-3-ol (dehydrolinolool).¹⁷⁸ The process occurs almost selectively (99.5%) as hydrogenation of the triple bond to a double bond; the catalyst activity in the heterogeneous process is maximal and is an order of magnitude higher than that of the traditional catalyst, namely, Pd supported on Sibunit.¹⁷⁸

The tetralin extract of carbon was subjected to hydrocracking in petroleum ether with the addition of a dispersed C₆₀/C₇₀ mixture (90 : 10) and without this mixture. Fullerenes exerted no noticeable effect on the course of hydrocracking.¹⁷⁹

The complex $\text{C}_{60}[\text{Pd}(\text{OAc})_2(\text{PPh}_3)]_3$ was reduced with hydrogen on heating to give a Pd–C₆₀ complex. Phenylacetylene, diphenylacetylene, cyclohexene and hex-1-ene were hydrogenated in the presence of 1 mol. % of this catalyst.¹⁸⁰ Alkenes were completely reduced. The yields were comparable to those attained in the hydrogenation over Pd/C but the reaction occurred faster. The mechanism of the catalytic influence of the C₆₀ substrate is unknown; however, it is assumed that metal fragments form active sites on the C₆₀ spheroid.¹⁸⁰

Photochemical oxidation of alkenes in the presence of silica gel modified with C₆₀(H)CH₂SiMe₂(OPrⁱ) has been carried out.¹²¹

In order to prepare new film-forming materials including those promising as semiconducting films (for example, for the manufacture of diodes), polyaddition of benzene to fullerene in the presence of Kovacic catalyst (CuCl₂ + AlCl₃) has been carried out.¹⁸¹ This gave the compound C₆₀Ph₁₉H₁₉, which might have resulted from the reaction of protonated C₆₀ with benzene. At 400 °C, this compound eliminates hydrogen to give C₆₀Ph₁₉. Both compounds form films from toluene solutions and C₆₀Ph₁₉ exhibits clear-cut luminescence in the blue-green region.

The structure and catalytic properties of ruthenium on the C₆₀ substrate (as well as on crude and extracted fullerene black and on the fullerene cathodic deposit) have been studied.^{182, 183} Highly dispersed amorphous Ru was prepared from Ru₃(CO)₂ by the impregnation/activation method. This system serves as an active catalyst for hydrogenation of CO and 2-cyclohexanone under atmospheric pressure.

The molecular sieve MCM-41 is used to prepare catalysts with high surface areas for reactions with bulky molecules. The addition of C₆₀ changes substantially the behaviour of the sieves during their dehydroxylation on heating, due to the abstraction of the hydroxy groups from the silanol fragments of the sieve to give C–H and C–OH groups followed by condensation of the C–OH groups or combination of C–OH with C–H.¹⁸⁴

Precursors of fullerene-containing chelates of the type

R = H, Me; X = H, Br,

have been synthesised;¹⁸⁵ these compounds may find application as supported catalysts and in homogeneous catalysis.

VII. Prospects for the practical use of fullerenes

Extensive practical use of fullerenes would be largely determined by their availability. According to the data for 1995,¹³ fullerenes were supplied by the Hoechst AG (Germany), SES Research (USA) and MER (USA) companies. The price of C₆₀ fullerene was about \$500 per kg in 1997.¹⁸⁶ Back in 1995 the MER company developed a contact arc process which provided a daily output equal to 30 kg of carbon soot with a high fullerene content. Methanofullerene[60]-61-carboxylic acid is also commercially available (Fluka, Switzerland).

According to the data of MER,¹⁸⁶ attention is attracted first of all by the possibility of using fullerenes for the production of rechargeable galvanic cells, with electrodes made of C₆₀/C₇₀ films applied onto various substrates and for the storage of hydrogen, in particular, in the fuel cells of electric cars, and the storage of adsorbed oxygen (which may be useful in medicine and in military engineering). Fullerenes have been patented as precursors of diamonds and diamond coatings, production of which from fullerenes is energetically more favourable than that from graphite. The use of fullerenes for strengthening metal surfaces upon insertion of carbide particles into a metal matrix is also promising. Films of compounds containing fullerene fragments could be used in nonlinear optics, optical computerisation and in sensor technology as solid sensors.

Molecular donor–acceptor charge transfer complexes can present considerable interest as the initial compounds for the manufacture of new materials,¹⁸⁷ for example, superconductors^{43, 153, 188} (superconductivity transitions up to 40 K have been observed).¹⁸⁸

Nitroxides with a fullerene fragment and various fullerene-pyrrolidines can find use in the synthesis of organic ferromagnets.^{75, 76} Films possessing valuable properties have been prepared based on fullerene-pyrrolidines.^{73, 74} Methano- and pyrrolidino-fullerenes are efficient photosensitisers for the generation of singlet oxygen.¹⁰² The formation of C₆₀ and C₇₀ fullerene adducts with porphyrins of phthalocyanines increases the photoinitiated electrical conductivity of the latter (see Ref. 53 and references therein). Nitrogen-containing fullerene derivatives immobilised on silica gel make it possible to develop new adsorbents.⁷⁰

The potential use of fullerenes as biologically active compounds has stimulated vigorous development of the chemistry of functional derivatives of fullerene, especially after 1993, when it was shown¹⁸⁹ that water-soluble fullerene derivatives with methane bridges inhibit HIV enzymes, namely, protease and reverse transcriptase; data on the biological properties of fullerene derivatives have been published.^{190, 191}

For biological assays, it is necessary to prepare functional derivatives soluble in water or in polar media with a stabilising fragment linked to the fullerene by a covalent bond. Nakamura *et al.*¹⁹¹ have classified the biologically active fullerene derivatives into two types: the detergent type (in which the side chain is modified by, for example, attachment of carboxylic acid residues *via* organic binding groups) and the spherical type, in which there are polar groups distributed over the fullerene sphere (this class includes fullerenols and amino adducts).

VIII. Conclusion

In recent years, exohedral addition and, especially, cycloaddition has remained the main line of functionalisation of fullerenes. These reactions have been employed to prepare a large number of new oxygen- and nitrogen-containing derivatives such as quinones, pyridones, nitrile oxides and pyrrolidine derivatives. The photophysical and photochemical properties of these compounds (fluorescence, phosphorescence) and the redox potentials of these derivatives depend on the degree of functionalisation and posi-

tions of functional groups in fullerene fragments. Fullerene derivatives containing heteroatoms can be used to model the photosensitisation and photosynthesis processes, including those involving singlet oxygen, which is important for the research into biological systems. An important aspect in the studies is development of the methods for selective multifunctionalisation, which would direct the addend to a particular site of the carbon cage.

Among the fundamental studies devoted to the properties of fullerenes, the syntheses of a catenane with a fullerene fragment, the preparation of hydrocarbon salts and the generation of the carbocation consisting of only carbon atoms deserve attention. While Kroto, one of the fullerene discoverers, was amazed by the ability of pure carbon to be dissolved in organic solvents, the preparation of an aqueous colloidal solution of C₆₀ seems even more remarkable.

The potential practical application of fullerenes and their functional derivatives is being studied along several paths. In the case of C₆₀ fullerene, this is mainly production of films deposited on various substrates including diamond-like ones, sensitisers and adsorbents for gases. The synthesis of new complexes and incarcenanes (fullerenes containing an element incorporated in the cage) is aimed at the preparation of new superconductors, dielectrics and ferromagnets. Numerous publications have been devoted to the synthesis of C₆₀ adducts in order to use them as the starting compounds in the synthesis of biologically active products.

The preparation of fullerene-based catalysts and catalytic systems and the synthesis of fullerene-containing polymers have been less developed. The progress along these lines might be expected in the future.

Stable tellurols and their metal derivatives

I D Sadekov, A V Zakharov

Contents

I. Introduction	909
II. Synthesis, reactions and structures of tellurols	909
III. Synthesis, reactions and structures of metal tellurolates	911
IV. Conclusion	922

Abstract. Data on the synthesis, reactions and structures of stable aromatic tellurols and sterically hindered tellurols containing E–TeH bonds (E = C, Si or Ge) are systematised and generalised. Methods for the preparation of various metal derivatives of tellurols as well as applications of these derivatives in the low-temperature synthesis of metal tellurides are considered. The bibliography includes 90 references.

I. Introduction

Tellurium analogues of alcohols and phenols, *viz.*, tellurols (RTeH), belong to a class of organotellurium compounds which are rather poorly studied. First representatives of these compounds, *viz.*, alkanetellurols, were synthesised back in 1926,¹ while rather stable aromatic tellurols, *viz.*, 2,4,6-trialkylbenzenetellurols and tris(trimethylsilyl)silanetellurols, were prepared only in 1991.² Based on these compounds and their analogues and derivatives, a wide range of tellurolates of various metals have been synthesised in recent years. Tellurolates of sterically hindered organoelement tellurols (Me₃Si)₃ETeH (E = C, Si or Ge) are of particular interest because these compounds can be used in the pyrolytic synthesis of metal tellurides. Since these compounds contain E–Te–H bonds (E = Si or Ge), they do not formally belong to tellurols. However, it is reasonable to consider here methods of their preparation, reactions and spectral characteristics, because these derivatives possess unusual properties, in particular, enhanced stability in the crystalline state and in solutions compared to true tellurols. In addition, tellurolates based on the above-mentioned compounds allow one to prepare metal tellurides at relatively low temperatures.^{3–7}

II. Synthesis, reactions and structures of tellurols

1. Synthesis and reactions of tellurols

The first alkanetellurol, *viz.*, ethanetellurol **1a**, was prepared by high-temperature alcoholysis of Al₂Te₃ at 250 °C.¹ Later on, this method was modified by Baroni.⁸ Oxidation of the resulting alkanetellurols can be prevented if the process is performed

under an atmosphere of hydrogen. Apparently, the overall reaction is described by the following equation:

R = Et (**a**), Me (**b**), Pr (**c**), Bu (**d**).

Alkanetellurols **1c,d** were also prepared by the reactions of the corresponding alkyl halides with a solution of sodium ethoxide saturated with hydrogen telluride at low temperature.⁸ However, attempts at synthesising methane- and ethanetellurols **1a,b** according to this procedure have failed.

R = Pr (**c**), Bu (**d**).

The method which is most generally used for the preparation of different types of tellurols involves the reactions of their lithium and sodium salts (methods for their synthesis are discussed in Section III.1) with protic acids. Thus treatment of sodium methanetellurolate, which has been prepared from dimethyl ditelluride upon cleavage of the Te–Te bond with sodium in liquid ammonia, afforded methanetellurol **1b**.^{9–11} Trideuteriomethanetellurol **1e** was prepared analogously.¹¹

R = Me (**b**), CD₃ (**e**); HX = H₂SO₄, H₃PO₄.

The acid H₃PO₄ is a protonating agent of choice¹¹ because the use of even dilute H₂SO₄ leads to partial oxidation of tellurol **1b** to dimethyl ditelluride.

Alkanetellurols **1** are liquids with an unpleasant odour. The yellowish colour of these compounds is caused by the presence of dialkyl ditellurides, which were formed either upon thermal decomposition of tellurols or upon their oxidation with atmospheric oxygen.^{9–11} Tellurols can be stored at the temperature of liquid nitrogen with exclusion of air because they readily decompose at room temperature.¹¹

Decomposition of methanetellurol under UV irradiation occurs in two stages. First, dimethyl ditelluride and hydrogen are formed and then more profound decomposition occurs to form methane, higher hydrocarbons and tellurium.¹¹

Attempts to synthesise benzene- and thiophene-2-tellurols by protonation of their lithium salts with trifluoroacetic acid in THF or of their sodium salts in an ethanol–ethyl acetate mixture have been unsuccessful.¹² Attempts to prepare benzenetellurol upon

Uspekhi Khimii **68** (11) 999–1014 (1999); translated by T N Safonova

methanolysis of (phenyltelluro)trimethylsilane have also failed.^{13–15} However, benzenetellurol^{12, 14, 15} and thiophene-2-tellurol,¹² which are prepared according to the above-described methods *in situ*, are efficient reducing agents for organic compounds.^{12, 15} In the presence of ZnI₂, they are used for converting carbonyl compounds into asymmetrical ethers.¹⁴

Arenetellurols were synthesised by protonolysis of suspensions of sterically hindered lithium arenetellurolates **2** (prepared by reducing the corresponding diaryl ditellurides with lithium triethylborohydride) with HBF₄ etherate in light petroleum. Compounds **3** were obtained in nearly quantitative yields.²

R = Me (**a**), Prⁱ(**b**), Bu^t (**c**).

Arenetellurols **3** are colourless crystalline compounds, which can be recrystallised from light petroleum at $-110\text{ }^{\circ}\text{C}$. However, these compounds are light-sensitive and begin to decompose at -40 to $-30\text{ }^{\circ}\text{C}$ to form metallic tellurium.² The thermal stability of arenetellurols **3** is independent of the bulkiness of the substituents. In particular, tellurol **3a** is more stable than **3c**.²

The most stable tellurols are organoelement tellurols (Me₃Si)₃ETeH (E = C, Si or Ge). Due to the presence of bulky substituents, metal tellurolates prepared from these tellurols are readily soluble in nonpolar organic solvents and exist as monomers or weakly associated aggregates. These properties together with the volatility and high thermal stability allow one to use salts of organoelement tellurols in the pyrolytic synthesis of metal tellurides (see Section III).

The first tellurol containing the Si–TeH bond to be synthesised was triethylsilanetellurol **4a**.¹⁶ This compound was prepared by treatment of bis(triethylsilyl) telluride with an equimolar amount of trifluoroacetic acid at $20\text{ }^{\circ}\text{C}$ and was isolated by vacuum distillation.

Under the action of an excess of CF₃CO₂H, the Si–Te bond in the tellurol **4a** was cleaved and triethylsilyl trifluoroacetate and elemental tellurium were formed as the final reaction products.¹⁶ Apparently, the latter was formed upon oxidation of intermediate H₂Te.

Sterically hindered tris(trimethylsilyl)silanetellurol (**4b**) was synthesised by protonolysis of lithium salts **5a**^{17–19} or **5b**²⁰ with trifluoroacetic acid in hexane^{17–19} or with HCl in toluene.²⁰ The salts **5a**²¹ and **5b**²² were prepared according to a standard procedure for the synthesis of these salts, which involves the insertion of the Te atom at the Si–Li bond in the complexes of tris(trimethylsilyl)silyllithium with THF (**6a**)²¹ or with dioxethane (DME) (**6b**).²²

L = THF: $n = 3$ (**6a**), $m = 2$ (**5a**); L = DME: $n = 1.5$ (**6b**), $m = 1$ (**5b**); HX = HCl, CF₃CO₂H.

Colourless crystalline tellurol **4b** is stable under an argon atmosphere in the dark for at least several days. In sunlight, solid tellurol **4b** turns dark but the spectral characteristics remain unchanged. In solutions, the tellurol **4b** rapidly decomposes under exposure to light to form a tellurium mirror.^{17, 18}

Protonolysis of lithium tris(trimethylsilyl)methanetellurolate (**5c**),²³ tris(trimethylsilyl)germanetellurolate (**5d**)¹⁹ and tris(triphenylsilyl)silanetellurolate (**5e**),²⁴ which have been preliminarily isolated and purified, with trifluoromethanesulfonic acid in ether^{17–19} or with trifluoroacetic acid in hexane²⁴ afforded tellurols **4c–e** in 57%–81% yields. Protonolysis of lithium salts **5e** in diethyl ether, which is more polar than hexane, was accompanied by partial decomposition of the tellurol **4e** resulting also in bis(triphenylsilyl) telluride and H₂Te.²⁴

M = C, R = Me, $n = 2$ (**5c**); M = Ge, R = Me, $n = 3$ (**5d**); M = Si, R = Ph, $n = 3$ (**5e**).

Tellurols **4c–e** are crystalline compounds the colour of which varies from yellow to orange. These compounds melt at temperatures above $120\text{ }^{\circ}\text{C}$. Compounds **4c,d**, like tellurol **4b**, were isolated and purified by sublimation under high vacuum, while tellurol **4e** was purified by recrystallisation from hexane at low temperature. The stability of tellurols **4c,d** is similar to that of tellurol **4b**,¹⁹ whereas tellurol **4e** is more sensitive to atmospheric oxygen.²⁴

The reactions of tellurols governed by the presence of the hydrotelluride function are poorly studied. Oxidation of the tellurol **4b** with oxygen afforded ditelluride **7**. Compound **7** can be more easily synthesised by the oxidation of the tellurolate **5a** with oxygen or CuCl^{17, 18} or by the oxidation of the tellurolate **5b** with iodine, because these procedures exclude the stages of isolation and purification of the tellurol.²⁰

The pK_a values of tellurols **4b–d** and of a number of related thiols and selenols were determined (photometrically, for solutions in isobutyl methyl ketone).¹⁹ The following values were obtained: 7.3 for HTeSi(SiMe₃)₃ (**4b**), 9.3 for HTeC(SiMe₃)₃ (**4c**), 7.4 for HTeGe(SiMe₃)₃ (**4d**), 8.3 for HSe(SiMe₃)₃, 10.7 for HSSi(SiMe₃)₃ (the synthesis was described in Ref. 25) and 10.8 for HSeC(SiMe₃)₃ (the synthesis was described in Ref. 26).

The acid strengths of silane- and germanetellurols **4b,d** are approximately 100 times higher than that of their carbon analogue **4c**. This is also true for the corresponding selenium derivatives. This tendency for the change in the pK_a values was attributed¹⁹ to the lower electronegativity of Si (1.9) and Ge (2.0) compared to C (2.5). For compounds HM(SiMe₃)₃ (M = S, Se or Te), the pK_a values increase in the series Te > Se > S.¹⁹ Thus the tellurol **4b** is a stronger acid than the corresponding selenol and thiol by a factor of 10 and 1000, respectively. The same tendency for the change in the acidity is typical of inorganic hydrides of the corresponding elements.²⁷

2. X-Ray diffraction analysis and ¹H and ¹²⁵Te NMR spectra of tellurols

The molecular and crystal structure of tris(triphenylsilyl)silanetellurol **4e** was established by X-ray diffraction analysis.²⁴ The Te–Si bond length is 2.511 Å and the Te–Si–C angles are in the range of 106.0–109.6°. Unlike Ph₃SiOH, which exists in the crystal as an H-bound tetramer,²⁸ the tellurol **4e** exists as a monomer (like triphenylsilanethiol Ph₃SiSH²⁹). In the crystal, there are no shortened or specific intermolecular contacts smaller than the sum of the van der Waals radii of the elements. Thus the Te···Te distances are 4.64 Å (the sum of the van der Waals radii is 4.40 Å).³⁰ Evidently, hydrogen bonds in the crystal of the tellurol **4e** are absent due to the low electronegativity of the tellurium atom.

The ¹H and ¹²⁵Te NMR spectroscopic data are given in Table 1.

Table 1. Data of ^1H and ^{125}Te NMR spectroscopy of tellurols **2** (CDCl_3 , -20°C), tellurols **4** (PhH , 20°C) and their analogues.

Compound	^1H NMR δ (see ^a)	^{125}Te NMR δ (see ^b)	$J_{\text{Te-H}}$ Hz	Ref.
2,4,6- $\text{Me}_3\text{C}_6\text{H}_2\text{TeH}$ (2a)	-2.68	-91.4	63	2
2,4,6- $\text{Pr}^i_3\text{C}_6\text{H}_2\text{TeH}$ (2b)	-2.95	-134.8	48.6	2
2,4,6- $\text{Bu}^t_3\text{C}_6\text{H}_2\text{TeH}$ (2c)	-1.25	153.8	51.9	2
$(\text{Me}_3\text{Si})_3\text{SiTeH}$ (4b)	-8.82	-955	74	17–19
	-8.83	-955.1	74.6	20
$(\text{Me}_3\text{Si})_3\text{CTeH}$ (4c)	-5.1	-63	101	19

Ph_3SiTeH	-6.45	-684	27.4	24
H_3SiTeH^c	-7.46	—	58	31
H_3GeTeH^c	-7.44	—	52	31

^a The chemical shifts of the protons bound to the Te atoms are given; ^b the chemical shifts relative to Me_2Te ; ^c the spectra were recorded in CDCl_3 at 20°C .³¹

The signals for the protons bound to the Te atoms in the tellurols **4b–e** containing the trimethylsilyl group are observed at substantially higher field (at δ from -6.45 to -8.82) than the analogous signals in the ^1H NMR spectra of the aromatic tellurols **2a–c** (at δ from -1.25 to -2.95). A comparison of the chemical shifts of the protons bound to the chalcogen atoms in the ^1H NMR spectra of tris(trimethylsilyl)silanechalcogenols $(\text{Me}_3\text{Si})_3\text{EH}$ ($\text{E} = \text{S}, \text{Se}$ or Te) are indicative of successive downfield shifts of these signals in the series $\text{Te} < \text{Se} < \text{S}$.¹⁹

The resonance signals for the ^{125}Te nuclei are observed as doublets in a very broad region (more than 1100 ppm), viz., from δ 153.8 for the aromatic tellurol **2c** (see Ref. 2) to δ -955 for tris(trimethylsilyl)silane tellurol **4b**.^{17–20} A substantial upfield shift for the compound **4b** was related to the lower electronegativity of the silyl substituents compared to that of aromatic substituents.¹⁸

III. Synthesis, reactions and structures of metal tellurolates

Until recently, alkane- or arenetellurolates of alkali metals, viz., of lithium, sodium, and, to a lesser degree, of potassium, were the best studied representatives of metal tellurolates. These compounds were prepared either by reduction of the corresponding ditellurides or by insertion of the tellurium atom at the C–Li bond of organolithium derivatives.^{32–36} However, they are unstable and are readily oxidised; therefore, none of these tellurolates was isolated in the individual form and structurally characterised. These compounds prepared *in situ* find wide use in the synthesis of various classes of organotellurium compounds and primarily of ditellurides and tellurides. Mercury(II) tellurolates $\text{Hg}(\text{TePh})_2$,^{37,38} $\text{Hg}(\text{TeC}_6\text{H}_4\text{Me-4})_2$,³⁸ $\text{Hg}(\text{TeC}_6\text{H}_4\text{-OEt-4})_2$,³⁹ $\text{Hg}(\text{TeBu}^n)_2$,⁴⁰ $\text{Hg}(\text{TeBu}^n)_2$,⁴¹ $\text{Hg}(\text{TeC}_2\text{F}_5)_2$ (see Ref. 42) and $\text{Hg}(\text{TeCF}_3)_2$ (see Ref. 43) were isolated in the individual state. However, these compounds in the solid state exist as polymers, which precluded their studies by X-ray diffraction analysis. Only the structure of a complex mercury tellurolate **8** was established by this method⁴⁵ (the synthesis was described in Ref. 44).

$\text{M} = \text{Na}, \text{K}$.

Mercury tellurolates are soluble in coordinating solvents such as 1,2-bis(diethylphosphino)ethane (DEPE) or 1,2-bis(dimethylphosphino)methane (DMPE).⁴¹ When the tellurolate and the

solvent were taken in a ratio of 1:2 or 1:1, coordination polymers or dimeric compounds of the $[\text{Hg}(\text{TePh})_2(\text{DEPE})]_2$ type, respectively, were formed.⁴¹ The structure of the latter compound was established by X-ray diffraction analysis.⁴¹ When heated in the solid state, the complexes of this type decompose to form mercury telluride, phosphine and the corresponding diorganyl ditelluride.⁴¹ The dimeric complexes decompose upon heating in solution.

Rather stable tellurols containing bulky organic radicals have been synthesised recently, which made it possible to carry out systematic studies of their reactivities and the properties of the respective metal tellurolates (these data were most completely surveyed in a review⁴).

In this section, we consider methods for the synthesis, reactions and crystal structures of metal tellurolates containing bulky organic radicals. We restrict ourselves to consideration of tellurolates in which metal atoms are bound only to tellurium atoms. Tellurolates of other types, for example, tellurolates of metal cyclopentadienyl derivatives are not considered in detail (the data on these compounds were reported in the review⁴).

1. General methods for the synthesis of metal tellurolates

Presently, four major procedures for the preparation of metal tellurolates are known. These tellurolates were isolated in the individual state and in some cases were characterised by X-ray diffraction analysis.

1. Tellurololysis of the M–N bond in metal *N*-trimethylsilylamides with stable free tellurols (most widely used).

This method was used for the preparation of tellurolates of Li,^{18,19} Na,¹⁸ K,¹⁸ Ca,^{46–48} Sr,^{46,47} Ba,^{46,47} Zn,^{17,49,50} Cd,^{2,49} Hg,^{49,51} Mn(II),^{52,53} Sn(II),⁵⁴ Pb(II),⁵⁴ Fe(II),⁵² divalent lanthanides (Eu,⁵⁵ Sm⁵⁵ and Yb⁵⁵) and trivalent lanthanides (La⁵⁶ and Ce⁵⁶) as well as of Al(III),⁵⁷ Sb(III)⁵⁷ $\{\text{Sb}(\text{NMe}_2)_3$ was used in the synthesis of $\text{Sb}[\text{TeSi}(\text{SiMe}_3)_3]_3$ and Bi(III).⁵⁷ Tellurolates of Mg,^{46,47} Zn,¹⁷ In(III),⁵⁷ Tl(I),⁵⁷ Zr(IV)⁵⁸ and Hf(IV)⁵⁸ were prepared by tellurololysis of the M–C bonds in metal alkyls or metal cyclopentadienyl derivatives with the use of tris(trimethylsilyl)silane tellurol **4b**.

2. Exchange reactions of metal tellurolates (most often, of lithium derivatives) with metal halides. These reactions are of a rather general character as well.

$\text{M} = \text{Li}, \text{Na}; \text{X} = \text{Cl}, \text{Br}$.

This method was used for the preparation of tellurolates of Cu(I),⁵⁹ Au(I),⁶⁰ Cd,⁶¹ Hg,^{49,51} Mn(II),⁵² Fe(II),⁵² Co(I),⁵² Cr(II),⁵² Ga(III)⁵⁷ and In(I).⁵⁷ Sodium tellurolates were used in the synthesis of Zn and Cd tellurolates.⁶² Tellurolates of divalent lanthanides (Yb, Sm and Eu,^{63,64}) were synthesised with the use of potassium derivatives of sterically hindered tellurols because it is impossible to separate lanthanide tellurolates from lithium or sodium halides formed in the exchange reactions with the use of lithium or sodium salts.

3. Reduction of the corresponding ditellurides with lithium triethylborohydride,^{61,65} sodium amalgam,^{18,61,66} potassium amalgam¹⁸ or potassium tris(*sec*-butyl)borohydride^{61,66} allows one to synthesise alkali metal tellurolates with sterically hindered ligands. The insertion of some metals (Hg,^{37–39,41–43,51} Cd⁴³ or Yb⁶⁷) at the Te–Te bond of tellurides also belongs to reduction reactions. This method was used primarily for the preparation of metal tellurolates **9a–f, i, j** containing not-very-bulky substituents at the tellurium atom. However, tellurolates **9g, h, j** were also synthesised by this method.⁵¹

Compound 9	M	R	Ref.
a	Hg	Ph	37, 38
b	Hg	4-MeC ₆ H ₄	38
c	Hg	4-EtOC ₆ H ₄	39
d	Hg	Bu	41
e	Hg	C ₂ F ₅	42
f	Hg	CF ₃	43
g	Hg	2,4,6-Me ₃ C ₆ H ₂	51
h	Hg	2,4,6-Pr ₃ C ₆ H ₂	51
i	Cd	CF ₃	43
j	Yb	Ph	67

It should be noted that dimesityl ditelluride readily reacts with metallic mercury in toluene at room temperature without a solvent to form mercury mesitylenetelluroate **9g**,⁵¹ while the reaction of bis(2,4,6-triisopropylphenyl) ditelluride is performed in a polar solvent, such as methanol, at room temperature. The latter reaction is reversible and the telluroate **9h** decomposes to the corresponding ditelluride and metallic mercury upon heating in methanol or upon recrystallisation from nonpolar solvents. Attempts to prepare mercury bis(2,4,6-tri-*tert*-butylphenyl)telluroate by the reaction of the corresponding ditelluride with metallic mercury have been unsuccessful.⁵¹

Ytterbium di(benzenetelluroate) was synthesised in liquid ammonia. After evaporation of the solvent and extraction with pyridine, the complex with composition (PhTe)₂Yb(Py)₅ was isolated.⁶⁷ Attempts to prepare Yb(III) telluroate by the reaction of Yb(III) chloride with sodium benzenetelluroate have failed because Yb(III) was reduced to Yb(II) and the same complex of divalent Yb, *viz.*, (PhTe)₂Yb(Py)₅, has been obtained as the only product.⁶⁷

The only copper(I) telluroate prepared by insertion of the copper atom at the Te–Te bond was Cu(I) trifluoromethane-telluroate.⁴³

Boiling of diaryl ditellurides with a copper powder in dioxane resulted in elimination of one tellurium atom to form diaryl tellurides in virtually quantitative yields.^{35, 36}

4. Insertion of the tellurium atom at the C–Li bond of the corresponding lithium derivatives was used for the preparation of lithium derivatives of some sterically hindered telluroles.^{17–20, 23, 61, 68}

Thus the reactions of organic derivatives of Al(I)⁶⁹ and In(I)⁷⁰ with elemental tellurium in toluene or hexane gave compounds **10a, b** in yields of > 80%. The structures of both compounds contain distorted heterocubane molecular cores M₄Te₄ (M = Al or In) (data from X-ray diffraction analysis).^{69, 70}

M = Al, R = C₅Me₅ (**a**); M = In, R = (Me₃Si)₃C (**b**).

The insertion of the Te atom at the M–C bond of tris(*tert*-butyl)gallium^{71, 72} or -aluminium⁷¹ occurs on stirring of a mixture of the reagents in toluene at room temperature. In this case, telluroates **11a, b** were obtained in ~ 60% yields. In boiling toluene, compounds **10c, d** were formed. These compounds were also formed upon heating of dimers **11a, b**.⁷² The structure of aluminium telluroate **11b** was established by X-ray diffraction analysis.⁷¹

M = Ga (**10c, 11a**), Al (**10d, 11b**).

The two latter methods are less common because they allow one to prepare telluroates of only a limited number of metals.

2. Alkali metal telluroates

Alkali metal telluroates were synthesised according to methods 1, 3 and 4 (primarily, according to methods 3 and 4). Tellurolysis of lithium and sodium bis(trimethylsilyl)amides with tris(trimethylsilyl)silanetelluroate **4b** afforded lithium telluroate **5f**¹⁸ and sodium telluroate **5g**.¹⁸ The reactions performed in hexane yielded alkali metal telluroates, which are not coordinated by solvent molecules or donor ligands.

M = Li (**f**, 54%), Na (**g**, 61%).

Potassium telluroate **5h** was prepared by the reaction of the telluroate **4b** with Bu^tOK.¹⁸

Alkali metal telluroates containing the bulky tris(trimethylsilyl)silyl or aryl substituents were prepared by reducing the corresponding ditellurides (method 3). The reactions are generally carried out in THF at room temperature. The resulting telluroates are isolated as complexes with THF or with other donor ligands. Thus reduction of the ditelluride **7** with potassium or sodium amalgam gave telluroates **5i, j** as complexes with THF or tetramethylethylenediamine (TMEDA).¹⁸

The reactions of ditellurides **12** (R = Me or Prⁱ) with lithium triethylborohydride in THF,⁶¹ with sodium amalgam in the presence of TMEDA^{61, 66} or DME⁶¹ as well as with potassium tris(*sec*-butyl)borohydride either in THF⁶¹ or followed by treatment with crown ether (18-C-6)⁶⁶ afforded complexes of telluroates **13a–f**.

Compound 13	Reducing agent	R	M	L	n	Yield (%)
a	LiBEt ₃ H	Me	Li	THF	1.5	80
b	LiBEt ₃ H	Pr ⁱ	Li	THF	2.5	48
c	Na/Hg	Me	Na	TMEDA	2	80
d	Na/Hg	Pr ⁱ	Na	DME	1	64
e	KBu ₃ BH	Pr ⁱ	K	THF	1.33	40
f	KBu ₃ BH	Pr ⁱ	K	18-C-6	1	47

Complexes of lithium telluroates were also prepared by the reactions of elementary tellurium with organolithium compounds.

Complexes **5b, k** were synthesised by the reaction of powdered tellurium with organolithium compound **14**.¹⁸

L = DME (**5b**, 82%), 12-C-4 (**k**, 79%).

The reaction of the lithium derivative **14** with Te in DME gave the complex **5b** in 72% yield.²⁰ Complexes of tellurolates **5c,d**,¹⁹ **15**^{61,68} and **16**⁶¹ were synthesised analogously.

M = C (**c**, 56%), Ge (**d**, 48%).

Complexes of alkali metal tellurolates containing bulky substituents are thermally stable at room temperature and can be stored without decomposition under an inert atmosphere for a long period of time. However, these compounds are readily oxidised in the solid state and in solution with atmospheric oxygen to give the corresponding ditellurides. As can be seen from the above-considered reactions, THF in the complexes is readily replaced by stronger donor ligands such as DME, TMEDA, 18-C-6 or 12-C-4.

Some reactions which were studied using alkali metal tellurolates **5a**^{17–19} and **5b**²⁰ as examples are shown in Scheme 1.

Scheme 1

E = Se (93%), S (90%).

It is known³⁶ that lithium and sodium alkane- and arenetellurolates are oxidised to the corresponding ditellurides. In this respect, the behaviour of lithium tris(trimethylsilyl)silane-tellurolate (**5e**) is unusual.²⁴ Its oxidation with atmospheric oxygen or the reaction with CuCl afforded only $(\text{Ph}_3\text{Si})_2\text{Te}$.²⁴

The exchange reactions of tellurium atoms in diaryl ditellurides³⁶ and in some tellurium-containing heterocycles⁷³ for sulfur or selenium atoms have long been known. These reactions proceed at high temperature. The tellurolate **5a** reacts with S or Se at -55°C . Based on this fact, Bonasia *et al.*¹⁹ considered the reactions of the tellurolate **5a** with selenium and sulfur (metathesis) yielding lithium tris(trimethylsilyl)silaneselenolate and -thiolate to be a new type of reactions in the chemistry of chalcogens.

X = Se, S.

Reactions of the tellurolate **5a** with chalcogens occur as the replacement of tellurium by a lighter chalcogen. It is known that in the reactions of lithium alkane- and arenetellurolates, lighter chalcogens are inserted into the bond between heavier chalcogen and lithium atoms to form lithium chalcogenylchalcogenolates **17**.⁷⁴

E¹ = Te; E² = Se, S; E¹ = Se, E² = S.

Unlike with lithium tris(trimethylsilyl)silane-tellurolate **5a**, the reaction of the carbon analogue of this compound, *viz.*, lithium tris(trimethylsilyl)methanetellurolate **5c**, with selenium at -55°C resulted in a dark-red solution containing, according to the ¹²⁵Te NMR spectrum, lithium tellurenylselenolate **18**. Attempts at isolating this compound in the solid state have led to its decomposition into a mixture of nonidentified compounds.¹⁹

The exchange reactions of tellurolates **5a** and **5e** with cyclopentadienyl complexes of Ti, Zr and Hf made it possible to synthesise new tellurium-containing complexes **19a–j**.^{24,75} The structures of the compounds **19d**, **g**⁷⁵ and **19f**²⁴ were established by X-ray diffraction analysis.

Compound 19	Cp	M	R	Yield (%)
a	C ₅ H ₅	Ti	Ph	75
b	C ₅ Me ₅	Ti	Ph	55
c	C ₅ H ₅	Ti	Me	86
d	C ₅ Me ₅	Ti	Me	70
e	C ₅ H ₅	Zr	Ph	71
f	C ₅ H ₄ Bu ^t	Zr	Ph	74
g	C ₅ H ₅	Zr	Me	75
h	C ₅ H ₅	Hf	Ph	67
i	C ₅ H ₄ Bu ^t	Hf	Ph	33
j	C ₅ H ₅	Hf	Me	72

Compounds of the type **19** were also formed in the reactions of lithium tellurolate **5c** with metal complexes.⁷⁵ However, the resulting products rapidly decomposed to give eventually Te, HC(SiMe₃)₃ and a mixture of nonidentified metal-containing compounds.

In the reactions of Ti, Zr and Hf cyclopentadienyl complexes with the tellurolate **5a**, the nature of the solvent is of considerable importance. Thus the reactions in hexane afforded tellurolates **19**, while the reaction of the compound **5a** with titanium complex in THF yielded the dimeric complex **20** and the ditelluride **7**.⁷⁵

The reactions of tellurolates **13a,b** with *cis*-bis(triphenylphosphine)platinum dichloride resulted in displacement of one chloride ligand to form tellurium-containing platinum complexes **21a,b**. The structure of the complex **21b** was established by X-ray diffraction analysis.⁶¹

R = Me (a), Prⁱ (b).

The structures of many complexes of alkali metal tellurolates with Lewis bases were established by X-ray diffraction analysis. Below are considered the characteristic structural features of these compounds. In the crystal, lithium tellurolate (THF)₂LiTe–Si(SiMe₃)₃ (**5a**) exists as dimers and contains the Li₂Te₂ core. The Te–Li bond lengths in the ring (2.82 and 2.88 Å) are close to the values predicted based on the ionic radii (Li⁺, 0.73 Å; Te^{2–}, 2.07 Å).⁷⁶ The Te–Si and Li–O bond lengths are 2.48 and 1.90 Å, respectively. The Li–Te–Li and Te–Li–Te bond angles are 90.4 and 89.6°, respectively.¹⁸

In lithium tellurolate **16**, the Li atom is tetrahedrally coordinated by two oxygen atoms of DME, the nitrogen atom and the tellurium atom.⁶¹ The Te–Li distance in this compound (2.717 Å) is smaller than that in the tellurolate **5a**. The Te–C bond length (2.142 Å) has the standard value.⁷⁷ The Te–Li–O bond angles are 125.8 and 118.2° and the Te–Li–N angle is 99.6°. However, it remains unclear whether this molecule retains N→Te coordination, which has been observed in analogous compounds with tellurium-containing substituents in the *ortho* position with respect to the CH(R)NMe₂ group (R = H or Me) in the aromatic rings [the N→Te bond lengths are 2.366⁷⁸ and 2.406 Å⁷⁹ in 2-iodotellurenylbenzyl dimethylamine and 2-(1-dimethylaminoethyl)benzenetellurium trichloride, respectively, which are substantially smaller than the sum of the van der Waals radii of Te and N (3.70 Å)³⁰].

In the complex **15**⁶¹ containing a bulky aryl substituent, the C–Te–Li angle is 99.1°, whereas the corresponding angles in the structurally similar sodium tellurolate **13c**⁶⁶ and potassium tellurolate **13f**⁶⁶ are 102.2° and 77.7°, respectively. The aryl ligand in the tellurolate **15** is planar. The Te atom deviates from the plane by 0.56 Å. The Te–Li bond length (2.82 Å) is close to the corresponding bond length in the tellurolate **5a**. The Te–C and Li–O bond lengths are 2.184 and 1.95 Å, respectively. The Te–Li–O angles are in the range of 108.8–115.2°.

In the crystal, potassium tellurolate **13f** exists as monomers. The Te–K distance (3.499 Å) is indicative of a weak interaction between the alkali metal atom and the tellurolate anion.⁶⁶ The Te–C distance is 2.15 Å and the C–Te–K angle is 77.68°. The average K–O bond length is 2.849 Å.

3. Alkaline-earth metal tellurolates

The major method for the preparation of alkaline-earth metal tellurolates **22** involves tellurololysis of di[bis(trimethylsilyl)amides] of the corresponding metals with tris(trimethylsilyl)silanetellurol **4b** in hexane at room temperature (the amide:tellurolol ratio is 1:2). In most cases, the resulting tellurolates were isolated as adducts with different Lewis bases.^{46,47}

Compound 22	M	L	<i>n</i>	Yield (%)
a	Mg	THF	2	68
b	Mg	Py	2	73
c	Mg	12-C-4	2	50
d	Ca	THF	4	46
e	Ca	Py	4	66
f	Sr	THF	4	25
g	Sr	Py	4	75
h	Ba	THF	4	52
i	Ba	Py	5	73

The reaction performed in toluene afforded compound **22d** in 85% yield.⁴⁸

Magnesium tellurolate **22j**, which does not contain coordinating solvents, was synthesised by tellurololysis of the Mg–C bond of dibutylmagnesium.^{46,47}

A complex of magnesium **22a** with tetrahydrofuran was prepared⁴⁷ by the reaction of mercury bis[tris(trimethylsilyl)silanetellurolate]⁴⁹ with an excess of powdered Mg in THF (the yield was 44%).

Tellurolates **22a–j** are yellow crystalline compounds, which are readily soluble in hydrocarbons and ether. These compounds are sensitive to atmospheric oxygen and moisture but can be stored under an inert atmosphere at room temperature for a long period of time. The reactions of tellurolates **22** with oxygen afforded ditelluride **7** and the reactions with water yielded the tellurol **4b**.

The tetrahydrofuran complexes slowly lose coordinated solvent molecules at room temperature and are readily converted into the pyridine complexes upon recrystallisation from pyridine.^{46,47} Treatment of magnesium tellurolates **22a, b** with 12-crown-4 resulted in replacement of both the coordinated solvent molecules (pyridine or THF) and the tellurolate ligands to form the ionic complex **22c**.^{46,47}

The ¹H NMR spectra of magnesium tellurolate **22j** in toluene-*d*₈ are indicative of the stereochemical flexibility of the latter in solutions.⁴⁷ At 20 °C, the ¹H NMR spectrum has a singlet signal, which is broadened as the temperature is decreased and is split into two peaks at –90 °C.⁴⁷ Apparently, this is due to a slow (within the NMR time scale) intramolecular exchange of the bridging and terminal ligands in the dimeric structure of the tellurolate at low temperature.⁴⁷

In the ¹²⁵Te NMR spectra of pyridine adducts **22b, e, g, i**, the signals for the ¹²⁵Te nuclei are observed in a rather narrow region from δ –1578 to –1405^{46,47} (Table 2).

The molecular and crystal structures of the tellurolates **22a**,^{46,47} **22d**^{46–48} and **22i**⁴⁷ were established by X-ray diffraction analysis.

In magnesium tellurolate **22a**, the Mg atom is tetrahedrally coordinated by two oxygen atoms of two THF molecules and two tellurium atoms.^{46,47} The Mg–Te bond lengths have similar values (2.720 and 2.714 Å), the Mg–O bond lengths are in the range of 2.035–2.038 Å and the Te–Mg–Te and O–Mg–O angles are 135.48 and 94.8°, respectively. The Te–Mg–O angles are nonequivalent, one angle at each tellurium atom being large (111.77 and 144.37°) and one angle being small (96.37 and 94.79°). This may be due to steric repulsions from the lone electron pairs of the tellurium atoms although a crystal packing effect is not ruled out.^{46,47}

The results of two independent crystallographic studies^{46,48} of calcium tellurolate **22d** agree with each other. The coordination polyhedron about the Ca atom is a distorted octahedron. The Ca–Te distance is 3.19 Å and the Ca–O distances are 2.36 and

Table 2. Data of ^{125}Te NMR spectroscopy of metal tellurolates.^a

^a The chemical shifts are given relative to Me_2Te ; ^b $J_{\text{Te}-\text{Cd}} = 1059$ Hz;^c $J_{\text{Te}-\text{Cd}} = 1821$ Hz; ^d $J_{\text{Te}-\text{Cd}} = 744$ Hz, $J_{\text{Te}-\text{P}} = 137$ Hz;^e $J_{\text{Te}-\text{P}} = 64$ Hz; ^f $J_{\text{Te}-\text{P}} = 79$ Hz; ^g $J_{\text{Te}-\text{P}} = 80$ Hz; ^h $J_{\text{Te}-\text{P}} = 78$ Hz;ⁱ the solvent is not mentioned; ^j t, $J_{\text{Te}-\text{P}} = 166$ Hz; ^k t, $J_{\text{Te}-\text{P}} = 190$ Hz.

2.41 Å. The tellurium ligands are in *trans* positions. The Ca—Te—Si angle is 128.5°.

In barium tellurolate **22i**, the five pyridine ligands are located in the equatorial plane and the two tellurium ligands are in axial positions. The Ba—Te distances are 3.38 Å, the Ba—N distance (average value) is 2.888 Å and the Ba—Te—Ba angle is 171.9°.⁴⁷

4. Aluminium, gallium, indium, antimony and bismuth tellurolates

In this section, we discuss methods for the synthesis of aluminium, gallium and indium tellurolates containing bulky substituents at the tellurium atom.

Tellurolates of Group IIIA elements were synthesised by tellurololysis of the N—M and C—M bonds with the tellurol **4b** (method 1).⁵⁷ This procedure was used for the preparation of tellurolates of Al **23a**, In(III) **23b** and Bi(III) **23c**.

Tellurololysis of the C—M bonds afforded tellurolates of In(I) **24a** and Tl(I) **24b**. Compound **24b** was isolated as a solvate with composition $\text{Tl}[\text{TeSi}(\text{SiMe}_3)_3](\text{C}_6\text{H}_{14})_{0.125}$.

M = In (**a**, 43%), Tl (**b**, 80%).

The synthesis of Sb(III) tellurolate **23d** was performed by the tellurololysis of tris(dimethylamino)antimony (**25**) instead of the antimony trimethylsilylamide derivative.⁵⁷

It should be noted that tris(dimethylamino) derivatives of Sb and Bi are convenient starting compounds in the low-temperature synthesis of tellurides of the corresponding elements. Thus polycrystalline Sb_2Te_3 and Bi_2Te_3 were prepared in high yields by the reactions of $(\text{Me}_2\text{N})_3\text{M}$ (M = Sb and Bi, respectively) with bis(trimethylsilyl) telluride.⁸⁰

M = Sb, Bi.

Method 2 consisting in the exchange reaction of metal tellurolates with metal halides is of lesser importance due to lower yields and lesser purity of the compounds formed. Thus tellurolates of Ga(III) **23e** and In(I) **24b** were synthesised by the reactions of the corresponding chlorides with lithium tris(trimethylsilyl)silanetellurolate **5a**.⁵⁷

Attempts to prepare Tl(III) tellurolate by the exchange reaction have been unsuccessful because the tellurolate **5a** was oxidised to the ditelluride **7** in the course of the reaction.⁵⁷

The tellurolate **22n** forms analogous adducts with a number of other monodentate phosphorus-containing ligands, *viz.*, with Me_2PPh , Et_3P and $(\text{cyclo-C}_6\text{H}_{11})_3\text{P}$. However, these adducts were not isolated in the individual state. Their formation was judged from the presence of high-field signals in the ^{31}P NMR spectra of solutions. Weak Lewis bases, such as Ph_3P and $(\text{MeO})_3\text{P}$, do not form complexes with **22n**.⁵⁴

Pyrolysis of the tellurolates **22n,o** under a stream of nitrogen at 250 °C afforded cubic tellurides SnTe and PbTe . However, these compounds contained admixtures of small amounts of carbon and hydrogen.⁵⁴ Thermolysis of the tellurolates **22n,o** can be performed by heating them in aromatic hydrocarbons. Thus PbTe was prepared by heating the tellurolate **22o** in toluene at 100 °C for 22 h. The addition of Lewis bases to solutions of the tellurolates **22n,o** promotes their decomposition to form metal tellurides. Thus the tellurolate **22o** was quantitatively converted into PbTe upon addition of an excess of MeCN to an ethereal solution.

Like silylamides of other metals, Fe(II) and Mn(II) di[bis(trimethylsilyl)amides] reacted with the tellurol **4b** in hexane at room temperature. However, attempts to purify the resulting tellurolates failed because of their very high solubility.⁵² Tellurolysis of Fe(II) and Mn(II) silylamides in the presence of Lewis bases afforded stable crystalline adducts **34a–c**.⁵²

$\text{M} = \text{Mn}$; $n = 1$, $\text{L} = \text{DMPE}$ (**34a**, 79%);

$n = 2$, $\text{L} = \text{Bu}^t\text{-C}_6\text{H}_4\text{N}$ (**34b**, 81%);

$\text{M} = \text{Fe}$, $n = 2$, $\text{L} = \text{DMPE}$ (**34c**, 71%).

The reaction of manganese silylamide with the sterically hindered arenetellurol **3a** was performed in the usual fashion and gave Mn(II) arenetellurolate **26e** in 95% yield.⁵³

Fe(II) , Mn(II) and Cr(II) tellurolates **34a, c, d** were also prepared by the exchange reactions.⁵² Since the reactions of dihalides of these elements with lithium tellurolate **5a** afford the ditelluride **7** and insoluble pyrophoric products with unidentified structures, the exchange reactions are carried out either in the presence of Lewis bases or starting from adducts of metal halides with DMPE .⁵²

$\text{X} = \text{Cl, I}$; $\text{M} = \text{Mn}$, $n = 1$ (**34a**, 80%); $\text{M} = \text{Fe}$, $n = 2$ (**34c**, 79%); $\text{M} = \text{Cr}$, $n = 2$ (**34d**, 74%).

The reaction of lithium tellurolate **5a** with CoBr_2 yielded Co(I) tellurolate **35** as the final product due to strong reducing properties of the compound **5a**.⁵²

The reaction of the adduct $\text{FeCl}_2(\text{DMPE})_2$ with the tellurolate **5a** (taken in an equimolar ratio) afforded tellurolate **36** with mixed

ligands (the yield was 88%).⁵² This compound was also prepared in 82% yield by ligand exchange between the tellurolate **34c** and $\text{FeCl}_2(\text{DMPE})_2$.

The Fe(II) tellurolate complex **34c** differs from other tellurolates and their complexes in the lability of the tellurolate ligands. This is evidenced by the above-considered ligand exchange reaction as well as by the data on the conductivity of a solution of the compound **34c** in MeCN .⁵² The molar conductivity of the solution ($182 \Omega^{-1} \text{cm}^2 \text{mol}^{-1}$) corresponds to that of an 1:1 electrolyte. Recrystallisation of the complex **34c** from MeCN afforded a salt-like complex **37**.⁵²

The complexes **34a–c** are coloured crystalline compounds, which are readily soluble in hydrocarbons. These compounds are air- and moisture-sensitive but are stable under nitrogen at room temperature. Among them, Mn(II) complexes **34a, b** are the most air-sensitive (they are oxidised in a few seconds). The complexes **34a–c** cannot be sublimed because they decompose on heating ($100\text{--}200^\circ\text{C}$, 10^{-3} Torr).⁵²

The complexes **34a, b, d** are paramagnetic. The magnetic moments are $2.7\text{--}5.9 \mu_B$.⁵² In the ^1H NMR spectra, the signals for the $\text{Si}(\text{SiMe}_3)_3$ groups are broad and are shifted downfield by 2–4 ppm compared to the signals for the analogous groups in diamagnetic compounds. Unlike silane complexes **34a, b**, Mn(II) arenetellurolate complex **26e** is soluble only in coordinating solvents like other polymeric complexes. The complex **26e** is extremely air-sensitive and does not sublime.⁵³ The reaction of the tellurolate **26e** with bipyridine gave the complex $[(2,4,6\text{-Me}_3\text{C}_6\text{H}_2\text{Te})_2\text{Mn}]_2(\text{bipy})_3$, which is substantially more soluble than the initial tellurolate.

The molecular and crystal structures of Sn(II) tellurolate **22n**⁵⁴ and of tellurolate complexes of Sn **33a**,⁵⁴ Mn **34a**,⁵² Fe (**34c** and **36b**)⁵² and Co **35**⁵² were established by X-ray diffraction analysis.

In the crystal, the tellurolate **22n** has the dimeric structure.⁵⁴ The Sn_2Te_2 core is nonplanar. The $\text{Sn} - \text{Te} - \text{Sn}$ and $\text{Te} - \text{Sn} - \text{Te}$ angles are 91.65° and 78.71° , respectively. The ligands are in *cis* positions. Thus, the fact that the metal atom bears a lone electron pair is the reason for the formation of a structure which differs from that of $\{\text{Zn}[\text{TeSi}(\text{SiMe}_3)_3]_2\}_2$ (**22k**).⁴⁹ In the compound **22k**, the tellurolate ligands are in *trans* positions. The bridging $\text{Sn} - \text{Te}$ bonds (2.946 and 2.956 Å) are substantially longer than the $\text{Sn} - \text{Te}_{\text{termin}}$ bonds (2.800 Å).

The $\text{Te} - \text{Si}$ bond length is 2.531 Å. The average $\text{Te}_{\text{bridg}} - \text{Sn} - \text{Te}_{\text{termin}}$ and $\text{Sn} - \text{Te}_{\text{bridg}} - \text{Si}$ angles are 89.27° and 107.22° , respectively.

In the complex **33a**, the geometry of the bonds about the tin atom is trigonal-bipyramidal.⁵⁴ The $\text{Te} - \text{Sn} - \text{Te}$ angle (98.86°) is somewhat larger than that in the initial tellurolate. The $\text{Te} - \text{Sn}$ bonds (2.834 and 2.849 Å) are somewhat longer than the $\text{Sn} - \text{Te}_{\text{termin}}$ bonds in the compound **22n**.

7. Copper, silver and gold tellurolates

Of copper, silver and gold tellurolates, only Cu(I) tellurolates which do not contain bulky organic radicals at the Te atom have been described previously. These compounds were prepared by the exchange reactions of sodium tellurolates with CuCl ^{84,85} or by the reactions of CuCl with triphenylstannyl tellurides **38a–c**.^{85,86}

The latter method is a procedure of choice because it allows one to obtain analytically pure tellurolates **39a–e** in higher yields.

R = Et (**a**), Bu (**b**), C₅H₁₁ (**c**), Ph (**d**), 4-EtOC₆H₄ (**e**).

The synthesis of Cu(I) benzenetellurolate **39d** was performed with the use of the corresponding germanium and lead derivatives, *viz.*, Ph₃GeTePh and Ph₃PbTePh, instead of Ph₃SnTePh.⁸⁷

The tellurolates **39a–d** are brown insoluble powders, which have apparently the polymeric structures.^{85, 86}

Attempts to prepare Cu(I) and Ag(I) tellurolates with bulky organic radicals by the exchange reactions of metal chlorides with lithium tellurolate **5a** have been unsuccessful.⁵⁹ Since tris(trimethylsilyl)silanetellurolate **5a** is a stronger reducing agent than the usual lithium and sodium tellurolates, it is readily oxidised by Cu(I) and Ag(I) chlorides to the ditelluride **7**.

However, the reactions with the use of a weaker reducing agent, *viz.*, lithium [tris(trimethylsilyl)]methanetellurolate (**5c**), instead of the tellurolate **5a** afforded Cu and Ag tellurolates **40a, b** with the bulky organic substituent at the tellurium atom.⁵⁹ The tellurolates **40a, b** were synthesised by the reactions of the tellurolate **5c** with tricyclohexylphosphine complexes of metal halides in toluene at room temperature and were isolated as the complexes with P(cyclo-C₆H₁₁)₃.⁵⁹

M = Cu, X = BF₄ (**a**, 51%); M = Ag, X = Br (**b**).

The synthesis of Au(I) tellurolates with sterically hindered radicals was carried out only by the exchange reactions.⁶⁰ Thus free Au tellurolates **41a–c** were prepared by the reactions of AuCl·THF with lithium tellurolates **5a, c, d**. The conditions for the preparation of Au(I) tellurolates are determined by the stability of the resulting compounds. Alkane-type tellurolate **41a** was synthesised in benzene at room temperature, while thermally unstable analogues, *viz.*, silane analogue **41b** and germane analogue **41c**, were prepared in ether at –78 °C. The latter two tellurolates were contaminated by LiCl. Attempts to purify these compounds led to their decomposition.

E = C (**41a**, 42%), Si (**41b**), Ge (**41c**).

Complexes of tellurolates **41a–c** with Ph₃P were synthesised by the exchange reactions between tellurolates **5a, c, d** and the AuCl triphenylphosphine complex.⁶⁰ The reactions were carried out under conditions identical with those used in the reactions with free tellurolates. The difference was that alkanetellurolate complex **42a** was also prepared in ether. The complex **42a** was synthesised by the reaction of the tellurolate **41a** with Ph₃P in benzene.⁶⁰

E = C (**42a**, 65%), Si (**42b**), Ge (**42c**).

The tellurolates **41a–c** are crystalline compounds, which differ substantially in thermal stabilities. Of these compounds, Au(I) alkanetellurolate **41a** is most stable, it decomposes only on melting and is resistant to water and air. Tellurolates **41b, c** decompose in solution even at –40 °C, which precludes their recrystallisation and purification. In the solid state, these compounds are resistant to water and air for at least 1–3 h.⁶⁰

The nature of the element bound to three trimethylsilyl groups affects the composition of thermal decomposition products of Au(I) tellurolates and their triphenylphosphine complexes. Only alkanetellurolate **41a** decomposes analogously to tellurolates of other metals containing the bulky (Me₃Si)₃SiTe group [Zn, Cd,⁸³ Sn, Pb,⁵⁴ lanthanides(II),⁵⁵ lanthanides(III)⁵⁶ and Zr⁵⁸] to form bis[tris(trimethylsilyl)methyl] telluride **43** and, apparently, gold telluride.

Decomposition of silane- and germanetellurolates proceeded in a different manner. Thus the tellurolate **41b** gave compound **44** as the major product. The analogous mixed germyl silyl telluride **45** was obtained from the tellurolate **41c**.

In the ¹²⁵Te NMR spectra of the tellurolates **41a–c** (see Table 2), the signals are substantially shifted upfield on going from alkanetellurolate **41a** (δ –302) to silanetellurolate **41b** (δ –1112) and germanetellurolate **41c** (δ –1093). Bonasia *et al.*⁶⁰ attributed this fact to stronger shielding of the tellurium atom in the compounds **41b, c**.

The molecular and crystal structures of the tellurolate **41a**⁶⁰ and its complex with triphenylphosphine **42a**⁶⁰ were established by X-ray diffraction analysis. The structure of the tellurolate **41a** comprises a nonplanar-square Au₄Te₄ core. The tellurium atoms occupy the vertices, each Te atom being bound to two Au atoms. The Au₄Te₄ core adopts a butterfly conformation with both wings of the butterfly being nearly coplanar. One wing comprising Te(1), Au(1), Te(2), Au(4) and Te(4) is coplanar to within 0.04 Å, while the second half consisting of Te(3), Au(2), Te(2), Au(3) and Te(4) is coplanar to within 0.09 Å.⁶⁰ The dihedral angle between these two mean planes is 144.98(6)°. All Au–Te bond lengths are 2.56 Å (average values). The Te–Au–Te fragments are almost linear; the Te–Au–Te angle is 175° (the average value). The Au–Te–Au angles vary in the range of 87–90°. The Te–C bond length in the tellurolate **41a** (2.23 Å) is virtually equal to that in the triphenylphosphine complex **42a** (2.224 Å).⁶⁰

In the complex **42a**, the Te–Au–P fragment is almost linear. The Te–Au–P and Au–Te–C angles are 174.3 and 104.1°, respectively. The Au–Te bond length (2.566 Å) is equal to that in the tellurolate **41a**. The intermolecular Au–Te contacts (3.74 Å) virtually coincide with the sum of the van der Waals radii of the elements (3.72 Å).

8. Zirconium and hafnium tellurolates

Zirconium tellurolate **46a** and hafnium tellurolate **46b** were prepared in 70%–85% yields by tellurolysis of the M–C bonds of metal tetraalkyl derivatives **47** with the tellurol **4b**.⁵⁸

R = Bn, Bu^tCH₂; M = Zr (a), Hf (b).

The tellurolates **46a,b** are high-melting crystalline compounds (**46a** is green and **46b** is red), which can be recrystallised from hexane. These compounds readily react with water and oxygen to give the tellurol **4b** and the ditelluride **7**.⁵⁸

Heating of zirconium tellurolate **46a** *in vacuo* from 200 to 375 °C afforded zirconium telluride ZrTe₃ contaminated by admixtures of carbon and hydrogen. In this case, volatile organic thermolysis products, *viz.*, bis[tris(trimethylsilyl)silyl] telluride (**32**) and tris(trimethylsilyl)silyl trimethylsilyl telluride (**44**), as well as nonidentified compounds containing the SiMe₃ group were obtained.⁵⁸

The reactions with Lewis bases are typical of the compounds **46a,b**, as of other tellurolates. Thus the reactions with 2,6-dimethylphenyl isocyanide afforded six-coordinate complexes **48a,b** of 1 : 2 composition.⁵⁸ The reactions with the bidentate DMPE ligand gave complexes **49a,b** of 1 : 1 composition.⁵⁸

R¹ = (Me₃Si)₃Si, R² = 2,6-Me₂C₆H₃; M = Zr (a), Hf (b).

Treatment of the complexes **49a,b** with 1 equiv. of DMPE afforded seven-coordinate complexes **50a,b** in 50%–80% yields as well as the telluride **32**.⁵⁸

An analogous tungsten complex **51** containing the terminal W = Te bonds was synthesised.⁸⁷

Later, complexes containing the Nb = Te,⁸⁸ Ta = Te⁸⁹ and Ge = Te⁹⁰ bonds were synthesised.

The complexes **50a,b** are red-brown crystalline air-sensitive compounds.⁵⁸ In solutions, these compounds are stereochemically fluxional. The ¹H and ³¹P NMR spectra recorded in toluene at –85 °C have sharp singlets. The signals for the SiMe₃ groups are broadened as the temperature is increased to 20 °C and coalesce at a temperature above 40 °C. The ¹²⁵Te NMR spectrum of the compound **50a** (see Table 2) has three signals at δ –706, –1173 and –1197. The high-field signals were assigned to two non-equivalent TeSi(SiMe₃)₃ groups and the low-field signal was assigned to the tellurium atom of the Zr = Te bond.

The structures of the tellurolate **46a** and the telluride **50a**⁵⁸ were established by X-ray diffraction analysis. The zirconium

atom in the molecule of the compound **46a** is bound to four tellurium atoms and has a pseudotetrahedral coordination environment. The Te–Zr bond lengths are in the range of 2.724–2.751 Å and the Te–Zr–Te angles vary in a rather wide range from 101.6 to 115.9°, which is apparently due to repulsions between the bulky (Me₃Si)₃SiTe groups.⁵⁸

In the complex **50a**, the coordination polyhedron about the zirconium atom is a distorted pentagonal bipyramid. Two DMPE ligands and one [tris(trimethylsilyl)]siletellurolate ligand lie in the equatorial plane. The second (Me₃Si)₃SiTe ligand and the tellurium atom of the Zr = Te bond occupy axial positions. The Zr–TeSi(SiMe₃)₃ bond lengths (2.939 and 3.028 Å for the axial and equatorial ligands, respectively) are substantially larger than those in the tellurolate **46a**, while the Zr = Te bond is substantially shorter (2.650 Å).⁵⁸

9. Lanthanide tellurolates

Recently, considerable attention has been focused on the synthesis of lanthanide tellurolates because these compounds can serve as precursors of lanthanide tellurides, which are of interest from the viewpoint of magnetic and luminescent properties.⁶⁴ The synthesis of lanthanide tellurides from elements is performed at high temperatures and is accompanied by formation of substantial amounts of admixtures due to the high oxophilicity of rare-earth elements. In this connection, the low-temperature synthesis of lanthanide tellurides from the corresponding tellurolates, which can be readily purified according to different procedures, is of particular interest.

One of the simplest tellurolates of this type, *viz.*, Yb(II) tellurolate **9j**, was synthesised by the reaction of diphenyl ditelluride with Yb in liquid ammonia.⁶⁷ Since the tellurolate **9j** is insoluble in usual organic solvents, it was isolated as a complex **52** after evaporation of ammonia and extraction of the residue with pyridine. The complex **52** is unstable and eliminates pyridine yielding the complex **53**.⁶⁷

An attempt to prepare Yb(III) tellurolate by the exchange reaction of YbCl₃ with sodium benzenetellurolate led only to Yb(II) derivative **53**.

The structure of the complex **52** was established by X-ray diffraction analysis.⁶⁷ The coordination polyhedron about the Yb atom is a pentagonal bipyramid. The equatorial positions are occupied by five pyridine ligands and the axial positions are occupied by two benzenetellurolate ligands. The Te–Yb–Te and Yb–Te–C angles are 175.5 and 103.6°, respectively. The average Yb–Te, Te–C and Yb–N bond lengths are 3.282, 2.192 and 2.618 Å, respectively.

Lanthanide(II) tellurolates **54a–c** containing the bulky mesitylenetellurolate residue were synthesised by the exchange reactions of lanthanide(II) halides **55** with potassium 2,4,6-trimethylbenzenetellurolate.^{63,64} When the reactions are carried out with the use of sodium or lithium tellurolates, lithium and sodium halides formed in the reactions cannot be completely separated from the major reaction products. Potassium bromide and iodide are readily precipitated from the reaction mixtures because they are less soluble in THF than the corresponding lithium and sodium halides.⁶⁴

Ln = Yb, $n = 2–3$ (**54a**, 85%–93%); Ln = Sm, $n = 2$ (**54b**, 67%); Ln = Eu, $n = 2$, (**54c**, 71%), X = Br, I.

The complexes of Yb(II) tellurolate with diglyme and DME (**54d,e**, respectively) were prepared analogously.⁶⁴

L = diglyme (**d**), DME (**e**).

An alternative approach to the synthesis of lanthanide tellurolates, which makes it possible to prevent the formation of alkali metal halides, involves the reactions of lanthanide alkoxides (aryloxides) with mesityl trimethylsilyl telluride. The driving force for these reactions is the formation of Si–O bonds. For example, this procedure was used for the preparation of the tellurolate **54a**.⁶⁴

The preparative usefulness of this procedure is impaired because the resulting trimethylsilyl ethers cocrystallise with, or coordinate, tellurolates **54** and are removed with difficulty.

The tellurolates **54a–e** are coloured crystalline compounds (**54a, b, d** are orange and **54c** is dark-green). These compounds are very air- and moisture-sensitive; Yb tellurolate **54a** is diamagnetic and the tellurolates **54c, d** are paramagnetic. The effective magnetic moments are 3.06 and 6.95 μ_B , respectively.⁶⁴

Pyrolysis of the complex **54a** in boiling toluene at 250–300 °C *in vacuo* afforded dimesityl telluride and a black insoluble precipitate. Annealing of the precipitate at 900 °C for 24 h gave cubic YbTe.⁶³

Representatives of lanthanide(II) tellurolates of yet another type, *viz.*, bis[tris(trimethylsilyl)silane]tellurolates **55a–c**, were synthesised by a slightly modified procedure of tellurololysis of silylamides of the corresponding metals **56a–c**. The reaction in diethyl ether in the presence of an excess of TMEDA afforded six-coordinate complexes **55a–c** in 40%–63% yields.⁵⁵

Ln = Yb (**a**), Sm (**b**), Eu (**c**).

The reaction performed with DMPE as a Lewis base yielded a seven-coordinate dimer **57**⁵⁵ containing the bridging DMPE ligand. The formation of the Eu(II) complex with the coordination number as large as seven is a consequence of the longer Eu–P bond compared to the Eu–N bond.⁵⁵

In the reaction with Eu(III) silylamide, the tellurol **4b**, which is a strong reducing agent, converted Eu(III) into Eu(II). The tellurol **4b** also reduced Yb(III) and Sm(III) silylamides.⁵⁵

The tellurolates **55a–c** are deeply coloured air- and moisture-sensitive crystalline compounds. After storage under nitrogen at room temperature for 12 h, these compounds begin to decompose. At –40 °C, these compounds remain unchanged within

several weeks.⁵⁵ The large magnetic moments of the complexes **55c** and **57** ($\sim 8.0 \mu_B$) preclude the use of NMR spectroscopy.

Like most of trimethylsilanetellurolates of other metals, the tellurolate **55a** decomposes upon heating (150–200 °C, 10^{-2} Torr) to form the telluride **32** and YbTe contaminated by a carbon admixture.⁵⁵

The molecular and crystal structure of the tellurolate **57** was established by X-ray diffraction analysis.⁵⁵

Unlike ytterbium, samarium and europium tris[di(trimethylsilyl)amides], which gave lanthanide(II) derivatives upon tellurololysis,⁵⁵ La(III) and Ce(III) silylamides were converted into lanthanide(III) tellurolates upon treatment with 3 equiv. of the tellurol **4b**⁵⁶ as evidenced by the data of ¹H and ¹²⁵Te NMR spectroscopy of the reaction mixtures. However, free La(III) and Ce(III) tellurolates **58a, b** are thermally unstable. Because of this, these compounds are isolated as complexes with DMPE **59a, b**, which are formed upon addition of an excess of the ligand to the reaction mixture. The yields of the complexes **59a, b** were no higher than 75%.⁵⁶

Ln = La (**a**), Ce (**b**).

Crystalline complexes **59** are coloured, *viz.*, **59a** is yellow and **59b** is orange. The complex **59a** is diamagnetic and the complex **59b** is paramagnetic ($\mu_{\text{eff}} = 2.28 \mu_B$). The data of dynamic multinuclear spectroscopy (¹H, ¹³C, ³¹P and ¹²⁵Te) are indicative of the stereochemical fluxionality of the compounds **59a, b** in solutions. Thus the ¹H NMR spectrum of the complex **59a** at 23 °C has a broad singlet of three equivalent tellurolate ligands and broad peaks of the methyl and methylene groups of the phosphorus-containing ligands. When the temperature is decreased to –84 °C, the tellurolate ligands give two peaks with the intensity ratio of 2:1 and the methyl groups of DMPE give two broad peaks with equal intensities. The ¹²⁵Te NMR spectra at –70 °C have two signals with the intensity ratio of 2:1. An analogous temperature dependence is also typical of the ¹³C and ³¹P NMR spectra.⁵⁶

As mentioned above, lanthanide(III) tellurolates in the absence of donor ligands decomposed to form bis[tris(trimethylsilyl)silyl] telluride **32** and a complex mixture of products from which compounds **60a, b** were isolated in low yields. The metal–tellurium clusters **60a, b** were considered⁵⁶ as intermediates in the pyrolytic conversions of the tellurolates **59a, b** into lanthanide tellurides. Pyrolysis of the compounds **59a, b** and **60a, b** *in vacuo* at 600 °C afforded lanthanide tellurides.⁵⁶

The structures of the compounds **59a** and **60b** were established by X-ray diffraction analysis.⁵⁶ The La atom in the complex **59a** has a pseudopentagonal-bipyramidal environment. Both phosphine ligands and one tellurolate ligand lie in the equatorial plane and two other tellurolate ligands are located in the axial plane. The La–Te_{eq} bond length is 3.141 Å and the La–Te_{ax} bond lengths are 3.168 and 3.170 Å, respectively. The Te_{ax}–La–Te_{ax} angle is 145.7°. Steric interactions between the equatorial tellurolate and phosphine ligands result in the difference in the La–P bond lengths (3.127, 3.143 Å and 3.208, 3.216 Å).

The molecule of the compound **60b** contains a six-membered $-\text{Te}-\text{Ce}-$ ring with the μ_3 -bridging $\text{Ce}(\text{TeR})_3$ fragments located above and below this ring. The $\text{Ce}-\text{Te}_{\text{termin}}$ bond lengths are smaller (3.026 Å) than the $\text{Ce}-\text{Te}_{\text{bridg}}$ bond lengths (3.183 and 3.235 Å). The Ce_3Te_3 bond lengths vary from 3.124 to 3.278 Å.

IV. Conclusion

As is evident from the present review, the synthesis of new metal tellurolates and their pyrolysis to the corresponding tellurides are of prime interest. It is in this field that the progress should be expected. Yet another line of investigation involves the synthesis of new stable tellurols. The stability of aromatic tellurols is determined by steric factors. Two-coordinate tellurium derivatives can be stabilised also by introducing substituents, such as COR, CH=N or N=N, which can form intramolecular coordination bonds with the tellurium atom, at the *ortho* position with respect to the tellurium-containing function. This method has not been applied in the chemistry of tellurols so far. Apparently, the synthesis of stable tellurols and intracomplex metal compounds based on these tellurols will be developed and will be the subject of further studies.

Abstract. The current state of research into the titanium and boron electrochemistry and high-temperature electrochemical synthesis of titanium diboride and titanium intermetallic compounds with the iron triad metals is analysed. The prospects for the development of these studies are discussed. Primary attention is paid to the electrochemical properties and stability of halide systems containing titanium in various oxidation states together with boron. The bibliography includes 81 references.

I. Introduction

Studies on the electrochemical properties of titanium and boron and the processes of joint electroreduction of two or more components from ionic melts present interest for both theoretical and practical purposes. On the one hand, the results of these studies help one to understand characteristic features of multi-electron processes and to follow the development of high-temperature electrochemical synthesis; on the other hand, they underlie the development of new technologies for the production of nontraditional materials with unique properties.^{1–3} Despite the numerous publications devoted to the electrochemistry of titanium and boron as well as titanium diboride, data on the forms of their existence, the mechanisms of joint and separate electroreduction in ionic melts (especially chloride and fluoride melts) are quite scarce and contradictory. These processes serve as the basis for the technology of the electrochemical production of titanium, boron, titanium diboride and titanium intermetallic compounds; therefore, studies in this field are topical for the development of modern high-temperature electrochemistry.

II. Electrochemical behaviour of titanium

Electrolysis of titanium melts is a promising method for the production of metallic titanium and the synthesis of high-melting compounds (carbides, borides, silicides, intermetallic compounds) based on it. However, the complex pattern of the behaviour of

titanium-containing melts accounts for the stringent requirements in the process engineering and selection of the salt systems. Thus it is necessary to study systematically and comprehensively the electrochemical and chemical properties of titanium in various oxidation states in molten electrolytes.

1. Electrolysis of titanium-containing melts

Titanium metal is mainly produced either by electrolysis of the melts of titanium oxygen compounds, fluorides or chlorides or by electrolytic refinement of crude titanium and its compounds.

Electrolysis of oxygen compounds of titanium has several advantages over electrolysis of other compounds, first of all, ready availability and low cost of the raw materials, namely, titanium dioxide and alkali metal titanates. These advantages also include simplicity of the equipment and the environmental safety of the process. Numerous publications have been devoted to the electrolysis of TiO_2 in melts of alkali metal chlorides or fluorides or potassium (sodium) hexafluorotitanate. The low solubility of titanium dioxide in various melts (0.02%–0.07%) precludes its use for the production of titanium. In addition, during electrolysis of the NaCl – K_2TiF_6 melt containing titanium dioxide, the dioxide is reduced at the cathode to Ti_2O_3 . This is accompanied by the formation of a non-decomposing precipitate near the cathode. Electrolytic preparation of pure titanium in this system is impossible because of the formation of titanium monoxide at the cathode.

Study of a similar system based on calcium chloride showed that in this case, titanium metal is formed in a secondary process, namely, reduction of TiO_2 at the cathode by calcium produced in electrochemical processes. Normal operation of the electrolytic cell requires a low concentration of TiO_2 in the electrolyte, its continuous feed to the cell and replacement of the electrolyte after it has been saturated with CaO . Electrolysis of TiO_2 dissolved in molten alkali metal borates or phosphates has been considered.^{4,5} The researchers point to the necessity of additional purification of the resulting metal from oxygen.

Thus, the use of oxygen compounds for the electrolytic preparation of titanium and the synthesis of its derivatives is hardly promising, because lower titanium oxides, which contaminate the product, are formed at the cathode.

Calculations and experimental results show that electrolysis in molten salts of oxygen-containing acids, alkalis, oxides or many other melts does not ensure the preparation of pure titanium. The range of molten media is mainly limited to metal halides. However, these compounds, too, are not all suitable for electrolysis. Indeed, metals of Group IV and of subsequent Groups of the

Periodic Table are usually much more electropositive than titanium; hence, halides of these metals are, most often, thermally unstable or possess low electrical conductivity. Alkali and alkaline earth metal chlorides and fluorides are best suited for this purpose.

Numerous studies have been devoted to the development of a method for the production of titanium by electrolysis of fluoride melts. Potassium and sodium fluorotitanates are recognised as the most promising titanium raw materials.^{5–9} It is not expedient to subject pure hexafluorotitanate to electrolysis. During electrolysis, it is reduced to K_2TiF_5 and, after that, the electrodes become passivated.

The system subjected to electrolysis is usually K_2TiF_6 dissolved in molten salts. An electrolyte consisting of potassium, lithium and sodium fluorides has been proposed as the medium for the electrolytic production of titanium.⁶ However, a process carried out in a purely fluoride melt can result in passivation of the anode by a gas film (anodic effect). In addition, since this melt is highly corrosive, the equipment soon goes out of service. Therefore, a mixture of alkali metal chlorides and potassium fluorotitanate has been proposed as the electrolyte for the electrolysis of titanium fluoride derivatives.^{5–9} When titanium metal reacts with a chloride–fluoride melt, a black crust insoluble in a mixture of alkali metal chlorides and fluorides is formed gradually on its surface. The existence of a fluoride complex of divalent titanium, $M_2[TiF_4]$, has been reported.⁸ Insoluble compounds formed at the cathode contaminate the cathodic product, which casts doubt on the expediency of using chloride–fluoride–fluorotitanate melts for producing pure titanium.

Preparation of titanium from titanium chlorides presents substantial interest. Titanium, having a variable valence, forms several chlorides, namely, $TiCl_4$, $TiCl_3$ and $TiCl_2$. The most readily available compound is $TiCl_4$; the production and purification of this compound on an industrial scale is now a routine practice. In the electrolysis of alkali or alkaline earth metal chlorides, $TiCl_4$ is either supplied onto the electrolyte surface or bubbled through the electrolyte, either neat or with a flow of an inert gas (see, for example, Refs 10, 11). Titanium tetrachloride is poorly soluble in molten alkali metal chlorides (the solubility is up to 2% at 1073 K); therefore, this technology does not provide high output. If the current density at the cathode is high, the alkali metal will be evolved together with titanium. It has been proposed to make use of this phenomenon, *i.e.* to carry out electrolysis at current densities sufficient for the evolution of the alkali metal. In this case, titanium tetrachloride is partially reduced by the reducing metal.

The solubility of titanium chlorides in which the metal oxidation number is less than four is substantially higher than the solubility of titanium tetrachloride. This fact has been taken into account in the development of a method for the preparation of titanium by electrolysis of its lower chlorides dissolved in chloride melts.¹⁰ Salts used in this process should be relatively pure as regards oxygen and elements that are more electropositive than titanium. Lower titanium chlorides can easily be prepared from titanium tetrachloride; they are readily soluble in molten salts and fairly stable at temperatures of electrolysis. These compounds possess high electrical conductivities and relatively low volatilities; however, they are chemically reactive. Under conditions of electrolysis, lower titanium chlorides react with almost any standard refractory lining material; evidently, the rate of such a reaction would depend substantially on the presence of oxygen in the cell.

A method has been proposed¹⁰ for continuous production of titanium by electrolysis of $TiCl_3$ and $TiCl_2$, which are formed in a separate reactor upon the reaction of titanium tetrachloride with hydrogen. To simplify this method, the synthesis of lower titanium chlorides and electrolysis can be carried out in one vessel. In this case, electrolysis occurs in two stages, namely, reduction of $TiCl_4$ to $TiCl_2$ and $TiCl_3$ at an auxiliary cathode and reduction of lower titanium chlorides to the metal on the main cathode.¹¹

It has been considered until recently that the cathodic process is a secondary reaction, consisting in the reduction of titanium by the alkali metal, which was evolved at the cathode. However, recent studies demonstrated that, under certain conditions, direct electrochemical discharge of the titanium ions occurs at the cathode. For this discharge to be possible, it is required, first of all, that the concentration of titanium ions in low oxidation states in the near-cathode layer be sufficiently high.

Electrolysis of titanium chlorides is carried out under the atmosphere of an inert gas (argon, helium). For rough purification of the electrolyte from moisture and occluded gases, the electrolytic cell is usually evacuated at 400–650 °C to a residual pressure of 10–20 mm Hg. Preliminary electrolysis at an auxiliary cathode with a voltage on the cell terminals equal to 1.8–2.0 V is also employed for this purpose. Other methods for the purification of the electrolyte also exist. To remove moisture, dry hydrogen hydrochloride is passed through the melt for a short period of time. Oxygen can be removed by passing tetrachloromethane through the melt. The cathode materials used in these processes are mainly tungsten, molybdenum, silver, steel or nickel. The best adhesion of the titanium deposits has been noted for silver cathodes; however, this metal is expensive. Liquid cathodes made of zinc or lead can hardly find wide application because they form intermetallic compounds with titanium, which are difficult to destroy.

During electrolysis of titanium chlorides, chlorine formed at the anode oxidises lower titanium chlorides present in the anode chamber to give $TiCl_4$, which is distilled off together with chlorine. In addition, electrolytic oxidation of $TiCl_2$ and $TiCl_3$ at the anode, leading to the same consequences, is possible. Meanwhile, titanium tetrachloride entering the cathode chamber would react with titanium metal, which would result in the loss of the pure metal. Therefore, the cathode and anode chambers should be separated by a diaphragm. The problem of selection of the diaphragm materials has not been solved yet, due to the high chemical reactivity of lower titanium chlorides; research along this line is now in progress. For instance, it has been proposed to manufacture the diaphragm from alumina (these diaphragms are not virtually metallised under certain conditions) or graphite (in this case, half-sintered metal is formed at the cathode at 1305 °C).^{4,5} It should also be noted that working with titanium chloride requires a high voltage at the electrolytic cell terminals (usually 9–12 V); therefore, power expenditure per unit product is high.

Whereas the expediency of one or another method for electrolytic production of titanium is still debated and electrolysis has not been adopted on an industrial scale, the efficiency of electrolytic refining of titanium is beyond doubt. The soluble anode can be manufactured from any material possessing electronic conduction, capable of reacting with the electrolyte and insoluble in it. Titanium forms lots of systems and compounds with such properties.

Powders with various chemical and grain-size compositions are currently produced from titanium by electrolysis with a soluble anode in the melts of alkali and/or alkaline earth metal chlorides. Electrolytic refinement of titanium is carried out using various electrolytes, namely, $NaCl$, $NaCl-KCl$, $NaCl-SrCl_2$, $NaCl-BaCl_2$, $KCl-LiCl$ and $KCl-NaCl-MgCl_2$. Electrolytes based on sodium chloride, an equimolar mixture of sodium and potassium chlorides and the $NaCl-KCl-MgCl_2$ ternary system are the most widespread. The electrolytic refinement of titanium consists in the anodic dissolution of the metal to be refined and cathodic deposition of the pure metal. Electrochemical investigations show that in the temperature range 750–850 °C, which is the best for the refinement, titanium passes from the anode to the melt as Ti^{2+} . An increase in the temperature or in the anode current density increases the yield of the Ti^{3+} ions. Upon anodic dissolution, titanium passes into the melt mostly in an ionic form, the average oxidation state being 2.02–2.13.

The total content of impurities, which are to be eliminated during titanium refinement (oxygen, nitrogen, hydrogen, carbon, iron) is normally relatively low, 1 mass %–2 mass %. In the studies dealing with the electrochemical refinement of titanium, special role belongs to the purification from oxygen. When the process is carried out under precisely pure conditions, the only way by which oxygen can pass from the anode to the cathode is the formation of the titanyl ion TiO^{2+} . Thermodynamic calculations indicate that the probability of formation of this ion is fairly low even at high concentrations of oxygen in the anode material. A significant role in the production of a high-quality powder at the cathode is played by the ratio of the titanium concentration in the electrolyte to the current density at the cathode. The best powders are obtained if this ratio ranges from 2 to 3. The anode current density during electric refinement should be 4–8 times lower than the cathode current density. In this case, divalent titanium disproportionates in the electrolyte (especially in the near-anode layer), resulting in the formation of highly dispersed metallic titanium in the bulk of the melt. The use of the refining tank for the synthesis of titanium borides is not expedient, due to the formation of an uncontrollable amount of dispersed titanium, which disrupts the stoichiometry of the product.

Various opinions concerning the role of fluoride ions have been expressed in studies dealing with the electrolytic refinement of titanium in mixed chloride–fluoride electrolytes (see, for example, Ref. 12). Some researchers believe that the addition of fluorides has a negative effect on the electrolysis characteristics (the anode material disintegrates, the current yield decreases). Conversely, some other investigators believe that fluoride additives are favourable for the performance characteristics of the process. It should be noted that anodic dissolution of titanium in a mixed chloride and fluoride electrolyte affords poorly soluble compounds of divalent titanium, which contaminate the cathodic product.

The foregoing demonstrates that halide melts are the most suitable systems for the high-temperature electrochemical synthesis of titanium compounds and production of the pure metal. However, when using chloride melts, one should create conditions for increasing the solubility of TiCl_4 and suppressing disproportionation, and when mixed chloride–fluoride electrolytes are used, the formation of poorly soluble divalent titanium fluoride should be prevented and the electroreduction of titanium complex ions should be performed in one stage.

2. State of titanium in halide melts

a. Thermodynamics of titanium-containing halide systems

Titanium halides react with titanium metal in molten alkali metal halides. The following heterogeneous equilibrium is established with time:

As a rule, one oxidation state of titanium predominates in the melt; the ratio of various oxidation states depends on the temperature and the nature of the salt acting as the solvent. Heterogeneous equilibrium (1) can be characterised by several parameters such as equilibrium constant, apparent standard potentials $E^*(\text{Ti}^{2+}/\text{Ti})$, $E^*(\text{Ti}^{3+}/\text{Ti})$ and the formal redox potential $E^*(\text{Ti}^{3+}/\text{Ti}^{2+})$.^{13,14} The equilibrium potential of the titanium electrode (E) would be simultaneously the potential of the Ti/TiCl_2 , Ti/TiCl_3 and $\text{TiCl}_2/\text{TiCl}_3$ systems. The apparent standard potentials and the formal redox potential are related (in accordance with the Luter rule) by the equation¹³

$$3E^*(\text{Ti}^{3+}/\text{Ti}) = E^*(\text{Ti}^{3+}/\text{Ti}^{2+}) + 2E^*(\text{Ti}^{2+}/\text{Ti}). \quad (2)$$

The task of finding these values reduces to the determination of the number of ionic forms of titanium in the potential measurement.

The equilibrium potentials of titanium in an equimolar mixture of potassium and sodium chlorides in the temperature

range 973–1148 K have been reported.¹⁴ The temperature variations of $E^*(\text{Ti}^{2+}/\text{Ti})$ and $E^*(\text{Ti}^{3+}/\text{Ti})$ are described by the following empirical equations:

$$E^*(\text{Ti}^{2+}/\text{Ti}) = -2.38 + 4.8 \times 10^{-4} T, \quad (3)$$

$$E^*(\text{Ti}^{3+}/\text{Ti}) = -2.16 + 3.2 \times 10^{-4} T. \quad (4)$$

The equilibrium potentials of titanium measured at 843 K vs. chlorine reference electrode amount to $E^*(\text{Ti}^{2+}/\text{Ti}) = -1.97$ V and $E^*(\text{Ti}^{3+}/\text{Ti}) = -1.90$ V.

In order to identify the full picture of equilibrium between metallic titanium and a chloride melt containing minor amounts of Ti^{4+} , in addition to Ti^{2+} and Ti^{3+} , the $E^*(\text{Ti}^{4+}/\text{Ti}^{3+})$ redox potential, and, hence, the standard $E^*(\text{Ti}^{4+}/\text{Ti})$ potential should be determined. The temperature variation of this potential in the $\text{KCl}-\text{NaCl}$ melt is described by the equation

$$E^*(\text{Ti}^{4+}/\text{Ti}) = -1.91 + 3.84 \times 10^{-4} T. \quad (5)$$

Various values for the arbitrary formal redox potential $E^*(\text{Ti}^{3+}/\text{Ti}^{2+})$ in a molten equimolar mixture of sodium and potassium chlorides, determined experimentally by potentiometric titration, have been reported in the literature: -1.807 ($T = 973$ K), -1.762 ($T = 943$ K), -1.726 V ($T = 984-1130$ K). The $E^*(\text{Ti}^{3+}/\text{Ti}^{2+})$ value calculated in accordance with the Luter rule from Eqn (2) using the known experimental $E^*(\text{Ti}^{3+}/\text{Ti})$ and $E^*(\text{Ti}^{2+}/\text{Ti})$ values is described by the equation

$$E^*(\text{Ti}^{3+}/\text{Ti}^{2+}) = -1.710 - 0.17 \times 10^{-4} T. \quad (6)$$

It can be seen that the theoretical value of the potential $E^*(\text{Ti}^{3+}/\text{Ti}^{2+})$ depends slightly on the temperature and at 1000 K it is equal to -1.727 V vs. chlorine reference electrode.

The known standard potentials for the Ti^{3+}/Ti and Ti^{4+}/Ti systems were used to calculate the $\text{Ti}^{4+}/\text{Ti}^{3+}$ redox potential and to elucidate its temperature dependence

$$E^*(\text{Ti}^{4+}/\text{Ti}^{3+}) = (-1.473 + 5.86 \times 10^{-4} T) \pm 0.007. \quad (7)$$

The variation of the equilibrium potential of titanium as a function of the concentration of titanium ions in the melt have shown that in alkali metal chloride melts, titanium is equilibrated with the Ti^{2+} and Ti^{3+} ions. Knowing the standard electrode potentials of the Ti^{2+}/Ti and Ti^{3+}/Ti systems, it can be written¹⁵

$$\log K = \log \frac{[\text{Ti}^{2+}]^3}{[\text{Ti}^{3+}]^2} = \frac{6 \times 10^4}{1.984T} [E^*(\text{Ti}^{3+}/\text{Ti}) - E^*(\text{Ti}^{2+}/\text{Ti})] \quad (8)$$

Thus the equilibrium constants for the reaction

can be calculated. For lithium chloride,

$$\log K = -4.234 + \frac{6351}{T}, \quad (10)$$

for potassium chloride,

$$\log K = -6.956 + \frac{8165}{T}, \quad (11)$$

for cesium chloride,

$$\log K = -6.956 + \frac{7440}{T}, \quad (12)$$

and for the $\text{KCl}-\text{NaCl}$ melt,

$$\log K = -5.038 + \frac{6774}{T}. \quad (13)$$

As the temperature increases, the equilibrium constant decreases, which points to disproportionation of Ti^{2+} . If the temperature remains constant, the equilibrium constant decreases with an increase in the radius (r) of the alkali metal cation of the molten salt, *i.e.* the equilibrium shifts towards disproportionation of Ti^{2+} . This dependence has the form

$$\log K = \frac{8468}{T} - \frac{1512}{Tr} - 9.073 - \frac{3.175}{r}. \quad (14)$$

A substantial number of studies have been devoted to the process of disproportionation (see, for example, Refs 16–18). The oxidation states of titanium can be described by four disproportionation reactions

These reactions occur simultaneously and are heterogeneous. The outcome depends on the experimental conditions, namely, temperature, composition of the atmosphere, surface area, and so on. It has also been noted that Ti^{3+} rapidly disproportionates in the lithium chloride melt. When lithium chloride is replaced by cesium chloride, the stability of Ti^{3+} increases. In halide melts, titanium metal reacts with the components of the melt. When the radius of the alkali metal cation in the melt is greater than the radius of potassium, Ti^{2+} ions appear; they disproportionate to give highly dispersed titanium metal; therefore, a high concentration of Ti^{2+} cannot be attained. In the case where the LiCl melt is used, the solution becomes rich in Ti^{2+} .

The main reaction which proceeds at a substantial rate in molten potassium chloride is

Thus, vast experimental data have been accumulated and a number of important practical conclusions have been drawn concerning the thermodynamics of titanium-containing chloride melts, namely, the equilibrium and standard potentials of titanium in various oxidation states were determined; the equilibrium constants for chemical reactions in the melts were calculated; and disproportionation of titanium ions in low oxidation states was detected. However, in some cases, the thermodynamic functions are rough. For example, the measurement of the equilibrium potentials of the Ti^{4+}/Ti , Ti^{3+}/Ti and Ti^{2+}/Ti systems does not appear quite correct because actually, the near-electrode layer would contain titanium ions in various oxidation states formed in chemical reactions. In addition, thermodynamic characteristics do not provide exhaustive information on the mechanism of electroreduction of titanium, which needs to be known for performing successful electrolysis of titanium-containing melts. Therefore, in addition to the thermodynamic characteristics, the mechanism of the electroreduction of titanium has also been studied.

b. Mechanism of the electroreduction of titanium

It is not always possible to interpret unambiguously experimental data characterising the mechanism and kinetics of electroreduction and electrooxidation of titanium complexes. The complexity of interpretation of these data is due to the fact that side processes, not related directly to electrode reactions, proceed in the melt. In some studies, it is suggested that titanium metal is evolved in the reaction of titanium-containing complex ions with an alkali metal, resulting from reduction at the cathode. In other studies, it is suggested that two processes of titanium deposition occur simultaneously; titanium is formed in the primary electrochemical process at the cathode

and in a secondary chemical process, thermal reduction by sodium in the bulk of the electrolyte. Some researchers believe that in the case of chloride melts, an alkali metal reduces Ti^{2+} ions (see, for example, Refs 19, 20) and in the chloride–fluoride melts, the species being reduced is Ti^{3+} . Titanium in higher oxidation states is preliminarily reduced to lower oxidation states by either electrochemical or chemical reactions. However, voltammograms characterising the cathodic evolution of titanium display a wave corresponding to the discharge of titanium complexes.¹⁸ In several studies (see, for example, Ref. 21), the mechanism of direct

reduction of TiCl_3 to the metal without the intermediate formation of Ti^{2+} has been assumed. A study of the electroreduction of TiCl_3 in the LiCl, CsCl and KCl–LiCl systems at 973 K by linear sweep voltammetry demonstrated that the reduction of Ti^{3+} in all three electrolytes involves the stage of recharge to Ti^{2+}

The stepwise character of the process was pointed out in several other publications.^{18, 22–26}

Electroreduction of titanium tetrachloride in the BaCl_2 – CaCl_2 – NaCl ,²² LiCl – KCl , KCl – LiCl – NaCl ²³ and BaCl_2 – KCl – LiCl ²⁴ melts occurs as three consecutive stages:

The voltammograms for the electroreduction of Ti^{2+} in the KCl – NaCl – TiCl_3 – NaF – $\text{Ti}(\text{solid})$ melt exhibit one clear-cut wave at potentials of $-(2.53–2.6)$ V vs. chlorine reference electrode, which corresponds to the electroreduction of titanium.²⁰

The diffusion coefficients for titanium in chloride melts have been calculated;^{21, 26, 27} in KCl – NaCl at 973 K, they are equal to 3.72×10^{-5} and $1.94 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$ for Ti^{3+} and Ti^{4+} , respectively. The diffusion coefficient for divalent titanium in the LiCl – KCl melt at 773 K amounts to $(1.54 \pm 0.17) \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$ (see Ref. 28).

Thus, certain progress in the study of chloride and chloride–fluoride titanium-containing melts has been achieved by now; however, the overall picture of the electrochemical and chemical behaviour of titanium in various oxidation states does not appear clear and unambiguous. There is no consensus of opinion on the mechanism of the cathodic process. Several aspects of the stability of systems containing titanium in various oxidation states are poorly documented, namely, which of the lower titanium chlorides is more stable and what is the limiting concentration up to which this stability is retained; what are the concentration limits for the stability of other titanium-containing species; what are the ratios of Ti^{2+} to Ti^{3+} in the melt at which the system remains stable, *i.e.* no disproportionation reactions occur, and what are the ways of suppressing these reactions. Answers to these questions present considerable interest from the practical viewpoint, because they would make it possible to create conditions for long continuous operation of an electrolysis cell and to estimate the influence of unstable titanium compounds on the technological parameters of the production of titanium and of the electrochemical synthesis of titanium compounds.

III. Electrochemical behaviour of boron

The electrochemical method permits preparation of high-purity boron in large quantities. In the first studies, carried out 70 years ago, elementary boron was produced by the electrolysis of borides. The product contained not more than 60%–70% of the target material, 20%–30% of oxygen and 5%–6% of the metal that served as the cathode material. When magnesium boride was used, elementary boron was formed at the cathode together with low-stability magnesium borides; the latter can be partially removed by treatment of the cathodic product with an acid.

Currently, oxygen-containing compounds of boron and boron halides are mainly used for the electrolytic production of boron. Numerous studies have been devoted to the electrolysis of oxygen compounds of boron. In all systems boron oxide serves as the source of boron.²⁹ When oxygen-containing melts are used, the process does not give high-purity boron because the product is contaminated by substantial amounts of oxygen. This is the major drawback of this method.

The use of purely fluoride electrolytes is limited because fluoride melts are corrosive and toxic.³⁰ The use of mixed chloride–fluoride electrolytes presents considerable interest; in this case, high-purity boron free from oxygen impurities can be obtained at relatively low temperatures, the corrosiveness of the melts being relatively low.^{30–36}

Several studies have been devoted to the mechanism of electroreduction of boron.^{37–46} The cathodic processes occurring during the electrodeposition of boron from a purely fluoride ($\text{LiF} - \text{KF} - \text{KBF}_4$) and fluoride–oxide ($\text{LiF} - \text{KF} - \text{B}_2\text{O}_3$) electrolytes have been studied.^{36,37} It was shown that in a purely fluoride melt, boron is reduced directly from the tetrafluoroborate complex anion in one step involving three electrons. In the $\text{LiF} - \text{KF} - \text{B}_2\text{O}_3$ system, boron oxide reacts with fluorine present in the electrolyte to give the $[\text{BF}_4]^-$ anion and oxyfluoride complexes, mainly those with a molar ratio of oxygen to boron equal to 1.66. The ratio of the concentrations of $[\text{BF}_4]^-$ and the oxyfluoride complexes is 0.1. The potentials of deposition of boron from these two electrochemically active species differ by 0.47 V, and the diffusion coefficient for $[\text{BF}_4]^-$ calculated from experimental data is $4.4 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ at 973 K.

In a study of the electrochemical properties of boron in chloride and chloride–fluoride melts, the solubility of BCl_3 in the CsCl melt was found to be $1.74 \times 10^{-1} \text{ mol.}\%$ at 973 K; thermodynamic functions of BCl_3 in CsCl were calculated, the equilibrium potentials of boron were determined and equations for them were reported.³² The equilibrium potentials of boron shift to the negative region in chloride–fluoride electrolytes, indicating that the reactivity of boron ions in fluoride complexes is lower than that in chloride complexes.^{31,32,34} The calculation of the average number of fluoride ions (three or four) in the complex ions by the procedure proposed by Ivanovsky *et al.*³¹ attests indirectly that in the temperature range studied, most of the boron ions in the chloride–fluoride melts occur in the $[\text{BF}_4]^-$ and $[\text{BF}_3\text{Cl}]^-$ groups. Based on the results of voltammetric studies, Chemezov³² arrived at the conclusion that electroreduction of boron in a chloride–fluoride electrolyte occurs by a one-stage mechanism; conversely, Tsiklauri *et al.*⁴¹ have discovered a recharge stage, $\text{B}^{3+} \rightarrow \text{B}^+$, followed by the discharge of B^+ at the cathode to give elementary boron.

For low current densities, charge transfer is the rate-determining step in the electrodeposition of boron, whereas for high current densities, the rate of the process is limited by the diffusion of boron from the bulk of the melt towards the surface. This is typical of both chloride and chloride–fluoride melts. A somewhat different opinion on the kinetics of electroreduction of boron is held by the authors of another study,³⁹ who claim that the rate of this process is limited by mass transfer over a broad range of polarisation rates and that the proper electrochemical stage is irreversible.

Examination of the switching-on curves (potential–time) for various polarisation current densities demonstrated³² that neither a homogeneous chemical reaction (*e.g.*, dissociation of the $[\text{BF}_4]^-$ or $[\text{BCl}_4]^-$ complexes), nor chemisorption of electrically active species on the electrode surface retards the reduction of boron in the melts studied. The $\log D - I/T$ plots (D is the diffusion coefficient of boron calculated from the Sand equation using the results of chronopotentiometric measurements, I is the current density and T is the temperature) in the temperature range 932–1123 K are straight lines; the calculation of the activation energy gives $35.5 \pm 2.3 \text{ kJ mol}^{-1}$ (see Refs. 31, 32). However, in another study,⁴¹ it has been stated that electrochemically active species (mainly molecular boron fluoride) are produced in a chloride–fluoride melt upon dissociation of boron complexes coupled with homogeneous exchange reactions between the initial complexes and the electrolyte.

Study of the solubility and the kinetics of electroreduction of BF_3 in the $\text{KCl} - \text{NaCl}$ melt at 973 K in the range of BF_3 pressures of $(1.01 - 5.05) \times 10^5 \text{ Pa}$ showed the presence of two sorts of electrochemically active species.⁴⁴ This accounts for the two

waves displayed on the voltammograms; the heights of the waves increase proportionally to the pressure. In the opinion of the researcher cited, the first wave corresponds to a two-electron transition involving BF_3 ; at the potential of the second wave, the product formed in the first stage is reduced, the mixed chloride–fluoride complex $[\text{BCl}_x\text{F}_3]^{x-}$ being involved in the cathodic process.

Thus, despite the large number of publications dealing with the electrochemical properties of boron, no clear views on the mechanism and kinetics of its electroreduction from halide electrolytes have been developed so far.

IV. Methods for the synthesis of titanium diboride. High-temperature electrochemical synthesis

The principal methods used to synthesise high-melting compounds have been classified²³ into the following groups: (1) direct synthesis from elements, (2) synthesis from solutions in melts, (3) thermal reduction of metal oxides by metals, (4) reduction of oxides and other compounds by nonmetals and their derivatives, (5) gas-phase synthesis, and (6) electrolysis of salt melts. This classification is also applicable to the methods used to prepare titanium diboride.

Direct synthesis from elements is based on the reaction of a metal (titanium) with a nonmetal (boron), which can be carried out (at various physical states of the elements) by fusing, sintering or hot pressing. In accordance with this, some researchers suggest conducting this synthesis by keeping samples of pure titanium for 5 h in amorphous boron at a temperature of 1273 K and a residual pressure of 0.133 Pa; according to other researchers, mixtures of titanium and boron powders should be heated by an electric discharge.⁴⁷ The advantages of this method include the possibility of preparing large amounts of the product, the possibility of hot moulding the product in order to manufacture the required articles, simplicity of the equipment and the relatively short time needed for the synthesis. The facts that it is difficult to prepare borides with a precise composition and that the temperature of the process is too high are drawbacks of the direct synthesis.

The synthesis from solutions in melts involves a chemical reaction between transition metal atoms and nonmetal atoms (or molecules of a nonmetal compound) occurring in molten salts or metals. An example is provided by the synthesis of titanium borides in an iron melt at temperatures of 1673–2273 K. This route can afford both pure, doped and complex (mixed) compounds. In addition, it ensures the recovery of metal serving as the solvent and is relatively simple. The drawbacks of this method include low yields and high cost of the product, caused by the large amounts of salts and metallic solvents consumed, the possible contamination of the product by the solvent, the necessity of vigorous stirring of solutions in melts in order to obtain homogeneous compounds and high temperatures of the process.

The thermal reduction of oxides consists in the reduction of titanium and boron oxides by a reducing metal (in the presence of oxygen-evolving compounds) to give borides at temperatures of 2273–3273 K over periods of 2–3 min. This is the simplest method among those listed above. However, it is not in general use because of the low quality and inhomogeneous composition of the products obtained in this way and also because it is difficult to isolate the product from the slag.

The fourth method is based on the reduction of oxides and other compounds by nonmetals and their compounds. For instance TiB_2 can be prepared by the reaction of BCl_3 with highly dispersed titanium at 873–1373 K. The advantages of this method include the possibility of preparing large quantities of the product and the fact that oxides and other readily available compounds of titanium and boron are suitable for the synthesis. The main drawback of this method is that the products of the synthesis are contaminated by metal and nonmetal oxides.

Gas-phase synthesis includes decomposition of chemical compounds followed by reactions of the fragments (both ions or

radicals and the atoms or molecules produced upon their reduction) occurring in the gas (vapour) phase to give high-melting compounds. A method for the synthesis of titanium diboride by the reduction of a vapour–gas mixture consisting of TiCl_3 and BCl_3 by hydrogen at temperatures of 1273–3773 K and pressures of 1–3 atm has been described.⁴⁷ The major advantage of this method is the possibility of preparing single crystals and coatings on various materials. The inhomogeneity of the phase composition and the relatively low yields of the products as well as complexity of the equipment and the processes involved are drawbacks of this technique.

High-temperature electrochemical synthesis from molten salts can be regarded as being one of the most promising methods for the preparation of high-melting compounds. The advantages of this method are relative simplicity of the equipment, the ready accessibility of the initial compounds, the possibility of preparing simple or complex composite coatings of high-melting compounds, the relatively low temperature of the process, and the possibility of controlling the morphology and the composition of the cathodic deposit by varying the electrolysis parameters. The theoretical grounds of this method have been described in detail,⁴⁸ and examples of its practical implementation can be found in reviews.^{49,50}

Depending on the nature of the electrolyte used, two variants of electrochemical synthesis of titanium diboride can be distinguished, namely, syntheses from oxygen-containing systems and from halide systems.⁵¹ The former variant commonly employs systems based on alkali and alkaline earth metal borates, which differ in the manner of saturation of the melt by the synthesis components. Boron can be introduced in the melt as B_2O_3 , and titanium can be added as TiO_2 ; the concentration of titanium in the electrolyte can be maintained by anodic dissolution of titanium metal.⁵¹ However, though seemingly advantageous, the synthesis based on oxygen-containing systems suffers from serious drawbacks. Specifically, the reaction temperatures are too high (> 1023 K), and a pure product (free from oxygen) cannot be prepared in this way.

The second variant can be implemented using either purely fluoride electrolytes, for example $\text{F/Li, Na, K, LiF-KF, Li, Rb, Cs/F}$ and cryolite and mixed chloride–fluoride electrolytes. The sources of titanium and boron in this case are either titanium and boron fluorides or soluble anodes made of boron, titanium and boron carbides or titanium diboride. The use of mixed chloride–fluoride electrolytes with the lowest possible content of fluorine is the most interesting. This decreases the corrosion activity and the cost of the melt; in the case where a soluble anode is used, the formation of fluorocarbons can be avoided and the stage of hydrotreating of the cathodic deposits can be simplified.

The mechanism of the cathodic process in the electrochemical synthesis of titanium diboride in the LiF-KF melt has been studied.^{52,53} Potassium hexafluorotitanate and tetrafluoroborate were used as the sources of titanium and boron. It was found that reduction of Ti^{4+} in the $\text{LiF-KF-K}_2\text{TiF}_6\text{-KBF}_4$ system occurs in two steps

This is followed by the reduction of boron complexes to elementary boron, which then reacts with the reduced titanium to yield titanium diboride. This is accompanied by electrode depolarisation, which is due, in the opinion of the researchers, to the great negative value of the Gibbs energy for the formation of TiB_2 .

Thus, analysis of the studies devoted to the methods of electrochemical synthesis of titanium diboride shows that mainly applied studies can be found in the literature. The information available from the literature is inadequate to interpret the mechanism of the synthesis; therefore, this process needs to be studied more comprehensively.

V. Electrochemical properties and stability of halide systems containing titanium in various oxidation states and boron

1. Study of electrochemical properties and stability of titanium-containing systems

Experiments on the stability of halide systems containing titanium in various oxidation states and boron and on the electrochemical synthesis of TiB_2 and titanium intermetallic compounds have been performed under an argon atmosphere, inert with respect to the melts under study.

The voltammograms characterising the electroreduction of Ti^{3+} at polarisation rates of $> 0.5 \text{ V s}^{-1}$ (Fig. 1) exhibit two persistent waves with clear-cut peak currents. The waves are due to the recharge and discharge of titanium ions

Figure 1. Voltammograms for the electroreduction of Ti^{3+} ions in the KCl-NaCl-TiCl_3 melt.

$T = 1000 \text{ K}$, $[\text{TiCl}_3] = 8.3 \times 10^{-5} \text{ mol cm}^{-3}$, chlorine reference electrode; polarisation rate $/\text{V s}^{-1}$: (1) 1.0; (2) 0.1; (3) 0.05.

To confirm the assumption that the potentials of the second wave correspond to the reduction of titanium complexes to the metal, potentiostatic electrolysis was carried out at these potentials. X-Ray diffraction identification of the electrolysis products showed the presence of titanium metal on the cathode.

When the potential sweep rate is $< 0.1 \text{ V s}^{-1}$, the peak current of process (25) becomes feebly defined and at polarisation rates of $< 0.05 \text{ V s}^{-1}$, the waves of processes (25) and (26) coalesce. As a consequence, the overall process appears as occurring in one stage (see Fig. 1, curve 3). In all probability, this is the reason for the disputes concerning the number of stages in the reduction of Ti^{3+} (see Refs 47, 51), because most of the studies have been carried out at polarisation rates close to the steady-state values (not higher than 10 mV s^{-1}).

Analysis of voltammograms of the type presented in Fig. 2 showed that at high polarisation rates, processes (25) and (26) are not complicated by any additional reactions and, in the range of TiCl_3 concentrations studied (up to 10 mass %), they completely obey the Faraday law. This is confirmed by the fact that the peak currents follow a linear dependence on the concentration of TiCl_3 .

The dependence of the peak potential on the polarisation rate and the magnitude of the transport coefficient αn , equal to 0.45, imply that at high polarisation rates, the charge transfer step in the recharge process (25) is retarded. The diffusion coefficient is equal to $(3.5 \pm 0.3) \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$.

The abnormal increase in the $i_p/V^{1/2}$ ratio at $V < 0.5 \text{ V s}^{-1}$ (see Fig. 2) is evidently due to the fact that the recharge is complicated by a catalytic reaction, *i.e.* electroreduction is accompanied by regeneration of electrochemically active species.

Figure 2. Variation of $i_p/V^{1/2}$ vs. $V^{1/2}$ (i_p is the peak current, V is the polarisation rate) for processes (25) (1) and (26) (2) in the KCl–NaCl–TiCl₃ melt.

$T = 1000$ K, $[\text{TiCl}_3] = 5.5 \times 10^{-5}$ mol cm⁻³.

This might be disproportionation of the divalent titanium formed. For a redox process not accompanied by catalytic reactions, the ratio of the peak currents of the waves obtained in the forward (cathodic) and reverse (anodic) recording of voltammograms should be equal to unity. If this ratio is greater than unity, the product of electroreduction enters into a subsequent chemical reaction; when this is disproportionation, it increases the current and changes correspondingly the $i_p/V^{1/2}$ value. Study of cyclic voltammograms for process (25) has confirmed⁵⁴ that disproportionation of divalent titanium occurs in the near-electrode layer

The minimum lifetime of the divalent titanium species is 0.08–0.8 s for the TiCl₃ concentration ranging from 5×10^{-4} to 5×10^{-5} mol cm⁻³; the rate constant for disproportionation is $(2.2 \pm 0.2) \times 10^4$ cm² mol s⁻¹.

Methods for controlling the course of electroreduction by varying the acid–base properties of the medium have been considered^{53–57} in relation to oxygen-containing complex ions. According to the idea of these studies, the electrochemical activity of oxygen-containing anions is due to the mechanism of formation of electrochemically active species peculiar to molten salts, namely, the acid–base interactions in the melt. The formation and interactions of electrochemically active species in the near-electrode layer occur at a limited rate because these processes require rearrangement of the structure of reacting species. Thus, by changing the acid–base properties of the medium, one can influence the mechanism and the rate of the process in a specified manner.

Elimination of disproportionation reactions by changing the mechanism of the process can be attained in two ways, namely, by addition of either cations possessing greater polarising ability than potassium and sodium or anions having stronger basic properties than the chloride anion. In the former case, the acidity of the melt diminishes, while in the latter case, the basic properties of the electrolyte are enhanced (for instance, when sodium fluoride is introduced).

The mechanism of the cathodic process in the electroreduction of titanium trichloride in chloride melts with different cationic compositions has been studied.⁵⁸ It was found that reduction of titanium in the cesium chloride melt occurs *via* recharge stage (25), whereas in an eutectic LiCl–KCl melt, when the temperature diminishes to 673 K, trivalent titanium is reduced to the metal in one stage

However, the LiCl–KCl system cannot be used for the synthesis of titanium diboride because the minimum temperature for the onset of the electrochemical synthesis markedly exceeds 673 K and amounts to 843 K.

It has been found⁵⁹ that fluoride ions added to the melt replace the chlorine in the titanium complex species and, as a consequence, the electroreduction process switches to a one-stage mechanism.

In order to elucidate the potential for the synthesis of titanium diboride from chloride and fluoride electrolytes, it is significant to study the influence of fluoride ions, in particular, the $[\text{Ti}^{3+}]:[\text{F}^-]$ molar ratio, on the mechanism of titanium electrodeposition and the type of titanium species in the melt. It is also necessary to determine the optimum electrolyte composition,⁶⁰ which would preclude both disproportionation reactions and the formation of lower titanium fluorides, insoluble in the melt.

As shown above, electroreduction of trivalent titanium in the chloride melt includes the recharge to the divalent state. Upon introduction into the chloride melt of fluoride ions in the ratio $[\text{Ti}^{3+}]:[\text{F}^-] > 1:2$, the peak current of the recharge wave decreases proportionally to the content of fluoride ions in the electrolyte. In addition, as the current of the recharge wave decreases, the peak current of the $\text{Ti}^{2+} \rightarrow \text{Ti}$ discharge wave proportionally increases. When the molar ratio $[\text{Ti}^{3+}]:[\text{F}^-] = 1:2$ is attained, the recharge wave is no longer displayed on the voltammogram and the discharge of the complex ions of titanium becomes a one-stage process (Fig. 3). The switching to a different mechanism is accompanied by the simultaneous shift of the wave potentials towards more negative values. Experimental results imply that the change in the anionic composition of the melt upon the introduction of fluoride ions results in the formation of mixed chloride- and fluoride-containing complexes. The replacement of chlorine in the $[\text{TiCl}_6]^{3-}$ complex (this is the species in which TiCl₃ occurs in the KCl–NaCl melt) by the smaller fluoride ion makes this complex stronger and changes the mechanism of its reduction. The fact that the mechanism changes at $[\text{Ti}^{3+}]:[\text{F}^-] = 1:2$ suggests that the composition of the resulting titanium complex is $[\text{TiF}_2\text{Cl}_4]^{3-}$.

Titanium chloride–fluoride complexes occur in equilibrium with components of the melt; generally, the equilibrium is described by the equation

Electroreduction involves dissociated species $[\text{TiF}_x]^{3-y}$, the concentration of which is lower than the total concentration of titanium in the electrolyte.

The dependence of the potential of the reduction wave peak on the polarisation rate in the broad range of potential sweep rates and also the value $\alpha n = 1.0 \pm 0.05$, found from the Matsuda–Ayabe equation, imply that the charge transfer step is slow.

The diffusion coefficient calculated from the Delahay equation using peak currents corresponding to the total concentration

Figure 3. Voltammograms for the electroreduction of titanium ions in the KCl–NaCl–NaF–TiCl₃ melt at a $[\text{Ti}^{3+}]:[\text{F}^-]$ molar ratio, equal to 1:0 (1), 1:1 (2), 1:2 (3), <1:2 (4).

$T = 1000$ K, polarisation rate 1.0 V s⁻¹, $[\text{Ti}^{3+}] = 1.55 \times 10^{-4}$ mol cm⁻³, chlorine electrode as the reference electrode.

of titanium in the melt is equal to $(3.0 \pm 0.4) \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$. The underestimated value of the diffusion coefficient, $(0.7 \pm 0.4) \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$, found using the currents corresponding to high polarisation rates confirms the assumption that the concentration of electrochemically active species under these conditions does not coincide with the total titanium concentration in the melt.

The number of ligands attached to the initial $[\text{TiF}_2\text{Cl}_4]^{3-}$ species during titration of the melt by fluoride ions, determined on the basis of the slope of the straight line plotted in the 'shift in the wave peak – depolariser concentration' coordinates ($\Delta E - \ln c_{\text{F}^-}$) (Fig. 4) is equal to two. With allowance for the composition of the initial species, the composition of the titanium complex in the bulk of a melt containing an excess of fluoride ions should be $[\text{TiF}_4\text{Cl}_2]^{3-}$. Then the formation and discharge of electrochemically active titanium complexes can be described by the following scheme:

Figure 4. Calculation of the coordination number of titanium in the complexes occurring in the KCl–NaCl–NaF–TiCl₃ melt.

Thus, the electroreduction of trivalent titanium in the near-electrode layer of a chloride melt involves disproportionation of divalent titanium. In a chloride melt, the $\text{Ti}^{3+} \rightleftharpoons \text{Ti}^{2+}$ recharge is a catalysed process and the charge transfer step is retarded over a broad range of polarisation rates. Stabilisation of the KCl–NaCl–TiCl₃ system can be attained by changing the acid–base properties of the melt by introducing fluoride ions into the chloride electrolyte, which results in the formation of mixed chloride and fluoride complexes such as $[\text{TiF}_2\text{Cl}_4]^{3-}$. The reduction of these complexes at the molar ratio $[\text{Ti}^{3+}]:[\text{F}^-] < 1:2$ occurs in one stage involving the transfer of three electrons.

2. Study of electrochemical properties and stability of boron-containing systems

In order to arrange a high-temperature electrochemical synthesis of titanium diboride, it is necessary that the potentials of the evolution of products used in the synthesis be close. Therefore, investigations into the electrochemical properties and stability of boron-containing chloride–fluoride melts are topical. Analysis of the published data indicates that, despite the fact that numerous studies have been devoted to electroreduction of boron complexes, there are still no clear views on the electroreduction mechanism or the composition of the boron-containing species existing in chloride–fluoride melts.

The voltammograms of the electroreduction of boron exhibit one wave in the potential range from -2.35 to -2.7 V with a clear-cut peak current (Fig. 5). Further polarisation results in an increase in the current, caused by the discharge of alkali metal ions. The potentiostatic electrolysis at the potential corresponding to the reduction wave affords elementary boron. The dependence of the peak potential of the wave of electroreduction of boron

Figure 5. Cyclic voltammograms for the $\text{B}^{3+} \rightarrow \text{B}$ process occurring in the KCl–NaCl–NaF–NaBF₄ melt (vs. chlorine reference electrode). $[\text{B}^{3+}]:[\text{F}^-]$: (1) 1:0, (2) 1:7, (3) 1:14.

complexes on the polarisation rate, the substantial difference between the wave peak potentials found in the forward and reverse recording of voltammograms, and the values $\alpha n = 0.96$ – 1.08 for the three-electron process calculated from the Matsuda–Ayabe equation lead to the following conclusion. In the range of polarisation rates from 0.1 to 20.0 V s^{-1} , the discharge of boron complexes is irreversible, *i.e.* it is controlled by the rate of charge transfer.⁶¹

The $[\text{BF}_4]^-$ ions added to a chloride melt enter into an exchange reaction with chloride anions to give mixed chloride–fluoride complexes

The unstable boron complexes undergo thermal dissociation, which can be generally represented by the following scheme:

Electroreduction involves species resulting from dissociation of the initial complexes; the concentration of these species in the melt bulk is small compared to the total concentration of boron ions in the electrolyte. Thus, the melt contains simultaneously two sorts of species, namely, the initial $[\text{BF}_{4-x}\text{Cl}_x]^-$ complexes and electrochemically active species $[\text{BF}_{4-x}]^{x-1}$. Upon the discharge of boron complexes, the near-electrode layer becomes depleted in the $[\text{BF}_{4-x}\text{Cl}_x]^-$ complexes, which displaces the equilibrium towards the formation of electrochemically active species. Analysis of the $i_p/V^{1/2} - V^{1/2}$ dependence shows⁶² that a decrease in the potential sweep rate diminishes the influence of dissociation on the electroreduction of boron complexes. The influence of $i_p/V^{1/2}$ on $V^{1/2}$ can be extrapolated to the $i_p/V^{1/2}$ axis if the peak current of the wave corresponds to the total concentration of boron in the melt. The linear type of dependence of the peak currents on the boron concentration in the melt implies that the preceding chemical reaction exerts no retarding influence under these conditions. The diffusion coefficient calculated from the Delahay equation using the peak current values corresponding to the total concentration of boron in the melt is equal to $(3.3 \pm 0.4) \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$.

Thermal dissociation of alkali metal fluoroborates added to a chloride melt yields volatile boron fluorides, poorly soluble in the melt and passing into the gas phase. This results in a lower concentration of electrochemically active species and, hence, in a lower rate of boron electroreduction.⁶³ The non-controllable change in the concentration of one component hampers the selection of operating conditions suitable for the electrochemical synthesis of titanium diboride. Therefore, it is necessary to find a method for stabilisation of the chloride melt containing an alkali metal fluoroborate. It has been shown^{61,62} that the introduction of NaF into the KCl–NaCl–NaBF₄ melt induces a shift of the

peak potential of the wave corresponding to the discharge of mixed chloride–fluoride boron complexes, due to the replacement of chloride ions by fluoride ions. When $[B^{3+}]:[F^-] \geq 1:2$, the melt is stabilised upon the formation of mixed chloride–fluoride complexes of boron and the rate of the reduction of boron no longer varies with time. It is of interest to determine the composition of boron-containing complexes in the initial chloride melt and the complexes formed upon titration of the melt by fluoride ions.

The coordination number of boron in the chloride–fluoride complex was calculated using a procedure taking account of the dependence of the shift of the wave peak potential for the reduction of boron complexes on the concentration of the free ligand in the melt. The concentration of the free ligand was assumed, as the first approximation, to be equal to the total concentration of fluorine added to the melt. The coordination number determined from the slope of the straight line plotted in the $\Delta E - \ln c_{F^-}$ coordinates (Fig. 6) is equal to unity, i.e. during titration of the KCl–NaCl–NaBF₄ melt by fluoride ions, one fluoride ion adds to the initial species. Hence, the mixed chloride–fluoride complex of boron in the NaCl–KCl melt has the composition $[BF_3Cl]^-$ and the species occurring in the melt with excess fluoride ions is BF_4^- . The application of a correction for the concentration of the bound ligand, determined by the molar ratio $[B^{3+}]:[F^-] = 1:1$, did not alter the results.

Figure 6. Calculation of the coordination number of boron in the complexes occurring in the KCl–NaCl–NaF–NaBF₄ melt.

Based on the foregoing, it can be concluded that the formation of mixed chloride–fluoride complexes of boron can be described by the following equations.

In the absence of excess fluoride ions in the melt

and in the presence of excess fluoride ions in the melt

VI. Electrochemical synthesis of titanium diboride and titanium intermetallic compounds in a chloride–fluoride melt

1. Joint electroreduction of titanium and boron in the chloride–fluoride melt and electrodeposition of titanium diboride powders

It has been shown⁶⁴ that the addition to the KCl–NaCl–NaF–KBF₄ melt of titanium trichloride in a concentration close to half that of potassium tetrafluoroborate results in a sharp increase in the current at potentials 0.25 V more positive than the potential of reduction of titanium complexes. This brings about a wave characterised by a steeper slope than the waves for the discharge of the titanium and boron complex ions. This wave is displayed on voltammograms over broad ranges of polarisation rates and TiCl₃ and MBF₄ concentrations (Fig. 7). If the ratio $[Ti^{3+}]:[B^{3+}] = 1:2$ does not hold, then electroreduction

Figure 7. Voltammograms for various processes ($T = 1000$ K, polarisation rate 1.0 V s^{-1} , chlorine reference electrode); (1) electroreduction of titanium from the NaCl–KCl–NaF melt containing $4.5 \times 10^{-5} \text{ mol cm}^{-3}$ of TiCl₃; (2) electroreduction of boron from the NaCl–KCl–NaF melt containing $8 \times 10^{-5} \text{ mol cm}^{-3}$ of NaBF₄; (3) electrochemical synthesis of titanium diboride from the NaCl–KCl–NaF–TiCl₃–NaBF₄ melt ($[Ti] + [B] = 1.2 \times 10^{-4} \text{ mol cm}^{-3}$).

of TiB₂ is followed (before the discharge of the alkali metal) by the discharge of the excess (with respect to this ratio) of a component (titanium or boron). When this ratio is lower than 1:2, this wave is exhibited at less negative potentials than in the case where the ratio is greater than 1:2. The cyclic voltammograms (reverse recording) for $[Ti^{3+}]:[B^{3+}] = 1:2$ were found to contain one peak, while those for $[Ti^{3+}]:[B^{3+}] \neq 1:2$ exhibit at least two peaks. Identification of the products of potentiostatic electrolysis demonstrated that the electrolysis product obtained at the potential of the first cathodic wave is titanium diboride, while that deposited at the second cathodic wave potential is titanium diboride together with the component (either titanium or boron) in excess with respect to the ratio $[Ti^{3+}]:[B^{3+}] = 1:2$.

The formation of titanium diboride is accompanied by evolution of a substantial amount of energy; therefore, its synthesis proceeds at more positive potentials than the separate reduction of either component of the synthesis. Depolarisation is equal to 0.15–0.3 V (with respect to the initial components), depending on the electrolyte composition. Comparison of the dependences of $i_p/V^{1/2}$ on $V^{1/2}$ for the joint and individual electroreduction of titanium and boron shows that at high polarisation rates, the peak current of the synthesis wave is much lower than the sum of the partial currents corresponding to the discharge of the titanium and boron complexes. This fact implies that the process is retarded due to the preceding chemical reaction; the higher the polarisation rate, the more pronounced the retardation (Fig. 8). This is due to the fact that the titanium and boron complex ions present in the melt form mixed complexes such as $[B_2TiF_xCl_y]$.⁶⁵ The absence of a horizontal section on the $i_p/V^{1/2}$ vs. $V^{1/2}$ plot (as well as on the plots for the partial currents for titanium or boron), which would be due to the flow of electrochemically active species moving from the bulk melt, provides grounds for considering, according to the diagnostic electrochemical criteria, that the lifetime of the arising species is short with respect to the lifetime of species formed by titanium and boron in the corresponding systems. A decrease in the polarisation rate results in a lower contribution of the formation of joint complexes. Extrapolation of this dependence for the limiting current to the rate axis gives the current corresponding to the total concentration of titanium and boron in the melt.

The introduction of boron as BF_4^- into the chloride melt containing $[TiCl_6]^{3-}$ ions gives rise to exchange reaction (35). The fluoride ion thus liberated adds to the titanium complex

When there is no excess fluoride ions in the melt, the composition of the joint complex is $[B_2TiF_8Cl_4]^{3-}$. The wave of

Figure 8. Variation of $i_p/V^{1/2}$ vs. $V^{1/2}$ for a number of processes; (1) electroreduction of titanium complexes, $[Ti] = 6 \times 10^{-5} \text{ mol cm}^{-3}$; (2) electroreduction of boron complexes, $[B] = 1.2 \times 10^{-4} \text{ mol cm}^{-3}$; (3) electrochemical synthesis of titanium diboride, $[Ti] + [B] = 1.8 \times 10^{-4} \text{ mol cm}^{-3}$, $[Ti^{3+}]:[B^{3+}] = 1:2$.

the joint electroreduction (synthesis) is extended along the potential axis; the peak width reaches 0.5 V and the potential difference between the peaks of the waves displayed during the forward and reverse recording of voltammograms is 1.0 V. The introduction of fluoride ions into the melt decreases the width of the wave and shifts the wave to the negative region; the difference between the potentials of the peaks of the cathodic and anodic waves decreases simultaneously. For the molar ratio $([Ti^{3+}] + [B^{3+}]):[F^-] \geq 1:15$, the wave width and the difference between the peak potentials barely change.

The shift of the peak potentials of the synthesis wave towards negative values is due to the formation of stronger complexes upon the attachment of the fluoride ions in the melt to the initial complex species

The fact that the peak and half-peak potentials of the synthesis waves do not depend on the polarisation rate as well as the S-shape of the voltammograms imply a reversible step of charge transfer at polarisation rates of $< 2.0 \text{ Vs}^{-1}$. The number of electrons involved in the elementary electrochemical step, calculated using the Matsuda–Ayabe equation, is equal to 9. This means that the discharge of the arising joint complexes at a polarisation rate of $< 2.0 \text{ Vs}^{-1}$ involves simultaneous transfer of nine electrons without kinetic limitations. Study of the electrochemical behaviour of a titanium diboride electrode in a chloride–fluoride melt showed that there is no equilibrium between the electrode and the melt and that the electrochemical step proper is reversible. During dissolution of titanium diboride, limitations appear associated with the chemical interaction at the electrode–melt interface.

As noted above, the charge transfer steps in the separate discharge of titanium and boron complexes are retarded and the electrochemical stage of the synthesis of titanium diboride is reversible. This confirms the assumption that the complexes react chemically in the bulk of the melt to give electrochemically active species, the discharge of which is reversible.

The calculation of the coordination number for a mixed titanium and boron complexes shows that during titration of the melt with fluoride ions, four fluoride ions are attached to the initial species, $[TiB_2F_8Cl_4]^{3-}$, to give $[TiB_2F_{12}]^{3-}$.

It has been established relying on chronovoltammetric measurements^{72,73} that, for the discharge of joint titanium and boron complexes to persist, the molar ratio $([Ti^{3+}] + [B^{3+}]):[F^-] = 1:4$ (for $[Ti^{3+}]:[B^{3+}] = 1:2$) should be maintained in the melt.

The results obtained were taken as the basis for practical implementation of the high-temperature electrochemical synthesis of titanium diboride. The influence of temperature, current density, and the concentrations of the synthesis components on the composition and properties of the product were studied. A

crucial condition for this process is that the molar ratio $[Ti^{3+}]:[B^{3+}] = 1:2$ is maintained in the melt. In this case, a homogeneous phase of titanium diboride is deposited at the cathode over a broad range of current densities. If this condition is not fulfilled, titanium diboride is deposited at the cathode at relatively low current densities (up to 0.5 A cm^{-2}), while at higher current densities, it is deposited together with the component present in excess with respect to this ratio. The total concentration of titanium and boron in the electrolyte in the 0.6 mol.%–30 mol.% range does not influence significantly the product composition or economical characteristics of the process. A decrease in the total concentration to $< 0.6 \text{ mol.}\%$ is not expedient for technological reasons (frequent correction of the cell, low current density and low output), whereas an increase in the concentration to $> 30 \text{ mol.}\%$ brings about a greater loss of boron due to the thermal dissociation of potassium tetrafluoroborate, enhanced corrosiveness of the melt, and difficulty in washing out the cathodic deposit.

The temperature threshold for the onset of the electrochemical synthesis of titanium diboride in the system studied is 873–893 K.⁶⁶ The optimum temperature range is 963–1123 K. An increase in the temperature above 1123 K is not expedient as it diminishes the thermal stability of the cell and deteriorates the conditions of the formation of the metal salt precipitate. In the temperature range of 963–1123 K, highly dispersed titanium diboride powders with a specific surface area of up to $10 \text{ m}^2 \text{ g}^{-1}$ are produced.

Dispersed powders of titanium diboride were obtained using the $KCl-NaCl-NaF$ (30 mol.%)- $TiCl_3$ (5 mol.%)- KBF_4 (10 mol.%) system as the electrolyte, current densities of 0.5 to 1.6 A cm^{-2} , and a temperature of 1023 K. The degree of dispersion of the powders increased with an increase in the current density; when the current density was $< 0.5 \text{ A cm}^{-2}$, dendrites were formed, while at a current density of $> 1.6 \text{ A cm}^{-2}$, titanium diboride was deposited at the cathode together with an alkali metal.

2. Joint electroreduction of titanium, nickel, cobalt and iron and electrodeposition of titanium intermetallic compounds

In the electrolysis of melts containing simultaneously titanium and iron (nickel, cobalt) chloride, powdered intermetallic compounds (IMC) of titanium, $TiFe$, $TiFe_2$, Ti_2Ni , $TiNi_3$ and $TiCo$, are formed at the cathode.^{67–69} The ways of controlling the processes of formation of IMC have been studied allowing for the mechanisms proposed for high-temperature electrochemical synthesis.

Electrochemical behaviour of titanium and iron chlorides occurring in the melt has been studied by linear chronovoltammetry with cyclic potential sweep according to the three-electrode scheme.⁶⁷ The dependence of the limiting current on the concentration was non-linear (unlike this dependence for simple reversible or irreversible processes). The fact that the height of the wave remains constant when the potential sweep rate increases above 0.5 Vs^{-1} implies a retarding influence of the preceding chemical reaction. The illegibility of the peak wave also confirms that the chemical and electrochemical stages are coupled.⁷⁰ It was noted⁶⁷ that potential of the cathode current shifts to the negative region and that the difference between the peak and half-peak potentials of the cathode current increases with an increase in the potential sweep rate. In view of the foregoing, with the assumption of first-order chemical reactions, two stages of high-temperature electrochemical synthesis can be distinguished.

1. Chemical reaction to give the equilibrium

where $z = 3x + 2y$, which shifts towards the formation of the heteronuclear complex $[Ti_xFe_y]^{z+}$; the heat of formation of the corresponding intermetallic compound increases.

2. Electrochemical reduction of the heteronuclear complex cation after the discharge potential has been attained

Analysis of the diffusion coefficients shows that charge numbers of 3 and 4 are preferred for complex IMC (the particular number depends on the particular compound). Therefore, the intermetallic chloride complexes discharged at the cathode are $[\text{TiFe}_2]\text{Cl}_3$ and $[\text{TiFe}]\text{Cl}_3$.

A series of experiments dealing with the influence of the concentration of titanium on the peak potential of nickel discharge has been carried out.⁶⁸ Titanium is formally considered as a 'quasi-ligand', although, in accordance with the views of the coordination chemistry of melts,⁷¹ it is incorporated in the nucleus of the heteronuclear complex $[\text{Ti}_x\text{Ni}_y]^{n+}$. The variation of the difference between the potentials of nickel reduction ΔE_{pNi} in the presence and in the absence of TiCl_3 as a function of the Napierian logarithm of the ratio of TiCl_3 and NiCl_2 concentrations has three linear sections characterised by different slopes and a horizontal section for a large excess of titanium (Fig. 9). The formal coordination numbers of nickel with respect to titanium (the number of titanium atoms per nickel atom in the complex), determined from the slopes of the linear sections, are 0.4, 0.95 and 1.78. They are close to theoretical values of 0.33, 1.0 and 2.0 respectively, which correspond to the heteronuclear complexes $[\text{TiNi}_3]^{n+}$, $[\text{TiNi}]^{n+}$, $[\text{Ti}_2\text{Ni}]^{n+}$. The assumed formation of these complexes has been confirmed⁶⁸ by X-ray diffraction analysis of the products of electrolysis at the potential of the intermediate wave of the synthesis; in addition to nickel, the powder contained intermetallic compounds TiNi_3 , TiNi and Ti_2Ni .

The reaction of NiCl_2 and TiCl_3 can be represented in the following way. According to spectroscopic measurements,⁷² Ni^{2+} and Ti^{3+} cations form octahedral complexes $[\text{NiCl}_6]^{4-}$ and $[\text{TiCl}_6]^{3-}$ with chloride anions. Evidently, when the titanium concentrations are low ($5 \times 10^{-5} \text{ mol cm}^{-3}$) and the ratio $[\text{Ti}]:[\text{Ni}] = 1:1$, only these nickel and titanium complexes exist. The fact that upon an increase in the titanium concentration, a wave for the discharge of the intermetallic compound $[\text{Ti}_x\text{Ni}_y]^{n+}$ appears between the discharge waves for titanium and nickel implies⁶⁸ a reaction between the two species to give heteronuclear complexes according to the following equations

When titanium is present in a 25-fold (or higher) excess with respect to nickel, the potential of nickel discharge does not shift to negative values. Apparently, this situation corresponds to that in systems with excess complex-forming ions. In these systems, the structures of complexes are distorted; they are destroyed or turn into chain structures or into structures of individual molten salts.⁷¹

A study of the electrochemical behaviour of titanium and cobalt present simultaneously in chloride melts⁶⁹ has been the

Figure 9. ΔE_{pNi} vs. $\ln(c_{\text{TiCl}_3}/c_{\text{NiCl}_2})$ plot for the $\text{KCl}-\text{NaCl}-\text{NiCl}_2-\text{TiCl}_3$ melt; $T = 973 \text{ K}$.

The numbers on the curve are explained in the text.

generalising stage in the investigations into the possibility of producing intermetallic compounds of titanium with iron group elements by high-temperature electrochemical synthesis. The appearance of the synthesis wave and the character of its variation for $\text{Ti}-\text{Co}$ and $\text{Ti}-\text{Ni}$ systems are similar.⁶⁸ The negative slope ratios for the variation of the product of the limiting cathode current by the polarisation rate vs. the limiting cathode current of the synthesis wave makes it possible to propose a process of electrochemical reduction of the heteronuclear complex $[\text{TiCo}]^{n+}$. The electrolysis yields a black finely dispersed metallic powder, TiCo . The powder is based on aggregates of dendrites with an average size of $20 \mu\text{m}$. The specific surface area of the powder is $30 \text{ m}^2 \text{ g}^{-1}$.

The works that are worth mentioning among the most recent studies devoted to the electrochemistry of titanium and its alloys include investigation of the influence of the cationic and anionic compositions of the melts on the corrosion of titanium in alkali and alkaline earth metal halides,⁷³ deposition of silicon,⁷⁴ silver^{75,76} and copper^{77,78} protective coatings onto titanium articles and preparation of titanium and its alloys for deposition.⁷⁹ Electrochemical behaviour of titanium and boron and electrodeposition of titanium intermetallic compounds have been studied in detail.^{80,81}

Abstract. Published data on reactivity and oxidation of lignin and model compounds with hydrogen peroxide, ozone and chlorine dioxide as well as on oxidative destruction of the sulfate pulp lignin with various reagents during bleaching are systematised and generalised. Concepts of lignin activation towards its selective oxidation and kinetic features of sulfate pulp oxidative delignification are considered. The bibliography includes 157 references.

I. Introduction

Wood represents a complex polymeric composition in which lignin and cellulose are the main components.^{1–7} During its processing, lignin and cellulose undergo a variety of parallel redox transformations and behave as a single complex (technical pulp).

Selective oxidative destruction of lignin in pulp, especially in sulfate pulp where lignin has been modified during the sulfate pulping process of the native polymer, is a difficult problem, mostly due to the complexity of lignin, which is built up of a multitude of non-uniform structural elements, and the extremely high variability of properties of this polyfunctional polymer.

The problem of oxidative destruction of residual lignin[†] with peroxy reagents [O_3 , $RC(O)OOH$, H_2O_2] is of considerable practical importance since current manufacture of pulps (predominantly of sulfate pulps) consumes a million tons of chlorine for bleaching and results in toxic chlorine-containing pollutants, including dioxins.

The known multi-step schemes for complete oxidative destruction of the residual lignin with various sets of reagents

have been developed empirically. Such schemes usually have no solid physicochemical background and, as a result, do not always take into account the impact of the preceding technological operations on the physicochemical properties of the residual lignin and the effect of acid-base catalysis. Consideration of these factors takes on especial significance on replacement of the chlorine and chlorine-containing compounds (used so far in the pulp industry) by hydrogen peroxide, oxygen and ozone, which are ecologically friendly but possess relatively low reactivities towards lignin.

The reactivities of the native and residual lignins in pulps and the mechanisms of lignin reactions with various reagents during pulp preparation from a wood raw material have been considered in a series of reviews.^{4,8–10} The last two of them,^{9,10} present a survey of the mechanisms of elementary reactions and characteristics of the majority of reagents used in wood chemistry and depict reaction schemes for the low-molecular-weight compounds that model lignin fragments. However, all these data allowed one only to explain rather than to predict the results of the action of any particular oxidant on the residual lignin. This is associated with the fact that the oxidative destruction of the residual lignin during pulp delignification is usually performed in several stages, because lignin cannot be selectively and completely oxidised in one step with any particular reagent.

It should be noted that lignin (more correctly, lignins) represent chemically labile polyfunctional polymers, which cannot be isolated as individual compounds in native states. Consecutive stages of oxidative destruction on each occasion deal with a 'different' lignin of a lignino-cellulose composition (technical pulp). Any chemical action on lignin not only alters its functional and polymeric composition but it also changes the number, ratio and strength of electrophilic and nucleophilic centres and the contents of 'weak' bonds in a lignin macromolecule.

The necessity to account for, and systematise, all the above-mentioned factors has led to the development of a new approach, in which the multi-step process of oxidative destruction of the residual lignin is considered as a united combination of redox transformations, wherein each particular stage 'prepares' and activates lignin for the subsequent technological stage through creation in lignin of new centres reactive towards nucleophilic or electrophilic reagents.

[†] Lignin that remained in the sulfate pulp after cooking.

This review includes a brief description of the lignin structure, a consideration of the reactions of some model compounds which are hard to oxidise with oxygen, hydroperoxide anions, ozone and chlorine dioxide as well as delignification of the sulfate pulp with hydrogen peroxide and ozone and activation of lignin towards its oxidative destruction with various reagents. It also introduces a concept of selective lignin oxidation by consecutive action of peroxy reagents, which has led to the development of the most efficient schemes for pulp bleaching. In addition, the kinetic features of oxidative lignin destruction in the processes of the sulfate pulp delignification are discussed.

II. Lignin structure

Lignins represent macromolecular polyfunctional aromatic compounds; a structural model of softwood lignin according to Freudenberg is described in Scheme 1. Being the components of wood tissues, lignins are responsible for vital mechanical, chemical and biological functions,^{1–4} viz., they impart durability and protection against oxidation and microbial action. Lignin is biosynthesised in close proximity to macromolecules of cellulose and non-cellulosic polysaccharides, which results in a lignin–carbohydrate polymeric matrix. Chemical, physicochemical and mechanical interactions of lignin with cellulose ensure the formation of a complex polymeric composition, viz., the wood tissue, and predetermine the reactivities of its main components in chemotechnological processes. Wood lignins are built up of substituted phenol–propane units. Guaiacyl- and syringylpropanol units are the most common structural elements.^{11–17}

R = H, OMe.

The structural units are linked to each other with various ether and carbon–carbon bonds.^{18–21}

Because of structural irregularity and great variety of the chemical bonds in lignin, the description of its macromolecule as a simple combination of a few (or a multitude of) monomers (substituted phenol–propane units) seems to be impossible.^{22–26} The structure of lignin is still the subject of model studies.^{27–30}

Several lignin structures, *e.g.*, that shown in Scheme 1,²⁸ have been proposed based on the results of studies of lignin ethanolysis, thioacetolysis, oxidation^{31–33} and hydrogenolysis³⁴ products, data of elemental analysis, functional group determinations, comparative analysis of properties of native lignin and synthetic dehydropolymers (DHP) built of substituted phenol–propane units, spectroscopic data (¹H and ¹³C NMR, IR, UV),^{20, 22, 35, 36} the results of gel and gas chromatography and mass spectrometry. A segment of lignin macromolecule represented in the Freudenberg scheme contains 18 phenol–propane units and reflects the ratio of the main types of structural units, bonds and functional groups. This scheme can be supplemented by alternative structural elements, *e.g.*, 6b, 13b, 14b, 13c and 14c. Later, Adler³⁷ suggested a structural scheme for a segment of the fir-wood lignin

Scheme 1

Table 1. Types and number of linkages between the structural elements in different lignin models.¹⁸

Linkage type	Number of linkages per 100 phenol–propane units ^a		
	I	II	III

macromolecule comprising 16 phenol–propane units. It is obvious that in such small segments it is rather difficult to take precisely into consideration the ratio of certain lignin structural elements and bonds. A recently proposed³⁸ model of fir-wood lignin contained 28 phenol–propane units and included some alternative structural elements that were previously absent in the Adler scheme. In addition to the models with a relatively small number of phenol–propane units built up by random combination of functional groups, bonds and structural elements, several more complete computer structural models for fir-wood lignin have been suggested. Thus the Glasser model³⁹ for lignin with molecular weight > 17 000 contains 94 phenol–propane units and takes into account most of the known analytical data. The results of simulations of the lignin structure (models suggested by Glasser,³⁹ Erickson⁴⁰ and Nimz⁴¹) are presented in Table 1.

The structural heterogeneity of lignins is associated with specific features of lignin biogenesis in wood tissues. The first stage of lignin biosynthesis is the enzymic oxidative deprotonation of *p*-hydroxycinnamyl alcohols (coumaryl, coniferyl and sinapyl alcohols) leading to the formation of a system containing the radicals **1a–e** (Scheme 2).³⁸

Scheme 2

Recombination of two radicals affords one of 36 possible dimers. Upon the action of peroxidases, the latter undergo further oxidation producing dimeric radicals which, in turn, can form several hundred combinations of tetramers. The random character of the electron localisation predetermines the sporadic character and irregularity of the lignin structure.^{3,5}

However, not all combinations in the coupling of monomers are of the equal probability. It has been shown by quantum-chemical calculations that the electron density distribution favours the formation of the ether C(β)–O–C(4) linkage resulting from the coupling of radicals **1a** and **1b**. Indeed, this linkage type predominates in lignins (Table 1). The functional group distribution with regards to the linkage types for the C(α), C(β) and C(γ) atoms in the side chain is described by the Ridholm diagram³⁸ (Table 2). Thus, the literature data available to date do not provide an unambiguous definition of lignin as an individual chemical compound and this substantially prevents assessment of its reactivity by the methods of classical organic chemistry, *i.e.*, by studying reactions of simple monomers and dimers mimicking different substituted phenol–propane structural units of lignin. Such studies may only provide helpful information regarding the elementary reactions of the lignin functional groups with oxidants rather than predict unambiguously their reactions with lignin itself.

The residual lignin in sulfate pulp from *Pinus radiata* has been studied by means of mass spectrometry and ¹³C NMR spectroscopy.³⁶ Residual lignin was isolated by treating the sulfate pulp with cellulase. As the duration of sulfate cooking is increased, the number of the C–C bonds increases and the portion of the β-aryl-ether bonds in the residual lignin is decreased, thus indicating the higher degree of lignin condensation. Despite the reduction of a

Table 2. Functional group distribution in lignin according to bond types based on ¹³C NMR spectroscopic data (the Ridholm diagram).

^a Molecular formula for a structural unit of fir-wood LMP is C₉H_{8.8}O_{2.4}(OCH₃)_{0.96}. ^b Molecular formula for a structural unit of pine-wood sulfate lignin is C₉H_{7.9}O_{2.1}S_{0.1}(OCH₃)_{0.82}. ^c Calculated by difference. ^d Method of differential UV spectroscopy based on the measurement of a difference in absorption of compounds with ionised and non-ionised phenolic and hydroxy groups in solutions of different pH.¹²

percentage of the β-aryl-ether bonds in lignin from 70% to 50%, the portion of these bonds in the residual lignin remained to be considerable even in the cases of low lignin content in pulp upon profound delignification. The sulfate lignin differs from slightly modified lignin of mechanical pulps (LMP) in the content of functional groups (Table 3).

The sulfate pine-wood lignin contains fewer carbonyl and aliphatic hydroxy groups and more carboxy and phenolic OH groups.^{1–3} It is free from the coniferyl–aldehyde groups, which are lost during the sulfate cooking,⁴² and virtually free from the benzyl alcohol OH or ether groups. During the sulfate cooking partial loss of the γ-hydroxymethyl and methoxy groups is also observed. In addition, contrarily to LMP, sulfate lignins contain the thiol group and elementary sulfur.^{8, 42}

Softwood lignins are mostly built up of guaiacol derivatives, while guaiacol and syringol derivatives are the main constituents of hardwood lignins. Thus non-fractionated sulfate birch-wood lignin contains approximately equal amounts of both types of derivatives.³⁶ The fractionation of lignin has shown that the ratio of syringol and guaiacol derivatives is increased from 0.8 to 1.5 with diminishing of the lignin molecular weight from 3500 to 650.²⁹

Examination of DHP has shown that these compounds have different structures and properties depending on the manner of addition of initial monomers (substituted phenol–propane units) to the reaction mixture. When the monomer is added in one portion, the couplings of dimeric radicals with a monomer occur more rarely than in the gradual addition, whereas the couplings of a ‘monomer–monomer’ type become more abundant. In this case, the C(β)–C(5) bonds predominate.¹⁵ The probability of the radical coupling of a ‘polymer–polymer’ type is higher on gradual addition of the monomer due to the low concentration of the latter. In this case, the C(β)–O–C(4) bonds predominate. It should be noted that recent hydrodynamic investigations of DHP and slightly modified softwood lignins do not quite agree with this hypothesis of the existence of two types of lignins.²

The native lignin is synthesised in plants from monomeric molecules that usually have from two to four functional groups.^{15, 28} The formation of both branched chains and network structures (at gel-point) is theoretically possible.²⁴ As has already

been pointed out, the interaction of the growing lignin polymeric chains with surrounding macromolecules of non-cellulosic polysaccharides in plant tissues results in the formation of an amorphous lignocellulosic matrix. According to the Erin’sh hypothesis,^{7, 26} the three-dimensional structure of this matrix represents a superposition of three networks, *viz.*, a network of hydrogen bonds between lignin and carbohydrates (H-network), a network of the lignin–carbohydrate bonds (LC-network) and a network of lignin itself. The most important arguments in favour of this hypothesis are insolubility of native lignin in all neutral solvents without preliminary chemical or mechanical treatment and high polydispersity of lignins isolated from wood tissues. Based on the theory for branching processes, the average molecular masses for sol fractions of model lignin compounds have been calculated³⁰ to be 1300–13 800. According to these values, the lignin extracted with ethanol in the absence of catalysts can be considered as a sol fraction of the native lignin. A new promising direction in the study of biosynthesis and the structure of lignin is a computer-assisted simulation of the growth of fractal clusters with fractional dimensionalities.²⁴

Thus the currently available results of direct and indirect chemical, physicochemical and physical investigations taken altogether do not allow one to define unambiguously the formula and all levels of structural organisation for lignin. The properties and reactivities of industrial lignins depend to a considerable extent on the preparation methods.^{1, 17} The residual lignin is the most condensed and high-molecular-weight part of the lignin matrix involved into a lignin–cellulose composition, and its selective removal from cellulose fibres can only be achieved with the use of oxidants.⁴³ The presence of different types of functional groups and bonds in sulfate lignin and in the residual one predetermines a wide range of reagents used for lignin oxidative destruction in the preparation of cellulose from raw wood materials.

The main method for the study of lignin transformations is based on the analysis of reaction products resulting from the reaction of model compounds with oxidants. The most efficient reagent used for oxidative destruction and solubilisation of residual lignin in the pulp bleaching are molecular chlorine,^{44–46} sodium hypochlorite,^{47–49} hypochlorous acid,^{48, 50} sodium chlorite,⁵⁰ chlorine dioxide,^{51, 52} organic^{9, 10, 53} and mineral⁵⁴ peroxy acids, hydrogen peroxide,^{55–57} oxygen^{58, 59} and ozone.^{60–62} One of promising approaches to oxidative destruction of residual lignin in industrial pulps during bleaching is the biotechnological method.^{63, 64}

Molecular chlorine is widely employed in the pulp industry for oxidation of lignin during the pulp bleaching, however, its application is accompanied by concomitant formation of a number of toxic aromatic chlorine-containing products,^{65, 66} including dioxins.⁶⁷ The use of sodium hypochlorite for the pulp bleaching is accompanied by the formation of chloroform.⁶⁸ Chlorinated hydrocarbons are dangerous for both living organisms and the Earth ozone layer. Therefore, the oxidation processes based on the use of environmentally safer reagents, such as hydrogen peroxide, chlorine dioxide and ozone, are of great importance. The reactions of model lignin compounds with these reagents are discussed below.

III. Oxidation of model compounds

1. Oxidation with hydrogen peroxide and oxygen

In an alkaline medium, hydrogen peroxide can undergo various transformations. When the concentration of a base is high, the decomposition of H₂O₂ follows predominantly a radical mechanism with the formation of molecular oxygen:^{69, 70}

The oxidation of lignin with oxygen in an alkaline medium is accompanied by generation of the radical anions $\text{O}_2^{\cdot-}$, hydroxyl radicals and singlet oxygen ($^1\text{O}_2$). The schemes of generation of the reactive oxygen forms and their mutual transformations are described by the following equations

Comparison of these equations with the equations (1)–(5) shows that both systems contain all the above-mentioned species independently of the oxidant used (O_2 or H_2O_2).^{70, 71} The equations (8), (9) and (11) account for the chemiluminescence observed in the oxidation of lignin with oxygen.^{71–73} The decomposition of H_2O_2 is catalysed by transition metal ions (Fe, Mn, Cu, Zn, *etc.*) that are present in plant tissues and lignin.^{59, 74, 75}

The rate and the depth of the lignin oxidation with H_2O_2 and O_2 depends on the reaction conditions. The reaction (6) leads to the single-electron oxidation of a phenolic fragment in lignin.

The superoxide radical anion $\text{O}_2^{\cdot-}$ takes part in the single-electron transfer as a reducing agent and in nucleophilic deprotonation [equation (7)] and substitution reactions. In aqueous and non-aqueous media, this radical anion can oxidise hydroquinones⁵³ and aromatic dianions.^{69, 70} Vanillin, acetovanillone and guaiacol are resistant to the action of the radical anion in aprotic (pyridine, DMSO) solvents, while α -methylvanillyl alcohol is rapidly oxidised by this oxidant to acetovanillone and hydroquinone is oxidised to acids.⁷⁶ Despite the oxidation of some model compounds, the sulfate lignin itself does not undergo any noticeable changes except the partial loss of the phenolic hydroxy groups (according to the data of liquid chromatography, ^1H NMR, IR and UV spectroscopy).^{77–79}

The hydroxyl radical $\text{HO}^{\cdot}$ acts as an electrophile to form σ -complexes with aromatic structural units of lignin. The latter undergo subsequent transformations involving cleavage of the side-chain C–C bonds of lignin, cleavage of the aryl–aryl bonds and demethylation.^{80, 81} The radicals $\text{HO}^{\cdot}$ also induce lignin hydroxylation, cleavage of biphenyl bonds and degradation of aromatic rings.⁴³ In this respect, these radicals are more reactive than $\text{O}_2^{\cdot-}$. On the contrary, in reactions with carbohydrates,^{71–73} the radical $\text{HO}^{\cdot}$ is less reactive: its addition to the aromatic fragments of lignin occurs fivefold faster than hydrogen abstraction from carbohydrates. Unlike $\text{HO}^{\cdot}$, the superoxide radical anions react with lignin with difficulty but easily destroy cellulose.⁷⁰ This apparently is a result of a different ratio of the nucleophilic and electrophilic reactive centres in lignin and carbohydrates.

It was found⁷⁰ that lignin and catechol are readily oxidised at pH 14 with hydrogen peroxide even at room temperature producing the radical anions $\text{O}_2^{\cdot-}$. The latter are detected by the appearance of an intense violet colour in the presence of Tetrazolium Violet 1–2 min after the beginning of the reaction. Such model compounds as guaiacol, isoeugenol, vanillic and

ferulic acids, β -guaiacyl ether of α -guaiacylethanone and β -guaiacyl ether of α -guaiacylethanol did not react with H_2O_2 even at 60 °C for 4 h. An important practical outcome of this study was the finding that catechol and the Pepper lignin do not virtually undergo oxidation at $\text{pH} \leq 11.0$. On increasing pH to 12.25, the rate of the catechol oxidation is sharply increased, which is rationalised⁷⁰ as the result of the second-step dissociation of catechol ($\text{p}K_a \sim 12.5$, for the first step $\text{p}K_a = 9.45$). Kinetic studies provide evidence on an induction period prior to the appearance of H_2O_2 in the system, which catalyses the process described by the following equations

Thus, at high concentration of a base (NaOH), low content of oxygen and moderate temperatures the most probable reaction centres in lignin are the catechol structural units, and hydrogen peroxide acts on lignin in the same manner as does oxygen.

The oxidation of dimeric model lignin compounds of the 1,2-diarylpropane-1,3-diol type with hydrogen peroxide and oxygen has been studied⁷⁹ in the example of 1-(4-hydroxy-3-methoxyphenyl)-2-(4-hydroxy-3-methoxyphenyl)propane-1,3-diol (**2a**) and 1-(3-ethoxy-4-hydroxyphenyl)-2-(4-hydroxy-3-methoxyphenyl)propane-1,3-diol (**2b**). It was preliminarily shown that compound **2b** forms 3-(3-ethoxy-4-hydroxyphenyl)-2-(4-hydroxy-3-methoxyphenyl)prop-2-en-1-ol (**4b**) and 3-ethoxy-4,4'-dihydroxy-3'-methoxystilbene (**5b**) (side reaction) dianions at pH 11–13 in the absence of oxygen (in vacuum), the equilibrium mixture containing *ca.* 95% of the initial dimer (Scheme 3).

Analogous stilbene derivatives were earlier^{80, 81} obtained from diols of the type **2a,b**. However, the α,β -elimination products are formed in higher yields only in the case of structures containing hydroxymethylphenyl fragments.⁸²

Vanillin and ethylvanillin instead of stilbene dianions **4b** and **5b** were obtained in experiments with preliminary passage of air or

nitrogen through the system, thus indicating the oxidative character of the process. This result can be explained by rapid autooxidation of the initially formed stilbenes with a trace amount of oxygen dissolved in the alkaline solution.

The oxidation of diol **2b** with a solution of H_2O_2 stabilised at pH 10.5 results in the formation of ethanol, methanol ethylvanillin and small amounts of other compounds (the conversion of the initial diol is 30%) (Table 4). After 4 h of the treatment, 85% of hydrogen peroxide still remained unconsumed. Some amount of H_2O_2 is lost due to decomposing, and about 1%–2% of the oxygen thus generated is consumed in the oxidation of diols as follows from the analysis of stilbene and the initial diol autooxidation products.

Diols of the type **2** are less reactive towards H_2O_2 than the products of their initial oxidation.⁷⁹ According to the composition of the oxidation products, the main direction of the oxidation of these diols with the stabilised hydrogen peroxide (*i.e.*, in an oxygen-free system) involves the nucleophilic attack of the HO_2^- anions on quinonemethide anion **3** and the oxidation of stilbene dianion **4**. The hydroperoxide thus formed undergoes consecutive rearrangement and fragmentation yielding the hydroquinone dianion (**6**) and α -(4-hydroxy-3-methoxyphenyl)- β -hydroxypropanol anion (**11**). The latter is converted into the guaiacylglycol anion (**8**) (Scheme 4).

The oxidation of phenylpropan-2-one with hydrogen peroxide follows the same mechanism, this reaction may be regarded as an alkaline analogue of the Baeyer–Villiger reaction.⁸² It should be noted that dihydroxyphenyl derivatives, like guaiacylglycol, have also been obtained by the action of basidiomycetes *Phanerochaete chrysosporium* on diols of the type **2**.⁸³ The same mechanism for conversion of α -hydroperoxide into guaiacylglycol and ethylvanillin has been proposed in another study.⁸⁴

The mechanism of oxidation of stilbenes **4b** and **5b** with hydrogen peroxide in alkaline media in the absence (or virtual

^a Reaction conditions: 45 °C, 4 h, pH 10.5, [dimer] = 0.07×10^{-3} , [DTPA] = 0.4×10^{-3} , $[\text{MgSO}_4]$ = 0.16×10^{-3} mol litre⁻¹, $[\text{H}_2\text{O}_2]/[\text{dimer}]$ = 3. ^b Same reaction conditions but without addition of DTPA and MgSO_4 . ^c Reaction conditions: 45 °C, 4 h, pH 10.5. ^d Hydroxyethylvanillin in the case of the method *B*.

absence) of oxygen is rather difficult to describe in detail since the hydroperoxide anion, as a strong nucleophilic reagent, cannot directly attack the electrophilic alkene structures. The oxidation occurs as the result of preliminary rearrangement of the stilbene dianion **4b** into quinonemethide and subsequent attack by the hydroperoxide anion. ω -Hydroxyacetoguaiacone, ethoxyhydroquinone and acetoguaiacone were expected to be the products of these reactions. However, only a trace amount of ethoxyhydroquinone has been detected (Table 4). Thus, the reaction of non-dissociated hydrogen peroxide with the stilbene **4b** seems to be more probable.⁷⁹

Comparison of the results of oxidation of the diol **2** with a non-stabilised alkaline solution of hydrogen peroxide at constant pH 10.5 with those obtained in its oxidation with stabilised H_2O_2 in the absence of oxygen (Table 4) allows one to reveal a number of differences, *viz.*, the decomposition of non-stabilised hydrogen peroxide is almost complete, the degree of conversion for the initial diol is increased from 30% to 69%, the yields of the oxidation products (especially of ethanol, methanol, ethylvanillin and alkoxyhydroquinone) are higher, and the products contain the following organic acids:⁷⁰

Acid	Yield (%)
Succinic	≤ 1
Oxalic	≤ 1
Hydroxymaleic	1–2
Malonic	5
Glycolic	1–2

These differences are explained by the presence in the reaction mixtures of some additional oxidants: oxygen, hydroxyl radicals and superoxide radical anions along with non-stabilised hydrogen peroxide, which are formed in the reactions (1)–(4). In the other

words, the oxidation process induces the generation of new oxidants.

$$R^1 = \text{OH, OAc}; R^2 = \text{Me, Et.}$$

The action of oxygen generated upon decomposition of hydrogen peroxide results in the formation of quinoid products.

Quinonemethides of the type **3** and *o*-quinones which appear in the reaction mixture are oxidised by hydroxyperoxide anions to carboxylic acids.

When the diol **2b** is allowed to react with H₂O₂ in the absence of a stabiliser and without maintenance of pH at 12.5, the pH value is decreased to 10 due to the accumulation in the reaction

Scheme 5

mixture of carboxylic acids. Simultaneously, there is observed an increase in the portion of nonconsumed diol and an increase in the total yield of ethylvanillin and ethoxyhydroquinone (from 15% to 29%) as a consequence of the increased concentrations of hydroperoxide anion and non-dissociated hydrogen peroxide in the solution.

The particular contribution of oxygen generated *in situ* in the total oxidation process was estimated in the oxidation of the diol **2b** with molecular oxygen, which allowed the authors⁷⁹ to propose a more detailed mechanism for this reaction (Scheme 5), which takes into account the published data.^{80,81} As has already been shown, the diols **2a,b** are partially converted in alkaline media into the stilbene dianions **4** and **5**, which undergo intense oxidative destruction with oxygen. According to the much higher yield of methanol compared with that for ethanol, the reaction predominantly proceeds by a pathway involving the intermediate formation of hydroperoxide **15**.

The data considered above show that model structures like **2a,b** have low reactivity towards hydroperoxide anion but can be relatively easily oxidised with oxygen to low-molecular-weight products. In the presence of hydrogen peroxide, stabilisers, and at $\text{pH} \leq 10.5$, the main oxidising reagent is the hydroperoxide anion, whereas molecular oxygen and its other reactive forms, *i.e.*, O_2^- , O_2 and $\cdot\text{OH}$, become the major oxidants upon increase in pH to 12.

Alkaline hydrogen peroxide readily oxidises α,β -unsaturated ketones of the coniferyl aldehyde type and α,β -diketones but not α -ketones with an etherified phenolic hydroxy group, nor (virtually) propioveratrone and α -hydroxypropioveratrone.⁷⁹

α -Ketones are oxidised through addition of the hydroperoxide anion to the electrophilic carbon atom of the carbonyl group with the intermediate formation of a quinoid compounds. Following recovery of the aromatic system, an ester is formed, which is then hydrolysed. The products of such reactions are vanillyl alcohol and a carboxylic acid with the same aliphatic radical as in the initial ketone⁸² (Scheme 6).

In the case of model compounds of the general formula $\text{ArCH}_2\text{C}(\text{O})\text{Me}$, the intermediate formation of enolic tautomers is observed.¹⁰ An investigation of the oxidation of a series of ketones bearing different substituents in the positions 3 and 4 of the benzene ring has shown⁸² that these reactions mainly result in the rapid cleavage of the initial phenylpropan-2-one into benzaldehyde and acetic acid (Scheme 7).

The mechanism of these reactions apparently involves an attack by the hydroperoxide anion of an enolic tautomer on its $\text{C}(\alpha)$ atom and an intermediate formation of β -hydroxyhydroperoxide anion, fast protonation of this anion by water and subsequent attack by the hydroperoxide anion on the $\text{C}(\beta)$ atom of the initial carbonyl group, leading eventually to synchronous cleavage of the $\text{O}-\text{O}$ bond in the intermediate organic peroxide

and the $\text{C}(\alpha)-\text{C}(\beta)$ bond. The oxidation of α,β -unsaturated ketones of the coniferyl aldehyde type to benzaldehyde occurs *via* the corresponding hydroperoxides and epoxides (Scheme 8).

The reactions of the hydroperoxide anions with quinoid structures result either in the ring opening or in the splitting off of the side chains (Scheme 9).^{8,85} In the oxidation of methoxy-substituted quinones, the demethoxylation and formation of methanol were also observed.

The oxidation of the quinone rings represents apparently a longer reaction pathway in lignin oxidative destruction, even if decomposition of non-terminal units is considered. This requires a larger amount of an oxidising reagent for the scission of the carbon chains than for the side-chain oxidation.

An important feature of the reactions shown in Schemes 6–9 consists in participation of the hydroperoxide anion as a reactive nucleophilic species, which reacts with electron-withdrawing (electrophilic) sites of lignin.

In an acidic medium, the mechanism of reaction of hydrogen peroxide with organic compounds is analogous to that of peroxy acids. In this case, either a protonated hydrogen peroxide H_3O_2^+ or a hydroxonium ion are those reactive electrophilic species which attack the aromatic structures.¹⁰

The oxidation of model lignin compounds with hydrogen peroxide and peroxy acids mainly results in the hydroxylation of the aromatic nuclei, oxidative demethoxylation, oxidative benzene ring opening, splitting off of the side-chains, cleavage of the $\text{C}(\beta)-\text{O}$ ether bonds and formation of epoxides (Scheme 10).

Scheme 9

Scheme 10

Salts of peracetic, performic and mono- and diperoxysulfuric acids in alkaline media are employed as the oxidants for oxidative delignification of wood tissues and mechanical pulps.^{8–10, 86–88} Under conditions favouring stabilisation of the peroxy anion, this acts as a nucleophilic reagent.

The oxidation of structures of the benzyl alcohol type with hydrogen peroxide and peroxy acids to ketones and aldehydes may follow the radical mechanism involving hydroxyl radicals.^{8–10, 85}

It should be noted that studies on the oxidation of compounds that mimic the lignin structural fragments are only useful in drawing a probable scheme (and in some cases, in elucidation of the mechanism) of reactions of the residual pulp lignin. In fact, the processes of oxidative destruction of the residual lignin under the action of a majority of peroxides do not go to completion (except for ozonolysis) and kinetic parameters determined for the oxidation of model compounds substantially differ from those observed during the lignin destruction in a polymeric lignocellulosic matrix.

2. Ozonolysis of model compounds

Reactions of ozone with organic compounds are widely used in organic synthesis, qualitative and quantitative analyses and chemical technology. The mechanisms of these reactions have been considered in detail.^{89, 90} In application to lignin, ozonolysis has been employed to prove its aromatic nature, to determine the nature of substituents in the aromatic rings⁹¹ and to study the three-dimensional structure of side chains in the phenol–propane structural units.⁹²

3. Oxidation of lignin with chlorine dioxide

Chlorine dioxide oxidises lignin in lignin–cellulose matrices without affecting cellulose. Lignin phenolic structural units are oxidised with ClO_2 upon abstraction of the hydrogen atoms from the phenolic hydroxy groups. Muconic acids and quinoid compounds are the final products of such reactions, which are formed without loss of the methoxy groups^{99–101} (Scheme 14).

In the case of aromatic ethers, *e.g.*, 4-methyl-2,3',4'-trimethoxydiphenyl ether (**18**), three different directions for the reaction with chlorine dioxide are possible.^{99,100} These involve the formation of quinoid structures, opening of one of the aromatic rings and cleavage of the diaryl ether bond leading to the formation of hydroquinone and phenol derivatives (Scheme 15).

Veratryl β -guaiacyl ether (**19**) undergoes homolytic fragmentation under the action of chlorine dioxide, one of the reaction products being veratraldehyde. In parallel, the oxidative dehydrogenation of the α -hydroxy group occurs (Scheme 16).

The oxidation of 4,4'-dihydroxy-3,3'-dimethylstilbene (**20**), 4-hydroxy-3,3',4'-trimethoxystilbene (**21**) and 3,4,3',4'-tetramethoxystilbene (**22**) (the most common model compounds of native and residual lignins) with chlorine dioxide has been studied.^{99–101} The main transformations of stilbenes **20–22** are shown in Scheme 17.

Yet another model compound of the residual lignin is 3,4-dimethoxy- β -(2-methoxyphenoxy)styrene (**23**). It reacts with chlorine dioxide by a similar mechanism (Scheme 18). The oxidation involves the formation of a complex of the oxidant with the π -electronic system of the alkene fragment.¹⁰¹ In an acidic medium, this complex is protonated to form a resonance-stabilised radical cation and HClO_2 . The addition of ClO_2 to the β -radical generated leads first to the chlorous ester (**A**), which is

further converted into the ester **B**, from which aldehydes, ketones and esters are formed as the final products.

A possibility of the formation of 1,1-bis(3,4-dimethoxyphenyl)ethylene (**24**) from the corresponding stilbene as a result of aryl radical migration has been shown.¹⁰²

Scheme 16

Scheme 17

$\text{R}^1 = \text{R}^2 = \text{H}$ (**20**); $\text{R}^1 = \text{H}$, $\text{R}^2 = \text{Me}$ (**21**); $\text{R}^1 = \text{R}^2 = \text{Me}$ (**22**).

Scheme 18

Unlike stilbenes **20–23**, compound **24** does not undergo fragmentation under the action of chlorine dioxide. Among the

reaction products, only mono- and dichlorinated derivatives have been found. Oxidative demethoxylation also takes place.

In general, the early stages of the reactions of model lignin compounds with chlorine dioxide result in the formation of conjugated carbonyl groups, *i.e.*, in new chromophoric groups and systems which, as has been shown earlier, are readily oxidised with hydrogen peroxide according to the ionic mechanism involving the nucleophilic addition of the hydroperoxide anion.

IV. Combined action of oxidants on the sulfate pulp lignin

As has already been mentioned, lignin remaining in the sulfate pulp after cooking represents the most condensed, and strongly bound to polysaccharides, part of modified natural lignin (residual lignin). Despite the fact that the composition (various combinations of bonds, functional groups and structural units) and three-dimensional (network^{5,7,26} and fractal^{22,24,25}) polymeric structure of lignin do not allow prediction of the degree and the rate of its oxidative destruction, analysis of the results of the studies on an oxidation of model lignin compounds with hydrogen peroxide, oxygen, ozone, chlorine dioxide and other reagents (*vide supra*) makes it possible to elucidate general features of this process.^{8–10}

The reactivity of lignin towards oxidants depends on the nature of the reactant and the presence of nucleophilic and electrophilic sites in the lignin macromolecule. Under conditions of acid and base catalysis, each particular reagent can produce differently reacting species depending on the medium acidity. A classification of reagents¹⁰ used for lignin oxidation according to their electron-donor and electron-acceptor properties (or nucleophilicity and electrophilicity, respectively) is given in Table 5. The mechanisms of their interaction with lignin and the reactivity of residual lignin itself substantially affect the rate and the depth of the sulfate pulp delignification and a number of the operation steps in pulp bleaching.

The oxidation of nucleophilic alkene fragments in lignin occurs as the initial addition of an electrophile followed by the attack of a nucleophile (Scheme 19).¹⁰ The addition of electrophiles to lignin results in the appearance of new electrophilic sites in the lignin macromolecule and their activation towards the action of nucleophiles.

If one form of the reagent predominates and no cooperation exists between nucleophilic and electrophilic species, the rate of dissolution of the electrophilic reaction products of residual lignin is substantially decreased, which apparently leads to deceleration of the sulfate pulp delignification and to non-rational consumption of bleaching reagents in the chemotechnological processes. The efficiency of the sulfate pulp delignification is especially low when such environmentally safe reagents as hydrogen peroxide and ozone are used compared to chlorine-containing reagents (Table 6).¹⁰³

Normally, complete dissolution of the reaction products of lignin with electrophilic oxidants requires treatment with alkali, *i.e.*, the second stage in the pulp bleaching process is the treatment of pulps with a nucleophilic reagent (alkali). As a rule,

Table 6. The depth of oxidative destruction of lignin in sulfate softwood pulps with equivalent amounts of different reagents.⁹⁵

Reagent (conditions)	Oxidant consumption (% of the pulp mass) ^a	Depth of residual lignin oxidation ^b
Ozone	0.59	0.19
Hydrogen peroxide	1.26	0.30
Ozone + extraction with a NaOH solution	0.59	0.42
Sodium hypochlorite (pH 10)	2.63 ^c	0.53
Sodium hypochlorite + hypochlorous acid (pH 7.5)	2.63 ^c	0.64
Chlorine dioxide	1.00	0.67

^a With respect to the reagent mass. ^b Corresponds to the degree of lignin conversion; the initial lignin content in sulfate softwood pulp is expressed as 76 permanganate units (1 p. u. is referred to the content of lignin in pulps according to Björkman, State standard 6845-54). ^c Per active chlorine unit (active chlorine is defined as an overall amount of chlorine-containing oxidants determined by iodometry).

Cl₂ + NaOH and O₃ + NaOH pairs are used for this purpose. In the second stage, some part of chlorine in chlorolignin is replaced by hydroxy groups, thus enhancing the hydrophilicity of the chlorinated lignin. Delignification of the sulfate pulp can be enhanced by applying 'oxidative alkalification', whereon oxidants such as sodium hypochlorite or hydrogen peroxide are added to an alkaline pulp solution.¹⁰⁴ The hypochlorite anion (ClO⁻) acts on lignin as a nucleophilic reagent, while H₂O₂ in the absence of stabilisers and at high alkalinity of the medium generates various forms of oxidants:

The electrophilic mechanism predominates in the oxidation of lignin;^{10,15,18,105} this has earlier been shown for some lignin model compounds.^{75–80}

Table 5. Reactive forms of the reagents, involved in pulp bleaching processes.

Process (medium)	Substrate	Reagent type	Reactive form	Reacting species	Number of electrons involved in the reaction
Oxidation (acidic)	aromatic and unsaturated structures	electrophile	cation	H ⁺ , OH ⁺ , O ₃ , Cl ⁺ , NO ⁺ , NO ₂ ⁺	2
			radical	H [·] , HO [·] , HO ₂ [·] , O ₂ [·] , Cl [·] , ClO [·] , ClO ₂ [·] , NO [·] , NO ₂ [·]	1
Reduction (alkaline)	non-conjugated and conjugated carbonyl compounds	nucleophile	anion	H ⁻ , HO ⁻ , HO ₂ ⁻ , ClO ⁻ , ClO ₂ ⁻ , S ₂ O ₄ ²⁻	2
			radical	H [·] , e _{aq} ⁻ , SO ₂ ^{·-}	1

Note. The list of reacting species includes both commercial bleaching reagents and the species that are not commercial bleaching reagents but can take part in various pulp bleaching processes.⁹

The most important characteristic of a delignifying reagent is the minimum content of lignin in pulp rather than the portion of lignin removed by this reagent from the pulp (bearing in mind that the initial content of lignin in pulps may vary) at which delignification with this reagent, taken in small excess, is terminated. According to this criterion, the reagents used for delignification of the sulfate pulp (after cooking) can be arranged in the following order: oxygen < hydrogen peroxide < chlorine (with subsequent extraction with a NaOH solution) < sodium hypochlorite < chlorine dioxide.¹⁰³

Lignin in industrial pulps (including sulfate pulp) cannot be selectively destroyed to give water-soluble products and completely removed from pulps by either of the oxidants. To achieve complete delignification (and concomitant bleaching) of sulfate pulp, it is necessary to combine oxidative treatment with different reagents in several (from two¹⁰⁶ to five–seven¹⁰⁷) stages.

Since the 1950s, a large number of publications has appeared that are devoted to the problem of more efficient lignin oxidation with oxygen and hydrogen peroxide aimed at the development of environmentally safe technologies. It should be noted that hydrogen peroxide was used first only for the 'oxygen-induced' type of lignin transformations (quite often together with molecular oxygen¹⁰⁷) because most of researchers referred to the hydroperoxide anion exclusively as the class of 'lignin-preserving reagents',^{10, 75} probably judging from the results of industrial application of these reagents in pulp bleaching.

V. Lignin activation towards oxidative action of oxygen and hydrogen peroxide

Not only chlorine but also nitrogen oxides NO and NO₂ can be used in the bleaching of sulfate pulps.¹⁰⁸ The pulp treated with these oxides is then better bleached with sodium hypochlorite or hydrogen peroxide rather than undergo alkaline extraction as a version of processing.

The use of nitrogen oxides or a system HNO₃–NaNO₂ to increase the efficiency of subsequent sulfate pulp delignification with oxygen has been described.^{109–112} The treatment with nitrogen oxides was applied as an 'activating stage'. According to the published data,¹¹¹ the effect of activation is based on lignin fragmentation as the result of electrophilic substitution and elimination of side chains in phenol–propane structural units, together with partial destruction of the residual lignin. The electrophilic reagent in this process is NO₂⁺ generated in the reaction mixture.¹¹³

Preliminary activation with nitrogen oxides makes it possible to reduce twofold the content of lignin in pulps (hardness) following treatment with oxygen (or H₂O₂ under conditions of the 'oxygen'^{109–112} mechanism): from 10 to 5 Kappa units[§] for

different sorts of pulps. The minimum value of pulp hardness given in some studies^{109–112} equals 3.5 Kappa units, while that in another study was¹¹⁴ ~ 7.0–7.5 Kappa units. In the latter work, the pulp pretreatment with other oxidants (chlorine, chlorine dioxide, ozone, *etc.*) was proved to be efficient. It has also been found¹¹¹ that the selectivity of the sulfate pulp delignification with oxygen and hydrogen peroxide is higher in the case of preliminary pulp treatment with chlorine and ozone than with nitrogen oxides. The minimum hardness of pulps was 6–9 Kappa units after treatment with chlorine (chlorine usage rate was 1%–3% with respect to the mass of absolutely dry pulp) and 6.1 Kappa units after ozonolysis (O₃ usage rate — 1%) at the degree of polymerisation in the range of 1300–1400. This degree of polymerisation without pulp pretreatment was observed only for pulps with hardness of about 15 Kappa units (after pulp delignification with oxygen under pressure of 0.5 MPa in the presence of 0.5% MgSO₄ at 110 and 120 °C or with hydrogen peroxide under the same conditions in the presence of 4% NaOH).

It should be noted that a mixture of nitrogen oxides and oxygen was initially proposed to be used in the pulp pretreatment step for lignin activation.¹¹² However, oxygen only caused stronger destruction of cellulose. Methods involving lignin activation with nitric acid permit removal of up to 75% of residual lignin from pulps.[¶]

One of extremely toxic side products of the lignin nitration is hydrogen cyanide, which is formed at high concentrations of nitrogen oxides. Sodium nitrite, nitrous acid, peroxyntitric acid as well as a redox-composition NaNO₂–H₂SO₄ and some others have been proposed as safer reagents.^{116, 117} After oxidation in these systems and delignification with oxygen, the content of lignin in pulps is reduced to 8–9 Kappa units.

The common principle of the methods of lignin oxidation considered above (oxidation during bleaching of the sulfate pulp) based on lignin activation by the action of nitrogen oxides, chlorine and chlorine dioxide is as follows: (E⁺ + H₃O⁺)–(E⁺ + OH[–]), *i.e.*, an electrophile in an acidic medium—an electrophile in an alkaline medium (see also Refs 118–121).

It has been shown^{122–126} that hydroperoxide anions also delignify pulps even somewhat better than oxygen and concomitant radicals generated upon hydrogen peroxide decomposition (or directly upon the action of O₂). In the absence of a hydrogen peroxide stabiliser and at pH ≥ 12, the realisation of the mechanism H₂O₂ → O₂ leads to 45% delignification of the sulfate softwood pulp, while in the presence of a stabiliser (sodium silicate, *etc.*) and at pH about 10 solubilisation of the residual lignin reaches 50% at the initial content of lignin of 76 permanganate units (p. u.).¹²⁷ However, even this depth of lignin conversion is achieved only in the case of pretreatment of unbleached pulp with a weakly acidic solution for removal of cations of transition metals. Preliminary washing of sulfate pulps with acids or solutions of chelating reagents reduces the loss of hydrogen peroxide due to its decomposition and to some extent decreases pulp destruction with superoxide radical anions.

Methods of acid-catalysed and acid-electrophilic activation of the residual lignin based on acid treatment of the residual lignin in sulfate pulps and aimed at partial hydrolysis of the C(β)–O–C(4) ether bonds at temperatures above 70 °C have been proposed.^{123–126, 128–131} Such pretreatment not only changes the structure of the residual lignin, but also activates it to the action of the hydroperoxide anions owing to formation of the carbonyl groups near the site of the ether bond cleavage. Following acid-catalysed activation, the degree of lignin conversion in sulfate hardwood pulps is increased from 0.5 to 0.8 upon the oxidative destruction with hydroperoxide anions. The addition of an oxidant (hydrogen peroxide, monoperoxysulfuric acid)

§The Kappa unit characterises the lignin content in industrial pulps accepted as a standard unit in Russian State Standard 1 007 074 and in a number of foreign standards.

¶Quantification of lignin in pulps expressed in Kappa units gives overestimated values for the depth of delignification compared to that determined by photometry.¹¹⁵

at the stage of activation leads to additional fragmentation of lignin and its more rapid solubilisation in the next technological step including oxidation with the hydroperoxide anions.

The acid-catalysed activation makes somewhat more efficient the lignin destruction under the action of oxygen in highly basic media. However, this effect is nearly the same as that achieved on treatment of lignin with acids at room temperature (removal of cations and destruction of sulfides¹³⁰) or with chelating reagents^{132, 133} where the maximum degree of lignin conversion is about 0.5 and cellulose undergoes higher hydrolytic destruction.

In general, all schemes of oxidative delignification of the type 'reagent + catalysis' can be arranged according to the degree of lignin conversion in sulfate pulps in the following order:¹³¹ oxygen in alkaline media ($O_2 + OH^-$); hydroperoxide anions in alkaline media ($HOO^- + OH^-$); acid-catalysed activation + oxygen in alkaline media [$(H_3O^+) - (O_2 + OH^-)$]; acid-electrophilic activation + oxygen in alkaline media [$(NO_2^+ + H_3O^+) - (O_2 + OH^-)$]; acid-catalysed activation + hydroperoxide anions in alkaline media [$(H_3O^+) - (HOO^- + OH^-)$]; acid-electrophilic activation + hydroperoxide anions in alkaline media [$(OH^+ + H_3O^+) - (HOO^- + OH^-)$].

The selectivity of action of hydroperoxide anions on the residual lignin in sulfate pulps is described by a plot of the degree of cellulose polymerisation as a function of the degree of lignin conversion (Fig. 1).

Figure 1. Dependence of the degree of polymerisation (P^V , measured by viscosimetry) on the relative lignin content $[L]$ of sulfate softwood cellulose upon delignification under the action of HOO^- : (1) without preliminary activation; (2) after preliminary acid-catalysed activation.

In the studies on the mechanism of the acid-catalysed activation it was found that the reduction of activated lignin in sulfate pulps with sodium borohydride at pH 10 leads to partial deactivation of lignin^{129, 130} towards the hydroperoxide anions. In this particular case, successive treatment of lignin with two different nucleophilic reagents did not give the expected result, although the former ($NaBH_4$) acts as a reducing agent, and the latter (HOO^-) acts as an oxidant.

VI. Ozonolysis of sulfate pulps

Ozonolysis is one of the methods of delignification of sulfate pulps in the course of bleaching. The selectivity of lignin oxidation in the ozonolysis depends on the conditions and, first of all, on the pH of a medium. In neutral media (pure water), destruction of cellulose predominates.⁹⁷ To perform the sulfate pulp delignification, ozonolysis is carried out in acid media (pH 2–3) in which, as well as in alkaline media, the destruction of cellulose is substantially lower.⁹⁷ The selectivity of delignification is also influenced by the character of the preozonolysis treatment and by the lignin content in pulps subject to ozonolysis.¹³¹

The products of lignin ozonolysis formed upon treatment of unbleached sulfate softwood pulps with ozone are not dissolved instantly (Figs 2 and 3, curves 1). Using photometric assay of the lignin content, it was found that the changes in selectivity of the

Figure 2. Dynamics of changes in lignin content $[L]$ in sulfate softwood pulp during its delignification with ozone: (1) ozonolysis; (2) ozonolysis and subsequent extraction with a solution of NaOH; p. u. are permanganate units.

Figure 3. Selectivity of delignification of sulfate softwood pulp with ozone (θ is the degree of lignin conversion equal to the portion of solubilised lignin): (1) after ozonolysis; (2) after ozonolysis and extraction with a solution of NaOH.

oxidative processes during the ozonolysis of sulfate softwood pulps have a rather unusual character. At high lignin contents in pulps, the destruction of cellulose is predominant. Then, in parallel with a decrease of the lignin content, the direction of the process is gradually changing and, after dissolution of a half of the initial lignin, the selective pulp delignification becomes the major process.[†] A part of ozonolysed lignin is dissolved in an alkaline medium (Figs 2 and 3, curves 2). Special tests have shown that destruction of cellulose upon ozonolysis in the presence of lignin is higher indeed. The ozonolysis of pulps partially delignified by other reagents (*i.e.*, semibleached) is also accompanied by destruction of cellulose. However, this destruction is always less than in the ozonolysis of unbleached pulps with high initial lignin content.

The highest degree of the residual lignin oxidation and complete solubilisation of the ozonolysis products in acid media are observed in the case of lignin pretreatment with hydroperoxide anions.¹³⁶ A similar effect is achieved on treating lignin with sodium borohydride. Obviously, a decrease in the number of carbonyl and aldehyde groups in the side chains of the lignin phenol–propane units due to their oxidation or reduction (upon the action of HOO^- or BH_4^- , respectively) favours more selective oxidation of lignin aromatic rings with ozone.

The best results are achieved by successive treatment of lignin, at first, with hydrogen peroxide in an acid medium (with

[†] Assay of lignin content $[L]$ by permanganate method¹²⁷ (especially in Kappa units^{107, 127, 134, 135}) in pulps with a low lignin content typical of semibleached pulps can be incorrect because of deviation of the relationship 'Kappa number – lignin rate' from linearity at $[L] \leq 1\% - 2\%$.

Table 7. Effect of sulfate softwood pulp pretreatment on solubilisation of the residual lignin in the ozonolysis (reagent usage rate constituted 0.225% from the mass of absolutely dry pulp).¹³¹

Pretreatment scheme	Lignin content prior to ozonolysis ^a	Lignin content after ozonolysis ^a		Degree of delignification in one and two stages (%)		Portion of solubilised lignin (%) ^b
		O ₃	O ₃ –NaOH	O ₃	O ₃ –NaOH	
Without pretreatment	91	87	68	4	25	16
OH ⁺ –HOO [–]	33	11	11	67	67	100

peroxyacids), then with a solution of hydrogen peroxide stabilised at pH 10 and finally with ozone in an acid medium (OH⁺ → HOO[–] → O₃, Table 7).¹³¹

Thus, according to both absolute and relative parameters, the maximum solubilisation of the residual lignin in the ozonolysis of semibleached sulfate pulps is achieved after pretreatment with hydroperoxide anions. On the whole, with consideration of sulfate pulp cooking and preliminary acid-catalysed electrophilic activation, the optimum sequence of the operations is as follows: sulfate cooking (SH[–] + OH[–]) → acid-catalysed electrophilic activation (OH⁺ + H₃O⁺) → delignification with hydroperoxide anions (HOO[–] + OH[–]) → ozonolysis (O₃ + H₃O⁺), *i.e.*, an alternation of treatments in acid and alkaline media.

VII. A schematic approach to the selective destruction of residual lignin with peroxy reagents

The oxidative destruction of lignin as a heterochain polymer containing ether bonds predominantly of the C(β)–O–C(4) type occurs under conditions of acid or base catalysis.^{12,13,137} The alternation of the action of acids (H₃O⁺) and bases (OH[–]) allows one to achieve partial sulfate pulp delignification.¹²⁴ It should be noted, however, that the treatment of pulps according to the HCl–NaOH scheme requires rather drastic conditions and the selectivity of delignification is low: along with twofold reduction of the lignin content, the degree of polymerisation of cellulose is also diminished almost twice.¹²² The analysis of the published data on delignification of industrial pulps with chlorine-containing reagents and oxygen in alkaline media as well as the experimental studies of various compositions of oxidising reagents and media have shown that the oxidation schemes without alternation of treatments in acid and alkaline media are less efficient (Table 8).¹³¹

The properties and reactivities of lignins depend on the methods of their preparation. Therefore, the schemes in Table 8 include the stage of sulfate cooking.

In order to achieve selective oxidative lignin destruction under the action of peroxy reagents with minimal changes in cellulose, it is necessary to apply a complex of different chemical operations which combine a pulp delignification stage and a stage of activation of the residual lignin towards the action of other reagents.

The residual lignin is more labile than cellulose, and its reactivity depends on the method of its preparation or pretreatments. Therefore, enhancement of reactivity of lignin as a result of activation is also a method for an increase in the selectivity of the sulfate pulp delignification.

An electrophilic attack of lignin by peroxy reagents (hydrogen peroxide, peroxy acids, ozone) is realised in acid media, whereas the presence of stabilisers and weakly alkaline media are necessary for treatment of lignin with nucleophiles.^{8–10}

On the basis of the aforesaid, the most important factors affecting the selectivity and depth of the sulfate pulp (and other pulps) delignification can be deduced. These are:

- (1) the reactive form of a reagent;
- (2) the nature and the number of reactive sites in the residual lignin;
- (3) acid–base catalysis;
- (4) cooking method and type of pulp pretreatment.

As the result of an analysis of the selectivity and depth of oxidative destruction of lignin with different chlorine- and oxygen-containing reagents, a general statement concerning the selectivity of oxidative lignin destruction with peroxy reagents has been formulated:¹³¹ the oxidative destruction of the residual lignin is a maximum provided the stages based on the action of electrophilic and nucleophilic reagents alternate, and that the

Table 8. Schematic presentation and operational schemes for oxidative destruction of residual sulfate lignin.

	(Na ₂ S)–H ₂ O ₂ /NaOH	(OH [–])–OH [–]	≤ 50	37, 96, 98, 105
(N [–])–N [–]	(Na ₂ S)–H ₂ O ₂	(OH [–])–OH [–]	< 50	104, 112, 114

Note. Here and in Table 9, the reagents and species participating in the process of sulfate cooking are presented in parentheses; E⁺, electrophile, N[–], nucleophile.

most complete destruction of the chromophore-containing structures is achieved by the action of electrophilic reagents in acid media and of nucleophilic reagents in alkaline media as described by the general formula $[(E^+ + H_3O^+) - (N^- + OH^-)]_n$.

At first glance (from the position of organic chemistry), this statement seems to be obvious. However, its formulation became possible only after development of the methods of pulp delignification with hydroperoxide anions, acid-catalysed and acid-electrophilic activation of the residual lignin as well as after studies on ozonolysis of unbleached and semibleached sulfate pulps^{114, 124–126, 128–130} and generalisation of studies on activated pulp delignification with oxygen in alkaline media.^{109–112, 118–121} All this made it possible to establish a close relationship between the general concepts of organic chemistry and new experimental results obtained in studies on the sulfate pulp delignification with peroxy reagents.

Deviations from the order of operations described above (including the cooking stage) lead to substantial decrease in the lignin reactivity towards oxidants (even to such a reactive one as chlorine dioxide) and, as a consequence, to a decrease in the depth of oxidative delignification and to loss of the pulp brightness (Table 9).

Table 9. The effect of the sequence of oxidative treatments on the depth of delignification of sulfate softwood pulps.

Run	Schematic presentation	Reagents	Degree of lignin conversion (%)	Pulp brightness (%)
1	$(N^-) - E^+ - N^-$	$ClO_2 - H_2O_2$	91	79
2	$(N^-) - N^- - E^+$	$H_2O_2 - ClO_2$	85	62
3	$(N^-) - E^+ - N^-$	$ClO_2 - H_2O_2$	82	80
4	$(N^-) - N^- - E^+$	$H_2O_2 - ClO_2$	87	65
5	$(N^-) - E^+ - N^-$	$H_2O_2 - H_2O_2$	52	64
6	$(N^-) - N^- - E^+$	$H_2O_2 - H_2O_2$	40	57

Note. Usage rates for reagent are the same in pairs of runs: (1) and (2), (3) and (4), (5) and (6). Usage rate: ClO_2 in runs (1), (2), 0.8%, in runs (3), (4), 1.3% from the pulp mass; H_2O_2 in runs (1)–(4), 2.0%, in runs (5), (6), 1.0% [run (5) at pH 2 and 10, run (6) at pH 10 and 2 in the first and second stages, respectively].

On the basis of the statement mentioned above, a number of methods for sulfate pulp bleaching and ways of activation of the residual lignin with hydrogen peroxide and ozone have been proposed^{124, 125, 129, 130} which are not inferior in the selectivity of delignification to the bleaching processes based on the use of chlorine-containing compounds.

VIII. Kinetic methods for assessment of residual lignin reactivity

Depending on the mechanism of lignin destruction, different kinetic models for assessment of its reactivity are employed. Most often, these are correlations for homogeneous reactions with an assumption that these reactions are homogeneous and heterophase¹³⁸ and that the volume of the phase where the reaction takes place is constant.^{139, 140}

In addition to the kinetic methods for examination of homogeneous reactions,¹⁴¹ kinetic models of topochemical reactions are widely applied for description of chemical transformations of lignin, first of all, the Avraami–Kolmogorov–Erofeev equation.¹⁴² The validity of this equation is substantiated only formally, while no physical correlation between topochemical models and the processes of delignification has been found. It was shown¹⁴³ that a diffusion kinetics model is more appropriate to the description of the kinetics of softwood pulp delignification in organic solvents in which the rate-determining step is diffusion

of lignin and hemicellulose destruction products into the cooking solution.

Since lignin is a polymer which is chemically and physically bound in pulp to polysaccharides the processes of the lignin chemical transformations should be considered as reactions in a polymeric matrix. The kinetics of chemical reactions in polymers is featured by the influence of various levels of the local matrix organisation and temperature-dependent matrix reorganisations on the conformity to the Arrhenius law, what is manifested in the so-called polychronous kinetics.^{144–147}

A model of polychronous kinetics has been used for the first time by Bel'kova *et al.*^{148, 149} in the study of pulp delignification with nitric acid. Later, this model was applied to the study of softwood lignin destruction in alkaline media^{150–153} and to oxidative lignin destruction in pulp bleaching processes.^{130, 154–156} The application of the polychronous kinetics theory to the description of processes of chemical destruction and solubilisation of lignin (*i.e.*, wood delignification) under the action of various reagents is based on three postulates. The first one is that reactions occur either in a solid phase or in an interface and are characterised by kinetic non-equivalence of chemically homogeneous species. The second one is that under isothermic conditions the processes do not proceed to completion, and at a certain depth of the conversion, the sharp deceleration of the reactions (the so-called kinetic stop) takes place. The third postulate says that the depth of the conversion depends on the temperature.

Thus the major features of chemical processes that follow the polychronous kinetics are their kinetic stop and non-observance of the principle of the temperature–time superposition. Although at higher temperature the reactions proceed deeper, they also stop at a certain point. According to the 'classical' approach,¹⁴⁴

$$n(\tau, T) = n_0 \int_{\ln k_{\min}}^{\ln k_{\max}} f(\ln k) G(k, \tau) d \ln k = n_0 \int_{\ln k_{\min}}^{\ln k^*} f(\ln k) d \ln k,$$

where $n(\tau, T)$ is the number of species which has entered into the reaction after time τ at temperature T ; $f(\ln k)$ is a distribution function; $G(k, \tau)$ is a function describing the kinetics of the process in an elementary group with fixed values of the activation energy (E); $k(E) = k_0 \exp(-E/RT)$ is the reaction rate constant; $k_{\min}$ and $k_{\max}$ are the minimum and maximum rate constants, respectively; G for the simplest case is expressed as $G_1 = \exp(-k_1 \tau)$.

The kinetic curves are straightened in the coordinates $C/C_0 - \ln \tau$ (straight lines of the type $y = ax + b$). From these equations the values for $k_{\min}$, $k_{\max}$ and the parameter of the kinetic non-equivalence [$S = \ln(k_{\max}/k_{\min})$] are found using the relationships¹⁴⁴

$$1 - \theta = a - b \ln \tau,$$

where $a = 1 - \ln 1.76 k_{\max} / \ln(k_{\max}/k_{\min})$, $b = (\ln k_{\max} - \ln k_{\min})^{-1}$. In general case, $\ln \tau = \ln k$.

Recent publications^{146, 147} consider the kinetic peculiarities of reactions in a polymeric matrix not as a violation of the classical Arrhenius law but, in contrast, as a particular case of a general model for polychronous kinetics (the so-called integral Arrhenius law).

As a rule, in studies of the delignification processes (including those for oxidative destruction of the residual lignin), the necessity of imposing limitations in the framework of the formal kinetic analysis often arises. Such a lignocellulosic composite as unbleached sulfate pulp is so complex in structure and functional composition that the formulation of a direct kinetic model for the description of its oxidative destruction under the action of radicals and ions generated from peroxy reagents seems to be impossible.

By comparison with other kinetic approaches, the model of polychronous kinetics allows one to characterise more completely the processes of oxidative destruction of the residual lignin by the effects observed in delignification of a lignocellulosic material (see Refs 154–157 on polychronous kinetics for the oxidative deligni-

Figure 4. Kinetic compensative effect.

fication of sulfate pulps with hydroperoxide anions and oxygen). The main kinetic peculiarities of oxidative lignin destruction (on bleaching of sulfate softwood pulps) with peroxy reagents include the existence of the kinetic stop and kinetic compensative effect (KCE, a linear relationship between preexponential factors K_{eff}^0 for separate ensembles of macromolecules and effective activation energy E_{eff} , Fig. 4), the dependence of the highest degree of lignin conversion (from 0.07 to 0.55¹⁵⁷) on the parameter of kinetic non-equivalence S and temperature (Fig. 5) and the non-linear character of the relationship between $\ln \tau$ and $1/T$ in the temperature range from 293 to 373 K (Fig. 6).

The values of the rate constants (k) for oxidative delignification in the temperature interval from 80 to 100 °C range approximately from $10^{17} \exp(-143 \text{ kJ mol}^{-1}/RT) \text{ s}^{-1}$ to $16 \exp(-19 \text{ kJ mol}^{-1}/RT) \text{ s}^{-1}$. The larger values correspond to low-temperature processes with a degree of lignin conversion $\theta = 0.35$, while the smaller values of the rate constant correspond to high-temperature processes with a degree of lignin conversion $\theta = 0.10$.

At a low degree of lignin conversion ($\theta \leq 0.1$) under the action of hydroperoxide anions, the rate of delignification is apparently determined by diffusion of the soluble products of lignin destruction (their molecular weight can reach 15 000–25 000) from the lignocellulosic matrix.¹⁴⁸ Preliminary treatment of the residual lignin does not virtually affect the rate of the pulp delignification, since this treatment does not change the structure of cellulose fibres. With an increase in the degree of lignin conversion, the rate of the process sharply (exponentially) falls down, while the effective energy of activation rises. These effects are probably caused by slow molecular relaxation in a polymeric matrix so that the time for realisation of the most energetically favourable activated complex during an elementary reaction act (a kinetic constituent) is insufficient.¹⁴⁴

On the one hand, the acid-catalysed and acid-electrophilic activations of the residual lignin lead to its destruction and better solubilisation (due to the smaller size) in alkaline media. On the other hand, they activate the lignin electrophilic sites. In the range of moderate temperatures (313–333 K), the preactivation results

Figure 5. Effect of temperature on the parameter of lignin kinetic non-equivalence (S) in the oxidative pulp delignification with hydrogen peroxide.

Figure 6. Plot of $\ln \tau$ as a function of $1/T$ for various ensembles of lignin macromolecules in the sulfate pulp delignification in a stabilised solution of hydrogen peroxide at $\theta = 0.1$ (1); 0.2 (2); 0.3 (3); 0.4 (4); 0.5 (5); 0.55 (6).

in diminishing of the kinetic non-equivalence for lignin reactive sites (at 333 K the activated lignin has $S = 21$ –23, while non-activated one has $S \sim 30$). Despite the fact that the values of the minimum rate constant differ for different methods of lignin preactivation and that this constant bears an obvious physical meaning [$-\ln k_{\text{min}} = \ln \tau (\theta = 1.00)$, where $\ln \tau (\theta = 1.00)$ is a logarithm of the time of complete lignin conversion], unambiguous interpretations based on analysis of this constant are hardly possible due to the very low values of this constant. The main manifestation of the lignin activation is an increase in the maximum degree of lignin conversion in its oxidative destruction with hydroperoxide anions and certain decrease in the parameter of kinetic non-equivalence associated probably with destruction-induced changes in the morphological structure of cellulose fibres.

IX. Conclusion

Lignin substantially differs in its behaviour in chemical reactions from low-molecular-weight model compounds, first of all, in a diversity of transformations and their depths. The reactivity of the residual lignin and the depth of its oxidative destruction with peroxy reagents depend to a considerable extent on the character of chemical pretreatments, which functionalise lignin and affect various structural changes in the polymeric lignocellulosic matrix. The depth of lignin destruction in the processes of pulp bleaching with peroxy reagents can be enhanced owing to alternation of the action of electrophilic and nucleophilic reagents under conditions of acid and base catalysis, respectively.

However, the quantitative assessment of the lignin reactivity is rather difficult to perform because of the chemical and structural (topological and supramolecular) heterogeneity of industrial lignin, structural heterogeneity of the polymeric lignocellulosic matrix and some kinetic peculiarities of reactions in polymers. Aforementioned features of lignin, its polyfunctionality as well as diversity of oxidants, generated in reactions of oxygen, hydrogen peroxide and ozone, and the differences in mechanisms of the reactions of these reagents with lignin in acid and alkaline media provide a reason to consider the oxidative destruction of the residual lignin as a complex fundamental problem that demands further investigations.

Despite some achievements in the studies of lignin reactions, an increase in the reactivity of the residual lignin remains a very important practical problem due to the permanently rising requirements for the environmental safety of technological processes in the pulp industry. Examination of the behaviour of lignin in chemical reactions and technological processes involving hydrogen peroxide, oxygen and ozone is not unambiguous, and further investigations and data systematisation are necessary in this field. Exploration of selective oxidative lignin destruction is a

very important direction in wood chemistry, organic chemistry, chemistry of high-molecular-weight compounds and related fields of the sciences.

IV. Nondestructive physicochemical methods	962
V. Conclusion	963

Abstract. The history and state-of-the-art in the detection, quantitative determination and characterisation of the primary structure of alginic acids and their salts (alginates) are reviewed. A brief survey of the structure and properties of these polysaccharides is given. Numerous analytical methods including chemical, physicochemical and enzymic procedures for the structural analysis of alginates which can also be used for the investigation of other uronic acid-containing polysaccharides are discussed. The bibliography includes 211 references.

I. Introduction

Alginic acids were first isolated from several brown algae by Stanford more than 100 years ago.¹ Later, these polysaccharides were detected in all brown algal species without exception as cell wall and intercellular matrix components. Their content in the biomass may amount to 40% of the dry weight; this strongly depends on the species and growth conditions.^{2–4} Some bacteria (mostly, the representatives of the genera *Azotobacter*⁵ and *Pseudomonas*⁶) also produce alginic acids. In 1982, alginates were unexpectedly detected in one of the species of calcareous red algae belonging to the family Corallinaceae.⁷ Our recent studies^{8,9} have shown that the presence of alginates is virtually a characteristic feature of the representatives of this family. In other plants, these polysaccharides have not been found.

Alginic acids are polyuronides, *i.e.*, polysaccharides the molecules of which are built up of uronic acid residues. At first, D-mannuronic (**1**)^{10,11} and then L-guluronic (**2**)¹² acids were identified as the components of alginic acids.

Partial hydrolysis and isolation of the corresponding disaccharide revealed that the residues of both uronic acids are the components

of the same polymeric molecule.¹³ According to present-day concepts based on numerous studies including methylation,^{14,15} periodate oxidation^{16,17} and several physicochemical methods of structural analysis (mostly, NMR spectroscopy^{18–21}), molecules of alginic acids are linear and made up of β -D-mannuronic and α -L-guluronic acid residues (in the pyranose form) linked by 1 $\rightarrow$ 4 bonds.

Bacterial alginic acids differ from the algal ones in that some of their hydroxy groups are usually acetylated.^{22,23} Acetyl groups occupy positions 2 or 3 (sometimes, both simultaneously) in D-mannuronic acid residues.²⁴ The degree of polymerisation of native polymers is rather high and the number of monosaccharide residues may amount to 1000–10 000.

Alginic acids isolated from various sources can differ in the ratios of mannuronic and guluronic acids (M/G)²⁵ and in the distribution of the monomers along the polymeric chain. Fractionation of oligomeric products formed upon partial hydrolysis has shown that some regions in the molecules of alginic acids are built of only one uronic acid species (M-blocks and G-blocks). These blocks are separated by fragments which contain approximately equal amounts of both monosaccharides arranged into more or less strictly alternating sequences (MG-blocks).^{26,27} Such a peculiar structure is a result of stepwise biosynthesis of polysaccharide molecules where the formation of linear mannuronan precursors is followed by epimerisation of some β -D-mannuronic acid residues at the C(5) atom under the action of a specific enzyme, mannuronan-C(5)-epimerase, resulting in the appearance of α -L-guluronic acid residues within the polymer structure.²⁸

The size and mutual distribution of individual blocks strongly affect the properties of alginic acids and their salts (alginates). As a matter of fact, β -D-mannuronic and α -L-guluronic acid residues, being structurally very close [they differ only in the configuration at one of the asymmetric centres, *viz.*, at the C(5) atom], have opposite conformations of the pyranose rings ($^4C_1$ and $^1C_4$, respectively), which results in completely different shapes of the polymeric molecules in the poly-M and poly-G regions (Fig. 1). This creates spatial conditions for the tight binding of bivalent metal cations with G-blocks. Moreover, the coordination with such cations favours the cooperative binding of different molecules of the polymer with one another,²⁹ eventually resulting in the formation of ionotropic gels (Fig. 2). Therefore, the total content of α -L-guluronic acids (in the first approximation) or, more precisely, the relative length of G-blocks are important criteria of the most valuable property of alginates, *viz.*, their ability to form gels.^{30–32} The block structure is responsible for many other characteristics of alginates including their biological activity.^{33–35}

Figure 1. The conformations of monosaccharide units in the molecule of alginic acid.

By virtue of their unique physicochemical properties, alginic acids and their salts have found wide application in the production of foods and in some other branches of industry^{36,37} including biotechnology and medicine.³⁸ This explains the fact that the majority of reviews devoted to alginic acids provide information about their structure, biosynthetic mechanisms and practical application, but pay insufficient attention to problems concerned with the analytical chemistry of alginates. Thus a special issue of the journal *Carbohydrates in Europe*, which is all devoted to alginates and consists of four reviews describing the chemistry and physical properties,³⁹ genetics and biosynthesis of alginates,⁴⁰ as well as biotechnological and clinical applications of alginate gels⁴¹ and commercial applications of alginates,⁴² is laid out on this principle.

Because of considerable practical utility of alginates, their isolation from brown sea weeds has become the main goal of their processing. It is obvious that estimation of alginic acid content in the algal biomass and standardisation of alginic acid preparations and alginate-containing products demand elaboration of convenient analytical procedures, while structural characterisation of these polysaccharides is necessary for determining the most rational approaches to the utilisation of particular preparations containing alginic acids. Proper allowance must be made for the fact that the analytical chemistry of alginates has specific features as compared with that of other polysaccharides.

Alginic acids form water-soluble salts with monovalent cations but are precipitated upon acidification. Alginates of many bivalent cations, particularly, of Ca^{2+} , Sr^{2+} and Ba^{2+} , are insoluble in water. This property is utilised in the isolation of alginic acids from algae.⁴³ At first, bivalent cations and concomitant water-soluble polysaccharides are extracted from the bio-

mass with a dilute mineral acid; then alginic acids are extracted with an alkaline solution with subsequent precipitation from the extract by treatment with ethanol,⁴⁴ acidification or conversion into Ca^{2+} salt.⁴⁵ Preparative yields of alginic acids may be used for determination of their content in the algal biomass; it should be remembered, however, that the results obtained with the use of different isolation procedures can give substantially different results for the same algal specimen. This depends on a number of factors, such as reagents used, the number of precipitations and the degree of achieved purity. Thus special experiments aimed at comparing the efficiency of three most popular laboratory procedures^{46–48} revealed that the relative scatter in the values of preparative yields of alginates may amount to 20%–40%.⁴⁹ Additional problems may arise when this approach is used for the analysis of food compositions where the behaviour of pectin components is similar to that of alginates as regards their extraction and precipitation.

Some procedures for the estimation of alginic acids are based on specific reactions of uronic acids. These reactions include decarboxylation and degradation under the action of concentrated sulfuric acid with subsequent formation of coloured products in the presence of carbazole, indole, 3-hydroxybiphenyl, *etc.* These methods have found wide application, although it is evident that the presence of other polysaccharides containing uronic acids in the specimen under study will inevitably give erroneous results of alginate assays.

The use of acid hydrolysis of alginates for the preparation of monomeric uronic acids is a rather complex problem. Glycosidic bonds of uronic acid residues are highly resistant to acid hydrolysis. Low solubility of alginic acids in acid media creates an additional problem. Total acid hydrolysis of alginic acids is accompanied by the destruction of some monomers. It is of note that L-guluronic acid residues are destroyed faster than D-mannuronic acid residues and specific losses of each monomer depend on the pattern of their block distribution within the polymeric molecule. Therefore, it is very difficult to select versatile conditions for hydrolysis and to find correction factors for the destruction of monomers that would be equally suitable for the determination of the composition of alginates differing considerably in the ratios and the distribution of uronic acid residues in their molecules.

Nondestructive physicochemical methods, in the first place, ^1H and ^{13}C NMR spectroscopy, have assumed great importance in structural characterisation of alginic acids. These methods can be used both for the determination of the monomer ratio in alginic acid molecules and their characterisation in terms of their arrangement into individual blocks. In the subsequent sections, the above-mentioned analytical approaches will be considered in more detail and illustrated, mostly by the studies of sea weeds, although these methods are equally suitable for the characterisation of bacterial alginates. Additional information can be retrieved from several reviews devoted mostly to alginates of bacterial origin.^{50–55}

II. Chemical methods

1. Assays based on cation exchange

If a starting material is used in sufficiently large amounts (*i.e.*, the alginic acid content in a sample under study is no less than 100 mg), alginic acids can be determined by the gravimetric method. Polymeric alginic acids are precipitated upon acidification of weakly alkaline solutions, while calcium alginate is precipitated from neutral sodium alginate solutions upon addition of calcium chloride. Drying of the precipitates is problematic, since these compounds tightly retain water and are readily decomposed on heating. Volumetric analysis is more preferable in experiments with smaller amounts of the material. In this case, the polysaccharide is also precipitated as calcium salt, this is washed with a dilute acid to remove metal cations, and the insoluble alginic acid is washed with water and titrated with

Figure 2. The coordination of calcium ions by α -L-guluronic acid residues in the molecule of an alginate (*a*) and the role of these ions in intermolecular interactions during gel formation (*b*) (the 'egg-box' model).²⁹

sodium hydroxide in the presence of phenolphthalein or using conductometric⁵⁶ or potentiometric⁵⁷ control. The formation of viscous sodium alginate solutions in the course of titration can be avoided if an excess of calcium acetate is added to alginic acid, and the liberated acetic acid is titrated.⁵⁸ A procedure is described which combines titration with colorimetry and is designed for the determination of the content of alginic acid in algae.⁵⁹

An alternative, rather lengthy procedure for quantitative analysis of alginates is based on the ability of alginic acid-containing algal biomass to bind calcium ions.⁶⁰ To this end, samples of a ground plant material are dialysed against dilute hydrochloric acid to remove metal cations; the mineral acid is removed by dialysis against water. Then, alginic acid is converted into calcium salt by dialysis against a calcium acetate solution; the excess of the reagent is removed by repeated dialysis against water. Upon this treatment, all the residues of uronic acids in the alginate are converted into calcium salts where one cation corresponds to two uronic acid residues. Bound calcium ions are then quantitatively extracted by dialysis against dilute hydrochloric acid. The calcium concentration in the diffusate is determined by atomic adsorption spectrophotometry, and the alginate content in the original biomass is calculated. The main drawback of this method is that the presence of other polyanions (e.g., sulfated polysaccharides) in the biomass can overestimate the experimental results.

As polyanions, alginic acid molecules form salts with coloured inorganic (bivalent copper cations⁶¹ or ruthenium red⁶²) and organic cations (cationic dyes of the Methylene Blue type^{63–65}). In this case, quantitative assays are based on the measurement of the decrease in the optical density of the original coloured solution upon formation of poorly soluble salts or on the changes in the spectral characteristics of the dye (metachromasia) due to its binding to the polymer. This method, which is characterised by high sensitivity and precision, has been recently proposed for quantitative determination of alginates in microcapsules used in cell transplantation.⁶⁶ The experimental procedure is based on the analysis of metachromatic changes in the spectrum of 1,9-dimethyl-Methylene Blue as a result of its interaction with the alginate. This type of reactions also includes precipitation of polyanions (as salts) with cationic detergents (Cetavlon precipitation).⁶⁷ Polyhexamethylenebiguanidinium chloride used for the precipitation of alginic acids is the most studied reagent of this class.⁶⁸ Precipitation of alginic acids with this reagent is virtually independent of the presence of salts (< 2.5%), pH (5.5–7.6), temperature (10–60 °C) and the M/G ratio. The analytical procedure is based on the measurement of the decrease in the reagent absorption at 235 nm. Although this method was recommended for the analysis of industrial extracts of brown algae,^{69, 70} other acid polysaccharides can be precipitated by cationic detergents together with alginic acids. It was proposed⁷¹ to use coloured hydrazides formed by the reaction of 2-nitrophenylhydrazine in the presence of water-soluble carbodiimide in colorimetric assays of alginates and their fragments instead of coloured salts;⁷¹ however, this method has not found wide application.

2. Assays based on degradation of uronic acids

Heating of alginates results in decarboxylation and evolution of CO₂.⁷² The samples under study are usually heated with 19% HCl, and the CO₂ evolved is absorbed and weighed as in the micro-analytical determination of carbon in organic compounds by combustion.^{73, 74} Although this method was described in a popular practical guide to biochemical assays of algae,⁷⁵ it requires special skill and equipment (cf. Refs 76–78). This is also true for a modified decarboxylation procedure in which polysaccharide samples are heated with 57% HI and the CO₂ evolved is assayed by gas-liquid chromatography (GLC)⁷⁹ or direct non-aqueous titration.⁸⁰ It is obvious that other uronic acid-containing polysaccharides can interfere with the alginate assays.

Colorimetric assays of polyuronides based on acid degradation of their constituent monosaccharides have found much wider

application. The main reaction product formed upon heating of uronic acid derivatives with concentrated sulfuric acid is 5-formylfuran-2-carboxylic acid, which is rather stable under these conditions.⁸¹ The formation of degradation products of neutral sugars (5-hydroxymethylfurfural and furfural) from hexoses and pentoses, respectively, prevents its direct spectrophotometric analysis. It is therefore more expedient to use the ability of 5-formylfuran-2-carboxylic acid to form coloured products with various organic reagents, particularly with some aromatic nitrogen heterocycles and phenols, e.g., carbazole,^{82, 83} indole,⁸⁴ 3-hydroxybiphenyl⁸⁵ and 3,5-dimethylphenol.⁸⁶

Along with indisputable advantages (in the first place, the possibility to experiment with microquantities of material), colorimetric assays have obvious drawbacks, such as interference due to neutral sugars and different reactivities of individual uronic acids. This is the reason why the analytical procedure was repeatedly modified, although the reaction with carbazole had long been used for the determination of polyuronides including alginic acids.⁸⁷ Thus it was proposed to supplement the reaction mixture with boric acid in order to intensify the colour formation and to equalise the reactivities of different uronic acids.^{88, 89} The addition of sulfamate^{90, 91} or different temperature regimes⁹² were used in order to minimise the effects of neutral sugars. It was demonstrated that the composition of a specimen containing three uronic acids (glucuronic, galacturonic and mannuronic) can be calculated by conducting the reaction with carbazole in four different regimes.⁹³

The effect of ballast neutral sugars was estimated during the elaboration of a procedure for pectin assays.^{94, 95} It was found that 3,5-dimethylphenol⁸⁶ and 3-hydroxybiphenyl⁹⁶ have salient advantages over carbazole in pectin and hemicellulose assays.

In a more recent study,⁹⁷ Filisetti-Cozzi and Carpita proposed a method for the colorimetric assay of polyuronides including alginic acids, which took account of recommendations from previous investigations. This method utilised 3-hydroxybiphenyl in combination with the borate anion and sulfamate. Our recent studies have shown that 3,5-dimethylphenol is a more preferable specific reagent for alginic acids.⁸ We modified the procedure proposed by Scott⁸⁶ for the analysis of pectins and hemicelluloses to fit with the specific composition of alginates using greater amounts of borate and more prolonged heating of reaction mixtures at 70 °C. The results of these experiments weakly depended on changes in the ratios of D-mannuronic and L-guluronic acids in different alginate specimens.

The problem of selectivity of the colour reaction and the necessity to eliminate interference due to the presence of neutral sugars in the specimen under study is of prime importance in the analysis of heteropolysaccharides, such as plant hemicelluloses and complex pectins, animal mucopolysaccharides and many bacterial and fungal polysaccharides. In the case of alginic acids, the effect of neutral sugars can be eliminated by preliminary removal of ballast substances,⁹⁸ although this procedure complicates the experimental protocol. For example, ion-exchange chromatography on Dowex 1 × 2 was used for purification of an alginate isolated from the extracellular material of mucoid strains of *Pseudomonas aeruginosa*,⁹⁹ although DEAE-cellulose or DEAE-Sephadex are evidently more suitable.^{100, 101} In alginate assays in food products, it is recommended to conduct enzymic deproteination with subsequent precipitation of calcium alginate. The latter is carefully washed off from soluble carbohydrates and dissolved in cold 80% sulfuric acid or in hot sodium hexameta-phosphate solution; alginates are assayed in the resulting solutions using naphthoresorcinol,¹⁰² phenol^{103, 104} or trivalent iron sulfate¹⁰⁵ in concentrated sulfuric acid. The selectivity of these reagents is lower than that of 3-hydroxybiphenyl, 3,5-dimethylphenol and carbazole. The reaction with Fe₂(SO₄)₃ was successfully used for the study of seasonal changes and anatomic distribution of alginates in some species of brown algae.¹⁰⁶ In a more complicated procedure described by Toyoda *et al.*,¹⁰⁷ naphthoresorcinol-HCl was added to an alginate after its

precipitation as Cu^{2+} salt; the coloured reaction product formed thereupon was extracted with butyl acetate and quantitatively assayed using HPLC.

In the majority of the above-described reactions, concentrated sulfuric acid was used to destroy uronic acids; however, similar results can be obtained in polyuronide assays utilising the Bial reagent (orcinol in concentrated hydrochloric acid, usually supplemented with FeCl_3 ¹⁰⁸). In the case of alginates, the reaction with orcinol has certain advantages over the reaction with carbazole,¹⁰⁹ although analytical results also depend on the composition of the original polymer.¹¹⁰ Obviously, this dependence is the main limitation of the majority of alginic acid assays, since chemical properties of uronic acid residues strongly depend on whether it forms a part of a homo- or a heteropolymeric block. This circumstance is the main obstacle on the way to the design of versatile calibration curves for the determination of alginic acids with any ratio and any distribution of β -D-mannuronic and α -L-guluronic acids along the polymeric chain.

3. Assays based on acid hydrolysis of glycosidic bonds

As mentioned above, alginic acids, like other polyuronides, are hydrolysed with difficulty and under drastic conditions. This leads to partial degradation of the monosaccharides liberated, in the first place, of guluronic acid. In the hydrolysis products, the monomeric uronic acids are in an equilibrium with lactones. This all makes the analysis of alginic acid hydrolysates a rather complicated procedure. The method for determining the M/G ratio by polarimetry of the total hydrolysate of alginates in the form of brucine salts¹¹¹ has not found wide application, since it requires large quantities of the starting material and its high purity, for ballast carbohydrates significantly distort the results of polarimetric analysis. Therefore, in the overwhelming majority of cases the hydrolysates are analysed following preliminary separation of the hydrolysis products.

Some time ago, it was proposed to use paper chromatography for separation of the hydrolysis products; this procedure allowed for the first time the proof of the presence of guluronic acid residues in the polymers.¹² Later, conditions were elaborated for the separation of guluronic, mannuronic, galacturonic and glucuronic acids by paper electrophoresis.¹¹² However, these methods are suitable for qualitative rather than for quantitative analysis of hydrolysates. In more recent studies, thin-layer chromatography (TLC) on silica gel was used for the identification of depolymerisation products of alginic acids. This method is especially convenient for detecting small amounts of alginates in beer^{113–115} and other foodstuff; acid methanolysis is more preferable than hydrolysis. Thus TLC of the methanolysis products allows unambiguous identification of alginates even in the presence of other uronic acid-containing food polysaccharides.^{116,117} High-performance TLC was used to study alginate biosynthesis in *Pseudomonas aeruginosa*.¹¹⁸

A procedure based on ion-exchange chromatography has been developed for quantitative determination of uronic acids in hydrolysates and, correspondingly, for the calculation of the M/G ratio.^{110,119} The conditions of hydrolysis proposed by Haug and Larsen^{110,119} were used (almost without modification) in a great number of more recent studies. After treatment of alginate with 80% sulfuric acid at 0 °C, the mixture was incubated for 18 h at 20 °C, then water was added up to the acid concentration of 1 mol litre⁻¹ and the resulting mixture was heated for 5 h at 100 °C. After cooling, the hydrolysate was neutralised with calcium carbonate, alkalinised to pH 8.0, incubated for 30 min for lactone opening and chromatographed on a Dowex-1 column (acetate form) in a linear gradient of acetic acid (from 0.5 to 2 mol litre⁻¹). Under these conditions, guluronic acid was eluted from the column before mannuronic acid. The uronic acid content in the fractions was determined using the reaction with orcinol; the experimental value of M/G was multiplied by 0.66 in order to correct for guluronic acid losses due to its predominant degrada-

tion during hydrolysis. This method was used to characterise the alginates isolated from a great number of algal species.²⁵

Some more recent modifications were aimed at the improvement of hydrolysis conditions¹²⁰ and refinement of the correction coefficients.¹²¹ In particular, it was proposed to use 88% formic acid instead of sulfuric acid for diminishing the degradation of monomeric uronic acids.²² However, the main progress in this field is connected with elaboration of new technologies for separation and identification of the hydrolysis products. Thus high-performance liquid chromatography was widely used for ion-exchange separation of uronic acids;^{122–128} quantification of these compounds in the eluate can efficiently be performed by measuring intrinsic absorption at 210 nm,¹²⁷ by using refractometric¹²⁴ or pulse amperometric detectors¹²⁵ or in a reaction with cyanoacetamide¹²⁶ with subsequent spectrophotometry or spectrofluorimetry.¹²⁹

The new separation technique for uronic acids markedly accelerated and simplified the experimental procedure, but did not eliminate the distortions introduced by hydrolysis of alginates. A method for the analysis of real specimens of alginic acids isolated from different brown algal species¹²⁷ which utilises ion-exchange chromatography in an isocratic regime and UV-detection for monitoring elution, has gained especially wide popularity.

Yet another popular procedure for the quantification of hydrolysis of products of alginic acids is GLC, which requires additional chemical conversion of uronic acids into their volatile derivatives. Hydrolysis products normally represent a mixture of uronic acids with lactones. Substitution of methanolysis for hydrolysis yields a multicomponent mixture of methyl esters of methyl glycosides. Analysis of such mixtures (e.g., in the form of trimethylsilyl derivatives) is a rather complex problem,^{130–132} and the results obtained are of limited value for quantitative assays.

In order to simplify the composition of the mixtures to be separated, it was proposed to convert uronic acids into aldonic acid lactones (by reduction of the aldehyde groups with subsequent lactonisation^{133,134}) or alditols (by more profound reduction) with subsequent chromatographic separation as acetates.^{134–136} In the latter case, several approaches are used to distinguish uronic acid derivatives from the reduction products of neutral monosaccharides. For example, uronic acids are separated by treatment of hydrolysates with ion-exchange resins prior to reduction,¹³⁶ otherwise sodium borodeuteride is used for reduction followed by chromatomass spectrometry for the identification of reaction products.¹³⁷ It was also recommended to separate hydrolysates into two portions, in one of which neutral sugars are converted into aldononitrile acetates (the procedure employed results in degradation of uronic acids), and the other portion is used for complete reduction. Comparison of analytical data allows one to calculate the amounts of both neutral monosaccharides and uronic acids.¹³⁸ Neutral sugars and uronic acids can also be assayed simultaneously by converting the former into alditol acetates and the latter into *N*-propylaldonamide acetates *via* aldonolactones.¹³⁹

Attempts have been made to circumvent difficulties in alginic acid hydrolysis by reducing the carboxy groups in the polymeric molecule. This can be done either by preliminary esterification of the carboxy groups^{140,141} or by their activation with water-soluble carbodiimide with subsequent treatment with sodium borohydride at controlled pH.¹⁴² The reduction procedure for the determination of the composition of alginic acids was proposed in 1981;¹⁴³ however, further studies of the preparative reduction of alginic acids with water-soluble carbodiimide revealed that this reaction cannot be brought to completion.^{144,145} Thus treatment with an excess of carbodiimide caused a significant destruction of the original polysaccharide¹⁴⁴ concomitantly with the preferential reduction of the L-guluronic acid carboxy groups;¹⁴⁵ in the deficiency of this reagent, preferential reduction of the D-mannuronic acid carboxy groups took place.¹⁴⁴

A more recent study was specially devoted to comparison of different methods of reduction of the carboxy groups in polymers containing uronic acids.¹⁴⁶ The method based on activation of the carboxy groups with 1-cyclohexyl-3-(2-morpholinoethyl)carbodiimide *metho-p*-toluenesulfonate in 8 M urea¹⁴⁷ was found to be the most efficient procedure; however, in this case subsequent treatment with sodium borohydride caused only partial reduction of the carboxy groups and the results obtained for polysaccharides yielding viscous solutions were poorly reproducible. We have simplified the reduction procedure⁸ by using prolonged treatment of alginates with the so-called 'magic methanol'¹⁴⁰ (a methanol–chloroform–concentrated HCl mixture, 10:1:1) for esterification and by reducing the formed ester with a large excess of sodium borohydride in a concentrated imidazole buffer (pH 7.0, 0 °C), by analogy with a method proposed for the identification of esterified galacturonic acid residues in pectins.¹⁴⁸ The hydrolysis products of reduced polysaccharides were converted into aldono-nitrile acetates and analysed by GLC. The chromatograms revealed two peaks corresponding to gulose derivatives (1,6-anhydro- β -L-gulose and L-gulononitrile acetates) and a peak of acetylated D-mannononitrile. Despite incomplete esterification and, correspondingly, incomplete reduction, the M/G values calculated from the peak areas of the corresponding mannose and gulose derivatives coincided with the results of analysis of the ¹³C NMR spectra.

A procedure for the determination of the M/G ratio which consists in the reduction of the carboxy groups with subsequent methylation, reductive splitting of the polymer with triethylsilane in the presence of trimethylsilyl methanesulfonate and boron trifluoride etherate and identification of the anhydroalditols (in the form of the corresponding derivatives) using HPLC or GLC, proposed by Zeller and Gray,¹⁴⁹ seems to be too complicated for routine assays of alginic acids.

4. Partial hydrolysis for determining the block composition

As stated in the introduction, physicochemical properties of alginates are largely determined by the mode of distribution of the two uronic acid residues along the polymeric chain. This distribution pattern can be characterised chemically using partial acid hydrolysis.^{26,27} After short-term heating of alginic acid suspensions in dilute mineral acids (20 min, 100 °C, 0.3 M HCl), an oligomeric fraction with an average degree of polymerisation of ~ 20 and containing approximately equal amounts of both uronic acid residues (MG-blocks) passes into the solution. The insoluble residue additionally heated for 20 h with acid is separated into two fractions, *viz.*, a fraction soluble at pH 2.85 and insoluble one. These fractions also represent oligomers with average degrees of polymerisation of ~ 20 , but the former contains exclusively M-blocks (the mannuronic acid content exceeds 90%), while the latter consists of G-blocks (the mannuronic acid content is less than 10%). From the yields of all the three fractions, one can establish the distribution pattern of uronic acid residues in the linear chain of alginates. Using partial hydrolysis, it was demonstrated for the first time that alginates of different origin differ in fact in their block composition.¹⁵⁰ In subsequent studies, a similar approach was repeatedly used for characterisation of alginates (see, *e.g.*, Ref. 151).

A simplified procedure for the determination of the block composition of alginates was described by Penman and Sanderson.¹⁸ These authors proposed to use a one-step treatment of alginates with an acid (5 h, 100 °C, 0.3 M HCl) instead of two-step hydrolysis and to determine the yields of soluble and insoluble fractions colorimetrically, by reaction with phenol and concentrated sulfuric acid. The insoluble fraction obtained was analysed by ¹H NMR spectroscopy as a solution in D₂O at 80 °C rather than separated into blocks of different composition. The low-field region of the spectrum has a singlet for H(1) of the residue M at $\tau = 5.34$ (peak B), a doublet for H(1) of the residue G at $\tau = 4.96$ (peak A) and a singlet for H(5) of the residue G at $\tau = 5.56$ (peak C). The ratios of integral intensities B/A or B/C (these

values can be averaged) and the yield of the soluble fraction permit one to calculate the block composition of the original polysaccharide.

Yet another modification of the partial hydrolysis procedure is the use of ion-exchange and gel-permeation chromatography for the separation of oligomeric products.^{152,153} Using several commercial alginate preparations as examples, it was shown that the size of M-blocks varies in the range of 3–10, that of G-blocks varies in the range of 4–15 monosaccharide residues, while the distribution of monomers within MG-blocks is random.¹⁵²

Electrophoresis in polyacrylamide gel¹⁵⁵ was recommended for separation and quantitative determination of oligomannuronic and oligoguluronic acids with a degree of polymerisation varying from 2 to 9 obtained by partial hydrolysis of alginates.¹⁵⁴ In order to increase the electrophoretic mobility of the oligosaccharides and sensitivity of their assays, these were fluorescently labelled by reductive amination with 8-aminonaphthalene-1,3,6-trisulfonic acid.

III. Enzymic and immunological methods

All currently known enzymes able to depolymerise alginate molecules are lyases, *i.e.*, they catalyse β -elimination of the substituent from position 4 of the uronic acid residue rather than hydrolysis of glycosidic bonds.^{156–158} This cleavage results in the formation of a 4,5-unsaturated uronic acid residue (Scheme 1) at the newly formed end of one of the fragments. Since elimination results in disappearance of asymmetric centres at C(4) and C(5), the same unsaturated uronic acid is formed from both β -D-mannuronic and α -L-guluronic acids. This unsaturated residue has an intense absorption band at 230–240 nm, and the increase in optical density at 230 nm can be used as a convenient method for determining the enzymic activity of alginate lyases.¹⁵⁹ A mixture of oligomers with low degrees of polymerisation is a final product of enzymic treatment of polymeric alginic acids with alginate lyases.¹⁶⁰

Scheme 1

Alginate lyases have been detected in many organisms, *e.g.*, sea molluscs, echinoderms, bacteria and fungi.¹⁶¹ Molluscs (Gastropoda)¹⁶² and bacteria^{163–165} are the most convenient sources for the isolation of these enzymes. Alginate lyases of different origin differ essentially in their stabilities,¹⁶⁶ specificities^{167–169} and abilities to hydrolyse acetylated bacterial alginates.^{170,171} Thus M-lyases (polymannuronate lyases) normally isolated from molluscs are endoenzymes, which easily hydrolyse M- and MG-blocks without any effect on G-blocks.^{172,173} In contrast, G-lyases (polyguluronate lyases) hydrolyse G- and MG-blocks but are inert with respect to M-blocks.¹⁶² The substrate specificities of alginate lyases can be examined using a recently proposed procedure for depolymerisation of alginates on agar plates in the presence of calcium chloride¹⁷⁴ or using homopolymeric substrates containing a terminal fluorescent label.¹⁷⁵

A convenient and versatile procedure which takes into account the specificity of alginate lyases and is suitable for detection and analysis of alginates in solutions at concentrations

of 0.01 to 1 mg ml⁻¹ (see Ref. 176) was developed for quantitative determination of various alginic acids. The material under study was treated with a mixture of two enzymes of different origin, viz., a mixture of poly-M-lyase isolated from the mollusc *Haliotis tuberculata* and poly-G-lyase isolated from the bacterium *Klebsiella pneumoniae*; the absorption of reaction products was measured at 230 nm. With the use of an excess of enzymes it was shown that the final values of optical density were proportional to the initial concentration of the substrate. A combination of two enzymes made it possible to eliminate the effect of the variable composition of different alginates. It is noteworthy that the separate application of these enzymes can provide information about the block structure of various alginates. This recently developed procedure holds much promise, especially for future studies provided alginate lyases become commercially available.

Alginate lyases of known specificity are also used for obtaining information about the distribution of uronic acid residues and the sizes of individual blocks in alginates. It is bacterial enzymes that made it possible to establish, for the first time, the deviation of the uronic acid sequence in poly-MG from a strictly alternating pattern.^{160, 177} Some alginates were found to contain poly-M-blocks that are homogenous in size and have an average degree of polymerisation of 24;¹⁶⁰ however, more recent studies with other subjects established more variable distribution patterns of poly-G- and poly-M-blocks according to their size.^{178, 179}

The specificity of action of the enzyme isolated from the sea mollusc *Haliotis tuberculata* was studied in most detail. High-performance liquid chromatography was specially adapted for the separation of saturated and unsaturated oligoguluronates and oligomannuronates formed upon enzymic hydrolysis of alginates¹⁸⁰ and different procedures of NMR spectroscopy¹⁸¹ were specially developed for the elucidation of the structure of these oligosaccharides. It was found that alginate lyase effectively cleaves M–M and G–M bonds (but not G–G or M–G bonds) and that the pentamer of mannuronic acid is best bound to the enzyme active centre.

In an analogous study of recombinant bacterial alginate lyase,¹⁸² it was established that the enzyme cleaved exclusively M–M bonds. The enzymic action is blocked by the presence of the acetyl groups in mannuronic acid residues, which is characteristic of bacterial alginates. This enzyme was recommended for the preparative isolation of poly-M-blocks from acetylated polymanuronate of *Pseudomonas aeruginosa* and of poly-MG-blocks from another bacterial alginate containing residues of both uronic acids.¹⁸³

Alginates possess antigenic activity. Several attempts were undertaken to raise antibodies against definite structural elements of alginate molecules and to use these antibodies for the analysis of alginates by standard immunological procedures.¹⁸⁴ Specific antibodies (both polyclonal^{185, 186} and monoclonal¹⁸⁷) against alginates were used to localise the polysaccharide in various algal tissues; however, this assay was complicated by gel formation. Considering that gel formation decreases the ability of the corresponding sites in the alginate molecule to bind to antibodies and that the reaction conditions (pH, temperature, accessibility of Ca²⁺ ions and the nature of other buffer components) can strongly influence the results of immunological assays,¹⁸⁸ it may be concluded that these studies are still far from being completed and that the immunological behaviour of alginates and the specificity of the corresponding antibodies need additional investigation.

IV. Nondestructive physicochemical methods

1. IR spectroscopy

The total amount of polymers consisting of uronic acids can be determined from the intensity of the absorption band of the ionised carboxyl at 1607 cm⁻¹ in the IR spectrum of a sample solution in a D₂O-phosphate buffer.¹⁸⁹ It was recommended to determine semi-quantitatively the M/G value in alginates by

measuring the ratio of absorption band intensities at 808 (M) and 787 cm⁻¹ (G) in the IR spectra of specially prepared films.¹⁹⁰ Comparison of band intensities at 1320 (M) and 1290 cm⁻¹ (G) can also be used for this purpose.¹⁹¹ However, because of low precision and interference due to different factors these two methods have not found wide application. On the other hand, IR spectra provide valuable information about the presence of acetyl groups in bacterial alginates^{22, 99, 101} judging from intense absorption bands at 1250 and 1730 cm⁻¹.

Recently, it was proposed to use spectroscopy in the near IR region (400–2500 nm) for determination of the alginate content in brown algae biomass.¹⁹² The reflectance spectra recorded for powdered biomass samples are computer-processed at 9 parameters. The experimentally determined calibration curves allow the determination of alginate in the starting material with high precision. This method was successfully used for characterisation of biodegradation of the alga *Laminaria hyperborea* in which the alginate content varies from 2.2% to 40.8%. Horn *et al.*,¹⁹² who have developed this procedure, gave it a high estimate, although this analysis requires the use of a specially designed spectrophotometer. It was noted also that variable content of moisture and polyphenols in the specimens under study interfere with the analysis of alginates.

2. Circular dichroism

The three types of blocks present in alginate molecules differ essentially in their circular dichroism (CD) spectra; the poly-G spectrum lies completely in the region of negative molar ellipticity values, $[\theta]$, the poly-M spectrum has an intense positive band, while the poly-MG spectrum is characterised by intermediate values of $[\theta]$.^{193, 194} The CD spectra of natural alginates are characterised by a peak at 200 nm and a trough at 215 nm. It was found that the M/G ratio may be calculated from the observed ratio of peak height to trough depth using simple equations.¹⁹⁵ Therefore, this important parameter can be determined from the CD spectra even for milligram quantities of the alginate without any destruction of the polymer.

Since the CD spectra of mixed blocks (poly-MG) are not identical with the spectra of equimolar poly-M and poly-G mixtures, the determination of the block composition of alginates from their CD spectra is possible. A relatively simple computer-assisted calculation was proposed which mimics the real spectrum owing to a linear combination of three types of spectra characteristic of isolated blocks.¹⁹⁵ Although the shape of poly-MG spectra depends on the distribution of uronic acid residues within the blocks, which is not taken into consideration in the calculation procedure, the results obtained with known alginate specimens showed good coincidence with those earlier established using partial hydrolysis or NMR spectra. The CD spectra were subsequently used to characterise the block composition of alginates isolated from many species of brown algae or from different types of algal tissues.^{47, 196, 197}

3. ¹³C NMR Spectroscopy

A preliminary report concerning the interpretation of ¹³C NMR spectra of alginates was published in 1977 by Grasdalen *et al.*²⁰ who showed that the alginate spectra recorded at 25 MHz contained four signals in the anomeric resonance region rather than two signals, as might be expected for a polysaccharide made up of two uronic acid residues. This implies that the position of C(1) signals of both monosaccharides (M and G) depends on the nature of the neighbouring residue. The intensities of these signals could be used for estimating both M/G and the relative content (*F*) of pairs of monomers (MM, MG, GM and GG). Moreover, the signal corresponding to the C(5) atom of the residue M was represented in the spectrum by three lines, which suggests the dependence of the signal position on the nature of both neighbouring residues. This phenomenon could be used for quantification of the number of triplets with a central M residue within the polymer. It was found that the central line of the signal corre-

sponds to the central residues M of the MMM and GMG triplets, whereas the low-field and high-field lines represent the corresponding signals for GMM and MMG, respectively. Thus, the relative content of the latter two triplets in the alginate molecule can be measured directly, from the intensity of the corresponding signals, and the probability of the presence of triplets MMM and GMG in the polymeric chain can be calculated from the ratios: $F_{MMM} + F_{GMM} = F_{MM}$ and $F_{GMG} + F_{MMG} = F_{MG}$. The data calculated for several alginates showed good correlation with the results of chemical analysis. However, no possibility to determine the number of triplets with a central (G) residue was found in this pioneering study.

Later, in detailed studies Grasdalen *et al.*²¹ used a higher-resolution NMR spectrometer (50 MHz) and carefully selected the conditions for recording NMR spectra. The signals for the anomeric carbon atoms gave eight lines corresponding to the central units of eight theoretically possible triplets of the primary structure. The intensities of these lines were used to calculate the content of each type of triplets in several specimens of natural alginates. The validity of these calculations was partially confirmed by an analysis of signals corresponding to the carboxyl carbon atoms and to C(4) and C(5) atoms of the residue M, which also have multiplet structures, and by comparison of these data with the results of chemical assays. The average lengths of homopolymeric blocks can be calculated from the triplet content: $N_{G>1} = (F_G - F_{MG})/F_{GM}$ and $N_{M>1} = (F_M - F_{GM})/F_{MM}$.

It is of note that the most probable distribution of residues along the polymeric chain in synthetic binary copolymers formed by polymerisation of two different monomers can be calculated, taking into account the initial concentrations and relative reactivities of the monomers. However, the block composition of alginates usually differs from the calculated sequence, which is at variance with the mechanism of formation of these polysaccharides by copolymerisation of two monosaccharide precursors and is a convincing argument in favour of an alternative route of their biosynthesis involving mannuronan-C(5)-epimerase.^{198, 199}

¹³C NMR spectroscopy is an extremely convenient procedure for structural characterisation of alginates isolated from different natural sources (see, *e.g.*, Refs 8, 9, 200) or modified by enzymic treatment.²⁰¹ This was also used to monitor alginate biosynthesis in bacteria.²⁰² However, recent experiments have shown^{49, 203} that the reliability of determination of the block composition depends on M/G of the specimen under study. More adequate results were obtained for alginates with a high content of one of the monomers; if M/G is close to unity, the calculated values of individual block lengths can differ substantially from the results obtained upon chemical or enzymic hydrolysis.

¹³C NMR spectra were obtained not only for solutions but also for solid alginate samples.²⁰⁴ In the latter case, the resolution of peaks was much lower, especially for the anomeric carbon signals. Nevertheless, a complex spectral pattern could be represented as a sum of individual symmetric signals corresponding to the C(2)–C(5) atoms of both uronic acid residues, which made it possible to estimate the M/G ratio with a sufficiently high accuracy.²⁰⁴

4. ¹H NMR spectroscopy

The ¹H NMR spectra of alginates were studied in parallel with ¹³C NMR spectra in the hope to elaborate a more sensitive and accurate method for the determination of the content of monomers and their block distribution. It was shown¹⁹ that informative spectra of alginates can be obtained using a 100 MHz spectrometer after short-term mild acid treatment of samples, which reduces the viscosity of solutions. Although not all signals could be resolved in these spectra, the low-field region contained three well-defined peaks, *viz.*, A [H(1) of the residue G], B [a sum of H(1) of the residue M and H(5) of the residue MG] and C [H(5) of the residue GG], which made it possible to calculate the following values: $F_G = I_A/(I_B + I_C)$ and $F_{GG} = I_C/(I_B + I_C)$. Taking into

account that $F_G + F_M = 1$, $F_{GG} + F_{GM} = F_G$ and $F_{MM} + F_{MG} = F_M$ (for lengthy chains, $F_{MG} = F_{GM}$), the M/G ratio and the content of the four possible monomeric pairs in alginate molecules can be calculated. The parameters established for well-known specimens coincided with the results obtained by chemical methods and ¹³C NMR spectroscopy.

In a continuation of these studies, ¹H NMR spectra of alginates and their fractions were recorded at 400 MHz.²⁰⁵ As in the above-cited paper,¹⁹ the M/G values and contributions of the dimeric sequences (MM, MG = GM and GG) were calculated from the analysis of ¹H NMR spectra. In addition, higher resolution made it possible to isolate four signals corresponding to the H(5) atom of the central residue of α -L-guluronic acid in the four possible triads (GGG, MGG, GGM and MGM). The content of these trimers showed a good correlation with the values obtained by other analytical methods.

The ¹H NMR spectra of poly-M and poly-G, the components of a bacterial alginate produced by *Azotobacter vinelandii*, were further analysed using both one-dimensional and modern two-dimensional NMR techniques.^{206, 207} The unambiguous assignment of signals was performed on the basis of chemical shift theory, analysis of spin–spin coupling constants and measurements of the nuclear Overhauser effects. These data were used to study the interaction of poly-M- and poly-G-blocks with Ca²⁺ ions in aqueous media. A model for binding of calcium ions was proposed, which is based on the measurement of the relative intensity of cross-peaks in the two-dimensional spectra (NOESY) of the free polymer and its calcium salt. The experimental results are important for interpreting the gel-forming ability of alginates in the presence of calcium ions and elucidation of the role of calcium as a cofactor essential for the functioning of mannuronan-C(5)-epimerase.

High-resolution ¹H NMR spectroscopy was efficiently used for characterisation of many natural alginates, of both algal^{196, 208} and bacterial^{209, 210} origin, particularly for establishing the degree of acetylation and localisation of acetyl groups in bacterial alginates.²⁴ It was noted, however,²⁰⁴ that partial hydrolysis traditionally used for decreasing the viscosity of solutions of high-molecular-weight alginates prior to recording their proton NMR spectra can induce the precipitation of a portion of alginate and thus significantly distort the experimental results (M/G ratio).

V. Conclusion

As may be inferred from the survey, the analytical chemistry of alginic acids is a well-grounded and well-studied field. Numerous approaches have been proposed for the solution of analytical problems of different degrees of complexity, from quantitative determination of alginates in mixtures with other natural compounds to the analysis of uronic acid sequences in the linear molecules of these polysaccharides.

Alginate acids differ from other natural polyuronides in that they are made up of unique monosaccharides and are characterised by a peculiar distribution of monomers along the polymeric chain. Special approaches were elaborated for investigation of these structural features among which partial acid hydrolysis, enzymic degradation and some nondestructive physicochemical methods (in the first place, NMR spectroscopy) have proved to be especially efficient. The experimental findings have made it possible to formulate a concept of the primary block structure of alginic acids and to gain a deeper insight into the pathways of their biosynthesis leading to this structure. These results not only have a great theoretical significance, but are of great practical value, since they permit direct alteration of physicochemical properties of alginates by enzymic treatment.^{201, 211} However, it should be remembered that specific analytical approaches were elaborated for the solution of concrete practical problems and have certain limitations which have been mentioned in the review. Further in-depth studies into the structure and properties of alginates will

probably demand further improvement of existing methods of structural analysis of these polysaccharides.

The significance of analytical chemistry of alginates goes far beyond the confines of this class of biopolymers. As uronic acid-containing polysaccharides are widely spread in nature, many chemical methods designed for the detection and quantitative determination of alginates, particularly, the approaches based on specific degradation of uronic acids or chromatography of acid hydrolysates, are equally efficient in the analysis of plant mucilages, pectins, hemicelluloses, bacterial and fungal polysaccharides and animal glycuronoglycans.

Abstract. Photosensitised oxygen-independent chemical modification of nucleic acids including free-radical cycloaddition and electrophilic addition (type III photodynamic effect) are considered. The main attention is given to site-specific photomodification. New approaches to highly specific affinity modification of nucleic acids, *viz.*, sensitised photomodification with binary photoreagent–sensitiser systems and two-photon photosensitised reactions, are described. The prospects for application of electrophilic photoreagents for *in vivo* modification of nucleic acids are discussed. The bibliography includes 119 references.

I. Introduction

The development of methods for targeted chemical modification of nucleic acids (NA) at definite nucleotide sequences is of great importance for the study of cellular processes connected with gene expression,^{1,2} design of gene-addressed biologically active substances³ and the development of new technologies based on the use of oligonucleotide chips and microelements for new generations of computers.⁴

The targeted modification of NA is carried out with affinity reagents which can bind specifically to definite nucleotide sequences and contain reactive groups bringing about NA modification upon binding. Fragments of antibiotics,^{5,6} oligonucleotides^{3,7,8} and their derivatives^{2,9} are used for the recognition of definite nucleotide sequences. Compounds generating free radicals,^{3,10} alkylating reagents^{3,8} and photoreactive compounds^{2,3,7,11} are used as the affinity reagents.

Chemically reactive oligonucleotide derivatives can react with different cell components, which results in undesirable toxicity and considerable expenditure of reagents in side reactions. Photoreactive derivatives possess considerable advantages, *viz.*, they are nontoxic in the dark and their photoactivation is easily controlled. Considerable experience has been gained in the last few years in the area of synthesis, studies of physicochemical properties, biological application of novel reagents containing photoreactive groups and the determination of the structure of NA photomodification products under the action of these reagents.

Received 13 April 1999

Uspekhi Khimii 68 (11) 1062–1079 (1999); translated by R L Birnova

The design of DNA-cleaving reagents which are chemically stable and can be photoactivated is a topical problem. These reagents are helpful tools in the study of DNA structure when used as photonucleases, photofootprinting reagents and potential photoreagents in the phototherapy of cancer and various viral infections.^{11–13}

Photosensitised NA modification reactions are commonly referred to as photoinduced reactions occurring at wavelengths greater than the intrinsic absorption of NA.¹⁴ These reactions involve three main types,^{15,16} *viz.*, photooxidation with radical species or by photoinduced electron transfer (type I photodynamic effect), photooxidation with singlet oxygen (type II photodynamic effect) and oxygen-independent free-radical and electrophilic addition (type III photodynamic effect).

The classification of photosensitised reactions of NA is problematic and any description of them is ambiguous, for photochemical reactions are numerous, they occur in parallel and in low quantum yields. Their study is complicated by the fact that the same photomodification end products are formed by different mechanisms.⁷

This review is devoted to the analysis of the most important photosensitised, oxygen-independent free-radical and electrophilic addition reactions. One-photon^{17,18} and two-photon^{19,20} photochemical reactions of NA induced by far UV light (190–300 nm), photooxidation of DNA with singlet oxygen^{3,7,21} and radical species^{22–24} as well as oxidation caused by photoinduced electron transfer^{11,25,26} have been studied in sufficiently great detail and will not be considered in this review.

II. Free-radical cycloaddition and electrophilic addition photoreactions of nucleic acids

Several types of oxygen-independent photosensitised chemical modifications of NA are known,^{14,16} *e.g.*, free-radical photocycloaddition to the double bonds of bases,^{27–45} photoinduced alkylation,^{46–58} arylation,^{59–63} acylation^{27,64} and other electrophilic addition reactions. Modification of NA with highly electrophilic species formed during photochemical reactions is especially attractive, since the electrophilic species manifest pronounced selectivity with respect to nucleophilic bases, such as guanine and adenine. In turn, photocycloaddition reactions occur with high selectivity at the double bonds of the pyrimidine bases.²⁷

1. Free-radical photocycloaddition

Excitation of most ketones and thioketones gives rise to biradical species which initiate radical cycloaddition reactions involving the double bonds of the heterocyclic bases of NA. Psoralen and

thiopyrimidine derivatives are the most popular and efficient photoreagents of this type.

a. Photomodification of nucleic acids with psoralen derivatives

Psoralens (7*H*-furo[3,2-*g*][1]benzopyran-7-ones) are tricyclic aromatic compounds, which have a planar structure and can intercalate between base pairs of double-stranded DNA (ds-DNA). They contain two photoreactive double bonds, *viz.*, C(3)=C(4) in the pyrone ring and C(4')=C(5') in the furan ring.

R¹, R², R³ = H, Alk.

Irradiation of DNA duplexes at 310–420 nm in the presence of psoralens results in covalent binding of the latter to pyrimidine bases of DNA (preferentially, to thymine) at the C(5)=C(6) bond to give cyclobutane adducts (Scheme 1). Photoaddition reaction of psoralens to cytidine occurs 15-fold more slowly than that to thymidine.¹ Psoralens are bifunctional photoreagents; they can cross-link both DNA strands, especially when intercalating in the 5'-TpA-3' sequence.^{1, 28–38} 5'-TpA/3'-ApT fragments are present in signal sequences of many genes as potential targets for psoralen-containing oligonucleotides.

L is CH₂NH(CH₂)₂NH-p, R¹–R⁵ are fragments of oligonucleotide chains.

Using molecular modelling methods, it was shown¹ that psoralen incorporates between the nucleotides of a target in two different ways, *viz.*, between nucleosides N_{n+1} and N_n or between nucleosides N_n and N_{n-1}, where N_n is the nucleoside complementary to the 5'-terminal nucleoside of the psoralen conjugate. Spatial structure of the reaction centre which is the most favourable for photoaddition, is realised in the former case. The incorporation of psoralen is especially efficient where thymidine residues occupy positions *n* + 1 and *n* – 1, and adenosine residues occupy position *n* of the target. In this case, the reaction occurs

simultaneously in both directions. The yield of the cross-linked product of the type **1** amounts to 95%.

In recent years, psoralen-containing oligonucleotide derivatives have been used mostly for photomodification of ds-DNA.

Studies of Gunther *et al.*²⁹ have shown that the 16-membered conjugate Pso-CH₂NH(CH₂)₂NH-p-5'-TTTTCTTTTCCCCCT **2** forms a triplex with DNA regions of HIV-1 containing homopurine–homopyrimidine sequences. Psoralen intercalates into ds-DNA thus increasing the melting temperature of the triplex from 20 to 29 °C. Irradiation with UV light at wavelengths > 310 nm yields mono- and bis-adducts **3** and **1**, which is confirmed by their electrophoretic mobility. The addition of the furan ring of psoralen to the C(5)=C(6) bond of thymine next to the 5'-end of the homopurine sequence of the DNA-target gives the cyclobutane adduct **3**. This is followed by photochemical cycloaddition of the pyrone ring of the adduct **3** to the C(5)=C(6) bond of 3'-terminal thymine in the homopyrimidine chain, resulting in the bisadduct **1**.

The DNA region of HIV-1 contains two sequences which can serve as targets for the conjugate **2**. Both sequences are involved in cross-linkage with high efficiency. Besides, at higher exposures and higher concentrations of the oligonucleotide reagent **2**, cross-linking occurs in the regions where the 5'-terminal 8-membered fragment (T₄CT₃) of the conjugate **2** binds to ds-DNA. The reason for such modification is that the sequence (pC)₆ of the conjugate **2** cannot be fully protonated under physiological conditions, and the overall specificity of the 16-membered conjugate **2** is determined by the fragment (T₄CT₄). Substitution of (pG)₆ for (pC)₆ results in photomodification at only two specific sequences.²⁹

The dependence of the length of the oligonucleotide address on the degree of modification of target ds-DNA *in vitro* was studied.²⁹ It was shown that 10- and 16-membered psoralen-containing oligonucleotide conjugates were effective in sequence-specific photocross-linking of mouse ds-DNA, while an 8-membered oligonucleotide reagent had little effect. Binding of the 10-membered conjugate to ds-DNA occurred rapidly (in less than 10 min).

A conjugate of 5-alkoxypsoralen and 5'-pTTTTTC*C*TC*T-C*C*C*TC*T, where C* is 5-methylcytosine residue introduced for increasing the triplex stability, was used to inhibit the expression of the interleukin 2 α-chain receptor gene.³⁰ The conjugate bound to the promoter homopurine–homopyrimidine sequence to yield a triplex. The mutant form of the promoter containing a transversion of three nucleotides in the centre of the homopurine–homopyrimidine sequence was used as a control. The conjugate did not bind to the mutant promoter.

Irradiation with UV light (365 nm) was accompanied by photocycloaddition of the psoralen 3,4- and 4',5'-double bonds to the C(5)=C(6) bonds of the sequence 5'-TpA-3' at the duplex–triplex junction, resulting in the bisadduct **1**. The formation of a covalently bound triplex inhibited transcription *in vitro*, while transcription of the mutant form of the promoter was not inhibited. After *in vitro* photomodification of DNA, the photocross-linked triplex was transfected into human HeLa cells. The irradiated mutant promoter was transcribed with the same efficiency as the nonirradiated one; the activity of the irradiated promoter was inhibited by 80% (according to the photocross-linkage yield).

The formation of photoadducts in a triplex of a bacteriophage λ ds-DNA with a conjugate 4'-hydroxymethyl-4,5',8'-trimethyl-Pso-pAGGAAGGGGG was most extensively studied by Gasparro *et al.*³¹ The quantum yield (φ) of the monoadduct **3** was 0.0065, while that of the bisadduct **1** was 5 times as great. The formation of the bisadduct **1** implies that the C(4')=C(5') bond of the furan ring of psoralen reacted first and then the C(3)=C(4) bond of the pyrone ring. Otherwise, the bisadduct is not formed. It was therefore proposed to carry out the irradiation in a stepwise manner, *viz.*, first, with visible light (419–447 nm) and then with UV light (> 310 nm). The efficiency of photomodification upon irradiation with visible light was 400 times lower than with UV

light, but in this case the monoadduct **3** is formed at the T166 residue (yield 40%). Subsequent UV irradiation gives the bisadduct **1** (yield 62%) and monoadducts (yields at pyrimidine and purine residues were 9% and 22%, respectively). In this two-step irradiation, the total degree of photomodification of ds-DNA reached 95%.

Irradiation with visible light (419 nm, 30 min) of ds-DNA within a complex with a triplex-forming psoralen conjugate **2** yielded the monoadduct **3** in 87% yield. Further irradiation with UV light for 5 min resulted in the bisadduct **1** (in up to 92% yield).³¹ A conjugate 4'-hydroxymethyl-Pso-4,5',8-trimethyl-pAGGAAGGGG was used for site-specific injury of the supF-gene incorporated into vectors of *E.coli* phage λ ³² and virus SV40.³³ It was shown that the formation and photocross-linking of the triplex can also occur *in vivo*.³⁴

Inhibition of gene expression with a conjugate 5-hydroxy-Pso-pTC*TTC*TTC*C*TC*T-C*TT, where C* is 5-methylcytosine, in transfected HeLa cells is reported.³⁸ After UV irradiation (> 310 nm) of the triplex *in vitro*, the amplification of a DNA fragment was inhibited by 95%. Plasmid pCH110 was photo-modified and incorporated into HeLa cells. The activity of the gene of the incorporated β -galactosidase 5 h after transfection was 5%.

Penetration of psoralen derivatives through hydrophobic cell membranes and their resistance to nuclease hydrolysis could be enhanced if psoralen was coupled to distamycin-like imidazole (**4a**) and pyrrole (**4b** and **5**) derivatives.^{35–37}

The imidazole analogues of distamycin **4a** can deliver psoralen to GC-rich DNA regions, while the pyrrole analogues **4b** and **5**, to AT-rich DNA regions. The imidazole analogue **4a** photomodifies DNA 10 times more efficiently than the original psoralen. The efficiency of photomodification of ds-DNA with the pyrrole analogue **4b** is 1000 times greater than that with psoralen and 100 times greater than that with the imidazole analogue.¹

These data suggest that psoralen conjugates are promising reagents for photomodification of NA *in vivo*. High phototoxicity of psoralens as regards modification of ds-DNA is determined by the formation of bisadducts **1**.

b. Photomodification of nucleic acids with 4-thiopyrimidine derivatives

Along with psoralens, thiopyrimidine nucleotides, *e.g.*, 4-thiouridine (s⁴U) and 4-thiothymidine (s⁴T), are used as photoreagents able to undergo free-radical cycloaddition. The presence of a sulfur atom instead of an oxygen atom at position 4 causes a shift of the absorption spectrum towards the long-wave region ($\lambda = 330$ nm) and the appearance of new photochemical properties.^{39, 40}

Irradiation of thiopyrimidines with UV light (330 nm) leads to the population of the excited state S_2 which is rapidly (within 5 ps) and in high quantum yield ($\phi = 0.9$) converted into state T_1 . Photolysis of d(s⁴U) in water in the presence of oxygen yields dU.⁴⁰

Thiopyrimidine nucleotides can form covalent adducts with all natural nucleic bases, but the quantum yield of the photo-reaction with pyrimidine bases is higher than that with purines. Irradiation of the dinucleotide dTp(s⁴U) (**6**) gives two stable products **7** and **8** (quantum yield 0.02) (Scheme 2). It is assumed

Scheme 2

Figure 1. The structure of a ribozyme complex (bold-type) containing an RNA fragment.

that the [2+2]-cycloaddition of thiopyrimidine involving the excited C=S bond to the C(5)=C(6) bond of a pyrimidine results in the adduct **7** and subsequent chemical reactions yield the final product **8**.⁴⁰

Irradiation of the dinucleotide d(s⁴U)pT (**9**) afforded the adducts **10** and **11** (Scheme 2). In all probability, they are formed due to hydrogen abstraction from the methyl group of thymine by photoexcited thiouridine followed by recombination of radical species.⁴⁰

A significant advantage of thiopyrimidines as photoreagents is that the van der Waals radius of the sulfur atom is by only 0.45 Å larger than that of the oxygen atom. This does not affect the structure of oligo- and polynucleotides with incorporated thiopyrimidine residues.³⁹ The photochemical properties of thiopyrimidines were most completely employed in the study of the tertiary structure and mechanism of action of ribozymes (Fig. 1).^{39–45} Thiouridine residues were introduced into the RNA substrate at positions X. Irradiation of the ribozyme complex with RNA was accompanied by the formation of cross-links (indicated by arrows in Fig. 1). The photoaffinity modification data suggest that several alternative conformations appear in the ribozyme complex with RNA in different stages of a catalytic cycle of RNA hydrolysis.^{40–42}

2. Photoinduced alkylation of DNA

Numerous photochemical methods for the generation of electrophilic species that alkylate DNA have been described.^{27, 46–58} These methods involve the preparation of azacycloheptatetraene *via* an intermediate singlet nitrene by photodecomposition of aromatic azides,^{46–52} generation of quinolylmethylcarbocations by heterolytic photodecomposition of quinolylmethylisothiuronium salts,⁵³ preparation of quinonemethide by photoenolisation of 5- and 2-methylnaphthoquinone derivatives^{54–57} and generation of oxonium cations from monothioacetals by photoinduced electron transfer.⁵⁸

a. Photomodification of nucleic acids by aromatic azides

Oligonucleotide derivatives of aromatic azides are widely used in photomodification of DNA^{46, 47, 50–52} and RNA^{48, 49} owing to their high photoreactivity and accessibility.

Conformational changes of a *p*-azidophenacyl 5'-thiophosphate derivative of ribozyme L-21 Sca I were studied in different stages of binding and catalytic cleavage of an RNA-substrate.^{48, 49} Irradiation of the photoreactive ribozyme derivative with UV light (312 nm) in the absence of the RNA-substrate gives covalent adducts at the A88\A89\A90 residues (yield 12%). The photomodification affected the A114\A115 residues of ribozyme (yield 34%) within the complex with the fragment GGCCCU-CUAAAAA where ribozyme hydrolysed the phosphodiester bond between the uridine and adenine residues; in the absence of Mg²⁺ cations, the C102\A103\A104 residues were photomodified in 38% yield.⁴⁸ The data obtained made it possible to establish the position of the ribozyme internal guide sequence (IGS) containing the *p*-azidophenacyl residue in different stages of the catalytic cycle of RNA hydrolysis.^{48, 49}

Ethidium derivatives **12** and **13** proved to be the most efficient photoreagents for DNA modification.^{50, 51} In all probability, this is associated with the ability of these residues to intercalate into DNA and with the photochemical properties of aromatic azides. The photolysis products of the azides **12** and **13** in water have been studied.⁵¹ This reaction yields intermediate electrophilic species, *viz.*, the azacycloheptatetraene **14** and the aziridine **15**; which add water to give the adducts **16** and **17**. In both cases, the triplet nitrenes **18** and **19** were formed, which underwent nonproductive decomposition as regards NA photomodification, *viz.*, reduction to the amines **20** and **21**, respectively.

Formally, photolysis of the azide **13** in the presence of nucleophiles should give arylation products of the type **17**; however, these products have not been obtained and this azide is considered for convenience of comparison.

L = $\text{NHCO}(\text{CH}_2)_2\text{NH}_2$.

Heptanucleotide pCCAACA conjugates with the azides **12** and **13** linked through 5'-phosphate were used for site-specific photomodification of the ^{32}P -labelled complementary octanucleotide 5'-*pTGT TTGGC.⁵¹ The introduction of azidoethidium residues strongly stabilises the complementary complexes by increasing their melting temperature by 20–30 °C.

Irradiation of these duplexes with UV light (320 nm) results in covalent adducts in 40% and 60% yields, respectively. After treatment with piperidine which results in the cleavage of the DNA chain at the modified bases, the total degree of the octanucleotide photomodification increased up to 70% and 80%, respectively. The results of piperidine-catalysed cleavage led the authors to conclude that modification predominantly affected the C8 residue and, to a lesser degree, the G7 residue (indicated by arrows). The formation of up to 10 different adducts (many of which are unstable) was established by HPLC, but the attempts to isolate these adducts and to determine their structure were unsuccessful.

The oligonucleotides p(TC)₆Tp containing the azides **12** and **13** at their terminal phosphates were used for photomodification of ds-DNA in the triplex **22**.⁵⁰

22

Irradiation of the triplex **22** (320–420 nm) containing the conjugate 5'-(**12**)p(TC)₆T as a photoreagent resulted in spontaneous cleavage of the purine-rich chain at the residue G3 (the degree of photomodification was 15%) as well as in the formation of covalent adducts with this residue (yield 30%). The pyrimidine-rich chain was photomodified to a far lesser degree; this was accompanied by the formation of covalent adducts with the residue T4 (yield 10%).

With the 3'-(**12**)p(TC)₆T derivative as a photoreagent, the total degree of photomodification of both chains did not exceed 10%.

Irradiation of the triplex **22** with the 5'-(**13**)p(TC)₆T reagent resulted in highly selective photomodification of the pyrimidine-rich chain. No direct cleavage was observed in this case; the covalent adducts (yield 35%) and the product of modification of the residue T4 were detected using treatment with piperidine.

b. Photomodification of DNA with benzylisothiuronium salts

A study of photolysis of a series of benzyl compounds of the type ArCH_2X capable of generating carbocations revealed that the quinolyl-2(4)-methylisothiuronium salts **23** and **24** manifested the highest photoreactivity. Their irradiation with UV light (350 nm) in water gave the carbocations ArCH_2^+ (yield 90%, quantum yield 0.09).⁵³

dG is deoxyguanosine.

Photomodification of ds-DNA with the salts **23** and **24** resulted in insignificant cleavage of the target independent of its sequence. Most probably, the reaction occurs as hydrogen abstraction from deoxyribose by a benzyl radical ($\text{ArCH}_2^\bullet$) formed simultaneously with subsequent oxygen-dependent cleavage of the DNA-target. After treatment with piperidine, the degree of DNA modification increased 10-fold due to G-specific cleavage. It is assumed that quinoline residues intercalate into DNA in such a way that the positively charged isothiuronium residues of the reagents **23** and **24** are located on the duplex surface. Alkylation of guanine residues with a photoinduced quinolymethylcarbocation at position N(7) is considered to be the most probable mechanism of G-specific modification. The quantum yield of photoalkylation product formation is rather low [$\phi = (5-6) \times 10^{-6}$]; the yield of adducts with respect to the photoreagent does not exceed 1%.⁵³ Because of low efficiency of photoalkylation, these photoreagents have not found wide application.

c. Photoalkylation of nucleic acids with methylnaphthoquinones

Modification of single-stranded DNA (ss-DNA) with an oligonucleotide derivative of 5-methyl-1,4-naphthoquinone upon irradiation with UV light (> 345 nm) is the best studied example of photoinduced alkylation of NA.^{54–56} Unlike photomodification with the isothiuronium salts **23** and **24**, the products of oxidative cleavage of the DNA-target were not found and the alkylation product was exclusively formed in ~20% yield. Neither piperidine (DNA cleavage at the sites of bases alkylated at the nitrogen atoms of a heterocycle), nor sodium borohydride [cleavage at the sites of pyrimidine bases with a saturated C(5)–C(6) bond] effected cleavage of the DNA-target. Pre-irradiation of the photoreagent resulted in its complete inactivation due to the photodegradation of the substituted naphthoquinone.⁵⁴ It was shown that photogenerated quinonemethides alkylate G and C residues at the exocyclic amino groups. Such adducts are more resistant to alkaline hydrolysis of DNA than the ordinary alkylation products.⁵⁶

The efficiency of photoalkylation of DNA with oligonucleotide derivatives of 3-(1,4-naphthoquinonyl)thiopropionic acid with substituents at positions 2, 5 and 6 has been studied.^{55,56} 5-Methyl-substituted naphthoquinones proved to be the most photoreactive agents, the degree of alkylation of ss-DNA regions reached 27%. The yields of products of DNA alkylation with 2- and 6-methylnaphthoquinones did not exceed 6%–8%.

The mechanism of photoalkylation of DNA with 5-methylnaphthoquinone (**25**) in aqueous solutions has not been studied until very recently.⁵⁷ Upon photoexcitation, the naphthoquinone **25** is converted into 4-hydroxy-5-methylenenaphthalen-1(5*H*)-one (**26a**), which can be deprotonated to give the naphthoquinone-5-carbanion (**26b**) or protonated to give the corresponding carbocation **26c**. The reaction of the carbocation **26c** with nucleophiles (HX) is the limiting step of photoinduced alkylation.

Photolysis under physiological conditions results predominantly in the carbanion **26b** ($pK_a = 6.5$); the corresponding value for the carbocation **26c** is 1.1. This fact is the main reason for the low efficiency of DNA photoalkylation with methylnaphthoquinones.

d. Photomodification of nucleic acids with monothioacetals

Irradiation of 1,8-naphthalimidoacetaldehyde monothioacetals with UV light (> 330 nm) generates S-centred radical cations due to intramolecular electron transfer to the photoexcited naphthalimide. The radical cation dissociates into a carbocation and an alkylthio radical, which is rapidly reduced by the naphthalimide radical anion.⁵⁸

The carbocation reacts with nucleophiles (e.g., the reaction with MeOH in the absence of oxygen occurs with a 98% yield and a quantum yield of 0.038) to give alkylation products.

1,8-Naphthalimidoacetaldehyde monothioacetal was irradiated with UV light (366 nm) in the presence of a triplet sensitizer (acetophenone); in this case, 99% of the light was absorbed by acetophenone. It was thus demonstrated that the electron transfer occurs *via* the triplet state of naphthalimide.

Irradiation of supercoiled DNA of pBR 322 with UV light (365 nm) in the presence of this monothioacetal resulted in its conversion into cyclic DNA after heating. Adenine alkylated at position N(7) was the main DNA photomodification product.⁵⁸

Thus, several types of electrophilic photoreagents are currently known which can be used for photoalkylation of NA upon

irradiation with proximal UV light (320–400 nm). However, low efficiency of these reagents and the lack of photoreactivity in the visible region of the spectrum restricts their application for the *in vivo* photomodification of NA.

3. Photoarylation of DNA

Ruthenium(II) polypyridyl complexes photosensitize the formation of single-strand breaks in ds-DNA in low quantum yields [$\phi = (1-7) \times 10^{-6}$].^{59,60} The mechanism of cleavage was investigated with short 5'-labelled oligonucleotides, which were irradiated with visible light (436 nm) together with a $Ru(TAP)_3$ complex, where TAP is 1,4,5,8-tetraazaphenanthrene. It was found that the main photosensitized reaction is not the cleavage of oligonucleotide chains, but rather the formation of covalent adducts of the $Ru(II)$ complex with the oligonucleotide.^{59,61} The yield of adducts in the $Ru(bipy)_nL_{3-n}$ series, where $L = TAP$ or HAT, bipy is 2,2'-bipyridyl and HAT is 1,4,5,8,9,12-hexaazatriphenylene was rather high for $n = 0,1$, while no covalent adducts were formed for $n = 2,3$.

With an increase in n , the photochemical properties of $Ru(II)$ and $Os(II)$ complexes change, which is manifested in a bathochromic shift of absorption and fluorescence maxima and a decrease in the reducing potential (E_{red}^*) of the excited state (Table 1). Covalent adducts with the DNA-target are formed only in the case of $Ru(II)$ and $Os(II)$ complexes the E_{red}^* values of which exceed the redox potential of guanosine monophosphate ($E_{ox} = 0.92$ V).

Table 1. Photochemical properties of $Ru(II)$ and $Os(II)$ complexes: the absorption (λ_{max}) and fluorescence maxima (λ_{fl}); the values of the reduction potential (E_{red}^*) of photoexcited triplet states and the possibility of formation of covalent adducts with DNA.⁶¹

Complexes	λ_{max} /nm	λ_{fl} /nm	E_{red}^* /V	Adducts
$Ru(HAT)_3$	440	596	1.46	+
$Ru(bipy)(HAT)_2$	472	661	1.12	+
$Ru(bipy)_2(HAT)$	484	742	0.83	—
$Ru(TAP)_3$	437	608	1.32	+
$Ru(bipy)(TAP)_2$	465	649	1.06	+
$Ru(bipy)_2(TAP)$	484	714	0.86	—
$[Ru(bipy)_2]_2HAT$	572	800	1.03	+
$[Ru(phen)_2]_2HAT$	564	820	1.02	+
$Os(TAP)_3$	—	—	1.11	+

The bimetallic complexes $[Ru(bipy)_2]_2HAT$ and $[Ru(phen)_2]_2HAT$ (where phen is *o*-phenanthroline) attract substantial interest as electrophilic photoreagents, since they also form covalent adducts with DNA; their absorption maxima show bathochromic shifts by about 100 nm relative to monometallic complexes.

The covalent adduct formed by photomodification of ds-DNA with the $Ru(TAP)_3$ complex was isolated and characterized. The exocyclic 2-amino group of guanine was covalently bound to the C(2) position of TAP. Photomodification of DNA with $Ru(bpz)_3$ (bpz is 2,2'-bipyridaziny), $Ru(TAP)_2bipy$,⁶¹ $[Ru(phen)_2]_2HAT$ ⁶⁰ and $Os(TAP)_3$ ⁵⁹ complexes gave similar photoadducts.

Although the $Ru(II)$ polypyridyl complexes intercalate into ds-DNA through the major groove, the formation of covalent adducts takes place in the minor groove.

The mechanism of photosensitized arylation of DNA with $Ru(II)$ complexes has not been finally elucidated; however, it is

believed that the photoinduced electron transfer from the guanine residue to the excited ligand (TAP*) is followed by proton transfer from the radical cation $G^{+\bullet}$ to the radical anion $TAP^{-\bullet}$ as well as by recombination of radicals and oxidative rearomatisation of the TAPH₂ residue.^{59, 61}

Oligonucleotide conjugates of Ru(II) polypyridyl complexes were used to study photoinduced electron transfer,^{62, 63} but experimental support for complementarily addressed photomodification of DNA by these derivatives is lacking.

It should be noted that metal polypyridyl complexes open up new opportunities for the design of photoreagents that can be employed for the *in vivo* modification of NA. This is due to the fact that the properties of such complexes can be varied within a very wide range by changing the central metal atom and the ligands.

4. Photoacylation of DNA

It is known that photoinduced dissociation of dibenzoyldiazomethane (**27**) results in dibenzoylcarbene (**28**), which is converted into the electrophilic ketene **29** capable of reacting with nucleophiles following the Wolff rearrangement.^{27, 64} Thus its photolysis (366 nm) in the presence of 3',5'-di-*O*-(*tert*-butyldiphenylsilyl)-2'-deoxyguanosine gives a guanosine derivative **30** with an acylated exocyclic amino group.²⁷

Irradiation of dibenzoyldiazomethane (**27**) together with ss-DNA in the presence of the singlet oxygen trap, NaN₃, gave covalent adducts. Treatment of the latter with piperidine is accompanied by G-specific cleavage owing to the reaction with the ketene **29** and insignificant nonspecific cleavage due to hydrogen abstraction from deoxyribose by the carbene **28**.²⁷

Site-specific photomodification of a 25-membered fragment of ss-DNA with 8- and 15-membered complementary oligonucleotide conjugates having a substituent (R) at the 5'-terminal phosphate in the presence of NaN₃ results exclusively in covalent adducts in 32% and 47% yields, respectively.

R = 4-(PhC(O)C(=N₂)CO)C₆H₄CH₂OC(O)NH(CH₂)₆NH.

In both cases, treatment of photomodification products with piperidine caused cleavage of the DNA-target at the residue G18 located in the single-stranded fragment of the duplexes; in the case of the 15-membered reagent, additional cleavage occurred at the residue G14 (indicated by arrows). The greater part of the adducts is not cleaved with piperidine. The total degree of modification after treatment with piperidine increased up to 33% and 56%, respectively. The formation of piperidine-labile adducts is due to the acylation at the N(7) position of guanine, whereas that of piperidine-stable adducts, by the acylation at the exocyclic amino group.²⁷

Thus, substituted diazo ketones are promising reagents for G-specific photoacylation of NA.

5. Other electrophilic addition reactions

A series of 8-alkoxy-5-azidopsoralens were synthesised with the aim of integrating the photochemical properties of aromatic azides and psoralens and investigating their ability in the photomodification of NA. Irradiation of azidopsoralens in acetonitrile with UV light (351 nm) affords a triplet nitrene and an azacyclo-tetraene, whereas irradiation in water yields exclusively a triplet nitrene. The reactivity of these species is insufficient for efficient photomodification of DNA. Being a triplet sensitizer, psoralen favours the formation of a triplet nitrene. Such a detrimental effect of the psoralen residue on the photochemistry of the azido group is the reason for the inability of pBR322 DNA to undergo cleavage with 8-alkoxy-5-azidopsoralens upon UV irradiation.⁶⁵

Oligonucleotide reagents containing aromatic azido groups were also fairly inefficient in the photomodification of NA due to numerous side reactions. In the case of aromatic azides, the reaction does not occur *via* the highly reactive singlet nitrene **31** but rather *via* the much less reactive azacycloheptatetraene **32** formed from the nitrene **31** by rapid intramolecular ring expansion. Besides, nitro-, cyano-, formyl-, acyl- and, particularly, amino-substituents in aromatic azides accelerate intersystem crossing into a more stable but less reactive triplet nitrene **33** upon irradiation.⁵² The nitrene **33** is usually consumed in radical dimerisation reactions to give azo derivatives or is reduced to the corresponding aniline without formation of NA modification products (Scheme 3).

Scheme 3

Perfluoroaromatic azides represent a more promising class of photoreagents, since their photodissociation predominantly results in the singlet nitrene **31**.^{52, 66–68} The presence of fluorine atoms in *o*-positions relative to the azido group decreases the rate of azacycloheptatetraene formation 1700-fold.⁶⁶ In addition, the acceptor fluorine atoms increase the electrophilicity of the singlet nitrene 10-fold⁶⁷ and reactivities of the triplet nitrene and the azacycloheptatetraene, 1000 and 10 000-fold, respectively,⁶⁸ in comparison with nonfluorinated derivatives.

Dobrikov *et al.*^{46, 47} studied the effect of the aryl azide structure on the efficiency of site-specific photomodification of DNA by comparing the reactivities of oligonucleotide derivatives of 4-azido-, 5-azido-2-nitro- and 4-azidotetrafluorobenzamides. Upon irradiation with UV light, these compounds generate different species, *viz.*, azacycloheptatetraene **32**, the triplet (**33**) and the singlet (**31**) nitrenes, respectively; the yields of covalent adducts in site-specific photomodification were 5%, 15% and 70%, respectively.⁶⁷ The reactivity of the species **32** and **33** is insufficient for modification of NA. The specificity of photomodification of DNA-targets containing T, C, A or G residues opposite to the photoreagent was studied with an example of an

oligonucleotide reagent containing a perfluoroaryl azide residue **34** coupled through 5'-phosphate. Treatment of modification products with piperidine showed that the degree of modification of these residues was ~50%, the largest degree of modification being 40%, 45%, 45% and 65%, respectively.^{46,47,69} The reactions of the singlet nitrene **31** with the nitrogen atoms of the pyridine type of the heterocycles result in N-amination (Scheme 3). Photomodification of ss-DNA is most probably accompanied by electrophilic addition at position N(7) of guanine. The use of two oligonucleotide reagents complementary to the neighbouring regions of the DNA-target and containing two perfluoroaryl azide residues **34** at the contact site made it possible to increase the yield of covalent photomodification adducts to 80%.⁷⁰

A highly efficient site-specific photomodification of 27-membered fragments of ss- and ds-DNA with a 4-azidotetrafluorobenzamide derivative of p(T)₁₆ has been carried out.^{71,72}

Photomodification of ss-DNA within the triplex **35** occurred mainly at the bases G7 and G24 (bold-typed); the yields of covalent adducts amounted to 77%. Residues G7 of A-rich and G-22 of T-rich strands (the yields of covalent adducts were 37% and 16%, respectively) were the main sites of photomodification of ds-DNA within the triplet **36**. After piperidine treatment, the total degree of modification of the triplex **36** increased up to 50% in A-rich and up to 42% in T-rich strands due to noncovalent modification at pyrimidine bases.^{71,72}

The effects of *p*-substituents in perfluoroaromatic azides on the efficiency of site-specific photomodification of ss-DNA was also studied. The increase in the conjugation chain in substituted perfluoroaryl azides accelerates the intersystem crossing of the singlet nitrene into the triplet one and decreases the efficiency of DNA photomodification. Studies with pyridines as the chemical trap for the singlet nitrene **31** revealed that the yield of covalent adducts with DNA correlates with the yield of pyridine ylides in the photolysis of perfluoroaryl azides in 6 M pyridine. It was assumed that the electrophilic addition of the singlet nitrene to the nitrogen atoms of the pyridine type in NA bases is the most feasible mechanism of covalent adduct formation.⁷³

The efficiency of site-specific photomodification (irradiation with UV light, $\lambda = 303\text{--}370$ nm, irradiation power 0.5 mW cm^{-2} , 5 min, 4 °C, pH 7.0) of ss-RNA and ss-DNA fragments (5 mmol litre^{-1}) with oligonucleotide conjugates of perfluoroaryl azide **34** ($50\text{ mmol litre}^{-1}$) was compared by Levina *et al.*⁷⁴

Reagent	Yield of covalent adducts for targets (%)	
	5'-d(TGTTGGC)	5'-UGUUUGGC
5'- 34 -pd(AAACA)	~5	~5
5'- 34 -pd(CAAACA)	65	30
5'- 34 -pd(CCAAACA)	75	55

The efficiency of photomodification increases with an increase in the length of the oligonucleotide address. Photomodification of RNA occurs less efficiently than that of DNA, which most probably depends on the structures and stabilities of duplexes. Nevertheless, 6–7-membered ribonucleotide conjugates carrying a perfluoroaryl azide residue **34** at the 5'-terminal phosphate were

used to study the decoding centre of human 80S ribosomes.⁷⁵ Irradiation of a ribosome–tRNA–photoreactive mRNA analogue complex with UV light (270–380 nm) resulted in binding of the analogue to the 40S subunit (45%–55%) and 18S sRNA (8%–22%). Only one base, *viz.*, the residue G1207, underwent photomodification within sRNA.

Kazantsev *et al.*⁷⁶ studied the kinetics of site-specific photomodification of 26-membered ss-DNA with oligonucleotide conjugates of perfluoroaryl azide **34**. Irradiation with UV light (> 300 nm) resulted in the formation of covalent adducts; upon treatment with piperidine, cleavage (predominantly, at residue G19 and, to a lesser degree, at residues G17, A18 and G20) (indicated by arrows) occurred.

The kinetic data shown in Table 2 suggest that the efficiency of photomodification with 5'-*p*-azidotetrafluorobenzamide conjugates is not very high. The maximum degree of photomodification with a 11-membered conjugate was higher than that with 6- and 8-membered ones due to the higher value of the constant K_x . Irradiation of the conjugates in the absence of a DNA target resulted in photodeactivation and an approximately 200-fold decrease in affinity for the target.⁷⁶

Table 2. The association constants (K_x) of the conjugates with the target, the efficiency of photomodification within the duplexes (γ_{eff}) and maximum degrees of photomodifications (PZ) at 37 °C.

Photoreagent	$K_x/\text{mol litre}^{-1}$	γ_{eff}	PZ (%)
CTTACCCTTCTp- 34	8.4×10^6	0.2	70
ACCCTTCTp- 34	1.1×10^5	0.33	55
ACCCTTCTp- 34	1×10^5	0.27	40

Note. The concentrations of a DNA-target and the conjugates are $10\text{ mmol litre}^{-1}$ and $60\text{ mmol litre}^{-1}$, respectively (see Ref. 76).

Site-specific photomodification of a ss-DNA fragment with an oligonucleotide conjugate containing the azide **34** was carried out in order to elucidate the possible reasons for such photodeactivation.⁷⁷

Irradiation of a labelled reagent in the absence of the target also resulted in a partial loss of its affinity for the target; treatment with piperidine resulted in cleavage at all the bases of the address, the total degree of cleavage was 44%. Irradiation with an excess of a target and subsequent hydrolysis revealed that the modification of the address occurred at the residue A4 (yield 29%), *i.e.*, the formation of the duplex did not prevent the modification of the address. With a 5000-fold excess of the conjugate, photomodification affected the residue G3 of the target localised in the double-stranded fragment. The maximum yield of photomodification reaches 80%; γ_{eff} is close to unity.⁷⁷

Site-specific photomodification of a 37-membered DNA fragment with an oligonucleotide reagent carrying a perfluoroaryl azide residue at 3'-phosphate in complexes with human immunodeficiency virus reverse transcriptase (HIV RT)^{78,79} or with DNA-polymerase α has been carried out.⁸⁰

Irradiation of these complexes with UV light (> 300 nm) has led to cross-linking of the primer to matrices with 60%^{78,79} and 70%⁸⁰ efficiency. Treatment with piperidine resulted in cleavage of the target at the residue G19 which is located opposite the photoreagent incorporated into the primer.

Thus, by virtue of high reactivity of the species formed upon irradiation of perfluorinated azides, these have found wide application in photomodification of NA. The main disadvantage of these photoreagents is the lack of noticeable photoreactivity in the visible region of the spectrum, which restricts their application in complex biological systems.

III. Sensitised photomodification of DNA with binary systems

1. Photomodification of DNA with two-component (sensitiser – photoreagent) systems

Irradiation of DNA containing 5-bromo- or 5-iododeoxyuridine residues with UV light (302–313 nm) induces numerous photochemical reactions, *viz.*, modification of bases, cross-linking, single- and double-strand breaks, *etc.* (Scheme 4).^{23,81–88}

The mechanism of formation of single-strand breaks initiated by photolysis of halogenated pyrimidines was studied in detail for oligonucleotides **37** containing 5'-A^{Br}U sequences.^{23,81,82} Irradiation with UV light (302 nm) resulted in photoinduced electron transfer from adenine to the excited triplet state of bromouridine ³(BrU)* with the formation of a radical cation of adenine Ade^{•+}, and a radical anion of uridine (compound **38**). This is followed by elimination of Br[−] from the radical anion; the 5-uracil radical formed abstracts hydrogen from the adjacent C(1') atom to give the carbocation **39**.⁸¹ Addition of water to the C(1') atom of the carbocation **39** results in the 1'-hydroxy derivative **40**. Apurinisation of compound **40** and subsequent reactions bring about cleavage of the DNA chain. The structure of stable DNA cleavage products has been considered in a review of Pratiel *et al.*⁸¹ Similar reactions take place in self-complementary duplexes of the type 5'-d(GCA^{Br}UGC)₂ containing 5'-A^{Br}U sequences.⁸³

Irradiation (313 nm) of DNA containing 5-d¹U fragments results in alkali-dependent single-strand cleavage with the efficiency 0.5; its mechanism is somewhat different.⁸⁴ The photo-reaction occurs *via* the homolytic cleavage of the C(5)–I bond of uridine. The 5-uracil radical formed competitively abstracts hydrogen atoms from the C(1') or C(2') atoms of deoxyribose on its 5'-side.⁸¹ The efficiency of analogous cleavage induced by irradiation with UV light ($\lambda = 365$ nm) in the presence of Hoechst

33258 bisbenzimidazole **41** reaches 0.9. Under these conditions, the initial rate of sensitised photomodification is 4–5 times greater than the rate of photomodification in the absence of bisbenzimidazole. Binding of compound **41** to DNA occurs in the minor groove, where it strongly absorbs UV light (365 nm, 23 000 mol^{−1} litre cm^{−1}) and undergoes excitation. The electron transfer from bisbenzimidazole **41** to 5-d¹U induces elimination of I[−] and the formation of an uracil radical; reactions of the latter bring about photomodification of DNA.⁸⁴ Similar results were obtained in the photo-induced cleavage of DNA containing 5-dBrU fragments sensitised to long-wave UV light with bisbenzimidazole **41**.⁸⁵

It is believed that bisbenzimidazole dyes bind preferentially to (AT)₄- and (AT₃)A(5-BrU) sequences of DNA⁸⁶ and thus ensure high efficiency of electron transfer to the adjacent residues of halogenated pyrimidines.

In cells cultured on 5-dBrU-containing media, one 5-dBrU residue per ~ 200 nucleotides is incorporated into DNA. Irradiation of cells with UV light (365 nm) in the presence of bisbenzimidazole **41** induces the formation of protein – nucleic acid cross-links as well as single- and double-strand breaks of DNA and modification of bases,^{87,88} resulting in multiple aberrations of chromosomes and cell death. The death of cells irradiated in the presence of the photoreagent 5-dBrU and the sensitiser **41** occurs 30 000 times more efficiently than in the case of UV-irradiated native cells and 20 times more efficiently than in the case of 5-dBrU-containing cells irradiated in the absence of the sensitiser.⁸⁷

The use of two-component sensitiser – photoreagent systems has made it possible to combine high reactivity of the photoreagent with spectral-luminescent properties of the sensitiser.

2. Sensitised photomodification of DNA with binary systems of oligonucleotide reagents

For the majority of photoreactive derivatives, light absorption and dark reactions within a complementary complex with a DNA-target and in solution occur at the same rate. At best, this results in nonproductive decomposition of the photoreagent in solution and triggers undesirable side reactions.

However, the specificity of oligonucleotide derivatives is insufficient for modification of nucleic acids *in vivo*, since under physiological conditions (37 °C) stable complexes are formed at

Scheme 4

the oligonucleotide lengths of 12–13 bases. Oligonucleotides having the lengths of 18–20 bases, which is necessary for highly specific recognition of unique nucleotide sequences within the DNA structure, can form numerous imperfect complexes with incompletely complementary sequences.⁸⁹

To overcome these drawbacks, the separation of light absorption and photomodification was suggested. For this purpose, binary systems of the oligonucleotide conjugates **42** complementary to the adjacent sequences of a DNA-target and containing chemically inert groups, *viz.*, a sensitiser (S) and a photoreagent (R), have been developed. The groups S and R being brought together within the structure of the complementary complex form a photoreactive centre which can be activated by irradiation with long-wave UV or visible light due to a non-radiative transfer of the electron excitation energy from the sensitiser to the photoreagent. The thus excited photoreagent induces photomodification of only that DNA-target which is an integral part of the complementary complex.^{90–100} The lengths of both nucleotide addresses (both were decanucleotides) were chosen so that the melting temperature of the duplexes was $\sim 37^\circ\text{C}$; such short oligonucleotides cannot form imperfect duplexes with incomplete complementary sequences under physiological conditions.⁸⁹

Pyren-1-yl-methylamines (**43a–c**),^{89, 94–96} *N*-(5-fluoro-12-methylbenzo[*a*]anthracen-7-ylacetyl)ethylenediamine (**44**),^{90–93} anthracen-9-ylmethylamine (**45**)⁹⁸ and perylen-1-ylmethylamine (**46**)^{97, 99, 101, 102} derivatives were used as sensitisers, whereas perfluoroaromatic azides (*p*-azidotetrafluorobenzamides **34**,^{94, 95} *O*-(4-aminobutyl)-*p*-azidotetrafluorobenzaldoxime (**47**)⁹⁶ and *N*-(4-azidotetrafluorobenzylidene)-*N'*-(3-aminopropionyl)hydrazine (**48**)^{89–93, 101, 102} were used as photoreagents.

Several sensitisation mechanisms, *e.g.*, singlet–singlet energy transfer from a photoexcited sensitiser to a photoreagent,^{89–94, 98} a two-quantum triplet–triplet energy transfer^{95, 96} and photo-induced electron transfer from a photoreagent to an excited sensitiser,^{97, 99, 101, 102} have been suggested.

a. Singlet–singlet energy transfer

Singlet–singlet energy transfer occurs provided the energy of the 0,0-transition between the lowest vibrational levels of the ground and the first electronically excited states in the sensitiser molecule is greater than the energy of the corresponding transition in the photoreagent R molecule and the emission spectrum of the excited sensitiser (S*) overlaps with the absorption spectrum of the photoreagent R.¹⁰³

The energy of the 0,0-transition in aromatic azides is $\sim 70\text{ kcal mol}^{-1}$ and their weak $n\pi^*$ -absorption is observed at 450 nm.¹⁰⁴ Derivatives of polyaromatic hydrocarbons, *viz.*, pyrene **43**, benzoanthracene **44** and anthracene **45**, have high quantum yields of fluorescence and low Stokes shifts (*i.e.*, the minimum energy losses in photoexcitation and subsequent fluorescence). The energies of 0,0-transitions in unsubstituted pyrene, benzoanthracene and anthracene are equal to 76,¹⁰⁴ 72¹⁰⁵ and 73 kcal mol^{−1} (see Ref. 104) and exceed those of 0,0-transitions in the azides **34**, **47** and **48**. Thus, the fluorescence spectra of compounds **43–45** overlap with the absorption spectra of these azides.⁹¹

The efficiency of the energy transfer strongly depends on the distance between the sensitiser and the photoreagent and at commonly used micromolar concentrations of oligonucleotide derivatives the energy transfer from the sensitiser to the photoreagent does not occur in solution.

UV irradiation (365–390 nm) of ss-DNA complexes with an oligonucleotide conjugate containing a photoreagent in the absence (complex **49**) and in the presence (complex **50**) of a sensitiser results in covalent adducts. The azide **34** was used as a photoreagent (R), while the pyrene derivatives **43a–c** were used as sensitisers (S). Treatment of reaction products with piperidine showed that direct (within the complex **49**) and sensitised (within the complex **50**) photomodification affects the residue G11.⁸⁹

The initial rate and efficiency of direct (within the complex **49**) and sensitised (within the complex **50**) photomodification of the target depended on the localisation of the photoreagent and the sensitiser on the 3'- or 5'-phosphates as well as on the length of the linker between the sensitiser and the oligonucleotide address. Oligonucleotide derivatives containing a photoreagent at 3'-phosphate appeared to be more efficient, *viz.*, the yield of covalent adducts amounted to 70%. The rate of photomodification sensitised to UV light (365–390 nm) was 100–1500 times higher than that of direct complementarily addressed modification and decreased with an increase in the linker length in the series of the pyrenyl derivatives **43a–c**.⁹⁴

Photomodification of ss-DNA in the complexes **49** and **50** with the oligonucleotide azide derivative **48** has been carried out. At equimolar ratios of conjugate and target, the largest yields of covalent adducts of direct photomodification within the complex **49** (Fig. 2, curve 1) and of photomodification sensitised with the oligonucleotide benzoanthracene derivative **44** within the complex **50** (Fig. 2, curve 2) are identical ($\sim 30\%$), but the initial rate of the sensitisation reaction is 120 times greater than that of direct photomodification. The observed increase in the rate of photomodification is due to efficient energy transfer from the photoexcited sensitiser S* to the photoreagent R. With a 50-fold excess of oligonucleotide conjugates (curve 3), the initial rate of sensitised photomodification was not practically changed in comparison with the rate of sensitised modification represented by the curve 2, but the yield of covalent adducts increases up to 72%. The yield of direct photomodification products increases insignificantly under these conditions.^{90, 93}

To account for these results, the dependence of the yields of covalent adducts was studied with a deficit of the sensitiser and an excess of the photoreagent on the concentration ratio of the

Figure 2. The yield (A) of covalent adducts of an oligonucleotide conjugate containing an azide residue **48** to a complementary DNA-target upon irradiation with UV light (365–390 nm) of the complexes **49** (1) and **50** (2, 3); concentrations/ $\mu\text{mol litre}^{-1}$; oligonucleotide conjugates, 50 (1–3), DNA-target, 50 (1, 2), 1 (3).

sensitiser to the DNA-target (Fig. 3). In the absence of the catalytic effect of the sensitiser it should be linear as in the case of irradiation under such conditions (10 min, 4 °C) where the components of the complex **50** are not exchanged for the solution components (curve 1). With an increase in the irradiation time and in temperature, each sensitiser molecule initiates the modification of several target molecules (curves 2 and 3). Thus with a 100-fold deficit of the sensitiser (irradiation at 42 °C), each sensitiser molecule induces photomodification of up to 24 target molecules.⁹³

The specificity of direct and sensitised photomodification of a natural DNA-target was studied.^{91,92} A mixture of 18 fragments of ss-DNA of M13BMR4 was obtained by enzymatic hydrolysis. One of these fragments having the length of ~ 150 bases contained a sequence-target complementary to oligonucleotide addresses (similar to the complexes **49** and **50**); while other fragments did not contain this sequence. The results of direct and sensitised photomodification of a mixture of DNA restricts with an oligonucleotide conjugate carrying an azide residue **48** at ^{32}P -labelled 5'-phosphate are shown in Fig. 4.

Figure 3. The dependence of the relative yields (A) of the covalent adducts of sensitised photomodification within the complex **50** on the concentration ratio of the sensitiser (c_s) and DNA-target (c_{DNA}) upon irradiation with UV light (365–390 nm). The yield of adducts at an equimolar c_s/c_{DNA} ratio is taken as 100%. The concentration of the DNA-target and the oligonucleotide photoreagent is 50 $\mu\text{mol litre}^{-1}$. The irradiation was performed for 10 min, 4 °C (1); 90 min, 42 °C (2) and 300 min, 42 °C (3).

Figure 4. The temperature dependence of the yields of the covalent adducts (A) upon photomodification of a mixture of M13BMR4 ss-DNA restricts within the complexes **49** (1–3) and **50** (4–6) upon irradiation with visible light (400–480 nm)/°C: (1, 4) 4; (2, 5) 20; (3, 6) 37.

An excess of noncomplementary DNA fragments has practically no effect on γ_{eff} of sensitised modification (curve 6) in comparison with modification within the model complex **50**. The efficiency of direct photomodification of a mixture of restricts is noticeably decreased (curves 1–3) in comparison with γ_{eff} for the complex **49**, apparently due to the competition with partially complementary sequences of different fragments of M13 DNA. The efficiency and rate of direct photomodification weakly depend on temperature (curves 1–3). In the case of sensitised photomodification, its efficiency increases sharply with an increase in temperature from 4 to 37 °C (curves 4–6). In this case, the rate of the reaction increases first (curves 4, 5) and then decreases 2-fold as the melting temperature of the complex has been reached (curve 6).

Such a temperature dependence is due to the ability of the single-stranded fragment to form hairpins near the modification site; at low temperatures, the target sequence becomes inaccessible for oligonucleotide conjugates. The accessibility of the target sequence and the efficiency of sensitised photomodification increase with an increase in temperature, which causes the unwinding of the structured sites of ss-DNA.

At 37 °C, the initial rate of sensitised photomodification is four orders of magnitude higher (curve 6), and the degree of modification is 60 times greater than in the case of a direct reaction (curve 1). At the same temperature, the level of nonspecific modification of fragments of M13 DNA containing no complementary insert is ~ 1.5 times lower for the photosensitised reaction than for the direct one.⁹² It was found that the selectivity of sensitised photomodification determined as a ratio, γ_{eff} , of specific to nonspecific modification is 90 times greater than that of the direct reaction.^{91,92}

Modifications predominantly affect the G residues, the PZ value being dependent on their number in the $(\text{pG})_n$ -sequence of DNA-targets at the modification site. The yields of covalent adducts of direct modification at $n = 1, 2$ and 4 are 33%–41%, 68%–72% and 82%–85%, respectively, whereas those of photosensitised modification products are 62%–68%,^{89,98} 75%–82%^{94,98} and 98%–99%,⁹⁸ respectively.

The photomodification of a DNA-target (5'-*pATGGATT-CTTGAAGGGGACCGCATT) with a binary system of conjugates complementary to the underlined regions and containing anthracene **45** and azide **48** residues has been carried out. The results of treatment of the reaction products with piperidine show that photomodification predominantly affected the residues G15 and G16 and, to a lesser degree, the residues G14 and G17.⁹⁸ This finding made it possible to establish the structure of the binary

system of oligonucleotide conjugates with the DNA-target (data from two-dimensional ^1H NMR).¹⁰⁰ The probabilities of the contacts of perfluoroaryl azide residues with bases G14–G17 of the DNA-target were as follows: G14:G15:G16:G17 = 12:40:40:8.⁹⁸

b. Photoinduced electron transfer

In the foregoing section, it was demonstrated that the use of binary systems of oligonucleotide conjugates increases the initial rate of photosensitised photomodification of ss-DNA (100–10 000-fold in comparison with the rate of direct photomodification) and the efficiency of the specific reaction (by nearly two orders of magnitude). However, sensitisation due to singlet–singlet energy transfer does not fully prevent nonspecific modification, as is the case with long-chain (≥ 7500 bases) sequences. The occurrence of nonspecific reactions is due to the following. A conjugate containing a photoreagent binds to those complementary sequences of a DNA-target which have no adjacent sequences complementary to the conjugate containing a sensitizer.⁹⁰

In order to prevent nonspecific modification in the formation of imperfect complexes, each of the groups in the photoreactive centre should be inactive under irradiation conditions.

With this in mind, Dobrikov *et al.*^{97,99} developed a binary system of oligonucleotide derivatives of the sensitizer **46** and the photoreagent **48** complementary to the neighbouring regions of a DNA-target within the complex **50**; this system can be activated with visible light (440–580 nm).

The excitation energy ($E_{0,0}$) of the perylene derivative **46**, which was chosen as a sensitizer, is less (64 kcal mol^{-1})¹⁰⁴ than the energy of the 0,0-transition in aromatic azides, but perylene is capable of sensitising their photodecomposition due to photoinduced electron transfer from the azido group to the photoexcited sensitizer.¹⁰⁴

Figure 5 shows the results of direct photomodification of a DNA-target within the complex **49** upon irradiation with visible light (420–580 nm) (curve 1) and photomodification within the complex **50** sensitised with oligonucleotide derivatives of benzoanthracene **44** (curve 2) and perylene **46** (curve 3). The initial rate of perylene-sensitised photomodification is nearly 300 000 times higher and that of benzoanthracene-sensitised reactions is nearly 10 times higher in comparison to direct photomodification. Irradiation of the complex **49** with UV light (365–390 nm) results

Figure 5. The dependence of the yields of the covalent adducts of DNA photomodification in the complexes **49** (1) and **50** (2, 3) upon irradiation with visible light on exposure (H). The concentration of the DNA target is $1 \mu\text{mol litre}^{-1}$, that of oligonucleotide conjugates is $50 \mu\text{mol litre}^{-1}$. The irradiation was performed at the wavelengths/nm: 420–580 (1), 450–580 (2, 3). The oligonucleotide conjugate containing a benzoanthracene **44** (2) or perylene **46** (3) residue was used as a sensitizer.

in adducts (yield $\sim 30\%$) which are cleaved by piperidine at the guanosine residue G14 of the DNA-target (marked by an arrow). The visible light-induced photomodification within the complex **50** with a conjugate of perylene **46** gives covalent adducts (yield $\sim 70\%$) cleaved at the same guanosine residue, which is most likely due to electron transfer from the lone electron pair of the nitrogen atom in the azido group of the photoreagent to the photoexcited perylene.^{97,104} The perylene residue generates a radical anion which is rapidly oxidised by atmospheric oxygen to the corresponding 1,12-perylenequinone.⁹⁷ This is accompanied by a simultaneous formation of a radical cation from perfluoroaryl azide, which after a series of dark conversions induces DNA photomodification similar to that triggered by the singlet nitrene.

Sensitised photomodification (450–580 nm, 15 min) of a DNA sequence from the promoter region of the multiple drug resistance gene (MDR-1) containing four G residues in the region of the photoreactive centre with a binary system of oligonucleotide conjugates (complex **51**) occurs with nearly quantitative yield.^{101,102} Treatment of the reaction products with piperidine revealed that modification affected predominantly residues G15 and G16 and, to a lesser degree, residues G14 and G17. Photomodification did not take place in the absence of the sensitizer.

Thus, binary systems of oligonucleotide reagents containing perylene **46** and perfluoroaryl azide **48** residues can be used for quantitative photomodification of a DNA-target upon irradiation with visible light in the blue-green region of the spectrum (450–580 nm) where both components of the system are singly practically inactive.

IV. Two-quantum photosensitised modification of DNA

The $\cdot\text{OH}$ radical and singlet $^1\text{O}_2$ are the main reagents for nucleic acid photooxidation and possess high toxicity. It was therefore proposed to use photoreagents, which do not form active diffusing species. The chemical activity of photoreagents can be triggered by two-quantum excitation of higher electronic states.^{106,107} The progress in picosecond laser technologies has made it possible to conduct multiquantum reactions. Two-quantum excitation can be mediated by two different mechanisms, *viz.*, resonant two-quantum excitation and nonresonant two-photon excitation.

The former consists in a consecutive absorption of two photons *via* a real intermediate state of the absorbing species. This is populated in the absorption of the first quantum and is a starting point for the absorption of the second quantum. The real excited state has a definite lifetime (normally, 10^{-4} – 10^{-9} s). Photochemical modification of DNA can be performed both from higher singlet and triplet excited states.^{15,106,108}

The second mechanism, *viz.*, nonresonant two-quantum excitation, does not involve any real intermediate state. In this case, the second photon will be absorbed simultaneously with the first one, *i.e.*, within $\sim 10^{-15}$ s. Two-quantum (especially, nonresonant) excitation requires high light intensities ($I \geq 3 \times 10^{14} \text{ W m}^{-2}$).¹⁰⁸

Summation of light quantum energy needed for a photochemical reaction to take place is an important feature of two-quantum excitation mechanisms. Yet another peculiarity of two-quantum reactions is their correspondence to spectroscopic selection rules. If a photosensitizer molecule has a centre of symmetry, the absorption of each light quantum changes the parity of the wave function. Hence, two-quantum excitation can generate reactive states which are forbidden in single-quantum excitation.^{108,109}

1. Two-quantum nonresonant excitation

Two-quantum excitation is a promising field for practical application of known photoreagents, since it allows one to trigger photochemical reactions by irradiation with red and infrared light instead of ultraviolet and violet light. IR irradiation (750–1000 nm) can penetrate deeply into tissues, is not absorbed by cell components and does not induce cell injuries. The specificity of its action can thus be significantly increased.¹⁰⁸

Psoralens belong to the most promising candidates for photoreagents, but their spectral photosensitivity was limited by the range of 320–436 nm.^{108,110} Considerable progress was achieved in the past few years in overcoming this obstacle. Thus irradiation of 8-methoxy-, 4'-amino-4,5,8-trimethyl-¹⁰⁹ and 4'-hydroxymethyl-4,5',8-trimethylpsoralens¹¹¹ with a titanium-sapphire laser (730 nm) was accompanied by nonresonant two-quantum excitation and anti-Stokes fluorescence at 452 nm the intensity of which showed a quadratic dependence on the peak power of the laser.¹⁰⁸ The same photochemical reactions were triggered as in the case of single-quantum activation of psoralens with UV light (365 nm).

Photobiological properties of psoralen in two-quantum excitation were studied *in vivo* in inactivation of *Salmonella typhimurium* His-operon. Short-pulse ($\tau \sim 0.2$ ns), high-flux laser irradiation ($I = 3 \times 10^{14}$ W m⁻²) in the absence of psoralen was characterised by low mutagenicity; in the presence of psoralen, laser irradiation (730 nm) fully suppressed the expression of the His-operon due to the formation of covalent psoralen bisadducts with ds-DNA.¹⁰⁸

2. Two-quantum resonant excitation

Two-quantum resonant excitation consists in sequential absorption of two quanta of light, resulting in both higher excited singlet states (S_n):

and higher excited triplet states (T_n):

a. Two-quantum resonant singlet–singlet excitation

Photoexcitation generates primarily singlet states, S_n , characterised by higher energy but several orders of magnitude shorter lifetimes than the corresponding triplet states. Thus the lifetime of state S_n is less than 10^{-11} s, while that of state S_1 is usually 10^{-8} s. The appropriate conditions for bimolecular reactions from states S_n are attained in the case where the sensitiser forms a donor–acceptor complex with the molecule-target in the ground state or an exciplex in an excited state.¹¹¹

For realisation of this mechanism, the photoreagents should have a low yield of intersystem crossing (ISC) into the triplet state and the corresponding $S_1 \rightarrow S_n$ conversions. Some polymethine dyes ($\phi_{ISC} \leq 0.03$), tetraazaporphyrins ($\phi_{ISC} \leq 0.15$), Mg²⁺- and Zn²⁺-phthalocyanines (MPC²⁺, M = Mg, Zn) ($\phi_{ISC} \leq 0.06$), etc., meet these requirements.^{106,112}

Nonlinear absorption of MgPC²⁺ ($\epsilon_{681} = 2.2 \times 10^5$, $\phi_{\text{fl}} = 0.6$, $\tau_{\text{fl}} = 5$ ns) was observed in pulse ($\tau = 1.6$ ns) laser excitation (680 nm) with a pulse density of $> 10^{24}$ Einstein cm⁻² s⁻¹. The yield of two-quantum excited molecules reached $\sim 100\%$ at the pulse density of 10^{27} Einstein cm⁻² s⁻¹. The absorption spectrum of *MgPC²⁺ from state S_1 has a long-wave maximum at $\lambda = 710$ nm. Simultaneous irradiation of MgPC²⁺ with light of two different wavelengths ($\lambda = 680$ and 710 nm) results in efficient population of state S_n ($\tau \sim 15$ ps), which is insufficient for the normal course of bimolecular reactions but sufficient for a photoinduced electron transfer which is completed within 0.3 ps.¹⁰⁶

Laser-induced two-quantum photomodification of DNA sensitised by different intercalating dyes among which ethidium

bromide proved to be the most efficient one has been studied.^{113–115}

Site-specific two-quantum photomodification of ss- and ds-DNA with oligonucleotide conjugates of ethidium derivatives **20** and **21** has been carried out. Irradiation with a nitrogen laser (337 nm, $I = 150$ W m⁻²) results in stepwise two-quantum excitation of the chromophore intercalated into DNA with subsequent modification of the target. The energy of two quanta was sufficient for initiating different photomodification reactions including the cleavage of phosphodiester bonds.^{113,114} The focussed laser irradiation of the duplex

resulted in a spontaneous cleavage of the DNA-target at the residue G9 (yield $\sim 10\%$) and the formation of covalent adducts (yields 20%–40%).

The efficiency of spontaneous cleavage of the DNA-target showed a quadratic dependence on the irradiation power density. After piperidine-induced cleavage, the total degree of modification of the DNA-target increased due to cryptic modification and reached 90%. Unfocussed laser irradiation (2 W m⁻²) of the duplex gave exclusively covalent adducts (yield 40%).¹¹⁵

The mechanism of two-quantum cleavage is not finally elucidated yet. However, it was shown that an addition of chemical traps of radicals and ¹O₂ did not decrease substantially the efficiency of spontaneous cleavage. The majority of breaks are at a distance of not more than one base from the ethidium residue. Consequently, the migration radius of two-quantum excitation along the DNA chain does not exceed 4–5 Å.^{113,114}

The attachment of ethidium **20** to the heptanucleotide 5'-ACAAACCP caused an increase in the melting temperature of the duplex with the complementary octanucleotide 5'-pTGTTTGGC from 23 to 50 °C. Irradiation of the duplex with a nitrogen laser (337 nm, $\tau = 8$ ns, $I = 1200$ W m⁻², 4 h) up to complete photodegradation of the ethidium residue in the case of the 5'-ACAAACCP-**20** conjugate gives rise to covalent adducts (yield 40%). Their treatment with piperidine induced the cleavage at the residues G6 and G7 and increased the degree of injury of the target to 65% due to cryptic modification.⁵⁰ Irradiation of the octanucleotide 5'-pTGTTTGGC duplex with the 5'-ACAAACCP-**21** conjugate yields 55% of covalent adducts and 5% of direct cleavage products. Treatment with piperidine induces cleavage at the same residues (G6 and G7) (total yield 70%).

Irradiation of a ds-DNA triplex with the 5'-(TC)₆T derivative of ethidium **20** results in a direct cleavage (yield 10%) of the polypurine chain at residues G(–1), A(0), A(1) and G(2) relative to the position of ethidium within the triplex. This was not accompanied by any noticeable photomodification of the polypuridine chain.⁵⁰

The type of injuries and noticeable specificity of photomodification with respect to the electron-donor purine bases is consistent with the following mechanism. In the case of nano-second duration of the laser pulse, the triplet state cannot be formed and a two-quantum excitation passes into state S_n and is accompanied by ionisation and formation of an ethidium radical cation and a free electron. The former causes the electron abstraction from the purine bases of DNA or hydrogen atoms from deoxyribose. The quantum yield of ethidium bromide-sensitised photodegradation of DNA is very low ($\phi = 5 \times 10^{-8}$) due to a reverse electron transfer; however, in the presence of the chemical trap of electrons, *viz.*, methyl viologen, it increases by an order of magnitude.¹¹⁶

b. Two-quantum resonant triplet–triplet excitation

Binary systems of oligonucleotide reagents open up broad opportunities for the application of different mechanisms of two-quantum sensitisation in site-specific photomodification of

directionality of photomodification in the two-quantum sensitisation can be more useful in the study of biological complexes than with one-quantum sensitisation.

The use of nonresonant two-quantum excitation makes it possible to initiate photochemical reactions by irradiation with red and IR light but will hardly increase the specificity of photomodification. At such high peak intensities, all cell components which absorb in the UV region at a double frequency will be excited in a two-quantum mode. In this respect, two-quantum resonant excitation at two different wavelengths seems to be a more promising approach. In this case, only compounds the absorption of which is close to that of photosensitisers in both ground and excited states will be excited together with them, but the probability of this reaction is rather low.

The results described in the review suggest that a combination of binary systems of oligonucleotide conjugates with two-quantum excitation methods is the most helpful tool for selective photomodification of nucleic acids *in vivo*.

Abstract. Background and possibilities of practical applications of micellar liquid chromatography (MLC) are considered. Various retention models in MLC, the effects of the nature and concentration of surfactants and organic modifiers, pH, temperature and ionic strength on the MLC efficiency and selectivity are discussed. The advantages and limitations of MLC are demonstrated. The performance of MLC is critically evaluated in relationship to the reversed-phase HPLC and ion-pair chromatography. The potential of application of MLC for the analysis of pharmaceuticals including that in biological fluids and separation of inorganic anions, transition metal cations, metal chelates and heteropoly compounds is described. The bibliography includes 146 references.

I. Introduction

Studies of secondary chemical equilibria (acid–base, complexation, formation of ion pairs and solubilisation) in reversed-phase high-performance liquid chromatography (RP HPLC) have been gaining momentum in recent years since their consideration leads to a higher selectivity of separation. The application of surfactant solutions at concentrations above the critical micellar concentration (CMC) as mobile phases in RP HPLC has given birth to micellar liquid chromatography (MLC), which is an alternative to the classical RP HPLC with aqueous-organic eluents.^{1–4}

Micellar liquid chromatography offers a number of advantages compared to other chromatographic methods. First, owing to the dual nature of surfactants possessing both hydrophobic and hydrophilic properties, it is possible to carry out simultaneous separation of a mixture of ionic and non-ionic sorbates. Second, owing to the ability of micelles to increase solubility of uncharged sorbates in water, they can act as organic modifiers; it is noteworthy that micellar eluents are inexpensive and non-toxic. Third, it is possible to influence effectively the selectivity of MLC because

it depends on a large number of parameters: the nature of surfactants (*viz.*, their types and charges) and concentrations, additives of various organic modifiers, ionic strength (salt additives) and pH of the mobile phase and the nature of the stationary phase. Fourth, biological fluids can be injected directly into a chromatographic column without preliminary precipitation of proteins, because both anionic and non-ionic surfactants are capable of solubilising proteins. This simplifies preparation of samples and accelerates analysis of various medicinal preparations. Fifth, the sensitivity of determination is increased since the intensity of luminescence, low-temperature phosphorescence and absorption are enhanced for many substances in the presence of surfactants. Sixth, the use of micellar gradients makes it possible to carry out fast separations because there is no need for column conditioning upon replacement of the mobile phase as the concentration of the free surfactant in solution is virtually constant after equilibration of the column with the surfactant at concentrations above CMC. Seventh, many authors have demonstrated the existence of a correlation between the retention and partition coefficients in the octanol–water system and biological activity. In this context, MLC may be useful for estimating hydrophobicity of sorbates and predicting biological activity.

A substantial drawback of this method is lesser efficiency of separation compared to that in classical RP HPLC. Two ways have been proposed to overcome this drawback: to use the so-called hybrid eluents, *i.e.*, mobile phases with addition of small amounts of organic modifiers (usually, short-chain alcohols), or to raise the working temperature. The addition of alcohols to the micellar mobile phases leads not only to enhancement of the efficiency of separation, but also to changes in selectivity and to a faster analysis. Therefore, special attention has been paid in recent years to the MLC techniques using hybrid eluents.

Despite the fact that this method has been developing for only two decades (the first paper appeared in 1980⁵), several reviews^{2,6–9} devoted to the discussion of basic theoretical problems of MLC and to the most recent achievements⁷ have been published. However, in the Russian-language literature none of the numerous monographs or reviews devoted to HPLC make any mention of this method (except for Ref. 1 where only the notion of MLC is given).

The aim of this review is to fill this gap. The review generalises the retention models in MLC described in the relevant literature, discusses causes of low efficiency of separation and ways of its increase and the possibilities of modifying the selectivity of separation and gives examples of the use of MLC for the analysis

and determination of inorganic, medicinal and biologically active compounds.

II. Retention models for micellar liquid chromatography

Micellar liquid chromatography is a variant of partition chromatography where the sorbate molecules are partitioned between three phases: stationary phase, micellar and non-micellar (aqueous) mobile phases. In MLC, three equilibria are taken into consideration: sorbate partition between the micelle and the aqueous phase characterised by the partition coefficient P_{MW} , sorbate partition between the micelle and the stationary phase with the partition coefficient P_{SM} and sorbate partition between the stationary phase and the mobile aqueous phase with the partition coefficient P_{SW} . Several equations have been proposed to relate the retention of sorbates in MLC to the concentration of micelles.^{10–12} Armstrong and Nome¹⁰ express this dependence as

$$\frac{V_s}{V_e - V_0} = \frac{V(P_{MW} - 1)}{P_{SW}} [M] + \frac{1}{P_{SW}}, \quad (1)$$

where V_s , V_e and V_0 are the volume of stationary phase, the volume of sorbate elution and the void volume of the column, respectively; V is the molar volume of the surfactant, $[M]$ is the concentration of the surfactant in form of micelles in solution, which is calculated as $[M] = c - c_{cr}$, where c is the total surfactant concentration in solution and c_{cr} is the critical micelle concentration. The dependence $V_s/(V_e - V_0)$ on $[M]$ should be linear, whereas the value of $V(P_{MW} - 1)$ is equal to the constant of sorbate association with the micelles⁹ and may be obtained experimentally from the slope of the straight line and the magnitude of the intercept of this line on the ordinate.

Arunyanart and Cline Love¹¹ have proposed the equation relating the basic chromatographic parameter — capacity factor (k') — to the concentration of surfactant micelles.

$$\frac{1}{k'} = \frac{K_2}{\phi[L_s]K_1} [M] + \frac{1}{\phi[L_s]K_1}, \quad (2)$$

where K_2 is the constant of sorbate association with the micelle, ϕ is the phase ratio, $[L_s]$ is the ligand concentration in the stationary phase, and K_1 is the binding (adsorption) constant of sorbate from the mobile aqueous phase to the stationary phase.

In this case, the dependence of $1/k'$ on $[M]$ should be linear, while the constants of sorbate–micelle association can also be easily derived from experimental data. Equations (1) and (2) are therefore equivalent.¹³

Proceeding from the general model of secondary equilibria in chromatography,^{14, 15} Foley¹² has deduced the equation

$$k' = \left(\frac{K_{SM}[M]}{1 + K_{SM}[M]} \right) k'_{SM} + \left(\frac{1}{1 + K_{SM}[M]} \right) k'_S, \quad (3)$$

where K_{SM} is the constant of sorbate–micelle association, k'_S and k'_{SM} are the capacity factors of the sorbate and the sorbate–micelle complex.

Transformation of Eqn (2) with consideration of the fact that the sorbate–micelle complex is not retained, since the micelle is a component of the mobile phase, gives the equations

$$k' = \left(\frac{1}{1 + K_{SM}[M]} \right) k'_S \quad (4)$$

or

$$\frac{1}{k'} = \frac{K_{SM}}{k'_S} [M] + \frac{1}{k'_S}. \quad (5)$$

Equation (5) is equivalent to Eqns (1) and (2).

It should be noted that the constant of sorbate–micelle association derived from any equation — (1), (2) or (5) — is called the constant of association per monomer. As the concentration of micelles is expressed by the equation

$$[M] = (c - c_{cr})/n, \quad (6)$$

where n is the aggregation number, the multiplication of the constant K_2/K_{SM} or $V(P_{MW} - 1)$ by n gives the constant of association per micelle.

In the studies of the retention mechanism of hydrophobic, poorly water-soluble alkylbenzenes in MLC with non-ionogenic surfactants polyoxyethylene [10]- or -[23]-lauryl ethers (Brij-22 or Brij-35, respectively), Borgerding¹⁶ has modernised Eqn (1) and proposed a model of limited solubility. Assuming that $P_{MW} - 1 \approx P_{MW}$ and denoting the coefficient of sorbate partition between the stationary and mobile phase as $P_{SM} = P_{SW}/P_{MW}$, the equation

$$\frac{1}{k'} = \frac{1}{\phi} \left(\frac{V[M]}{P_{SM}} \right) + \frac{1}{\phi P_{SW}}, \quad (7)$$

was obtained, which in the extreme case (insolubility in water) is transformed into the equation

$$k' = P_{SM} \left(\frac{\phi}{V[M]} \right). \quad (8)$$

Analysis of Eqns (1) and (2) shows that as the concentration of micelles in the mobile phase increases the retention decreases ($1/k'$ increases), *i.e.*, the eluting strength increases with the concentration of micelles.

Equations (1) and (2) were both used for the determination of the constants of sorbate association with different surfactants in purely micellar as well as in hybrid eluents.^{10, 11, 17–20} In both cases, straight lines with good correlation coefficients were obtained;¹⁸ the values of association constants calculated by the two methods are also in good agreement.

It was noted that in the presence of the cationic surfactant cetyltrimethylammonium bromide the constants of association of a number of benzene and naphthalene derivatives with micelles are larger than those in the presence of the anionic surfactant sodium dodecyl sulfate,¹⁸ which can be explained by the preferred electrostatic interactions between the positively charged head groups of cetyltrimethylammonium bromide micelles and delocalised electrons of the aromatic ring of sorbates. However, still higher values of the constant of sorbate–micelle association were obtained in the case of the non-ionogenic surfactant Brij-35, which is difficult to explain if one considers solely the hydrophobic interactions.

As it follows from the basic equilibria taken into consideration in the deduction of Eqns (1) and (2), the values of P_{MW} and K_2 depend only on the nature of the sorbate and the micellar system used and are independent of the nature of the stationary phase.¹⁷ It should be noted that the error in the determination of dissociation constants also depends on the nature of the sorbate and is increased with its higher hydrophobicity [the P_{SW} values are large and the $1/P_{SW}$ value in Eqn (1) is small].

The addition of organic modifiers to a micellar system leads to changes in its characteristics (CMC and the aggregation number),^{21, 22} which should in turn result in the modification of sorbate–micelle interactions and, consequently, in changes in the retention.^{21, 22} The sorbate–micelle interactions are as a rule decreased in a medium modified by alcohols.⁹ Indeed, the constants of sorbate–micelle association calculated for a number of benzene and naphthalene derivatives are larger for sodium dodecyl sulfate and cetyltrimethylammonium bromide in purely aqueous micellar solutions than in solutions containing 5 vol.% or 10 vol.% of *n*-butanol as the modifier, which is related, according to Garcia *et al.*,²⁰ to the competition between the sorbate and modifier molecules for the interaction with the

micelles. Addition of salts (e.g., NaCl) to the system enhances the interaction between the sorbate and the sodium dodecyl sulfate micelle; in this case, the values of association constants are even higher than those in the purely micellar mobile phases.²⁰

Thus, the ability of micelles for selective solubilisation of the sorbate or interaction with it is the basis of separation in MLC using grafted alkyl stationary phases. It is known that the molecules of monomeric surfactants are easily adsorbed on such stationary phases thereby modifying their properties and making a definite contribution to the retention and selectivity in MLC. However, the equilibrium adsorption of surfactants on the stationary phase was not taken into account in the deduction of Eqns (1), (2) and (5).

Hu *et al.*^{23, 24} have given an explanation of the mechanism of chiral recognition in the separation of enantiomers of 2,2'-dihydroxy-1,1'-dinaphthyl- and -1,1'-dinaphthyl-2,2'-diyl hydrophosphates by MLC with the use of different salts of bile acids (e.g., sodium cholate) in the mobile phases. A three-phase system proved to be ineffective for this purpose. A new model of the heterogeneous stationary phase has been proposed: the ODS (octadecyl sulfate) stationary phase adsorbs micelles, and it is into these micelles that the analytes are distributed. Based on the existence of the following equilibria in the system

where A, M and L are the sorbate, the micelle and the solvated stationary phase, respectively, whereas the subscripts 'm' and 's' refer to the mobile and stationary phases, respectively, the following equation was deduced

$$\frac{1}{k'} = \frac{V_m}{K_3 K_4 V^L [L_s] + K_4 V_s^M [M_s]} + \frac{V_m^M [M_m]}{K_3 V^L [L_s] + V_s^M [M_s]}, \quad (10)$$

where V^L , V_s^M , V_m and V_m^M are the volumes of solvated stationary phase, micelles adsorbed on the stationary phase, micelles of solvent and micelles in the mobile phase, respectively; $[M] = c - c_{cr}$.

The retention mechanism depends on the concentration of a co-solvent (acetonitrile) in the mobile phase: at low concentrations of acetonitrile, its partition between the micelles in the mobile and stationary phases is dominant. At higher acetonitrile concentrations, the mechanism of chiral recognition is determined by the partition between the bulk of mobile phase solution and the micelles adsorbed on the stationary phase. However, consideration of the equilibrium of micelle adsorption on the stationary phase did not result in the modification of the general relationship between the retention and the concentration of micellised surfactant: as in the case of Eqns (1) and (2), the dependence of $1/k'$ on $[M]$ is linear.

In the deduction of equations, neutral organic compounds, mainly aromatic hydrocarbons, were used as model sorbates. The distribution of a sorbate in a micelle is determined by the nature of the micelle and the balance of hydrophilic and hydrophobic properties of the sorbate. The micelle has a lamellar structure. In

aqueous solution, it consists of a hydrocarbon nucleus, a water-hydrocarbon layer the thickness of which is usually 2 or 3 CH_2 groups and corresponds to the depth of penetration of water molecules inside the hydrocarbon part of the micelle or, conversely, of the hydrocarbon chains inside the aqueous phase (here, the hydrophilic-hydrophobic balance is established), a layer of hydrated polar groups and a heterogeneous layer of solution (the diffusive part of the double electrical layer in the case of ionic micelles) adjoining the micelle.²² Since the micelle is regarded as the macroscopically homogeneous medium, it cannot be indicated unequivocally where the sorbate is localised. As the existence of a correlation between the capacity factors and partition coefficients in the octanol-water system^{8, 9} has been demonstrated for many neutral organic compounds, it is believed that the basic interactions are hydrophobic; in this case, the sorbate is either in the hydrophobic hydrocarbon nucleus or in the layer nearest to it. In the course of partition of charged organic sorbates, in addition to hydrophobic interactions, electrostatic interactions should also be observed, including those with the stationary phase surface modified due to the adsorption of monomeric surfactants.

The retention of monoprotic,²⁵⁻²⁸ diprotic and zwitterionic (amino acids and peptides)²⁶⁻²⁸ compounds in MLC have been systematically studied. The retention of monoprotic compounds is described²⁶ by the equation

$$k' = \frac{\phi L_s (K_s^{\text{HA}} + K_s^{\text{A}} - K_a / [\text{H}^+])}{1 + K_m^{\text{HA}} [\text{M}] + (1 + K_m^{\text{A}} - [\text{M}] K_a / [\text{H}^+])}, \quad (11)$$

where K_s^{HA} , K_s^{A} , K_m^{HA} and K_m^{A} are the binding constants of a weak acid HA and the conjugate base A with the stationary phase ligands L_s and the micelle M, K_a is the constant of HA dissociation in aqueous solution, $[\text{M}]$ is the concentration of micelles calculated as the stoichiometric concentration of surfactant minus CMC. Equation (11) allows prediction of the retention at any concentration of micelles and protons.

For the diprotic sorbates in the mobile phase, the following equilibrium is established:

Each particle interacts with a micelle with the equilibrium constants K_{mc} , K_{mz} and K_{ma} , respectively, and with the stationary phase with the equilibrium constants K_{sc} , K_{sz} and K_{sa} , respectively. The following equation was proposed for calculating the capacity factor

$$\begin{aligned} k' = & \left[\frac{k'_c (1 + K_{mc} [\text{M}]) + k'_z (1 + K_{mz} [\text{M}]) K_{a1}}{[\text{H}^+]} + \frac{k'_a (1 + K_{ma} [\text{M}]) K_{a1} K_{a2}}{[\text{H}^+]^2} \right] / \\ & \left[\frac{1 + K_{mc} [\text{M}] + (1 + K_{mz} [\text{M}]) K_{a1}}{[\text{H}^+]} + \frac{(1 + K_{ma} [\text{M}]) K_{a1} K_{a2}}{[\text{H}^+]^2} \right], \end{aligned} \quad (12)$$

where k'_c , k'_z and k'_a are the capacity factors of the ions HABH^+ , $^-\text{ABH}^+$ and ^-AB , respectively; K_{ma} is the apparent dissociation constant in a micellar solution. Equations (11) and (12) are useful for studying the dependence of selectivity on pH of the mobile phase. They were deduced assuming the occurrence of only hydrophobic interactions of various particles (charged, uncharged, zwitterionic) with the micelle and the mobile phase with the consideration of secondary acid-base equilibria in the mobile phase.²⁶ Sorbate-micelle interactions in micellar chromatography of zwitterions were studied by Zibas.²⁷ Carmelo²⁸ used the example of cephalosporin to study the retention mechanism in the micellar liquid chromatography of zwitterions.

Since the hydrophobicity of inorganic anions is usually low and the main interactions in such systems are electrostatic, an ion-exchange model²⁹ was proposed for explaining the mechanism of separation of transition metal cations in MLC. In this model, ionic micelles (and the stationary phase coated with sodium dodecyl sulfate) are regarded as ion exchangers; retention is determined by the concentrations of micelles and counter-ions. For the ion exchange equilibrium

(Na^+ ions are counter-ions in the sodium dodecyl sulfate micelle, whereas the subscripts 'm' and 's' refer to the phases of micelles and solution, respectively; K_{ie} is constant), the following equation was obtained

$$\log K_{MW}^{\text{app}} = \log ([\text{Na}_m^+]^2 K_{ie}) - 2 \log [\text{Na}_s^+], \quad (13)$$

where K_{MW}^{app} is the apparent coefficient of sorbate partition between the aqueous and micellar phases. The value of K_{MW} was calculated using Eqn (11) proposed earlier by Okada^{30,31} for the retention in the exclusion MLC and simplified assuming that the inner volume of the ODS stationary phase is negligibly small

$$\frac{1}{V_r - V_0} = \frac{(K_{MW} - 1)v c_m + 1}{K_{SW} V_s}, \quad (14)$$

where V_r , V_0 and V_s are the volume of sorbate retention (elution), the void volume of the column and the stationary phase volume, respectively; v is the partial molar volume of micelle; c_m is the concentration of micelles equal, as in all the cases discussed above, to the surfactant concentration minus CMC; K_{MW} and K_{SW} are the coefficients of sorbate partition from the aqueous phase into the micelle and the stationary phase, respectively. Equation (14) is analogous to Eqn (1).

In order to minimise partition of sorbates into the stationary phase, it is recommended to supplement the eluent with salts and also with tartaric acid, which is a complexation agent.³² If the retention fits the ion-exchange model, the dependence of $\log K_{MW}^{\text{app}}$ on $\log [\text{Na}_s^+]$ should be linear, and this was confirmed for all metals, the slope of the straight line being equal to 2.

If complexation of metal ions with tartrate ions in the mobile phase (the complexes ML with the stability constant β_L and MHL^+ with the stability constant β_{HL}) is taken into consideration, Eqn (13) is transformed into (15) (K_2 is the constant of tartaric acid dissociation).

$$\begin{aligned} \frac{1}{K_{MW}^{\text{app}}} &= [\text{Na}_s^+]^2 \left(1 + \beta_{HL} [\text{HL}^-] + \frac{\beta_L [\text{L}^{2-}]}{K_{ie} [\text{Na}_m^+]^2} \right) = \\ &= [\text{Na}_s^+]^2 \left[\frac{1 + (\beta_{HL} [\text{H}^+]/K_2 + \beta_L) [\text{L}^{2-}]}{K_{ie} [\text{Na}_m^+]^2} \right] \end{aligned} \quad (15)$$

In this case too, a linear dependence of $\log K_{MW}^{\text{app}}$ on $\log [\text{Na}_s^+]$ was obtained for all metal ions, which implies that complexation does not influence the partition of sorbate into the micellar phase. This is understandable since in the presence of micelles the ionisation constants of weak acids (pK_a) increase,²¹ which leads to a lower concentration of the reactive ligand L^{2-} in the system. Thus for tartaric acid at pH 4.35, 50% of L^{2-} is present in the aqueous solution, whereas in the presence of sodium dodecyl sulfate its content is as low as 4%.²⁹

A mechanism based on the stoichiometric ion-exchange model for anions in the system with a cationic surfactant was proposed by Okada and Shimizu.³³ Based on the existence of equilibria of the analyte A and the counter-ion C

where the subscripts 'aq', 's' and 'm' refer to the aqueous solution, the stationary phase and the micellar phase, respectively; K_d is the equilibrium constant of the counter-ion transition from the micelle to the aqueous phase; K_{ies} and K_{iem} are the constants of ion-exchange equilibrium between the solution-resin and solution-micelle systems, the following equations were deduced

$$\frac{\phi}{k'} = \frac{[\text{C}_{\text{aq}}^-]}{K_{ies} [\text{C}_s^-]} \left(1 + \frac{K_{iem} c_m}{[\text{C}_{\text{aq}}^-] + K_d} \right), \quad (16)$$

$$\frac{n_s^c}{(V_r - V_0)[\text{C}_{\text{aq}}^-]} = \frac{1}{K_{ies}} \left(1 + \frac{K_{iem} c_m}{[\text{C}_{\text{aq}}^-]} \right), \quad (17)$$

where n_s^c is the number of counter-ion moles in the stationary phase, which is equal to the number of moles of hexadecyltrimethylammonium bromide adsorbed on the stationary phase; c_m is the concentration of micelles; V_r and V_0 are the volume of analyte retention and the void volume of the column, respectively. The concentration of the counter-ion in the aqueous phase $[\text{C}_{\text{aq}}^-]$ is determined as the sum of concentrations of the added counter-ion C^- (due to dissociation of micelles) and of the counter-ions of monomeric surfactants ($c - c_{\text{cr}}$). The retention of ions in ionic micellar chromatography can be described by the stoichiometric ion-exchange model, and it formally fits the pseudophase model where the concentration of the added counter-ion is sufficiently high; in this case, the concentration of the counter-ion formed upon dissociation of micelles may be neglected.

The model of micellar exclusion chromatography^{30,31} is based on Eqn (1) and takes into account that the micelles of cetyltrimethylammonium and dodecyltrimethylammonium chlorides³⁰ or sodium dodecyl sulfate can penetrate partly into the stationary phase (external solution). Micelles do not penetrate into the inner part of the stationary phase, but the latter contains surfactant monomers (internal solution) and ions are retained there owing to ionic interactions. In this case, the retention is described by the equation

$$\frac{1}{V_r - V_e} = \frac{(K_{MW} - 1)V c_m + 1}{V_i + V_s K_{SW}}, \quad (18)$$

where V_r , V_e , V_i and V_s are the volumes of sorbate retention, external solution, inner solution and stationary phase, respectively; K_{MW} is the coefficient of sorbate partition (ratio of concentrations) between the micellar phase and the internal solution phase; K_{SW} is the coefficient of sorbate partition (ratio of concentrations) between the stationary phase and the internal solution phase; V is the molar volume of surfactant; c_m is the concentration of micelles in the eluent. The dependence of $1/(V_r - V_e)$ on c_m is linear for both anions (IO_3^- , I^- , Br^- , NO_3^- , NO_2^-)³⁰ and cations (Pb^{2+} , Zn^{2+} , Co^{2+}).³¹

Thus, there are two basic models for describing MLC, viz., Eqns (1) and (2); they describe adequately the dependence of sorbate retention on the concentration of micellised surfactant and are based on three equilibria: sorbate partition between the micellar mobile phase and the aqueous mobile phase, between the micellar mobile phase and the stationary phase and between the stationary phase and the aqueous mobile phase. The major types of interactions are hydrophobic in the case of organic uncharged and charged sorbates and electrostatic for transition metal cations. The stationary phase is always modified due to the adsorption of monomeric surfactant molecules; this effect, however, was taken into account only qualitatively. In many cases, irreversible surfactant adsorption on various commercial silica gels with grafted C_{18} groups was observed.³⁴⁻³⁶ As shown in the example of cetyltrimethylammonium bromide, the amount of surfactant sorbed depends irreversibly on the sorbent character-

istics, the type of eluent and temperature.³⁶ In the case of sodium dodecyl sulfate, 6% of this compound initially adsorbed on the C₁₄ stationary phase is sorbed irreversibly.³⁵ On the whole, irreversible adsorption is more probable for monomeric stationary phases with a high density of grafted ligands and surfactants with a small polar head group (when both the surfactant and the grafted ligand have the alkyl chain length of more than 8 carbon atoms).³⁵ In the early stages of MLC studies it was believed that the surfactant adsorption is arrested after reaching CMC. In 1989, Borgerding *et al.*,³⁷ showed that more than 58% of the total amount of sodium dodecyl sulfate is adsorbed on Resolve C₁₈ when its concentration in the mobile phase varies in the range of 2 to 70 CMC. For Brij-22 and Brij-35, more than 50% of the total amount of adsorbed surfactant is sorbed on Resolve C₁₈ from solutions with the initial concentration > 50 CMC. Thus, the adsorption of both non-ionogenic surfactant and anionic surfactant continues after attaining CMC.

In their recent study, Hu and Haddad³⁸ tried to take into account the surfactant adsorption on the stationary phase surface. They also used a three-phase model. The stationary phase consisted of a surfactant adsorbed on an ODS sorbent. The sorbate localised in the extramolecular mobile phase A_m can bind to the surfactant on the stationary phase S_s in the form of an AS_s complex in conformity with the equation

and to the surfactant in the mobile phase S_m in the form of a complex AS_m in accordance with the equation

Direct transfer to the stationary phase of the sorbate bound to the surfactant in the mobile phase AS_m can also take place by the equation

The capacity factor can be expressed by the equation

$$k' = \frac{K_1 V_s^S [S_s]}{V_m + K_2 V_m^S [S_m]}, \quad (19)$$

where V_s^S , V_m and V_m^S are the volumes of surfactant adsorbed on the stationary phase bulk, of the solvent and of surfactant in the mobile phase, respectively.

It follows from Eqn (19) that

$$\frac{1}{k'} = \frac{V_0'}{K_1 W_s} + \frac{K_2 V_m^S [S_m]}{K_1 W_s}, \quad (20)$$

where $W_s = V_s^S [S_s]$ is the mass of surfactant adsorbed on the stationary phase; $V_m = V_m^S - V_0$. The dependence of $1/k'$ on $[S_m]$ (determined as the total surfactant concentration in the mobile phase) should be linear. The content of sodium dodecyl sulfate on the stationary phase was determined (16.5%) and found to be almost equal to the carbon:silicon ratio in the initial sorbent (17.1%). In other words, the octadecyl groups of the sorbent are covered to a large extent with the adsorbed surfactant, and the stationary phase may be regarded as the adsorbed surfactant. The dependence of $1/k'$ on $[S_s]$ is linear for the model sorbents studied, *viz.*, benzyltriethylammonium chloride and phenylalanine. It should be noted that Eqn (20) is analogous to Eqn (2), the only difference consisting in that Eqn (2) includes the surfactant concentration in the form of micelles in solution (minus CMC), while Eqn (20) contains the overall surfactant concentration in solution.

Consideration of some other equilibria (acid–base equilibria in the mobile phase or adsorption of micelles on the stationary phase) does not modify the dependence of retention on the concentration of micelles. Electrostatic interactions (ion

exchange between metal cations and the cations of the diffusive part of the double electrical layer) are taken into consideration in the MLC model in which retention is dependent on both the concentration of micelles and the concentration of counter-ions.

III. Efficiency of micellar liquid chromatography

One of the major drawbacks of the MLC method is its low efficiency compared to that of RP HPLC. There are several explanations of this phenomenon in the relevant literature. One of these³⁹ suggests that the main factor of the band blurring is the resistance to the sorbate mass transfer because of the poor wetting of the stationary phase. Yarmchuk *et al.*⁴⁰ presume that the resistance to the sorbate mass transfer exists due to both low rates of the sorbate efflux from the micelle and its slow desorption from the stationary phase. When constructing their model, these authors⁴⁰ took into account kinetics of sorbate adsorption onto, and desorption from, the stationary phase, on the one hand, and kinetics of the sorbate influx to, and efflux from, the micelle into the bulk of the non-micellar mobile phase, on the other. Having calculated the rates of all processes, they have shown⁴⁰ that the rate constants of the influx into the micelle are appreciably higher than the rate constant of the adsorption on the stationary phase (silica gel with the C₁-grafted radicals Supelcosil LC 1) because of the differences in the distance to be covered by the sorbate. Thus 0.10 M sodium dodecyl sulfate solution contains 9.03×10^{17} micelles cm⁻³. Consequently, in order to bring the sorbate from the bulk of solution to the surface of the stationary phase, it is necessary to encounter about 180 micelles, whereas an appreciably shorter distance must be covered for a repeated collision with the micelle. In order to pass from the micelle to the stationary phase, the sorbate should have a definite orientation relative to the stationary phase. No definite orientation is required for the reverse transition; the sorbate can enter the micelle at any point. The rate constants of these four processes depend on the nature of the sorbates.

Relatively small and well water-soluble molecules, having large rate constants of the influx into, and the efflux from, the micelle can move quickly in the bulk of solution, enter and leave micelles multiply before they reach the stationary phase surface. For such hydrophilic sorbates, the efficiency (mass transfer) is not limited by micellar equilibria. For the more hydrophobic sorbates the affinity to the micelle is higher and the rate constants of their efflux from the micelle are much lower (*e.g.*, for pyrene the efflux rate constant is 1000 times as low as that for benzene). Consequently, the hydrophobic sorbates remain in the micelle for an appreciably longer time, decreasing the mass transfer between the micelle and the stationary phase. Since there is an antiparallel correlation between the rate constants of the sorbate efflux from the micelle and the constants of desorption from the stationary phase, the hydrophilic sorbates can return more often to the bulk of aqueous mobile phase and be thereby close to equilibrium. The consequence of the differences in the rates of these processes for the hydrophilic and hydrophobic sorbates is fairly good efficiency for the former and smeared peaks for the latter.

In order to increase the efficiency and to improve the shape of peaks, it was proposed to add small amounts of organic modifiers to the mobile phase and to operate at higher temperatures.⁴⁰ Yarmchuk *et al.*⁴⁰ explain enhanced efficiency in the presence of 2 vol.%–5 vol.% of alcohols by the better mass transfer in the mobile phase owing to the increase in the rate of sorbate efflux from the micelle since the non-micellar part of the mobile phase becomes less polar. These authors relate the higher efficiency after an increase in temperature [for small sorbates of the benzene and phenol type the number of theoretical plates (*N*) is increased by 50%–100% at 50–60 °C] to both upgraded micellar kinetics and lower viscosity of the mobile phase. Addition of 3% of propanol to the mobile phase and an increase in temperature to 40 °C make it possible to attain efficiencies close to that of RP HPLC with aqueous–organic eluents.^{39,41} Enhanced efficiency is promoted

by the decrease in the surfactant concentration.⁴⁰ Indeed, Borgerding *et al.*⁴² have shown that the use of elevated surfactant concentrations can result in the total loss of efficiency. Another factor influencing the height equivalent to a theoretical plate (HETP) is the linear rate.⁴⁰ For small molecules (benzene), the derived dependence was almost analogous to that of usual RP HPLC, whereas for large molecules (naphthalene, anthracene) the efficiency drop with the increasing rate was appreciably larger. Yarmchuk *et al.*⁴⁰ recommend to operate at low flow rates.

The low efficiency of MLC is related^{36, 43–45} to the surfactant adsorption on the stationary phase surface, which results in poor mass transfer in the stationary phase.^{43, 44} Direct relationship between the amount of surfactant in the stationary phase and the decrease in efficiency was observed.⁴³

Based on the determination of diffusion coefficients for a series of sorbates (2-naphthol, *p*-nitroaniline, *p*-nitrophenol, naphthalenedisulfonic and naphthalenetrisulfonic acids) in the absence and the presence of sodium dodecyl sulfate and methanesulfonate in the mobile phase, Borgerding and Hinze⁴³ attempted to elucidate which of the mass transfer processes (in the mobile or the stationary phase) is causative of poor efficiency in MLC. All sorbates may be divided into two groups: the sorbates which interact actively with the micelles (2-naphthol, *p*-nitroaniline and *p*-nitrophenol) and those which do not interact and are repelled or excluded from the micelles (sodium 2,6-naphthalenedisulfonate, sodium 4,5-dihydroxynaphthalenedisulfonate and sodium 1,3,6-naphthalenetrisulfonate). The sorbates of the first group have noticeably lesser diffusion coefficients in the micellar mobile phases. Thus the diffusion coefficients of 2-naphthol and sodium 1,6-naphthalenedisulfonate are 6.0×10^{-6} and $6.71 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ in water, 5.67×10^{-6} and $4.73 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ in 0.1 M MeSO_3Na solution, and 0.90×10^{-6} and $4.0 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ in 0.1 M sodium dodecyl sulfate solution. If the band blurring determined the slow mass transfer in the micellar phase, one would observe different values of efficiency for the two groups of sorbates. Besides, no appreciable variation of *N* was noticed at different surfactant concentrations in the mobile phase. All this indicates that the most probable factor eliciting the deterioration of the efficiency is the resistance to mass transfer in the stationary phase. The MLC efficiency is strongly dependent on the flow rate. For example, in the case of *p*-nitroaniline the value of *N* for a $300 \times 4 \text{ mm}$ column with the cyanopropyl stationary phase increases from 400 to 1300 upon the decrease in the mobile phase flow rate from 1.5 to 0.25 ml min^{-1} . However, this cannot be regarded as the proof in favour of only a decelerated process of mass transfer in the mobile phase because, according to the van Deemter equation, both members contributing to HETP owing to the resistance to the mass transfer in the mobile and the stationary phases are proportional to the linear flow rate.

Borgerding *et al.*⁴² believe that the enhancement of efficiency in MLC with the micelles of ionic surfactants occurs owing to changes in the mobile phase: the repulsion barrier decreases because of the lower density of the electrical charge on the surface of ionic micelles. Indeed, the addition of alkanes has no effect on the surface density of charge and does not lead to higher efficiency for strongly hydrophobic sorbates. Addition of alcohols does not result in higher efficiency of MLC with non-ionogenic surfactants, *e.g.*, Brij-35.

In order to decrease the resistance to the mass transfer and to improve the MLC efficiency, Berthod and Roussel⁴⁶ proposed to use hybrid mobile phases. The addition of short- and medium-chain alcohols induces desorption of surfactants from the stationary phase, which leads to the improvement of mass transfer into the stationary phase (and from the stationary phase) and also ensures better wetting.^{37, 39, 41, 42} This effect is enhanced with increase in the modifier concentration and hydrophobicity.^{19, 37, 47} A study⁴¹ carried out on a broad set of sorbates showed that the higher efficiency of the column is observed not for all sorbates; nonetheless, it was concluded that the cause of

higher efficiency is the decrease in the amount of surfactant sorbed on the stationary phase.

Another mechanism of the effect of alcohols on the efficiency was proposed by Armstrong *et al.*⁴⁴ In their opinion, the use of hybrid eluents makes possible changes in the structure of the stationary phase itself from the block-like to the brush-like one, which can also improve the mass transfer into the stationary phase (and from the stationary phase). It is noted therewith that the use of hybrid eluents increases appreciably the efficiency in the case of hydrophobic rather than hydrophilic sorbates.^{35, 43–45}

As there is no consensus about the cause of poor efficiency in MLC, investigators come continuously back to this problem.^{35, 45, 48} Thus investigation of the effect of the nature of the organic modifier (ethyl acetate, *n*-propanol) on the efficiency of a column packed with different sorbents with the grafted C_{18} , C_8 , C_{18} or cyanopropyl groups in the elution by mobile phases with the surfactant concentrations above or below CMC made it possible to reveal a correlation between the column efficiency and the extent of wetting of the surface of grafted sorbents with an organic solvent.

Bailey and Cassidy⁴⁵ studied the effect of sodium dodecyl sulfate concentration (0–0.35 M) at the ionic strength of 0–0.3 M (NaClO_4) and of *n*-propanol (0–0.8 M) on the column efficiency. In the absence of micelles in the mobile phase, the efficiency of the column varies insignificantly. This suggests that the decrease in the amount of sodium dodecyl sulfate adsorbed on the stationary phase is not the cause of the efficiency increase in the presence of alcohols, contrary to what was thought by some investigators.^{35, 39, 41, 42} In the absence of micelles, at low alcohol concentrations (not exceeding 0.13 M), the column efficiency for benzaldehyde and acetophenone reaches its maximum, and this may be attributed to modification of the structure of the stationary phase surface. However, at high alcohol concentrations, which are commonly used for achieving better efficiency in MLC, the column efficiency remains approximately constant, which may be indicative of the absence of modification of the stationary phase surface in the presence of *n*-propanol. Studies of the factors that influence the mass transfer in the mobile phase in the range of sodium dodecyl concentrations from CMC to 0.3 M showed that at concentrations of 0.005–0.012 M this dependence passes through a maximum, the position of which depends on the sorbate hydrophobicity. At higher concentrations the efficiency decreases, which is consistent with the data reported by Yarmchuk *et al.*⁴⁰ In the presence of *n*-propanol, the maximum is broader and less clearly pronounced, whereas the column efficiency increases from 200–2200 to 700–3700 theoretical plates. These results led the authors to conclude that mass transfer in the stationary phase is not the main cause of low efficiency in MLC; this is apparently related to the processes of micellisation. In a micellar system, two oppositely directed processes take place continuously: desintegration of micelles and their formation. At the same time, two basic processes occur in the micellar system: rapid exchange of the surfactant monomer with the micelle [the lifetime of the surfactant molecule in the micelle is of the order of 10^{-7} s (see Ref. 22)] and the process of formation and disintegration of micelles [the half-life of the micelle is $10^{-3} - 1 \text{ s}$ (see Ref. 22)]. The latter can in turn be split into two processes: (1) a series of stepwise additions of single molecules to the surfactant aggregates with formation of micelles and (2) association of pre-micellar aggregates with formation of micelles. Either of these processes can influence the sorbate mass transfer between the eluent and the stationary phase. The addition of alcohols can influence these processes and enhance the kinetics of mass transfer in the mobile phase.

Villanueva Camanas *et al.*⁴⁹ studied the decrease in the efficiency due to the addition of alcohols to the mobile phase containing sodium dodecyl sulfate micelles in the elution of L-DOPA, 2-methyl-DOPA, norepinephrine, adrenalone, dopamine, isoproterenol on Spherisorb ODS-2 C_{18} . Analogous regularities were revealed earlier in the elution of amines.^{50, 51} It is presumed that the mass transfer is brought about through the

following mechanisms: (1) direct transfer from the micelles to the stationary phase, which is opposed by the electrical repulsion between them and (2) transfer through a continuous aqueous pseudophase. In the presence of alcohol, the polarity of the continuous aqueous pseudophase is decreased. On the one hand, this increases the rate of transfer of hydrophobic sorbates through this pseudophase, while on the other hand, the solubility and the rate of transfer of highly hydrophilic catecholamines is decreased, which accounts for the decrease in the efficiency.

Analysis of the band blurring in MLC was performed^{35,52} using the Knox equation

$$h = Av^{1/3} + B/v + C, \quad (21)$$

where $h = H/d_p$ is the reduced height equivalent to a theoretical plate, H is the height equivalent to a theoretical plate, d_p is the size of stationary phase particles, $v = ud_p/D_m$ is the reduced linear flow rate, u is the linear flow rate of the mobile phase, D_m is the coefficient of sorbate diffusion in the mobile phase, A is the coefficient which characterises the quality of the column packing and the decelerated mass exchange in the mobile phase outside the particles, B is the coefficient accounting for the contribution to the band blurring from the longitudinal diffusion and C is the coefficient describing the decelerated mass exchange in the stationary phase.

The dependences of h on v were determined³³ on one column using first an aqueous–organic mobile phase, then the micellar mobile phase and then again the same aqueous–organic phase. Two types of alkylated silica gels were used, *viz.*, a monomeric C_{18} sorbent and a C_{14} sorbent with high density of grafted alkyl groups ($3.5 \mu\text{mol m}^{-2}$), and two types of surfactants, *viz.*, sodium dodecyl sulfate (anionic surfactant) and Brij-35 (non-ionogenic surfactant). An increase in h was shown to occur mainly due to the higher values of coefficient A : for benzene with the aqueous methanol as a mobile phase, $h = 4.9$ at $v = 10$, whereas in the presence of sodium dodecyl sulfate at $v = 10.9$ the contribution from the coefficient A is 2.36 (48% methanol) and 6.9 (63% methanol), respectively. In micellar eluents, the contribution from the coefficients B and C also increases resulting in a stronger band blurring and lower efficiency. The decrease in the diffusion coefficient of sorbates upon their inclusion into the micelles induces the increase in B . The coefficient of sorbate diffusion in the stationary phase depends on the nature of the sorbate and decreases as the hydrophobicity increases; highly hydrophobic sorbates are transferred from the micelle directly into the stationary phase by-passing the extramolecular aqueous phase in which they are poorly soluble. The value of coefficient C increases in a micellar system (*e.g.*, up to 700% for propylbenzene). The decrease in the mass transfer coefficients may also be associated with poor wetting.^{2,39} The most important reason, however, is believed to be the surfactant adsorption on the stationary phase.^{16, 17, 43, 44, 50}

In the first place, adsorption of a surfactant on the stationary phase surface [a C_{18} sorbent adsorbs 70 mg g^{-1} of Brij-35, and a C_{14} sorbent adsorbs 140 mg g^{-1} (or $2.3 \mu\text{M m}^{-2}$) of sodium dodecyl sulfate] leads to a decrease in the pore volume, obstructs the smallest pores with diameter $< 7 \text{ nm}$ and reduces appreciably the surface area of the stationary phase and its permeability.³⁵ The consequence of this is the increase in the coefficient A values. Secondly, adsorption of a surfactant increases thickness of the organic layer of the stationary phase and decreases the mass transfer rate and the diffusion coefficients in the stationary phase and the coefficients of sorbate diffusion in the mobile phase.^{16, 42, 43, 46} This results in the increased values of the coefficients B and C . The surfactant adsorbed on the stationary phase can be eluted with a pure solvent; however, the adsorption may prove to be partially irreversible.^{32–34} Following operation with the use of micellar phases, the efficiency of a column drops drastically as is evident from the values of the coefficients A , B and C in the Knox equation for benzene. This is also the consequence

of changes in the porosity and permeability of the stationary phase.

Mobile phase	<i>A</i>	<i>B</i>	<i>C</i>
Methanol – water (30 : 70)	1.1	3.1	0.22
1.4% Sodium dodecyl sulfate in water	3.2	20	0.2
Methanol – water (30 : 70) after operation with sodium dodecyl sulfate	5.7	4	–0.7

Lavine and Hendayana⁵² studied the effect of temperature in the range of $25\text{--}45^\circ\text{C}$ on the dependence of h on v for acetophenone, nitrobenzene, benzene, methyl benzoate and toluene in MLC with an aqueous solution of sodium dodecyl sulfate. The values of the coefficients A , B and C for *p*-nitrophenol in 0.02 M sodium dodecyl sulfate solution were found to be 2.34 ± 0.14 , 7.43 ± 0.69 and 0.074 ± 0.013 at 25°C and 1.06 ± 0.13 , 11.4 ± 0.65 and 0.026 ± 0.010 at 45°C , respectively. The decrease in the coefficient B at 35°C (5.16 ± 0.66) is anomalous and inexplicable.⁵²

Noticeable enhancement of chromatographic efficiency with the increase in temperature occurs owing to the decrease in values of both the coefficients A (flow anisotropy) and C (mass transfer in the stationary phase). The decrease in A values with the increase in temperature may be explained by the decrease in the constant of sorbate partition between the micelle and the bulk of solution [K_2 , Eqn (2)] and, consequently, by the decrease in the proportion of sorbate bound to the sodium dodecyl sulfate micelles in the mobile phase. A decrease in the eddy diffusion is eventually attained. The decrease in the values of the coefficient C with the increase in temperature may be explained by the decrease in the adsorption of a surfactant on the stationary phase surface and the higher rate of sorbate mass transfer between the mobile and stationary phases. In addition, the fluidities of the grafted alkyl chains and the adsorbed surfactant are increased at higher temperature, which also decreases the resistance to the mass transfer in the stationary phase.

The values of the coefficient B increase considerably with temperature due to both the lower viscosity of bulk of the solvent and transition of part of the sorbate from the micelle to the solution.

In the example of separation of 12 polycyclic aromatic hydrocarbons on Nova-Pak C_{18} , the influence of the nature and the content of the alcohol and of the column temperature on the efficiency of separation in MLC with the use of sodium dodecyl sulfate was studied.⁵³ The number of theoretical plates increases with the increase in the surfactant concentration in the mobile phase up to 0.13 M. Upon transition from methanol to 2-propanol, the peak becomes more symmetrical, and one observes an increase in the efficiency for less hydrophobic sorbates (fluorene and chrysene). For more hydrophobic dibenzo[*ac*]anthracene, more symmetrical peaks were obtained with *n*-butanol, although in this case the changes in the efficiency were insignificant. It should be noted that in contrast to conventional HPLC, in MLC the number of theoretical plates is commonly calculated by the following formula⁵⁴

$$N = \frac{[41.7(t_R/w_{0.1})^2]}{(B/A + 1.25)}, \quad (22)$$

where t_R is the retention time, $w_{0.1}$ is the peak width at its 10% height, B/A is the factor of peak asymmetry.

An increase in temperature leads to insignificant enhancement of the efficiency and appreciable improvement of the shape of peaks. In this case, the effect of the flow rate on N at different temperatures depends on the sorbate hydrophobicity.

Studies of the effect of alcohols as modifiers of the mobile phase showed that the addition of small amounts of propanol or pentanol led to higher efficiency because of considerable decrease in the values of the coefficients A and C in Eqn (21).⁵² An increase in the coefficient B upon addition of an alcohol seems to occur due

to the lower viscosity of the mobile phase and a shift of sorbate equilibrium in the micelle–solvent volume system. Consequently, the mechanisms of the influence of the increase in temperature and addition of alcohols on the separation efficiency in MLC are similar in many respects.

Thus, Okada³² as well as Lavine and Hendayana⁵² related the deterioration of MLC efficiency to an appreciable increase in the coefficients A and C in the Knox equation. Flow anisotropy, resistance to mass transfer in the stationary phase and molecular diffusion contribute to the band blurring. To enhance the efficiency in MLC, it is recommended to use hybrid eluents.

IV. Selectivity of micellar liquid chromatography

The selectivity of separation in MLC is influenced by the type and concentration of the surfactant, the nature and concentration of the organic modifier, pH, ionic strength, temperature and the nature of the stationary phase. Of these factors, the effects of surfactant and modifier concentrations have been studied most extensively. In MLC, the eluting strength of purely micellar eluents is small, it increases with increase in the micelle concentration in the mobile phase.⁴⁷

1. Effect of surfactant concentration

Foley¹² deduced Eqn (23) for calculating the optimum concentration of micelles [rather than of the micellised surfactant as in Eqns (1) and (2)]

$$\text{pM}_{\text{opt}} \approx \log K_{\text{SM}} - \frac{1}{2} \log \frac{k'_s}{k'_1}, \quad (23)$$

where $\text{pM}_{\text{opt}} = -\log [M]$, K_{SM} is the constant of sorbate association with the micelle calculated per micelle rather than per monomer, k'_s is the factor of sorbate capacity (the extreme value), k'_1 is the sorbate capacity factor at a surfactant concentration of 1 mol litre⁻¹.

The optimum pM values for a broad spectrum of sorbates and three surfactants (sodium dodecyl sulfate, cetyltrimethylammonium bromide and Brij-35) were calculated using Eqn (23). The concentrations of surfactants calculated from Eqn (23) fall into a wide range and are the optima as regards selectivity rather than retention.

For dihydropyridines on a C₁₈ stationary phase, an increase in the surfactant concentration induces a trend towards changes in the retention mechanism from three partition equilibria to direct transfer from the micelles to the stationary phase.^{55,56}

Madamba-Tan *et al.*⁵⁷ used isocratic data to deduce the equation for predicting the retention times in the gradient regime of elution with a gradient of micelle concentration

$$t_R = (t_0/b)\{-1/k'_0 + [(1/k'_0)^2 + 2b(1-f)]^{1/2}\} + t_0 + t_D \quad (24)$$

where t_0 is the dead time of the column; b is the parameter of the gradient steepness; k'_0 is the capacity factor in the initial mobile phase; t_D is the delay time, *i.e.*, the time interval before the gradient does reach the upper part of the column; f is the part of the column through which the sorbate band has already passed and which is calculated from the equation

$$f = t'_D/t_R = \frac{[t_D(1 + 1/k'_0)]}{t_R}. \quad (25)$$

2. Effect of organic modifier concentration

The addition of an organic solvent to micellar eluents leads to simultaneous increase in the eluting strength and selectivity for some ionic and non-ionic sorbates.^{47,58,59} The increase in selectivity is related to the existence of competitive partition in MLC and to the unique capacity of micelles for solubilising separately molecules of sorbates and organic solvents.

Subsequent studies of the role of organic modifiers and micelles in the control of the eluting strength and selectivity in MLC in the example of small peptides, phenols, substituted benzenes and benzoic acids in a sodium dodecyl sulfate–water–

2-propanol system confirmed simultaneous increase in the eluting strength and selectivity;⁶⁰ in this case, the selectivity varies systematically and monotonically as the concentration of 2-propanol in the mobile phase increases. The concentration of micelles has the opposite effect on selectivity compared to that of 2-propanol. For those ion pairs the selectivity of which decreases as the concentration of 2-propanol increases, one observes enhancement of selectivity with the increase in concentration of micelles and *vice versa*. Thus, although the eluting strength of the mobile phase is increased with the increase in the concentration of micelles and organic solvent, the effects of these parameters may be quite different and even opposite. Micelles and 2-propanol compete for the interaction with sorbates, which influences the selectivity and retention.

The dependence of retention on the volume proportion (φ) of organic modifier is described by the equation⁴⁷

$$\ln k' = -S_{\text{hyb}}\varphi + \ln k'_0, \quad (26)$$

where S_{hyb} is the parameter of solvent strength, $\ln k'_0$ is the apparent (extrapolated) coefficient of sorbate capacity in a purely micellar mobile phase.

Equation (26) is analogous to Eqn (1) used for describing changes in the retention with the variation of the volume proportion of the organic modifier in RP HPLC. Combination of Eqns (26), (1) and (2) gives relations (27) and (28).

$$\ln(P_{\text{SW}}\Phi) = -S_s + \ln(P_{\text{SW}}^0\Phi), \quad (27)$$

$$\ln(K_{\text{MW}}[M] + 1) = -S_m + \ln(K_{\text{MW}}^0[M] + 1), \quad (28)$$

where S_s and S_m are the parameters which characterise the sensitivity to changes in the sorbate partition from the bulk of solution into the stationary phase and the micelles with variation of φ ; K_{MW}^0 is the constant of sorbate binding to a micelle, P_{SW}^0 is the coefficient of sorbate partition between the mobile and stationary phases for aqueous micellar eluents, *i.e.*, in the absence of an organic modifier.

The parameter S_{hyb} depends on S_s and S_m

$$S_{\text{hyb}} = S_s - S_m. \quad (29)$$

Several conclusions can be drawn from Eqns (27)–(29). First, the magnitude of the solvent strength parameter in hybrid eluents is smaller than that in aqueous-organic eluents. Second, S_m and, consequently, S_{hyb} depend on the micelle concentration. For two sorbates (a and b) and at two concentrations of organic solvent (φ_1 and φ_2) in the mobile phase, the following equation is valid

$$\ln \alpha_2 - \ln \alpha_1 = -(S_{\text{hyb}}^b - S_{\text{hyb}}^a)(\varphi_2 - \varphi_1), \quad (30)$$

while combination of Eqns (26), (29) and (30) gives Eqn (31).

$$\ln \alpha = (dS_m - dS_s)\varphi + \ln \alpha_0, \quad (31)$$

where $\alpha = k'_b/k'_a$ is the selectivity coefficient ($k'_b > k'_a$), α_0 is the selectivity coefficient in a purely aqueous micellar eluent, dS_m and dS_s are the differences in S_m and S_s for compounds a and b .

It follows from Eqn (31) that the selectivity ($\ln \alpha$) depends linearly on the volume proportion of the organic modifier in the mobile phase and decreases or increases monotonically depending on the dS_m/dS_s ratio for two sorbates. Thus for the majority of substituted benzenes, amino acids and peptides, the reverse dependence between retention and S_{hyb} is observed: the more strongly compounds are retained, the smaller is the S_{hyb} value. In this case, for most aromatic compounds, amino acids and proteins a direct dependence between retention and S_m and a reverse dependence between retention and S_s are observed. The influence of the sorbate structure on the value of S_{hyb} is reflected mainly on changes in S_s .

The influence of the concentrations of an organic solvent and micelles on different equilibria occurring in the system can clearly be seen if Eqn (1) or (2) is transformed into (32).

$$\alpha = \left(\frac{P_{SW}^b}{P_{SW}^a} \right) / \left(\frac{K_{MW}^a[M] + 1}{K_{MW}^b[M] + 1} \right) = \frac{\alpha_{SW}}{\alpha_{MW}}, \quad (32)$$

where α_{MW} is the parameter characterising the selectivity of binding of sorbates to the micelles, α_{SW} is the parameter characterising the selectivity of partition into the stationary phase.

The values of P_{SW} and K_{MW} decrease as the concentration of 2-propanol increases; however, the extent of decrease in these parameters is different for different sorbates, which leads to changes in selectivity. The concentration of micelles, in turn, influences the selectivity at a fixed concentration of an organic modifier mostly through the parameter α_{MW} : as the concentration of micelles increases the parameter α_{MW} decreases faster than the parameter α_{SW} , which is independent of $[M]$. The selectivity is increased because of this effect.

3. Effect of the nature of the organic modifier

The nature of the organic modifier of the mobile phase influences the selectivity of separation in MLC; however, this effect is not the same as that in RP HPLC. Usually lower alcohols from methanol to pentanol^{9, 35, 39, 41, 42, 47, 55, 57, 58, 60, 61–70} and also a pentanol–heptanol mixture (3 : 1)⁷¹ are used as modifiers in MLC. Diols,⁶¹ dipolar aprotic solvents,⁶¹ acetonitrile and tetrahydrofuran⁶⁷ were also used for this purpose. The principles of the choice of solvent selectivity in RP HPLC are based on the Snyder triangle of selectivity, but this approach proved to be inapplicable to MLC.⁶⁷ The selectivities of separation attainable with 2-propanol, acetonitrile and tetrahydrofuran belonging to different types of solvents are close,⁶⁷ whereas those with 2-propanol and n-butanol belonging to the same type exhibited strong differences.^{9, 65, 67} For example, in a model mixture of 15 polyaromatic hydrocarbons (PAH) in the absence of the modifier (0.15 M sodium dodecyl sulfate) in the mobile phase, many compounds are co-eluted, particularly the most hydrophobic ones.⁶⁵ In the presence of 15 vol.% methanol, the peaks of all compounds are well resolved. The quality of separation with 2-propanol instead of methanol is similar; in this case, the time of analysis is reduced from 45 to 25 min. However, the addition of only 7 vol.% of n-butanol degrades separation.

On the one hand, the addition of alcohols to the micellar mobile phase modifies appreciably the partition of sorbates between the micelles and the bulk of aqueous phase which becomes less polar.⁶⁴ On the other hand, alcohols decrease the amount of surfactant sorbed on the stationary phase and solvate the grafted hydrocarbon phase. Considering that n-butanol is endowed with a higher solvation capacity than methanol or 2-propanol, this should exert stronger effect on the partition of sorbates over three phases. This effect is particularly noticeable for more hydrophobic compounds.

The parameter S_{hyb} reflects the extent of solvation of sorbates by organic solvents, localisation of the molecules of sorbates and organic solvents in the micelles⁹ and hence, should depend on the nature of both the sorbate and the surfactant. Khaledi *et al.*⁴⁷ have found that for 14 aromatic compounds belonging to different classes the values of S_{hyb} in the cetyltrimethylammonium bromide micellar phase, modified by methanol, 2-propanol and n-butanol, vary in the order $S_{n-butanol} > S_{2-propanol} > S_{methanol}$, which coincides with the increase in the eluting strength of these modifiers in RP HPLC. An analogous sequence was obtained by Rodríguez Delgado *et al.*⁶⁵ for 15 PAH in the mobile micellar phase of sodium dodecyl sulfate modified with the same alcohols.⁶⁵ The higher values of the parameter S_{hyb} for 2-butanol indicate that it interacts with the micelles more actively, solvates the sorbates more effectively and can compete better with the micelles for the interaction with sorbates than does methanol.

Variation of S_{hyb} as a function of surfactant concentration is also different for different modifiers: as the concentration of sodium dodecyl sulfate in the mobile phase increases from 0.06 to 0.14 M, the ΔS_m varies by ~ 0.2 for methanol, ~ 0.4 for 2-propanol and ~ 2.0 for n-butanol.⁶⁵

Less hydrophobic sorbates interact strongly with the micelles (e.g., anthracene with cetyltrimethylammonium bromide⁴⁷ or naphthalene, acenaphthylene, fluorene and anthracene with sodium dodecyl sulfate⁶⁵). They are less accessible to such polar solvents as methanol. Consequently, the addition of modifying alcohols will have a weaker effect on their retention compared to that in RP HPLC. The interaction of sorbates with the micelles decreases as the hydrophobicity of alcohols increases. This effect is particularly well manifested for hydrophobic sorbates (having large partition coefficients in a water–micelle system) because of the competition between this alcohol and the micelles for the interaction with the sorbate.

The order of the variation of S_{hyb} as a function of the nature of the alcohol used proved to be the same in the systems with both cetyltrimethylammonium bromide⁴⁷ and sodium dodecyl sulfate.⁶⁵

It should be noted that the proportion of an organic modifier added to hybrid eluents does not usually exceed 10 vol.%. At larger contents of organic solvents, the retention mechanism can be changed to reach eventually that typical of RP HPLC; in this case, the system will lose all its advantages in selectivity. It was shown^{58, 59} that up to 20 vol.% of 1-propanol could be added to the micellar eluent without formation of the usual aqueous-organic system.

Based on the equations deduced for RP HPLC, Madambatan *et al.*⁷¹ have developed a new approach to the gradient elution with organic modifiers in MLC. When such gradients are used, equilibrium is established rapidly owing to a narrow interval of organic modifier concentrations in the gradient. This results in the reduction of the analysis time. Practical applications of propanol and acetonitrile gradients have been described.⁷² For example, separation of dansylated and bisdansylated amino acids in the isocratic regime requires 67 min. A gradient of 2-propanol (from 3 vol.% to 15 vol.%) in 5 min with subsequent isocratic elution for another 20 min allows separation of these compounds (the total separation time is 32.5 min, including the time necessary for the equilibrium onset).

According to Eqn (26), the retention of sorbates in MLC decreases as the concentration of organic modifier increases. This holds for the most systems studied in a narrow range of modifier concentrations (3 vol.%–15 vol.% of 2-propanol).⁶⁷ However, the dependence of $\ln k'$ on ϕ is not linear for some amino acids and alkylbenzenes with mobile phases containing sodium dodecyl sulfate or cetyltrimethylammonium bromide⁴⁷ and for some benzene and naphthalene derivatives in a sodium dodecyl sulfate–n-butanol–water system. For some other compounds, the dependence of $\ln k'$ on ϕ was linear only for the mobile phases supplemented with methanol.⁷² For this reason, a new model was proposed⁷² for describing the variation of the sorbate retention time in MLC with changes in the organic solvent concentration. In the example of separation of a mixture of catecholamines on a column packed with Spherisorb ODS-2, the dependences of k' , $1/k'$ and $\log k'$ on $[M]$ and ϕ were approximated using different polynomials up to the second power inclusive using the factor planning method (the factors planned were the surfactant concentration, the micelle concentration $[M]$ (up to 0.15 mol litre^{−1}) and the propanol concentration ϕ (up to 10 vol.%). The dependence of k' on $[M]$ and ϕ was shown to be a poorly expressed asymmetric hyperbolic surface with an extremum situated near the maximum values of $[M]$ and ϕ . The addition of 10 vol.% of propanol and 0.035 M sodium dodecyl sulfate led to a 58%–78% decrease in k' , whereas the increase in surfactant concentration in a purely micellar eluent from 0.035 to 0.15 M resulted in a 81% reduction of k' . The least approximation error was obtained using the equation

$$1/k' = A[M] + B\phi + C[M]\phi + D, \quad (33)$$

where $[M]$ is the micelle concentration, ϕ is the volume proportion of the organic modifier and A , B , C and D are constants.

Equation (33) gives a satisfactory description of the retention of amino acids, peptides, phenols and some other aromatic compounds (the coefficient of correlation between the calculated and experimental k' values is above 0.996).

The following equation was also proposed to describe retention:

$$1/k' = A[M] + B\varphi + C[M]\varphi + D\varphi^2 + E, \quad (34)$$

where A , B , C , D and E are coefficients.

For catecholamines, amino acids and phenols the coefficients of different members of Eqns (33) and (34) are the same, the contribution of the term $D\varphi^2$ to Eqn (34) is insignificant. Equation (33) gives too low values for the most hydrophobic surfactants. Equation (34) provides a better description of the retention.⁷⁰ The following equation was proposed

$$k' = \left[\frac{K_{SW}(1 + K_{SD}\varphi)}{1 + K_{AD}\varphi} \right] \left/ \left[\frac{1 + K_{AM}(1 + K_{MD}\varphi)}{(1 + K_{AD}\varphi)[M]} \right] \right., \quad (35)$$

where K_{AD} , K_{MD} and K_{SD} are constants reflecting the relative variation of the sorbate concentration in the aqueous phase, in the micelles and in the stationary phase, respectively, in the presence of a modifier compared to that in the purely micellar solution. Garcia Alvarez-Coque *et al.*⁷⁰ examined separation of nine sorbates on a column packed with Spherisorb ODS-2 (C_{18}) with a propanol-containing mobile phase of sodium dodecyl sulfate in order to assess the applicabilities of Eqns (33), (34) and (35) for the description of retention. The best results were obtained using Eqn (35). Thus in the description of retention of pyrene, Eqn (35) gives a substantially higher (> 50%) accuracy than does Eqn (33). Analogous mean relative deviations of the calculated k' values from the experimental ones were obtained for other sorbates. For the purely micellar eluents, Eqn (33) is transformed into well-known Eqn (2).

Thus, the simultaneous influence of both the surfactant and the organic modifier concentrations on the retention time was again demonstrated. It is these two factors that play the crucial role in the optimisation of separation conditions in MLC.

Strasters *et al.*⁵⁸ have proposed an iterative-regressive strategy for the choice of optimum conditions for the separation of model mixtures of ionogenic compounds: 13 amino acids and peptides with a sodium dodecyl sulfate–2-propanol–water mobile phase and 15 phenols with a myristyltrimethylammonium bromide–2-propanol–water mobile phase. Prediction of the retention of sorbates proved to be possible on the basis of only five experiments even when the values of parameters were far apart in the parametric space. The time of analysis was decreased 3–7-fold and the selectivity was enhanced.

In order to solve the problems of three-parametric optimisation in MLC where the variables are the concentrations of a surfactant, an organic modifier and pH of the mobile phase, a Turbo-Pascal (version 5.5) programme has been developed.⁵⁹ In the proposed model, it is necessary to derive 15 initial chromatograms in order to plot the function of response–criterion of separation (the resolution of a pair of components which are most difficult to separate and the total time of analysis are regarded as the separation criterion). This model is applicable for optimising the separation of a mixture of 9 amino acids and peptides using a hybrid eluent containing a phosphate buffer, sodium dodecyl sulfate and 2-propanol. Rukhadze *et al.*⁷³ have established the conditions for the separation of a mixture of five barbiturates by the three-factor method using the micelles consisting of sodium dodecyl sulfate and a mixed organic modifier [pentanol–heptanol (1:3)] at pH 2.5; the separation time was 40 min.

Potential advantages of the application of artificial neuronal computational networks instead of classical statistical methods for simulating the dependence of the retention time on the concentrations of surfactant and organic modifier have been demonstrated using a mixture of 27 dihydropyridines⁶⁸ or a

mixture of 23 benzene derivatives and PAH.⁶⁹ The effects of the network architecture (the binding mode of individual neurons), the nodal activation function, the number of layers and the mode of the data processing were studied. The linear activation function was shown to be optimal. It is necessary to use networks with the recurrent bonds; the best results were obtained using the logarithms of capacity factors as the output data.⁶⁹ In the case of dihydropyridines, 1–3 neurons and recurrent networks were used.⁶⁸ Different transmission functions (two sigmoidal, one logarithmic and one linear) were activated in the node of the hidden layer; of these the logarithmic function proved to be the optimum. The optimum number of nodes in the hidden layer was equal to three. The use of the magnitude reciprocal to the capacity factor enhances the performance of neuronal networks. It was shown⁶⁸ that there are appreciable differences between the possibilities of simulation of the retention of dihydropyridines with the aid of neuronal networks and by means of empirical equations.

4. Effect of the nature of the surfactant

The selectivity of separation in MLC may be influenced not only by the variation of the surfactant concentration but also by changes in the nature of the surfactants (*e.g.*, the alkyl chain length and charge). Thus a mixture of six vanillins was successfully separated using a mobile phase of 0.02 M sodium dodecyl sulfate solution (pH 3).⁷⁴ However, when cetyltrimethylammonium bromide was used, the retention time of four of six vanillins proved to be longer than in the case of sodium dodecyl sulfate, although in the latter case the mobile phase contained an appreciably larger number of micelles (the CMC of cetyltrimethylammonium bromide at 30 °C and of sodium dodecyl sulfate at 25 °C in distilled water are 0.9 and 8 mmol litre^{−1}, respectively). Thus, the interaction of the vanillins studied with the stationary phase modified by cetyltrimethylammonium bromide is stronger than that with the stationary phase modified by sodium dodecyl sulfate. Analysis of the regression dependences carried out with the aid of Eqn (2) showed that when sodium dodecyl sulfate is used, the elution order of the sorbates correlates with the magnitude of $\Phi[L_s]K_1$, and hence the selectivity is determined mostly by the stationary phase–sorbate interactions. It should be noted that for a number of compounds the retention time also correlates with K_2 . A decrease in selectivity with the increased concentration of sodium dodecyl sulfate, and hence with the quantity of micelles in the mobile phase, also indicates that the sorbate–micelle interaction begins to play a more important role. For cetyltrimethylammonium bromide, the order of elution correlates with changes in both $\Phi[L_s]K_1$ and K_2 , *i.e.*, the selectivity of separation is determined by the interactions of sorbates with both the micelles and the stationary phase.

The observed differences in selectivities are determined, in the opinion of some investigators,^{33,44,75} by the nature of the surfactant interaction with the stationary phase and by the properties of the modified surface. It follows from the models of surfactant adsorption that in the adsorption of sodium dodecyl sulfate the hydrophobic alkyl radical is inserted into the stationary C_{18} phase, whereas the hydrophilic polar heads are directed towards the bulk of mobile aqueous phase and form a hydrophilic layer, which results in a decrease in the stationary phase polarity. In the case of cetyltrimethylammonium bromide, the head groups seem to be localised nearer to the surface owing to additional hydrophobic interactions of the *N*-methyl groups of ammonium salts with alkyl radicals of the stationary phase. It is possible that they are partially incorporated into the grafted phase. A part of cetyltrimethylammonium bromide can be sorbed irreversibly; the positively charged head groups of the surfactant can form strong hydrogen bonds with the residual silanol groups of the stationary phase and at the sites of defects in the grafted layer. All this leads to an increase in the stationary phase hydrophobicity. Indeed, when aqueous-organic eluents are used before and after work with the micellar phases, the retention times of

compounds where sodium dodecyl sulfate is used are decreased, which points to a decrease in the hydrophobicity of the mobile phase, but they are increased with the use of cetyltrimethylammonium bromide, which suggests an increase in its hydrophobicity. Lavine *et al.*⁷⁴ presume that the irreversible adsorption of cetyltrimethylammonium bromide leads to a reduced activity of the residual silanol groups, which compensates for the increase in the stationary phase polarity associated with the presence of the charged head alkylammonium groups on the surface. On the whole, the stationary phase becomes less polar and more hydrophobic. Since compounds under separation (vanillins) are weak acids ($pK_a = 7.4-8.9$), they are characterised by specific interactions (hydrogen bonding) with the negatively charged layer of the head groups of sodium dodecyl sulfate, which results in higher selectivity than that in the case of cetyltrimethylammonium bromide.

Lavine *et al.*⁷⁶ have shown that the micelles of cetyltrimethylammonium bromide possess better selectivity with regard to compounds containing acidic functional groups. This is explained by the existence of a secondary chemical equilibrium which includes proton transfer from the ionogenic compound to the water molecules in the Stern layer of the surfactant micelle. The decrease in K_a from 0.5 to 3.0 can lead to the incorporation of the guest molecule into the cationic micelle.⁷⁷

The surfactants containing two or more hydrophobic 'tails' in the monomer, *e.g.*, didodecyltrimethylammonium bromide or dihexadecyl phosphate, form vesicles. The selectivity of separation with the use of vesicles in the mobile phase differs from that in MLC, which is associated with the increase in the number of sites accessible for solubilisation from five (in a micelle) to nine (in a vesicle).⁷⁸

5. Effect of pH

The effect of pH on selectivity is determined by the occurrence of different secondary equilibria in the mobile phase and the surfactant-induced shift of the ionisation constants of sorbates.²⁶ The influence of pH on the selectivity of separation of amino acids (*e.g.*, tryptophan and phenylalanine) was studied in aqueous, ion-pair and micellar eluents. The maximum selectivity was observed for the mean pK_a value of a pair of sorbates. The optimum selectivity α_{opt} may be calculated by the equation

$$\alpha_{opt} = \frac{2SS_m + SS_m^{1/2}(SS_m K_i^* + K_j^*)/(K_i^* K_j^*)^{1/2}}{2SS_m + SS_m^{1/2}(SS_m K_j^* + K_i^*)/(K_i^* K_j^*)^{1/2}}, \quad (36)$$

where SS_m is the mean self-selectivity (the ratio of capacity factors of two sorbate forms¹⁴), K_i^* and K_j^* are the apparent dissociation constants of sorbates *i* and *j* in aqueous, non-aqueous and micellar media.

The selectivity of separation of this pair of amino acids is a maximum in aqueous medium, ion-pair chromatography and micellar liquid chromatography at pH 2–2.5, ~4 and 5–5.5, respectively.

It should be noted that the surfactant-induced shifts of pK_a values do not necessarily result in enhanced selectivity. For example, for compounds having different pK_a values and hydrophobicity (isomeric chlorophenols), the micelles influence both parameters.⁷⁹

6. Effect of the nature of the stationary phase

The effect of the nature of the stationary phase is usually considered in MLC as a variation of the column efficiency due to different adsorption of surfactants. Alkylated silica gels C_1 , C_8 , C_{14} and C_{18} with different densities of grafted alkyl groups and cyanopropyl phases were studied. Yang and Khaledi⁸⁰ have demonstrated the advantages (higher selectivity and shorter analysis time) of fluorinated, chemically bound stationary phases compared to the alkyl ones for the separation of mixtures of amino acids, peptides, sulfonamides, phenols and alkylphenols

using the mobile phases containing anionic and cationic surfactants.

Model mixtures of vanillins were separated on columns packed with Apex IC₁₈ and Apex IC₈ (5 μ m) using the same mobile phases (0.02 M surfactant solution).⁷⁴ Both stationary phases provide effective separation upon elution with sodium dodecyl sulfate solutions; in this case, the retention is determined by the interaction of sorbates with the stationary phase. The retention times of sorbates on the C_8 phase are longer than those on the C_{18} phase, despite the fact that the latter is more hydrophobic and contains 13.3% of carbon (the C_8 phase contains 9.0% of carbon). This may be due to poorer sorption of sodium dodecyl sulfate on the C_{18} phase because of the higher density of grafted groups.⁸¹

The use of mobile phases containing the cetyltrimethylammonium bromide micelles also results in a stronger retention on the C_8 phase than on the C_{18} phase; however, in this case an additional effect consists in the alteration of the order of elution of some compounds. The low adsorption level on the C_8 phase could be the cause of the stronger retention than that on the C_{18} silica gel; this should not however result in the reversal of the elution order. The higher activity of the residual silanol groups on the C_8 sorbent compared to that on the C_{18} sorbent can neither explain the observed phenomenon since the elution order of sorbates in the methanol–water system is the same on both stationary phases. For this reason, Lavine *et al.*⁷⁴ have presumed that small pre-micellar aggregates of cetyltrimethylammonium bromide are formed inside the stationary phase and modify the retention of sorbates.

To explain the differences in selectivity observed in MLC, the interaction of sodium dodecyl sulfate and cetyltrimethyl- and dodecyltrimethylammonium bromides with Apex IC₁₈,⁸² Apex IC cyanopropyl and Apex IC₈⁸³ was studied using HPLC and ¹³C NMR. It was shown that the surfactant is adsorbed on the stationary phase and that this provides for a selective separation of isomeric vanillins. The use of sodium dodecyl sulfate makes it possible to achieve better separation of hydrophilic compounds because it forms a hydrophilic, negatively charged layer on the stationary phase surface. During adsorption of ammonium surfactants, the head groups are incorporated, at least partly, into the grafted phase owing to hydrophobic interactions of their methyl groups with the C_{18} radicals of the stationary phase.⁸² In the separation of a mixture of hydrophilic compounds with the aid of these cationic surfactants, the best results were obtained at high concentrations of the surfactant in the mobile phase, when the sorbate–micelle interactions are advantageous. The length of the hydrocarbon chain of the stationary phase is an important factor in the separation with the use of cetyltrimethyl- and dodecyltrimethylammonium bromide micelles: the behaviour of hydrophilic aromatic compounds on the C_8 and C_{18} phases is different.⁸³ It was noted⁸³ that when sodium dodecyl sulfate as well as cetyltrimethylammonium bromide are employed, the retention times of some ionogenic compounds are increased. This unusual phenomenon may be explained by strong interactions of the polar groups of the surfactant and the nitrile groups.

7. Effect of temperature

The effect of temperature is the least studied aspect of MLC. It is obvious from general speculations that the temperature should be higher than the Kraft point, which corresponds to the lower temperature limit for the existence of micelles (23 °C for cetyltrimethylammonium bromide⁷³). Researchers usually operate at higher temperatures (40–60 °C, most often at 40 °C) mainly because elevated temperatures enhance the chromatographic system efficiency and reduce the time of analysis.

The effect of temperature on the retention in MLC was investigated in thermodynamic terms.^{63,84} The retention of anthracene and its derivatives on C_{18} in a sodium dodecyl sulfate–1-propanol–phosphate buffer (pH 2.1) system was studied in the temperature range 303–353 K.⁸⁴ The results

obtained were interpreted using two models. There is no correlation between the enthalpies calculated in both models and the physicochemical properties of sorbate molecules. In the model based on the Van't Hoff equation without consideration of individual equilibria, the values of standard entropies correlate with the polarity of sorbate molecules.

Villanueva Camanas *et al.*⁴⁹ did not succeed in enhancing the efficiency of separation of some 6-mercaptopurine-based medicinal preparations by using sodium dodecyl sulfate and varying the temperature from 20 to 60 °C. They noted the influence of both organic modifiers (alcohols, acetonitrile) and temperature on the resolution owing to changes in selectivity; however, these parameters affect little the efficiency and their variation has insignificant practical application. As the studies devoted to a systematic investigation of the effect of temperature in MLC are very scarce, it is impossible to draw any generalising conclusions. It may only be said that it is advisable to use elevated temperatures in MLC for decreasing the viscosity of mobile phases. This increases the column efficiency and stabilises the operation of pumps the working pressures of which are restricted.

8. Effect of ionic strength

There are no separate studies concerning the investigation of the effect of ionic strength in MLC. Since the addition of salts leads to a lower CMC and, consequently, to an increase in the micelle concentration, the effect of ionic strength on selectivity may be described as the influence of the increasing concentration of micelles.

The selectivity of separation in micellar chromatography differs from that in conventional ion-exchange⁸⁵ and ion-pair chromatography. In MLC, after the column equilibration with 10^{-4} M cetyltrimethylammonium bromide solution, anions are eluted with 0.025 M NaCl solution in the following sequence: $\text{IO}_3^- < \text{NO}_3^- < \text{Br}^- < \text{NO}_3^- < \text{I}^-$ (see Ref. 30). The use of eluents containing high concentrations of an organic modifier (lower alcohols or acetonitrile) leads to degradation of micelles (in the presence of > 43.5% of methanol no micelles are formed at all⁸⁶), so that retention is controlled only by the extent of surfactant adsorption on the stationary phase, and the selectivity becomes the same as that in ion-exchange or ion-pair chromatography.

On the whole, it should be noted that studies of the effects of various factors on the selectivity in MLC should consider all three of the equilibria established in the system. In the first place, there is an interaction of sorbates with micelles, which is characterised by the association (binding) coefficient K_2 , and with the stationary phase characterised by the partition coefficient P_{SW} ; they have opposite effects on retention.

V. Retention and structure of sorbate molecules

In RP HPLC, three types of simulation of retention parameters (or their functions of parameters characterising specific features of the sorbate structure and influencing its chromatographic behaviour) are used, *viz.*, simple additive models, a retention–property correlation and a retention–structure correlation.¹ However, in ion-pair chromatography the complexity of the processes occurring prevents construction of models which describe the effect of structural characteristics of sorbates on retention. Nonetheless, there are indications¹ that the parameters of retention models may be related to the contributions from different structural fragments and to the Gantsch π -constants of hydrophobicity. It would seem that in MLC where interactions are more numerous than in RP HPLC and ion-pair chromatography, construction of such models is not feasible. However, the existence of a clear-cut dependence of solubilisation on hydrophobic and hydrophilic properties of sorbates has stimulated the attempts to apply correlations of the retention–property type, which relate the capacity factor and the partition coefficient in a 1-octanol–water system (P_{OW}).

Thus Khaledi and Breyer⁸⁷ have revealed that the values of k' correlate well with the $\log P_{\text{OW}}$ for 35 related compounds on the phenyl phase with a cationic surfactant; however, the dependence of $\log k'$ on $\log P_{\text{OW}}$ forms a plateau at high values of the partition coefficient, *i.e.*, for hydrophobic compounds. For aromatic compounds on the stationary C_8 and C_{18} phases, a better correlation was obtained for the dependence of $\log k'$ on $\log P_{\text{OW}}$, as in RP HPLC. The existence of a linear correlation $\log k' = f(\log P_{\text{OW}})$ was established for monosubstituted benzenes with sodium dodecyl sulfate, cetyltrimethylammonium bromide and Brij-35 as the mobile phases,⁸⁸ for a number of phenols and other monosubstituted benzenes with alcohol-modified mobile phases of sodium dodecyl sulfate and cetyltrimethylammonium bromide⁷⁶ and for a series of surfactants with mobile phases containing sodium dodecyl sulfate, cetyltrimethylammonium bromide and Brij-35.⁸⁹ A correlation between the $\log P_{\text{OW}}$ and the logarithms of the constant of sorbate association with the micelle was established.^{76,87,90} A linear correlation was found to exist between the $\log k'$ (the capacity factor in the absence of micelles) and $\log P_{\text{OW}}$.⁸⁷ The dependence of k' and $\log k'$ on $\log P_{\text{OW}}$ was studied by MLC for a series of benzene derivatives and surfactants on a stationary C_8 phase.⁹¹

Estimates of k' , k'_m (k' at zero micelle concentration) and P_{MW} were derived for 26 1,4-dihydropyridines, and it was shown that they correspond to the hydrophobicity scale.⁹² The best hydrophobicity scale is the $k' - \log P_{\text{OW}}$ correlation for the mobile phase of 0.031 M sodium dodecyl sulfate containing 3% of n-propanol; this phase is described by the equation $k' = 48/3 \log P_{\text{OW}} - 98.49$. The differences between the experimental and calculated values of $\log P_{\text{OW}}$ for 20 of the 26 compounds studied were found to be less than 3%.

A linear dependence was shown to exist between the free energy of transfer of a compound from the aqueous to the micellar phase in a water–octanol system for benzene and naphthalene derivatives in micellar¹⁸ and hybrid²⁰ eluents, as well as for substituted phenols.⁹³ The slope of the straight lines is virtually independent of the nature of the surfactant (sodium dodecyl sulfate, cetyltrimethylammonium bromide or Brij-35) or of the presence of an organic modifier.²⁰ This indicates that in all cases the reactions of sorbates with the micelles are based on hydrophobic interactions. For alkyl-substituted phenols, the value of the free energy of transfer of the aliphatic hydrocarbon groups is less negative for the sodium dodecyl sulfate micelles than in the octanol–water system, whereas for the phenols containing the OR, COR and COOR substituents the contribution to the hydrophobicity is larger in the presence of sodium dodecyl sulfate than in the octanol–water system.⁹³ These differences may be due to the fact that solubilisation of different sorbates can occur in the micelle at different sites which differ in dielectric constants, local microviscosity, steric factors and the occurrence of electrostatic interactions with the ionic head groups of surfactants for charged sorbates.

The second group of correlations relates retention to the structure of sorbates described with the aid of various descriptors,¹ the simplest of which is the number of the carbon atoms in the molecule (n_{C}). In the example of n-alkylbenzenes and alkylphenols in sodium dodecyl sulfate and cetyltrimethylammonium bromide-containing systems, including those with propanol added,¹⁹ it was shown that in contrast to RP HPLC where the dependence of $\log k'$ on n_{C} is linear, in MLC with both purely micellar and hybrid eluents only the dependence of k' on n_{C} is linear, whereas the dependence of $\log k'$ on n_{C} is better described by the quadratic function. Analogous dependences were derived in the studies of the retention of alkylbenzenes in the mobile phases containing Brij-22 or Brij-35.¹⁶ Alkylphenols in the micellar mobile phases of sodium dodecyl sulfate are an exception. For this group of compounds the dependence of $\log k'$ on n_{C} is linear, while the dependence of k' on n_{C} is quadratic, as in RP HPLC.¹⁹ For phenols and a hybrid sodium dodecyl sulfate mobile phase, the differences in k' and $\log k'$ are too small to allow one to

state with certainty which of the dependences is better approximated by the straight line. The cause of this phenomenon is not sufficiently clear. Khaledi *et al.*¹⁹ proposed two possible explanations. The first explanation is based on the difference in the location of various sorbates in (or on) the micelle since the heterogeneous nature of the micelles creates a unique situation where different sorbates in the same mobile phase have micro-environments differing in polarity. The second explanation relies on the model of interaction indices,^{94,95} according to which the dependence of $\log k'$ on the number of carbon atoms for aqueous-organic eluents is described by the equation

$$\log k' = (\log \gamma)n_C^2 + (\log \alpha)n_C + \log \beta, \quad (37)$$

where $\log \alpha$ and $\log \beta$ are constants and $\log \gamma$ is expressed by the Eqn (38)

$$\log k' \gamma = \frac{\Delta V_x \Delta I_x \Delta C_x C_M I_M}{2.3RT}, \quad (38)$$

where ΔV_x and ΔI_x are the changes in the sorbate volume and in the interaction index in a homologous series, ΔC_x and C_M are the proportionality constants for the sorbate and the mobile phase, I_M is the index of interaction for the mobile phase.

Usually the value of $\log \gamma$ for aqueous-organic eluents is so small that the first term of Eqn (37) may be neglected. It is probable that in MLC the product of $\Delta V_x \Delta I_x$ is somewhat larger for some homologues and this causes the departure of the dependence of $\log k'$ on n_C from linearity.

Nonetheless, Khaledi *et al.*¹⁹ have succeeded in revealing linear dependences of the logarithms of sorbate-micelle association (binding) constants (K_2) and of partition coefficients of sorbates between the extramolecular mobile phase and the stationary phase (P_{SW}) on n_C . Analysis of these dependences showed that the K_2 values for homologues are larger in the cetyltrimethylammonium bromide micelles than in the sodium dodecyl sulfate micelles, which points to a stronger interaction of sorbates with the cetyltrimethylammonium bromide micelles owing to the availability of hydrophobic environments. The slope of these straight lines is the measure of free energy calculated for the transfer of one methylene group from the bulk of solution into the micelle (dependence of K_2) or into the stationary phase (P_{SW}), and this slope is steeper for cetyltrimethylammonium bromide than for sodium dodecyl sulfate, which is indicative of the higher affinity of the methylene group of cetyltrimethylammonium bromide due to its larger hydrophobicity.

Hinze and Weber⁹⁶ proposed a more rigorous approach to the rationalisation of the non-linearity of the dependence of $\log k'$ on the number of the carbon atoms in the surfactant molecule in MLC in their paper entitled 'Why the relationship between the logarithm of k' and homologue number in micellar chromatography is not linear'. In RP HPLC, it is implied that each CH_2 increment in the chain of a homologue makes a constant contribution to the free energy of sorbate transfer between the mobile and stationary phases. In MLC, the retention of small-sized polar sorbates that are well soluble in water and poorly soluble in micelles is basically determined by the partition between the surfactant-modified stationary phase and the non-micellar mobile phase. In a homologous series, compounds become less water-soluble as their size increases, and in the extreme case of total insolubility in water the sorbates are partitioned between the chemically similar micellar phase and the surfactant-modified stationary phase. For this process, the free energy of one methylene group transfer from the mobile to the stationary phase (ΔG^m) is virtually equal to zero. As in MLC the ΔG^m value depends on the homologue size, the dependence of $\ln k'$ on the number of methylene groups in the sorbate (n^m) should not be linear.

$$\frac{1}{k'} = \left(\frac{V_m}{V_s} \right) \exp \left[\frac{\Delta G_{WS}^{fg} + n^m \Delta G_{WS}^m}{RT} \right] + \quad (39)$$

$$+ \left(\frac{V_x}{V_s} \right) \exp \left[\frac{\Delta G_{XS}^{fg} + n^m \Delta G_{XS}^m}{RT} \right]$$

where the subscripts 'X', 'W' and 'S' refer to the micellar, aqueous and stationary phases; V stands for the corresponding volumes of phases and the superscripts 'fg' and 'm' refer to the functional and methylene groups, respectively. The dependence of $\ln k'$ on n^m is described by the equation

$$\ln k' = -\ln[(1 - \Phi_x)\exp(a + n^m b) + \Phi_x \exp(c + n^m d)], \quad (40)$$

where $\Phi_x = V_x/V_m$ is the ratio of the volumes of micelles and stationary phase; a , b , c and d are constants. The parameters of a non-linear regression were calculated, the free energies of the methylene group transfer from the non-micellar part of the mobile phase (pure water or water containing 5 vol.% of alcohols) into the surfactant-modified stationary phase [parameter b , Eqn (40)] and the free energy of the methylene group transfer in the micelle-stationary phase system [parameter d , Eqn (40)] were estimated for alkylbenzenes with the use of sodium dodecyl sulfate-1-pentanol-water and Brij-35-water systems and also for methyl esters of fatty acids with the use of a sodium dodecyl sulfate-1-propanol-water system.

Recent years witnessed the appearance of more complex models which relate retention to the sorbate structure and which are based on the statistical analysis and the method of analysis of basic components.^{97,98} In the example of 17 surfactants with three different micellar mobile phases (sodium dodecyl sulfate, cetyltrimethylammonium bromide, Brij-35) it was shown that retention can be adequately described using only two of the nine descriptors: L/B (ratio of the maximum molecule length to its width) and one of the topological descriptors.⁹⁷ The contribution from the topological descriptors is most important in the case of cationic and anionic surfactants, whereas the electrostatic interactions are particularly substantial in the case of sodium dodecyl sulfate. Correlation equations of the types $\log k' = f(F, L/B, c)$ and $\log k' = f(n, L/B, c)$, where F is the correlation factor, c is the surfactant concentration in the micellar mobile phase, n is the number of π -electrons in the molecule, were derived. These equations are easier to use because the values of the corresponding descriptors can be calculated directly from the structural formulae of compounds. Analogous correlations can also be established for the partition coefficients P_{SM} , P_{SW} or P_{MW} since they can be calculated from experimental chromatographic data using Eqn (1) or (2).⁷⁶ For sodium dodecyl sulfate, correlations of the type $P_{SM} (P_{SW} \text{ or } P_{MW}) = f(L/B, F)$ were obtained; however, the regression is deteriorated in the sequence $P_{SM} > P_{MW} > P_{SW}$ because of the increased uncertainty of calculations.⁹⁷

In the hybrid mobile phases which contain sodium dodecyl sulfate with additions of methanol, 2-propanol or n-butanol the retention of unsubstituted PAH is described by the equation considering the size and shape of molecules.

$$\log k' = aF + bL/B + c, \quad (41)$$

where a , b and c are constants.⁹⁸

This model does not however describe methyl-substituted PAH. Therefore, new models were proposed which include electronic parameters allowing consideration of the distribution of electronic density in the molecule, *viz.*, dipole moments (DPMON) and the share of the non-polar unsubstituted surface area (NUSA/TSA) [Eqn (42)].

$$\log k' = aF + bL/B + c\text{DPMON} + d\text{NUSA/TSA} + e, \quad (42)$$

where a , b , c , d and e are constants. Equation (42) gives a satisfactory description of the retention of both unsubstituted and substituted surfactants upon addition of <20 vol.% of methanol or 2-propanol or <6 vol.% of n-butanol.

The influence of molecular structure on the constants of the sorbate-micelle and sorbate-stationary phase binding has been studied.^{99,100} The existence of a clear-cut linear dependence between the constants of the sorbate-micelle and sorbate-

stationary phase binding was demonstrated.¹⁰⁰ Fairly good quantitative dependences of the constants of sorbate–micelle and sorbate–stationary phase binding on solvatochromic properties were obtained.^{99, 100} The correlation between k' and solvatochromic parameters is better in the presence of tetradecyltrimethylammonium bromide micelles, whereas the correlation between $\log k'$ and solvatochromic properties is better in the presence of sodium dodecyl sulfate micelles; the addition of 7% of 2-propanol or 5% of butanol does not modify the strong correlations revealed for tetradecyltrimethylammonium bromide.⁹⁹ An important role in the retention of neutral sorbates is played by both the process of cavity formation and the hydrogen bonding. The examples considered above indicate that such models not only allow prediction of the retention of various sorbates but are also helpful for revealing interactions of sorbates with stationary and mobile phases.

Guermouche *et al.*¹⁰¹ studied theoretical aspects of the retention of 15 aromatic compounds in MLC using the zwitterion surfactant n-dodecyl 3-(*N,N*-dimethylamino)propane-1-sulfonate (DDDMAPS) and calculated the constants of equilibrium partition of sorbates using Eqn (1). Compared to the cationic and anionic surfactants in the DDDMAPS-containing mobile phases, the lowest values of K_{SW} and K_{MW} were obtained, which leads to larger capacity factors at a constant surfactant concentration. Sorbates are retained owing to hydrophobic interactions with the stationary phase and electrostatic interactions with the surfactant in the micelles as well as in the modified stationary phase. Molecular interactions were studied using the method of linear dependences of solvation energy.¹⁰¹ The sorbate size and basicity were shown to be the dominant factors affecting the retention. The dipolar environment in the zwitterionic DDDMAPS is larger and this influences the partition of sorbates: acidic sorbates are more easily bound to this surfactant.

A correlation between the retention and biological activity was established using models of the retention–property type. Breyer *et al.*¹⁰² revealed a clear-cut correlation between k' and biological activity, measured as $\log 1/c$, where c is the concentration required for a 50% inhibition of growth, for 26 *para*-substituted phenols. The advantage of this approach consists in that it uses a single parameter, *viz.*, retention in MLC, whereas normally three descriptors are used for estimating biological activity: $\log P_{OW}$, acid dissociation constant and resonance parameter. Owing to the unique properties of surfactant micelles in MLC, both hydrophobic and electronic interactions are combined in one parameter, *viz.*, k' . The nature and acidity of the stationary phase influence the correlation between k' and $\log 1/c$; the optimum system is cetyltrimethylammonium bromide supplemented with 10 vol.% of 2-propanol.

Escuder-Gilabert *et al.*¹⁰³ studied qualitative and quantitative correlations between the retention and the anesthetic strength, equianesthetic concentration, duration of action, toxicity and the half-life of anesthetics. Clear-cut correlations between k' and the anesthetic strength of compounds were established.

Deriving correct correlations requires reliable determination of the dead time (t_0) which is problematic in MLC. In MLC, the magnitude of t_0 is measured with respect to the introduction of water,^{93, 104} salt solutions (NaNO_3 ,^{25, 37} NaI and KI ^{11, 19}) and acetonitrile.⁶⁶

Torres Lapasio *et al.*¹⁰⁵ proposed four different criteria for determining the characteristic time at the beginning of chromatography (the time of the exit of the first peak, first perturbation) that may be called reference time.

1. Search for the first basic maximum or minimum.
2. Formation of groups reducing noises to a definite scale.
3. Formation of groups for scaling the slopes of the basal line noises.
4. First-derivative method consisting in the detection of an important change in the basal line slope upon the occurrence of a considerable perturbation. The best results are given by the noise-scaling criterion; in this case it is advisable to measure the

reference times upon addition of standard solutions or micellar solutions of sorbates. Determination of the reference time using a large number of different mobile phases has shown that it does not change noticeably as the mobile phase composition is modified.

VI. Analytical application of micellar liquid chromatography

The development of the theory of MLC was based on the studies of different organic compounds: non-ionogenic (substituted benzenes, phenols, naphthalenes, anthracenes, *etc.*) as well as ionogenic (amino acids and peptides), whereas practical uses of this method lie in the analysis of medicinal preparations (Table 1). Such an analytical application reflects several advantages of MLC: selectivity and capacity for simultaneous separation of ionic and non-ionic components of samples, direct introduction of biological samples without preliminary precipitation of proteins or extraction of drugs, as well as the possibility of fluorescence enhancement or stabilisation. Simplification of the sample preparation for the analysis of biological specimens is achieved owing to solubilisation of proteins on micellar aggregates since the protein–micelle aggregates have a large size and are not retained by the stationary phase. Low detection limits make it possible to detect specific compounds not only in pharmaceutical formulations but also in urine.

The possibility of enhancement of sensitivity of determination of some compounds in the presence of surfactants has been demonstrated. Thus the oxidation current of acetaminophen is increased in the presence of sodium dodecyl sulfate micelles.¹⁰⁸ An electrochemical detector with a cell of the 'reflecting wall of the three-electrode configuration' type with a carbon-fibre micro-electrode was designed for detecting acetaminophen. The compatibility of the separation by MLC with amperometric detection was first demonstrated by Khaleli and Dorsey;¹²⁶ dopamine was determined using a glassy-carbon electrode.¹²⁴

Steroids were determined in urine by the MLC method and detected using the terbium-sensitised fluorescence.¹⁰⁶ The micellar environment promotes an efficient Forster energy transition from donors (steroids) to acceptors [terbium(III) ions]. This method is highly sensitive and allows determination of as little as 100 pg of steroids in urine. This detection technique is appreciably more sensitive than the spectrophotometric detection,¹¹⁴ which is applicable only for the analysis of initial pharmaceutical preparations and is unsuitable for the analysis of biological samples.

The luminescence [sensitised by a terbium(III)–surfactant complex] in the inverted micelles in non-aqueous solutions (ethyl acetate or its mixture with hexane) was used for the detection of theophylline;¹²⁰ the presence of paraxanthin does not interfere with this determination due to the low efficiency of energy transfer to the lanthanide ion. This method minimises the fluorescence quenching induced by the use of inverted micelles in non-aqueous solvents.

Examples of the use of micellar mobile phases in the inorganic analysis are not numerous: separation of inorganic anions;^{30, 32, 85} cations of transition metals;^{9, 31} chelates;^{127–131} heteropolyacids;^{132, 133} different forms of arsenic,^{77, 134, 135} mercury,^{77, 135} selenium⁷⁷ and tin;^{77, 136} organic and inorganic compounds containing heavy metals.¹³⁷

Thus the separation of five anions on a column (250 × 5 mm) packed with ODS (5 μm) using 1.36×10^{-1} M aqueous cetyltrimethylammonium chloride as the eluent at a flow rate of 1.5 ml min^{-1} was effected within 10 min.⁸⁵ Detection was carried out at 205 nm. The order of elution: $\text{IO}_3^- < \text{NO}_2^- < \text{Br}^- < \text{NO}_3^- < \text{I}^-$ is analogous to the selectivity sequence for a typical, strongly basic anion exchange resin.

The use of micellar exclusion chromatography on a column packed with the Asahipak GC-310H sorbent, which is a polyvinyl alcohol gel, proved to be effective for the separation of both anions³⁰ and cations.³² In the separation of anions the elution order varies with the modification of hydrophobicity of the

Table 1. Determination of components of medicinal preparations by MLC using sodium dodecyl sulfate.

Components of medicinal preparations	Organic modifier	Detector	Detection limit	Object of analysis	Ref.
Steroids	acetonitrile	FL	100 pg	urine	106
Amiphenazole, amiloride, amphetamine, clostebol, ephedrine, phenylpropanolamine, methanediene, methoxyphenamine, nandrolone, spironolactone	—	SP	0.07–10.95 µg ml ⁻¹	"	107
Acetaminophen	n-propanol	EC	0.02 µg ml ⁻¹	"	108
Clenbuterol	n-butanol	SP	—	"	109

Note: FL, fluorescent; SP, spectrophotometric; EC, electrochemical (amperometric) detectors, respectively; ^a microemulsion.

surfactant alkyl chain: with 0.06 or 0.01 M cetyltrimethylammonium chloride mobile phase, the anions are eluted in the sequence $\text{IO}_3^- < \text{I}^- < \text{Br}^- < \text{NO}_2^- < \text{NO}_3^-$, whereas in the presence of dodecyltrimethylammonium chloride this order is $\text{IO}_3^- < \text{Br}^- < \text{NO}_2^- < \text{I}^- < \text{NO}_3^-$ (see Ref. 30).

Using micellar exclusion chromatography, Okada²⁹ separated Pb(II), Co(II) and Cu(II) in 0.05 M sodium dodecyl sulfate containing 0.08 mol litre⁻¹ of NaCl (pH 4.0) and also a mixture of cations of rare-earth elements (Yb, Ho, Dy, Tb and Pr) and of transition metals [Cu(II), Pb(II), Zn(II), Ni(II), Co(II) and Mn(II)] in the gradient mode of elution with a mixture of 0.025 M sodium dodecyl sulfate and 0.08 M α-hydroxyisobutyric acid (pH 4.0) or with 0.025 M sodium dodecyl sulfate and 0.08 M tartaric acid (pH 4.3).³¹ Separation of 8 transition metal cations [Fe(III) < Cu(II) < Zn(II) < Ni(II) < Pb(II) < Co(II) < Cd(II) < Mn(II)] was performed in 20 min on a column with Inertsil ODS-2 with an aqueous mobile phase containing 0.0945 mol litre⁻¹ of sodium dodecyl sulfate and 0.0684 mol litre⁻¹ of tartaric acid (pH 4.02).²⁹

Miura *et al.*¹²⁸ determined the distribution constants of 2-(2-thiazolylazo)-4-methylphenol (TAMP) and 2-(2-thiazolylazo)-5-dimethylaminophenol (TAAP) in solutions of non-ionic surfactants [poly(oxyethylene)-4-nonylphenyl ether (PONPE), poly(oxyethylene)oleyl ester (POOE), Triton X-100, POL-10]; these constants were found to decrease as the length of the oxyethylene chain increased. Rapid elution of TAMP and TAAP is achieved using surfactants with shorter oxyethylene chains

because the reagents have the higher affinity to the micellar phase. The retention time is reduced as the number of oxyethylene units in PONPE and POOE decreases.

PONPE-20 was used for the separation of metal chelates with TAAP.^{127, 128} Of the nine chelates studied, only the V(V) chelate is eluted selectively, the peak of Fe(III) chelate overlaps with the peak of the solvent front, while the reagent itself and other complexes are strongly retained (and some of them are possibly degraded) in the column.¹²⁷ Probably, the use of hybrid eluents (supplemented with organic modifiers) would yield better results. Separation of Cu(II), Zn(II), Ni(II) and Co(II) takes 45 min using a mobile phase containing 0.006 mol litre⁻¹ of sodium dodecyl sulfate, 0.002 mol litre⁻¹ of 8-hydroxyquinoline-5-sulfonic acid and pH gradients of 3.5 → 3.9.¹³¹ Determination of aluminium with a detection limit of 1 ppb in the form of chelates in human serum with 8-hydroxyquinoline was performed on a column packed with CAPCELL PAK MF ph-1 with an eluent containing 20 mass % of acetonitrile, 0.01 M sodium dodecyl sulfate, 10⁻⁴ M EDTA, 0.01 M *N,N*-bis(2-hydroxyethyl)-2-aminoethanesulfonic acid-based buffer (pH 7.0) with fluorescent detection (370–504 nm).¹³⁰ The contents of Ni(II), Co(II) and Cu(II) in metal alloys were determined using chelates with sodium diethyldithiocarbamate and the mobile phase containing 0.03 M cetyltrimethylammonium bromide, 10⁻⁴ M sodium diethyldithiocarbamate and 45% of 1-propanol (spectrophotometric detection).¹²⁹ The detec-

tion limits of Ni(II), Co(II) and Cu(II) were 68.1, 67.2 and 35.4 pg, respectively; the separation time did not exceed 6 min.

Compatibility of MLC with the mass-spectrometric determination with the use of induction plasma was demonstrated in the example of determination of arsenic using the cetyltrimethylammonium micelles.¹³⁵ In this case, the detection limits (90–300 pg) were comparable with that in ion-pair chromatography (0.4–1.2 ng cm⁻³ at a loop volume of 250 mm³ with detection by atomic-fluorescent spectrometry with preliminary generation of hydrides¹³⁸) but they were inferior to that in ion-exchange chromatography (20–91 pg¹³⁹). This may be due to the larger volumes of peaks and a complex composition of the mobile phase and, especially, to the influence of sodium ions from buffer solution which can suppress ionisation of arsenic.

A series of studies^{77, 135, 136} were devoted to the use of vesicles in MLC. If a micelle is a closed monolayer, then a vesicle is a closed bilayer. The cavity is filled with the substance which is contained in the environment.²² To be able to form vesicles the surfactant molecules should contain two (or more) hydrophobic hydrocarbon radicals with 16–18 carbon atoms. These requirements are met, for example, by didodecylmethylammonium bromide^{135, 136} and dihexadecyl phosphate.^{75, 136} These mobile phases can be used in combination with selective detection techniques, such as atomic-emission spectrometry with induction plasma (also after formation of hydrides), mass-spectrometry with induction plasma, atomic-absorption spectrometry of cold vapour and atomic-absorption spectrometry with electrothermal atomisation.

Interesting results were obtained in MLC of heteropolyanions:^{132, 133} a mixture of BW₁₂O₄₀⁵⁻, SiW₁₂O₄₀⁴⁻ and SiMo₁₂O₄₀⁴⁻ was separated within 10 min and a mixture of SiW₁₁FeO₃₉⁵⁻, BW₁₂O₄₀⁵⁻ and SiW₁₁O₃₉⁸⁻ within 7 min.

However, the results of the application of MLC in inorganic analysis, even though being interesting *per se*, are basically inferior to those achieved in ion-pair or ion-exchange chromatography.^{140–142}

VII. Comparison of the possibilities of ion-pair and micellar liquid chromatography

As the role of micelles is similar to that of organic modifiers owing to their ability to increase solubility of uncharged sorbates in water, MLC is usually compared to RP HPLC. Separation of uncharged and hydrophobic compounds, for which RP HPLC is widely used, is the field in which MLC is inferior as regards its efficiency, eluting strength and selectivity. The efficiency of columns in MLC is appreciably lower than that in RP HPLC and decreases as hydrophobicity of compounds increases. The micellar eluents are weak eluents; therefore, the retention times of hydrophobic sorbates are long. Selectivity is also low because of the similarity of processes which occur in the mobile and stationary phases,^{19, 66} although in a number of instances the reversal of the elution order is observed.^{143–145} All of these characteristics of the chromatographic system can be enhanced by the introduction of organic modifiers into the eluent; however, MLC will not all the same be competitive with RP HPLC in the separation of hydrophobic sorbates.

An advantage of the MLC method is the possibility of separating mixtures of ionic and non-ionic sorbates. Another method allowing solution of this problem is ion-pair chromatography. These methods have much in common: both use surfactants; electrostatic interactions play a substantial role (though if in ion-pair chromatography this role is crucial and determines retention, in MLC it is secondary), while organic modifiers regulate the eluting strength and selectivity of separation. Also, there are differences in principle between these two methods. Micellar solutions are considered in MLC as macroscopically homogeneous systems composed of two phases: the micelles and the bulk of aqueous solution. In the ion-pair chromatography, the mobile phases are homogeneous and consist solely of surfactant

monomers. Furthermore, the amount of surfactant adsorbed on the stationary phase increases with the concentration of the ion-pairing agent in the mobile phase. Descriptions of MLC by different authors are contradictory: some believe that the amount of adsorbed surfactant is almost constant after it exceeds CMC, while others argue that the surfactant adsorption remains substantial at concentrations several tens of times that of CMC.

Thorough comparison of the possibilities of both methods was carried out in the example of separation of amino acids and peptides.^{66, 146} The separation was performed using 2-propanol-modified sodium dodecyl sulfate-containing mobile phase. Investigation of the dependence of retention on the alcohol concentration showed that in the case of ion-pair chromatography the parameter of the solvent strength *S* correlates well with the logarithm of capacity factor in a purely aqueous phase ($\ln k'_0$). The selectivity of separation drops with the increasing content of the organic solvent in the mobile phase. Such dependences are also characteristic of RP HPLC. Totally different regularities were observed in MLC: variation of *S* proved to be reciprocal to changes in $\ln k'_0$, whereas the separation selectivity of most sorbate pairs increased as the content of the organic solvent in the mobile phase increased.

In MLC and ion-pair chromatography, the surfactant concentration has different effects on the retention of sorbates. In ion-pair chromatography the retention time of oppositely charged sorbates (at pH 2.5, the amino acids and peptides studied have a partial positive charge) increases with the concentration of the ion-pairing agent due to the larger amount of surfactant adsorbed on the stationary phase surface and forms a plateau upon saturation of the stationary phase. In MLC, the retention time is decreased as the total surfactant concentration in the system increases. In ion-pair chromatography there is no clear-cut dependence of selectivity on the ion-pair reagent concentration; though it is usually increased with the increase in concentration, particularly when sorbates differ in their charges. In MLC, the selectivity is as a rule enhanced as the micelle concentration increases. In ion-pair chromatography, the eluting strength of the mobile phase decreases as the ion-pairing agent concentration increases, whereas in MLC it increases with the concentration of micelles. Thus, the enhancement of selectivity and eluting strength occurs in parallel in MLC and antiparallel in ion-pair chromatography.

Many investigators noted better reproducibility of the retention characteristics in MLC compared to that in ion-pair chromatography. In the latter case, one often has to operate in the range where the retention is strongly dependent on the ion-pairing agent concentration; therefore, even minor changes in the mobile phase composition lead to a fairly appreciable variation of retention. Both methods were shown to have lower column efficiency compared to that in RP HPLC. Thus a new 25-cm long column packed with a C₁₈ sorbent had an efficiency of 14 000 theoretical plates in the elution with an acetonitrile–water mixture (25 : 75). In the presence of sodium dodecyl sulfate, its efficiency dropped to 5500 theoretical plates in both MLC and ion-pair chromatography. Nonetheless, the ion-pair chromatography has an advantage compared to MLC as regards the efficiency owing to the variation of the hydrophobic nature of the ion-pairing agent.

It should be noted in conclusion that MLC is an interesting method with the unique possibilities of selectivity variation; its theory has been well developed. The micellar liquid chromatography is an alternative to the RP HPLC method. Analytical chemists consider this method as the most useful in the analysis of biological specimens.

VII. Aryladamantanes	1016

Abstract. Published data on the synthesis of adamantane derivatives bearing various functional groups (halogen, hydroxy, nitrate, amino, carboxy and others) are systematised and generalised. The bibliography includes 236 references.

I. Introduction

Synthesis, reactivity and application of adamantane derivatives have been considered in several monographs and reviews.^{1–4} These compounds are used both in the synthesis of pharmaceuticals^{5,6} and for the preparation of novel polymers.^{7,8} It was found that introduction of an adamantyl fragment into medical compounds enhances their biological activities owing to the higher fat-solubility.^{6,9} Some adamantane derivatives exhibit antiviral activities, *e.g.*, 1-aminoadamantane and 1-ethylaminoadamantane hydrochlorides, which are the active principles of antiviral Mydantan and Remantadinum manufactured by the pharmaceutical plant in Olaine, Latvia.

Nucleophilic substitution reactions of hydrogen are most widely used in the synthesis of adamantane derivatives. Nevertheless, no special consideration of the reactions of adamantane and its derivatives in electrophilic media has been given before even in the most comprehensive monographs.^{10,11}

The present review systematises and generalises published data on the synthesis of functionally substituted adamantanes using reactions in electrophilic media.

II. Substitution reactions in the adamantane series in electrophilic media

Hydride transfer reactions in organic chemistry are most comprehensively revealed in monographs.^{12,13} In these reactions, aluminium halides, BF₃, sulfuric acid, carbenium ions, protonated quinones and azobenzenes and some other compounds are commonly used as acceptors of the hydride ion.

The reactions of adamantane in electrophilic media should be considered as nucleophilic substitution at the saturated carbon atom.^{10,11} These reactions for adamantane and its derivatives can follow only the S_N1 mechanism, *i.e.*, via adamantyl cations, which then react with nucleophiles.^{14–22} The reaction rates are mostly controlled by electronic factors, *viz.*, electron-donating properties of substituents, which serve as ‘internal’ nucleophiles thus delocalising the positive charge on the central carbon atom, electron-withdrawing properties of the substituents in the leaving groups, which decrease the basicity of these groups and electrophilic properties of a medium.

Only a few examples describing the nucleophilic substitution of hydrogen are known. These data mainly relate to the substitution of the hydride ion in polyhedranes (adamantane, proto- and homoadamantane, diamantane, bicyclo[3.3.1]nonane, *etc.*). The nucleophilic substitution of hydrogen in adamantane (**1**) has successfully been performed in electrophilic media (sulfuric acid, nitric acid, bromine), which, on the one hand, facilitated the hydride ion abstraction and, on the other hand, served as sources of nucleophilic species (HSO₄[–], ONO₂[–] and Br[–]).

Thus the bromination of adamantane (**1**) in liquid bromine occurs selectively at the bridgehead carbon atom yielding only monobromoadamantane **2**.^{14–16}

The reaction mechanism presumably involves the intermediate formation of the adamantyl cation **3**.¹⁶

The reaction of adamantane (**1**) with sulfuric acid leads to adamantanone (**7**).^{17–19} The reaction scheme includes the oxidation of **1** with 96% sulfuric acid to 1-hydroxyadamantane (**4**), the generation of the adamantyl cation **3** and the 1,2-hydrogen shift resulting in an equilibrium between 1-hydroxyadamantane (**4**) and 2-hydroxyadamantane (**6**) and the oxidation of 2-hydroxyadamantane (**6**) to adamantanone (**7**). The latter can also be formed, along with adamantane **1**, due to the intermolecular transfer of the hydride ion from 2-hydroxyadamantane (**6**) to the cation **3**.

Received 31 March 1999

Uspekhi Khimii 68 (12) 1102–1121 (1999); translated by S V Chapyshev

The reaction of 1-methyladamantane (**8**) with 96% sulfuric acid at 80°C leads to a complex mixture of products in which 5-methyladamantan-2-one (**9**) is the major component.¹⁹

In systems containing a strong mineral acid (H_2SO_4 , HNO_3) and trifluoroacetic anhydride, the role of the hydride ion acceptor is probably played by the cations HSO_3^+ or NO_2^+ , which are generated *in situ* from the corresponding acids and weakly nucleophilic trifluoroacetic anhydride.²⁰ Thus the reactions of adamantane (**1**) and aryladamantanes **10a–e** in such systems yield the corresponding trifluoroacetoxy-substituted adamantanes **11a–e**.²⁰

R = 4- $\text{NO}_2\text{C}_6\text{H}_4$ (**a**), 4- $\text{MeSO}_2\text{C}_6\text{H}_4$ (**b**), 3- NO_2 -4- MeC_6H_3 (**c**), 4- BrC_6H_4 (**d**), 4- $\text{MeO}_2\text{CC}_6\text{H}_4$ (**e**).

The reaction of adamantane (**1**) with concentrated nitric acid affords 1-adamantyl nitrate (**12**) and adamantane-1,3-diyl dinitrate (**13**).²¹

A mechanism of the formation of the nitrate **12** involving the stage of generation of the adamantyl cation **3** has been suggested^{22,23} based on studies of the behaviour of adamantane (**1**) in nitric acid and its mixtures with acetic acid.

Exploration of the behaviour of adamantane (**1**) in electrophilic media made possible the development of the methods of synthesis of 1-bromoadamantane (**2**), 1-hydroxyadamantane (**4**) and nitrate **12**, which are convenient starting materials for the preparation of various functionally substituted adamantanes. It should be noted that the latter of these three compounds is the most readily available. The functionalisation of adamantane has been achieved using sulfuric and nitric acids²⁴ or bromine as electrophilic media.

The reactions of adamantane (**1**) and its derivatives **14** with nucleophiles such as urea, urethane or nitriles in concentrated nitric acid or in a mixture of HNO_3 and AcOH afford functionally substituted adamantanes **15**.²⁴

$\text{R}^1 = \text{H, Me, Et}$; $\text{X} = \text{NH}_2\text{CO}$; $\text{R}^2 = \text{NH}_2, \text{OEt}$;
 $\text{X} = \text{CN}$, $\text{R}^2 = (\text{CH}_2)_2\text{OMe}$.

It has been shown^{18,19} that functionalisation of adamantane and its derivatives can be performed in liquid bromine, which also functions as a Lewis acid. As an example, synthesis of compounds **16–18** using this method can be mentioned. By comparison with adamantane (**1**), bromoadamantane (**2**) reacts faster in these reactions.^{25,26}

Yurchenko *et al.*^{27,28} have shown that adamantane (**1**) reacts with iodine monobromide in CCl_4 to give a mixture of 1-bromoadamantane (**2**) and 1,3-dibromoadamantane (**19**).

The authors believe that a dipole $\text{I}^{\delta+} - \text{Br}^{\delta-}$ with a partial positive charge on the iodine atom is responsible for the hydride ion abstraction from the adamantane molecule. Adamantyl cation **3** thus formed then reacts with the bromide anion. The dibromide **19** is formed from the bromide **2** according to the same mechanism.

UV-Spectral studies²⁹ showed that 1-bromoadamantane (**2**), 1-bromo-3-methyladamantane (**20**), 1-bromo-3,5-dimethyladamantane (**21**) and 1-bromo-3,5,7-trimethyladamantane (**22**) form molecular complexes with bromine, which have linear structures. Presumably, complexes of the π, σ -type with charge transfer from the lone pair of the bromine atom in bromoadamantanes to the molecule of Br_2 are realised in these cases. As a result, the polarisation of the C–Br bond is increased.

It is supposed³⁰ that the increase in the polarity of the C–Br bond in bromoadamantanes is associated with localisation of the positive charge in the centre of the adamantane cage rather than on the carbon atom of the C–Br bond. This is possible owing to the overlap of the inwardly directed, hybridised orbitals of the bridgehead carbon atoms in adamantanes. Complexation facilitates nucleophilic reactions at the carbon atom of 1-bromoadamantane (**2**). It has also been shown²² that the reactions that occur efficiently in liquid bromine, occur also in neutral solvents in the presence of molecular bromine, if its concentration is sufficient for the complexation.

The kinetics of the reactions of adamantane (**1**) and its derivatives and homologues with nitric acid in dichloromethane

Table 1. The rate constants for the reactions of adamantane derivatives with nitric acid in dichloromethane^a (Ref. 31).

 ONO ₂ (12)	20	0.025	0.24±0.01
 C(NO ₂) ₃ (28)	20	0.025	0.041±0.002

^a Initial concentration of HNO₃ was 4 mol litre⁻¹.

have been studied.³¹ Sequential methylation of the bridgehead positions of adamantane results in monotonic decrease in reactivity (Table 1), which is typical of the reactions involving the intermediacy of carbocations. The logarithms of the rate constants (*k*_{eff}) for these reactions calculated taking into account the statistical factor correlate fairly well (*r* = 0.993) with the logarithms of the rate constants for the solvolysis of the corresponding bromides (in 80% aqueous ethanol at 75 °C),³² which suggests that both types of reactions have similar mechanisms. Introduction of electron-withdrawing substituents into adamantane decreases the reactivities of its derivatives (Table 1). A correlation between the logarithms of the rate constants and the σ^* Taft constants is observed (*r* = 0.99, ρ^* = -0.77) for adamantanes substituted by the CH₂CO₂Me, CO₂Me, ONO₂ and C(NO₂)₃ groups. The sign of the reaction constant indicates that these substituents destabilise the positively charged intermediate species. The rather high absolute value of the ρ^* constant suggests that transition states in the reactions of adamantanes with nitric acid are highly polar.

The kinetic isotope effect for the reactions of 1,3,5-trimethyladamantane (24) and 7-deuterio-1,3,5-trimethyladamantane (25) is 4.4±0.3.³¹ This suggests that the dissociation of the C—H bond at the tertiary carbon atom is the rate-determining step. It is worth mentioning that the kinetic isotope effect for the reactions of adamantane (1) with nitronium salts is 1.86 (Ref. 33) and that for

the oxidation of isobutane with a mixture of H₂SO₄ and HNO₃ is 2 (Ref. 34).

The activation energy and entropy for the reaction of 1,3,5-trimethyladamantane (24) are equal to 43±7 kJ mol⁻¹ and 147±24 J mol⁻¹ K⁻¹, respectively.

Judging from these data, it is reasonable to assume that the reaction of adamantane (1) with nitric acid involves the intermediate formation of the adamantyl cation 3. The rate-determining step of this process is obviously the abstraction of the hydride ion from the tertiary carbon atom by an electrophile, which is most likely the nitronium ion. The adamantyl cation 3 thus formed is further stabilised by adding a nucleophile.³¹ The reactions of saturated hydrocarbons with sulfuric or nitric acids or their mixtures are well known. The mechanism of activation of the C—H bonds in adamantane or, in the other words, the mechanism of the hydride ion transfer is discussed in Refs 35–37. In adamantane and its homologues, this activation can be realised by three routes.

Route *a*Route *b*Route *c*

Of these three, no route can be ruled out from consideration, since each of them leads to the adamantyl cation 3. Route *a* implies realisation of a transition state **A** with a five-coordinate carbon atom. Such a transition state is used³⁵ to describe hydride ion transfer in the reactions of alkanes with carbocations in sulfuric acid or with nitronium salts. The nitration of alkanes according to Olah,³⁸ viz., with nitronium salts in a mixture of dichloromethane and sulfolane at 25 °C in the dark in the absence of moisture, giving rise to a mixture of nitroalkanes and nucleophilic substitution products also invokes the realisation of the transition state with a five-coordinate carbon atom. However, the question whether the transition state **A** is converted into the final products by proton abstraction or by the elimination of HNO₂ and subsequent reaction of the cation 3 with a nucleophile still remains open.

The route *b* has already been considered in detail for the reactions of adamantane (1) in such electrophilic media as liquid bromine, sulfuric and nitric acids. In these cases, the initially formed adamantyl cation 3 reacts further with HSO₄⁻, ONO₂⁻, Br⁻ or other nucleophilic species. The reactivity of adamantane in these electrophilic media decreases in the following order: H₂SO₄ > HNO₃ > Br₂.

The reactions of adamantane (1) through a stage of single-electron transfer (route *c*) are also possible. However, this is considered in a limited number of publications (see, for example, Ref. 36).

The anodic oxidation of alkyladamantanes in dry acetonitrile yields 1-acetamido-3-alkyladamantane 29, while the anodic fragmentation of the same compounds leads to 1-acetamidoadamantane (30). The ratio of the reaction products depends on the nature of the alkyl substituents.³⁶

R = H, Et, Prⁱ, Bu^t.

Later, the decomposition of 1,1'-azoadamantane (**31**) into adamantyl radical **B** involving the stage of the formation of [AdN=NAd]⁺⁺ (Ad is 1-adamantyl) (route *c*) was described.³⁷ Thus the reaction of 1,1'-azoadamantane (**31**) with thianthreinium perchlorate in acetonitrile affords 1-acetamidoadamantane (**30**) in 90% yield.

31

III. Halogenoadamantanes

Halogenoadamantanes can be obtained from both adamantane itself and its derivatives bearing hydroxy, nitroxy and other nitrogen-containing functional groups or halogen atoms.

After the first reports^{14,15} on the synthesis of halogenoadamantanes from adamantane (**1**), several publications appeared in the literature, describing methods of introduction of fluorine, chlorine, bromine and iodine atoms into the adamantane molecule, which involve the intermediate formation of the adamantyl cation **3**. Using these methods, four halogen atoms can be introduced in the bridgehead positions of adamantane.

1-Fluoroadamantane (**33**) has been obtained by the reaction of adamantane (**1**) with a mixture of poly(hydrogen fluoride) and pyridine (30% Py, 70% HF).³⁹ The fluorination is carried out in the presence of nitronium tetrafluoroborate. The complex **32** with the five-coordinate carbon is assumed to be formed in the attack of the nitronium cation on adamantane, which then decomposes to give 1-fluoroadamantane (**33**).

1-Fluoroadamantane (**33**) can also be prepared by the reaction of adamantane (**1**) with xenon fluoride⁴⁰ or with ClF₃.⁴¹ In the latter case, 1,3-difluoro- and 1,3,5-trifluoro-adamantanes were formed together with the 1-fluoroadamantane (**33**). The reaction presumably involves the intermediacy of a complex with five-coordinate carbon and the adamantyl cation.⁴¹

Sulfur tetrafluoride reacts with adamantane in the presence of sulfur monochloride to give a mixture of 1-fluoro- (**33**) and 1,3-difluoro-adamantanes (**34**).⁴²

The fluorination of 1,3-dimethyladamantane (**23**) over CoF₃ affords a mixture of perfluorotrimethylbicyclo[3.3.1]nonane and perfluoro-1,3-dimethyladamantane (5%–10%).⁴³ The fluorination of 1,3-difluoro-5,7-dimethyladamantane, prepared by the reaction of 1,3-dihydroxy-5,7-dimethyladamantane with SF₄ (125 °C, 4 h), over CoF₃ also leads to a mixture of perfluorinated derivatives.⁴³

1-Fluoro- (**33**), 1,3-difluoro- (**34**), 1,3,5-trifluoro- and 1,3,5,7-tetrafluoro-adamantanes have been obtained by the action of sulfur tetrafluoride on adamantane (**1**).⁴⁴

Much more attention is paid to the problem of the adamantane chlorination. Molecular chlorine, organic and mineral acid chlorides, AlCl₃, FeCl₃ and others are used as chlorinating agents.

1-Chloroadamantane (**35**) can be obtained either by the treatment of adamantane (**1**) with a mixture of iodine and sulfuric acid in dichloromethane followed by passing of molecular chlorine through the reaction mixture⁴⁵ or by the reaction of adamantane (**1**) with molecular chlorine adsorbed on SiO₂.⁴⁶

Acyl chlorides RCOCl (R = Me, Prⁿ, Prⁱ, Ph, cyclohexyl) in the presence of AlCl₃ are also rather efficient chlorinating agents. Thus the reaction of adamantane (**1**) with acetyl chloride yields 1,3-dichloroadamantane (**36**).⁴⁷

1,3,5-Trichloroadamantane (**37**) is obtained by the reaction of adamantane (**1**) with thionyl chloride in the presence of AlCl₃ at 75 °C.⁴⁸

In this reaction, adamantane sulfinyl chloride (**38**) is formed as the minor product probably due to the nucleophilic attack by the lone electron pair of the sulfur atom of thionyl chloride on the carbenium ion **3**.

Adamantane (**1**) reacts with sulfonyl chloride in sulfolane at 60 °C to give 1-chloro- (**35**) and 2-chloro-adamantanes (**39**) in 97.5% and 2.5% yield, respectively.⁴⁹ 1-Chloroadamantane (**35**) is also obtained by the reaction of adamantane with phosphorus trichloride in trifluoroacetic acid.⁵⁰

Unlike pure fluorosulfonic acid, which reacts with adamantane (**1**) to give 1-hydroxyadamantane (**4**),⁵¹ chlorosulfonic acid halogenates adamantane at -5°C [the ratio of reactants 1 : (8–10)] providing 1-chloroadamantane (**35**) in 60% yield.⁵²

Synthesis of 1-chloro-, 1,3-dichloro- and 1,3,5-trichloro-adamantanes by the reaction of adamantane (**1**) with chlorosulfonic acid has been described.⁵³ When the reaction mixture is kept below 5°C for less than 1 h, 1-chloroadamantane (**35**) is formed in 18.7% yield. 1,3-Dichloroadamantane (**36**) is obtained in 80.7% yield after 50–60 h, and 1,3,5-trichloroadamantane (**37**) is obtained in 70% yield after 140–240 h of the reaction. Either 1-chloro-3,5-dimethyl- or 1,3-dichloro-5,7-dimethyladamantane is formed in the chlorination of 1,3-dimethyladamantane (**23**) depending on the reaction conditions. 1,3,5-Trimethyladamantane (**24**) gives 1-chloro-3,5,7-trimethyladamantane.

1,3,5,7-Tetrachloroadamantane (**40**) has been obtained by heating 1,3,5-trichloroadamantane (**37**) with chlorosulfonic acid for 150 h at 70°C .⁵⁴

Chlorination of adamantane (**1**) and its homologues can be accomplished with alkyl halides in the presence of Lewis acids. Thus the treatment of 1-ethyladamantane (**41**) with a mixture of *tert*-butyl bromide or *tert*-butyl chloride and AlCl_3 affords 1-chloro-3-ethyl-, 1,3-dichloro-5-ethyl- and 1,3,5-trichloro-7-ethyl-adamantanes.⁵⁵

A mixture of 1,3-dichloro- (**36**), 1,3-dibromo- (**19**) and 1-bromo-3-chloro-adamantanes was obtained by refluxing adamantane (**1**) in CCl_4 in the presence of boron tribromide and aluminium bromide.⁵⁶

A mixture of 1-chloro- (**35**) and 1,3-dichloro-adamantanes (**36**) was formed in the reaction of adamantane (**1**) with CCl_4 in the presence of AlCl_3 at 20°C .⁵⁷

1,3,5,7-Tetrachloroadamantane (**40**) was prepared in 55% yield by refluxing adamantane (**1**) with AlCl_3 in CCl_4 .⁵⁸

The reaction of adamantane (**1**) with AlCl_3 in CCl_4 for 4 h at 20°C affords 1,3-dichloroadamantane (**41**) in 49% yield.⁵⁹

The effects of solvents and Lewis acids on the chlorination of adamantane (**1**) have been studied in detail.^{59,60} The yields and the ratio of 1-chloro- (**35**) and 2-chloro-adamantanes (**39**) obtained in these reactions in the presence of FeCl_3 or SbCl_5 are listed in Table 2. The yields of 1-chloroadamantane (**35**) are higher when SbCl_5 is used as a catalyst. The ratio of the isomers is influenced by the nature of the solvent and the Lewis acid.

The mechanisms of the halogenation reactions of adamantane considered above are probably not purely ionic, since 2-chloro-adamantane (**39**) can be formed exclusively by the free-radical mechanism.

Two different mechanisms can be suggested for the reactions in the presence of FeCl_3 : the route *a* involving direct reaction of the radical **B** with FeCl_3 and providing 1-chloroadamantane (**35**) and the route *b* implying the intermediacy of the cation **3**.

(a) FeCl_3 ($-\text{FeCl}_2$); (b) FeCl_3 ($-\text{FeCl}_2$, $-\text{Cl}^-$).

The reaction of adamantane (**1**) with SbCl_5 can also be described by a scheme including a stage of the adamantyl radical **B** formation.

The chlorination of adamantane (**1**) in the presence of AlCl_3 and AgSbF_6 has been studied by Olah *et al.*⁶¹ A mixture of 1-chloro- (**35**) and 2-chloro-adamantanes (**39**) (in 63.2% and 2.9% yields, respectively) is formed when the ratio of the reactants Cl_2 : AlCl_3 : AdH is 1 : 0.1 : 1 (21 h, 25°C). If the ratio

Table 2. Chlorination of adamantane (**1**) in the presence of FeCl_3 and SbCl_5 .^{59,60}

Solvent	Temperature / $^{\circ}\text{C}$	FeCl_3			SbCl_5		
		Time / h	Total yield of 35 and 39 (%)	Ratio of 35 and 39	Time / h	Total yield of 35 and 39 (%)	Ratio of 35 and 39
CCl_4	78	6.5	4	11 : 1	3	7–9	(11–15) : 1
		54	64–72	(12–15) : 1	4	14–20	(13–15) : 1
		—	—	—	36	66–79	(11–16) : 1
CH_2Cl_2	40	7	2	20 : 1	0.5	24	31 : 1
		10	4	28 : 1	1	40–42	(35–39) : 1
		—	—	—	3	68–79	(36–42) : 1
CH_2Cl_2 , CCl_4	48	2.5	3	42 : 1	2	52	22 : 1
		4.5	3–6	(27–42) : 1	5	75	21 : 1
		7	8–9	(23–30) : 1	6.5	76	22 : 1

$\text{Cl}_2:\text{AgSbF}_6:\text{AdH}$ is 5:1:10 (21 h, -15.5°C), the yields of 1-chloro- (**35**) and 2-chloro-adamantanes (**39**) are 62.4% and 1.2%, respectively. In addition, 1-hydroxyadamantane (**4**) is formed in 36.3% yield. On the other hand, the ratio of 1-chloroadamantane (**35**) to 2-chloroadamantane (**39**) in photochemical chlorination was 1:(0.6–2.1).⁶²

It is known that triphenylmethyl cation is an effective acceptor of the hydride ion (*i.e.*, this serves as a 'soft' organic acid in terms of the HSAB principle). Using this cation, it is possible to generate carbenium ions from hydrocarbons and functionalise them by the reactions with appropriate nucleophiles. Triphenylmethyl cation can be used in such reactions as a catalyst. In this case, triphenylmethane derivatives serve as the sources of nucleophiles which react with the newly formed carbenium ions and also regenerate the triphenylmethyl cations.

X^- is a weakly nucleophilic anion.

This type of functionalisation has been studied for various hydrocarbons, including adamantane.⁶³

$\text{Y} = \text{OH}, \text{Cl}, \text{OMe}, \text{O}(\text{CH}_2)_2\text{OAc}.$

The reaction was carried out in a mixture of CH_2Cl_2 and MeNO_2 at 70°C using $\text{Ph}_3\text{COSO}_2\text{CF}_3$ (0.05 mol per mol of AdH) as a precursor of triphenylmethyl cation. The results obtained are listed in Table 3.

Table 3. Functionalisation of adamantane (**1**) by triphenylmethane derivatives.⁶³

Y	Ratio $\text{Ph}_3\text{CY}:$ $:\text{AdH}$	Time /h	Yields (%) ^a			
			AdY	Ph_3CH	AdOH (4)	AdH (1)
OH	1:1	14	59(57)	80		40
Cl	1:1	9	78(40)		0	10
OMe	1.25:1	2.5	31(20)	87	12	20
$\text{AcO}(\text{CH}_2)_2\text{O}$	1.25:1	3.5	50(40) ^b	71	15	10

^a Determined by GLC, the isolated yields are given in parentheses; ^b after deacylation.

As can be seen from the Table 3, such functional groups as Cl and OH are readily introduced into adamantane and these exchange reactions can find synthetic application. The yields of the ethers are substantially lower, probably because of competitive disproportionation of trityl ethers.

Several studies have been devoted to the preparation of bromoadamantanes. As has been mentioned above, 1-bromo-2-adamantane (**2**) was synthesised in 78% yield by the reaction of adamantane (**1**) with bromine in the presence of AlCl_3 .¹⁵

The synthesis of the bromide **2** by the oxidative bromination of adamantane (**1**) with the stoichiometric amount of bromine or an alkali metal bromide in trifluoroacetic acid in the presence of nitrogen-containing oxidants such as alkali nitrates or nitrites or NO_2 has been proposed as an alternative. This affords 1-bromo-2-adamantane (**2**) in quantitative yield.⁶⁴

Anhydrous AgSbF_6 in CH_2Cl_2 catalyses the bromination of adamantane. At -45.5°C , 1-bromo-2-adamantane (**2**) is obtained in 54.1% yield.⁶⁵ A strongly polarised complex of Br_2 with AgSbF_6 is supposed to be the brominating species in this reaction.⁶⁵

1-Hydroxy- (**4**), 2-bromo- (**42**) and 1-fluoro-adamantanes (**33**) are also formed in this reaction.

A two-electron three-centre transition state of the carbenium type is believed⁶⁵ to be realised in this reaction.

Synthesis of 1,3-dibromo-2-adamantane (**19**) by the reaction of adamantane (**1**) with bromine in the presence of AlBr_3 (78% yield) or in the absence of a catalyst in autoclave at 150°C for 22 h (12.4% yield) has been described.^{15, 66–70}

A detailed study⁶⁶ of the reaction of adamantane (**1**) with bromine in the presence of a mixture of AlBr_3 and BBr_3 has been performed. It was shown that the composition of the reaction products depends on the ratio of the catalysts used. Later, 1,3-dibromo-2-adamantane (**19**) was obtained in 97% yield by the bromination of adamantane (**1**) in the presence of Fe and small amount of water.⁶⁸

The reaction of adamantane (**1**) with bromine in the presence of Fe in Freon-113 (1,1,2-trichloro-1,2,2-trifluoroethane) or in hexafluorobenzene affords dibromide **19** in 97.3% yield and of 99% purity.⁶⁹ A complex mixture of products comprising 1,3,5-trichloro- (**37**, 27.3%), 1-bromo-3,5-dichloro- (16.6%), 1,3-dibromo-5-chloro- (27.4%), 1,3,5-tribromo- (12.0%), 1-bromo-3,5,7-trichloro- (10.8%) and 1,3-dibromo-5,7-dichloro-adamantanes (5%) were obtained in the presence of AlCl_3 .⁶⁹

The treatment of adamantane (**1**) with bromine at 100°C under 27.2 atm also yields 1,3-dibromo-2-adamantane.⁷⁰

1,3,5,7-Tetrabromo-2-adamantane (**43**) has been obtained in 75% yield by heating 1,3,5-tribromo-2-adamantane (**44**) with bromine and AlBr_3 in an autoclave at 150°C for 2 h.¹⁶

Synthesis of 1,3,5,7-tetrabromo-2-adamantane (**43**) by bromination of adamantane (**1**) has also been performed under relatively mild reaction conditions (an equimolar amount of AlCl_3 , 30 min at 20°C and then 3 h at 60°C).⁷¹

1,3,5-Tribromo-2-adamantane (**44**) has been synthesised⁷² from adamantane (**1**) under the conditions used earlier¹⁵ for the preparation of 1,3-dibromo-2-adamantane (**19**).

1,3-Dibromo- (**19**) and 1,3,5,7-tetrabromo-adamantanes (**43**) have been prepared from salts of the corresponding acids by the Hunsdiecker reaction.^{73, 74}

Interestingly, 1,3,5,7-tetrabromoadamantane (**43**) has also been synthesised by the reaction of 2-chloroadamantane (**39**) with bromine in the presence of the equivalent amount of AlBr_3 .⁷⁵ No product containing the chlorine and bromine atoms together in the same molecule was detected in this reaction.

The methods for direct iodination of adamantane (**1**) are unknown. Iodoadamantanes can be obtained by a substitutive iodination of chloroadamantanes or hydroxyadamantanes. These methods are considered below.

Halogenated adamantanes can also be synthesised from adamantanes bearing other functional groups. A possibility for halogen exchange in halogenoadamantanes upon their treatment with appropriate hydrogen halides has been demonstrated.^{76,77}

1-Fluoroadamantane (**33**) has been obtained by the treatment of 1-chloro-, 1-bromo- or 1-iodoadamantane with a mixture of poly(hydrogen fluoride) and pyridine in the presence of nitronium tetrafluoroborate or sodium nitrate.⁷⁸

$\text{X} = \text{Cl}, \text{Br}, \text{I}$.

1-Fluoro- (**33**), 1,3-difluoro- (**34**) and 1,3,5,7-tetrafluoroadamantanes (**45**) have also been synthesised by the reactions of the corresponding bromides **2** and **43** with ZnF_2 or AgF .⁷⁹

1-Bromo- (**2**) and 1-iodo- (**46**) adamantanes have been obtained by the reaction of 1-chloroadamantane (**35**) with gaseous HBr or HI in CCl_4 or CH_2Cl_2 in the presence of FeBr_3 .⁸⁰ The latter was prepared *in situ* from $\text{Fe}(\text{CO})_5$ and Br_2 .

$\text{X} = \text{Br}$ (**2**), I (**46**).

A similar procedure has been proposed⁸¹ to exchange the bridgehead halogen atoms in bromo- and iodoadamantanes. The method is based on the generation *in situ* of an aluminium halide catalyst by the reaction of an excess of aluminium with bromine in a halogenated solvent. The results obtained are summarised in Table 4. In CH_2I_2 , exchange of bromine by iodine in 1-bromo- (**2**) and 1,3,5,7-tetrabromo- (**43**) adamantane occurs at room temperature in several minutes and is accompanied by the formation of adamantane (30%). Using this method, 1,3,5,7-tetraiodo- (**47**) adamantane was obtained in 83% yield.

1,3,5,7-Tetraiodo- (**47**) adamantane is formed from 1,3,5,7-tetrabromo- (**43**) in 75% yield.⁸²

The replacement of the fluorine atoms in 1,3,5-trifluoro-7-trifluoromethyl- (**48**), 2,2,5,7-tetrafluoro- (**49**), 2-trifluoromethyl-5,7-difluoro- (**50**) and 1,3,5,7-tetrafluoroadamantane (**45**) by the bromine atoms under the action of BBr_3 has been studied.⁸³ The exothermic reactions of compounds **48**, **49** and **50** with BBr_3 begin at room temperature, whereas the exchange of the fluorine atoms in 1,3,5,7-tetrafluoroadamantane (**45**) by the bromine atoms requires heating.

Only the bridgehead fluorine atoms were found to be exchangeable. The trifluoromethyl groups are completely inert towards the action of neat BBr_3 . However, the addition of a catalytic amount of AlBr_3 allows the exchange of the fluorine atoms in the trifluoromethyl groups by bromine. The reactions were carried out with a great excess of BBr_3 , which serves simultaneously as a reagent and as a solvent.⁸⁴

Table 4. Reaction conditions and yields of halogenoadamantanes.⁸¹

Substrate	Solvent	Temperature /°C	Time /min	Product	Yield (%)
1-Bromo- (2)	CH_2I_2	20	0.5	1-Iodo- (46)	47
	CHCl_3	65	1.5	1-Chloro- (35)	89
1,3,5,7-Tetrabromo- (43)	CH_2I_2	80	15	1,3,5,7-Tetraiodo- (47)	83
	CHCl_3	20	1200	1,3,5,7-Tetrachloro- (40)	88

As reported by Cuddy *et al.*,⁸⁵ 2,2-dibromoadamantane (**52**) isomerises in the presence of AlBr_3 . However, this dibromide can be obtained by the reaction of 2,2-difluoroadamantane (**51**) with BBr_3 . No isomerisation of the reaction product was also observed in the reaction of 2,2,5,7-tetrafluoroadamantane with BBr_3 .⁸⁶

1-Hydroxyadamantane (**4**) or its nitrate **12** are widely used as starting compounds in the synthesis of halogenoadamantanes. Thus 1-fluoroadamantane (**33**) was obtained by the reaction of 1-hydroxyadamantane (**4**) with boron trifluoride diethyl etherate.^{87–89}

By analogy with the halogen substitution, pyridinium poly(hydrogen fluoride) was employed for the replacement of the adamantane hydroxy group by the fluorine atom.^{90,91} 1-Fluoro- and 2-fluoro-adamantanes are formed from the corresponding alcohols in virtually quantitative yields. For the preparation of adamantanes with other halogen atoms, this reagent is used in combination with the appropriate metal or ammonium halide.

$\text{M} = \text{Na}, \text{K}, \text{NH}_4$; $\text{X} = \text{Cl}, \text{Br}, \text{I}$.

A convenient procedure for the replacement of the hydroxy group by iodine is the use of a mixture of Me_3SiCl and NaI .⁹² For example, 1-iodo- (46, yield 80%) and 1-hydroxy-3-iodo-5,7-dimethyl-adamantanes (**53**) have been prepared by this procedure. In the latter case, only one hydroxy group can be substituted even with an excess of the halogenating reagent.

The replacement of the hydroxy group in compound **4** by a halogen can be performed by the reactions with halogens, alkali metal halides or hydrohalic acids in sulfuric acid. Thus 1-bromoadamantane derivatives have been obtained by the reactions of 1-hydroxyadamantane (**4**) and its derivatives with bromine in sulfuric acid.^{93,94}

1,3-Dibromo-5,7-dimethyladamantane has been prepared by the reaction of 1,3-dihydroxy-5,7-dimethyladamantane (**54**) with bromine in oleum.^{95–97}

The hydroxy groups in the hydroxy ketone **55** and hydroxy carboxylic acids **56** and **57** have successfully been replaced by halogens.^{98–101}

(a) HBr , $\text{X} = \text{Br}$ (83%); (b) SOCl_2 , $\text{X} = \text{Cl}$ (90%).

(a) PBr_5 , $\text{X} = \text{Br}$; (b) $\text{KI}, \text{H}_3\text{PO}_4$; $\text{X} = \text{I}$.

The replacement of the hydroxy group in 2-hydroxyadamantane-1-carboxylic acid (**56**) by halogens presumably follows the $\text{S}_{\text{N}}2$ mechanism.

1,3-Diiodoadamantane has been obtained by the reaction of 1,3-dihydroxyadamantane with hydroiodic acid.¹⁰²

Yet another method for the introduction of the halogen atoms into adamantanes is the reactions of adamantyl nitrates with hydrohalic acids or their salts in sulfuric acid.

Thus the nitrate groups in 1-adamantyl nitrate (**12**) and adamantane-1,3-diyl dinitrate (**13**) have successfully been replaced by the chlorine or bromine atoms using the reaction of these adamantanes with potassium (sodium) chloride or bromide in 98% sulfuric acid.¹⁰³

$\text{M} = \text{Na}, \text{K}$; $\text{X} = \text{Cl}, \text{Br}$.

1-Bromo-(2),¹⁰⁴ 1,3-dichloro- (**36**) and 1,3-dibromo-adamantanes (**19**)¹⁰⁵ were obtained in a similar manner.

Under the action of halogenating agents on adamantanes bearing Alk , Ph , CO_2H , CF_3 , $\text{C}(\text{NO}_2)_3$, NO_2 , NH_2 and other groups either the adamantane hydrogen atom in the 3-position or the substituent is replaced depending on the nature of the substituent.

No problem arises in the bromination of 1-bromo-3-methyl-,¹⁰⁶ 1-methyl- (**8**),^{107,108} 1-ethyl-,¹⁰⁹ 1-*tert*-butyl-,¹¹⁰ 1,3-dimethyl- (**23**),¹⁰⁸ 1,3,5-trimethyl- (**24**)¹¹¹ and 1-ethyl-3-methyl-adamantanes with bromine.¹⁰⁶ The yields of the corresponding bromoadamantanes are almost quantitative.

The bromination of 2-(1-adamantyl)-2-bromopropane (**58**) is worth a more detailed consideration, since the structure of the product obtained in this reaction has not initially been established. It was supposed that 2-(3-bromo-1-adamantyl)-2-bromopropane is formed in the bromination of compound **58** with bromine at 70–80 °C for 2 h.¹¹²

However, further studies^{113, 114} have shown that it was the side chain that underwent bromination of 1-isopropyladamantane (**59**) yielding 2-(1-adamantyl)-1,3,3-tribromoprop-1-ene (**60**), and compound **58** is brominated to give tetrabromo-substituted derivative **61**.

Analogous products were obtained in the bromination of 1-isopropyl-3,5,7-trimethyladamantane and 2-bromo-2-(3,5,7-trimethyl-1-adamantyl)propane.¹¹³ A mechanism involving the intermediate formation of cations **62**, **63** and the tribromide **60** has been proposed¹¹³ to account for the reaction of 2-(1-adamantyl)-2-bromopropane (**58**) with bromine.

Judging from the ratio of the rate constants for solvolysis of 2-(1-adamantyl)-2-bromopropane (**58**) and 1-bromo-3-isopropyladamantane ($10^4:1$), an assumption was made¹¹² that the rates of bromination of the side chain and nucleus in 1-isopropyladamantane (**59**) should also differ by four orders of magnitude. However, since only the nucleus of 1-isopropyladamantane is brominated in the reaction, a complex reaction scheme including several rearrangements of carbenium ions was proposed to account for this contradiction.

In fact, solvolysis of bromides and bromination involving the saturated carbon atom occur most likely by different mechanisms.¹¹³ The rate-determining stage in the solvolysis is the formation of a carbenium ion, whereas the rate of the bromination is determined by a stage which precedes the ionisation, *e.g.*, the formation of a complex $R^+ - H - Br^+ - Br^-$. The energy of such a complex is lower if the adamantane nucleus rather than side chain takes part in the complex formation.

The reaction of 2-methyladamantane (**64**) with a 10% solution of bromine in CCl_4 leads to 2-bromo-2-bromomethyladamantane (**65**), while a mixture of *exo*- and *endo*-2-bromo-4-(dibromomethylidene)adamantanes (**66**) is formed upon refluxing 2-methyladamantane (**64**) with bromine for 4–5 h. A scheme of the formation of compound **66** has been proposed.¹¹⁵

A mixture of 1-bromo-2-methyl-, 1-bromo-4-methyl- and 1-bromo-3-methyl-adamantanes was formed upon treatment of 2-methyladamantane with bromine.¹¹⁶

Table 5. The rate constants for the solvolysis of alkylbromoadamantanes in 80% ethanol.

Compound	$10^5 k$ /s ⁻¹	k_{rel}	$\Delta H^\ddagger$ /kcal mol ⁻¹	$\Delta S^\ddagger$ /cal mol ⁻¹ deg ⁻¹
1-Bromoadamantane (2)	8.76 (22.5)	1.00 (1.0)	23.1 (23.63)	-10.1 (-9.6) ^a
1-Bromo-3-methyl- adamantane (20)	6.05 (15.9)	0.69 (0.7)	23.6 (24.36)	-9.6 (-8.1) ^a
1-bromo-3-ethyl- adamantane	8.42 (22.5)	0.96 (1.0)	23.3 (24.5)	-9.4 (-7.0) ^a
1-Bromo-3-isopropyl- adamantane	11.9 (32.1)	1.36 (1.4)	24.5 (24.0)	-5.4 (-7.8) ^a
1-Bromo-3,5-dimethyl- adamantane (21)	4.12	0.47	24.5	-7.4
1-Bromo-3,5,7-tri- methyladamantane (22)	(6.93)	0.31 (0.31)	—	—

Note. According to the data in Ref. 117 (70 °C). Data from Ref. 109 (Et_3N , 75 °C) are given in parentheses.

^a $\Delta S^\ddagger$ values at 60 °C.

The effect of the nature and number of alkyl substituents on the stability of the adamantyl cations can be evaluated by an analysis of the rate constants for the solvolysis of the corresponding alkylbromoadamantanes (Table 5).¹¹⁷

As expected, the more the number of methyl groups in 1-bromoadamantane, the lower the rate of solvolysis. However, this is increased in the series 3-methyl-, 3-ethyl- and 3-isopropyl-substituted 1-bromoadamantanes (6.05×10^{-5} , 8.42×10^{-5} and 11.9×10^{-5} , respectively).

Both the aromatic ring and the adamantane nucleus are expected to be susceptible in the bromination of aryladamantanes.

1-Phenyladamantane (**67**) reacts with bromine under reflux to give a mixture of products from which no individual compound was isolated;¹¹⁸ however, 1-(4-bromophenyl)adamantane (**68**) was obtained at 0 °C, and 1-(3,4-dibromophenyl)adamantane (**69**) as the product of substitution of two hydrogen atoms in the aromatic ring was prepared at 25 °C.¹¹⁹

The introduction of the carboxy group into position 3 of the adamantane nucleus in 1-phenyladamantane does not affect the character of the phenyl ring substitution. On the other hand, if electron-donating substituents are present on the phenyl ring, the corresponding dibromides are formed even at 0 °C.¹¹⁹

$R^1 = H, CO_2H$; $R^2 = OMe, OH, Me$.

The bromination of 4-(1-adamantyl)acetanilide (**70**) with bromine in acetic acid leads to 4-(1-adamantyl)-2-bromoacetanilide (**71**).¹²⁰

Treatment of 1-nitroadamantane with bromine in the presence of an equimolar amount of AlBr_3 was shown¹³¹ to afford 1,3-dibromoadamantane (**19**) in 26%–30% yield.

A method for the preparation of phosphorus-containing adamantanes by the reactions of hydroxy- and nitroso-substituted adamantanes with phosphorus trichloride or acid chlorides of trivalent phosphorus has been developed.^{132–134}

From the data presented above one can conclude that the introduction of the halogen atoms into adamantanes can be performed by various halogenating agents, *viz.*, halogens, hydrogen halides, thionyl chloride, chlorosulfonic acid, alkali metal halides in sulfuric acid, a mixture of nitronium tetrafluoroborate with pyridinium poly(hydrogen fluoride), *etc.* The choice of the reagent is dictated by the nature of leaving group. The $\text{NO}_2\text{BF}_4\text{--PyH}^+(\text{HF})_n\text{F}^-$ system is the most versatile reagent, which can be employed for the replacement of the hydrogen and halogen atoms and hydroxy groups in adamantanes by fluorine atoms. From the practical standpoint, the most convenient method for the introduction of a halogen into adamantanes consists in the treatment of hydroxy- and nitroso-adamantanes with hydrohalic acids or their salts in concentrated sulfuric acid.

IV. Synthesis of hydroxyadamantanes and their nitrates

Adamantane (**1**) and 1-bromoadamantane (**2**) are most widely used as starting compounds in the synthesis of hydroxyadamantanes and their nitrates.

Preparation of adamantane-1-ol (**4**) by the hydrolysis of 1-bromoadamantane (**2**) was described for the first time by Landa *et al.*¹⁴ This compound was also obtained by the reaction of 1-bromoadamantane (**2**) with silver nitrate in aqueous THF.¹⁵

The reactions of 1-bromoadamantane (**2**) with silver nitrate in different solvents (benzene, phenol, dichloromethane, diethyl ether) was studied; it was shown that 1-adamantyl nitrate is formed in quantitative yield if the reaction is carried out in ether.¹³⁵

Since the increase in the number of bromine atoms in adamantanes makes them more resistant to hydrolysis, 1,3-dihydroxy- (**84**), 1,3,5-trihydroxy- (**85**) and 1,3,5,7-tetrahydroxyadamantanes (**86**, 84% yield) were obtained by the reaction of the corresponding bromides with Ag_2SO_4 in concentrated sulfuric acid.^{136, 137}

Hydrolysis of 1,3-dibromoadamantane (**19**) in an autoclave at 190–200 °C in alkaline, neutral and acidic media affords 1,3-dihydroxyadamantane (**84**) in quantitative yield.¹³⁸ When the reaction is carried out at lower temperature, 1-bromo-3-hydroxy-

adamantane could be isolated. 1-Hydroxy-3-methyladamantane was obtained from 1-bromo-3-methyladamantane (**20**).¹⁰⁹

3-Bromoadamantane-1-carboxylic acid (**72**) undergoes the replacement of the bromine atom by the hydroxy group in 3 M aqueous alkali.¹²²

The rate constants for the hydrolysis of 1-bromoadamantane (**2**), 3-bromoadamantane-1-carboxylic acid (**72**) and 1,3-dibromoadamantane (**19**) (100 °C, 74% aqueous dioxane) were found¹¹⁸ to be equal to 7.98×10^{-4} , 1.3×10^{-5} and $2.4 \times 10^{-6} \text{ s}^{-1}$, respectively.

Hydroxyadamantanes were also prepared by the reactions of adamantane and its derivatives with sulfuric, nitric, fluorosulfonic and trifluoroacetic acids.

Treatment of adamantane (**1**) with a mixture of Br_2 and nitric acid affords 1-hydroxyadamantane (**4**).¹³⁹ This compound was also obtained by the action of 69% nitric acid on 1-bromoadamantane (**2**).¹⁴⁰

(a) HNO_3 , Br_2 , $\text{R} = \text{H}$; (b) HNO_3 , $\text{R} = \text{Br}$.

A one-step method for the preparation of adamantane-1-ol (**4**) from adamantane (**1**) by the reaction with a mixture of trifluoroacetic acid and Bu^tOH (55 °C, 12 h, the ratio $\text{AdH}:\text{Bu}^t\text{OH}:\text{CF}_3\text{CO}_2\text{H}$ is 1:2.5:17) in dichloromethane was proposed.^{141, 142} A reaction scheme including the intermediate formation of the adamantyl cation **3** was suggested.

The use of the system trifluoroacetic acid–56% nitric acid made possible the preparation of 1-aryl-3-hydroxyadamantanes by the replacement of hydrogen in aryladamantanes. In the case of reactive aryl substituents, the oxidation is accompanied by the nitration of the aromatic ring.²⁰ The reaction conditions and the yields of the corresponding alcohols are listed in Table 6.

Treatment of adamantane with 100% nitric acid affords 1-hydroxyadamantane-4-one in 77% yield.⁹⁸

Hydroxyadamantanes **87** were obtained by the reactions of adamantane (**1**) and its homologues with fluorosulfonic acid.⁵¹

$\text{R}^1 = \text{R}^2 = \text{H}$; $\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{H}$; $\text{R}^1 = \text{R}^2 = \text{Me}$.

1-Hydroxyadamantane (**4**) is a reaction product of adamantane (**1**) with the system bis(trimethylsilyl) peroxide–trifluoromethanesulfonic acid.¹⁴³

Adamantanes with the hydroxy group at the bridgehead carbon atom can be obtained by the isomerisation of 2-alkyl-2-hydroxyadamantanes on treating them with concentrated sulfuric acid. Thus 2-hydroxy-2-methyladamantane (**88**) is converted into tertiary alcohols **89–91** (a mixture of *Z*- and *E*-isomers) under the action of 96% H_2SO_4 .¹⁴⁴ The composition of the reaction products depends on the temperature and time of the reactions.

Table 6. Synthesis of hydroxyadamantanes.²⁰

Substrate ^a	<i>t</i> /h	Products	Yield (%)
AdC ₆ H ₄ Me-4 (2.4 : 1)	2	HO-  -C ₆ H ₃ Me-4-NO ₂ -3	20
		 -C ₆ H ₃ Me-4-NO ₂ -3	62
AdC ₆ H ₃ Me ₂ -3,4 (3.6 : 1)	3	HO-  -C ₆ H ₂ Me ₂ -3,4-NO ₂ -5	26
AdC ₆ H ₄ NO ₂ -4 (2.4 : 1)	2	HO-  -C ₆ H ₄ NO ₂ -4	60
AdC ₆ H ₄ Br-4 (1.2 : 1)	2	HO-  -C ₆ H ₄ Br-4	32
AdC ₆ H ₃ Me-4-NO ₂ -3 (3.6 : 1)	3	HO-  -C ₆ H ₃ Me-4-NO ₂ -3	58
AdC ₆ H ₄ CO ₂ H-4 (1.2 : 1)	2	HO-  -C ₆ H ₄ CO ₂ H-4	11

^a The ratio HNO₃ : substrate is given in parentheses.

At 25 °C, 2-hydroxy-2-methyladamantane (**88**) gives a mixture of alcohols **90** and **91**, while at 45 °C (10 min), 1-hydroxy-3-methyladamantane (**89**) is the major reaction product.¹⁹

In trifluoroacetic acid, 2-hydroxy-2-*R*-adamantanes isomerise into *Z*- and *E*-isomers of 1-hydroxy-4-*R*-adamantanes.¹⁴⁵

Thus the isomerisation of 2-hydroxy-2-methyladamantane (**88**) leads to a 1:1 mixture of *Z*- and *E*-isomers of 1-hydroxy-4-methyladamantane in 90% overall yield.

The well-known method for the preparation of alcohols such as deamination of amines is also used in the synthesis of hydroxyadamantanes.^{146–151} Thus the deamination of 1,3-diaminoadamantane (**92**) and 1-amino-3-hydroxyadamantane (**93**) by the action of NaNO₂ in acetic acid was shown to result in the formation of 1,3-dihydroxyadamantane **84**.¹⁴⁶

Besides the expected 1-hydroxyadamantane (**4**), adamantane (**1**) was identified as the reaction product in the deamination of 1-aminoadamantane (**80**).¹⁴⁹

The deamination of 1-aminoadamantane (**80**), including that in the presence of benzene and anisole, has been studied in detail.¹⁵⁰ It was expected that the adamantyl cation **3** would alkylate the arenes, react with external nucleophiles or rearrange.

However, no aryladamantane was found among the reaction products when the deamination was carried out in the presence of benzene or anisole (Table 7).¹⁴⁸

Table 7. Deamination of 1-aminoadamantane (**80**).¹⁴⁸

Reagent	Reaction conditions		Yield (%)	
	Solvent	<i>T</i> /°C	4	94
NaNO ₂	AcOH, H ₂ O	85	97.0±1.0	3.0±1.0
NaNO ₂	HCl, H ₂ O	85	100	
<i>n</i> -C ₅ H ₁₁ ONO	AcOH, PhH	refluxing	40.0±0.5	59.0±0.5
<i>n</i> -C ₅ H ₁₁ ONO	AcOH, PhOMe	the same	100	

The deamination of 2-amino-2-hydroxy- (**95**) and 2-amino-1,3-dihydroxy-adamantanes (**96**) is accompanied by a carbon skeleton rearrangement leading to the formation of tricyclic ketones **97** and **98**.¹⁵¹

Hydroxyadamantanes are also synthesised from the corresponding nitrates, which, as was mentioned above, are prepared by the treatment of adamantanes with nitric acid.²¹ Later, the reactions of substituted adamantanes with nitric acid in acetic anhydride was studied.¹⁵² In these reactions, 1-chloro- (**35**) and 1-bromo-adamantanes (**2**) produce nitrate **12** due to the replacement of the halogens. As regards adamantane-1-carboxylic acid

(73), 1-(trinitromethyl)adamantane (28) and the nitrate 12, they undergo the replacement of the hydrogen atom in the 3-position.

R = CO₂H, C(NO₃)₃, ONO₂.

Adamantanes with nitrogen-containing functional groups like NHCO₂Me and NO₂ react with nitric acid through the replacement of these groups by the nitrate group.

Upon treatment with a mixture of nitric acid and acetic anhydride, urethanes give nitrourethanes and 1-aminoadamantane (80) gives 1-nitroxy-3-nitroadamantane.¹⁵²

A method for the preparation of alkyladamantanols by the hydrolysis of the corresponding nitrates in 25%–30% nitric acid has been described.¹⁵³

R¹ = Me: R² = R³ = H; R² = Me, R³ = H; R² = R³ = Me;
R¹ = Et, R² = R³ = H.

The preparation of hydroxyadamantanes from their nitrates is the most convenient method, taking into account its simplicity and availability of the starting materials. Using this method, 1-hydroxyadamantane (4), 1,3-dihydroxyadamantane (84), 3-hydroxyadamantane-1-carboxylic acid and many other compounds have been synthesised.

Later, this method was extended to 2-substituted adamantanes.^{154–156}

V. Synthesis of adamantanecarboxylic acids

The Koch–Haaf reaction is widely used in the synthesis of carboxylic acids of the adamantane series. Adamantane (1), 1-bromoadamantane (2), 1-hydroxyadamantane (4) and its nitrate 12 are used as starting compounds.

Adamantane-1-carboxylic acid (73) was obtained by the reaction of 1-bromo- (2) or 1-hydroxyadamantane (4) with formic acid in sulfuric acid^{15, 157} or of adamantane (1) with formic and sulfuric acids in the presence of *tert*-butyl alcohol.^{158, 159}

As was shown by Langhals *et al.*,¹⁶⁰ the maximum yield (84%) of adamantane-1-carboxylic acid (73) was achieved when the ratio AdOH (4):HCOOH:H₂SO₄ was 1:1:24. The yield is decreased in a deficiency of formic acid.

Adamantane-1-carboxylic acid (73) was also obtained from adamantane (1) in 20% oleum.^{161, 162} The reaction is assumed¹⁶¹ to involve the intermediate formation of the adamantyl cation 3.

To synthesise adamantanecarboxylic acids from adamantane, the latter is made to react with CO in sulfuric acid or in oleum (autoclave, 90–160 °C).^{163, 164} This provides a mixture of adamantane-1-carboxylic acid (73) and adamantane-1,3-dicarboxylic acid in the ratio of 1:6.

(1-Adamantyl)acetic acid is synthesised from 1-bromo- (2) or 1-hydroxyadamantanes (4) and dichloroethylene in 80%–100% H₂SO₄ in the presence of BF₃ at 0–15 °C.¹⁶⁵ The preparation of adamantylacetic acids from functionally substituted adamantanes and adamantane homologues has also been described.¹⁶⁶

R¹ = Br, OH, OAc; R², R³, R⁴ = H, Me.

The reactions of adamantane and its derivatives with trichloroethylene in the presence of 90% sulfuric acid yield the corresponding α-chloroacetic acids.¹⁶⁷

X = H, Br, OAc; R¹, R² = H, Me; R³ = H, Br, CH₂CO₂H.

3-Alkyladamantane-1-carboxylic acids are obtained from alkyladamantanes in sulfuric acid in the presence of *tert*-butyl alcohol and 95% formic acid.

Using this approach, 3-methyl-, 3,5-dimethyl- and 3,5,7-trimethyladamantane-1-carboxylic acids have been synthesised in 72%, 49.8% and 38.5% yields, respectively.¹¹¹ Also, the synthesis of 3-methyl-,¹⁰⁶ 3-methyl-5-ethyl- and 3-bromomethyladamantane-1-carboxylic acids¹⁰⁷ as well as of 3-carboxymethyl-1-adamantyl-, 3-carboxymethyl-5-methyl-1-adamantyl- and 3-carboxymethyl-5,7-dimethyl-1-adamantylacetic acids¹²⁶ has been described. Adamantane-2-carboxylic acid was synthesised from 2-hydroxyadamantane (6).^{168, 169}

Adamantanecarboxylic acids bearing the trifluoromethyl groups were also prepared by the Koch reaction.¹⁷⁰

The reactivities of the trifluoromethyl- and trifluoroethyl-substituted adamantanes were shown¹⁷¹ to be lower than those of non-fluorinated adamantanes due to the more difficult hydride ion abstraction from the former with the generation of the corresponding carbenium cations. Therefore, the preparation of 3-fluoromethyladamantane-1-carboxylic acid from 1-trifluoromethyladamantane required that the reaction of the latter with CO was carried out in a mixture of nitric and sulfuric acids.¹⁷¹

Treatment of adamantane (**1**) or 2,2-difluoroadamantane (**51**) with a mixture of formic acid, SF₄ and HF in dichloromethane yielded trifluoromethyl-containing adamantanes (e.g., compound **99**) rather than the corresponding carboxylic acids. These are formed as the result of reactions of intermediate carboxylic acids with SF₄.¹⁴⁷

Studies of the reaction of 2-fluoroadamantane-2-carboxylic acid (**100**) with SF₄ and HF were undertaken to clarify the mechanism of these transformations.¹⁴⁸ This reaction afforded 4,4-difluoro-1-trifluoromethyladamantane (**99**), thus supporting the reaction scheme proposed earlier.¹⁴⁷

Dicarboxylic acids of the adamantane series were also synthesised by the Koch–Haaf reaction. Thus adamantane-1,3-dicarboxylic acid was obtained from 1,3-dibromoadamantane (**19**) or 3-bromoadamantane-1-carboxylic acid (**72**).^{16, 122}

A two-step synthesis of adamantane-1,3-dicarboxylic acid and (3-carboxymethyl-1-adamantyl)acetic acid from adamantane (**1**) or the corresponding monocarboxylic acids has been proposed.^{172–175}

Adamantane-1,3-dicarboxylic acid (**101**) or (3-carboxymethyl-1-adamantyl)acetic acid (**102**) can be prepared from the corresponding monocarboxylic acids. In these cases, the reactions are carried out in a mixture of nitric and sulfuric acids with formic acid or CO and dichloroethylene as the carboxylating reagents for the former and the latter, respectively.¹⁷³

Using regression analysis, it was established that the best yields of the acids **101** (94%) and **102** (66%) starting from adamantane (**1**) are achieved with a mixture of nitric and sulfuric acids in 60% oleum.¹⁷⁴

Dicarboxylic acids of the adamantane series, like the acid **102**, are of interest as starting materials in the synthesis of polyamides and polyesters.^{176–178}

Adamantanecarboxylic acids can be prepared from the corresponding nitrates. Thus adamantane-1-carboxylic acid (**73**) has been obtained in 94% yield from 1-adamantyl nitrate (**12**) and formic acid in sulfuric acid.^{104, 179}

The preparation of carboxylic acids **103** from aryl- and alkyl-substituted adamantyl nitrates **104** has been described.^{180–182}

R¹, R², R³ = H, Alk, Ar;

(a) HCO₂H, H₂SO₄ (*d* = 1.84 g cm^{−3}), *n* = 0;

(b) CH₂=CCl₂, H₂SO₄, *n* = 1.

Using this approach, the corresponding dicarboxylic acids have been obtained from nitrates of 3-hydroxyadamantane-1-carboxylic and (3-hydroxy-1-adamantyl)acetic acids, however, more concentrated sulfuric acid was required in this case.¹⁸³

A mixture of 1-formyladamantane and ethyladamantane-1-carboxylate results from the formylation of adamantane in CH₂Br₂ in an atmosphere of CO in the presence of superacid systems as catalysts.¹⁸⁴

VI. Aminoadamantanes

The great interest in the synthesis of amino-substituted adamantanes is caused first of all by the discovery that 1-aminoadamantane hydrochloride (**80**) is active against influenza virus.

Amines of the adamantane series are obtained by the reactions of 1-bromoadamantane (**2**), 1-hydroxyadamantane (**4**) or 1-adamantyl nitrates with ammonia, amines, amides or nitriles of carboxylic acids, urea, *etc.*

R¹ = Hal, OH, ONO₂; R² = H, Alk, Ar.

Oleum, concentrated H₂SO₄ or HNO₃ are used as an electrophilic medium. *N*-Adamantylamides are converted into the corresponding amines by alkaline or acid hydrolysis. 1-Aminoadamantane is synthesised from 1-bromoadamantane (**2**) under the action of ammonia at 200 °C for 6 h.¹⁸⁵

The preparation of compounds of the general formula AdNR¹R² [R¹, R² = H, Ph, Alk(C₁–C₁₂), AlkO, cyclo-Alk, HetAr, *etc.*] has been described.¹⁸⁶ Thus 1-dodecylaminoadamantane was obtained by the reaction of 1-bromoadamantane (**2**) with dodecylamine for 8 h.

1-Aminoadamantane can be synthesised under fairly mild conditions with the use of amides, e.g., formamide. The reaction of 1-bromoadamantane (**2**) with formamide is carried out in concentrated H₂SO₄.^{187, 188} *N*-(1-Adamantyl)formamide thus formed is converted into 1-aminoadamantane under the action of 10% NaOH or 20% HCl. This method served as the basis for the manufacture of 1-aminoadamantane hydrochloride (**80**) (Amantadine, Mydantan and Symmetrel).¹⁸⁹

The reactions of 1-hydroxyadamantane with alkylamides in trifluoroacetic acid have been proposed for the preparation of *N*-[1-(1-adamantanyl)alkyl]amides.¹⁹⁰

N-Alkyl-1-aminoadamantanes, including 1-methylaminoadamantane hydrochloride (**105**), were obtained from the bromide **2** and *N*-alkylacetamides.¹⁹¹ In these reactions, silver sulfate was used as an electrophilic catalyst.

The synthesis of aminoadamantanes by the reactions of urea or its alkyl derivatives with 1-halogenoadamantanes has been described in some patents.^{192–194} As a rule, the reactions are carried out at high temperature.

Stetter *et al.*¹⁹⁵ were the first to have studied the reactions of 1-bromo- (**2**) and 1-hydroxyadamantane (**4**) with acetonitrile in the presence of acid catalysts (the Ritter reaction). 1-Acetamidoadamantane was obtained by these reactions in 61% yield. Diethylene glycol was used as a medium for the alkaline hydrolysis of 1-acylaminoadamantane.¹⁹⁶

The reaction of hydrocyanic acid with adamantane (**1**) in sulfuric acid in the presence of a hydride ion acceptor leads to 1-formamidoadamantane. The influence of the reaction conditions on the yield of this product has been studied by Haaf.¹⁹⁷

The reaction is carried out at 21–26 °C in an excess of 96%–100% H₂SO₄ using the molar ratio adamantane:acceptor:HCN = 0.1:0.4:1.7.

R	X	Solvent	Time /h	Yield (%)
Bu ^t	OH	n-hexane	1.5	78
EtCHMe	OH	the same	2.0	75
Bu ^t	OH	cyclohexane	1.0	60
Bu ^t	Cl	CCl ₄	1.5	42

In the reaction of adamantane with acetonitrile under similar conditions, 1-acetamidoadamantane was obtained in 36% yield.¹⁹⁷

Nitriles of not only aliphatic monocarboxylic acids, but also of saturated dicarboxylic acids (maleic, adipic) and unsaturated monocarboxylic acids, *e.g.*, acrylic, have been used in the reactions with 1-bromoadamantane (**2**).¹⁹⁸

Adamantyl cation can be generated in the Ritter reaction using NOPF₆.¹⁹⁹ The reactions of 1-bromoadamantane (**2**) with acetonitrile and propionitrile in the presence of NOPF₆ and subsequent hydrolysis resulted in *N*-adamantylamides.

Alcohols react nicely with acetonitrile in the presence of H₂SO₄. Thus 3-ethyl-1-hydroxy-5,7-dimethyladamantane in the reaction with acetonitrile in sulfuric acid gives the corresponding acetamide **107**.²⁰⁰

The preparation of 3-aminoadamantane-1-carboxylic acid (**108**) from adamantane-1-carboxylic acid (**73**) has been described.²⁰¹

Diamines are of particular importance for the chemistry of polymers. Methods for the synthesis of diaminoadamantanes have been reported in several patents.^{102, 202, 203} Thus 1,3-diaminoadamantane (**92**) was prepared by the ammonolysis of 1,3-diiodoadamantane. The reaction is carried out at 260 °C under a pressure above 1000 atm.¹⁰² 1,3-Diaminoadamantane (**92**) is also synthesised by the reactions of hydrocyanic acid with 1,3-dichloro-, 1,3-dibromo- or 1,3-dihydroxy-adamantanes in sulfuric acid.²⁰²

Diaminodimethyladamantane (**109**) is obtained by the reactions of 1,3-dichloro- and 1,3-dibromo-5,7-dimethyl-adamantanes with acetonitrile.²⁰³

Nitrates of the corresponding alcohols can also be used as starting compounds in the synthesis of aminoadamantanes. Thus 1-acetamidoadamantane is formed in the reaction of 1-adamantyl nitrate (**12**) with acetonitrile.²⁰⁴

It was later shown that adamantane (**1**) and its homologues can be functionalised with urea in a mixture of acetic acid and HNO₃.²⁰⁵ The isolation of only the *N*-alkylation products of urea provides evidence in favour of the intermediacy of carbocations.

R = H, Me, Et.

Carboxylic acids can also serve as starting compounds in the synthesis of the corresponding aminoadamantanes.²⁰⁶ Thus adamantane-1-carboxylic acid (**73**) in 100% sulfuric acid produces the adamantyl cation (**3**), which then reacts with HCN or RCN

providing *N*-adamantylformamide or *N*-adamantylacetamide in 56% and 51% yields, respectively.

VII. Aryladamantanes

Halogenoadamantanes, adamantanol and their *O*-nitrates are used for the alkylation of aromatic compounds with adamantane.

The reaction of bromoadamantane (**2**) with benzene has been used by Stetter *et al.*¹⁵ to prepare phenyladamantane (**67**). The synthesis of some other adamantane-substituted aromatic compounds was also described.^{207, 208}

Either adamantane with several phenyl groups or benzene bearing up to three adamantyl substituents are formed in the reaction of 1-bromoadamantane (**2**) with benzene in the presence of Lewis acids, depending on the ratio of the reactants.^{209, 210}

1,3,5-Triadamantylbenzene (**110**) has been synthesised by the reaction of benzene or 1-phenyladamantane (**67**) with 1-bromoadamantane (**2**) in liquid SO₂ in the presence of AlCl₃.²¹⁰ A small amount of *p*-diadamantylbenzene was also isolated.

1,3,5-Triphenyladamantane and 1,3,5,7-tetraphenyladamantane have been synthesised by the reaction of 1-bromoadamantane (**2**) with benzene in the presence of *tert*-butyl bromide and a catalytic amount of AlCl₃.²⁰⁹

It was shown²¹¹ that the reaction of 1-bromoadamantane (**2**) with toluene in the presence of water resulted only in 4-(1-adamantyl)toluene, while a mixture of 4-(1-adamantyl)toluene and 3-(1-adamantyl)toluene was obtained in the presence of ZnCl₂ or FeCl₃.

1-Bromoadamantane (**2**) reacts also with naphthalene, 2-methylnaphthalene, biphenyl, anthracene, phenanthrene and fluorene to give the corresponding substituted adamantanes.²¹²

The reactions of naphthalene and its derivatives with 1-bromoadamantane (**2**) were the subject of several studies.^{213–219}

Thus the reaction of 1-bromoadamantane (**2**) with naphthalene in the presence of FeCl₃ at 60–140 °C leads to 2-(1-adamantyl)naphthalene. The second molecule of adamantane is introduced either in the 6- or 7-position.²¹⁵

According to Stewart–Breigleb models of 1- and 2-adamantyl naphthalene, the molecule of the former is much more sterically hindered due to the spatial interaction of the hydrogen at the C(2) atom of the adamantane fragment and the H(8) atom of naphthalene.

Attempts to obtain 2-(1-adamantyl)naphthalene by the isomerisation of 1-(1-adamantyl)naphthalene were unsuccessful. 2-(1-Adamantyl)naphthalene has been synthesised by the reaction of 1-hydroxyadamantane (**4**) with naphthalene in the presence of phosphoric anhydride.²¹⁶ *N*-Acetyl-1-aminonaphthalene is alkylated under these conditions with hydroxyadamantane to give the corresponding 4-adamantyl-1-aminonaphthalene.²¹⁶

Phenol, anisole, catechol, 2,6- and 3,4-dimethylphenols, *o*-, *m*- and *p*-cresols, diphenyl ether and others were also reacted with 1-bromoadamantane (**2**).^{220–227}

Thus phenol, 2,6- and 3,4-dimethylphenols and catechol react with 1-bromoadamantane (**2**) in the absence of a catalyst.²²²

R¹, R² = Me; R¹ = H, Me.

2,6-Di(*tert*-butyl)phenol and 2-methoxyphenol react with 1-bromoadamantane (**2**) at 130–140 °C to form 4-adamantylphenols. The alkylation of *m*-aminophenol with 1-bromoadamantane (**2**) leads to adamantane-substituted *m*-aminophenol.²²³ 4,4'-Diadamantyl diphenyl ether is formed upon heating of 1-bromoadamantane (**2**) with diphenyl ether in carbon disulfide in the presence of aluminium chloride. In the presence of zinc chloride and at elevated temperature, the oligomer **111** becomes the major product.^{207, 223}

The possibility of alkylation of phenylchlorosilanes with 1-bromoadamantane (**2**) has been demonstrated.²²⁸

It should be noted that the reaction of 1-bromoadamantane (**2**) with methyl(phenyl)dichlorosilane results in a mixture of mono- and polyadamantylbenzenes.²²⁸

1,3-Dichloro- and 1,3-dibromo-adamantanes react with aryl(alkyl)chlorosilanes at 160–200 °C in the presence of ZnCl₂ to give 1,3-di(alkylchlorosilylalkyl)phenyladamantanes **112**.²²⁹ 1-(Alkylchlorosilylalkyl)phenyladamantanes are also formed in appreciable yields.

X = Cl, Br; R = CH₂SiMe₃, C₂H₄SiMe₃, C₂H₄SiMeCl₂, C₂H₄SiCl₃, CH₂SiMe₂Cl, CH₂SiCHCl₂, CH₂SiCl₃.

1,3-Dibromoadamantane was found to be more reactive than its 1,3-dichloro-analogue and aryl(alkyl)chlorosilanes can be arranged according to their reactivity in the following order: PhCH₂SiMe₃ > PhC₂H₄SiMe₃ > PhC₂H₄SiMeCl₂ > PhC₂H₄SiCl₃ > PhCH₂SiCH₂Cl > PhCH₂SiMeCl₂ > PhCH₂SiCl₃.

Mono- (**12**) and dinitrate **13** were also used as the alkylating reagents. The nitrate **12** readily reacts with benzene, toluene, ethylbenzene, *p*- and *m*-xylenes and anisole yielding the corresponding mono- and di-substituted adamantanes.²³⁰ The preparation of 1,3-diaryladamantanes from the dinitrate **13** was also described.²³⁰

The nitrates **113** were used in the synthesis of diadamantyl-substituted arenes.¹⁸⁰

Reactions of 1-adamantyl nitrate (**12**) with such heterocyclic compounds as thiophene, 2-nitrothiophene, thiophene-2-carboxylic acid, furan and 2-furoic acid have been described.²³¹ The alkylation was carried out in concentrated sulfuric acid at -5°C ; the corresponding 1-hetaryladamantanes were obtained in 40%–60% yields.

Data concerning the relative reactivities of 1-bromoadamantane (**2**), 1-hydroxyadamantane (**4**) and its nitrate **12** in the reaction with isopropylbenzene have been reported.²³² The highest yield of *p*-adamantylisopropylbenzene was obtained from adamantyl nitrate.

In recent years, an efficient procedure for the introduction of the adamantyl substituent into the aromatic ring of crown ethers by their direct alkylation with hydroxyadamantane in the presence of boron trifluoride diethyl etherate as a catalyst has been developed.²³³

1-Hydroxyadamantane (**4**) has been used as an alkylating reagent for 1,2,4-triazoles and 5-R-tetrazoles.^{234–236} Its reactions with tetrazoles in 85% sulfuric acid gave the corresponding 2-(1-adamantyl)tetrazoles **114**, while a mixture of 2-(1-adamantyl)tetrazoles **114** and 1-(1-adamantyl)tetrazoles **115** was formed in 94% sulfuric acid.

(a) 85% H_2SO_4 ; (b) 94% H_2SO_4 .

The studies of the reactions of adamantanes in electrophilic media have expanded the general concept of the mechanism of C–H bond activation and made it possible to develop preparative methods for the synthesis of halogen-, hydroxy- and nitroxy-substituted adamantanes. The latter are of particular interest as starting materials. Among the methods of adamantane functionalisation, the reactions with urethanes, amides and nitriles in nitric acid or its mixtures with AcOH or Ac_2O are worth especial attention. Some of these reactions have formed the basis for technological processes in the manufacture of pharmaceuticals Remantadinum and Mydantan.

Abstract. Non-isothermal modes of branching-chain reactions are analysed. Characteristic features of these reactions caused by the simultaneous action of the reaction chain avalanche and self-heating are considered in terms of concepts of the modern theory. New data are presented indicating that chain branching is the predominant factor in gas combustion processes not only at very low pressures, as it was assumed earlier, but also at atmospheric and higher pressures. The specific character of the temperature dependence of the rate of chain reactions and data dealing with the discovery of a special chain combustion mode, chain thermal explosion, are considered. The efficiency of chemical control of chain combustion in any mode including explosion, flame propagation and its transition to detonation by virtue of highly efficient non-corrosive inhibitors is demonstrated. The bibliography includes 135 references.

I. Introduction

The significance of the discovery of branching-chain processes (BCP) and chain combustion^{1–3} for the development of chemistry is well known. A special place in the variety of the kinetic features of this frequently encountered class of reaction belongs to the combustion mode, which differs fundamentally from the 'purely thermal' combustion both in phenomenological features and the factors determining this mode. In recent years, it was shown that the branching-chain mechanism (BCM) predominates in most gas combustion processes not only at very low pressures, as had been considered until recently, but also at atmospheric pressure and at higher pressures. Combustion in air of virtually any hydrogen-containing compound (including hydrocarbon fuel), inorganic gaseous hydrides, and many pyrophoric compounds containing

no hydrogen follows a BCM. Branching-chain decomposition of, for example, nitrogen trichloride is known.³

Until recently, the theory of BCP has considered only isothermal chain combustion processes which take place at pressures factors of tens or hundreds lower than atmospheric pressure, mainly in the vicinity of the first ignition limit (P_1) (Fig. 1). Under isothermal conditions, no self-heating or convection is involved; therefore, chemical mechanisms play the crucial role. Thus, this approach proved fruitful in identification of the chemical factors and elucidation of their role in chain combustion. However, chain combustion processes at pressures markedly higher than P_1 are exothermic and proceed at high rates; hence, they are accompanied by a substantial increase in the temperature of the reaction mixture. The combined influence of two fundamentally different factors, the avalanche multiplication of the intermediate active species and self-heating, both accelerating the process, determines the specific character of virtually all features of branching-chain combustion, which differ fundamentally from those of 'purely thermal' combustion caused by self-heating and heat transfer. Unlike the theory of BCP, the scope of combustion

Figure 1. Region of self-ignition of a stoichiometric mixture of H_2 with O_2 in a reactor 7.4 cm in diameter with the surface coated with KCl.^{3,6} (1), (2) and (3) are the first, second and third ignition limits, respectively.

theory has actually been limited until recently to the latter type of combustion, this chemical process being represented as a simple one-step or, rarely, two-step reaction. Only quite recently was systematic investigation into the specific features of non-isothermal BCP started.

This review covers the regularities of BCP under non-isothermal conditions, brought about by self-heating of the reacting gas, and the role of chain mechanism over a wide range of pressures including the pressure region important for practical purposes. The data presented bring to light the governing role of chain mechanism under atmospheric and higher pressures in any mode of gas combustion; they demonstrate the specific pattern of the temperature variation of the BCP rate, disclose the chain thermal explosion mode and reveal the important role of BCM in the origination of detonation. Efficient methods and means for the chemical control of ignition, developed combustion, explosion and deflagration-to-detonation transition are described. New aspects of the relevant sections of the combustion theory and chemical kinetics are considered.

II. The main differences between thermal and chain ignition

Ignition and developing combustion are progressively self-accelerated chemical reactions. The kinetics of these reactions are characterised by not only increasing rates but also increasing accelerations (see, for example, Refs 3–5):

$$\frac{dW}{dt} > 0, \quad \frac{d^2W}{dt^2} > 0, \quad (1)$$

where W is the reaction rate and t is time.

Among other factors, ignition and combustion are governed by the positive feedback between the reaction rate and self-heating. Thermal ignition, caused by this factor alone, occurs if the rate of heat evolution (q_+) prevails over the rate of heat removal (q_-) and if the increase in the heat evolution rate upon rise of the temperature is more pronounced than the increase in the heat removal rate, *i.e.* the following conditions should be satisfied simultaneously:^{3–5}

$$q_+ \geq q_-, \quad (2)$$

$$\frac{dq_+}{dT} \geq \frac{dq_-}{dT}, \quad (3)$$

where

$$q_+ = WQ, \quad (4)$$

Q is the heat of the reaction,

$$q_- = \frac{\alpha S(T - T_0)}{V}, \quad (5)$$

α is the heat removal coefficient, S and V are the surface area and the volume of the reaction chamber, respectively, and $(T - T_0)$ is the difference between the temperatures of the reaction mixture and the reactor walls.^{3–6} The equality signs in relations (2) and (3) refer to the critical condition of thermal ignition.

In the theory of combustion, a chemical process is usually represented as a simple reaction, the rate of which depends on the temperature according to the Arrhenius law. Since the reaction rate (and hence, the rate of heat evolution), unlike the rate of heat removal, increase non-linearly with temperature, inequality (3) starts to be fulfilled, in addition to relation (2), after a definite temperature has been attained during heating. Therefore, accumulation of thermal energy in the reaction system becomes progressive, which results in an accelerated rise in temperature. Correspondingly, the chemical process becomes progressively self-accelerated, *i.e.* thermal ignition takes place.

Branching-chain ignition, unlike the thermal one, is caused by avalanche-like multiplication of active intermediate products — free atoms, radicals and, in some cases, excited species — upon

fast reactions with the starting reactants and with one another.^{1–8} This type of multiplication takes place if the rate of generation of active species, chain carriers (CC), is greater than the rate of their decay. The rate of BCP is

$$W = -\frac{d[B]}{dt} = w_0 + k_b n[B], \quad (6)$$

where $[B]$ and n are the concentrations of the starting reactant and the CC, respectively, w_0 is the rate of chain initiation, *i.e.* the rate of appearance of CC in reactions involving only the starting molecules, and k_b is the effective rate constant for chain branching (the rate-determining step of the process).^{1,3,8}

The change in the CC concentration is described by the equation

$$\frac{dn}{dt} = w_0 + (f - g)n, \quad (7)$$

where f and g are the branching and chain termination rates for unit concentration of CC (specific rates with respect to CC), equal to

$$f = 2k_b[B], \quad (8)$$

$$g = k_{het} + k_{hom}[B][M] \quad (9)$$

(k_{het} and k_{hom} are the effective rate constants for the heterogeneous and termolecular termination, respectively, and $[M]$ is the concentration of the gas mixture).^{1–3} The difference $(f - g)$ is often denoted by φ .

It follows from Eqn (6) that at initial stages of the process, when the decrease in the concentration of the starting compounds is still insignificant but the w_0 value can already be neglected, the following relations hold:

$$W \sim n,$$

$$\frac{dW}{dt} \sim \frac{dn}{dt},$$

$$\frac{d^2W}{dt^2} \sim \frac{d^2n}{dt^2} \quad (10)$$

because the relative change in the concentration $[B]$ is much smaller than the relative change in n .

It is obvious that for $f > g$, the concentration of CC increases with time with progressive self-acceleration, *i.e.*

$$\frac{d^2n}{dt^2} > 0. \quad (11)$$

The same follows from Eqn (7). Correspondingly, the rate of variation of the concentrations of the starting compounds in their reactions with active intermediate species, *i.e.* the rate of the process as a whole, increases progressively. This is indicated by relation (10) provided that inequality (11) holds. The attainment of a high reaction rate over a short period of time as a result of progressive self-acceleration is ignition. Thus, chain self-acceleration is caused by the positive feedback between the reaction rate and the CC concentration [see Eqns (6) and (7)]. Self-acceleration passes to the chain ignition mode in the case where multiplication of active intermediate species becomes avalanche-like because the multiplication rate exceeds the decay rate. Self-heating is not necessary for chain ignition. During progressive self-acceleration, high reaction rates can be attained; being exothermic, the reaction is accompanied by substantial light and heat evolution when the reactant concentrations are sizeable. This is a consequence of chain ignition alone.

It can be seen from Eqn (7) that, when $f < g$, the process occurs from the very beginning in a qualitatively different kinetic mode in which the increase in n (and, hence, in W) is retarded

$$\frac{d^2n}{dt^2} < 0.$$

In this mode, as the concentration of CC approaches the steady state value

$$n_{st} = \frac{w_0}{g - f}$$

the right-hand side of Eqn (7) and, correspondingly, dn/dt diminish and approach zero, which implies a complete cessation of increase in n and W . Since the rate of reaction between valence-saturated compounds w_0 is very low, it follows from the last-mentioned expression that under conditions where chain termination substantially prevails over chain branching (*i.e.* the g value noticeably exceeds f), the steady-state values of n and W are also extremely low.

Thus, the relation

$$f \geq g \quad (12)$$

is the condition for chain ignition. The equality sign determines the critical condition for transition from the steady-state mode, in which the reaction rate is extremely low, to the chain ignition and combustion mode.

For initial stages, when the variation of the f and g values during an isothermal reaction can yet be neglected, integration of Eqn (7) gives ^{1,3,7}

$$W = \frac{w_0}{f - g} \{ [\exp(f - g)t] - 1 \}. \quad (13)$$

It can be seen from this expression [see also Eqn (7)] that at $f > g$, the rate of the process increases with progressive self-acceleration, whereas at $f < g$, the increase in the reaction rate becomes less pronounced until a steady-state rate is attained.

It is noteworthy that, to consider the f and g values invariant with time, it is not enough to assume the process to be isothermal and neglect only the consumption of the initial compounds, as has been done until recently (see below). Heterogeneous propagation of reaction chains is not taken into account in Eqn (13) either.⁹

Since f and g depend on the initial reactant concentrations, temperature and the reactor geometry in different ways, the ratio of these parameters is governed by the reaction conditions. It has been found ^{1-3,6} that the specific patterns of the dependence of f and g on $[B]$ and $[M]$ and on the temperature stipulate the existence of two limiting pressures of ignition, which are both much lower than atmospheric pressure. For most combustible gases, these limiting values coalesce as the temperature diminishes, thus forming an ignition peninsula ^{1-3,6-9} (see Fig. 1).

If the chains branch upon reactions of CC not only with the initial molecules but also with one another (non-linear branching), the ignition condition can be written as follows:

$$f \geq g - 2(w_0 k_+)^{1/2}, \quad (14)$$

where k_+ is the effective rate constant for non-linear branching.³ When there is no external source of atoms or radicals, the second term in the right-hand part of the equation is much smaller than the first one and the ignition is actually determined by relation (12). Therefore, expression (12) is used in this paper, although the discussion equally refers to expression (14).

If the quadratic chain termination (*e.g.*, recombination of the CC) is taken into account in addition to the linear chain termination, characterised by the parameter g , the rate of variation of n in the one-center consideration can be written as

$$\frac{dn}{dt} = w_0 + (f - g)n - k_- n^2, \quad (15)$$

where k_- is the rate constant for the quadratic termination.

The solutions of Eqn (7) at $f > g$ are unstable (Lyapunov instability), while the solutions of non-linear equation (15) are stable at any ratio of f to g (when $f > g$, the stability is non-asymptotic). Proceeding from this fact, some researchers (see, for example Refs 10–15) who, unlike some other authors,¹⁻⁹ define ignition as a kinetic mode described by only unstable solutions of equations, concluded that chain self-ignition requires self-heating, allowing for which accounts for the instability of the solutions.

Thus they disclaimed one of the most important statements of the BCP theory, *viz.* the assumption that self-heating is not obligatory for chain self-ignition to occur. According to this view, it was proposed to elucidate the ignition conditions resorting to analysis of the character of solutions of the set of kinetic equations together with the heat balance equation and regarding the ignition limit as the condition of coalescence of stable and unstable singular points (bifurcation) on the concentration–temperature phase plane. However, this definition of ignition and this approach to the determination of its limit do not correspond to the essence of this phenomenon and, therefore, contradict experimental data. Experiments show that chain ignition is possible even when the reaction system is monotonically cooled provided that inequality (12) holds. This can be illustrated in relation to a model BCP — combustion of H_2 with O_2 above the first ignition limit.¹⁶ When the pressure is low (~ 0.1 Torr) and only slightly exceeds P_1 (by 5%–8%), burning lasts for 10–15 s after an induction period. In addition to the monotonic decrease in the pressure, caused by the reduction of the number of gas moles in the reaction, the specially arranged monotonic decrease in the temperature immediately after admission of the mixture in the reactor can also be observed during this period. Ignition was detected as the appearance of chemiluminescence after the induction period and the progressive acceleration of the consumption of the reactants.

It has been shown ¹⁷⁻¹⁹ that equations such as (15) (or, in a more general case, a set of equations with negative quadratic terms corresponding to the concentrations of CC), although all of their solutions are stable, describe two qualitatively different isothermal modes of BCP: progressive self-acceleration ($d^2W/dt^2 > 0$) up to high rates, *i.e.* ignition, and the extremely slow reaction with establishment of a steady-state rate ($d^2W/dt^2 < 0$). It was also demonstrated that transition from one isothermal mode to the other following variation of the initial conditions has a critical character and is determined by the equality

$$f = g \quad (16)$$

both with and without allowance for the quadratic termination. If the rate constants appearing in f and g are known, the critical conditions of ignition, for example, the first and second limits calculated from expression (16) taking account of (8) and (9), coincide with the experimental values (*e.g.*, see Refs 3, 8, 20–23). This confirms once again the statement that self-heating is not a necessary condition for chain ignition.

Thus, when the notion of ignition is defined correctly, kinetic equations permit one to describe its origin without self-heating. Strict mathematical analysis of differential equations of ignition and combustion in terms of the above definition of this phenomenon as a kinetic mode characterised by progressive self-acceleration has been carried out.^{24,25} The quantitative theory of the first and second ignition limits underlie precision methods for determination of rate constants.^{20,23,26-32} When reactions (most of all, bimolecular) of CC with one another and heterogeneous development of reaction chains are taken into account, the theory also describes quantitatively the kinetics of isothermal chain combustion near the first limit, isothermal critical phenomena within the ignition region, and hystereses of various kinetic characteristics over a broad pressure region.^{9,33-36}

Azatyán³⁷ has considered the difference between thermal and chain self-acceleration from the molecular-kinetic viewpoint, *i.e.* in terms of the mechanism assuming an increase in the number of species able to overcome the energy barrier to the reaction during the process (Fig. 2). The values marked on the abscissa axis are activation energies for the reactions of the initial molecules with each other (E_1) and with active intermediate species (E_2). The areas under the Boltzmann curves of the distribution of species over energy, to the right of E_1 and E_2 correspond to the number of the initial molecules whose energy exceeds the energy needed for them to enter into the reactions. As the temperature increases, the distribution curve shifts to the right (see Fig. 2); thus, the number

Figure 2. Equilibrium energy distribution of the initial molecules at temperatures T_1 (1) and T_2 (2) ($T_1 < T_2$); E_1 and E_2 are the activation energies of reactions of the initial molecules with one another and with chain carriers, respectively.

of molecules of the initial compound able to overcome the energy barriers E_1 and E_2 increases. In the case of BCP, the number of species able to overcome the energy barrier and enter into the reaction increases even if no rise in temperature occurs in the reaction mixture (the distribution function does not shift towards higher energies). This is due to multiplication of free atoms and radicals in their reactions with the starting compounds, which require overcoming the barrier E_2 , which is much lower than E_1 . The area under the distribution curve on the right of E_2 (the fraction of initial molecules capable of reacting with free atoms and radicals) is quite large even at relatively low temperatures. Since reactions of atoms and radicals with the initial molecules not only give final products but also result in regeneration and multiplication of these atoms and molecules, the process self-accelerates even without self-heating. If $f > g$, progressive self-acceleration is observed, *i.e.* ignition takes place. Thus, chain ignition and combustion are due to chemical factors; they differ fundamentally from the self-heating factors and can alone ensure the progress of the reaction in this mode.

In the chain combustion accompanied by self-heating, the distribution curve also shifts towards higher temperatures; therefore, the number of species capable of reacting increases due not only to the chain avalanche but also to an additional increase in the number of reactive substances (both intermediate and initial), caused by the rise in temperature. This enhances additionally the chain avalanche. The specific features of combustion caused by the joint effect of the chain avalanche and self-heating are considered in Sections V and VIII. When the initial concentrations of reactants increase above the region of the first limit, self-heating which accompanies chain combustion becomes more and more pronounced, its influence on chain combustion being largely determined by the specific character of energy liberation during these processes.

Thus, the phenomena of chain and thermal ignition are caused by fundamentally different factors; the processes determining the critical conditions for their origination and the mechanisms of self-acceleration are also dissimilar. Self-heating is not a necessary condition for chain ignition.

III. Specific features of the energetics of branching-chain processes

In simple exothermic reactions, the energy equal to the difference between the chemical energies of the initial and final components is converted only to the kinetic energy of particles, *i.e.* it is liberated as heat. On the contrary, the greater part of the energy evolved during the developing BCP combustion is converted into chemical energy of active intermediates. This is a crucial factor determining the kinetic features of BCP.

Table 1. Energy characteristics of the elementary reactions of a chain cycle.

Number of step	Reaction	ΔH /kJ mol ⁻¹	E /kJ mol ⁻¹
I	$\text{H} + \text{O}_2 = \text{OH} + \text{O}$	66.9	69.9
II	$\text{OH} + \text{H}_2 = \text{H}_2\text{O} + \text{H}$	-60.7	21.5
III	$\text{O} + \text{H}_2 = \text{OH} + \text{H}$	8.4	43.5
II	$\text{OH} + \text{H}_2 = \text{H}_2\text{O} + \text{H}$	-60.7	21.5
A	$2\text{H}_2 + \text{O}_2 + \text{H}_2 = 2\text{H}_2\text{O} + 2\text{H}$	-46.1	

Let us consider the liberation of energy in a developing chain combustion over one chain cycle[†] for the model reaction of H_2 with O_2 using a procedure similar to that used in a previous study.³ In this particular case, a chain cycle consists of the elementary reactions presented in Table 1; the Table also presents the respective changes in the enthalpy (ΔH) and the activation energies (E). The ΔH values were calculated from thermochemical data;³⁸ the E values correspond to the recommendations given in the literature.^{39,40}

It can be seen that each chain cycle yields two additional chain carriers, free hydrogen atoms, in addition to two molecules of the final product. If the overall reaction

followed a molecular pathway, it would give off 477.8 kJ mol⁻¹ of heat. Meanwhile, the real process A, which follows a BCM, affords only 46.1 kJ mol⁻¹ per branching-chain cycle, *i.e.* less than 10% of the heat of the overall process B.

As noted above, in conventional exothermic reactions, the difference between the chemical energies of the starting compounds and the reaction products is converted almost entirely into heat (to within a very small fraction of energy dissipated as radiation). Conversely, in a developing branching-chain combustion process, a substantial portion of the difference between the energies of the initial and final components is spent for the formation of free atoms and radicals, *i.e.* it is accumulated in the system as chemical energy of unpaired spins. This type of energy is the most rational for self-acceleration of the process not only due to the very high chemical reactivity of species with a free valence but also because they can be regenerated in reactions with the initial valence-saturated reagents. Indeed, the fraction of heat evolved during combustion and used to increase the number of the initial molecules able to overcome the energy barrier to a molecular reaction is extremely low because the activation energy is high. The rest of the thermal energy is dissipated or wasted in heating the final products. Meanwhile, the reactions of CC characterised by low energy barriers involve a much greater percentage of the initial molecules; in addition the free-valence energy (in the form of high reactivity) is actually transferred as a baton to the newly formed atoms and radicals and even provides for their multiplication. Only when the content of the initial reactants in the gas mixture decreases and the final stage of combustion, in which recombination becomes more significant, is approached, does energy evolve as heat. Of course, at the initial stages of the process when the content of reactants is still high, chain carriers also recombine partially, simultaneously with their participation in chain propagation (see Table 1, steps I–III). The role of chain termination by the route representing back reaction with respect to step I is especially significant in the combustion of hydrogen-containing compounds even at low pressures.⁹

The percentage of energy evolved in the chain termination, which ensures self-heating of the reaction mixture, depends on the rate of heterogeneous recombination, the heat of which is

[†] A chain cycle is the repeating set of several elementary reactions of CC including the CC regeneration.^{3,8,31}

extracted by the reactor walls. For example, at very low pressures (near the first limit), chain termination is heterogeneous, the energy evolved being almost entirely absorbed by the reactor walls. In the above example of energy evolution in a chain cycle, only the indicated $\sim 10\%$ of the energy of overall process B is evolved in the bulk of the gas phase. At low pressures, virtually all the heat evolved is extracted by the reactor walls through conductive heat transfer, because the duration of combustion is hundreds or thousands times longer than the characteristic time of heat removal. This accounts for the fact that virtually no self-heating is observed near the first limit.

The numbers of free atoms and radicals diminish upon recombination; nevertheless, the concentrations of these species in the area of branching-chain combustion are many orders of magnitudes higher than the thermodynamically equilibrium values and even than those concentrations which would exist without chain branching. This is confirmed by direct measurements of concentrations of atoms and radicals during chain combustion processes of various types (see, for example, Refs 41–47).

The overall reaction A of a chain cycle shows that only one third of the consumed dihydrogen is converted into atomic hydrogen. The rest of dihydrogen is used in the formation of H_2O . It is due to this fact that the free energy (G) decreases to a degree which permits accumulation of atomic hydrogen (and other CC), bringing about a local increase in G . The overall change in the free energy G is negative; therefore, combustion proceeds spontaneously. In view of the foregoing, it becomes clear that the statements that half the dihydrogen in an oxygen–hydrogen flame is converted into atomic hydrogen, which can be found in the literature (see, for example, Ref. 48), are at variance with the thermodynamic prohibition; indeed, realisation of this process would require absorption of a large amount of heat ($\Delta H \approx 200$ kJ per mole of O_2) and a nearly equal increase in the free energy (the entropy change is insignificant in this case). This means that such a process cannot occur spontaneously. It is also obvious that the number of free hydrogen atoms cannot exceed the number of H_2O molecules formed, even if they did not recombine at all (this can also be seen from the final stoichiometry of the chain cycle). Therefore, concentrations of hydrogen atoms (such as those presented in Fig. 136 in a monograph⁴¹) much greater than the total concentration of H_2O in the flames of stoichiometric (or enriched in the combustible component) H_2 – O_2 mixtures are impracticable.

Since the concentrations of excited species in branching-chain combustion are much higher than the equilibrium values, the radiation of such flame is much more intense than that in a non-chain combustion. In some processes, chain branching involves species in not only vibrationally^{49–55} but also electronically^{53, 54} excited states. The inverted population of energy levels corresponding to a branching-chain mechanism is used in chemical lasers.^{56–58}

Thus, high concentrations and high reactivity of reactive intermediate species as well as their ability to be regenerated and multiplied in reactions with the initial compounds determine the advantage of the BCM over a non-chain mechanism. This advantage is realised not only at low pressures.

It has been noted in studies,^{59, 60} devoted to the elucidation of the mutual influence of chain branching and self-heating, that, when $f > g$, the W , dn/dt and dW/dt values are related to n through positive feedback [see also Eqns (7) and (10)]. The branching rate constant (k_b), which is related to the kinetic coefficient f [see Eqn (8)], increases with temperature according to the Arrhenius law. The temperature dependence of g is much weaker than that for f . Moreover, as noted above, in the case of termolecular chain termination, g decreases with increase in temperature. Therefore, an increase in temperature sharply increases the difference $f - g$, which appears in Eqn (7) as a positive factor in n ; thus, the positive feedback of n with dn/dt , W , and dW/dt values is enhanced. The progressive growth of W

and dW/dt brings about a similar progressive increase in the rate of heat evolution (q_+) and a rise in temperature. Thus, self-heating intensifies the chain avalanche and the process acceleration, and the enhancing chain avalanche, in turn, accelerates self-heating. This non-additive combined action of chain branching and self-heating accounts for the specific character of non-isothermal BCP including the specific temperature dependence of the chain combustion rate.

IV. Temperature dependence of the specific rate of branching-chain processes

The kinetic features of a BCP have been considered in substantially fewer studies than the first and second ignition limits. The temperature dependence of the BCP rate has received even less attention. On the basis of experimental data referring to very low pressures, it has been found⁴¹ that the rates of combustion of H_2 and CO in oxygen are proportional to the rates of the steps

Relying on this fact, it was claimed that temperature variations of these and some other branching-chain processes ‘should evidently obey the Arrhenius law’. In another study,⁵⁵ this statement has been extended and it has been suggested that the rates of the rate-determining step and the chain process as a whole follow identical patterns of temperature variation. The fact that the chain propagation reactions (including the rate-determining step) constitute a branching chain is, however, ignored. This means that the temperature dependence of the reaction rate is determined not only by the temperature dependences of the rate constants of these steps themselves but, to a larger extent, by the temperature variation of the concentrations of chain carriers. Therefore, attempts to describe the temperature variation of the BCP rate by an Arrhenius function give different activation energies for the same chain process (depending on the process conditions);^{61–66} in addition, the resulting values are usually very high (in some cases, > 600 – 700 kJ mol^{−1}). This is not only much greater than the activation energy values typical of reactions involving free atoms or radicals but also exceeds the activation energies of reactions of the initial valence-saturated molecules with one another and even the energies needed to cleave the bonds in these molecules. Obviously, these ‘activation energies’ do not correspond to the real energy barriers to the reactions and only point to the fact that the temperature variation of the specific rate of a BCP deviates crucially from the Arrhenius law. This also follows from the unnaturally great magnitudes of ‘pre-exponential factors’ for the rate constants (see, for example, Refs 61, 65).

Vedenev *et al.*,¹⁵ who considered the role of self-heating in the ignition of H_2 and O_2 , transformed the exponential quantity of the Arrhenius function for the rate constant using the known⁵ ‘exponential quantity expansion’ technique. Subsequently, the resulting new function was expanded into the Taylor series with respect to the temperature, the series being restricted to the linear term. Meanwhile, the nonlinear character of the temperature dependence of the reaction rate is the most important feature of combustion; when it is neglected, the notion of combustion itself loses its meaning (see, for example, Ref. 5).

The temperature dependence of the BCP rate has been presented^{1, 7, 41} by the following expression:

$$W = \frac{A \exp(-E/RT)}{1 - B \exp(-E_1/RT)}, \quad (17)$$

where A and B are temperature-independent factors and E and E_1 are effective activation energies. However, this formula is inapplicable to a real process. Indeed, if $B \exp(-E_1/RT) > 1$, then $W < 0$, which has no physical meaning. In addition, at a particular finite temperature corresponding to the equality

$$B \exp\left(-\frac{E_1}{RT}\right) = 1,$$

the rate of the process becomes infinitely great, even at the beginning of the reaction, which has no physical meaning either.

The drawbacks of Eqn (17) are due to the fact that it has been derived using the following formula for the length of branching reaction chains (v_b):^{1,3,7}

$$v_b = \frac{\alpha}{\beta - \delta}, \quad (18)$$

where α , β and δ are the probabilities of chain propagation, termination and branching, equal to the ratio of the effective rate of the corresponding step to the sum of the rates of all these steps.

When deriving Eqn (17), Semenov^{1,7} substituted the v_b value expressed by Eqn (18) into the known relation

$$W = w_0 v, \quad (19)$$

where v is the chain length, and also took into account the temperature dependence of the rate constants included in the α , β and δ values.

However, we have shown⁵⁹ that Eqn (18), which has been used also in other studies,^{41,65,67} does not correspond to the real process. For example, for $\delta > \beta$, *i.e.* under conditions corresponding to ignition and combustion, it gives inevitably a negative value for the chain length. The $\beta - \delta$ difference, appearing in the expression for the flame propagation rate, has resulted (when $\delta > \beta$) in imaginary values for this rate.⁶⁷

In our study,⁵⁹ a fundamentally different expression for v_b has been proposed

$$v_b = \frac{(\alpha/\beta)[(\alpha\delta h/\beta)^m - 1]}{\alpha\delta h/\beta - 1}. \quad (20)$$

Here h is the average number of new branches for one branching step,

$$m = k_b[B]\alpha_1\delta t, \quad (21)$$

where α_1 is the probability that at least two of the active sites formed in the multiplication step enter into chain continuation reactions.

Unlike expression (18), Eqn (20) affords real, positive values of the chain length for any ratio of the branching and termination probabilities. This equation also shows that v_b (the length of the growing chain) increases with time, the kinetics of this increase being dependent on the ratio of probabilities of the reaction chain branching and termination, which is consistent with the essence of this phenomenon. Under conditions where the inequality $\alpha\delta h > \beta$ holds, the increase in v_b and, according to Eqn (19), also the increase in W proceed with progressive acceleration up to fairly high values. However, when $\alpha\delta h < \beta$, the increase in the v_b and W values slows down until steady-state values are attained. The critical point for the transition from one kinetic mode to the other is determined by the equality:

$$h\alpha\delta = \beta. \quad (22)$$

It can be seen from Eqn (21) that the exponential quantity m includes the k_b value, which is an Arrhenius function of temperature. Therefore, in the combustion mode, *i.e.* for $\alpha\delta h > \beta$, the temperature dependences of v_b and W_b contain a positive Boltzmann factor in the exponential quantity (the double exponent law) and, thus, they differ fundamentally from the Arrhenius law.

When deriving the analytical expression for the variation of the BCP rate as a function of temperature,⁵⁹ we took into account the fact that the contribution of w_0 to the rate of variation of CC concentrations in a propagating combustion process is insignificant, except for the very early steps of the process. This provides grounds for neglecting the w_0 value in Eqns (6) and (7) for the time

$t > t_0 \approx 2.5/\varphi$. Integration of the equation obtained in this way from Eqn (7)

$$\frac{dn}{dt} = (f - g)n, \quad (23)$$

with allowance for the f value [see Eqn (8)] and for the temperature dependence of k_b , gave the following expression for the temperature variation of the concentration of chain carriers:⁵⁹

$$n = n_0 \exp\left\{\int_{t_0}^t \left[f_0 \exp\left(-\frac{E_b}{RT}\right) - g\right] dt\right\}. \quad (24)$$

Here n_0 is the concentration of chain carriers at t_0 , E_b is the activation energy of branching, $f_0 = 2k_b^0[B]_0$, where k_b^0 is the pre-exponential factor for the constant k_b , $[B]_0$ is the initial concentration of the reactant B participating in the chain branching step.

By substituting this expression into the rate equation

$$W = k_b n_0, \quad (25)$$

we obtain the temperature dependence of the specific rate⁵⁹

$$\frac{W}{[B]_0} = k_b n_0 \left\{ \exp \int_{t_0}^t \left[f_0 \exp\left(-\frac{E_b}{RT}\right) - g \right] dt \right\}. \quad (26)$$

The rate constants for chain termination vary with temperature to an appreciably lesser extent than the rate constant for branching; therefore, the temperature dependence of the rate of the process is mainly determined by the first term in the square brackets.

Thus, when the difference $\varphi = f - g$ is positive, *i.e.* in the chain combustion mode, the increase in the specific rate of BCP with temperature is due not only to the increase in k_b but also (to a greater extent) to the substantial increase in the n value, the temperature dependence of which [see Eqns (24) and (26)] contains this rate constant and its Boltzmann factor in the positive exponential quantity.

This type of dependence was verified experimentally in relation to a model BCP, namely combustion of H_2 with O_2 near the first ignition limit.⁶⁰ The reaction was carried out at several temperatures, which were maintained in each experiment using a thermostat. The high-speed recording of pressure, chemiluminescence and temperature were carried out. Due to the low pressures of the mixture, exceeding only slightly the pressure of the first ignition limit P_1 , to heterogeneous chain termination, which ensured removal of the energy of recombination, and to the high rate of conductive heat removal, the process was virtually isothermal at each specified temperature. The time taken to reach the maximum reaction rate counted from the end of the induction period was 0.36–0.5 s, which is thousands of times longer than the time of heat removal. The degrees of conversion considered were relatively low; hence, the consumption of O_2 could be neglected without substantial error, *i.e.* the subintegral function in expression (26) could be considered to be constant. Thus, as applied to the given reaction, Eqn (26) can be represented in the form

$$\frac{W}{[O_2]_0} = k_1[H]_0 \exp\left\{\left[2k_1^0[O_2]_0 \exp\left(-\frac{E_1}{RT}\right) - k_{het}\right](t - t_0)\right\}. \quad (27)$$

In this expression, E_1 is the activation energy of the rate-determining step (branching), equal to 69.9 kJ mol⁻¹, and k_{het} is the rate constant for heterogeneous decay of H atoms, which is known^{3,8} to be equal to $2k_1[O_2]_1$, where $[O_2]_1$ is the O_2 concentration at the first ignition limit. This expression was used to determine the ratios of the rates of the virtually isothermal chain combustion at various temperatures. Table 2 presents the results obtained experimentally and by calculations using Eqn (27). The third column contains the value for the increase in the reaction rate calculated in accordance with the Arrhenius law using the same activation energy for the branching step.

Table 2. Ratios of the reaction rates at the temperatures 773 and 768 K.

$t - t_0 / s$	Experiment	Calculation by formula (27)	Calculation by the Arrhenius law
0.06	1.60	1.45	—
0.08	1.70	1.62	1.07
0.10	1.62	1.75	—

Since self-heating of the mixture in these experiments is rather weak and remains almost constant, it can be neglected when considering the ratio of the rates with an even smaller error. It can be seen from Table 2 that the experimental reaction rate increment caused by the rise in temperature is in agreement with that calculated from Eqn (27) and exceeds substantially the value expected relying on the Arrhenius law. Slight increase with time of the value presented in the third column is due to the fact that consumption of O_2 was not taken into account.

The unusually sharp temperature dependence of the branching-chain combustion rate ('the double exponent law') is brought about by the positive feedback relationship between the n value and dn/dt , W and dW/dt , considered above, which results in a non-additive combined effect of the chain avalanche and self-heating on the process rate. The double exponential law determines the enhanced sensitivity of the rate of a chain reaction to temperature variations; in particular, this facilitates fulfillment of condition (3). Yet another important feature of the temperature dependence of the BCP rate is that it varies exponentially as a function of the difference between the branching and chain termination specific rates ($f - g$). Therefore, both the reaction rate itself and its temperature dependence are highly sensitive to reactant concentrations and other parameters of the reaction system.

Equation (20) also indicates that, when the inequality $\alpha\delta h < \beta$ holds, the chain length reaches the steady-state value

$$v_b = \frac{\alpha}{\beta(1 - h\alpha\delta/\beta)}.$$

In accordance with equality (16), the process rate also reaches a steady-state value under these conditions, the self-acceleration of the reaction diminishing from the very beginning. Substitution of the v_b value from the last equality into Eqn (19), with allowance for the temperature dependences of the rates of the steps determining the α , β and δ values, gives an expression similar to (17), which refers only to a very slow steady-state reaction without ignition.

Thus, the BCP rate follows different temperature variation patterns, depending on whether the reaction occurs in the combustion mode or in the very slow mode without progressive self-acceleration.

The pattern of the temperature variation of the BCP rate identified in the study of Azatyan⁵⁹ provides an interpretation for the unusually high effective activation energies, different for the same reaction depending on the experimental conditions, found in the studies noted above. In fact, any continuous function, including that for the temperature dependence of the reaction rate, can be represented approximately, in some narrow range of the argument, in the form

$$W(T) = b \exp\left(-\frac{a}{RT}\right),$$

where a and b are coefficients which are constant over the temperature range considered and play the roles of activation energy and preexponential factor, respectively.

By taking the logarithm of both parts of this expression with allowance for the condition of contact between the specified and approximated functions and by differentiation with respect to T , we obtain

$$a = RT_0^2 \left[\frac{d \ln W(T)}{dT} \right]_{T_0}, \quad (28)$$

$$b = W(T_0) \exp \left\{ T_0 \left[\frac{d \ln W(T)}{dT} \right]_{T_0} \right\}, \quad (29)$$

where T_0 is the center of the temperature range considered. The rate of BCP depends sharply on the temperature [see expression (26)]; therefore, if this dependence is represented by the Arrhenius form, the derivative appearing in square brackets in expression (28), and, hence, the effective activation energy prove to be abnormally high. Since f and g , present under the first exponent in relation (26), depend on the process conditions in different manners [see Eqns (8) and (9)], the effective activation energy of this BCP should change appreciably upon variation of the reaction conditions. This is confirmed by all the experimental data. When the temperature variation of the BCP rate is described using an Arrhenius function, the 'pre-exponential factor' b found from Eqn (29) becomes too great and has no physical meaning.

V. The governing role of the branching-chain mechanism in the ignition and combustion of gases under atmospheric and higher pressures

The theory of BCP was based only on experimental data obtained under isothermal conditions because virtually all experimental studies on the kinetics of chain combustion have been performed at very low pressures in the absence of self-heating. It is clear that characteristic features of an isothermal process cannot be extended to non-isothermal conditions; therefore, the theory developed resorting to experimental data which refers only to isothermal regimes should be actually regarded as a theory of isothermal chain processes. Elucidation of the role of chain branching and avalanche multiplication of active intermediate species in the phenomenology of the process over a broad range of pressures (including atmospheric and higher pressures) presents considerable interest both for the theory of chemical kinetics and combustion and for the solution of applied problems related to the control of combustion modes.

It has been considered until recently that the BCM plays a crucial role only in combustion at very low pressures, tens or hundreds times lower than atmospheric pressure (see, for example, a number of publications^{3-7, 41, 55, 68-76}). Interpretation of the nature of the third combustion limit is an important point in the formation of these views. The pressure of this limit (P_3) for, for example, H_2-O_2 mixtures, lies in the range of > 40 kPa (which includes atmospheric pressure) and increases with a decrease in the temperature^{3, 6} (see also Fig. 1). According to the generally accepted views, ignition in the region of P_3 is a non-chain process brought about only by self-heating, which accompanies the reaction (see, for example, several publications^{3-7, 13, 41, 48, 55, 69-82}). An important role of a chain mechanism has been recognised only for very low pressures located in the ignition peninsula, closer to the first ignition limit (region I in Fig. 1).

The statement that the reaction in the region of P_3 is a thermally induced non-chain process has been substantiated by the facts that ignition at this (and higher) pressures is accompanied by great self-heating of the reaction mixture and by explosion and that the P_3 values for a hydrogen-air mixture calculated from the critical condition of thermal explosion^{5, 82} are in good agreement with the results of experimental measurements reported in other publications.^{83, 84} For instance, it has been stated in a monograph³ (p. 436) that 'the excellent agreement between the calculations and experiments indicates unambiguously that the third limit for mixtures of hydrogen with oxygen has a thermal nature.' Similar statements can be found in some other studies.^{4, 5, 41, 55}

The interpretation of the third ignition limit as a non-chain phenomenon is equivalent to the assertion that ignition and combustion of gases under atmospheric and higher pressures are induced only by self-heating. Indeed, since the third limit includes these pressures, the factors determining ignition and combustion play a crucial role at any pressure in the region of P_3 and above. In addition, since propagation of, for example, a laminar flame occurs as layer-by-layer ignition following the heat transfer from the burning area to a neighbouring layer of the mixture which has not yet reacted, the view of non-chain 'purely thermal' character of ignition at pressures near P_3 is equivalent to the statement that the flame propagates through a non-chain process.

Oxidation of hydrogen is usually regarded as a model BCP, because the main steps of its mechanism and a number of kinetic features are common to processes of this type. Many regularities of other branching-chain reactions and combustion processes are interpreted by proceeding from the views on the H_2 oxidation. This also refers to the view that the role of BCM at atmospheric and higher pressures and at high temperatures is insignificant. For instance, it is claimed in a monograph⁷⁰ (p. 52) that 'Branching-chain reactions are not so frequently encountered; moreover, for combustion temperatures above 1000°C, which exist even in the flames of dilute hydrogen–oxygen mixtures, thermal self-acceleration exceeds markedly the acceleration related to the branching-chain propagation. The latter is apparently the only mechanism of acceleration in some cool flames, for example, in CS_2 – O_2 cool flames. This self-acceleration mechanism seems to predominate also in the cool flames of hydrocarbons and other organic compounds. However, self-acceleration in so-called hot flames, *i.e.* those normally dealt with in practice, occurs by a thermal rather than chain mechanism.' Below it is also written that 'an increase in the temperature in a reacting system induces thermal explosion at pressures below those for which the condition of chain explosion is met ...' (p. 182).

Actually, this has been the generally accepted opinion. Even nowadays, only the two lower limits are usually considered to be the limits of chain ignition; plots for only these limits are usually included in the graphical depiction of chain combustion regions.^{3–7, 48, 58, 74–81, 85, 86} Branching-chain chemical processes are considered as a class of reactions, which although interesting, occur only in the exotic region of very low pressures and relatively low temperatures.

Characteristic features of combustion at higher pressures have been interpreted taking self-heating as the only reason for self-acceleration of the process (see, for example, studies^{3–7, 68–82, 87, 88}). Meanwhile, some specific features of combustion at atmospheric pressure point to a very important role of a chain mechanism. One of these features is the effect of small admixtures of propane on the ignition of carbon monoxide in air under atmospheric pressure; these admixtures can either promote or inhibit the reaction depending on the amount added (Fig. 3).⁸⁹ The important role of BCM in the combustion of gases is also indicated by the results of studies on the mutual effect of chain avalanche and self-heating and on the temperature dependence of the BCP rate, which refer not only to low but also to atmospheric and higher pressures.^{37, 59, 60} The contribution of a chain mechanism has been taken into account in the interpretation of ignition delay at near-atmospheric pressures⁹⁰ and in the numerical solution of equations related to combustion.^{91–93} However, as has been correctly noted,^{92, 94} combustion has been usually represented as a one- or two-step reaction, the temperature dependence of the reaction rate being written as an Arrhenius function (see, for example, Refs 95–98). Even when the steps that can compose reaction chains were taken into account in the numerical modelling of combustion, they were still inserted in the reaction mechanism together with a large number of other (including insignificant) steps. The relative roles of the chain and thermal factors either have not been considered at all or, in those cases where pressure exceeded the second ignition limit, ignition

Figure 3. Ignitability of a $CO + O_2$ mixture in N_2 vs. the content of propane at 0.1 MPa and 293 K; (1) in the presence of 0.11% of water vapour, (2) the mixture was dried with dry ice.

and combustion have been considered to be non-chain processes.^{72–76, 99–102} Although Zel'dovich *et al.*⁴ admits that most combustion processes follow chain mechanisms, he still considers these processes, as other researchers, only from the viewpoint of thermal combustion and uses the corresponding equations.

Our analysis^{103, 104} shows that the views according to which the BCM is restricted to the region of very low pressures are faulty. The substantial increase in the temperature and the appearance of thermal explosion are often regarded as evidence supporting the 'purely thermal' character of the third ignition and combustion limit under these conditions. However, any process, irrespective of its type and chemical mechanism, is able to switch to the thermal explosion mode provided that the conditions expressed by Eqns (2) and (3) are fulfilled.¹⁰³ This is equally true for chain processes. A specific feature of BCP is the fact that, owing to chain avalanche, reactions can proceed in the combustion mode even in those cases where conditions (2) and (3) do not hold. When these conditions are fulfilled, chain combustion passes into a mode in which the chain avalanche is accompanied by thermal avalanche. Moreover, in the case of BCM, transition to the thermal avalanche mode should occur in broader ranges of initial conditions and kinetic parameters than in the case of non-chain reactions. Indeed, if condition (12) holds and the reaction proceeds in the chain combustion mode, the rate of heat evolution reaches great values even at relatively low temperatures and low concentrations of the reactants. This facilitates fulfillment of the self-heating condition [see relation (2)]. In addition, the exceptionally sharp, non-Arrhenius temperature variation of the rate of chain combustion [see function (26)] makes easier the fulfillment of the second necessary condition for the generation of chain avalanche, relation (3). Therefore, as indicated by experimental data reported in the literature,¹⁰⁵ branching-chain combustion can readily switch to a mode involving a thermal avalanche (chain-thermal explosion) even when the reactant concentrations and temperatures are so low that thermal explosion is impossible and, hence, it is not observed in non-chain processes (see below).

Thus, substantial self-heating and thermal explosion do not give occasion for rejecting the important role of chain mechanism in ignition and combustion at atmospheric and higher pressures: these phenomena are also peculiar to branching-chain reactions. The agreement between the calculated and experimental temperatures of the third ignition limit is not a convincing argument either. These calculations were performed⁸² using the expression obtained for the critical condition of thermal explosion

$$\frac{QEr^2W}{RT_0^2\lambda} = \delta_{cr}, \quad (30)$$

where r is the radius of the reactor, λ is the heat conduction coefficient of the gas mixture, δ_{cr} is a dimensionless critical parameter; for example, for a cylindrical reactor it is equal to two.¹⁰⁶ The empirical formula for the rate constant for H_2 oxidation, obtained previously⁶¹ using the data related to pressures approaching P_3 ,

$$w = kP_{H_2}^2 P_{H_2O}, \quad (31)$$

(where P_{H_2} and P_{H_2O} are the partial pressures of hydrogen and the water vapour formed, respectively, and k is an empirical rate constant) was substituted into the above expression.

The temperatures of the ignition limit at atmospheric pressure found from expression (30) were consistent with the results of measurements^{83,84} carried out in reactors with various diameters. This provided grounds to conclude that BCM does not play any role in the ignition at the third limit and that combustion at these or higher pressures is brought about only by accelerating self-heating.^{3-5,41,55} In other publications,³⁻⁵ it has been assumed that a chain process is possible at the third limit over a KCl surface but only as an exception.

In our study,¹⁰³ we attracted attention to the fact that, since expression (30) was derived without any restrictions regarding the type of reaction or its chemical mechanism, it is also applicable to BCM. Therefore, the agreement between the results of calculations by Eqn (30) and experimental results can be considered equally reasonably to be an indication of a branching-chain reaction mechanism. It was also noted that Eqn (31) used in these calculations is empirical; it has been selected in accordance with the observed kinetics of the overall process. Therefore, the fact that Eqn (31) holds cannot serve as evidence supporting a molecular (rather than chain) mechanism either. Thus, the consistency of experimental data with the results of calculations according to Eqn (30), valid for reactions of any type, does not provide grounds for rejecting an important role of chain avalanche in combustion in the region of high pressures.

It is also noteworthy that, in addition to the experimental data mentioned above,^{83,84} which agree with the calculations,⁸² some other data which differ markedly from the calculated results are also known (see, for example, Refs 62, 63, 65). Since Eqn (30) was derived for reactions of any type, discrepancy between the data found from this equation and those obtained experimentally may point to inconsistency of some calculation variables with the experimental conditions; however, in some cases, this discrepancy can imply an inadequate description of the phenomenon by kinetic equations. For example, it is stated in a study¹⁰¹ devoted to the numerical simulation of hydrogen combustion that the calculation carried out with the assumption of a constant temperature does not attest to the possibility of sharp transition from the slow process mode to the ignition mode in the vicinity of the third ignition limit. According to this calculation, the reaction rate only increases smoothly following an increase in the initial pressure of the mixture, *i.e.*, the process does not proceed by a chain mechanism. This result, however, cannot be regarded as evidence for the 'purely thermal' character of the real ignition limit because the calculations were based on kinetic equations the order of which does not correspond to the real reaction course. More precisely, the equations in the study cited were set up under the assumption that the rate constants for the heterogeneous decay of active intermediate species (including HO_2 radicals) were proportional to the heterogeneous recombination coefficients, *i.e.*, it was assumed that the rate of heterogeneous chain termination is limited by the probability of adsorption of CC upon collisions with the surface (the kinetic control of heterogeneous chain termination) even at pressures of the third ignition limit. Meanwhile, by using known coefficients of the heterogeneous decay of the H and O atoms and OH and HO_2 radicals even on inert surfaces and the diffusion coefficients for these species and by comparing the rates of their decay in the kinetic and diffusion regimes, one can easily make certain that heterogeneous chain termination reactions at high pressures are mainly limited by the

diffusion rate rather than by the probability of adsorption upon collision with the surface. For example, the coefficients for the heterogeneous decay of CC reported in the study in question¹⁰¹ are matched by chain termination rate constants that are several times greater than those observed with the rate-determining role of diffusion and calculated by the known formula³

$$k_D = \frac{39D}{d^2}, \quad (32)$$

where D is the diffusion coefficient of an active intermediate species, d is the reactor diameter, and the numerical factor with D allows for the spherical shape of the reactor.

Thus, the slowest (rate-determining) step in the capture of active species by the surface under conditions used in the study cited¹⁰¹ is diffusion rather than the attachment of the species to the surface. Since the diffusion coefficient (and, hence, the rate 'constant' k_D) is inversely proportional to pressure, the order of kinetic equations with respect to the gas concentration should be three rather than two. Therefore, if the rate-determining role of diffusion is taken into account even when self-heating is neglected, solution of the set of kinetic equations in a particular temperature range indicates that, in addition to the two critical pressures (P_1 , P_2), there exists the third critical pressure (P_3) of chain self-ignition, which is much higher than P_1 and P_2 . When the initial pressure reaches each of these limits, the slow, steady-state reaction mode sharply switches to fast, progressive self-acceleration, *i.e.* ignition. When self-heating is not taken into account, the pressure P_3 becomes somewhat overestimated compared to the experimental value. This is due to the fact that at these high pressures, slight self-heating which accompanies the reaction in the slow mode facilitates somewhat the fulfillment of the condition of chain ignition; due to the slight increase in the temperature, chain branching starts to prevail over chain termination at lower pressures than it would occur without self-heating. An analytical expression indicating the presence of three self-ignition limits without self-heating has been obtained and verified by numerical solution of a set of equations.¹⁰⁷

In order to find whether ignition, combustion and explosion at high pressures are brought about by the avalanche-like progressive self-heating alone or they are due, most of all, to chain branching, one should consider a feature of the process peculiar to only one of these two accelerating factors, either self-heating or chain avalanche. As specific features exhibited near atmospheric pressure or at higher pressures, we have chosen¹⁰³ the dependence of the process kinetics and the P_3 value on the chemical properties of the reactor surface and the influence of minor admixtures on the ignition and flame propagation including its transition to detonation.

Experimental data demonstrating the dependence of the P_3 value and the process kinetics on the material of the reactor surface are known. For example, it has been shown^{4,29} that P_3 above a KCl surface is markedly higher than those above quartz and glass surfaces. Numerous data (see, for example several studies^{6,29,62,63}) indicate that the process kinetics at the third-limit pressures depend on the chemical properties of the reactor walls. Hysteresis phenomenon is known, which means, for example, that the kinetic behaviour of the reaction system in a particular experiment depends on what reaction has been carried out in the preceding experiment prior to evacuation of the reactor.^{6,62,108-111} However, these data have not been taken into account in considering the role of chain mechanism in the ignition and combustion near atmospheric pressure. Meanwhile, if the process were 'purely thermal', neither the reaction kinetics nor P_3 would depend on the material or, particularly, on the 'previous history' of the surface. This dependence is exactly a characteristic of radical and chain reactions. It is an integral feature of the third ignition limit and of the reaction kinetics observed when the reactants contact with a solid surface. It is also noteworthy that the results of calculations without allowance for heterogeneous chain propagation and chemical modification of

the surface cannot correspond to the process characteristics observed experimentally even though a large number of reactions are included in the process scheme and self-heating is taken into account. For example, the results of the calculation of the temperature dependence of the first ignition limit reported in a study¹⁰¹ do not correspond to the experimental data presented in the same publication because heterogeneous chain propagation is not taken into account. In some studies devoted to the numerical solution of sets of equations for the third limit, heterogeneous reactions are completely neglected (see, for example, Refs 112, 113).

The chain mechanism of the process at atmospheric pressure is also indicated unambiguously by the data on the influence of admixtures of some compounds on the ignition of various combustible gases; in some cases, the dependence of the efficiency of an admixture on its amount has an extremum (see Fig. 3).⁸⁹ Yet another example is the decrease in the upper concentration limit of hydrogen ignition in air at atmospheric pressure from 75% to 55% in the presence of 1.5% of dibromotetrafluoroethane.¹⁰³

Until recently, the influence of additives on ignition has been explained in applied studies either by dilution of the mixture and by the change in its thermal characteristics (increase in the heat capacity, acceleration of heat removal) or regarded as being equivalent to ionisation or chain termination without giving preference to either of these reasons (see, for example, Refs 114–117). However, small amounts of additives (0.3%–1.5%) cannot dilute a mixture, change heat capacity or decrease self-heating to a noticeable extent.

It is obvious that a theory in which self-heating is considered to be the only reason for the generation and progress of combustion cannot account for the pronounced influence of small admixtures of chemical substances on these processes at near atmospheric and higher pressures. It does not explain either the dependence of the efficiency of an admixture on its chemical properties or the above-mentioned extremum character of the effect of propane in concentrations of about tenths of percent. It is notable that the substantial effect of small admixtures on ignition and combustion, which, as can be seen from the given examples, is manifested, in particular, at atmospheric pressure, is actually ignored in the studies on the theory of combustion, in which various aspects of combustion, ignition and explosion are considered in detail. In some recent publications, the dissimilar influence of various admixtures on combustion has been taken into account by introducing empirical coefficients.¹¹⁶ However, the use of only empirical parameters to describe the features observed does not allow one to explain the essence of the phenomenon. In addition, when extrapolations or even interpolations are made, this can distort the results because empirical 'constants' usually vary as functions of concentrations, temperature, *etc.* Meanwhile, the influence of very small amounts of inhibitors on the ignition and combustion over the whole range of pressures (including atmospheric and higher) indicates that they affect the competition between the chain branching and chain termination processes. The effect of inhibitors is due to the fact that they react with atoms and radicals to give radicals of a different type unable to regenerate active species.³¹

Some investigators claim (see, for example, Refs 6, 117) that the inhibitory effect can be explained by assuming that the role of chain branching is substantial only up to the instant of ignition and that the inhibitor suppresses only this pre-flame mode, thus preventing heat evolution. However, one can easily make certain that a chain reaction can proceed at a noticeable rate outside the ignition region only in the case where the chain branching rate is a shade lower than the chain termination rate, *i.e.* if f is slightly smaller than g . On heating, the f value increases exponentially together with the rate constant for branching [see expression (8)], whereas the g value, which relates at these pressures to termolecular termination, decreases. Therefore, even when the self-heating is slight and is much smaller than that needed for thermal ignition, f becomes greater than g , *i.e.* condition (12) is met.

Thus, the mixture enters the region of chain ignition and ignites as a result of generation of a chain avalanche. For example, simple calculations carried out using Eqn (13) demonstrate that heating by only several degrees is enough for the ratio of branching to termination rates (f/g) in the $2\text{H}_2 + \text{O}_2$ mixture at 1 atm and 830 K to change from 0.95 (at which the reaction occurs in a steady-state mode and is virtually unnoticeable) to 1.05 and for chain ignition to occur. Note that under this conditions, substantial self-heating prior to ignition is impossible anyway, because the heat has time to dissipate due to the extremely low reaction rate ($f < g$).

Experimental data and the calculation using Eqn (13) demonstrate that, even when a mixture is located only 5% below the ignition region, the increase in the reaction rate becomes extremely low and soon ceases. Self-heating becomes substantial only under conditions of developed chain combustion and enhances the chain avalanche. However, as noted above, for self-heating to become a heat avalanche, fulfillment of condition (3) is also required. This requirement, however, can be not realised until the end of chain combustion (see below).

Analysis of the equation for the length of a branching chain and of the temperature dependences of the chain branching and termination rates has shown^{59, 103} that at any pressure, self-heating in a branching-chain process results first in the fulfillment of condition (12) and, only after that, does chain ignition occur.

The conclusions made in several studies^{59, 103, 104} concerning the predominant role of the BCM in the combustion at atmospheric and higher pressures and the simultaneous action of chain avalanche and self-heating have been verified experimentally.^{89, 105, 118–121} The governing role of the branching-chain mechanism in the combustion of carbon monoxide in air at atmospheric pressure was demonstrated in a study,⁸⁹ in which the main reactions responsible for the promotory and inhibitory influence of admixtures are also presented. As an example, below we consider the results¹¹⁸ dealing with the influence of various additives, inert diluents and chemically active compounds (inhibitors), on the ignition and on the intensity of combustion in the model hydrogen oxidation process. The reactions were carried out in a metallic evacuated closed reactor with a height of 25 cm and a diameter of 8.5 cm. Gas mixtures were prepared in the reactor according to partial pressures of the components with an accuracy of 0.6%. Within some period after the preparation, necessary for intermixing, the mixtures were conflagrated by pulse heating of a nichrome coil. The setup permitted the duration and power of the conflagrating pulse to be controlled. The chemiluminescence and pressure variations accompanying the ignition were detected using a FEU-39 photomultiplier (wavelength range 300–600 nm) and a quick-response pressure sensor, respectively. The signals from the sensors were recorded using a two-channel digital memory oscilloscope. After combustion had been completed, chromatographic analysis was carried out. The initial pressure of the mixture was 1 and 5 atm in various series of experiments.

The results of the measurements showed that the minimum concentration of argon needed to prevent the hydrogen–air mixtures of any composition from ignition, *i.e.*, the so-called peak concentration of the diluent, is higher than 85 mol. %. The peak concentrations of inhibitors are much lower: for dibromotetrafluoroethane [chladone (Halon) 114B2] and a complex inhibitor of the AKAM series they do not exceed 16% and 9.5% (Fig. 4). The addition of, for example, 2.5% of the AKAM inhibitor decreases the upper concentration ignition limit (UCIL) from 75% to 45%. Meanwhile, the same amount of argon decreases the UCIL only to 73%. The much higher efficiency of inhibitors compared to that of argon and the dependence of the effect of inhibitors on their chemical properties indicate that small admixtures of inhibitors (unlike argon) influence ignitability through chemical reactions with the chain carriers. Thus, ignition of H_2 , like that of CO , in the presence of hydrogen-containing compounds at the atmospheric pressure (see Fig. 3) follows a chain rather than a 'purely thermal' mechanism.

Figure 4. Concentration limits of ignition (1, 2) and boundaries of the chain-thermal explosion region (3) for hydrogen – air mixtures containing various amounts of inhibitors X: halon 114B2 (1) and AKAM-3 (2, 3); dashed lines correspond to ignition with a very high conflagration power in a small reactor.

The inhibitory action is due to fast reactions of the inhibitor with CC. In particular, the effect of the halon 114B2 is mainly determined by the reaction

resulting in the replacement of atomic hydrogen by a haloalkyl radical unable to regenerate chain carriers.

Experimental data obtained in a study¹¹⁸ made it possible to elucidate the role of a chain mechanism in a developed combustion process. Since hydrogen oxidation is accompanied by monotonic decrease in the number of moles of the gas mixture, the increase in the pressure observed during the reaction carried out in a confined space can be due only to rise in the temperature of the reacting gas, *i.e.* its self-heating. Correspondingly, the rate of the pressure increase and the maximum pressure surge characterise the intensity of combustion. The kinetics of the reaction can also be judged from the rate of the growth and the maximum value of the chemiluminescence intensity.

The experiment with variation of the mixture composition made it possible to identify two kinetic modes of combustion. In the absence of inhibitors, the combustion of mixtures of hydrogen with air containing more than 16 vol. % and less than 60 vol. % of H_2 proceeds in a mode characterised by a very sharp pressure increase — to 6–7 atm (the initial pressure being 1 atm). This pressure surge points to an increase in the temperature to at least 2000 K. The process is accompanied by a characteristic bang. The time it takes to reach the maximum pressure and chemiluminescence intensity in these mode is 1–2 ms, *i.e.* it does not exceed the characteristic time of the heat removal from the reactor. This is the explosion mode, the kinetics of which differ substantially from the kinetics of ignition occurring in mixtures with compositions close to the concentration limits, *i.e.*, those containing more than 60 vol. % or less than 16 vol. % of H_2 . The maximum pressures and chemiluminescence intensities and the rates of their growth attained in the ignition of these ‘near-limit’ mixtures are substantially lower. The temperature increases to 1300–1600 K. On smooth variation of the initial composition of the mixture, the transition of the process from one kinetic mode to the other is discontinuous, *i.e.* has a critical nature. Thus, ignition and combustion of hydrogen–air mixtures at atmospheric pressure can occur in two different kinetic modes depending on the initial composition; one mode does not involve thermal explosion, although it is accompanied by substantial self-heating, while the other one occurs as a thermal explosion. The parameters of the reactor used (calibre 3.1) precluded detonation. It is known that thermal combustion (unlike chain combustion) does not involve two different kinetic modes.

Figure 5. Dependence of ΔP_m on the initial content of admixtures X: argon (1), halon (2), AKAM-3 inhibitor in a mixture of 40% of H_2 with air (3).

To elucidate the role of chain mechanism in the kinetics of developed combustion, argon and inhibitors were admixed (in various amounts) to the initial mixture. The plots for the maximum pressure gain (ΔP_m) vs. the contents of various admixtures — argon and inhibitors (halon and AKAM) — in a mixture of 40% of hydrogen with air, based in the results of several series of experiments, are presented in Fig. 5. The dependence of ΔP_m on the amount of an admixture characterises the efficiency of the influence of this compound on the process. In the absence of additives, ignition and combustion of this mixture switch to the explosion mode described above. It can be seen from the Figure that the inert gas decreases the ΔP_m value only slightly. The explosive character of the process does not change. This influence of argon is due merely to the dilution of the mixture. The dependence of the efficiency of the action of halon and AKAM on the amount added (curves 2 and 3), when this amount is insufficient to dilute the mixture noticeably or to change substantially its heat capacity or heat conductivity, differs qualitatively from that observed for mixtures with an inert diluent. Curve 1 has no turns over the whole range of argon concentrations employed. Conversely, curves 2 and 3 exhibit sharp inflections at points a_1 , b_1 and a_2 , b_2 , respectively. When the concentrations of the admixtures correspond to points b_1 and b_2 , the maximum chemiluminescence intensity (not shown in the Figure) also changes abruptly. In addition, the efficiency of the influence of inhibitors on the combustion intensity is much greater than the efficiency of the influence of argon and depends on their chemical properties (*cf.* curves 1, 2 and 3). When the content of AKAM is greater than 3.4 vol. %, this hydrogen – air mixture does not ignite (no pressure and chemiluminescence growth are observed). At these inhibitor concentrations, the reactants are barely consumed after the source of conflagration has been switched on. The mixture can be ignited only when the content of halon is less than 6% and that of AKAM is less than 3.4%. Thus, a mixture containing 40% of H_2 and 3.4% of the inhibitor AKAM corresponds to the concentration limit of ignition. The same is true for a mixture with 6% of halon.

The smaller the amount of an inhibitor, the more intense the ignition: as the content of an inhibitor in the initial mixture decreases, ΔP_m increases (see Fig. 5). When the reactant mixture contains 3.2% of halon, the final degree of conversion of O_2 during combustion is 40%–50%. When the concentration of AKAM is higher than 1.2% or that of halon is higher than 3.05%, the combustion does not pass to explosion, although the increase in pressure, which accompanies the ignition, points to substantial self-heating. The intensity of combustion increases with a decrease in the concentration of the inhibitor. These facts indicate directly that in this mode, developing combustion is substantially depressed by the inhibitor; hence, the process follows a BCM and its kinetics are mainly determined by the competition between chain branching and chain termination. Thus, chain mechanism

determines the kinetic features of the process not only before ignition and during the induction period, as has been assumed in the consideration of the influence of admixtures on the delay of ignition, but also under conditions of developing combustion after ignition has started.

The absence of signs of explosion in this combustion mode implies that the chain avalanche developing due to fulfillment of condition (12) and accompanied by self-heating owing to fulfillment of relation (2) is the only factor which accounts for the progressive self-acceleration of the reaction. The condition for thermal explosion [inequality (3)] is not met for these mixtures and self-heating only enhances the chain avalanche. This implies that the combustion of mixtures with compositions close to the concentration limits, which occurs without explosion in the absence of inhibitors, is also due only to chain avalanche enhanced by self-heating.

The comparison of the action of inert gas and inhibitor admixtures in the experiment in question¹¹⁸ made it possible to establish the governing role of the branching-chain mechanism in the transition of combustion to explosion and in the explosion itself. When the initial content of the inhibitors decreases, the maximum combustion intensity and the ΔP_m value increase discontinuously (see Fig. 5, regions to the left of points b_1 and b_2). The time it takes to reach these maximum values decreases sharply and the process is accompanied by a click typical of an explosion. Judging by the ΔP_m value, the temperature in this case exceeds 2000°C.

Thus, there are two critical concentrations for each inhibitor, one of them corresponding to the ignition condition and the other (lower) corresponding to the transition of combustion into a chain-thermal explosion (see Fig. 4, curves 2 and 3, respectively).

The fact that the slopes of curves 2 and 3 on the left of points a_1 and a_2 in Fig. 5 are much greater than the slope of curve 1 means that in the explosion mode, too, halon and AKAM have a much stronger effect on the combustion than the inert gas. The difference between the slopes of curves 2 and 3 reflects the dissimilar efficiency of the inhibitors, which depends on their chemical properties. Hence, the effect of halon and AKAM on the explosion intensity, unlike that of argon, is due to chemical reactions (inhibition) rather than to dilution. The fact that the slope of curve 3 is greater than that of curve 2 is consistent with the greater inhibiting activity of AKAM compared to that of halon. These data indicate unambiguously that a chain mechanism predominates in the mode of combustion which is realised when conditions (3), (13) and (2) are fulfilled and which has been named¹¹⁹ chain-thermal explosion (CTE).

Experiments in which the initial pressure of the mixtures was 5 atm have given similar results.¹¹⁸

VI. Specific features of heterogeneous reactions determining the dependence of combustion characteristics on the surface properties at high pressures

Dependence of the kinetic parameters and critical conditions on the properties of the surface is an essential feature of BCP at any pressure. In particular, ignition limits include not only critical pressures or concentrations, as has been considered until recently, but also the dependence of these characteristics on the composition and properties of the surface adsorption layer and the ability of adsorbed species to enter into not only recombination reactions but also reactions leading to regeneration of CC. Therefore, to interpret correctly the characteristic features of the process, the reasons for this dependence should be identified and taken into account. In our studies,^{9, 36, 121} we interpreted the dependences of the process kinetics and the P_3 value on the properties of the reactor surface over a broad range of pressures (from a very low to atmospheric pressure), both found experimentally in the same studies and reported in the literature,^{6, 62, 63, 65, 110} within the

framework of the concept of the chain mechanism of ignition and combustion near atmospheric pressure and heterogeneous propagation of the reaction chains.^{9, 54, 122} The hysteresis phenomena mentioned above were also interpreted.[‡] The dependence of the BCP characteristics on the surface properties points unequivocally to an important role of heterogeneous reactions involving CC in the competition between the reaction chain branching and termination. Since the same amounts of reactants are admitted into the reactor in each experiment, the influence of a preceding experiment on the process characteristics is due only to reactions involving the adsorbed intermediate species, which have been formed in the previous experiment and have not been removed completely during evacuation. The atoms and radicals adsorbed on the surface can participate in the propagation of reaction chains. It has been established^{9, 33–36, 54, 122} that in the combustion of, for example, H_2 , heterogeneous chain propagation involves the HO_2 radicals formed in the reactions of adsorbed H atoms with O_2 and also in the gas phase. In this review, we consider those heterogeneous reactions which are significant at high pressures. It has been noted^{9, 122} that, due to high pressures, adsorption of HO_2 from the gas phase is limited by diffusion. Therefore, if each adsorbed HO_2 radical participated in chain termination, no dependence of, for example, P_3 on the properties of the surface would be observed. The presence of this dependence indicates that reactions of some of the adsorbed HO_2 radicals result ultimately in the regeneration of chain carriers, *i.e.*, active species that pass in the gas phase. The following reactions can be cited as examples of regeneration of CC with participation of adsorbed radicals:^{9, 36, 122}

where Z is an adsorption site, R is a radical, the arrow marks the departure of a species into the gas phase. In the first reaction, the H atom passes from an adsorbed HO_2 radical to an O_2 molecule which attacks it from the gas phase.

Since the rates of reactions of adsorbed species depend on the properties of the surface, these properties also influence the fraction of the surface HO_2 species that regenerate the CC. When this fraction (θ) is taken into account, the effective rate constant for the heterogeneous chain termination is

$$k_{het} = k_{het}^0(1 - \theta), \quad (33)$$

where k_{het}^0 is the rate constant for the capture of CC by the surface. Unlike k_{het}^0 , which is determined by the rate of diffusion, the θ value depends on the type of bonding between HO_2 and the surface, *i.e.* on the properties of the surface adsorption layer.³⁶ Therefore, despite high pressures, k_{het} depends on the state of the surface. The surface is subject to the action of the chain reaction products. During evacuation of the reactor, the chemisorbed radicals are removed incompletely, and, after a new portion of the mixture has been admitted, they react with the gas-phase components of the fresh mixture; it is in this way that the 'surface memory' is manifested. The hysteresis phenomenon is also observed in many catalysed oxidation and pyrolysis processes.^{108–111, 123}

It has been shown^{9, 36} that regeneration of atoms and radicals with participation of the CC adsorbed from the gas phase (heterogeneous chain propagation) differs fundamentally from the heterogeneous formation of active species in the reactions involving only initial molecules (heterogeneous initiation). This difference is due to the much higher rates of heterogeneous chain

‡ It is noteworthy that until recently, the majority of researchers have not taken into account heterogeneous chain propagation (see, for example, Refs 92–95, 98).

propagation reactions and to their more important and diversified functional role in BCP. It is this type of reaction rather than chain initiation (which is significant in catalytic reactions according to the generally accepted view) that accounts for the dependence of the process kinetics on the properties of the surface (including hysteresis). Under certain conditions, heterogeneous chain propagation also influences the critical conditions for flame propagation¹²¹ and CTE.¹⁰⁵

VII. The role of chain mechanism in the transition from deflagration combustion to detonation

The branching-chain mechanism plays the governing role in the ignition and combustion at atmospheric pressure; therefore, competition between chain branching and termination also has a crucial influence on the propagation of, for example, a laminar flame, *i.e.* layer-by-layer ignition of a combustible gas. This conclusion was verified experimentally in a study of the influence of inhibitors on the rate of flame propagation¹¹⁸ and in a study dealing with the dependence of the concentration limits of flame propagation on the composition of the adsorption layer on a contacting surface.¹²¹

The influence of inhibitors on the flame propagation velocity was studied in 2-m long horizontal tubes with diameters of 2.4 and 5.4 cm. The ignition was carried out at the end face of the tube and the track of the flame was recorded based on chemiluminescence, the signal of which entered a photoelectric multiplier through three quartz windows, located along the reaction tube, and a branched optical waveguide. It was shown that inhibitors not only narrow down the concentration range of ignition but, at concentrations lower than the first critical concentration (*i.e.* corresponding to the regions confined by curves 1 and 2 in Fig. 4), they also decrease the flame propagation velocity. In addition, if the flame is not stationary and accelerates, inhibitors decrease the acceleration rate. Thus, chain branching also plays the governing role in flame propagation, and this enables one to control both its concentration limits and velocity by using inhibitors. When the inhibitor concentration exceeds a certain value, the flame becomes diminishing.

A correlation between the critical conditions for flame propagation and the chemical properties of the surface contacting with the gas has been elucidated.¹²¹ The study was based on the hysteresis of the upper concentration limit of flame propagation discovered and studied for the combustion of hydrogen in air in a reactor characterised by an especially great surface area-to-volume ratio. When the initial content of H₂ in the mixture was successively increased in each experiment (*i.e.* when the limit was approached from the side of the ignition region), higher values were attained than in the case where the concentration of H₂ decreased and the limit was approached from the side of non-ignitable mixtures. The reactor was evacuated after each experiment; therefore, the dependence of the critical condition of ignition on whether or not combustion had occurred in the previous run was due only to the change in the chemical properties and functions of the adsorption layer of the reactor surface under the influence of intermediate products of combustion, namely, adsorbed CC (see the previous Section). These results are directly related to the filtration and catalytic combustion.

Transition from deflagration to detonation is known to occur as a result of progressive self-acceleration of a flame to velocities higher than the sound velocity (and generation of a shock wave thereupon) at the cost of the energy of a chemical reaction.^{4,6} The fact that inhibitors retard the flame propagation and switch it to a damped regime permitted us to conclude that transition of deflagration to detonation can be prevented by using inhibitors. This was accomplished in another study¹²⁴ for various conditions of combustion at atmospheric pressure. The results of bench testing of an air-feed jet engine are presented in Fig. 6. Suppression of detonation in a hydrogen–air mixture containing 40% of H₂ was also attained in a plexiglass reaction tube of length 600 cm

Figure 6. Regions of normal and detonation combustion of hydrogen–air mixtures for the operation of a bench of an air-feed jet engine in the presence of various amounts of the AKAM inhibitor; (1) detonation, (2) normal combustion.

by introducing 2.5% of an inhibitor of the AKAM series.¹⁰³ High-speed filming made it possible to determine exactly the site where detonation arose. It was shown that addition of 0.5% and 1.0% of an inhibitor extends substantially the induction period of detonation and, when the amount is > 2%, detonation does not occur.⁸

It has been shown²¹ that heterogeneous propagation of reaction chains influences the reaction kinetics not only under conditions of developed combustion but also during the induction period (τ). This manifests itself as a decrease in the time τ and as a hysteresis similar to the hysteresis of the upper concentration limit of flame propagation in hydrogen–air mixtures described above.¹²¹ In both cases, the phenomenon is due to the heterogeneous chain propagation reactions involving adsorbed atoms and radicals left on the surface after the previous experiment, because evacuation of the reactor between the experiments does not remove completely the adsorbed species. Heterogeneous chain propagation might influence in a similar way the induction period of detonation in the transition of deflagration combustion to detonation, for example, in shock tubes. This should show as shortening of the pre-detonation period under the influence of detonation of a stoichiometric mixture or a mixture enriched in the combustible component performed in the preceding experiment. Under these conditions, despite the high pressures, the access of gas species to the surface is facilitated by turbulence.

The temperatures typical of a hydrogen detonation wave in air are 2100–2800 K depending on the composition of the mixture.⁴ In addition to the experimental data presented above, the determining role of a chain mechanism at these temperatures and atmospheric pressure is confirmed by comparison of the rate of consumption of dioxygen in the reaction with H₂¹⁰³

which is the rate-determining step of the process occurring by a molecular mechanism, with the rate of dioxygen consumption in the chain pathway, *i.e.* in the reaction with atomic hydrogen

This step determining the rate of the reaction chain is followed by chain continuation steps

The ratio of the rate constants for these reactions, k and k' found using concentrations of atomic hydrogen in H₂ flames at 2500 K recommended in reference literature^{39,40} and those measured experimentally or calculated^{125,126} is less than

§ The study on the inhibition of detonation was partly performed together with H Gg Wagner.

5×10^{-2} . Thus, more than 95% of O_2 is consumed in the chain process even without allowance for the fact that the primary reaction products are atoms and radicals able to start reaction chains.

At high pressures and temperatures, in addition to the above step, an important channel of branching is provided by the following sequence of reactions (see, for example, Ref. 107):

The above data pointing to the predominant role of the chain mechanism even at about 2500 K also indicate that under conditions where detonation has already occurred, inhibitors are still able to influence the process substantially up to destruction of the detonation wave.

Thus, despite the fact that chain combustion at high pressures is accompanied by intense self-heating of the reaction mixture, which enhances the chain avalanche and, under particular conditions, switches the process to the CTE mode, it is sufficient to weaken the chain avalanche, for example, by adding a small amount of an inhibitor, to diminish appreciably the rate of any mode of the process down to complete suppression of the combustion.^{16, 103, 105, 118, 121, 124} The high sensitivity of the process to the influence of inhibitors is due to the fact that the BCP rate, the temperature dependence of the BCP rate and other important characteristics of the process are largely determined by the difference between the chain branching and termination rates [$f-g$, see Eqns (7) and (20)] rather than by the absolute magnitudes of these rates. Therefore, to suppress combustion, the inhibition rate should not necessarily be close to the branching or termination rates taken separately. It is only required that the inhibition rate be commensurate with the difference between these rates. Note that the difference $f-g$ appears in the exponent of power in the function for the temperature dependence of the BCP rate.

The concentration limits of ignition of hydrocarbons in air are markedly narrower than those for ignition of hydrogen–air mixtures (see, for example Ref. 6), although heats of combustion of hydrocarbons are much greater. This is due to the fact that the combustion is inhibited; the hydrocarbon itself acts as the inhibitor because the chain carriers H, O and OH react with its molecules and are thus replaced by less reactive intermediate species.³¹

To conclude this section, we shall list briefly the characteristic features of gas-phase combustion near atmospheric pressure that cannot be interpreted without taking account of the governing role of the branching-chain mechanism of the process and competition of the reaction chain branching and termination.

1. The substantial influence of inhibitors and promoters on all modes of combustion including ignition, developed combustion, explosion, deflagration flame propagation and transition to detonation.

2. The presence of two different kinetic and, correspondingly, thermal modes of chain combustion; the critical character of transition of the process from one mode to the other.

3. Dependence of the critical ignition conditions, the chain-thermal explosion, flame propagation and the process kinetics on the properties of the contacting surface and on the composition of the adsorption layer even if the access of CC to the surface is limited by diffusion.

4. The unusually strong temperature dependence of the specific rate of the process, which differs fundamentally from the Arrhenius law.

5. The much narrower concentration limits of ignition for hydrocarbons in air compared to those for hydrogen in air, although the molar heats of combustion of hydrocarbons are substantially higher.

Unlike the traditional, ‘purely thermal’ approach, the theory of non-isothermal chain processes developed in a number of studies,^{59, 103, 104, 119, 121} which takes into account not only linear but also non-linear heterogeneous and homogeneous reactions of CC and heterogeneous chain propagation, accounts for all the above-listed and some other features observed. Previously these characteristic features of combustion have not been considered.

VIII. Thermal modes of chain combustion in the low-pressure region

When conditions of chain combustion ensuring self-heating of the system are met and the rate of chain combustion obeys a very strong, non-Arrhenius temperature dependence, which facilitates the fulfillment of condition (13), chain combustion is able to switch to the CTE even at low pressures and temperatures, where processes not occurring by a branching-chain mechanism cannot pass to the chain explosion mode. This has been demonstrated^{16, 105, 125} for the oxidation of H_2 , SiH_4 and GeH_4 . It was shown in these experiments that existence of two different kinetic (and, correspondingly, thermal) modes is peculiar to branching-chain combustion irrespective of whether or not heat and mass transfer, convection, or concentration and temperature gradients are present in the system.

Combustion was performed in temperature-controlled heated quartz reactors, the walls of which had been treated preliminarily with hydrofluoric acid, which ensured small coefficients for the decay of CC on the surface, kinetic control of the heterogeneous chain termination and very low P_1 values. This virtually excluded the presence of CC concentration, process rate, or temperature gradients in the reactor; thus, combustion was uniform throughout the whole bulk. The use of mixtures prepared beforehand ruled out the possibility that the process would be controlled by diffusion. High-speed recording of chemiluminescence in the wavelength range of 200–600 nm and at the pressures of the mixture was carried out from the instant the reaction mixture was admitted into the evacuated reactor until the combustion was over. In experiments with SiH_4 and GeH_4 actual concentrations of these compounds were also recorded based on the intensity of the corresponding absorption bands in the IR spectra. Prior to the measurements, the mixture under study was ignited repeatedly until quantitative reproducibility of the state and properties of the surface was attained.

The ratio of chain branching to termination rates was varied by changing the initial pressure of the mixture, and, hence, the reactant concentrations inside the ignition region. When the pressures P_0 exceeded the first ignition limit, the branching rate for unit concentration of CC, *i.e.* the f value, increased proportionally [see also expression (8)]. Since the role of termolecular reactions near the first ignition limit is insignificant, the g value [see expression (9)] is virtually equal to k_{het} . Upon an increase in P_0 , this constant does not change or even decreases if the rate of capture of chain carriers by the surface is limited by diffusion to the surface. In both cases, in the low-pressure region, an increase in P_0 results in higher f/g ratios and, what is more important, the difference $f-g$ also increases. Correspondingly, the growth of n and W is enhanced [see Eqns (7) and (10)] and heat evolution accelerates. As a consequence, under conditions of developed combustion, self-heating is significant even at pressures slightly exceeding P_1 ; it sharply increases on further increase in P_0 . This pressure dependence of the process characteristics permitted the researchers to vary the kinetics of combustion and, correspondingly, the intensity of heat evolution.

To record correctly self-ignition from its very beginning and to transfer combustion to explosion, a special technique was used which ensured that the delay time of self-ignition was longer than the time it took for the gas mixture to enter a heated reactor and for a stationary pressure to be established. The essence of the method is introduction into the reaction mixture of tenths of percent of ethane as an inhibitor, which delays the ignition, being

partially consumed. The ignition occurs only after the diminishing concentration of the inhibitor reaches a critical value. The remainder of the inhibitor burns during the ignition, and combustion proceeds in the presence of the inhibitor, which is rapidly spent.

As an example, Fig. 7 presents the pressure oscillograms for the combustion of a stoichiometric mixture of H_2 with O_2 in a reactor with a diameter of 5.5 cm.¹⁶ Point *A* corresponds to the beginning of the admission of the combustible mixture to the reactor and point *B* marks the onset of self-ignition. Since the number of moles of the gas mixture steadily decreases during the hydrogen oxidation, the observed increase in pressure during the propagating combustion can be due only to self-heating of the mixture, as in the experiments at high pressures described above. The initial pressures in runs 1 and 2 differed by 2.25%, those in runs 2 and 3 differed by less than 0.5%. Nevertheless, as can be seen from oscillograms, the combustion kinetics in runs 2 and 3 were much more different than those in runs 1 and 2. The maximum self-heating in runs 1 and 2 was 200–250°C (measurements were carried out using a quick-response gas thermometer — a high-sensitivity quartz membrane manometer). Meanwhile, self-heating in runs 3 and 4 was almost an order of magnitude greater. It can be seen that variation of P_0 in the vicinity of a particular value (in this case, 26.7 Torr) resulted in a discontinuous change in the maximum temperature (see Fig. 7*b*). The ignition in runs 3 and 4 and at higher initial pressures was accompanied by a sonic effect — a click. These findings indicate that in runs 3 and 4, condition (3) holds in addition to relation (2). Thus, runs 1 and 2 correspond to non-isothermal chain combustion without explosion, whereas runs 3 and 4 correspond to a CTE realised at very low pressures. Attention is attracted to the low activation energy of the rate-determining step of the process, namely reaction I ($< 70 \text{ kJ mol}^{-1}$).

Figure 7. Pressure oscillograms for combustion of a stoichiometric mixture of H_2 with O_2 in a reactor of diameter 5.5 cm at an initial temperature of 728 K (*a*) and change in temperature vs. initial pressure of the reaction mixture in the same experiments (*b*).

P_0/Torr : (1) 26.1, (2) 26.7, (3) 26.8, (4) 27.2.

Figure 8 shows the temperature dependences of P_1 and P_2 (curves I and IV) measured in the same series of experiments as the data of Fig. 7. The region between curves I, II and IV in Fig. 8 is the region of self-ignition and chain combustion without explosion. Oscillograms 1 and 2 in Fig. 7 correspond exactly to this region near curve II. The region above curve II to the right of curve I is the region of CTE. The point marked by the arrow is the limit of CTE found from the data of Fig. 7. It can be seen that the CTE region is confined on the low-temperature side by the second ignition limit at any composition of the mixture; as the region of chain ignition narrows down due to an increase in the content of the inhibitor, the CTE region narrows down in a similar way. Thus, CTE can arise only in the developing chain combustion. The CTE limit (curve II in Fig. 8) is higher than the first chain ignition limit because origination of a CTE requires that the chain combustion rate and the temperature be sufficiently high for the second condition for thermal explosion, relation (3), also to hold.

Figure 8. Regions of chain ignition and CTE in a stoichiometric mixture of H_2 and O_2 ;

(I, IV) the second and first limits without an inhibitor; (II, III) the CTE limit in reactors of diameters 5.5 and 3.3 cm, respectively. The content of the inhibitor in the initial mixture (mol. %): (1, 2) 0, (3) 0.2, (4) 0.3, (5) 0.4, (6) 0.7.

The limit itself depends only slightly on the temperature because the critical rate of the chain process at which combustion turns into explosion also depends slightly on the initial temperature.

In the experiments the results of which are presented in Figs. 7 and 8, the pressures P_1 were only 12–13 Pa, depending on the temperature, which is ~ 200 times lower than the CTE limit. Under these conditions, chain termination and the heat evolution which accompanies it in the CTE proceed in the gas phase. It has been verified¹⁰⁵ whether chain combustion could turn into CTE at a lower rate of heat evolution, namely, under conditions of heterogeneous chain termination ensuring virtually complete removal of the energy of recombination of atoms and radicals by the reactor walls. The rate constant for chain branching in the oxidation of monosilane, carried out for this purpose, is much greater than that for the oxidation of H_2 ; therefore, it should be expected that the conditions for CTE — relations (2) and (3) — would be met at even lower pressures and temperatures than in the combustion of H_2 with O_2 . At low pressures, chain termination occurs on the reactor walls; hence, the recombination energy is removed almost entirely from the reaction medium and heat evolution in the reaction bulk substantially decreases. In addition, the activation energy of the rate-determining step of this chain process does not exceed 25 kJ mol^{-1} (see Ref. 129), which is much lower than the values needed for the generation of thermal explosion in non-chain processes.^{3,5}

Chain termination in this reaction system also occurred in the kinetic region. The reaction was carried out under conditions of double self-ignition of SiH_4 in a confined space. The first ignition occurred near the reactor surface, while the second one occurred over the whole bulk (this was established by the kinetic method of separate photometry¹²⁸).

When the initial pressure exceeded a definite critical value by only a few percent, the intensity of combustion in the second outburst increased by a factor of several dozens (Fig. 9). The combustion proceeded dozens of times faster, its duration diminished and became shorter than the characteristic time of heat removal. This points to the switching of the combustion to the CTE mode. The same is indicated by the data obtained upon partial replacement of O_2 by He or Ar. The thermal conductivity of argon differs slightly from that of O_2 . Therefore, replacement of 50% of O_2 by Ar does not change the CTE limit (Fig. 10). In the case where oxygen is replaced by helium, the CTE limit markedly increases, because thermal conductivity of helium is much greater. Thus, in the combustion of SiH_4 , the chain-thermal explosion occurs even at pressures of about 200–300 Pa (see Figs 9, 10), which is an order of magnitude lower than the CTE pressures for the $2H_2 + O_2$ mixture. Nevertheless, the boundary of CTE remains very sharp even in dilute mixtures.

Figure 9. Chemiluminescence oscillograms obtained for ignition of the $0.05 \text{ SiH}_4 + 0.95 \text{ O}_2$ mixture at an initial temperature of 363 K and different P_0/P_1 ; (1, 2) are the numbers of outbursts.

Figure 10. Self-ignition (I) and CTE (II, III) limits for various mixtures; (1, 2) $0.05 \text{ SiH}_4 + 0.95 \text{ O}_2$; (3, 4) $0.05 \text{ SiH}_4 + 0.45 \text{ O}_2 + 0.50 \text{ Ar}$; (5, 6) $0.05 \text{ SiH}_4 + 0.045 \text{ O}_2 + 0.50 \text{ He}$.

When the initial pressure increases, combustion in the first outburst does not pass to the CTE mode because this outburst is located just near the surface, and the heat evolved is quickly removed by the walls (almost 50 times as fast as in the second outburst).

The fact that replacement of some of the O_2 by Ar or He does not change the self-ignition limit implies that the chain termination step occurs in the kinetic region (see Fig. 10, curve I). There are no gradients of CC concentrations or the process rate in this reaction system until combustion passes to the CTE mode; thus, the presence of two different combustion modes is inherent in the reaction kinetics itself.

At low pressures, as at the atmospheric pressure, the process passes to the CTE mode after the critical reaction rate has been attained during the chain combustion. The concentration range of the CTE is much narrower than the concentration range of ignition (similarly to Fig. 4). In the case of mixtures the composition of which does not differ much from the stoichiometric composition, chain combustion at atmospheric pressure switches to the CTE within a very short period of time after chain ignition has started; hence, the process is perceived only as an explosion.

The experimental data on the combustion of H_2 and SiH_4 at low pressures presented here demonstrate that the ignition peninsula is kinetically non-uniform; it is divided by a sharp boundary into a region of chain combustion that does not pass to the explosion mode and the region of CTE, characterised by a markedly greater self-heating and by a more vigorous behaviour of the process. These data also indicate that combustion switches to chain-thermal explosion even when the low pressure and temperature and the efficient heat removal from the reaction system make impossible a thermal explosion by a non-chain mechanism. The activation energies of the limiting steps of a BCP are much lower than the energy needed to bring about an explosion in a non-chain reaction.

A chain-thermal explosion differs from a classic explosion not only by its fundamentally different mechanism and a broader range of initial conditions under which it can occur but by very sharp critical conditions even at low pressures, which is due to the 'double exponent law'. In simple types of reactions, explosion becomes degenerate despite the very high activation energies.^{130, 131} Degeneration of a BCP is possible in processes characterised by rarely branching (although long) chains, for example, in reactions of CO with O_2 in the presence of very small amounts of hydrogen-containing compounds.¹³² The difference between the CTE and a non-chain explosion also shows in the fact that, when heterogeneous reactions play an important role, the course of the CTE depends on the composition and properties of a contacting surface.

Since the kinetics of a chemical reaction determines the macrokinetic features of the process, it should be expected that different kinetic modes of the reaction would be matched by different velocities of flame propagation. Study of the two kinetic modes of chain combustion, one of which is the CTE, elucidation of the differences between these modes, manifested as specific features of the process macrokinetics, and concentration and temperature fields, and determination of the critical conditions for the transition between these modes present considerable interest both for the BCP and combustion theory and for practical purposes (for example, to ensure explosion safety).

The existence of two modes of branching-chain processes in the region of ignition peninsula is indicated by the results of the numerical solution of equations corresponding to the generalised kinetic scheme of a BCP below the second ignition limit under static conditions, together with the equation for the heat balance of the reaction system.^{37, 133–135} The parameter χ , equal to the ratio of the heat evolution rate to the heat removal rate, varied in these calculations. Figure 11 presents the kinetic curves for the variation of the relative concentration of one CC (x) for various χ . As the χ value approaches 1.381, the change in the reaction kinetics becomes more and more pronounced, the transition from 1.381 just to 1.382 inducing an abrupt increase both in the maximum x value and in the rate of its growth.

It is notable that, despite a large number of studies dealing with the numerical solution of equations describing combustion of gases, the CTE phenomenon has not been recognised even after publication of works^{16, 105, 118, 119, 133} in which this mode has been detected both experimentally and theoretically. This may be explained by the fact that the discovery of specific features of

Figure 11. Kinetic curves for the CC at various ratios of the rates of heat evolution and heat removal (the parameter $\chi \times 10^3$) constructed based on a generalised kinetic scheme for a BCP.¹³³ The values $10^3 \chi$: (1) 0, (2) 1.00, (3) 1.20, (4) 1.30, (5) 1.35, (6) 1.37, (7) 1.38, (8) 1.381, (9) 1.382, (10) 1.383, (11) 1.39, (12) 1.41, (13) 1.50, (14) 2.00, (15) 2.50.

combustion inaccessible to a physical experiment has not been the aim of these calculations; they have been usually undertaken in order to describe particular observations or to compare experimental and calculated characteristics of a process (most often, the induction period) using a large number of parameters for calculations. In addition, when the pressure is relatively high, chain combustion rapidly switches to the CTE and, therefore, the whole process is identified with this mode and is regarded as being 'purely thermal'.

It should be noted that in the solution of sets of equations describing non-isothermal combustion of various gas mixtures, the temperature dependence of the heat of reaction is usually neglected. Meanwhile, since the heat capacities and the temperature dependences of the heat capacities of the reactants and products are different, the heat of a non-isothermal reaction changes as the reaction proceeds, this change being quite substantial in many cases. As a consequence, the real rate of heat evolution differs from the value calculated using an invariant heat of the reaction. Correspondingly, the calculated temperature also differs from the real one. Since the rate of a BCP follows an unusually strong temperature dependence and is inversely related to self-heating, it is obvious that errors in the calculation of the temperature result in deviations of the calculated reaction rates and other kinetic characteristics of the process from those observed experimentally. Therefore, the results of calculations of this type are reliable only for qualitative discussions.

IX. Conclusion

The results of experimental and theoretical studies carried out in recent years indicate that branching-chain mechanisms and competition between branching and termination of reaction chains are the governing factors in the gas-phase ignition and combustion of hydrogen-containing and many other compounds not only at very low pressures (tens or hundreds of times lower than the atmospheric pressure) but also at atmospheric and higher pressures. Self-heating becomes substantial only during developing chain combustion and enters a positive feedback with chain avalanche. It has been found that combustion, being a chain process over the whole pressure range studied, can be caused, depending on the initial reactant concentrations, either by the chain avalanche alone, enhanced by self-heating, or by simultaneous action of chain avalanche and avalanche-like accumulation of thermal energy in the reaction system. The second mode can occur only after chain ignition and after a particular rate of chain reaction and, correspondingly, the rate of heat evolution have been attained. The transition between these modes induced by variation of the initial conditions is a critical process. The competition of chain branching and termination throughout the whole range of pressures (both low and high) determines the kinetic features of each combustion mode including ignition, developed combustion, chain-thermal explosion (unknown until recently), flame propagation and its transition to detonation. The branching-chain mechanism also determines the dependence of characteristic features of combustion on the properties of the contacting solid surface under conditions where the access of atoms and radicals to the surface is unhindered (for example, when the ratio of the surface area to the reactor volume is great or in the case of turbulent movement of gases). This relates, for example, to fluid bed and catalytic combustion and to the transition from deflagration to detonation. Thus, the main factor governing the regularities of the gas combustion of hydrogen-containing and many other compounds was actually identified.

Elucidation of the governing role of the branching-chain mechanism in the gas-phase combustion processes at atmospheric and higher pressures and the regularities discovered open up new prospects for the theory of chemical kinetics, first of all, as regards chain processes, and for combustion theory. The data obtained recently would help in the solution of important applied problems. This is confirmed by the above-cited examples, which

demonstrate that the use of proposed and tested highly efficient non-corrosive and inexpensive inhibitors can help in controlling not only ignition but also the intensity of developed combustion and explosion, the velocity of flame propagation and its transition to detonation. The predominant role of a chain mechanism at temperatures typical of detonation creates conditions for controlling also the velocity of a detonation wave, within certain limits, by using inhibitors and promoters. Development of the scientific foundations of the chemical control of all the combustion modes mentioned above by selection and application of appropriate inhibitors and promoters is a topical theoretical and practical task.

The review was supported by the Russian Foundation for Basic Research (Project No. 99-03-32250).

VI. Conclusion	1061

Abstract. Characteristic features of functioning and practical application of enzyme-based biosensors for the determination of environmental pollutants as enzyme inhibitors are considered with special emphasis on the influence of the methods used for the measurement of the rates of enzymic reactions, of enzyme immobilisation procedure and of the composition of the reaction medium on the analytical characteristics of inhibitor assays. The published data on the development of biosensors for detecting pesticides and heavy metals are surveyed. Special attention is given to the use of cholinesterase-based biosensors in environmental and analytical monitoring. The approaches to the estimation of kinetic parameters of inhibition are reviewed and the factors determining the selectivity and sensitivity of inhibitor assays in environmental objects are analysed. The bibliography includes 195 references.

I. Introduction

Biochemical analytical methods have assumed great importance in the last years. They provide information about qualitative and quantitative composition of a subject under study on the basis of *in vitro* and *in vivo* studies of biochemical processes, which involve enzymes, antibodies, DNA, *etc.* The main advantage of biochemical methods is that the formation of analytical signals simulates the processes occurring in the living beings, which offers a unique possibility for rapid and selective detection of biologically active substances and elucidation of the mechanism of their effects on living organisms.^{1,2}

Enzymic methods of analysis relate to biochemical methods. Enzymes have long attracted the attention of analytical chemists as highly efficient protein catalysts.^{2,3} By virtue of their unique properties, such as high selectivity and sensitivity towards specific substrates and functioning in aqueous media at ambient temperatures,^{4,5} enzymes appear to be ideal analytical reagents for the determination of biologically active substances by diverse kinetic

methods. The development of enzymic methods of analysis was, to a certain extent, stimulated by the increasing demand for clinical and toxicological assays (*e.g.*, determination of major metabolites, diagnostics of various diseases and dysfunctions of discrete organs of an organism on the basis of changes in the composition of biological fluids, *etc.*).

The possibility of usage of enzymes for the determination of specific substrates and effectors has been at the centre of discussion since the late 1940's, *i.e.*, since the beginning of the first systematic *ex vivo* studies of enzyme properties. However, the difficulties connected with the isolation of enzymes, their low stability in solution and high cost of analyses impeded the practical application of novel methods. As a result, until the early 1970's it was thought that enzymic methods ranked below routine physicochemical analyses. The situation changed radically owing to the progress in engineering enzymology and industrial biotechnology (*viz.*, to large-scale production of a great variety of enzyme preparations, which sharply reduced their cost) and to the development of novel methods for stabilisation of enzymes including their fixation (immobilisation) on inert carriers.⁶ Of no less importance for the development of enzymic methods of analysis was the creation of special-purpose measuring devices called biosensors.^{2,3} In those, enzymes are integrated into a single system comprising a device for detecting biochemical signals (a sensor or a transducer) and a reaction medium containing essential stabilisers, effectors and other low-molecular-weight components required for their steady functioning. With the advent of biosensors, the maintenance of optimal experimental conditions and measurement of analytical signals have become routine laboratory procedures available for users having no special biochemical training or skills. It is the manufacture of biosensors that has opened the way for commercial application of enzymes for the determination of biologically active compounds. In 1996, the world's market of biosensors including those designed for clinical assays of glucose, urea, lactic acid and other essential metabolites (~ 70% of the total sales) amounted to US \$ 508 million.⁷

The commercial success of medical biosensors is not exclusively due to their demand and considerable investment into scientific research. At a sufficiently high lower level of metabolite assays of the order of 10^{-4} mol litre⁻¹, high selectivity is the main requirement for the method. Thus, the advantages of enzymes as analytical reagents are especially well realised in biosensors.

The situation with enzymic monitoring of environmental pollutants is different in principle. Only cholinesterase-based biosensors designed for the detection of residual organophos-

Uspekhi Khimii 68 (12) 1142–1167 (1999); translated by R L Birnova

phorus pesticides in water and agricultural products⁸ and immuno-enzymic diagnostica for specific haptens have found commercial application. The reasons preventing practical application of enzymic methods in environmental monitoring are due to specific features of subjects under study and more strict requirements for analytical characteristics of determination of environmental pollutants in comparison with subjects of clinical analysis.⁹

As the requirements for the maximum permissible concentrations of toxic agents become more rigorous, novel procedures are required for the determination of pollutants (*e.g.*, dioxins and pesticides in drinking water and foods, radionuclides, *etc.*) at the level of 10^{-12} mol litre⁻¹ (Ref. 10). Such low concentrations can be detected only in those cases where the pollutant is an effector (*viz.*, an inhibitor or an activator) of the corresponding enzymic reaction rather than its substrate.

Besides, qualitative and quantitative compositions of the main components of those items that subject to environmental and analytical monitoring (*e.g.*, natural and sewage waters, soils, sewage water sediments, *etc.*) are much more diverse than the compositions of biological media analysed with the use of medical biosensors. This imposes additional demands on the selectivity of biochemical signals and the methods used for their measurement. Many compounds, such as salts of alkaline and alkaline-earth metals, biogenic amines, phenols and surfactants, influence not only the rate but also the sensitivity of enzymic reactions with respect to inhibitors. Low temporal stability of specimens, high degree of mineralisation (which is especially apparent in the case of sewage water and silt extracts), the presence of microheterogeneities (suspensions, emulsions), coloured compounds, *etc.*, also restrict potential applications of biosensors. These limitations can be overcome through the use of special methodological approaches, since the use of biosensors for the analysis of environmental subjects differs in principle from their application for medical purposes.¹¹

The present review summarises the published approaches to the development of biosensors designed for the determination of environmental pollutants as enzyme inhibitors and demonstrates the potentials of purposeful control over the selectivity and sensitivity of biosensors used for the assay of toxic substances.

II. Biosensors: general characteristics and functional features

The term biosensors refers to devices which contain a biological element (an enzyme or a cell culture, microorganisms, biological tissues, antibodies, *etc.*) and a means for measurement of the reaction (response) of this element to the alteration of the qualitative composition of the medium.^{3,11} Some authors apply the term 'biosensors' to the supramolecular level of organisation of a biological component and thus separate enzyme-based or immune sensors from microbial and tissue biosensors.¹²

A general scheme of a biosensor assembly is shown in Fig. 1. Irrespective of its application, each biosensor consists of three elements, which determine its operational and analytical characteristics, *viz.*, a sensor, a biological component itself and a reaction medium. In addition to the subject to be assayed (*e.g.*, a substrate or an effector), the latter includes enzyme stabilisers, a supporting electrolyte, screening reagents, buffer components, *etc.*

The choice of a method used for detecting analytical signals determines not only the convenience of operation but also the limit of detection of the substrate. Preference is given to versatile methods and detectors of similar type for measuring the rates of different enzymic reactions. Electrochemical biosensors are represented by Clark's oxygen electrode, amperometric hydrogen peroxide sensors, pH-metric electrodes, field transistors and conductometric cells. In recent years, planar thin- and thick-filmed electrodes prepared from metals and carbonaceous materials which are photolithographed or screen-printed onto plastic or ceramic planar surfaces have received wide acceptance.^{13,14}

Figure 1. A schematic diagram of a biosensor; (1) sensor (electrode); (2) biological element; (3) working solution, *i.e.*, the reaction medium containing the analysed sample.

The selectivity of signal detection with a biosensor is provided by the selection of operation conditions for the measurement (the electrode potential, the composition of the reaction medium, *etc.*) as well as by optimisation of the biosensor design. Thus the use of electron transfer mediators makes it possible to decrease the working potential of an electrode and to exclude side oxidation (reduction) of electroreactive admixtures present in the specimen.¹⁵ The use of additional membranes diminishes the effect of the buffer capacity of the specimen and the pH of the working solution to the response of pH-metric biosensors.¹⁶

The general requirements for biosensors developed for environmental and analytical monitoring were formulated by the US Environmental Protection Agency (EPA).^{11,17} They are as follows: low cost of assays (US \$1–15 per assay), the possibility of detection of toxic substances at the level of 1 mg litre⁻¹–1 µg litre⁻¹ and within the range of detectable concentrations of not less than two orders of magnitude, duration of analysis of 1–60 min, short-term (1–3 h) training of laboratory personnel, application of zero or minimum supply voltage, specificity with respect to one or a group of related compounds, simplicity of the sampling procedure and portability of the device (which is designed to be easily moved by one man or transported by car).

1. The choice of an enzyme

The choice of biological elements (enzymes) to be incorporated into biosensors is usually made on the basis of a concept about the pathways of biochemical transformations of a particular compound for substrate assays or the mechanism of its toxic effect for inhibitor assays. Obviously, the great diversity of living organisms and well-characterised enzymes makes it possible in principle to detect any biologically active compound in various ways. A combination of several enzymes providing consecutive conversions of the substrate in a biosensor assembly adds new features. In each particular case, the accessibility of an enzyme (simplicity of the isolation procedure or commercial availability), its storage and immobilisation stability, efficiency of measurement procedures, detection limits and ranges of measurable substrate/inhibitor concentration are taken into account. A change in the analytical characteristics of inhibitor assays within the same enzyme–substrate system is attained by varying the sources of the enzyme, the method used for its immobilisation, the measurement conditions and the steps involved in the incubation procedure.

The data concerning the application of enzymes for assaying environmental pollutants as inhibitors [with the exception of cholinesterase (ChE) biosensors, see below] published in 1993–1998 are presented in Table 1. The results obtained in earlier studies are documented in several reviews.^{1,9–11} It should be noted that far from every publication provides analytical characteristics of inhibitor assays, *viz.*, detection limits or the lowest limits of measured concentrations, sensitivity of assays, range of detectable concentrations, *etc.* In many cases, biosensors are used to merely demonstrate the efficiency of an idea of determination of toxic substances with immobilised enzymes (see, *e.g.*, Ref. 41) or for calculation of kinetic parameters of inhibition, usually, with reference to inhibition of free enzymes.

Table 1. Some characteristics of methods used for inhibitor assays in the environment and the experimental parameters, viz., concentration range (c /mol litre⁻¹), limits of detection (LD/mol litre⁻¹) and inhibitor concentrations inducing a 50% decrease in the biosensor response (I_{50} /mol litre⁻¹).

Enzyme	Method	Conditions of measurement and enzyme stabilisation	Inhibitor	Parameters of determination of the inhibitor			Ref.

Oxidoreductases							
Cytochrome oxidase (EC 1.9.3.1)	amperometric (cyclic voltamperometry)	the enzyme was incorporated into a carbon paste together with azolectin and cytochrome <i>c</i> from horse heart; phosphate buffer, pH 7.0	cyanides	$(0.5-12) \times 10^{-6}$	—	—	18
	amperometric (linear voltamperometry)	electrochemical polymerisation of pyrrol on a planar gold electrode with subsequent immobilisation with glutaraldehyde; phosphate buffer, pH 7.0	atrazine	—	5×10^{-6} (see ^a) 1×10^{-5} (see ^b)	—	19
	pulse amperometry, chronocoulometry	immobilisation by cross-linking with glutaraldehyde on the surface of a glassy carbon electrode in the presence of a mediator (1,2-naphthoquinone-4-sulfonate); phosphate buffer, pH 7.0	benzoic acid	$1 \times 10^{-5}-5 \times 10^{-4}$	3×10^{-6} (see ^c)	—	20
	UV/visible spectrophotometry	the enzyme, myoglobin and hemoglobin were incorporated into a sol-gel matrix	nitrogen(II) oxide and carbon monoxide	around 10^{-6}	—	—	21
Tyrosinase (EC 1.14.18.1)	amperometric (cyclic voltamperometry)	the enzyme was incorporated into a carbon paste (4%); phosphate buffer, pH 7.0; catechol was used as a substrate	cyanides	—	1×10^{-5}	—	18
	amperometric (Clark's electrode)	sorption on paper with subsequent application of a dialysis membrane; hexane saturated with phosphate buffer, pH 7.0; catechol was used as a substrate	phenylthiourea	—	0.013×10^{-6}	0.80×10^{-6}	22
			<i>N,N</i> -diphenylthiourea	—	0.045×10^{-6}	1.83×10^{-6}	
			ethylphenylthiourea	—	0.078×10^{-6}	3.08×10^{-6}	
			benzylthiourea	—	0.104×10^{-6}	4.58×10^{-6}	
			isopropylthiourea	—	0.137×10^{-6}	5.55×10^{-6}	
			allylthiourea	—	0.181×10^{-6}	6.91×10^{-6}	
	amperometric (linear voltamperometry)	the enzyme was immobilised on the electrode surface; phosphate buffer, pH 7.4; phenol was used as a substrate	benzoic acid, thiourea, propyl gallate	—	—	—	23
	amperometric (by quinone reduction current)	immobilisation in polypyrrol formed on the electrode surface by oxidation of substituted pyrrol; catechol, dopamine, L-DOPA and epinephrine were used as substrates; air-saturated phosphate buffer, pH 6.5	3,4-dichlorophenol	—	0.4×10^{-6}	—	24
			chloroisopropyl phenylcarbamate	—	2×10^{-6}	—	
			3-chloroaniline	—	2×10^{-6}	—	
			atrazine	—	4×10^{-6}	—	
			cyanide	—	0.02×10^{-6}	—	
amperometric (detection of stationary signals)	the enzyme was incorporated into a carbon paste prepared from mineral oil without a cross-linking reagent (immersion or planar electrodes); phenol was used as a substrate; phosphate buffer, pH 7.4	hydrazine	—	—	4.5×10^{-4}	25	
		methylhydrazine	—	—	5.5×10^{-4}		
		dimethylhydrazine	—	—	6.3×10^{-4}		
amperometric (cyclic and pulse amperometry, chronocoulometry)	the enzyme was immobilised on the surface of a glassy carbon electrode by cross-linking with glutaraldehyde without the carrier; phosphate buffer, pH 7.0; potassium ferricyanide is used as a mediator	cyanides	around $10^{-3}-10^{-4}$ (see ^c)	—	—	26

^a Hydrodynamic method. ^b Flow-through method. ^c Calibration curve. ^d Thiourea, thiocyanates and azides do not interfere with the determination up to concentration 1×10^{-3} mol litre⁻¹. ^e µg litre⁻¹. ^f The values of $p_c = -\log c$ (mol litre⁻¹) are given. ^g mg litre⁻¹. ^h The parameters for the listed pesticides were obtained using bienzyme and hybrid (in parentheses) biosensors.

This complicates comparison of experimental results obtained by different authors.

The majority of publications devoted to the practical application of analytical enzymic methods deal with the studies of biosensors including peroxidase, tyrosinase and urease. Other enzymic systems are described in only a limited number of papers, although their potentials are rather high.

Different organic compounds are determined with horseradish peroxidase, which is resistant to denaturing reagents and elevated temperatures and manifests high specific activity, and is a reliable and sensitive tool for determining the rates of enzymic reactions. The rate of peroxidase-based oxidation of different substrates can be used for determining the concentration of hydrogen peroxide; therefore, this enzyme is a common constituent of two-enzyme biosensors designed for assaying substrates or effectors of oxidoreductases.^{2,3} Tyrosinase (polyphenol oxidase) fulfils similar biochemical functions by oxidising various biogenic phenols.

Peroxidase and tyrosinase inhibitors can block the active sites of enzymes (due to the complex formation with metal cofactors and uncoupling of an electron transfer chain) or manifest non-specific inactivating effects by disturbing the tertiary structures of proteins. For example, the results of Hg(II) and Fe(III) assays which employed peroxidase with photometric detection of signals^{53–55} and phenylthiourea derivatives assays using an electrochemical tyrosinase biosensor²² (both processes were characterised by low detection limits) have made it possible to recommend these methods for direct assays of toxic compounds in environmental objects without sample concentration.

The main advantage of peroxidase and tyrosinase in comparison with other enzymes consists in the possibility of using them as biosensor constituents for measurements in organic or aqueous-organic media,^{56–58} including inhibitor assays.^{22, 29, 31–33, 59, 60} This makes it possible to use biosensors as detectors in liquid chromatography⁶¹ and to carry out inhibitor assays directly on organic extracts. On the whole, the stability of enzymes in organic solvents is lower than in aqueous media, however, definite approaches to their stabilisation do exist.⁶² In the case of inhibitor biosensors able to function in aqueous-organic and non-aqueous media, enzymes are incorporated into hydrophilic polymers based on polyaniline,⁶¹ a hydrophilic vinyl chloride and pyrrole copolymer Eastman AQ^{31–34} and hydrogels based on hydroxycellulose²⁹ and methyltriethoxysilane.³⁵ Electrical conductivity is achieved by adding 1%–20% of a buffer solution or a tetraalkylammonium salt to the organic solvent. Kinetic parameters of both the enzymic reaction and the enzyme–inhibitor interaction depend on the nature of the solvent and the inhibitor. Usually, the presence of polar organic solvents miscible with water decreases the sensitivity of the biosensor to reversible inhibitors of tyrosinase and peroxidase, such as thiourea and dithiocarbamate derivatives. Nonpolar solvents have insignificant effects on the inhibition kinetics.

Urease catalyses the hydrolysis of urea. High substrate specificity of the enzyme and ease of potentiometric or photometric determination of the hydrolysis product, *viz.*, ammonia, provide the practical application of urease for the determination of residual heavy metal salts in environmental objects.

Thus a flow system consisting of 26 glass capillaries with a total volume of 100 μl was developed for the determination of urease inhibitors in natural and sewage waters. Urease was immobilised on the inner surface of the gelatinised capillaries by physical sorption.⁶³ A water sample and a substrate solution were consecutively pumped through the capillary tubes with a peristaltic pump for 15–240 and 20 min, respectively, and the urease activity was measured from the concentration of the ammonia formed using a potentiometric method. The activity of immobilised urease was preserved after continuous pumping of solutions for 8 h. The use of this system made it possible to detect the presence of carbaryl (1×10^{-4} mol litre⁻¹) (4 h) and copper(II) salts (1×10^{-7} and 1×10^{-9} mol litre⁻¹) (1 and 4 h). A similar

indicator system based on a urease reactor (a column filled with glass beads with immobilised urease) was used to evaluate the general contamination of waters with heavy metals.⁶⁴ Ammonia concentration was measured by a photometric (with the Nessler reagent) or a potentiometric method. The detection limits of the majority of heavy metals were $(1–2) \times 10^{-6}$ mol litre⁻¹, those for iron were $10^{-8}–10^{-9}$ mol litre⁻¹. The selectivity of individual metal assays could not be reached. This system was tested in the monitoring of pollution of drinking water sources in the Moscow Region.

Urease biosensors based on pH-sensitive field transistors possess enhanced analytical characteristics for the determination of metal ions. The progress in this area was achieved owing to both the use of ultrathin membranes contacting with the electrode and the coating of biosensors with ion-exchange polymers, which favour the concentration of cations on the electrode surface.^{51, 52}

Microorganisms and sections of biological tissues incorporated into biosensors may sometimes be regarded as sources of the corresponding enzymic activity. This can increase the stability of the response and reduce the cost of biosensors, since the enzymes are in a customary microenvironment in the presence of the necessary stabilising agents and effectors. The cells possess natural mechanisms, which protect enzymes against autooxidation and hydrolysis by proteolytic enzymes. Besides, inactivated enzymes are continuously reproduced owing to catabolic intracellular processes. Some applications of tissue sections of mushroom carposomes as a source of tyrosinase²⁸ and of potato as a source of acid phosphatase⁴⁶ are given in Table 1.

Biosensors based on the use of complete biochemical cycles in which inhibition of a particular biochemical function is measured as an analytical signal offer radically new possibilities. Special mention should first be made of the use of biosensors for the assay of herbicides (algicides) and evaluation of general toxicity in respect of the respiratory activity of microorganisms.

Biosensors designed for measuring concentrations of phytotoxic chemical compounds incorporate chloroplasts as the biological components (as whole cells of unicellular microalgae^{65–67} or within thylakoid membranes isolated from these cells⁶⁸). Illumination of chlorophyll generates a photocurrent measured as the current of oxidation of electron acceptors added to the solution instead of natural acceptors, *viz.*, carbon dioxide. Ferricyanide,⁶⁸ soluble ferrocene derivatives^{65, 66} and diaminodurene⁶⁷ are used as mediators. The reduction of the photocurrent is a measure of the herbicide effect of the toxicants. Thus in the case of *Synechococcus* *sp.* cells, the detection limit of *sym-triazine*-based pesticides is 2 μg litre⁻¹, that in the case of *Chlorella vulgaris* cells is ~ 1 mg litre⁻¹. When thylakoid membranes isolated from spinach cell cultures were used, a 50% reduction of the photocurrent was observed at the following concentrations (mol litre⁻¹): 1×10^{-6} (diuron), 9×10^{-6} (atrazine), 5.5×10^{-4} (sodium nitrite), 1.7×10^{-3} (sodium sulfite), 7.2×10^{-3} [Cu(II) salts], 1×10^{-3} (Pb), 1.8×10^{-3} [Hg(II)], 2×10^{-3} (Zn) and 4×10^{-3} (Cd). These data suggest that biosensors based on chloroplasts and microalgae are promising tools, especially for the determination of residual herbicides. However, these biosensors cannot compete with enzymic ones in terms of sensitivity of metal ion assays (see Table 1).

Biochemical oxygen demand (BOD) is measured with the aid of microbial biosensors designed for detection of toxic substances in aqueous media.^{69–71} The magnitude of BOD can be established within 15–40 min (*cf.* 5–20 days in the titration method) by the rate of oxygen consumption in cells immobilised on the oxygen electrode membrane. The presence of toxic substances decreases the rate of oxygen consumption. In toxicity studies, a sample is introduced simultaneously with the nutrient (determination of respiratory activity) or after it (by a characteristic bend on the respiration curve).^{72–74} Commercial systems for monitoring of the toxicity of sewage waters (*e.g.*, Toxiguard,⁷³ RODTOX^{72, 75}) were developed based on some microbial biosensors. Microbial biosensors for toxicity studies allow the detection of different

substances with a broad spectrum of toxic effects ranging from disturbance of transmembrane oxygen transport (surfactants, petroleum products) to uncoupling of oxidative phosphorylation and inhibition of oxidoreductases (phenols, cyanides, heavy metal ions). However, adaptive protective detoxification mechanisms decrease the sensitivity of microbial biosensors to individual groups of toxic agents in comparison with enzyme-based electrodes. Thus the detection limit of Cu(II) ions is $0.2 \text{ mg litre}^{-1}$ with the yeast-based electrode.¹

In addition to respiratory activity, the intensity of luminescence of luciferase microorganisms (a biosensor version of the Microtox test) can serve as the measure of toxicity.⁷⁶ The use of an electrode containing an immobilised revertant strain of *Salmonella* for the screening of chemical compounds possessing mutagenic activity has been described.⁷⁷

2. Effect of enzyme immobilisation

Immobilisation of enzymes usually causes significant alterations in the analytical characteristics of inhibitor assays. The main reasons for the change in the sensitivity of enzymes to inhibitors upon their transition from the native to the immobilised state are as follows:^{3,5} (1) diffusion-dependent retardation of the reagent (substrate, inhibitor, reaction product) transfer to the membrane including steric hindrances in the accessibility of the active site of an enzyme for high-molecular-weight inhibitors and/or substrates (e.g., proteolytic enzymes), (2) changes in the enzyme micro-environment (buffer capacity, dielectric conductivity, ionic composition) and concomitant changes in electrostatic interactions and activity coefficients of the reagents.

There is no unequivocal evidence so far that the change in the enzyme affinity for a substrate or an inhibitor upon immobilisation is due to the changes in the tertiary or quaternary structure of the protein. Physical sorption or covalent cross-linking of protein globules with bifunctional reagents results in modification of very few surface functional groups. Since active and allosteric sites occupy a small part of the protein globule surface, any change in the structure of protein globules upon immobilisation is hardly likely.

Optimisation of the immobilisation procedure is aimed at retaining the activity of immobilised enzymes and implies mild, sparing treatment in order to preserve the microenvironment of the enzyme active site. This allows one to consider the enzyme-containing film on the biosensor surface as a solid solution where the native protein is uniformly distributed and 'fixed' in a homogeneous medium, which is denser and more viscous than water. Despite its obvious arbitrary character, in many cases this model describes adequately the behaviour of biosensors incorporating an immobilised enzyme.

Diffusion-dependent retardation of the reagent transfer is the main reason for discrepancy in the results of inhibitor assays employing native and immobilised enzymes. Depending on the ratio of the rates of transfer of the substrate into the membrane and its enzymic conversions, one can distinguish two regimes of biosensor functioning^{3,78} which differ in stationary distribution of the substrate throughout the membrane.

Kinetic regime. The rates of transfer and diffusion of a substrate from the solution into the membrane and its diffusion into the membrane are higher than the rate of its enzymic conversion. The reactants are uniformly distributed throughout the membrane and the active sites of enzymes are saturated with the substrate. In this case, the rate of the formation of the reaction product (and, consequently, the response of the biosensor) is determined exclusively by the kinetics of the enzymic reaction. This regime is particularly suitable for detection of enzyme effectors. However, any decrease in the enzymic activity caused by desorption, spontaneous inactivation or microbial degradation influences the biosensor response. The kinetic regime is observed in the case of low specific activities of immobilised enzymes, small thickness of the membrane and lack of the substrate transfer retardation at the membrane–solution interface.

Diffusion-dependent regime. If the activity of an enzyme is high, its diffusion-controlled transfer does not fully compensate for the decrease in the substrate concentration in the enzymic reaction. As a result, the membrane incorporating the enzyme is not saturated and part of the enzyme active sites are unoccupied. The electrode response is steady and remains at this level despite the variations in the activity of the immobilised enzyme unless the reaction regime is changed. The diffusion-dependent regime is observed in the case of high specific activity of the enzyme, retardation of the substrate transfer (e.g., when additional covering membranes decreasing the rate of the substrate transfer from the solution into the enzyme-containing layer are used), etc.¹⁶

If the reaction occurs in the diffusion-dependent regime, the sensitivity of inhibitor assays is lower than in the kinetic regime. A decrease in the concentration of active sites of enzymes as a result of their interaction with their inhibitors is partly compensated for by the involvement of free, nonreacted sites in the enzymic reaction which occurs independently of the enzyme–inhibitor interactions. Thus on going from the native to the immobilised enzyme, the limits of detection of Hg(II) with choline oxidase and glycerol 3-phosphate oxidase increase 2- and 2.5-fold, respectively, while the limits of detection of Hg(II) with lactate oxidase and glutamate oxidase, of cadmium with D-amino acid oxidase and of V(V) with alcohol oxidase increase more than 20-fold.⁴⁴ Moreover, many metal ions inhibit native enzymes without influencing the activities of immobilised preparations. The limit of detection of paraoxon for a luminescent biosensor containing ChE, choline oxidase and peroxidase was $0.75 \text{ } \mu\text{g litre}^{-1}$ when ChE was used as a solute and the other two enzymes were immobilised in an acrylate gel and $125 \text{ } \mu\text{g litre}^{-1}$ when all the three enzymes were immobilised.⁷⁹

The diffusion-dependent and kinetic regimes represent extreme functioning regimes for biosensors and are separated by a vast transition region where the biosensor response is determined by both kinetic parameters of the enzymic reaction and the diffusion coefficients of the reagents. A comprehensive mathematical description of responses of amperometric and potentiometric biosensors has been given.^{3,80–84} However, these models do not take account of the pH dependence of the rate of the enzymic reaction, which is a rough approximation, since the change in pH value of an enzyme-containing membrane can vary from 1 to 3 units during the measurements of biosensor responses.

No simulation of the effect of inhibitor on responses of biosensors including stationary and dynamic responses caused by the addition of substrates (dynamic or transition responses) have been carried out thus far. This may be due to significant complication of the mathematical model in comparison with the description of kinetics of reactions of immobilised enzymes. Besides, in the majority of cases kinetic parameters of individual stages of the inhibition reaction essential for simulation are unknown.

In the simplest case, the effect of an inhibitor can be described in terms of a mathematical model of the biosensor response in the absence of the inhibitor. In the case of uniform distribution of the inhibitor throughout the membrane, a decrease in the biosensor response can be simulated using the dependences of the biosensor response on the substrate concentration calculated for different rates of enzymic reaction. A change in the biosensor response as a result of its contact with the inhibitor will be similar to that observed in the case where a smaller concentration of the enzyme is used for the preparation of the membrane.

This approach does not take into account the effect of enzyme immobilisation on the mechanism of inhibition. In particular, on going from native to immobilised ChE the mechanism of inhibition by *N*-methyl-4-piperidinyl benzylate or tacrine (1,2,3,4-tetrahydro-9-aminoacridine)⁸⁵ is changed, which is associated with steric factors (e.g., limited access of the inhibitor to the membrane or a change in the ratio of substrate/inhibitor concentrations in the membrane in comparison with that in solution) rather than with changes in the mechanism of enzyme–inhibitor

interactions. The necessity of estimating the contribution of the final rate of the inhibitor transfer into the membrane brings about additional problems.

III. Determination of kinetic parameters of inhibition

The choice of methods for quantitative evaluation of effects of inhibitors on immobilised enzymes incorporated into biosensors is determined by the type of interactions in 'enzyme–substrate–inhibitor' systems and the procedure used for measuring of analytical signals implemented in biosensors. Hereinafter it is assumed that the enzymic reaction occurs in accordance with the classical Michaelis–Menten mechanism:^{4, 5}

where E is the enzyme, S is the substrate, ES is the enzyme–substrate complex and P is the enzymic reaction product.

An important feature of the inhibition mechanism is the reversibility of interaction of the inhibitor with the active site of the enzyme. It is necessary to distinguish between reversible and irreversible enzyme inhibition upon its reaction with the inhibitor in the absence of the substrate depending on the type of dissociation of the enzyme–inhibitor complex.

where I is the inhibitor, E–I is the enzyme–inhibitor complex and I' and I'' are the inhibitor decomposition products. If the dissociation of the E–I complex occurs with simultaneous decomposition of the original inhibitor, the inhibition is irreversible ($k_2 \gg k_{-1}$); if the dissociation of the complex into the original molecules prevails ($k_{-1} \gg k_2$), the inhibition is reversible.

The indication to the type of inhibition does not provide any information about the possibility of restoration of enzymic activity after the interaction of the inhibitor with the enzyme. Thus carbamates cause irreversible inhibition of ChE, but spontaneous hydrolysis of carbamoylated ChE occurs very fast and the enzyme activity is completely restored. The reactivation rate constant of carbamoylated acetyl cholinesterase (AChE) from electric eel is 0.012 min^{-1} , while that of phosphorylated AChE is 10^{-5} min^{-1} and the corresponding value for the hydrolysis of the acetylated enzyme formed upon enzymic cleavage of the substrate is $6 \times 10^5 \text{ min}^{-1}$ (see Ref. 86). Inhibition of urease with heavy metal ions is also expected to be reversible; however, the restoration of enzymic activity requires the use of complexones, e.g., EDTA.^{51, 52} Toxic irreversible inhibitors, e.g., contaminants-xenobiotics, are more dangerous to living organisms than reversible inhibitors because of the low rate of spontaneous reactivation and the lack of efficient detoxification mechanisms.

1. Irreversible inhibition

Irreversible inhibition is evaluated quantitatively by the level of enzymic activity before and after the contact of the enzyme with the inhibitor. If the concentration of the inhibitor is much higher than that of the active sites of enzymes, irreversible inhibition will be described by a second-order kinetic equation⁸⁷

$$\ln \frac{v_0}{v_t} = k_{II} c_I \tau, \quad (3)$$

where v_0 and v_t are the initial rates of the enzymic reactions before and after the contact of the enzyme with the inhibitor, respectively, k_{II} is the inhibition bimolecular rate constant, c_I is the

concentration of the inhibitor and τ is the duration of the enzyme–inhibitor interaction (incubation step). The value of k_{II} depends on the nature of the enzyme and the inhibitor as well as on the reaction conditions and rate constants in separate steps of the reaction. In particular, at $\tau \rightarrow 0$:

$$k_{II} \rightarrow \frac{k_1 k_2}{k_{-1} + k_2}.$$

The value of k_{II} describes the inhibitory activity of the toxicant better than I_{50} , since it allows comparison of the results obtained under different experimental conditions, particularly, for different τ .

If the concentrations of the enzyme active sites and the inhibitor are comparable, the dependence of the relative decrease in the rate of the enzymic reaction on the inhibitor concentration for strictly irreversible inhibition is linear. However, this dependence, as applied to biosensors, is not realised, since the specific activity of immobilised enzymes should be rather high in order to provide high accuracy of measurement of the response.

In the case of irreversible inhibition (*i.e.*, at low rate of spontaneous reactivation), the inhibiting effect depends on the time of incubation and the calibration curve for the inhibitor assay is linear in the $c_I - \ln(v_0/v_t)$ coordinates and passes through the origin of the coordinates. Moreover, the relative decrease in the activity of the enzyme (the biosensor response) as a result of incubation does not depend on the concentration of the substrate, which is especially important for optimisation of conditions of inhibitor assays.

2. Reversible inhibition

A kinetic description of reversible inhibition is more complex than that of irreversible one, since the interaction of the enzyme active site with the substrate and the inhibitor may occur in different ways:

Here E–S–I is the enzyme–substrate–inhibitor complex, K_i and αK_i are the equilibrium constants of the enzyme–inhibitor interaction, k_1 , k_{-1} , k_2 , αk_{-1} and βk_2 are the rate constants of the corresponding steps of the enzymic reaction. Usually, for the inhibitors $\alpha > 1$ and $\beta < 1$, but at $\beta \rightarrow 0$ the coefficient α is < 1 . For enzyme activators, the kinetic mechanism of which is described by the same equation, $\alpha < 1$ and $\beta > 1$.

Knowing the dependences of reaction rates on concentrations of the substrate and the inhibitor, one can determine the type of inhibition and the values of K_i and αK_i .^{88, 89} In actual practice, extreme cases may occur. Thus at $\alpha \rightarrow \infty$, complete competitive inhibition takes place. The latter also includes the interaction of the enzyme with an irreversible inhibitor in the presence of the substrate. If $\alpha \rightarrow 0$, the inhibition is referred to as non-competitive. The corresponding constants for the formation of inhibitory complexes, K_i and αK_i , are termed as competitive and non-competitive ones. Mixed type of inhibition is characterised by a combination of competitive and non-competitive inhibition, *i.e.*, in this case the inhibitor binds both to the active centre of the enzyme and the enzyme–substrate complex. Incompetitive inhibition is a particular case of mixed inhibition, if $\alpha = 1$ and $\beta = 0$.

The competitive (K) and incompetitive (K') components of mixed inhibition are calculated from the dependence of relative changes in the rate of the enzymic reaction on the concentrations of the substrate and the inhibitor:

$$\frac{v_0}{v_i} = \frac{K_M(1 + c_I/K) + c_S(1 + c_I/K')}{K_M}, \quad (5)$$

where v_0 and v_i are the reaction rates in the absence and in the presence of the inhibitor and K_M is the Michaelis constant of the enzymic reaction in the absence of the inhibitor.

The total inhibiting effect is described by the reduced inhibition constant

$$\bar{K}_i = \frac{K_i K'_i}{K_i + K'_i}.$$

The constants k_{II} and K_i reflect the sensitivity of the enzyme–substrate system to the inhibitor. Their values can be used for the identification of inhibitors using a set of enzymes differing in their sensitivities to toxic agents. If the experiments are run under identical conditions (incubation time for irreversible inhibitors, substrate concentration for reversible inhibitors), it is sufficient to determine the relative changes in the rate of the enzymic reaction according to the formulae:

irreversible inhibition

$$\frac{(k_{II})_1}{(k_{II})_2} = \left(\ln \frac{v_0}{v_i} \right)_1 / \left(\ln \frac{v_0}{v_i} \right)_2; \quad (6)$$

reversible inhibition

$$\frac{(\bar{K}_i)_1}{(\bar{K}_i)_2} = \left(\frac{v_0}{v_i} \right)_1 / \left(\frac{v_0}{v_i} \right)_2.$$

The indices 1 and 2 refer to the kinetic data obtained in experiments with enzyme preparations differing in the degree of purity, the method of isolation, the source, *etc.*⁹⁰

The relative sensitivity of enzymes to a definite group of inhibitors is established in a similar way. By illustration, the sensitivity of ChE isolated from different sources can be characterised by the relative value:

$$\exp \left(\sum_n \frac{\ln(k_{II}^i/k_{II}^0)}{n} \right),$$

where the index i relates to the enzyme the relative sensitivity of which is being calculated, the index 0 relates to the reference enzyme and n designates the number of inhibitors. The ratio of inhibition constants, k_{II} , is established for each insecticide and is then summated for all the pesticides under study.⁹¹

Estimation of inhibition parameters of immobilised enzymes including those incorporated into biosensors can also be used in the case of kinetic regimes. Biosensors in which the enzyme is immobilised on the electrode surface (without any carrier) or in a thin hydrophilic layer which has no substantial effect on the diffusion coefficients of the substrate and the inhibitor are best suited for this purpose. Albumin, polysiloxanes, silicates, hydrophilic polymers of the Eastman AQ 55D type, *etc.*, are used as carriers.

The feasibility of formal equations for Michaelis–Menten kinetics provides indirect evidence for the lack of diffusional limitations. In particular, for tyrosinase- or peroxidase-based biosensors the current (I) of the reduction of the reaction product (quinone) or of the oxidised form of the mediator can be used as a measure of the rate of the enzymic reaction. The calibration curve for the substrate is linearised in double reciprocal coordinates $I^{-1} - c_S^{-1}$, whereas the segment intercepted on the abscissa gives the value of K_M^{-1} as well as the Lineweaver–Burk equation. Other kinds of anamorphoses of kinetic curves known in homogenous enzymic reaction kinetics can also be used for this purpose. Thus a calibration curve for determining reversible competitive or uncompetitive inhibitors at a constant concentration of the substrate is linearised in the coordinates $I^{-1} - c_I^{-1}$; the inhibition constant, K_i , is determined from the segment intercepted on the abscissa.²⁴

In some cases, it is more preferable to use the degree of inhibition of the enzyme (Y) instead of the biosensor response. This offers a possibility of using the data obtained for different

experimental conditions for calculation. For example, the value of Y relates to the response of an amperometric biosensor:

$$Y = \frac{c_{E-I}}{c_{E-I} + c_E} = \frac{c_I}{c_I + K_i} = \frac{\Delta I}{I_0}, \quad (7)$$

where c_{E-I} , c_E and c_I are the concentrations of the enzyme–inhibitor complex, of the free centres of the enzyme and of the inhibitor, respectively, ΔI is the change in the biosensor response upon inhibition and I_0 is the biosensor response before the contact of the enzyme with the inhibitor.^{29, 31–34} Derivation of Eqn (7) *a priori* entails a fully competitive type of inhibition, since it is in this particular case that the decline of the response will be proportional to the concentration of the enzyme–inhibitor complex.

For practical purposes, the ratio (7) is linearised in the $Y/c_I - Y$ coordinates (the Scatchard equation) to determine K_i :³¹

$$\frac{Y}{c_I} = -\frac{Y}{K_i} + \frac{I_0}{K_i} \quad (8)$$

or in the $Y/(1-Y) - c_I$ coordinates (the Hill equation):⁹²

$$\frac{Y}{1-Y} = \frac{I}{I_0 - I} = \left(\frac{c_I}{K_i} \right)^x = \left(\frac{c_I}{I_{50}} \right)^x, \quad (9)$$

where x is the empirical Hill coefficient; $x = 1$ in the case of the Michaelis–Menten mechanism, the value x for organic solvents increases to 3–4.^{18, 22, 29} The Hill coefficient serves as a criterion of efficiency of the catalysis I_0/K'_M (K'_M is the experimental value of the Michaelis constant) and the effect of the solvent on the kinetics of the enzymic reaction.

Equations (7)–(9) were obtained assuming that the response of the biosensor is proportional to the rate of the enzymic reaction. On the whole, the dependence $v - I$ is sigmoidal and is approximated by a linear dependence in a narrow range of substrate or inhibitor concentrations.

In the case of irreversible inhibition, the inhibition bimolecular constant is calculated from Eqn (3). By expressing v_0/v_i through the degree of inhibition Y , we obtain the following ratio:

$$k_{II} = -\frac{\ln(1-Y)}{c_I \tau}. \quad (10)$$

The plots are linearised in the $\ln(1-Y) - c_I$ coordinates or, if the degree of inhibition is expressed on a percentage basis, $\ln(100-Y) - c_I$.⁹³

If the kinetic parameters k_{II} and K_i are used for comparative characterisation of the enzyme–inhibitor interaction, it should be remembered that they do not provide any direct information about the analytical characteristics of inhibitor assays, such as limits of detection or a concentration range.

IV. Optimisation of operating conditions for inhibitor assays

1. Concentration of the substrate

A crucial role in the choice of experimental conditions belongs to the choice of working concentrations of the substrate. In irreversible inhibition, the relative decrease in the rate of enzymic reactions does not depend on the measurement conditions. If a change in the rate of an enzymic reaction by 15%–25% is taken as a statistically significant quantity, the limit of detection estimated by Eqn (3) is $(0.13 - 0.22)/k_{II}\tau$. In particular, the calculated values of the limit of detection of organophosphorus pesticides ($\tau = 2 - 30$ min, $k_{II} = 10^5 - 10^7$ mol⁻¹ litre min⁻¹), are in the range of $10^{-9} - 10^{-7}$ mol litre⁻¹, which is consistent with the published data for enzymic assays of pesticides with free ChE.^{8, 86, 94}

The value of v_0/v_t can be determined by analysis of any characteristics of the system which are proportional to the reagents concentration, *e.g.*, the time needed for reaching a definite (normally, not more than 30%) level of substrate conversion:

$$\frac{v_0}{v_t} = \frac{t_i}{t_0},$$

where t_0 and t_i are the times of the enzymic reactions before and after the interaction of the enzyme with the inhibitor, respectively.

The choice of small initial concentrations of substrates ($c_S \ll K_M$) has a number of advantages. If a substrate participates in several enzymic reactions (the presence of enzymes with low substrate specificity in the original preparation, significant differences in the kinetic parameters of isoenzymes) or if several substrates interact with the same enzyme, the general view of the equation describing the rate of the target enzymic reaction will be complicated:

$$v_0^1 = \frac{v_{\max}^1 c_S^1}{\left[1 + \sum_{i=2}^{i=n} \frac{c_S^i}{K_M^i}\right] K_M^1 + c_S^1}, \quad (11)$$

where $v_{\max}^1$ is the maximum rate of the enzymic reaction; the index 1 relates to the target enzymic reaction the rate of which is being determined and the index i relates to reactions between competing substrates/enzymes which occur in parallel. If the initial rate of the substrate c_S^1 is sufficiently small ($c_S^1 \ll K_M^1$), the equation is simplified:

$$v_0^1 = \frac{v_{\max}^1}{K_M^1} c_S^1,$$

and the effect of simultaneously occurring reactions can be neglected.⁹⁵

For competitive and mixed-competitive ($\alpha > 1$) inhibition, the limit of detection of the inhibitor decreases with an increase in the substrate concentration. At $c_S \ll K_M$, the limit of detection of environmental pollutants ($K_i = 10^{-4} - 10^{-6}$ mol litre⁻¹) by the most common methods is $(0.15 - 0.25)K_i$ or in the range of $10^{-5} - 10^{-7}$ mol litre⁻¹.

At $c_S \gg K_M$, the limit of detection of non-competitive inhibitors ($\alpha = 1$) does not depend on the substrate concentration. For uncompetitive and mixed-non-competitive inhibition ($\alpha < 1$), the limit of detection of inhibitors decreases with an increase in the substrate concentration. In other cases, any increase in the substrate concentration will increase the limit of detection of the inhibitor.

While estimating limits of detection, one should remember that inhibitory effects are established on the basis of results of two response measurements, *viz.*, before and after the contact of the enzyme with the inhibitor. Therefore, the minimum value of the degree of inhibition is equal to the double measurement accuracy of the biosensor response to the substrate. The metrological characteristics of sensors incorporated into biosensors can be used as a preliminary estimate. Thus the magnitude of steady-state oxidation (or reduction) currents on solid electrodes can be measured with $\sim 1\% - 2\%$ accuracy, while that of the potential of the ion-selective electrode is $\sim 3\%$. Consequently, the minimum significant inhibition corresponds to a decrease in the amperometric and potentiometric responses by not less than $2\% - 4\%$ and $\sim 6\%$, respectively. Even in those cases where the calibration curve for the inhibitor is plotted from the absolute value of the response, it is assumed that the initial response of the biosensor (before its contact with the enzyme) is constant. In other words, the measurement error of the biosensor response after its contact with the inhibitor includes the measurement error of its response to the substrate. Therefore, whilst choosing a detection method (for irreversible, non-competitive, uncompetitive and mixed-non-competitive inhibitors) preference should be given

to the methods which ensure more accurate measurements of the biosensor response rather than the possibility of detection of smaller concentrations of the substrate. In other cases, sensors allowing maximum reduction of working concentrations of the substrate will be the sensors of choice.

2. Enzyme reactivation

The ability of enzymes to regain their activity after measurement of the inhibitory effect is a prerequisite for repeated application of biosensors. In the case of reversible inhibitors, this is achieved by washing of biosensors or enzyme-containing membranes with working buffer solutions which may contain stabilisers or enzyme cofactors preventing its inactivation. In some cases, natural reactivation occurs so slowly that under real experimental conditions it is necessary to use special reagents accelerating the dissociation of enzyme-inhibitor complexes. For example, heavy metal assays make use of complexing or precipitating reagents, such as EDTA, potassium iodide, sulfur-containing organic compounds (cysteine, dithiothreitol, *etc.*);^{36, 51, 52, 96, 97} while antidotes (*i.e.*, substances that counteract poisons in human beings) are often used as reactivating reagents in the analysis of organic inhibitors. Thus 2-PAM (2-pyridinaldoxime methiodide) or TMB-4 [1,1'-trimethylenebis(4-hydroxyiminomethyl)pyridinium dibromide monohydrate] which accelerate hydrolysis of the phosphorylated active site of ChE are used for reactivation of the enzyme after its interaction with organophosphorus compounds.⁹⁸

The efficiency of enzyme reactivation depends on the nature of the reactivating agent, the degree of enzyme inhibition, the nature of the carrier and the time elapsed between inhibition and reactivation. By illustration, phosphorylated ChE which is reactivated at $\sim 70\%$ inhibition restores up to $95\% - 100\%$ of its initial activity, which makes it possible to use the same immobilised enzyme for 15–20 assays.⁸ When heavy metal salts are used as inhibitors, the reactivation amounts to $70\% - 80\%$ if the enzyme is immobilised on nitrocellulose⁹⁶ and up to 100% if gelatine is used as a carrier.⁹⁷

The effects of reactivating reagents, similar to those of inhibitors, are strictly selective. Therefore, the former can be used for separation of inhibitory effects of individual toxic agents present in the same solution as well as for selective determination of individual inhibitors. Thus it was proposed to determine Fe(III) ions according to their reactivating effects on peroxidase inhibited with cyanides or salicylic acid,⁵³ and to determine EDTA according to its reactivating effect on urease inhibited with Cu(II) ions.⁵² An addition of sodium iodide allows one to separate the inhibitory effects of Ag(I), Hg(II) and other heavy metal ions on urease⁵¹ and ChE.⁹⁸

An excess of reactivating reagents can decrease the enzyme activity down to complete irreversible inhibition as a result of elimination of cofactors from the active site or the formation of more potent inhibitors, *viz.*, the products formed in the reaction of the reactivating reagent with the toxic compound.⁹⁹ However, in some cases, reactivating reagents act as allosteric activators of enzymes.

3. Acidity of the working solution

The activities of enzymes and their sensitivities with respect to inhibitors are strongly pH-dependent; therefore, a crucial role in inhibitor assays is played by the correct choice of buffer solutions and pH.

In the overwhelming majority of studies, the optimisation of the composition of reaction media is aimed at eliciting maximum response of the biosensor with respect to the substrate, but not to the inhibitor. Indeed, in many cases, especially in the case of irreversible and non-competitive reversible inhibition, the pH of the medium corresponding to the maximum inhibitory effect is close to that providing optimum functioning of the enzyme (*e.g.*, in the cyanide assay with cytochrome oxidase,¹⁸ in dithiocarbamate and cyanide assays with tyrosinase and peroxidase^{27, 59} and

in organophosphorus pesticide assays with ChE and tyrosinase).^{8,30} In all those cases where the inhibitors had competitive or irreversible inhibiting action, the maximum sensitivity of the response of amperometric biosensors with respect to inhibitors was determined by the I_0/K_i ratio and the magnitude of the biosensor response to the substrates.

In many cases, the pH of the buffer solution can strongly influence the extent of inhibition. In particular, such effects are observed if the inhibitor is involved in acid–base reactions; it is noteworthy that only one of the equilibrium forms interacts with the enzyme. For example, the pH dependence of the inhibitory effect of metal ions on ChE is due to accumulation in solutions of metal hydroxo complexes MOH^+ , which competitively inhibit the enzyme.¹⁰⁰ As a result, the effects of Cu(II), Ni and Fe(II) ions are manifested in a very narrow range of pH which is limited from the alkaline region by the commencement of precipitation of the corresponding hydroxides. Apparently, the optimum value of pH (5.0) for Hg(II) determination with peroxidase in the presence of thiourea is associated with the hydrolytic stability of the inhibitor.⁵³ Colloidal solutions of heavy metal hydroxides can also inhibit enzymes, at least after long-term incubation. Thus the inhibitory effect of Hg(II) salts on urease was studied at pH 8.9;¹⁰¹ the maximum inhibitory effect of beryllium ions on alkaline phosphatase is manifested at pH 9.8.¹⁰²

Instability of inhibitors is yet another reason for the deviation of the working pH from the optimum values. Some organophosphorus pesticides are spontaneously hydrolysed in alkaline media, which markedly decreases the reproducibility of inhibition of free and immobilised ChE.⁸

Immobilisation of enzymes can significantly alter both the value of pH corresponding to the optimum enzymic activity and the sensitivity of the enzyme to the inhibitor. This is due to a change in ionic equilibrium constants caused by the differences in dielectric conductivity and ionic strength of the microenvironment of the enzyme active site and the solution. Enzyme carriers and ballast proteins being electrolytes can represent ion-exchange materials thereby increasing buffer capacity of the enzyme microenvironment and decreasing the rate of removal of hydrogen ions formed upon enzymic reactions into the solution.^{78,103} Therefore, the results of investigations of free enzymes demand verification when passing to the study of immobilised enzymes. For example, if ChE is immobilised by microencapsulation into cellulose trinitrate, the maxima of the enzymic activity and sensitivity towards organophosphorus pesticides are shifted to the alkaline region (to pH 9–10).¹⁰⁴ The pH maximum is not changed upon immobilisation of ChE on paper (7.5–8), but the sensitivity of the biosensor response to pH decreases in comparison with the corresponding dependence of the free enzyme.⁸

In some cases, a change in the pH dependence of inhibition due to immobilisation extends the range of compounds that can be determined. Thus hydrazinium dialkyl dithiophosphates inhibit microbial carboxyesterase at pH 3.5–4.5 but have no effect on free ChE. On the other hand, these compounds cause reversible inhibition of ChE immobilised on paper with a gently sloping maximum at pH 6.0.¹⁰⁵

When immobilised enzymes are incorporated into biosensors, the working range of pH can be narrowed due to the instability of the material used for the preparation of biosensors. For example, destruction of the electrode material limits the pH value for the operation of a cholinesterase biosensor based on a carbon–epoxide composition:¹⁰⁶ the assays of organophosphorus pesticides were carried out at pH 7.0, although the maximum enzymic activity was observed in the pH range 8.0–9.0. In the case of electron transfer mediators, the response of oxidoreductase biosensors was also pH-dependent, which can be ascribed to the change in the redox potential of the mediator.^{35,107,108}

4. The presence of effectors

The effect of compounds present in solution and affecting the enzymic activity is non-additive. Irreversible inhibitors used in low concentrations represent the only exception.

The presence of both a reversible effector and a substrate reduces the irreversible inhibition owing to the so-called protective effect.¹⁰⁹ In the course of incubation, the active site of the enzyme binds to the reversible effector to form a labile complex, which is inaccessible to an irreversible inhibitor. Following addition of the substrate, the complex dissociates, resulting in partial restoration of enzymic activity. In the majority of cases, the protective effect impairs the analytical characteristics of irreversible inhibitor assays, *viz.*, any effectors present in the sample under study including such widespread compounds as alkali and alkaline-earth metal salts, can increase at definite concentrations the limit of detection of the irreversible inhibitor. Therefore, the maximally permissible concentration of salts in the sample is specified to meet the requirements inherent in the methods of enzymic analysis of environmental pollutants irrespective of whether a free enzyme or a biosensor is used in the assay.

In some cases, enzyme effectors produce a synergistic effect, resulting in a considerable decrease in the limit of detection of the inhibitor or in an increase in the selectivity of measurement. Thus peroxidase ensures a highly sensitive determination of heavy metal salts; the inhibitory effects of Hg(II), Pb, Cd and Bi(III) increase following preincubation of the enzyme with thiourea or with 1,4-dithiothreitol for Bi(III)^{54,55} bringing about nonspecific inactivation of enzymes. With *o*-dianizidine as a substrate, the limit of detection of Hg(II) is 1×10^{-5} mg litre⁻¹, that with 3,3',5,5'-tetramethylbenzidine is 3×10^{-6} mg litre⁻¹. Cadmium and bismuth interfere with the assay when present in a 1000- or 10000-fold excess with respect to mercury. In contrast, organomercurials suppress the inhibitory effects of sulfur-containing compounds (phenylthiourea, 1,4-dithiothreitol). Thus, the selectivity and sensitivity of the method can be varied by changing the duration of incubation, the nature of the substrate and the second effector.

In the presence of magnesium ions, the sensitivity of zinc¹¹⁰ and beryllium¹⁰² ion assays with alkaline phosphatase increases, but the reproducibility of the signal decreases, as a rule. A sharp increase in the sensitivity of ChE to pesticides (chlorofos, 2,4-D, DDT) and heavy metals was observed¹⁰⁴ in alkaline borate buffer in the presence of calcium ions. This effect is manifested within rather narrow ranges of pH and effector concentrations. Interestingly, 2,4-D and DDT do not inhibit free ChE; therefore, in this case either a cooperative effect of calcium ions and pesticide molecules on the active site of the enzyme is manifested or indirect indication of toxic agents, *e.g.*, owing to elimination of the activating effect of calcium ions on ChE upon its incorporation into the enzyme–inhibitor complex or to spatial blockade of the access of hydrophobic pesticide molecules to the enzyme-containing membrane.

V. Cholinesterase-based biosensors

Cholinesterase is being especially widely used and thus deserves special consideration. This enzyme is the subject of up to 60% of publications devoted to biosensors. The interest in ChE of practitioners in environmental and analytical monitoring and toxicology is due to the broad range of inhibitors which involve such widespread toxicants as organophosphorus compounds, heavy metal salts, surfactants, *etc.*^{8,86,94}

Acetylcholinesterase provides hydrolytic cleavage of a natural neurotransmitter, *viz.*, acetylcholine, *i.e.*, it is responsible for the discreteness of transmission of nerve pulses.¹¹¹

Cholinesterases differ in their substrate specificities. Thus acetylcholinesterase (AChE) (EC 3.1.1.7) hydrolyses acetylcholine at the highest rate and does not hydrolyse butyrylcholine. Its activity is inhibited by an excess of a substrate, since deacylation is inhibited by the binding of the second acetylcholine molecule to the anionic site of the acyl-enzyme.¹¹² Butyrylcholinesterase (BChE, EC 3.1.1.8) catalyses hydrolysis of butyrylcholine with the highest efficiency but can also react with acetylcholine. Therefore, this was termed pseudo- or nonspecific cholinesterase, in contrast with the true, specific AChE.

At present, various ChE preparations for biochemical assays including the most popular AChE reagents from electric eel ('Sigma', USA, 'Boehringer', Germany) and BChE from equine blood serum (Joint-Stock Company 'Biomed', Perm, Russia; 'Sigma', USA) are manufactured on an industrial scale. These preparations are available as freeze-dried powders, AChE is also purchased as frozen aqueous solutions containing ammonium sulfate.

Numerous esters of phosphoric, phosphonic and pyrophosphoric acids, carbamates and sulfonic acid esters are irreversible and specific inhibitors of ChE. They bind covalently to the active site of the enzyme to form phosphorylated (carbamoylated, sulfonylated) ChE. Organophosphorus compounds (parathion, diazinon, malathion, *etc.*) are very weak reversible inhibitors of ChE *in vitro*. This is due to the inability of the sulfur atoms to form hydrogen bonds with the hydroxy group of serine-200. In the organism of insects, thionophosphorus pesticides are oxidised by nonspecific oxidases to oxygen analogues. Thus parathion gives paraoxon, malathion gives malaoxon, *etc.*¹¹³ As a result, the inhibitory effect of pesticides increases 10 000-fold and even more. Metabolic activation of the insecticide as a result of the so-called lethal synthesis decreases the hazard of acute poisoning of humans with simultaneous preservation of high insectoacaricidal activity of the preparations. Prior to determination of thionophosphorus pesticides with ChE, they were oxidised to the corresponding oxygen analogues with bromine water¹¹⁴ or 50% nitric acid.¹¹⁵ An effective procedure has been also developed for the oxidation of thionophosphates with chlorine or bromine generated *in situ* by galvanostatic electrolysis.¹¹⁶

Quaternary ammonium salts, acridine derivatives and metal ions are also known as reversible inhibitors of ChE. The activity of ChE decreases also in the presence of polar organic solvents miscible with water.¹¹⁷

Cholinesterase is widely used for the determination of residual organophosphorus and carbamate-type pesticides in water, aqueous and aqueous-organic extracts from plants, soil, food products, *etc.* The published data (1993–1998) concerning cholinesterase biosensors designed for pesticide assays are listed in Table 2.

Enzyme–inhibitor specificity. The analytical parameters of determination of ChE inhibitors strongly depend on the source of the enzyme. Cholinesterases from insects manifest the highest sensitivity with respect to organophosphorus pesticides.^{91, 150, 151} Thus the inhibition constant, k_{II} , of dimethyl dichlorovinyl phosphate (DDVP) is $5 \times 10^5 \text{ mol}^{-1} \text{ litre min}^{-1}$ for AChE from *Drosophila melanogaster*, while that for AChE from bovine erythrocytes is $< 10^3 \text{ mol}^{-1} \text{ litre min}^{-1}$ (see Ref. 91). Cholinesterase from cockroach allows one to determine DDVP at a concentration of $8 \times 10^{-9} \text{ mol litre}^{-1}$, whereas in the case of mammalian enzymes the limits of detection are 10–100 times as high.¹⁵⁰ Insect ChEs are also sensitive to organochloric pesticides (2,3-D, DDT, *etc.*), which seem to be reversible inhibitors.

These enzymes are difficult to isolate in sufficiently large amounts, which restricts their practical application. In future, the situation may change owing to the progress in gene engineering. The preparation of AChE from *Drosophila melanogaster* by incorporation of a mutant gene responsible for AChE synthesis into the genetic apparatus of microorganisms has been described. The yield of AChE was several milligrams per litre of the cultural fluid. This preparation is characterised by high sensitivity to

organophosphorus and carbamate-type pesticides despite its low activity in comparison with the natural AChE from the same source.⁹¹

Cholinesterases from blood serum¹⁵² and brain¹⁵³ of various fish and avian¹⁵⁴ species as well as from the squid optical ganglion¹⁵⁵ are promising for analytical determination of inhibitors. The problems of low stability can be partly solved by immobilisation of the enzymes in gelatine or agar.

The majority of cholinesterase biosensors utilise only three commercial preparations of ChE, *viz.*, AChE from the electric organ of eel *Electrophorus electricus*, bovine erythrocytes and BChE from equine blood serum. Comparison of analytical characteristics (see Table 2) demonstrates difficulties in establishing enzyme–inhibitor specificities for different biosensors. Thus the reported limits of detection of paraoxone using inhibition of AChE from electric eel vary from 10^{-7} (Refs 47 and 134) to $4 \times 10^{-11} \text{ mol litre}^{-1}$ (Ref. 136); for chlorofos (trichlorofon) and its active principle (DDVP), the scatter in the limits of detection amounts to five orders of magnitude, *viz.*, from 10^{-11} (Ref. 104) to $10^{-6} \text{ mol litre}^{-1}$ (Ref. 134).

The experimental value of k_{II} for AChE from electric eel ($< 10^3$ – $4 \times 10^4 \text{ mol litre}^{-1} \text{ min}^{-1}$) is smaller than that for BChE from equine blood serum (8×10^4 – $2 \times 10^5 \text{ mol litre}^{-1} \text{ min}^{-1}$) according to different authors (Refs 86, 91 and 156). It should be mentioned that the sensitivity of chlorofos detection with AChE-based biosensors is higher and the limit of detection is lower than the corresponding analytical characteristics of butyrylcholinesterase-based biosensors. The reason, as in the case of many other similar discrepancies, may be due to diffusion-dependent inhibition of the biosensor response. Commercial preparations of AChE from electric eel normally have high specific activity, which exceeds manyfold (sometimes, hundreds times) that of BChE from equine blood serum. The latter enzyme forms denser films upon immobilisation than the immobilised AChE with high content of the ballast protein. As a result, the biosensors operate in a diffusional-kinetic regime, and the inhibitory effect of the pesticide is reduced.

Special mention should be made of early studies aimed at determining thionophosphorus pesticides without preliminary oxidation. Thus the limits of detection of malathion (carbofos) without preliminary oxidation were 0.1 (Ref. 122) and even 1.6–4.6 mg litre^{-1} (Refs 157 and 158), whereas that after oxidation with bromine water was of the order of $10^{-4} \text{ mg litre}^{-1}$ (Ref. 159).

From the standpoint of toxicology, it is the inhibition of AChE that presents special interest. The calculated values of inhibition constants of AChE (k_{II}) correlate with the mean lethal concentrations (LC_{50}) for mice and rats as well as with hygiene and sanitary MPC standards for natural water reservoirs.^{86, 113, 134} Nevertheless, the use of BChE incorporated into biosensors gives in general comparable limits of detection of pesticides which differ not more than 100-fold in both directions (see Table 2). In order to extend the range of compounds that can be determined by this method, some investigators deliberately decrease the selectivity of the biosensor response through simultaneous use of several ChE isolated from different sources.^{115, 160} Tissue homogenates or biological fluids possessing esterase activity (blood, liver homogenates, *etc.*) are used for the same purpose.^{161–163} By selecting substrates of different specificity, one can vary the set of esterases the activity of which is to be monitored. Thus the use of indophenyl acetate makes it possible to record the overall response of BChE and carboxylesterases. Acetyl(thio)choline is used to detect the responses of AChE and BChE, while butyryl(thio)choline is used for the BChE signal. This extends the potentialities of identification of toxic agents.

Immobilisation (stabilisation) of ChE sometimes plays a crucial role. Immobilisation decreases (or rarely increases) the sensitivity of biosensors with respect to inhibitors in comparison with the free enzyme. Covalent immobilisation by cross-linking of ChE on the electrode surface or an appropriate carrier using glutar-

Table 2. Some characteristics of methods used for the determination of pesticides with ChE-based biosensors and experimental parameters, *viz.*, concentration range ($c/\text{mol litre}^{-1}$) and limits of detection ($\text{LD}/\text{mol litre}^{-1}$).

Note. The following abbreviation were used: pH-ISE is pH-sensitive ion-selective electrode; DDVP is dimethyl (2,2-dichlorovinyl) phosphate; ^a mg litre ^{−1} ; ^b the values of $p_c = -\log c/\text{mol litre}^{-1}$ are listed; ^c µg litre ^{−1} ; ^d mol ^{−1} litre min ^{−1} ; ^e mol litre ^{−1} .								

Note. The following abbreviations were used: pH-ISE is pH-sensitive ion-selective electrode; DDVP is dimethyl (2,2-dichlorovinyl) phosphate; ^a mg litre⁻¹; ^b the values of $p_c = -\log c/\text{mol litre}^{-1}$ are listed; ^c µg litre⁻¹; ^d mol⁻¹ litre min⁻¹; ^e mol litre⁻¹.

aldehyde (in vapour or as an aqueous solution) ^{118–120, 129, 130, 133, 134, 137, 138, 149} or carbodiimide ^{127, 128, 135, 136, 140} are conventionally used. A decrease in enzymic activity as a result of covalent immobilisation depends on the concentration of the cross-linking reagent, the duration of treatment, the initial activity of the enzyme and the nature of the carrier. The losses are minimal (20%–40% of the initial enzyme activity) when protein films are prepared from albumin and gelatine, which are also cross-linked, and in the immobilisation of ChE on aminated carriers of the Immobilon or Biotin type. Highly reactive enzyme-containing membranes are prepared by incorporating enzymes into hydrophilic gels based on acrylamide, ^{79, 159} a *N*-vinylpyridinium–vinyl chloride copolymer, ^{132, 142} polyethyleneimine, ^{121, 123} tetramethyl orthosilicate ¹⁴⁷ and polyurethane. ¹⁶⁴ Biosensors prepared with such membranes are characterised by a rapid response to the substrate; however, the lifetime of immobilised enzymes is much less than that of enzymes obtained by covalent immobilisation on inert carriers.

Under field conditions, it is especially convenient to use biosensors with disposable membranes which can easily be replaced in the case of enzyme inactivation. Disposable membranes are prepared on the basis of inert carriers, such as nylon, ^{122, 125, 145, 165, 166} paper and various cellulose derivatives, ^{40, 93, 96, 104, 105, 124, 167, 168} aluminium hydroxide, ^{164, 169} industrially manufactured membranes (for dialysis and immunoblotting) or carriers for affinity chromatography. ^{122, 140, 141}

The largest losses (up to 99% of the original ChE activity) were observed upon cross-linking of enzyme globules with aqueous solutions of glutaraldehyde on inert carriers, which do not react with the cross-linking reagent, ¹²⁴ such as cellulose trinitrate or paper. Such considerable losses are compensated for by high storage stability of the membranes (up to 6 months at room temperature) and operation lifetime (for over two weeks in a buffer solution within the biosensor).

As a rule, immobilisation of ChE does not envisage the use of additional water-soluble stabilisers. However, in some cases 0.1%–3% glycerol, glycine, non-ionogenic synthetic surfactants, 0.01%–0.05% gelatine, magnesium and calcium salts (in the case of AChE) are used to stabilise the activity of the free enzyme.

Stabilisers are necessary when ChE is used in aqueous solutions for analytical purposes, since the stability of even freshly prepared solutions is low. Thus ChEs from insects are completely inactivated within several hours, ¹⁷⁰ AChE from electric eel is stable in a concentrated ammonium sulfate solution. Stabilisers increase the storage stability of enzymes. They form films in which the enzyme is in a solid solution. Such preparations are readily soluble and yield stable solutions the activity of which is not changed during the measurement of the inhibitory effect. In other cases, stabilisers are added directly to the enzyme solution for the same purpose. The addition of stabilisers also decreases the losses of enzymic activity in the course of immobilisation. ¹³⁶ Cellulose and dextran derivatives, other polyalcohols and some non-ionogenic surfactants are used as ChE stabilisers. Probably, they inhibit nonspecific sorption of the protein on glass or a plastic, integrate inhibitors (especially, transition metal ions) into inert complexes or stabilise the tertiary structure of the protein. Incorporation of ChE into tregalose ¹⁶⁹ and *N*-phthalylchitosane ^{73, 116, 155, 171} films for the development of colorimetric indicator devices designed for the determination of ChE inhibitors has been described. Stabilisers suppress the interfering effects of metal ions but do not change the kinetic characteristics of irreversible inhibition of ChE by organophosphorus pesticides.

With a decrease in the diffusion-dependent limitations of biosensor responses, *i.e.*, in the case of thinner membranes and lower specific activity of enzymes, the results of inhibitor assays obtained with free and immobilised enzymes are close. Therefore, amperometric biosensors based on membranes with lower enzy-

mic activities than those used in potentiometric biosensors acquire certain advantage due to higher sensitivity of substrate assays.

On the other hand, comparison of efficiencies of potentiometric and amperometric biosensors under identical conditions shows that the advantages of amperometric detection are not so obvious. ⁹⁴ Thus in experiments with disposable membranes with ChE immobilised on nylon, nitrocellulose or in gelatine, potentiometric biosensors manifested lower limits of detection of paraxon and DDVP. ^{93, 172} This may be due to the interfering Faraday effects, particularly, to additional generation of hydrogen ions upon thiocholine oxidation on the electrode.

Calculation of inhibition bimolecular constants from calibration curves of pesticide assays utilising a potentiometric biosensor with disposable membranes according to Eqn (10) gave overestimated values in comparison with inhibition of the free enzyme under identical conditions. One of possible reasons for increased sensitivity of pesticide assays in the case of immobilised ChE is adsorptive accumulation of pesticides on inert carriers. In particular, this can be confirmed by the fact that non-ionogenic surfactants used in concentrations which do not influence the activity of native ChE, produce differentiating effects on the response of cholinesterase-based biosensors to various inhibitors, *viz.*, the irreversible inhibition effect of pesticides is increased, while the reversible inhibition effect of fluorides or heavy metal ions is decreased. Small concentrations of surfactants also suppress the protective effects of reversible inhibitors in organophosphoric pesticide assays. ¹²⁵ This effect is due to sorption of surfactants on the membrane surface, which facilitates the transfer of hydrophobic organic pesticide molecules to the membrane, while the transfer of small hydrophilic ions (reversible ChE inhibitors) is impeded. The effect of surfactants is a maximum for hydrophilic carriers (paper, nylon) and a minimum for nitrocellulose membranes. The difference between inhibition bimolecular constants for free and immobilised enzymes changes in the same series. For hydrophobic nitrocellulose, the difference is a maximum, while that for hydrophilic paper and gelatine is virtually absent. ^{173, 174}

Increased sensitivity of inhibitor assays upon enzyme immobilisation is observed not only for ChE. The limit of detection of heavy metals with oxidoreductases immobilised in albumin films decreases in the following order (mg litre⁻¹): from 0.25 to 0.05 for Hg(II), from 1.00 to 0.05 for Cu(II) (alcohol oxidase), from 1.00 to 0.10 for Ni (sarcosine oxidase) and from 0.50 to 0.015 for Se(IV) (glutathione oxidase). ⁴⁴ Obviously, electrostatic interactions of metal ions with charged carriers play an important role in these processes along with nonspecific sorption.

Monitoring of environmental objects. Virtually, all the data listed in Table 2 relate to model solutions containing only one ChE inhibitor. The use of cholinesterase-based biosensors for the analysis of real objects is complicated, firstly, because of the presence of considerable amounts of natural enzyme effectors (alkaline-earth metal ions, biogenic amines, *etc.*) in analysed samples and secondly, due to simultaneous presence of several inhibitors with different mechanisms of action. This fact significantly complicates the interpretation of experimental results: one has either to confine oneself to qualitative detection of anti-acetylcholinesterase compounds in analysed samples or to have recourse to their preliminary separation at the expense of simplicity and rapidity, which are the main advantages of enzymic assays.

Commercial production of test systems based on ChE and designed for monitoring residual organophosphorus and carbamate-type pesticides in environmental objects and foodstuff has already been set up. These systems, which represent indicator kits with colorimetric indication are manufactured by 'Boehringer

Mannheim' (Germany)¹⁷⁵ and 'Ohmicron Environmental Diagnostic Inc.' (USA)¹⁷⁶ and ensure qualitative detection of organophosphorus pesticides with limits of detection ranging from 0.05 to 30 $\mu\text{g litre}^{-1}$.

In the 1970's, the manufacturing company 'Midwest Research Institute' (USA) produced a family of automated indicator systems CAM-1,2 (Continuous Alarm Monitor), which represent alarm devices for detecting toxic war gases of neuromuscular action and are adapted to civil needs.¹⁶⁴ These systems are supplied with pumps and aspirators and operate in a semi-automatic regime. The minimum concentrations of pesticides detectable in air and water are as follows (mg litre^{-1}): paraoxon, 0.1; DDVP, 0.2; diazinon, 0.2; dursban, 4.3; difonate, 10; malathion, 17–70 (depending on the brand); temic, 0.5; furadan, 0.75; mesuron, 12 and sevin, 20. Their service cycle includes automated substitution of enzyme-containing polyurethane reactors and electrochemical purification of electrodes, they are supplied with an acoustic signal device of contamination.

A potentiometric biosensor containing AChE immobilised in gelatine on the surface of a pH-metric glass electrode was used to control the quality of waters in the river Seine (France).^{177, 178} The limits of detection of pesticides with this biosensor were as follows (mg litre^{-1}): 0.003 (ethylparaoxon), 0.005 (methylparaoxon) and 0.014 (malathion, ethyl- and methylparathion). Some countries including Russia have begun the commercial production of indicator tubes which contain ChE and chromogenic substrates and are designed for standard aspirators used in air sampling.¹⁷⁹

At present, the possibility to use ChE for environmental and analytical monitoring is chiefly associated with the creation of a market of cheap electrochemical sensors which can form the basis for mass-scale production of disposable cholinesterase-based biosensors that are compatible with standard measuring devices (voltamperographs, ionometers, *etc.*). Such sensors can be manufactured by photolithographic methods. Because of High-Tech production, small size (several square millimetres) and low enzyme expenditure (~ 0.1 unit per electrode), the cost of such biosensors does not exceed US \$1–5. The production of pH-sensitive field transistors and microplanar conductometric devices is currently under way.^{118–120} A technology for the production of screen-printed metal-coated and carbon-paste electrodes with plastic mounts has been developed.¹⁸⁰ The cost of equipment needed for their production amounts to US \$30 000, which is comparable with the cost of a general-purpose voltamperograph. At present, screen-printed electrodes are manufactured in the Czech Republic,¹³³ Italy^{180, 181} and Germany.¹⁸² All of them represent a combination of a working, auxiliary electrode and a reference electrode (Ag/AgCl), which have various geometries, are arranged into a single block (sometimes, in pairs) and operate in a differential regime.

The progress in the design of biosensor elements demands adequate solution of methodological problems. As expected, the effect of the matrix of the analysed subject does not seem to be of crucial importance.¹¹⁵ Biosensors are used for the determination of residual organophosphorus and carbamate-type pesticides in vegetables, fruits, juices,^{137, 138, 183} soils and silt sediments.^{134, 184} The only limitation in the analysis of surface waters is their mineralisation, which should not exceed $0.1 \text{ mol litre}^{-1}$ (Refs 122 and 177). It has to be specified, however, that the accuracy of pesticide assays with biosensors was checked using a method of additives rather than independent methods. Chromatographic methods were used for the estimation of the correctness of measurements only in the case of carbamate-type pesticide assays in vegetables,¹³⁸ of organophosphorus and carbamate-type pesticide assays in fruits and vegetables¹⁸³ and of organophosphorus pesticide assays in natural waters (freezing and subsequent thawing of standard samples).¹²⁸ The divergence of experimental results was $\sim 30\%$, which was accepted to be satisfactory.

A number of simplified sampling techniques have been developed which help elimination of laborious procedures connected with the removal of organic solvents. Thus, a 10-minute

extraction with acetone followed by 10-fold dilution of extracts allows reliable determination of up to 0.1 mg kg^{-1} of pesticides (diazinon, chlorofos, tetraethyl monothiopyrophosphate) in wheat grains and combined fodders.¹⁷² However, in this method the level of extraction is 60%–80%, which means that it is only possible to detect hazardous contamination of the products with pesticides.

If the information about the nature of toxic agents is absent, a reduced biosensor response should not necessarily be related to the concentration of the compound under study. The difference in inhibition bimolecular constants does not allow one to regard the degree of inhibition as a measure of net (molar or mass) content of pesticides even in the absence of interfering factors (diffusion-dependent inhibition of biosensor responses, protective action of effectors, *etc.*). A concept of a standard toxicant has been proposed according to which the net content of pesticides is expressed in units of concentrations of the pesticide used as a standard judging from the inhibitory effects they produce. DDVP,¹⁶⁴ paraoxon,¹³² parathion¹¹⁵ and carbaryl^{180, 181} were recommended as candidates for such standards. The inhibiting effects of other pesticides are calculated with the help of relative toxicity coefficients. The latter are determined in model pesticide solutions of equal concentration by estimating the degree of inhibition of ChE (*i.e.*, a relative decrease in the biosensor response). Undeniably, these coefficients are not equal to the ratio of inhibition constants and depend on experimental parameters including the choice of pesticide concentrations. Similar limitations are typical of calculations of pesticide concentrations expressed as factors of excess over MPC.

Simultaneous use of several biosensors including enzyme-based ones affords additional possibilities for differentiation of biosensor responses. In contrast with the above-described determination of the ratio of inhibition constants ($k_{\text{H}1}/(k_{\text{H}2})$, in this case the result is obtained instantaneously, which makes it possible to use a set of biosensors^{47, 63, 185} (or a multichannel multisensor^{40, 41}) for on-line or even flow measurements.

Hydrolytic enzymes, *e.g.*, urease,^{40, 41} acid and alkaline phosphatases^{47, 185} and glucose oxidase^{40, 41} can also be used for this purpose together with ChE. Unfortunately, enzyme–inhibitor specificity of these enzymes does not allow simultaneous qualitative and quantitative determination of inhibitors. In the best case, adequate interpretation of experimental results can be achieved through the use of chemometric methods, *e.g.*, by estimating individual contributions of Hg(II) ions and the overall effect of all pesticides.¹⁸⁵ However, in this case, too, the mutual effect of solution (sample) components is questionable, since the information about the relative sensitivity of biosensor responses is obtained for single-component solutions. Even with the use of experimental planning methods for the choice of conditions for detecting inhibitor signals, the possibility to separate the contributions of individual inhibitors was established for sufficiently high concentrations (1 mg litre^{-1}), which exceeded the existing hygiene and sanitary standards a thousand-fold.

To some extent, the selectivity of effects produced by reacting reagents can assist in interpretation of experimental results. Thus the anti-cholinesterase effect of metal ions can be suppressed by EDTA and sodium iodide, which allows manifestation of the toxic effect of pesticides.^{1, 97} Contrariwise, ChE added to analysed samples can bind trace amounts of anti-cholinesterase pesticides and then the toxic effects of other pollutants can be determined with other enzymes or indicator organisms.¹

In another approach, the very fact of ChE inhibition is considered as a proof of contamination without regard for the qualitative and quantitative composition of the analysed sample.¹⁸⁶ This approach is widely used in toxicological studies which make use of a special term, 'anti-cholinesterase activity' for a substance or tested subject.^{187, 188} The activity of AChE from blood or brain serves as a measure of chronic poisoning of living organisms with sublethal concentrations of pesticides.^{189, 190} The

total inhibitory effect of toxic agents (*i.e.*, the anti-cholinesterase activity of the medium) can also be used for detection of hazardous poisoning levels and for outlining the main tendencies in their variability. Studies of inhibitory effects of silt sediments in the rivers of the Morava Basin which employed biosensors based on AChE from electric eel revealed a relationship between biosensor signals (the inhibition was studied by following relative changes in the dynamic responses) and agricultural impact on the given territory.¹³⁴ The biotesting conducted by the methods accepted in biological monitoring of surface and sewage waters established a correlation between the degree of inhibition of BChE immobilised on paper or nitrocellulose and the death rate or retardation of growth of hydrobionts of the Cladocera family (crayfish *Daphnia magna* Straus) and the protococcal alga (*Chlorella vulgaris* Beyer).^{191, 192} In the first place, this correlation was established for specific inhibitors of ChE. An analysis of real environmental objects revealed a certain divergence of results obtained by different methods. For example, studies of more than 200 samples of sewage waters from industrial and agricultural enterprises with the aid of potentiometric cholinesterase-based biosensors and acute toxicity tests of waters for the presence of Infusoria (*Paramecium caudatum*) have made it possible to classify all sewage waters into three groups according to the contamination source, *viz.*, (1) sewage waters from machine-building plants which are predominantly contaminated with heavy metals (high death rate among *Paramecium caudatum* with moderate levels of ChE inhibition); (2) sewage waters from petrochemical plants and enterprises of food industry which are contaminated with petroleum products, fats and other high-molecular-weight organic compounds (high death rate among *Paramecium caudatum* in the absence of ChE inhibition) and (3) sewage waters from agricultural enterprises and surface run-off wastes from rural areas (lack of toxicity for Infusoria, low and medium levels of ChE inhibition).¹⁹³

The methods which combine biological and biochemical parameters of water quality (and, in prospect, other generalised hydrochemical parameters) seem to hold especially great promise, primarily due to the possibility to extend the range of potential toxic agents present in environmental objects.

VI. Conclusion

The explosive development of enzymic methods for monitoring of environmental objects has become possible because of a combination of fundamental and applied investigations at the boundaries between biochemistry, biotechnology, toxicology, analytical chemistry and environmental monitoring. With the advent of biosensors, purely laboratorial complex biochemical methods have been transformed into easy-to-handle measuring tools, which are comprehensible for the untrained personnel and are suitable for field use.

This does not mean, however, that the design of biosensors is exclusively confined to the selection of appropriate detectors and immobilisation of enzymes. Investigators are faced with the necessity to solve complicated problems connected with functional features of enzymes to be incorporated into biosensor membranes as well as with optimisation of measurement conditions and effects of template components. A transition from a free enzyme to a biosensor results in the narrowing of the range of experimental facilities used in the study of biologically active substances. Thus the minimum concentrations of substrates and the specific activity of enzymes are limited, while biosensors sometimes require *a priori* non-optimal conditions for their functioning, which are restricted by detectability parameters or specific applications. Optimisation of the biosensor design and the choice of service conditions always involve a compromise between the requirements for the accuracy of response detection, the sensitivity of inhibitor (substrate) assays and the limitations imposed by actual conditions of field tests.

Realisation of specific functioning of biosensors designed for evaluation of toxic effects of environmental pollutants has stimulated the research carried out for commercial purposes. In the first place, this relates to disposable biosensors based on screen-printed and solid-state sensors as well as to the simplest indicating devices with visual indication of signals. Their practical application is still limited due to complexity of interpretation of experimental results and inadequacy of the standardising basis, which bans the use of the data obtained by biochemical monitoring methods for ecological expertise. For this reason, only cholinesterase-based biosensors have found application in environmental and analytical monitoring, although biosensors allow the detection of virtually all priority-driven toxic agents with the exception of dioxins and radioactive compounds.

Nevertheless, the development of biosensors for the determination of environmental pollutants is a very promising trend, primarily because they meet demand. The methods based on the use of biosensors compete favourably with modern methods of toxicological and biological monitoring. To their obvious advantages one may relate small dimensions, ease of signal detection, possibility of integration of biosensors into automated control systems and, last but not least, possibility of quantification of toxicological effects. In our opinion, further developments in this field will proceed along three main lines.

1. Further development of the principal elements aimed at improving the metrological and operational characteristics of transducers and transition to polyenzyme sensors (*e.g.*, multi-sensors, sensor arrays), which help establish not only the presence of inhibitors in analysed subjects but also their nature.

2. Further extension of the range of tested compounds, mostly through optimisation of service conditions for measurement and sampling rather than by increasing of the number of enzymes; further improvement and application of biosensors designed for use in organic solvents, particularly those used as detectors in flow-injection analyses and liquid chromatography.

3. Further development of methodical and methodological aspects of applicability of biosensors in environmental and analytical monitoring; design of expert systems for estimation of biological (physiological) activity of chemical compounds, toxic effects of solid industrial and vital activity wastes; combination of biosensors with conventional methods of biological monitoring and, as a consequence, increasing the information content of biochemical monitoring; large-scale application of methods for chemometric treatment of experimental results.

The integration of different methods and approaches to environmental and toxicological monitoring of environmental objects is still in progress. Recent developments in the field of biosensors are not confined to routine application of enzymes as analytical reagents. Biosensors are used as biochemical models of living organisms and the approaches used therein are related to toxicology and biotesting.¹⁹³ First attempts have been undertaken to direct alteration of the enzyme structure with a view to changing its inhibiting specificity.⁹¹ This approach makes use of 'artificial enzymes' (*i.e.*, oligonucleotides or polymers); their synthesis and selection were performed using molecular recognition of specific toxic agents.¹⁹⁴

And, finally, the vast experience gained in the study of biosensors has served as a basis for the design of entirely new devices, *viz.*, DNA-sensors allowing direct control over mutagenic and genotoxic properties of environmental pollutants.¹⁹⁵ The specificity of their functioning goes far beyond the scope of this review, although their role in the development of new methods of monitoring of environmental objects is now apparent.
