The number of studies in the field of the design of molecular ferromagnets increases rapidly. Owing to the aforementioned high integration requirements concerned with the problem, experts in the field of inorganic, organometallic or organic chemistry and in materials science, chemical physics and physics of magnetism are involved in collaboration. The results of these studies are extremely 'scattered' in scientific publications; therefore, biennial international conferences on molecule-based magnets play an important uniting role (see, *e.g.*, Refs 15 and 16). The proceedings of these conferences are published in the journal *Molecular Crystals and Liquid Crystals* (see, *e.g.*, Refs 17 and 18). However, these are far from being the only international conferences with scientific sections devoted to molecular ferromagnets (see, *e.g.*, Refs 19 and 20).

In this review, we made an attempt at the generalisation and systematisation of the main approaches and strategies existing at present in the field of the synthesis of molecular ferromagnets. As a rule, the design of particular compounds triggers an entire complex of studies dealing with the analysis of structure, magnetic-structural relationships and mechanisms of exchange interactions between the unpaired electrons in paramagnetic centres. In all of the molecular ferromagnets discussed in the present review the structure of a molecule or a bridging ligand involves at least one carbon atom. The presence of one carbon atom, or better several carbon atoms, reflects the common desire of the researchers to use as soon as possible all the potential of synthetic organic chemistry in the given area.

Here we do not consider the classical magnetically active systems in which the metal atoms in the solid phase are separated by the individual oxygen, carbon, sulfur, halogen or boron atoms.

II. Systematisation principles

For a systematic generalisation of chemical compounds involved in the design of molecular ferromagnets, we offer a specific

'language'. It is therefore reasonable to discuss the principles underlying its construction. In this work we speak of metal-containing molecular ferromagnets as being two or three-dimensional systems (as regards their structures);[‡] hence the common features of all of the systems under consideration are the presence of a paramagnetic metal ion in a compound and the presence of a bridging group of atoms linking the metal ions to form a layer or a framework. Therefore, the description of a particular system can be given by the key formula M_nM' , where M and M' are paramagnetic metal ions (the same, different or existing in different oxidation states) and n is the smallest number of atoms in a bridging unit connecting the M and M' ions.

Thus, we shall refer cyanide complexes of metals containing, *e.g.*, such fragments as $V^{3+} - C \equiv N - V^{3+}$, $Cr^{3+} - C \equiv N - Ni^{2+}$ and $Fe^{2+} - C \equiv N - Fe^{3+}$ to the $M2M'$ class, since the bridging cyanide is a diatomic unit. Carboxylate, oxalate, bipyrimidine, azide or dicyanamide polynuclear complexes containing triatomic bridges as the shortest ones belong to the $M3M'$ class.

According to the above approach, the complexes with 3- and 2-imidazoline derivatives are regarded as $M4M'$ systems.

Heterospin polynuclear metal complexes with nitronyl nitroxyl radicals or 2-imidazoline 3-oxide paramagnetic derivatives, which play the bridging role, belong to the $M5M'$ systems.

More complicated situations are also possible where one bridging ligand can form exchange channels with different numbers of atoms between the metal ions or the bridging function is played by several ligands creating the exchange channels with different numbers of bridging atoms. We designate such systems as $MnnM'$, if the ligands are the same, and $Mn(n')M'$ if the ligands are different. Fragments of an $M31M'$ system with one ligand and $M3(3)M'$ and $M3(1)M'$ systems with different bridging ligands are shown below as examples.

[‡] It should be noted that structural dimensionality, *i.e.*, molecular (zero-dimensional), chain (one-dimensional), layered (two-dimensional) and framework (three-dimensional) compounds, should not be confused with magnetic dimensionality, *i.e.*, isolated exchange clusters (zero-dimensional), exchange chains (one-dimensional), *etc.*; in many cases, the structural and magnetic dimensionalities do not correlate.

The systematisation suggested here is general and is not limited to specific metal ions or bridging ligands.

III. M2M' systems

The molecular ferromagnets of the M2M' class primarily include coordination compounds with the bridging cyanide ligands. The ability of homo- and heterometallic hexacyanides to undergo ferro- and ferrimagnetic ordering at low temperatures has been known for a long time (see, *e.g.*, Refs 21 and 22). However, the problem was recently considered in a different way^{23–31} and an essentially new contribution to the design of high-temperature molecular ferromagnets of the M2M' type based on metal cyanide complexes was made.

The first synthetic coordination compound, *viz.*, Prussian blue, whose framework structure was established by Buser *et al.*,³² may be considered as an ancestor of this group of molecular ferromagnets. The highly symmetrical octahedral coordination anion $[\text{M}(\text{CN})_6]^{n-}$ serves as a starting block for the construction of two- and three-dimensional structures.³³ If an additional M' ion is introduced, the system can undergo polymerisation along two or three mutually perpendicular directions.

Prussian blue itself, $\text{Fe}_4^{\text{III}}[\text{Fe}^{\text{II}}(\text{CN})_6]_3 \cdot x\text{H}_2\text{O}$ ($x = 14–16$), has a framework structure (cubic face-centred structure) and undergoes a magnetic phase transition at 5.6 K.³⁴ The low temperature of the magnetic ordering is due to the fact that the Fe^{II} ion is in the low-spin d^6 state. As a result, the exchange interactions between the paramagnetic centres (the Fe^{III} ions) located in the $\text{Fe}^{\text{III}}-\text{N}\equiv\text{C}-\text{Fe}^{\text{II}}-\text{C}\equiv\text{N}-\text{Fe}^{\text{III}}$ fragments at a distance of 10.6 Å from each other are rather weak.²⁶ Thus, it seemed reasonable to assume that the magnetic ordering temperature will be higher if all of the metal ions are paramagnetic. Verdaguer *et al.*,^{23–31} were the first to perform a directed synthesis of Prussian blue analogues in which the iron ions were replaced by other metal ions in variable ratios. Table 1 presents some data for hexacyanometallates of the general formula $\text{M}_3[\text{M}'(\text{CN})_6]_2$ from which it is possible to follow the regularities of changes in the magnetic ordering temperature (we do not specify its type, *i.e.*, ferromagnetic, ferrimagnetic or antiferromagnetic).

Table 1. Magnetic ordering temperatures for hexacyanometallates $\text{M}_3[\text{M}'(\text{CN})_6]_2$.

M	T_c /K	M	T_c /K
$\text{M}_3[\text{Cr}(\text{CN})_6]_2$		$\text{M}_3[\text{Mn}(\text{CN})_6]_2$	
V^{II}	315	Mn^{II}	37
Cr^{II}	240	Ni^{II}	37
Cu^{II}	66		
Mn^{II}	60	$\text{M}_3[\text{Fe}(\text{CN})_6]_2$	
Ni^{II}	53	Cu^{II}	20
Co^{II}	23	Mn^{II}	9
Fe^{II}	16	Ni^{II}	23
		Co^{II}	15

In a series of complexes containing the $[\text{Cr}(\text{CN})_6]^{3-}$ anions, the values of T_c are always higher than those for the analogues with the $[\text{Mn}(\text{CN})_6]^{3-}$ or $[\text{Fe}(\text{CN})_6]^{3-}$ anions; the highest T_c values are observed for $\text{V}_3[\text{Cr}(\text{CN})_6]_2$ and $\text{Cr}_3[\text{Cr}(\text{CN})_6]_2$. The latter is commonly depicted as $\text{Cr}_5(\text{CN})_{12}$. Thus, there is an obvious trend of the increase in the critical temperature if the compounds involve V^{II} , Cr^{II} and Cr^{III} containing a significant number of unpaired electrons in the t_{2g} orbitals. Hexacyanometallates $(\text{Et}_4\text{N})_{0.5}\text{Mn}_{1.25}[\text{V}(\text{CN})_5](\text{H}_2\text{O})_2$ ($T_c = 230$ K), $\text{Cs}_2\text{Mn}[\text{V}(\text{CN})_6]$ ($T_c = 125$ K),³⁰ $\text{Cs}_{0.75}[\text{Cr}_{2.125}(\text{CN})_6]$ ($T_c = 190$ K)²⁵ characterised by high T_c also contain the V^{II} or Cr^{II} ions, which is not quite convenient from the practical viewpoint as they are unstable in this oxidation state under ordinary conditions. Nevertheless, the compound $\text{V}_{0.42}^{\text{II}}\text{V}_{0.58}^{\text{III}}[\text{Cr}^{\text{III}}(\text{CN})_6]_{0.86} \cdot 2.8\text{H}_2\text{O}$ with $T_c = 315$ K obtained in an inert atmosphere (it is sensitive to the atmospheric oxygen) retains its magnetic properties for several weeks when dispersed in kerosene or mixed with a glue.²⁷ Based on this compound, a thermomagnetic switch and a device for the absorption of solar energy were designed and these were shown to function properly.^{24, 35}

The character of exchange interactions in the $\text{M}-\text{N}\equiv\text{C}-\text{M}'$ clusters can be predicted with high reliability under the assumption that these interactions between the unpaired electrons on the e_g orbitals of one metal and the unpaired electrons on the t_{2g} orbitals, orthogonal to the former, of another metal should be ferromagnetic, while the interactions between the unpaired electrons on the t_{2g} orbitals of both metals should be antiferromagnetic.^{23–25, 36, 37} By calculating the number of possible channels of exchange interaction according to the ferromagnetic (F) and antiferromagnetic (AF) mechanisms, it is possible to predict the character of ordering in the solid phase of a specific hexacyanometallate. Below the critical temperature, ferromagnetic ordering

of the spins of the paramagnetic centres predominates if $F > AF$, and antiferromagnetic ordering predominates if $AF > F$.

According to this scheme, in all of the hexacyanometallates with $T_c > 100$ K discussed above, where the $t_{2g}-t_{2g}$ interactions predominate and the exchange interactions between the paramagnetic centres of the neighbouring metal ions are antiferromagnetic, the magnetic moments of the sublattices of one metal ion are partially compensated by the magnetic moments of the sublattices of the other metal ion below the critical temperature. In systems of the type $Ni_3[Cr(CN)_6]_2$ and $Cu_3[Cr(CN)_6]_2$, the unpaired electrons lie on orbitals of different symmetries (e_g and t_{2g}), and the exchange interactions between the paramagnetic centres in these systems are ferromagnetic, which is favourable for the synthesis of compounds with high spontaneous magnetisation.²³

The results obtained²³⁻³¹ stimulated the study^{38,39} of a series of solids $(Ni_xMn_{1-x})_{1.5}[Cr^{III}(CN)_6] \cdot 8H_2O$. The solids with this composition were obtained in two ways:

(1) by mechanically mixing pure $Ni_{1.5}[Cr(CN)_6] \cdot 8H_2O$ and $Mn_{1.5}[Cr(CN)_6] \cdot 7.5H_2O$; in the former, the unpaired electrons of the neighbouring paramagnetic centres (Ni^{II} , Cr^{III}) are coupled by ferromagnetic exchange interactions [the exchange interaction integral (J) is positive]; in the latter, the spins of the neighbouring centres (Mn^{II} , Cr^{III}) mostly interact antiferromagnetically ($J < 0$);

(2) by mixing at the molecular level, *i.e.*, in the synthesis of $(Ni_xMn_{1-x})_{1.5}[Cr^{III}(CN)_6] \cdot 8H_2O$; the value of x was set by the initial ratio of the reagents $NiCl_2$, $MnCl_2$ and $K_3Cr(CN)_6$.

As expected, the characteristics of the mixture obtained by the former method are additive values proportional to the fractions x and $1-x$ of the mixed compounds; for example, the magnetisation of the mechanical mixture grows linearly as x increases from 0 to 1. The variation of the characteristics of the phase obtained by the latter method (magnetisation, the Weiss temperature, coercive field) with x is essentially different due to the competition between the ferro- ($J > 0$) and antiferromagnetic ($J < 0$) interactions. As a result, *e.g.*, the spontaneous saturation magnetisation (J_s) quickly decreases from $4.38 \mu_B$ to almost zero when x increases from 0 to 0.43; when x increases from 0.43 to 1, J_s quickly increases from ~ 0 to $5.57 \mu_B$ according to the equation

$$J_s = 2\mu_B \left[\frac{3}{2} + \frac{3[x - 2.5(1-x)]}{2} \right].$$

The coercive field is a maximum (680 G) at $x \simeq 0.43$ where the parallel spins of Cr^{III} and Ni^{II} are almost completely compensated by the antiparallel spins of Mn^{II} . For this reason, the experimental temperature dependences of magnetisation for the $(Ni_{0.38}Mn_{0.62})_{1.5}[Cr^{III}(CN)_6] \cdot 8H_2O$ phase coincided with the theoretical Neel curves: when measurements were carried out in an external field of 1000 G (stronger than the coercive field), the $J_s(T)$ dependences contained two maxima, while in an external field of 10 G (weaker than the coercive field) one maximum was observed and the curve intersected the abscissa axis (*i.e.* the magnetisation sign changed) at ~ 40 K. (It should be noted that at $x = 0$ or 1, the magnetisation of the specimens below the critical temperature increased monotonically as the temperature was decreased; these measurements were carried out in a field of 1000 G.) As a result, the magnetisation of a specimen at temperatures below 40 K was positive in an external magnetic field of $H > H_c$ and negative in a field of $H < H_c$.

Thus, it was shown^{38,39} that by varying the composition of a compound by chemical methods, it was possible to obtain phases in which the direction of the magnetic poles of the species was changed under the effect of an external magnetic field.

The critical temperatures of Prussian blue analogues capable of magnetic ordering can also be changed by electrochemical⁴⁰ or optical stimulation.⁴¹ In the latter case, consecutive irradiation of, *e.g.*, $K_{0.2}Co_{1.4}[Fe(CN)_6] \cdot 6.9H_2O$ with red ($\lambda = 660$ nm) and blue ($\lambda = 450$ nm) light at a sufficiently low temperature (5 K) made it possible to increase and then to decrease the magnetisation of the

specimen; this is of undoubted interest for those engaged in the development of magnetic-optical memory blocks. Pioneer studies^{40,41} showed that the targeted selection of photosensitive hexacyanometallates can be carried out by molecular design. Japanese researchers implemented light-controlled inversion of magnetic poles on specimens of the mixed ferri-ferromagnet $(Fe_{0.4}Mn_{0.6})_{1.5}[Cr(CN)_6] \cdot 7.5H_2O$ ⁴² and developed a technology for growing thin coloured magnetic films of $(Fe_xCr_{1-x})_{1.5}[Cr^{III}(CN)_6] \cdot zH_2O$ on electrode surfaces.⁴³

A principle for the synthesis of hexacyanometallates with high critical temperatures was suggested.^{25,30} It was found in studies of specific hexacyanometallate series that the synthesis of molecular ferromagnets (structural analogues of Prussian blue) should be based on ions of the first transition period metals (V^{II} , V^{III} , Cr^{II}), despite their small stability under ordinary conditions. Comparison of the magnetic properties of $Cs_2Mn^{II}[V^{II}(CN)_6]$ (see Ref. 30) with those of $CsMn^{III}[Cr^{III}(CN)_6] \cdot H_2O$ (see Refs 44 and 45) and $Mn^{II}[Mn^{IV}(CN)_6] \cdot xH_2O$, which are isostructural to the former, is indicative in this respect (see also Table 1).⁴⁶ All the three compounds contain Mn^{II} ions in the high-spin d^5 configuration in a weak ligand field (N_6 -octahedral coordination environment) and metal ions in the d^3 configuration (V^{II} , Cr^{III} and Mn^{IV}) located in a strong ligand field (C_6 -octahedral coordination environment).

The basic difference between the compounds of this period is that the energy of the t_{2g} orbitals for d^3 ions decreases with an increase in the element atomic number, *i.e.*, on going from V^{II} to Cr^{III} and then to Mn^{IV} . For example, the magnetic ordering temperatures of 125, 89.8 and 48.7 K for $Cs_2Mn^{II}[V^{II}(CN)_6]$, $CsMn^{III}[Cr^{III}(CN)_6] \cdot H_2O$ and $Mn^{II}[Mn^{IV}(CN)_6] \cdot 1.14H_2O$, respectively, show that the introduction of a d^3 transition metal ion with higher energies of the t_{2g} orbitals results in compounds with higher temperatures of the magnetic phase transition into the ferromagnetic state. In other words, the more effective the dative bonding of the bridging cyanide ligands due to bonding of their π^* orbitals the higher the energy of interaction between the spins of the neighbouring paramagnetic centres. In addition, the increase in the energy of exchange interaction between the unpaired electrons of the neighbouring paramagnetic centres is known to correlate with the increase in the magnetic ordering temperature.⁴⁷

Unfortunately, it has to be noted that the technique for the synthesis of hexacyanometallates as single crystals of high quality, which is important for a detailed study of magnetic-structural relationships, has not been developed yet. As a rule, conclusions on the structure of compounds are based only on the analysis of powder diffractograms. In addition, all Prussian blue analogues with a cubic symmetry of the crystal structure do not manifest magnetic anisotropy.⁴⁸ These facts stimulated the synthesis of other cyanide complexes. Of the studies in this field, it is necessary to note the synthesis of the first paramagnetic tetrahedral cyanometallate $[Ph_3P=N=PPh_3]_2[Mn^{II}(CN)_4]$ the structure of which has been established completely.⁴⁹ Based on this compound, $Mn^{II}[Mn^{II}(CN)_4]$ having a interpenetrating diamond-like structure was obtained.⁵⁰ By itself, $Mn^{II}[Mn^{II}(CN)_4]$ is ordered antiferromagnetically, but the authors have a good reason to believe that representatives of the future family $M'[Mn^{II}(CN)_4]$ ($M' \neq Mn^{II}$), unlike $Mn^{II}[Mn^{II}(CN)_4]$, should have uncompensated spins and should behave as ferrimagnets below T_c . Single crystals of $Mn_2(H_2O)_5[Mo(CN)_7] \cdot 4H_2O$ (α -phase) and $Mn_2(H_2O)_5[Mo(CN)_7] \cdot 4.75H_2O$ (β -phase) were obtained by slow mutual diffusion of deoxygenated solutions of $K_4[Mo^{III}(CN)_7] \cdot 2H_2O$ and $Mn(NO_3)_2 \cdot 6H_2O$ in a nitrogen atmosphere.⁴⁸ Both phases are monoclinic and have the same temperature of magnetic phase transition into the ferromagnetic state (51 K). The phases are unstable in air, but in special experiments it was possible to detect strong magnetic anisotropy on single crystals of the α -phase.

Thus, the transition from Prussian blue analogues with cubic structure to less symmetrical compounds has expanded the range of magnetically active polymeric cyanometallates with strong

anisotropy of magnetic properties. Compounds of this type are still rather rare, but their number increases gradually. A two-dimensional heptacyanomolybdate-based polymer, *viz.*, $\text{KMn}_{1.5}(\text{H}_2\text{O})_3[\text{Mo}(\text{CN})_7] \cdot 3\text{H}_2\text{O}$ grown as single crystals,⁵¹ and octacyanometallates $[\text{M}(\text{CN})_8]^{3,4-}$, where $\text{M} = \text{Nb}^{\text{IV}}, \text{Mo}^{\text{V}}$ or W^{V} , were reported at the Sixth Conference on molecular ferromagnets. The latter also undergo magnetic phase transition at rather high temperatures, *viz.*, at ~ 40 K for $\text{Cu}_3[\text{W}(\text{CN})_8]_2 \cdot 3.4\text{H}_2\text{O}$ and at ~ 50 K for $\text{Ni}_3[\text{W}(\text{CN})_8]_2 \cdot n\text{H}_2\text{O}$.⁵²

A problem in the design of molecular ferromagnets based on cyanometallates is that the cyano group, which is a bridging ligand, cannot be functionalised. As a matter of fact, this limits the possibilities of synthetic organic chemistry in the design of molecular magnets to the variation of the metal ions. The situation can be improved if some of the metal ions have previously been 'dressed in a coordination coat' in such a way as to reserve coordination sites for the approach of bridging cyanide groups. Certainly, the number of bonds between such metal ions and the bridging cyanide ligands is decreased, but the coordination environment acquires the possibility to affect the electronic structure of M' and the steric structure (and hence the magnetic characteristics) of the compound as a whole. Scheme 1 shows the simplest versions of the formation of three- or two-dimensional polymeric structures with M and M' ions alternating along different directions, *viz.*, the framework motif (*a*),⁵³ the square (*b*)^{54, 55} and the honeycomb (*c*) lattices.⁵⁶

Scheme 1

In fact, the situation can turn out to be much more complex. In a hybrid version of the design of molecular ferromagnets based on a hexacyanometallate of one metal and a chelate of another,^{54, 57, 58} the reaction of $\text{K}_3[\text{Fe}(\text{CN})_6]$ with *trans*- $[\text{NiCl}_2(\text{en})_2]$ (where en is ethylenediamine) gave the complex

$[\text{Ni}(\text{en})_2]_3[\text{Fe}(\text{CN})_6]_2 \cdot 2\text{H}_2\text{O}$, whose structure was characterised. It was found that in the solid phase, only three of the six cyanide ligands in the $\text{Fe}(\text{CN})_6$ fragments participate in the formation of the bridging bonds with the Ni^{II} ions of the $\text{Ni}(\text{en})_2$ fragments; 2/3 of the $\text{Ni}(\text{en})_2\text{N}_2$ fragments contain a *cis*-coordinated Ni^{II} ion, while 1/3 contain a *trans*-coordinated Ni^{II} ion. As a result, in a crystal polymeric bands are extended along one of the crystallographic axes, while polymeric layers are formed along the other two directions. The interaction between the unpaired electrons in the $\text{Ni}^{\text{II}} - \text{N} \equiv \text{C} - \text{Fe}^{\text{III}}$ fragments, as in the usual hexacyanoferrate $\text{Ni}_3[\text{Fe}(\text{CN})_6]_2$ (see Table 1), is of ferromagnetic character, and at temperatures below 18.6 K the complex $[\text{Ni}(\text{en})_2]_3[\text{Fe}(\text{CN})_6]_2 \cdot 2\text{H}_2\text{O}$ undergoes a magnetic phase transition into the ferromagnetic state.

To date, a rather wide range of molecular ferromagnets of this group with various organic ligands have been studied. These include $\text{PPh}_4[\text{Ni}(\text{pn})_2][\text{M}(\text{CN})_6] \cdot \text{H}_2\text{O}$, $[\text{Ni}(\text{pn})_2]_2[\text{Fe}(\text{CN})_6]\text{X}$ and $[\text{Ni}(1,1\text{-dmen})_2]_2[\text{Fe}(\text{CN})_6]\text{X}$, where $\text{M} = \text{Fe}, \text{Cr}$ and Co , pn is 1,2-diaminopropane,⁵⁹ 1,1-dmen is 1,1-dimethylethylenediamine and $\text{X} = \text{ClO}_4^-, \text{BF}_4^-, \text{PF}_6^-, \text{CF}_3\text{SO}_3^-, \text{BzO}^-, \text{I}^-, \text{N}_3^-, \text{NCS}^-, \text{NO}_3^-$ (see Ref. 60) and $[\text{Ni}(\text{tren})]_3[\text{Fe}(\text{CN})_6]_2 \cdot 6\text{H}_2\text{O}$, where tren is the tetradentate tris(2-aminoethyl)amine.⁶¹ Using a classical macrocyclic ligand, 1,4,8,11-tetraazacyclotetradecane (cyclam), the following compounds: $[\text{Ni}(\text{cyclam})]_3[\text{Cr}(\text{CN})_6]_2 \cdot 5\text{H}_2\text{O}$,⁵⁶ $[\text{Ni}(\text{cyclam})]_3[\text{Fe}(\text{CN})_6]_2 \cdot 6\text{H}_2\text{O}$ and $[\text{Fe}(\text{cyclam})][\text{Fe}(\text{CN})_6]_2 \cdot 6\text{H}_2\text{O}$, which are polymeric in the solid phase, have been synthesised and studied.⁶² The efficiency of complexes of trivalent manganese with various polydentate Schiff's bases in the formation of heterometallic complexes with hexacyanometallates $[\text{Mn}(\text{CN})_6]^{3-}$ and $[\text{Fe}(\text{CN})_6]^{3-}$ has been shown.^{63–67} The critical temperatures range from 2 to 16.2 K for the group of compounds studied.

The $[\text{Ni}(\text{bpm})_2]_3[\text{Fe}(\text{CN})_6]_2 \cdot 7\text{H}_2\text{O}$ complex, where bpm is bis(1-pyrazolyl)methane, with a rather high critical temperature has been synthesised and studied.⁶⁸ The solid phase of this compound is formed from pentanuclear heterometallic complexes $[\text{Ni}(\text{bpm})_2]_3[\text{Fe}(\text{CN})_6]_2$ linked into a diamond-like lattice by a system of hydrogen bonds involving molecules of crystallisation water. Although water molecules are generally poor conductors of exchange interactions,^{69–72} high T_c (23 K) has been found for the $[\text{Ni}(\text{bpm})_2]_3[\text{Fe}(\text{CN})_6]_2 \cdot 7\text{H}_2\text{O}$ phase. Dehydration of the compound results in the destruction of the structure and, as a consequence, in the loss of the magnetic ability. This situation is rather typical, *i.e.*, the destruction of a system of hydrogen bonds forming a two- or three-dimensional structure of a compound results in the loss of the ability to undergo magnetic phase transition into the ferro- or ferrimagnetic state.^{73, 74} However, it should not be considered that disintegration of a highly dimensional structure into separate polynuclear exchange clusters always results in zero-dimensional magnetic systems.

In recent years, studies in a specific area of the design of molecular ferromagnets, namely, large exchange clusters, is being developed intensely.^{14, 75–78} Compounds of this type are nanoscale polynuclear molecular particles with a high degree of aggregation, such as $\text{Mn}_{12}\text{O}_{12}(\text{CH}_3\text{COO})_{16}(\text{H}_2\text{O})_4 \cdot 2\text{HOAc}$, $\text{Co}_8\text{O}_4(\text{PhCOO})_{12}(\text{DMF})_4$, $\text{NBu}_4[\text{Mn}_8\text{O}_6\text{Cl}_6 \cdot (\text{PhCOO})_7(\text{H}_2\text{O})_2]$ and $\text{Fe}_{11}\text{O}_6(\text{OH})_6(\text{PhCOO})_{15}$. Large polynuclear complexes arouse interest from the biochemical viewpoint as models of active polynuclear centres in enzymes.⁷⁹ On the other hand, despite the molecular nature of these compounds, the same effects as for the classical bulk magnets, including the original hysteresis loops that appear due to tunnelling effects between multiple spin conditions of different multiplicities, have been observed for them. One can find more details on the magnetic properties of these systems elsewhere, *e.g.*, in Refs 80–88. Almost all of them contain polynuclear complexes with carboxylate, oxo and/or hydroxo bridging ligands.

A new possibility in the design of heterometallic polynuclear molecular complexes with the use of hexacyanometallates discussed above was shown.^{24, 89} The reaction of $\text{K}_3[\text{Cr}(\text{CN})_6]$ with

$[\text{NiL}(\text{H}_2\text{O})](\text{ClO}_4)_2$, where L is tetraethylenepentamine, which blocks five coordination sites in the coordination sphere of Ni^{II} , resulted in $\{\text{Cr}[(\text{CN})\text{NiL}]_6\}(\text{ClO}_4)_9$; its solid phase is formed by heptanuclear molecular exchange clusters $\text{Cr}^{\text{III}}\text{Ni}_6^{\text{II}}$ with ferromagnetic exchange interactions between the Cr^{III} and Ni^{II} ions.

One cannot rule out that new dendritic molecular magnets will be obtained from polynuclear compounds of this type.^{90, 91}

The examples presented above show that the systematic development of methods for the synthesis of polymeric cyanide complexes with paramagnetic metal ions has made it possible to overcome, to a considerable degree, the above-mentioned 'drawbacks' inherent in the nature of Prussian blue analogues and, in addition, to contribute significantly to the supramolecular chemistry of metal cyanide complexes.^{33, 92–100}

IV. $\text{M}_3\text{M}'$ systems

1. Oxalates

The oxalate complexes of metals constitute the most representative group of molecular ferromagnets of the $\text{M}_3\text{M}'$ class.^{101–127} Okawa *et al.*^{101–103} were the first to pay special attention to polymeric heterometallic oxalates. They chose these compounds taking into account the available data on polynuclear complexes with ferromagnetic exchange interactions between the unpaired electrons of the paramagnetic centres located on orbitals of different symmetries.^{37, 104–108} It was thus desirable to obtain two- or three-dimensional heterospin structures 'pierced' by ferromagnetic pair exchange interactions (Fig. 1). It is absolutely unnecessary for a magnetic phase transition that all intra- and intermolecular exchange interactions be exclusively ferromagnetic; however, it should be noted that if only ferromagnetic exchange channels are present in the structure of a compound, higher values of magnetisation can be reached than in the case of

Figure 1. Scheme of the formation of a layered structure (a) and a fragment of framework structure with identical chiral centres (b); (a) 'honeycomb' motif; the light and dark circles indicate the alternating chiral (Λ and Δ) fragments of $\text{M}(\text{ox})_3$ (ox is oxalate); the squares indicate the cavities that can be occupied by spacers (lacking counterions or solvent molecules);¹⁰² (b) 'fused decagons' motif.^{111, 117}

Table 2. Critical temperatures for oxalate complexes.

Compound	T_c / K	Structure dimensionality	Ref.

Note. The following abbreviations are used: bipy is bipyridyl, phen is phenanthroline, and dto is dithiooxalate.

antiferromagnetic interactions between unpaired electrons. The directed design of heterospin systems has made it possible to obtain^{101–103} solid of $\text{NBu}_4[\text{M}(\text{ox})_3]$ ($\text{M} = \text{Cu}^{\text{II}}, \text{Mn}^{\text{II}}, \text{Fe}^{\text{II}}, \text{Co}^{\text{II}}, \text{Ni}^{\text{II}}$) with magnetic ordering at 6–14 K (Table 2).

A three-dimensional framework structure was originally postulated for $\text{NBu}_4[\text{M}(\text{ox})_3]$, although it was shown later^{109–113} that these solids have layered honeycomb structures. One has to note the studies of $\text{NBu}_4[\text{Mn}(\text{ox})_3]$ single crystal,^{109, 110} where strong anisotropy of the magnetic properties has been revealed. If measurements were made along the crystallographic axis c , which is perpendicular to the polymeric layers and coincides with the direction of the magnetic moments of Mn^{II} and Cr^{III} , the dependence of magnetisation on the magnetic field strength $M(H)$ was saturated in fields of ~ 0.05 T. If the external magnetic field was oriented perpendicularly, *i.e.*, inside the nets of the polymeric layers, the $M(H)$ curve was far from saturation in the field of 10^4 G = 1 T. Later, a study of magnetic-structural relationships for $\text{NPr}_4[\text{Mn}^{\text{II}}\text{Cr}^{\text{III}}(\text{ox})_3]$ and $\text{NBu}_4[\text{Mn}^{\text{II}}\text{Fe}^{\text{III}}(\text{ox})_3]$ single crystals and a study of the magnetic structure in a neutron diffraction experiment with $[\text{P}(\text{C}_6\text{D}_5)_4][\text{Mn}^{\text{II}}\text{Cr}^{\text{III}}(\text{ox})_3]$ ¹¹⁴ powder confirmed that the magnetic properties of this type of subjects have strong anisotropy.

From the conceptual viewpoint, a series of studies^{111, 117, 118} into the role of templates promoting the formation of either two-dimensional layered polymeric structures with a honeycomb motif (see Fig. 1 a) or three-dimensional frameworks with a motif of fused decagons (see Fig. 1 b) is important. The following principles for the construction of two- and three-dimensional polymeric oxalate structures were revealed: assembling a structure from various alternating distorted octahedral chiral (Λ and Δ) $\text{M}(\text{ox})_3$

fragments results in polymeric layers with metal ions arranged in one plane, whereas assembling a polymeric structure from the same fragments of the same chirality gives a polymeric framework structure. As a whole, the two-dimensional honeycomb structure is achiral, and the distance between the layers is determined by the size of the cations located in the space between the layers. The three-dimensional structure formed from fused decagons is always chiral.

It was found that the $[XR_4]^+$ cations, where $X = N$ or P and $R = Ph, Pr, Bu$ or C_5H_{11} , favour the separation of two-dimensional honeycomb-like layered structures containing $[M^{II}M^{III}(ox)_3]_n^{n-}$, where $M^{II} = V, Cr, Mn, Fe, Co, Ni, Cu, Zn$; $M^{III} = V, Cr, Fe$, into the solid phase, while tris-chelated metals cations, e.g., $[M(bipy)_3]^{2+/3+}$ (*bipy* is bipyridyl), cause the cross-linking of the polymeric anionic oxalate framework of $[M^{II}_2(ox)_3]_n^{2n-}$, $[M^I M^{III}(ox)_3]_n^{2n-}$ or $[M^{II}M^{III}(ox)_3]_n^{n-}$ into a three-dimensional framework of decagons.^{117, 120} Another motif found in the solid phase of lanthanide-containing oxalates $[Ln^{III}-Cr^{III}(ox)_3] \cdot nH_2O$ is composed of polymeric chains the shape of which resembles 'rope ladders'.¹¹⁹ It was also found that framework structures similar to oxalates can also be obtained with the use of dithiooxalates (dto, see Table 2) as the bridging ligands.¹²⁰

The progress of studies into the design of layered and framework molecular ferromagnets based on oxalate complexes has also stimulated interest in these compounds as a new type of microporous materials suitable for the separation of racemic mixtures and for directed asymmetric synthesis, as well as for catalysis. It has been shown for the layered polymeric microporous compound $Na_2(NMe_3Ph)_3[Cr(ox)_3]_2Cl \cdot 5H_2O$ that partial removal of the template from the compound by cation exchange at room temperature and even its complete removal by thermal treatment of the specimen accompanied by removal of water of crystallisation did not result in the loss of crystallinity.¹²¹ This behaviour is similar to that of zeolite materials, therefore the phases under consideration can actually prove to be efficient for the separation of chiral subjects.

Compounds with high negative magnetisation of approximately the same magnitude as that of solid solutions of classical ferrosilicates and the cyanide phases $(Ni_x^{II}Mn_{1-x}^{II})_{1.5} \cdot [Cr^{III}(CN)_6] \cdot 8H_2O$ discussed above, were described in Refs 124 and 125. The authors studied the specially selected series of layered polymeric oxalate complexes $A^I[M^{II}Fe^{III}(ox)_3]$, where $A^I = NPr_4^+, NBu_4^+, N(n-C_5H_{11})_4, PBu_4^+, PPh_4, NBu_3^+(C_6H_5CH_2), Ph_3PNPPh_3, AsPh_4$; $M^{II} = Mn, Fe$, in which the interlayer distance can be adjusted by varying the cation A^I . Compounds with $M^{II} = Fe$ behave as ferrimagnets with the ordering temperature of 33–48 K. For five of these compounds, transition from positive to negative magnetisation has been recorded at ~ 30 K in weak magnetic fields (~ 100 G). Such transitions are most characteristic of compounds with the highest critical temperatures. Moreover, characteristic changes were found in the series $N(n-C_nH_{2n+1})_4[Fe^{II}Fe^{III}(ox)_3]$, where $n = 3-5$. It was established that T_c increases with the interlayer distance; at low temperatures, magnetisation changes from positive for $n = 3$ to negative for $n = 4$ and 5.¹²⁵

Single crystals of the layered polymeric heterometallic oxalate $N(n-C_5H_{11})_4[Mn^{II}Fe^{III}(ox)_3]$ could be grown and the anisotropy of its magnetic properties was studied.^{109, 110, 114, 125} Studies into the anisotropy of the magnetic properties of single-crystal molecular ferromagnets are still rather rare, therefore they always arouse vivid interest. It was found¹²⁶ that $N(n-C_5H_{11})_4 \cdot [Mn^{II}-Fe^{III}(ox)_3]$ with $T_c = 27$ K, as $NBu_4[MnCr(ox)_3]$ discussed above, has strong magnetisation anisotropy. The uncompensated magnetic moment directed perpendicularly to the plane of the polymeric layers (*i.e.*, in the same direction as in $NBu_4[MnCr(ox)_3]$) is rather small, *viz.*, $8.78 \times 10^{-5} \mu_B$ per magnetically active atom, which can be explained by the small angle of rotation of the

magnetic sublattices ($\sim 0.001^\circ$) and the small difference between the *g*-factors of the d^5 metal ions.¹²⁶

Table 2 lists the characteristics of a large group of polymeric metal oxalates, which allows some generalisations to be made. However, the overall picture for the understanding of the magnetic properties of compounds belonging to this class is still far from completion.^{127, 128} Nevertheless, methods for directed synthesis of layered polymeric or framework polymeric metal oxalates have been developed to date, and it has become clear what the resulting chirality of the subjects would be and what spatial structure they would have. In addition, it is possible to adjust the distances between the layers in a series of layered compounds by varying the size of the cation A^I located in the interlayer space.^{74, 121}

Experiments show that the highest magnetic ordering temperatures ($\sim 40-50$ K) are reached if a compound contains a combination of metal ions having high spins (high-spin Mn^{II} , Fe^{II} , Fe^{III}), in accordance with the correlation $T_c \propto JS_1S_2$ (where S_1 and S_2 are the spins of the first and second paramagnetic centres, respectively). When metal ions are combined, it is possible to predict the temperature range in which the critical temperature of the expected compound will fall. Thus, the introduction of diamagnetic ions (for example, lithium or sodium ions) in polymeric oxalate systems leads to an increase in the distances between the paramagnetic centres, a reduction of the energy of exchange interaction between them and, hence, a sharp decrease in the critical temperature. On the other hand, the fact that the critical temperatures of the known framework oxalates (3D structures) are much lower than those of layered polymeric compounds (2D structures) requires a quantum-chemical explanation. The role of relativistic effects is not quite clear; the necessity of taking them into account in the description of the magnetic properties of heterometallic polymeric oxalates containing paramagnetic 4*d*- or 5*d*-metal ions was pointed out in Ref. 127. Such properties appear due to a significant spin-orbital interaction in these elements.

It may seem that the design of oxalate systems is limited only to the replacement of metal ions and template cations. This is hardly true. Certainly, oxalate polymers are the basic systems for the synthesis of the M3M' class ferromagnets. On the other hand, current studies encourage a wider use of various diamagnetic and paramagnetic ligands which are structural analogues of the oxalate anion and hence favour the development of the synthesis of new molecular magnets. For example, the aforementioned dithiooxalate,^{120, 129, 130} imidazoles,¹³¹ imidazoleacetate¹³² and biimidazole¹³³ may be regarded as such ligands.

In addition, investigations into the design of polynuclear mixed-ligand compounds, in which not all but only one or two ligands are oxalates,^{134, 135} are certainly of interest. For example, the structure of complexes $M_2^{II}(dpm)(ox)_2 \cdot xH_2O$, where $M = Mn, Cu$; $x = 6, 5$, respectively, and *dpm* is bipyrimidine (Fig. 2),^{135, 136} is topologically identical with the honeycomb structure of layered polymeric oxalates (see Fig. 1*a*). The way of self-organisation of three-dimensional frameworks upon formation of mixed-ligand complexes with an oxalate anion and bipyridyl has been studied.¹³⁷ Thus, addressing mixed-ligand complexes is also promising in the design of new molecular ferromagnets.

Figure 2. Scheme of a layered polymeric structure ('honeycomb' motif) of $M_2^{\text{II}}(\text{dpm})(\text{ox})_2 \cdot x\text{H}_2\text{O}$ ^{135, 136} and $M_2^{\text{II}}(\text{dpm})(\text{N}_3)_4$ ^{138–140}. The double lines indicate the bridging oxalate or azide anions connecting the metal ions into chains, which are, in turn, linked by the bridging bipyrimidine ligands into layers.

2. Azides

The above approach to the synthesis of layered polymeric compounds based on mixed-ligand complexes of metal oxalates with bipyrimidine, but with the use of azide ligands instead of oxalate ones, has been developed further.^{138–140} The authors succeeded in synthesising and studying a series of layered polymeric complexes with composition $M_2(\text{N}_3)_4(\text{dpm})$, where $M = \text{Co}^{\text{II}}, \text{Fe}^{\text{II}}$ and Mn^{II} . The structural motif of polymeric honeycomb-like layers in $M_2(\text{N}_3)_4(\text{dpm})$ is exactly the same as that in $M_2^{\text{II}}(\text{dpm})(\text{ox})_2 \cdot x\text{H}_2\text{O}$ (see Fig. 2) with only one difference: the role of a bridge is played by two bridging μ -(1,1)-azide ligands instead of the oxalate anion, *i.e.*, according to the systematics accepted, the $M_2(\text{N}_3)_4(\text{dpm})$ complexes correspond to the $M_3(1)M'$ class. The authors believed that the introduction of the azide anion into polymeric structures would be expedient for obtaining polymers with exchange interactions alternating in sign (ferromagnetic – antiferromagnetic). As a rule, strong antiferromagnetic exchange interaction (-200 to -400 cm^{-1}) predominates in exchange clusters linked by a bridging oxalate anion or bipyrimidine.^{13, 141, 142} However, it is known that in binuclear exchange clusters linked by azide following the μ -(1,3) pattern, the exchange interaction is antiferromagnetic,¹⁴³ while in those linked following the μ -(1,1) pattern, it is ferromagnetic.^{144, 145–162}

Experimental studies of the magnetic properties of the $M_2(\text{N}_3)_4(\text{dpm})$ complexes have shown that competition between ferro- and antiferromagnetic exchange interaction channels does exist in them, and at low temperatures ($< 12 \text{ K}$) these compounds behave as metamagnets with high critical magnetic fields ($> 2 \text{ T}$).¹³⁸ It should be noted that the ferromagnetic character of exchange in μ -(1,1) type binuclear azide exchange clusters was confirmed by quantum-chemical studies of the $[\text{M}(\mu\text{-}1,1\text{-N}_3)_2\text{M}]$ and $[\text{M}(\mu\text{-}1,1\text{-N}_3)_3\text{M}]$ fragments, where $M = \text{Cu}^{\text{II}}, \text{Ni}^{\text{II}}, \text{Mn}^{\text{II}}$ (see Ref. 146). For example, for the copper complex, the results of

calculation for the distribution of spin density qualitatively agree with the experimental results of a polarised neutron diffraction study. The spin density distribution obtained in the calculated model is a superposition of the electron delocalisation and spin polarisation effects: delocalisation of unpaired electrons from the $d_{x^2-y^2}$ orbitals to the donor atom of the ligand decreases in the series $\text{Cu} > \text{Ni} > \text{Mn}$, while spin polarisation in the same series increases because of the increase in the number of unpaired electrons.¹⁴⁶ It was also found that the exchange is hardly affected by deviations of the uncoordinated azide ligand from the plane of the $\text{M}(\mu\text{-N})(\mu\text{-N})\text{M}$ fragment, which opens the possibilities for a more flexible and versatile design of highly dimensional structures with the μ -(1,1) bridging azide.

In the synthesis of a layered polymer $\text{Ni}(\text{N}_3)_2\text{L}$, where L is 2,2-dimethylpropane-1,3-diamine,^{163, 164} advantage was taken of the diversity of coordination capabilities of the N_3^- ligand known for polynuclear complexes with azide ligands.^{147–157} The bidentate ligand was shown not to participate in the formation of bridging bonds. The layered polymeric structure is formed by only the azide anions, some of them serving as μ -(1,1) bridges and others as μ -(1,3) bridges. The magnetic ordering temperature for $\text{Ni}(\text{N}_3)_2\text{L}$ was found to be rather high ($T_c = 55 \text{ K}$), although the residual magnetization at 4.2 K is very low ($6 \times 10^{-3} \mu_B$). Below the critical temperature, this compound behaves as a weak ferromagnet, but the reason why the weak ferromagnetism appeared (antisymmetric exchange^{165–168} or *g*-factor anisotropy of the nickel ion¹⁶⁹) remains obscure.

Similar magnetic behaviour has been recorded for a series of layered polymeric coordination compounds $\text{Mn}(\text{N}_3)_2\text{L}_2$, where L stands for monodentate ligands, *e.g.*, pyridine, 3-acetylpyridine, 4-acetylpyridine, 4-cyanopyridine or ethylisonicotine.^{170–172} In polymers with exclusively μ -(1,3) bridging function of the azide ligand, antiferromagnetic exchange interactions between the manganese ions occur, whereas in polymers with alternating μ -(1,1) and μ -(1,3) bridging azides, alternation of ferromagnetic and antiferromagnetic channels of exchange interaction is observed. At low temperatures ($< 16\text{--}40 \text{ K}$) the ESR signal from polycrystalline specimens broadens and compounds behave as weak ferromagnets with small magnetic moments.¹⁷²

3. Dicyanamides

The first reported molecular ferromagnets^{173–178} were based on polymeric dicyanamide derivatives of transition metals $(\text{ML}_2)_\infty$, where $\text{L} = \text{N}(\text{CN})_2^-$; $M = \text{Co}, \text{Ni}$. In solid $(\text{ML}_2)_\infty$, each ligand has tridentate bridging coordination (Fig. 3a).

Each $\text{N}(\text{CN})_2^-$ bridging ligand is bound to metal ions through two terminal nitrogen atoms of the nitrile groups and the central amide nitrogen atom. In turn, each metal ion is bound to six different $\text{N}(\text{CN})_2^-$ ligands, four of which are coordinated by the nitrile nitrogen atoms and two are coordinated by the amide nitrogen atoms. This results in a framework structure similar to that of rutile. These compounds undergo magnetic phase transition into the ferromagnetic state at 9 K (Co) and 20 K (Ni). An important result of these studies is that no ordering effects were detected down to 2 K for the isostructural compound $(\text{CuL}_2)_\infty$ characterised by the pronounced Jahn–Teller effect, which is inherent in Cu^{II} . $(\text{CuL}_2)_\infty$ behaves as a usual paramagnet over the entire measurement range. In our opinion, this behaviour is due to a considerable elongation of the bonds between the copper ions and the amide nitrogen atoms in the structure of $(\text{CuL}_2)_\infty$,¹⁷³ *i.e.* the magnetic structure consists of the chains $[\text{—Cu—}(\text{N}\equiv\text{C—N—C}\equiv\text{N})_2\text{—Cu—}(\text{N}\equiv\text{C—N—C}\equiv\text{N})_2\text{—}]_\infty$ with Cu^{II} ions that weakly interact through five bridging atoms (Fig. 3). As regards the magnetism, $(\text{CuL}_2)_\infty$ belongs to the M_5M' class rather than to M_3M' as is the case for $(\text{CoL}_2)_\infty$ and $(\text{NiL}_2)_\infty$. Band chains of this type with weakly interacting manganese ions, $[\text{—Mn—}(\text{N}\equiv\text{C—N—C}\equiv\text{N})_2\text{—Mn—}(\text{N}\equiv\text{C—N—C}\equiv\text{N})_2\text{—}]_\infty$, have been reported.¹⁷⁹ They were detected for solid $\text{MnL}_2(\text{CH}_3\text{OH})_2$, which confirms the assumption stated above.

Figure 3. Scheme of decomposition of a three-dimensional framework structure of $(ML_2)_\infty$ (a) into separate chains (b) upon increase in the metal–amide nitrogen atom distance.

Experiments with the use of neutron diffraction on $(ML_2)_\infty$ powders ($M = Co, Ni, Mn$) and measurements of specific heat capacity of these compounds in the region of magnetic phase transition were carried out.^{176–178} It was possible to determine correctly the Curie temperatures for the ferromagnets, viz., cobalt (8.7 K) and nickel (19.7 K), the Neel temperature for an anti-ferromagnet $(MnL_2)_\infty$ (16 K), to determine the magnetic structure of the compounds and to establish that $(CoL_2)_\infty$ exists as two polymorphic modifications, one of which (α) can undergo ferromagnetic ordering below the critical temperature. In the studies of the magnetic properties of $(ML_2)_\infty$ ($M = Fe, Co, Ni$) and alloys $[Ni_{0.5}Co_{0.5}L_2]_\infty Ni(OH)_{2-x}L_x$, some unusual properties of these compounds were reported.^{180, 181} First, an increase in the pressure to 17 kbar makes it possible to increase the critical temperature of the phase by $\sim 10\%$; this is an important feature of molecular ferromagnets that rather commonly have a ‘loose’ structure. Second, anomalously high coercive fields are characteristic of the molecular ferromagnets studied: 710, 7975 and 17 800 G, respectively, for the nickel, cobalt and iron complexes.^{182–184} The latter value is not only the highest in the series of molecular ferromagnets but also exceeds the coercive fields for Sm–Co and Re–Nd–B alloys (the coercive field for classical magnetically hard materials reaches 10^3 – 10^4 G).¹⁸²

Thus, the examples presented above show that the organic dicyanamide anion can be efficiently used in the design of molecular ferromagnets.

4. Dioxamates

An original approach to the design of polymeric heterospin systems based on mixed-ligand complexes with polydentate ligands was developed.^{185–195} The construction of these systems is a multistage directed design of molecular ferromagnets starting from the synthesis of a specific polyfunctional ligand (various dioxamates) and allowing one to obtain a solid heterospin layered polymer with a strictly determined alternation of paramagnetic centres. In the first stage, a complex of Cu^{II} with a tetradentate ligand is formed, and then cross-linking of copper-containing fragments into a chain occurs through the formation of chelate complexes of Mn^{II} with the oxygen atoms of the oxamate groups. The Mn^{II} ion cannot compete with Cu^{II} for the donor nitrogen atoms, as its thermodynamic constants of complex formation with

$X = H, OH$.

nitrogen-containing ligands are much smaller than those for copper. As a result, a chain with regular alternation of Cu^{II} and Mn^{II} is formed.

Mutual arrangement of the paramagnetic centres belonging to different chains is an essential factor. It was found^{185–187} that in the case of N,N' -propane-1,3-dioldioxamate ($X = H$), the Cu^{II} ions in solid $MnCuL \cdot 5H_2O$ are arranged above Cu^{II} ions, while the Mn^{II} ions are above Mn^{II} ions; the magnetic moments of ions belonging to different chains are oriented oppositely (due to the predominant antiferromagnetic exchange interactions) and compensate each other (Fig. 4a). The magnetic moments in the copper and manganese sublattices generally tend to compensate each other. As a result, the compound is ordered antiferromagnetically at low temperature ($T_c = 2.2$ K).

Figure 4. Antiferromagnetic spin ordering of neighbouring chains with resulting zero (a) and non-zero (b) magnetic moment.

In an attempt at changing the mutual arrangement of the metal ions, the authors synthesised the $MnCuL' \cdot 3H_2O$ complex, where L' is N,N' -(2-hydroxypropane-1,3-diyl)dioxamate ($X = OH$). In the solid phase of this compound, the chains $(\dots Cu \dots Mn \dots)_\infty$ are shifted relative to each other in such a way that the OH groups of one chain form hydrogen bonds with the water molecules coordinated by the Mn^{II} ions of the other chain. As a result, a staggered arrangement of the Cu^{II} and Mn^{II} ions appears (Fig. 4b). The magnetic moments of ions from different chains tend to be oriented oppositely. However, in this case each Cu–Mn pair forms a difference magnetic moment, and on the whole, uncompensated magnetic moment of the manganese and copper sublattices appears, as inside these sublattices all spins are oriented in the same way. As the temperature is decreased, the $MnCuL' \cdot 3H_2O$ structure is ordered ferromagnetically ($T_c = 4.6$ K). A series of molecular ferromagnets with the Curie temperatures of 5–22 K were obtained using this approach.^{188–193} The antiferromagnetic character of exchange interaction between the neighbouring Cu^{II} and Mn^{II} ions in these compounds was confirmed by polarised neutron diffraction.¹⁹⁴

A method for the synthesis of the multispin compound $R_2Mn_2(CuL)_3(DMSO)_2 \cdot 2H_2O$, where R is the 2-imidazoline 1-oxyl 3-oxide-containing radical cation; L is the *o*-phenylene-

dioxamate anion, was developed.^{196,197} The structure of the compound consists of a system of almost perpendicular (73°) interlocked networks analogous to those of layered polymeric oxalates (see Fig. 1a), the only difference being that the vertices of each hexagon are occupied by the Mn^{II} ions, while the midpoints are Cu^{II} ions.

The tetradentate ligands L play the role of bridges connecting Mn^{II} and Cu^{II} . Each of the oxygen atoms of the nitronyl nitroxide is coordinated by Cu^{II} ions from different networks, which results in the formation of additional polymeric chains in the crystal; the compound is ordered as a ferrimagnet below 22.5 K. Using this approach, the authors obtained a series of molecular ferromagnets $(\text{R-Rad})_2\text{M}_2(\text{CuL})_3$, where R-Rad is the 2-(4- N -alkylpyridinium)-4,4,5,5-tetramethyl-2-imidazoline 1-oxyl-3-oxide cation, $M = \text{Mn}^{\text{II}}, \text{Ni}^{\text{II}}, \text{Co}^{\text{II}}$, with critical temperatures in the range of 22–37 K.¹⁹⁸

V. $\text{M4M}'$, $\text{M5M}'$ and $\text{M7M}'$ systems

In the Introduction, we discussed the importance of involvement of synthetic organic chemistry in the design of molecular ferromagnets. However, in the classes of compounds considered above, it is not always possible to attach additional functional groups to the bridging ligand atoms. Besides, simple elongation of the hydrocarbon chain will result in a sharp decrease in the energy of exchange interactions between the unpaired electrons of the paramagnetic centres. To resolve the situation, one can use stable nitroxides; the methods for their synthesis and modification are well developed (see, *e.g.*, Ref. 11). The bridging heterospin structures are shown below. Depending on the nature of the group X , these systems can contain a minimum of four atoms in the bridge. Fragments of bridging structures representing derivatives of stable 2-imidazoline^{199–214} and 3-imidazoline^{215–227} nitroxides and acyclic polynitroxyls linked through benzene or heterocyclic rings are also shown.^{12, 228–231}

Substituents R^n in nitroxides may be varied over a broad range. The presence of one or several $\geq \text{N} \cdot \text{O}$ groups (preferably, with the greatest possible delocalisation of spin density over the bridging organic fragment) makes it possible to maintain efficient exchange interactions between the unpaired electrons of the metal ions and the nitroxyl radicals.

A group of chain polymers based on mixed-ligand complexes of Mn^{II} and Ni^{II} hexafluoroacetylacetonates with nitronyl nitroxides (structure D) and capable of ferrimagnetic ordering at $T < 8$ K has been reported for the first time in Refs 232–235. The solid phases formed by polymeric chains of $[\text{Mn}(\text{hfacac})_2\text{L}]_\infty$, where hfacac is hexafluoroacetylacetonate and L represents polynitroxyls, are characterised by similar ordering.^{236,237} Studies of these subjects led to the conclusion that, despite the strong intrachain exchange (the integral of exchange interaction is greater than 250 cm^{-1}),²³⁴ one cannot hope to obtain ferromagnets with high Curie temperatures from these compounds due to the very low energies of intermolecular exchange interactions. However, the design of molecular magnets makes it possible to pass from chain structures to structures with higher dimensionality.

In particular, synthesis of a series of triradicals with structures of the F type has been developed. High conformational mobility of acyclic nitroxyl fragments linked by single bond to an aromatic ring enabled the realisation of a framework structure in the complex $[\text{Mn}(\text{hfacac})_2]_3\text{L}_2$ (L is a triradical; $R^2, R^4, R^5 = \text{H}$; $R^1, R^3, R^5 = \text{Bu}^t$), which is ordered as a ferrimagnet at 46 K.^{238–240} Each coordination matrix $[\text{Mn}(\text{hfacac})_2]$ is bound to two ligands, whereas each ligand is surrounded by three different $\text{Mn}(\text{hfacac})_2$ units. Nevertheless, it should not be thought that a framework polymer is always formed at the stoichiometric ratio $\text{M}(\text{hfacac})_2 : \text{nitroxyl} = 3:2$. We found that this composition can also be observed for specific trinuclear molecules with radicals²⁴¹ which are formed particularly often in the synthesis of mixed-ligand complexes of $\text{Cu}(\text{hfacac})_2$ with nitroxides (Fig. 5).^{204, 209, 219, 221, 242}

If the compounds have the same composition, one has to pay special attention to the possibility of formation of polymorphic modifications, as their magnetic properties can differ considerably.^{199, 222, 232, 243, 244}

Figure 5. Molecular structure of the complex $[\text{Cu}(\text{hfacac})_2]_3\text{L}_2$.

Scheme 2

Scheme 2 shows that *trans*-coordination of the bridging 2-imidazoline nitronyl nitroxyl ligands in Mn(hfacac)_2 results in the formation of polymeric chains (α) in the solid which undergoes three-dimensional magnetic ordering below 6 K.²³² *cis*-Coordination of radicals results in hexanuclear separate molecules (β) due to closure of a 36-membered macrocycle formed by the manganese atoms and the O–N–C–N–O fragments of the paramagnetic ligand.¹⁹⁹

The ground state of hexanuclear molecules is that with $S = 12$ in the temperature range from 5 to 300 K; the β -modification behaves as an ordinary paramagnet.

The bischelate of divalent nickel with acetonyl 3-imidazoline nitroxide derivative NiL_2 (Fig. 6) also exists as two polymorphic modifications (α and β).²²² Both modifications have layered polymeric structures. The goffered layered structure of the solid is formed owing to coordination of the nitroxyl oxygen atoms of the neighbouring bischelates by the nickel ion. The coordinated oxygen atoms of the nitroxyl groups are *trans*-coordinated in the α -modification and *cis*-coordinated in the β -modification. In solid $\alpha\text{-NiL}_2$, the antiferromagnetic exchange interactions between the unpaired electrons of the paramagnetic centres in the $\text{>N}\dot{\text{O}}\text{--Ni}^{\text{II}}\text{--O}\dot{\text{N}}\text{<}$ fragments predominate, and μ_{eff} approaches zero as the temperature is lowered. In $\beta\text{-NiL}_2$, the antiferromagnetic ($J \approx -115 \text{ cm}^{-1}$) and ferromagnetic ($J \approx 10 \text{ cm}^{-1}$) exchange compete, which results in antiferromagnetic ordering at $T_c = 14 \text{ K}$ (Fig. 7).

Taking into account the stereochemical non-rigidity of bischelates of the NiL_2 type, it is possible, by selecting the crystallisation conditions, to obtain modifications having either a molecular structure incapable of cooperative magnetic ordering or a layered polymeric structure that displays a tendency towards cooperative magnetic ordering.^{243, 245}

Perhaps, the only factor that limits the possibilities of the design of molecular ferromagnets from complexes with nitroxyl radicals is that the $\text{>N}\dot{\text{O}}$ group, which results from the oxidation of the corresponding hydroxylamine, is a weak donor of electron density. However, coordination of the nitroxyl group or any other way of its inclusion in the network of polymeric exchange channels are necessary for cooperative magnetic ordering.²²⁰ Therefore,

Figure 6. Fragments of layered polymeric structures of α - and β - NiL_2 ; (a) NiL_2 complex; (b) coordination of the Ni atom in $\beta\text{-NiL}_2$; (c) layered polymeric structure of $\alpha\text{-NiL}_2$; (d) layered polymeric structure of $\beta\text{-NiL}_2$.

metal hexafluoroacetylacetonates have mostly been used as acceptor matrices in early studies of heterospin systems based on complexes of transition metals with stable nitroxides.^{7, 11} It was shown²⁴⁶ that fluorinated carboxylates of metals can be used instead of hexafluoroacetylacetonate matrices; heterospin compounds capable of magnetic ordering at 21–24 K were obtained from mixed-ligand complexes of manganese bis(pentafluorobenzoate) with 2-imidazoline nitroxide.

It is possible in principle to get rid of the ‘ballast’ diamagnetic anionic ligands, such as hexafluoroacetylacetonate or carboxylate, if the organic radical is originally constructed in such a way that it can play both the roles of a bridge and an anion. We succeeded in synthesising a vast group of molecular ferromagnets of this type with layered polymeric or framework structure (Table 3). Scheme 3 illustrates the formation of polymeric layers in heterospin bischelates based on complexes of transition metals with derivatives of the stable 3-imidazoline nitroxide.

$R^1 = CF_3, COOMe, COOEt$; $R^2 = Me, H, Cl, Br$; $M = Cu, Ni, Co$.

High-quality single crystals of intracomplex chelates can be obtained from various organic solvents; therefore, it was possible to determine the crystal and molecular structures for all of the heterospin compounds listed in Table 3. A distinctive feature of the composition of the compounds studied is the presence of non-crystallisation molecules of alcohols in the crystal. In the solid phase, the metal ion coordinates the oxygen atoms of the OH groups belonging to two ROH fragments, then the ROH–ML₂–HOR groups are linked by hydrogen bonds ROH...O–N< with two neighbouring ROH–ML₂–HOR units. As a result, the bridging alcohol molecules ‘cross-link’ the

ML₂ fragments to form polymeric layers (monohydric alcohols) or a three-dimensional framework (dihydric alcohols), *i.e.* the two- or three-dimensional structure is formed by hydrogen bonds.^{247, 248, 250–253}

It should be noted that a separate metal ion in ML₂(ROH)₂ is surrounded by a large number of ‘organic’ atoms (C, H, N, O). For example, there are 90 C, H, N and O atoms altogether per each Ni^{II} ion in NiL₂(n-C₅H₁₁OH)₂; in spite of this, the compound is capable of cooperative magnetic ordering at low temperature. Removal of the alcohols and transition to layered polymeric structure in solid ML₂ leads to the loss of its ability to undergo ferromagnetic ordering.^{222, 248} At first glance, this seems paradoxical, as the transition from ML₂ to ML₂(ROH)₂ is accompanied by an abrupt increase in the fraction of the organic component in the compound, and hence, a decrease in the number of paramagnetic centres per unit volume of the solid phase of the complex. Nevertheless, it is such changes that determine the ability to undergo magnetic phase transition typical of weak ferrimagnets.²⁴⁷

It was found by comparison of the magnetic properties of the isostructural complexes NiL₂(ROH)₂ and NiL₂(H₂O)₂ (see Ref. 72) that the introduction of water molecules in the exchange channel >N–O...HOH–M^{II}–HOH...O–N< results in a sharp decrease in the exchange interaction energy and, hence, the loss of ability to undergo magnetic phase transition, despite the structural identity of the exchange channels in NiL₂(H₂O)₂ and NiL₂(ROH)₂. The high kinetic stability of complexes with alcohols, especially dihydric ones, was noted. For example, no changes in the composition and properties of NiL₂(MeOH)₂ and

$\text{NiL}_2[\text{HO}(\text{CH}_2)_4\text{OH}]$ were recorded upon their storage under normal conditions for 10 years. Large single crystals (with sizes from several millimetres to two centimetres) of many compounds of this series are also storage-stable. The possibility of obtaining complexes of transition metals with nitroxyl radicals in the form of sufficiently large single crystals makes them convenient subjects for studying the anisotropy of the magnetic properties^{233–235, 238, 245, 247} and the spin density distribution using polarised neutron diffraction.^{256–259} For example, Fig. 8 shows the results of a study of the magnetisation anisotropy for $\text{NiL}_2(\text{MeOH})_2$ and $\text{NiL}_2(\text{EtOH})_2$ and demonstrates the relation between the direction of easy magnetisation axis for single-crystal $\text{NiL}_2(\text{EtOH})_2$ as a macrosubject and the direction of the second-order crystallographic axis of the crystal microstructure. The coincidence of these directions is a prerequisite (within the framework of the classical magnetism concept) for single crystals belonging to the space group $P2_1/c$.¹⁶⁸

It was established in systematic studies of transition metal complexes with stable 3-imidazoline nitroxides that the structural dimensionality of a solid can be controlled by varying the substituents R^1 and R^2 in the side chain of the ligand. If R^1 is not an electron density acceptor (alkyl, aryl), the solid phase of the complex has a molecular structure with a square or tetrahedral environment of the metal ion. If R^1 is a strong electron density acceptor (for example, CF_3 , COOEt), the central metal ion

coordinating the donor atoms of the neighbouring molecules also becomes a strong acceptor. The coordination number of the central ion is completed to 6 and a layered polymeric structure is formed.^{72, 260} In the case where the acceptor ability of a metal ion attained only due to the introduction of an electrophilic substituent R^1 is insufficient to implement a two-dimensional solid state structure, the introduction of additional acceptor groups, for example, halogen atoms, as the substituent R^2 is effective.²⁵³

In the examples of heterospin complexes discussed above, the 3-imidazoline nitroxyl radical plays the role of a tridentate bridge. Recently, heterospin layered polymers with deprotonated nitronyl nitroxyl radicals (NIT) containing an imidazole (Im) or benzimidazole (BzIm) substituent at position 2 of the paramagnetic heterocycle were described.^{261, 262}

Such substituents perform the tetradentate bridging function ($\text{M53M}'$ systems). Complexes with composition $[\text{Mn}_2(\text{NITIm})_3] \cdot \text{ClO}_4$, $[\text{Mn}_2(\text{NITBzIm})_3] \cdot \text{ClO}_4$ and $[\text{Mn}_2(\text{NITIm})_3] \cdot \text{BF}_4$ ordered as weak ferromagnets at 1.4, 40 and 3.6 K, respectively, deserve special attention.²⁶²

The layered polymeric structure of these complexes with honeycomb motif is the same as that of the layered polymeric oxalate (see Fig. 1a) or azide complexes (see Fig. 2). This fact agrees completely with the general requirement for the arrangement of a layered polymeric structure with a metal:bridging radical ratio of 3:2 with alternating chiral (Λ and Δ) fragments formed by the metal ions. This indicates that molecular ferromagnets of this structural type have a common architecture. A systematic study of magnetic-structural relationships only for compounds of this structural type will make it possible to obtain a series of molecular ferromagnets with different magnetic characteristics (critical temperatures, spontaneous magnetisation, coercive fields).

Like for oxalate molecular ferromagnets,^{125, 263} the critical temperature of heterospin layered polymers was found to depend on the nature of uncoordinated anions (ClO_4^- , BF_4^-);^{261, 262} varying the latter serves as an additional means for affecting the magnetic parameters of the solid phase. In addition, the interlayer distances in the imidazole complex $[\text{Mn}_2(\text{NITIm})_3] \cdot \text{ClO}_4$ increase as the temperature is decreased, which decreases the critical temperature of this complex in comparison with the benzimidazole complex $[\text{Mn}_2(\text{NITBzIm})_3] \cdot \text{ClO}_4$.

VI. The problem of organic ferromagnets

The general problem of the creation of molecular ferromagnets was intensely fed 15–20 years ago by theoretical studies^{264–269} and experiments^{270–275} aimed at the synthesis of the so-called high-temperature, purely organic ferromagnets, *i.e.*, compounds the solid phase of which has no metal-containing components at all. Experimental results on the synthesis of purely organic ferromagnets have not been confirmed in many aspects and are subject to criticism.^{276–281} In the review¹ where the results of studies on organic ferromagnets were generalised and analysed in detail, it was noted that a most complex problem in the creation of such compounds is that the intermolecular exchange interactions in solid organic paramagnets are rather weak because of the large distances between the paramagnetic centres. In fact, the Curie temperatures for the purely organic ferromagnets known to date do not exceed 1–2 K.^{282–303}

Figure 8. Scheme demonstrating the coincidence of the directions of the twofold symmetry axis (arrow inside the cell) and the direction of the easy magnetisation axis in the single crystal (arrow inside the crystal) for $\text{NiL}_2(\text{EtOH})_2$ (a) and dependences of $\mu(H)$ showing the magnetisation anisotropy of single crystals of $\text{NiL}_2(\text{MeOH})_2$ (b) and $\text{NiL}_2(\text{EtOH})_2$ (c).²⁴⁷

Perhaps, the only exception is the value of 16.1 K recorded for the adduct of C_{60} fullerene with tetrakis(dimethylamino)ethylene (TDAE) with composition $C_{60}(TDAE)_{0.86}$ (see Ref. 304). However, the nature of the ferromagnetism of $C_{60}(TDAE)_{0.86}$ remains unclear, although there was no doubt that the adduct did not contain ferromagnetic admixtures.

A series of molecular organometallic ferromagnets based on salts of sandwich radical cations of decamethylferrocenium type with radical anions of such π -acceptors as tetracyanoethylene or tetracyanoquinodimethane have been synthesised and studied.^{3–6, 305–316}

The solid phases of these compounds involve molecular packing with alternating paramagnetic donors and acceptors (... $D^{+\bullet}A^{-\bullet}...$... $D^{+\bullet}A^{-\bullet}...$). The reasons for the bulk magnetic ordering in them became the subject of extensive theoretical studies.^{1, 6, 317–319} The compounds have critical temperatures from 2.3 to 8.8 K and are stable only in an inert atmosphere.

A similar series of donor-acceptor systems capable of magnetic ordering at 3–13 K was obtained from derivatives of porphyrin or phthalocyanine macrocyclic complexes with organic radical anions.^{320–325} Judging by the temperature of bulk magnetic ordering, compounds of metals with the tetracyanoethylene radical anion (TCNE) with composition $M(TCNE)_2(CH_2Cl_2)_y$ [$M = Mn^{II}$ ($T_c = 75$ K), Fe^{II} ($T_c = 75$ K)]^{326, 327} and especially the vanadium compound $V(TCNE)_x(CH_2Cl_2)_y$, where $x \approx 2$ and $y \approx 0.5$, are prominent among these subjects. The latter compound behaves as a ferromagnet up to the temperature of thermal decomposition (> 350 K).^{6, 328, 329} Unfortunately, the compound is extremely unstable in contact with air, and its structure could not be elucidated.

Nevertheless, it is substantiated that a phase which is saturated with an organic component and contains solvate molecules of dichloromethane (tetrahydrofuran or acetonitrile)³²⁹ is capable of magnetic ordering at high temperatures. This means that, in principle, it is not forbidden to obtain purely organic ferromagnets with high critical temperatures in which the exchange interactions between the paramagnetic centres are sufficiently strong. Recently, we found in a study of the first stable vinyl-nitroxyl (L)³³⁰

that antiferromagnetic exchange chains with an exchange energy of $J/k \approx 100$ K are formed in this solid. Due to such a high antiferromagnetic exchange energy, the magnetic moment of the

radical L does not reach the theoretical value ($1.73 \mu_B$) even at room temperature and equals $1.49 \mu_B$, *i.e.* high exchange interaction energies can also occur in compounds with a molecular structure. On the other hand, as already noted, mutual orientation of magnetic orbitals in the solid phase of L is such that the exchange interactions between the paramagnetic centres are antiferromagnetic, and the magnetic moment approaches zero as the temperature is lowered. However, examples of organic radicals are known in the solid phases of which the intermolecular exchange interactions are ferromagnetic^{297, 298, 331–333} and even ferromagnetic chains are formed.³³⁴ Besides, antiferromagnetic exchange is not an insurmountable obstacle to cooperative ordering, because a ferrimagnet can be obtained²⁶⁷ by using heterospin bi- or polyradicals³³⁵ or by cocrystallisation of mono- and bi- or polyradicals.²⁶⁷ It is possible that a purely organic ferromagnet, maybe even one with a molecular structure and with a sufficiently high critical temperature (exceeding the boiling point of liquid helium) will be synthesised.

VII. Conclusion

This review analyses the main classes of chemical compounds for which the basic methods for designing high-dimensionality multi-spin systems which tend to cooperative magnetic ordering have been discussed. The development of any method for designing molecular ferromagnets is undoubtedly a laborious and lengthy process. About ten years ago, the determination of the first approaches to the design of various classes of molecular ferromagnets had only started. To date, vast and valuable experimental material has been accumulated: critical temperatures above room temperature (315–330 K) have already been achieved for molecular ferromagnets;^{336, 337} compounds with anomalously high coercive fields have been synthesised;^{180, 181} a number of compounds have been obtained as single crystals stable under ordinary conditions.^{8, 247} The prospects of the practical application of molecular ferromagnets in various electronic and magnetic devices as well as for data recording, magnetic visualisation and protection against low-frequency magnetic fields are under discussion.^{3, 6, 24} An original photomagnetic device with a cyanide molecular ferromagnet as a working element was shown at the XXXIIIrd International Conference on Coordination Chemistry.³⁵

The prospects of progress in the area of molecular ferromagnets are difficult to predict. However, it is doubtless that these compounds are promising, as they represent light, transparent and mainly dielectric materials obtained under mild conditions, with specific properties commonly not typical of the classical magnetic materials.³³⁸

We did not dwell upon details of analysis of the magnetic properties of molecular ferromagnets, as this has been done exhaustively in several monographs,^{13, 339–342} and a detailed discussion of the diversity of magnetic properties of molecular ferromagnets might be an independent topic of a separate review. Let us just note that the authors often introduce a large number of exchange parameters (J_1, J_2, J_3 etc.) in the spin-Hamiltonian when analysing the experimental temperature dependences $\chi(T)$ or $\mu(T)$ for complex multi-spin systems with various channels of exchange interactions. If this approach is used, it should be taken into account that the introduction of additional parameters improves the fitting of the experimental curves, but the errors of the model in the determination of the parameters can increase to such an extent (by several orders) that these additional parameters would be utterly uncertain.³⁴³ The reliability of the exchange parameters obtained from the experiment is extremely important for the subsequent quantum-chemical analysis of the mechanisms of exchange interaction between the paramagnetic centres.

Abstract. The general principles of the concept of oxidation state stabilisation are formulated. Problems associated with the preparation and provision of the highest valent forms of transition elements are considered. The empirical data concerning the synthesis of new compounds of rare-earth elements and *d* elements in unusually high oxidation states are analysed. The possibility of occurrence of the oxidation states + 9 and + 10 for some elements (for example, for iridium and platinum in tetraoxo ions) are discussed. Approaches to the realisation of these states are outlined and it is demonstrated that solid phases or matrices containing alkali metal cations are the most promising systems for the stabilisation of these high oxidation states. Selected thermodynamic features typical of metal halides and oxides and the regularities of the changes in the extreme oxidation states of *d* elements are considered. The bibliography includes 266 references.

I. Introduction

According to traditional concepts, chemical compounds contain elements in definite oxidation states (OS). These concepts form the basis of, for example, authoritative handbooks on inorganic and coordination chemistry.^{1,2} A hypothesis for the stabilisation of the oxidation states has been offered rather long ago. The theoretical and experimental aspects of this hypothesis were discussed in the early 1960s (see, for example, Refs 3–7). More recently, the experimental aspect of the problem of the existence and OS stabilisation was repeatedly considered in connection with the discovery of noble gas compounds,⁸ studies of chemical properties of transactinides^{9,10} and the preparation of compounds of Np^{VII}, Pu^{VII},¹⁰ Am^{VII},^{11–14} Cm^{VI},¹⁵ Rn^{VI},¹⁶ Cf^V,¹⁷ Cm^V,^{15,18} Au^V,¹⁹ Ag^V,²⁰ Es^{IV},¹⁸ Cu^{IV},²¹ Tm^{IV},²² and lanthanides and actinides in the lowest oxidation states.^{23–29} Worthy of mention are investigations that have demonstrated the similarity

of the properties of heavy actinides and lanthanides, the discovery of the specificity of the so-called tetrad effect in lanthanide compounds,^{23,29,30} the preparation of Fe^{VIII} (see. Refs 31 and 32) and the detection of Co^{VI} in a cesium ferrate matrix.^{33,34} Studies of the properties of elements with atomic numbers 104, 105 and 106, *viz.*, rutherfordium, dubnium and seaborgium,^{35,36} and the possibility of generation of Hg^{IV} (see Refs 37 and 38) are also worthy of note.

Recently, new aspects of the problem under consideration became apparent to researchers in connection with the development of novel techniques for the stabilisation of oxidation states. With this in mind, Yatsimirskii^{39,40} and Parry⁴¹ examined the OS stabilisation upon coordination based on the original data. Previously, we have considered different aspects of this problem. In particular, we have discussed the stability of the highest OS of lanthanides in fluoride systems,^{29,42} the effect of outer-sphere cations on the stability of coordination compounds,⁴³ the ways of attaining high OS in the oxidative fluorination reactions,⁴⁴ procedures for the identification of the valent forms of transition elements⁴⁵ and some problems associated with the concept of valence,⁴⁶ in particular, some aspects of the problem of OS stabilisation in the solid phase⁴⁷ and the possibility of generation of high valent forms ($\geq +8$) of the heaviest transition elements (Ir, Pt, Au and Hg).⁴⁸ The validity of the principles reported in Ref. 48 was confirmed by direct quantum-chemical calculations.⁴⁹

In the present review, we consider some problems of OS stabilisation in relation to new evidence on their stability and touch on the problem of the extreme valent possibilities of transition elements. The concept of 'oxidation state stabilisation' is useful in this discussion because it provides ideas and mechanisms which allow researchers not only to perform experimental studies but also to interpret the results obtained. Let us formulate the general principles of this concept.

II. A concept of oxidation state stabilisation

It is generally assumed that chemical compounds contain elements in certain OS, which are stabilised by various forces. The character of chemical processes which result in a change in the oxidation state depends on the properties of the ion to be stabilised and the corresponding coordination environment.^{7,50,51} In the studies of OS stabilisation, the possibility of formation of compounds of a particular element in the particular OS and their stability are determined and the conditions for the synthesis of these com-

pounds are searched for, *i.e.*, techniques and procedures for the preparation of compounds with the predetermined property, *viz.*, OS, are developed and factors that affect the stability of OS are revealed (for example, phenomenologically).

Quite apparently, it is impossible to reveal the stabilisation factors without considering the problem of stabilisation of coordination polyhedra and crystalline phases. The strength of the corresponding chemical bonds and the stability of OS can be enhanced by stabilising coordination polyhedra.^{52–56}

Within the framework of the concept under consideration, it is assumed that the OS stabilisation implies an increase in the lifetime of the oxidised (reduced) form in an oxidant–reductant dynamic system compared to the standard. This system is characterised by certain thermodynamic and kinetic parameters (for example, by the Gibbs potential, vapour pressure, the activation energy, the reaction order, *etc.*). To stabilise OS, one can vary these parameters or change the ‘thermodynamics’ and/or ‘kinetics’ for those that are more favourable for the increase in the lifetime of the oxidised (reduced) form.

Let us consider the following transformation:

The $\text{Pr}_{\text{aq}}^{\text{IV}}$ aqua ion exists in aqueous media for ~ 200 ns,^{57, 58} whereupon this ion is transformed into the $\text{Pr}_{\text{aq}}^{\text{III}}$ aqua ion. When phosphotungstic acid is introduced into this dynamic system, a Pr^{IV} heteropolycompound [containing an ion of the probable composition $\text{Pr}^{\text{IV}}\text{W}_{12}\text{O}_{40}^{5-}$ (see Ref. 59)] is formed and the lifetime of the ‘oxidised’ form containing Pr^{IV} is increased to 10–15 min. Consequently, a change in the coordination environment about the Pr^{IV} ion is accompanied by a change in its stability. We do not consider the kinetic characteristics of redox processes in the absence and in the presence of heteropolyacids. However, it is evident that a change in the nearest environment of the central ion in the complex is reflected in the kinetic parameters.

The problem of stabilisation has two aspects. The first aspect is associated with the ways of attaining the desired oxidation state. The second aspect concerns the stability of this state. It is the provision of the stability of the OS over a period of time which is sufficient for its formation, identification and utilisation of the properties that receives primary attention.

The stability of chemical compounds with respect to decomposition into elements is determined by the total energy of the ligand–central atom system:

$$E_{\text{tot}} = \sum E_i + E' + E'' + E_c, \quad (2)$$

where E_i is the bond energy of the i th molecular orbital of the isolated complex formed upon interaction of the electron system of the central atom with the ligand, E' is the energy of stabilisation due to loss of degeneracy, E'' is the energy of repulsion between the ligands and E_c is the energy of stabilisation due to establishment of the long-range order (crystal lattice).⁵¹

Analysis of Eqn (2) demonstrates that the stability of compounds is governed by a combination of properties of the central atom and the ligand environment as well as by the crystal structure. Many researchers have reached this conclusion in an empirical consideration of the problem (see, for example, Refs 4 and 5).

The factors that affect the stability of OS are diverse in nature and generally act simultaneously and competitively.⁵ However, these factors can be, though rather arbitrarily, divided into thermodynamic (the first group) and kinetic (the second group) factors. The factors of the first group determine the possibility of formation of a particular ligand environment about the central atom (the formation of the short-range or long-range order). The factors of the second group affect the rate of formation of the desired environment. Taking into account the aforesaid, the following ways of stabilising OS can be distinguished.

1. Stabilisation through coordination. This stabilisation is realised in the chemical process owing to the formation of the nearest environment of the central atom in the complex, which is

more stable than those in free ions in the gaseous state or in solvated ions in solution. In this case, the ligands, the geometry, *etc.* are selected.⁷

2. Stabilisation by the crystal lattice, which is realised due to an increase in the coordination saturation of the central atom in the course of formation of crystals compared to the coordination saturation of ions in the gaseous state or in solution.^{7, 47}

3. Kinetic stabilisation due to minimisation of kinetic barriers that appear in the course of formation of the thermodynamically more favourable nearest environment of the central atom.⁷

A particular technique for the stabilisation should be chosen taking into account the properties of both the reagents and the expected reaction products containing the ion (atom) to be stabilised. Thus, the stability of compounds in which the coordination polyhedron about the ‘highly oxidised central atom’ is formed from the most stable F^- and O^{2-} ions, which are the strongest, difficultly oxidisable and difficultly deformable, are generally a maximum. Probably, only these ligands in the nearest coordination sphere of the central atom are suitable for stabilisation of the high and the highest unstable OS. Therefore, compounds with oxide and fluoride coordination polyhedra are generally considered in studies on the stabilisation of the highest OS.

Direct and inverse problems can be distinguished in the analysis of problems associated with the stability of valent forms.

The problem is said to be direct if physicochemical characteristics of an oxidant–reductant system, for example, redox potentials, are determined experimentally or calculated. The problem is said to be inverse if the conclusion about the stability of the oxidation state is made from a change in the selected parameters (properties) which can be related to OS in some series of compounds.

These problems can in principle be solved because rather simple correlations exist between the energy characteristics of the ions to which particular valent forms are assigned.

Actually, the quantum-mechanical parameters which characterise the electron density distribution and which are calculated taking into account only the electrostatic interactions between nuclei and electrons (the first-order perturbation theory) directly correlate with the oxidation states of the elements. This can be exemplified by the linear equation for the chemical shifts in the Mössbauer spectra (Fig. 1).^{32, 60, 61}

$$\delta = a + bx,$$

where δ is the chemical shift, $a = 1.834$, $b = -0.456$ and x is OS.

There are rather simple correlations between the enthalpies of formation of halides MHal_n and the enthalpy increments of M^{n+} ions calculated according to the additive schemes.⁶² These correlations can be interpreted in a different way (see, for example, Ref. 63) because of the ambiguity of the approaches used by chemists or, more precisely, due to the fact that none of approaches can be extended indiscriminately to all compounds.

Figure 1. Dependence of the chemical shift relative to sodium nitroprusside on OS of the metal for iron derivatives.^{32, 60, 61}

In the general case, the direct and inverse problems cannot be solved. This is associated with many factors but the main reason is that M_{aq}^{n+} aqua ions that exist in solutions are known only for a limited number of elements (generally, in the lowest OS). As the atomic number of the element is increased, the covalence of the M–L bond and the role of relativistic effects, including spin-orbital interactions, are increased, which is accompanied by the enhancement of the characteristic features of the ions more complex than aqua ions (for example, of actinyl ions⁶⁴). An analogous situation is observed as the OS is increased.

The definition of the notion 'oxidation state' is the key in the analysis of the problems associated with the concept under consideration. This problem, which is directly related to the 'problem of valence,' is intricate. In particular, the problem of the relationship between the valence number, the effective charge and OS is still topical, although it has been discussed many times. This aspect of the chemical structure theory turned to be so contradictory that it has been suggested,⁶⁵ without going into terminological details, to consider the valence only as a number, to retain its classical content and to give up attempting to treat all modern discoveries in the field of chemical bonds in the context of this notion. However, more recently (see, for example, Refs 66 and 67) attempts to calculate the valence numbers have been undertaken. No consideration is given to these and other calculation procedures in the present discussion, but it should be noted that none of the available procedures is versatile.

The measure of the valence or OS can be most readily determined by the number of gram-equivalents of the oxidising or reducing agent per gram-atom of the element (metal or metalloid) which is either consumed or acquired when the element is transformed to the compound or vice versa. It is advantageous to take a one-equivalent oxidation or reduction process as the standard process, the choice of a particular one-equivalent conversion being of no importance. The above-described determination of the valence number[†] is convenient because it is based on experimental grounds and is invariant with respect to the model of the electronic structure of the compound.

We emphasise that the positive or negative value of OS does not imply that the corresponding charge is located on the atom. The determination of the valence on the basis of the number of gram-equivalents means the thermodynamic relations from which neither the spatial arrangement of the atoms nor characteristics of the bonds (for example, the bond order, which cannot be determined spectroscopically) can be directly obtained. The gram-equivalent is a complex parameter, which covers all interactions in the compound, and it cannot be represented either as a charge or as a number of bonds.

The valence (or OS) is a classification notion used in crystal chemistry or for systematising educational data on inorganic chemistry. For example, Kossel's views were consistently used in the monograph⁶⁹ for tetrahedral systems. Chemical compounds of the element in the same oxidation state can be characterised by different electron density distributions, coordination polyhedra and the bond character. This is not surprising because specific electronic properties of atoms, which can be judged from the results of physical methods, are nothing more than a consequence of the manifestation of a particular valence. The above-considered determination of the valence number does not contradict the notions⁷¹ of the electronic state fluctuation, processes of electronic ordering and, consequently, fractional OS for transition elements. These are the properties of the element which exists in a

particular OS or possesses a definite valence. These properties should be specially studied and systematised.

The results of calculations of the enthalpies of formation of inorganic halides and oxides according to additive schemes provide certain support for the above approach to the determination of the valence.^{62, 72–75}

Calculations of the enthalpies (energies) of inorganic halides and oxides are based on the classical structure theory, which has been conceptually refined by Tatevskii.^{76, 77} According to the known approximation of this theory, the macrocharacteristic, such as the self-energy, can be represented as a sum of increments (E_j) that characterise contributions of the so-called effective j th atoms with the valence number (n), $j^{(n)}$:

$$\Delta U = \sum E_{j^{(n)}}. \quad (3)$$

The application of this equation to inorganic subjects is limited. Equation (3) cannot be directly used even in the seemingly simple case, *viz.*, in the case of compounds of various metals of the same stoichiometry, because one has to solve a system of k equations of the type

$$\Delta U_{A_x B_y} = x E_{A^{(n)}} + y E_{B^{(n)}} [E_A = \Phi(n), E_B = \text{const}] \quad (4)$$

in $k + 1$ unknowns. One more equation is required to obtain a solution. We found an equation of relationship,^{62, 73, 78} which is an empirical correlation between the enthalpy of formation of compounds MX_n and the enthalpy of the following type:

$$H_{M^{(n)}} \equiv \frac{\sum I_i}{I_1} \Delta_s H_M,$$

where I_i are stepwise ionisation potentials and $\Delta_s H_M$ is the enthalpy of sublimation of the metal.

The equation takes the form of the following additive four-membered equation:

$$\Delta_f H_{MX_n}^0 = H_{M^{(n)}} + n H_X + n H_{M^{(n)}-X} + y H_{X-X}, \quad (5)$$

where $H_{M^{(n)}}$ is the enthalpy corresponding to the contribution of the central atom, H_X , $H_{M^{(n)}-X}$ and H_{X-X} are the enthalpies corresponding to the contributions of the ligand X and of the $M^{(n)}-X$ and $X-X$ bonds, respectively. Examples of selected dependences of the enthalpies of formation of chlorides and fluorides on the first term of Eqn (5) are given on Fig. 2 and in Table 1.

Figure 2. Dependence of the enthalpy of formation of gaseous monohalides on the partial enthalpy $H_{M(0)}$; (1) chlorides; (2) fluorides.

[†] In this approach, the valence numbers coincide with the so-called Jorgensen's formal OS (or the Russian term 'degrees of oxidation'). The application of the latter is improper because of the absence of charges on atoms. Crystal-chemists use 'formal charges' on atoms in calculations^{68, 69} and reject the reality of these charges by introducing the notion 'effective charges.' The valence balance or valence strengths would be more properly used (this approach was used, for example, in Ref. 70).

Note. The characteristic groups, *i.e.*, the sets of compounds of elements of the corresponding vertical groups in the short version of the Periodic system, are given in boldface type.

$$\Delta_f H^\circ = A + BH_{M^{(n)}}.$$

A similar situation is also observed for other halides and oxides.

The so-called characteristic sets of compounds can be distinguished in these linear dependences. The Group I elements are characteristic for monohalides (see Fig. 2), the Group II elements are characteristic for dihalides, *etc.* In other words, the characteristic sets of compounds of elements with the *i*th valence are comparable with the lists of the elements in the vertical groups of the short version of the Periodic system.

Taking into account the additive equation (5) and the linear dependences of the enthalpies of formation of gaseous halides on the enthalpies $H_{M^{(n)}}$, it can be concluded that grouping of compounds is dictated by the argument, while the character of the change in the function is determined by the remaining terms of the additive sum in Eqn (5).

The relationship between the enthalpy increments is such that the first terms of the sum (5) have the maximum values. This makes it possible to construct the hierarchy which defines the energetics of compounds and which is based on the classical structure theory.^{76,77}

This theory assumes the application of the model of pairwise interactions. A certain energy increment can be related to each pairwise interaction (the procedure is described in the monograph⁷⁶). The values of the increments depend on the following characteristics: chemical individuality, sort, type, kind and variety. On the whole, these characteristics comprise a 'tree' of chemical states. The first characteristic is determined by the position of the element in the Periodic system. The second characteristic is associated with the valence. The third characteristic is connected with the geometry of the nearest environment of

the central atom. The last two mentioned characteristics reflect finer details of the structure, for example, geometrical or optical isomerism.

The characteristics of the sort (valence), which determine, in particular, clustering of halides (or oxides) in the dependences analogous to those shown in Fig. 2, can be assigned to the parameter $H_{M^{(n)}}$. As a consequence, the valence is determined through the gram-equivalent, *i.e.*, through the thermodynamic relations.

The oxidation states can be determined by direct (chemical) and indirect (physical) methods. Oxidimetric and electrochemical techniques were referred to as the chemical methods in Ref. 45. Procedures for the analysis based on one-equivalent transitions of the types $I^- \rightarrow (1/2)I_2$ and $Ce^{III} \rightarrow Ce^{IV}$ as well as on processes described by a known number of equivalents ($MnO_4^- \rightarrow Mn^{II}$ and $Cr_2O_7^{2-} \rightarrow Cr^{III}$) are very popular. Of the above-mentioned procedures, iodometric techniques are most widely used because of their simplicity, availability and versatility.

For example, the applications of the iodometric analysis to fluoride-containing oxidants, which include compounds of *d* and *f* transition elements, and to platinum compounds were considered.^{79,80} Fluorides of Ln^{IV} , Cu^{II} , Cu^{III} , Ag^{II} , Ag^{III} , Ag^V , Au^V , Ni^{III} , Ni^{IV} , Mn^{III} , Mn^{IV} , Co^{III} , Fe^{III} , Fe^{IV} , Cl^{III} , Br^{III} , Br^V , Xe^{II} , Xe^{IV} , Xe^{VI} , *etc.* were analysed. The iodometric procedure was used in the analysis of alkaline solutions of iron derivatives in the highest oxidation states (Fe^{IV} , Fe^{VI} and Fe^{VIII}).⁸¹ In this case, not only the OS of iron but also the concentration of the metal in solution was determined.

The determination of the final state after titration is the key to oxidimetric (in particular, iodometric) procedures. Thus experiments with platinum compounds demonstrated⁸⁰ that $Pt^{2.3+}$ was the final state in the titration of iodide complexes, which does not prevent the analysis.

Evidently, the main drawback of oxidimetric procedures is the absence of selectivity. This calls for studies aimed at revealing reasons for redox transformations. For example, the analysis of alkaline solutions of iron in the highest oxidation state was accompanied by additional studies of solutions by Mössbauer spectroscopy, which have demonstrated that the iodometric data correspond to the valence transitions of iron.⁸¹

Much the same is true for electrochemical methods, *viz.*, for polarography and coulometry. Cyclic voltammetry in combination with coulometry is a convenient procedure for the determination of gram-equivalents in metal complexes.⁸² For example, two reversible one-electron waves corresponding to the $Ir^{VI} \rightarrow Ir^{V} \rightarrow Ir^{IV}$ transformations are observed in the cyclic voltammograms of reduction of the electrochemically oxidised hydroxo complexes of Ir^{IV} .^{83,84} Electrochemical methods can be applied not only to solutions but also to melts. For example, these procedures were used for revealing the nature of the processes in salt melts and for determining conditions for stabilisation of the highest transition-element OS in these melts.⁸⁵

Chemical methods for the OS determination are effective only in combination with physical methods. The most commonly used methods are magnetochemistry, ESR, electronic, Mössbauer and X-ray spectroscopy, X-ray photoelectron spectroscopy, X-ray diffraction analysis and methods of vibrational spectroscopy.⁴⁵ To answer the question about the element OS, it is necessary to know, first, the correlations between OS and the parameter observed and, second, the reasons for deviations from these correlations if these deviations are observed or expected. For example, the number of outer electrons withdrawn from the electronic configuration of the free atom often corresponds to the element OS. In addition, the number of gram-equivalents of the oxidising (reducing) agent consumed in the oxidimetric titration corresponds to the number of *d* (or *f*) electrons of the metal ion (for a series of important regularities, see Refs 86–88).

Below are considered procedures for the stabilisation of the highest OS of particular elements.

III. Rare-earth elements

The known OS^{89, 90} for rare-earth elements (REE, Ln) are listed in Table 2. For rare-earth elements, OS + 3 is generally realised in a rich variety of their compounds; OS + 2 belongs to the lowest OS and is not considered in the present paper because many studies were devoted to this problem and the results have been reviewed.²³

Table 2. Known oxidation states of rare-earth elements.^{89, 90}

OS	La	Ce	Pr	Nd	Pm	Sm	Eu	Gd	Tb	Dy	Ho	Er	Tm	Yb	Lu
+2	?	?	+	+	?	+	+	?	?	+	+	+	+	+	?
+3	+	+	+	+	+	+	+	+	+	+	+	+	+	+	+
+4		+	+	+		+			+	+			+		

Note. Hereinafter, the following notations are used: +, this OS exists; ?, indirect evidence is available and reliable proof is absent.

1. Complexes of Ln^{IV} with organic ligands

The problem of preparation of rare-earth complexes in high OS with organic ligands arose in the 20th century.^{91–93} These compounds are often characterised by high stability constants and are very promising, for example, for the separation of rare-earth elements and actinides.^{94–96} In the 1970s, it was established that intramolecular redox processes cannot be completely eliminated even in Ce^{IV} compounds (see, for example, Ref. 97), and the number of studies aimed at this particular application became fewer. However, it was reported⁹⁸ that the influence of these processes in rare-earth complexes with diphthalocyanines was a minimum, and it was concluded that these subjects contain Ln^{IV} ions throughout the entire lanthanide family. Nevertheless, a number of facts do not allow one to accept this interpretation of the data made in the work cited. In studies of transition metal complexes in the highest OS with carboxyl-containing chelating agents, hydroxy carboxylic acids, polydentate acyclic ligands, crown ethers and β -diketones, it was demonstrated that redox processes occur in all cases, though at different rates.⁹⁷ In other words, intramolecular redox interactions can only be partially suppressed (but not completely excluded) by choosing an appropriate ligand. Phthalocyanine can be readily reduced due to the presence of a large number of multiple bonds. Even if rare-earth complexes under consideration possess high stability, one cannot expect that intramolecular redox processes would be completely suppressed taking into account extremely high values of the redox potentials of the Ln^{III}/Ln^{IV} pairs (for example, the values of E° were estimated as equal to 2.83.0 V for Ln = Tb and Pr^{99, 100}). Apparently, additional supporting evidence for the existence of Ln^{IV} in diphthalocyanines is required.¹⁰¹

2. Complexes of Ln^{IV} with inorganic ligands

The data on the behaviour of Ln^{IV} (Ln = Ce, Pr, Nd, Tb and Dy) in aqueous media are limited mainly by those for Ce^{IV} compounds. The Ce^{IV} ion is a rather strong oxidant ($E^\circ_{\text{Ce}^{IV}/\text{Ce}^{III}} = 1.66 \text{ V}^{99, 100}$). These ions are formed in the reactions with the participation of oxidants such as bromate (see, for example, Ref. 102) and are stabilised by various inorganic ligands with different efficiency. Interestingly, Ce^{IV} compounds containing chloride ions in the nearest coordination sphere exist although Cl[−] ions are known as reductants. For example, a large series of hexachlorocerates(IV) M₂Ce^{IV}Cl₆ (M^I = NR₄⁺, PR₄⁺, AsR₄⁺, H₃O⁺, Rb⁺ and Cs⁺) were prepared and their structures and stabilities were studied.^{103–112} It was demonstrated¹¹³ that the anionic [CeCl₆^{2−}] complex exists in aqueous media for a rather long period of time and an excess of chloride ions even somewhat stabilises this complex. The cesium salt (air-stable below 300 °C) is a convenient gravimetric form in the chemical analysis and separation of alkali metal cations.¹⁰⁵

Data on the existence of Tb^{IV} and Pr^{IV} in aqueous media are scarce. Note that the information on the preparation of Pr^{IV} and Tb^{IV} acido complexes (nitrates, sulfates and chlorides) in aqueous solution was disproved.¹¹⁴ As mentioned above, reliable data on the Pr^{IV} ions were obtained by pulse radiolysis:^{57, 58} the short-lived absorption was assigned to the Pr^{IV} aqua ion. The Pr^{IV} ion is unstable due to the larger value of the Pr^{IV}/Pr^{III} pair redox potential. The preparation of aqueous solutions of Pr^{IV} phosphotungstate was reported.^{115–117} The possibilities of studying this deep coloured complex are limited since this complex exists in a solution for only several minutes even at low concentrations. As a consequence, detailed information on this complex is absent.

Tetravalent terbium ($E^\circ_{\text{Tb}^{IV}/\text{Tb}^{III}} \approx 2.8 \text{ V}$) is also stabilised in a salt of phosphotungstic acid.^{59, 117, 118} Its solutions can be stored at room temperature for several months. Phosphotungstic acid can be very efficiently used for stabilising strong oxidants, such as actinide ions, and the complexation leads to a decrease in the E° value by $\sim 1.0 \text{ V}$.^{118, 119} The evidence on the existence of Pr^{IV} and Tb^{IV} ions in these compounds suggests that the above conclusion is true for lanthanides as well.

While on the subject of aqueous media, Pr^{IV} and Tb^{IV} hydroxides should be mentioned. Treatment of alkaline suspensions of Tb^{III} hydroxide with such reagents as O₃, S₂O₈^{2−} and IO₄[−] is accompanied by the formation of Tb^{IV} hydroxide.¹²⁰ Treatment of binary and complex Pr^{IV} and Tb^{IV} fluorides with alkaline solutions also resulted in the isolation of hydroxides.¹²¹ Note that the yield of Ln^{IV} hydroxide decreases as the stability of Ln^{IV} ions decreases. Thus when the corresponding fluoride complex was treated with cold alkali, Tb^{IV}O₂·*n*H₂O was obtained in almost quantitative yield, the yield in the case of Pr^{IV} was substantially lower and Dy^{IV} hydroxide was formed only in trace amounts.¹²¹

To summarise, the stabilisation of Ln^{IV} in solutions is insufficiently efficient due to a limited number of inorganic ligands which are able to decrease the redox potential of the system to a reasonable value. The stability of Ln^{IV} is substantially higher in the solid state than in solutions, which is manifested not only in the higher thermal stability of the solid compounds compared to that of the complexes in solutions but also in the broad assortment of the corresponding tetravalent ions^{89, 122, 123} that occur in solid phases.

Solid fluoride complexes of Ce^{IV}, Tb^{IV}, Pr^{IV}, Nd^{IV}, Dy^{IV}, Tm^{IV} and Sm^{IV} (the data on the last two mentioned complexes were reported in Refs 22 and 29) and binary Ce^{IV}, Tb^{IV} and Pr^{IV} fluorides (the synthesis of pure PrF₄ was described for the first time in Refs 124 and 125) have been prepared to date. Binary oxides PrO_{2−*x*} and TbO_{2−*x*} (*x* < 0.5) and complex compounds were detected in oxygen-containing systems.^{126, 127} A large number of Ln^{IV} ions (Pr^{IV}, Tb^{IV}, Nd^{IV} and Dy^{IV}) are stabilised in BaCeO₃,^{128–130} which serves as a matrix. Stabilisation was performed under an atmosphere of oxygen at 1200–1400 °C.^{128, 129, 131}

Therefore, the stability of a metal–ligand system in the solid phase (*i.e.*, in the presence of long-range order) is higher than that of this system in solution. The coordination effects that occur in the solid state diminish the intermolecular metal–ligand distances in the nearest coordination sphere about the central atom of the complex compared to the internuclear distances in the binary compounds,¹³² which also favours the stabilisation of the Ln^{IV} ions.

The currently available evidence allows one to consider the regularities of stabilisation of the highest OS of lanthanides. Analysis of the stability of Ln^{IV} compounds based on the published data^{29, 43, 133–137} allowed conclusions^{29, 137} that the efficiency of Ln^{IV} stabilisation can be judged from only two groups of data. The first group includes the data on redox potentials or ionisation potentials of lanthanide atoms. However, this information does not allow reliable conclusions about the stability of Ln^{IV} because $E^\circ_{\text{Ln}^{IV}/\text{Ln}^{III}}$ are calculated by empirical methods and only the data on Ce^{IV} derivatives provide trustworthy basis for these calculations. The experimental E° values

for other $\text{Ln}^{\text{IV}}/\text{Ln}^{\text{III}}$ pairs cannot be obtained due to the high oxidising capacity of Ln^{IV} , which does not allow one to construct an equilibrium electrochemical cell. The solution of the direct problem of the stability presents difficulties because the initial data are scarce. The series of the relative stabilities of oxidation states^{122, 123} obtained on the above basis reflect only roughly the actual situation. Therefore, an alternative method which consists in the solution of the above-mentioned inverse problem is used for obtaining data on the stability of Ln^{IV} .

The thermodynamic characteristics of Ln^{IV} fluorides with composition Cs_3LnF_7 were reported.¹³⁵ The thermal stabilities of the same fluorides were also studied by methods of non-isothermal kinetics. The thermodynamic values were determined according to procedures of differential thermal analysis,¹³⁸ which have been developed and tested in special experiments, with the use of a specially designed sealed nickel cell whose sensitivity is close to that of the cell of a differential scanning calorimeter.^{139–141} These procedures make it possible to obtain data on the enthalpies of fluorination reactions.

The most reliable values of the enthalpies and Gibbs energies of the reactions

for all rare-earth elements (Table 3) can be obtained on the basis of the available data^{135–137} and results of calculations of the Born–Haber cycle.^{135, 142–144}

Table 3. Results of calculations of the enthalpies of process (6) (kJ mol^{-1}) according to the Born–Haber cycle.¹³⁵

Ln	ΔU	$-\Delta_r H^\circ$	Ln	ΔU	$-\Delta_r H^\circ$
Ce	3608	331	Tb	3809	239
Pr	3656	164	Dy	3827	95
Nd	3730	90	Ho	3852	22
Sm	3753	31	Er	3904	58
Eu	3774	–68	Tm	3986	136
Gd	3793	–184	Yb	3998	47

It was confirmed^{135, 142–144} that in the LnF_4 series the cerium compound is the most stable one, this is followed by the terbium and praseodymium derivatives in order of decreasing stability. The thermal stability of the M_3LnF_7 complexes decreases in the following order: $\text{Ce} > \text{Tb} > \text{Pr} > \text{Dy}$.^{137, 145, 146}

The thermodynamic stability of the complexes with respect to elimination of fluorine according to reaction (6) decreases on going from Ce to Sm: $\text{Ce} > \text{Tb} > \text{Pr} > \text{Dy} > \text{Tm} > \text{Nd} > \text{Sm}$. The stability of the highest OS (+4) of lanthanides decreases in the same order.

The regularity which is observed in the lanthanide series and is referred to as the ‘tetrad effect’ has been refined.^{29, 137} In the series of the rare-earth elements, ‘nodal points’ exist in which the probability of changes in the composition, structure, the type of phase diagram and some other parameters is a maximum. The lanthanide family is divided into four segments (from whence the name ‘tetrad’ follows). This effect is most pronounced in the middle of the 4f series, which corresponds to the ‘gadolinium break’.^{29, 147, 148} This effect is most clearly manifested in the atomic properties (ionisation potentials, electron affinity, Gibbs energy, enthalpies of gaseous ions, *etc.*). The tetrad effect was attributed to the specific change in the electrostatic term of the exchange interaction of the f electrons in the Ln series.¹⁴⁵

The thermodynamic data (ΔH° and ΔG°) for Ln^{IV} fluorides reproduce the tetrad effect.^{29, 135} However, the distinguishing feature is that this effect is of different importance for the middle elements of each half of the series. This effect is more pronounced in the middle of the second half of the series. As a consequence, the

stability of Tm^{IV} is anomalously high compared to that of Sm^{IV} due to the effect of the condensed state.

Actually,^{137, 149} the difference between the lattice energies of $\text{Ln}^{\text{III}}\text{F}_3$ and $\text{Ln}^{\text{IV}}\text{F}_4$ or of $\text{M}_3\text{Ln}^{\text{IV}}\text{F}_7$ and $\text{M}_3\text{Ln}^{\text{III}}\text{F}_6$ (ΔU) and the differences between the corresponding enthalpies of formation (ΔH°) are related to the fourth ionisation potentials of the lanthanide atoms (I_4) by the following equation:

$$\Delta H^\circ + \Delta U + \text{const} = I_4.$$

The ΔU values in the lanthanide series change ‘smoothly’ (see Table 3) so that these values for the second half of the 4f series are substantially larger than those for the first one. Since the dependence of I_4 on the atomic number of the element is nonlinear and is governed by the tetrad effect, the ΔH° (ΔG°) values should be changed analogously. This implies that the enthalpies (Gibbs energies) of formations of Tm^{IV} compounds should be larger in magnitude than the corresponding values for the Sm^{IV} compounds.

3. The effect of complexation

A large number of tetravalent rare-earth elements are stabilised in cesium fluoro complexes. The higher stability of the complexes compared to the corresponding binary compounds has been discussed many times (see, for example, Refs 29 and 42). In the solid phase, the stabilisation occurs due to the positive charge of the outer-sphere cation, which compensates for the negative charges on the complex anions.⁴³ The absence of the outer-sphere cations in the structure of a compound leads to a distortion of the coordination polyhedron of the central atom as a result of which the overall atomic system is destabilised. For example, the structure of AuF_5 is built of octahedra linked to each other and twisted into a helix.¹⁵⁰ In Au^{V} complex fluorides, there is no need for such twist and the anion has an octahedral shape.¹⁵¹

4. Valence possibilities of lanthanides

Efforts were made to extend the series of lanthanides which could be transformed into the highest OS and to reveal the possibilities of attaining OS higher than +4 by experimental methods.^{121, 124, 137, 140, 141}

In the solution of the first problem, reactions were found which are characterised by minimal kinetic barriers to processes of formation and the maximum possibility of the $\text{Ln}^{\text{III}} \rightarrow \text{Ln}^{\text{IV}}$ transformation.⁴⁴ The reaction that proceeds according to the following general equation:

is most suitable.

This reaction was successfully used for the preparation of Cs_3TmF_7 ; Tm^{IV} was identified by physicochemical methods. Experimental evidence (the data from differential thermal analysis) for the existence of Sm^{IV} was obtained.⁴⁴

The solution of the second problem was considered using praseodymium, which exhibits the most promise for preparing the highest valent forms, as an example.¹³⁷ Various high- and low-temperature fluorination reactions of binary and complex chlorides, fluorides, nitrates and sulfates under diverse reaction conditions (with variations of the temperature and the duration of the reaction, in the presence or in the absence of a solvent, *etc.*) were studied. The most powerful oxidants, including fluorine, krypton difluoride, *etc.*, were used. It appeared that in all cases fluorination afforded only Pr^{IV} compounds. Taking into account this fact and based on the theoretical grounds, it was concluded^{29, 137} that +4 is the extreme OS for 4f elements due to strong localisation of 4f states in the atomic core of lanthanides and the presence of serious energy hindrances to the subsequent ionisation. These 4f elements differ sharply from 5f elements.

In conclusion, it should be noted that OS +4 for the rare-earth elements are also stabilised in other solid systems, in particular, in perovskites BaTbO_3 , SrCeO_3 ,¹⁵² $\text{Ba}_{1-y}\text{Sr}_y\text{PrO}_3$, $\text{BaCe}_y\text{Pr}_{1-y}\text{O}_3$ and $\text{Sr}_y\text{Ba}_{1-y}\text{PrO}_3$,¹⁵³ oxide superconductors

$\text{Pb}_2\text{Sr}_2\text{Ce}_{1-x}\text{Ca}_x\text{Cu}_3\text{O}_8$ ¹⁵⁴ and $\text{Pb}_2\text{Sr}_2\text{RCu}_3\text{O}_8$ ($\text{R} = \text{Ce}, \text{Pr}, \text{Tb}$ or Am ¹⁵⁵) and manganites $\text{Y}_{1-x}\text{Pr}_x\text{Sr}_2\text{Cu}_{2.85}\text{Re}_{0.15}\text{O}_{7+\delta}$,¹⁵⁶ $\text{Pr}_{1-x}(\text{Ca},\text{Sr})_x\text{MnO}_3$,¹⁵⁷ $\text{Pr}_{0.6}\text{Ca}_{0.4}\text{MnO}_3$ ¹⁵⁸ and $\text{Pr}_{0.6}(\text{Ca},\text{Sr})_{0.4}\text{MnO}_3$.¹⁵⁹

IV. Transition elements

Of all transition metals, the Group VIII elements, silver, gold and mercury are of most interest because researchers faced serious problems when preparing their highest valent forms.

1. Highest valent forms of iron

Until recently, it was assumed that the maximum valence of iron is no higher than +6 and this fact was even substantiated theoretically. Quantum-chemical calculations for Fe, Ru and Os tetroxides¹⁶⁰ demonstrated that FeO_4 is characterised by high populations of the atomic states, which excludes the formation of strong Fe–O bonds. However, this fact does not necessarily indicate that this compound, though unstable, cannot be prepared. For iron, an OS of +5 was observed only in one compound, *viz.*, in $\text{La}_2\text{LiFeO}_6$, which was prepared at high pressure and was well studied.¹⁶¹ The seemingly well-known ferrates(VI) continue to attract the attention of researchers. For example, the mechanism of decomposition of ferrate(VI) was considered in Ref. 162. At the same time, Fe^{IV} compounds remain poorly studied.

The processes that occur in alkaline media upon anodic dissolution of metallic iron under conditions of high current density were studied in detail.^{31, 32, 163–178} The conditions for formation of ferrate(VI) were found,^{31, 32, 168–173} qualitative notions of the mechanism of this process were developed and explanations were offered for the decomposition of concentrated ferrate(VI) solutions to form iron(III) hydroxide. Abnormal properties of ferrate solutions were observed. The detailed studies of these properties allowed conclusions to be made about the existence of ferrates(IV) in alkaline media (previously, it was believed that these compounds are unstable in aqueous solutions) as well as about the occurrence of FeO_4 .^{31, 32} These compounds were identified by electronic spectroscopy of solutions, Mössbauer spectroscopy and some other methods. The justified assumptions were made that ferrate(VI) may undergo disproportionation and thermal stimulation of the latter afforded Fe^{VIII} and Fe^{IV} derivatives.

Iron tetroxide is very unstable. It can be isolated in a relatively pure form by extraction from solutions of ferrates in CCl_4 . The extracts were distilled at 30 °C to give products in yields no higher than 25%–30%. These properties were used in the preparation of highly pure iron.^{179–181} Solutions of Fe^{VIII} undergo autocatalytic decomposition to Fe^{III} hydroxide and can exist only when the concentration of iron is lower than 0.01 mol litre^{−1}. The Mössbauer spectra (77 K) of aqueous–alkaline systems containing Fe^{VIII} have a singlet line belonging (judging from the value of the chemical shift δ) to the highest valent form of iron.³²

Ferrate(VI) in an aqueous–alkaline medium is so stable that its solutions under normal conditions can be stored for at least two years. This compound is formed not only in the course of the above-mentioned disproportionation but also under prolonged action of oxygen on alkaline solutions of Fe^{III} hydroxo complexes.^{178–181}

The data on FeO_4 essentially supplement the known regularities of the Periodic system and, in addition, make it possible to establish a qualitative correlation between the stability of the compounds and the occupancies of the orbitals determined by quantum-chemical methods.

2. Copper, silver and gold

The data on OS of copper, silver and gold are given in Table 4. For this group of elements, OS $\geq +3$ are unstable, although, strictly speaking, even OS of +2 is unstable. For example, one of the manifestations of the effect of variable valence, *viz.*, the fluctua-

Table 4. Oxidation states of copper, silver and gold.

OS	Cu	Ag	Au
+1	+ (see ^a)	+ (see ^a)	+ (see ^a)

+5		+ (see ^d)	+ (see ^d)

^a Known in many compounds. ^b Undergoes disproportionation. ^c For oxides. ^d For fluorides.

tion of the charge state, is observed for Cu^{II} ions. Apparently, this results in such a value of the redox potential $E^\circ_{\text{Cu}^{\text{III}}/\text{Cu}}$ that the Cu^{II} ion can be considered as an oxidant.

The problem of the existence of the highest valent forms for Cu, Ag and Au is still not completely solved. This is particularly true for gold. The first Au^{V} compound, *viz.*, the fluoro complex with the bulky $\text{Xe}_2\text{F}_{11}^+$ cation, was prepared only in 1972.¹⁸² Since that time, some other Au^{V} compounds have been synthesised. In particular, AuF_5 and fluoro complexes with cations of alkali and alkaline-earth metals were prepared. However, no compounds with ligands other than fluoride were found.¹⁸³ The questions of whether Au^{IV} can be isolated and whether OS higher than +5 can be realised are still open. The same is true for silver compounds. Thus, only the Ag^{V} derivative with composition $\text{Cs}_2\text{Ag}_{1/2}^{\text{V}}\text{Ag}_{1/2}^{\text{III}}\text{F}_6$ is known.¹⁸⁴

These problems have been considered many times.^{150, 151, 185–197} New binary (AgF_3) and complex fluorides of Cu^{III} , Ag^{I} , Ag^{II} , Ag^{III} , Au^{III} , Au^{V} and $\text{Ag}^{\text{III, V}}$ with various outer-sphere cations were synthesised and studied. Many of the synthetic reactions of these compounds have been examined and the factors that affect the yields of the products and, consequently, the stabilisation of the corresponding OS have been revealed.¹⁹⁷ Finally, data which can be interpreted in the context of disproportionation of Au^{V} were obtained in studies of thermolysis products of Au^{V} fluoro complexes.¹⁵⁰ In fact, there is no direct evidence for the presence of a disproportionation product, *viz.*, of a fluoride more enriched with fluorine than AuF_5 , in the gaseous phase.

The data on the preparation of Cu^{IV} as Cs_2CuF_6 and Cu^{IV} oxide were reported in Refs 198 and 199, respectively. The latter experiments were carried out under high oxygen pressure. The oxide contains Cu^{III} and Cu^{IV} stabilised in the perovskite lattice with composition $\text{La}_{1-x}\text{Sr}_x\text{CuO}_3$ ($0 \leq x \leq 0.25$).

The formation of mixed-valence states is typical of Cu, Ag and Au both in the fluoride and oxide systems. In oxide superconductors and related compounds, these states of copper are of great importance. In superconductors, the OS of copper varies from +1 to +2.33. In this case, the π -orbitals of oxygen atoms make significant contributions to the corresponding molecular orbitals. The mixed-valence states^{200, 201} are responsible, for example,²⁰² for a ‘charge-stabilised’ distortion of $\text{NaBa}_2\text{Cu}_3\text{O}_6$. Of the recent works in this field, let us note Refs 203–205. The unusual properties of gold oxides in oxide films were described.^{206, 207} In this connection, recall the effects associated with the dynamics of the electron density in the solid phase.⁷¹ The unit cell can contain metal ions in different OS that occupy crystallographically non-equivalent positions, metal ions in different OS that occupy equivalent positions and, finally, metal ions in the so-called fluctuating state where fast oscillations (which are equivalent to electron transitions between different OS) of electron density occur at each lattice centre. The existence of the mixed-valence state is an indication of valence instability. This problem as well as the factors favourable for disproportionation were considered.⁴⁸ The existence of copper in the mixed-valence state ($\text{Cu}^{\text{III, IV}}$) in oxides is indicative of a decrease in the stability of OS +4 of copper compared to that observed in the fluoride due, apparently,

to the presence of the essential π -component of the metal–ligand bond in the oxide. Taking into account the existence of copper in the $\text{Cu}^{\text{III}}/\text{Cu}^{\text{IV}}$ state, it is believed that +4 is the extreme oxidation state for copper.

3. Heavy platinum elements

Difficulties emerge in the realisation of the highest OS for heavy 5d transition elements (Table 5). This is particularly true for Ir, Pt, Au and Hg. It can be seen that the maximum oxidation state attained for platinum metals is equal to +6, which is, apparently, far from the extreme value. The main and most reliable information on the properties of the strongly oxidised ions of the above-mentioned elements concern predominantly their fluorides, although scattered data on oxide systems have been recently reported.

Thus attempts were made to synthesise iridium compounds in the highest OS under high oxygen pressure (it is known^{211,212} that high pressure favours attainment of unusual OS of transition elements).^{208–210} The properties of a new series of oxides with the distorted K_2NiF_4 structure of composition $\text{A}_2\text{M}^{\text{VI}}\text{O}_6$ ($\text{A} = \text{Ba}$ or Sr ; $\text{M} = \text{Sr}$, Ca , Mg or Zn) containing iridium in OS of +6 were reported.^{208,209} The structural and magnetic properties of the $\text{Sr}_2\text{Rh}^{\text{IV}}\text{O}_4$ and $\text{Sr}_2\text{Ir}^{\text{IV}}\text{O}_4$ compounds, which are analogues of La_2CuO_4 , were studied.²¹³ X-Ray and neutron diffraction studies demonstrated the distortion of the ideal structure of the K_2NiF_4 type. Oxoplatinates with composition $\text{Ln}_2\text{M}^{\text{IV}}\text{O}_6$ ($\text{Ln} = \text{La}$, Pr , Nd , Sm , Eu or Gd ; $\text{M} = \text{Mg}$, Co , Ni or Zn) were prepared.²¹⁴

Note also the electrochemical studies of hydroxo complexes of iridium in OS of +4, +5 and +6^{83,84} and studies aimed at preparing platinum and iridium compounds in the highest OS in alkaline solutions.^{215–219} Solutions of hydroxo complexes of platinum and iridium were treated with ozone and the resulting compounds were studied by various methods, including ESR, electronic absorption spectroscopy, cyclic voltammetry and chemical analysis. It was established that the platinum hydroxo complexes afforded the previously unknown platinum superoxo complexes $[\text{Pt}(\text{OH})_5(\text{O}_2^-)]^{2-}$, $[(\text{OH})_5\text{Pt}(\mu\text{-O}_2^-)\text{Pt}(\text{OH})_5]^{3-}$ and $[(\text{OH})_4\text{Pt}(\mu\text{-O}_2^-)(\mu\text{-OH})\text{Pt}(\text{OH})_4]^{2-}$. In the case of iridium, hydroxo complexes of iridium in OS of up to +6 inclusive were detected in solution along with the peroxo and superoxo complexes of iridium of the $[(\text{OH})_5\text{Ir}^{\text{IV}}(\mu\text{-O}_2^-)\text{Ir}^{\text{III}}(\text{OH})_5]^{5-}$ {or $[(\text{OH})_5\text{Ir}^{\text{III}}(\mu\text{-O}_2^-)\text{Ir}^{\text{III}}(\text{OH})_5]^{5-}$ } type.²¹⁸ This suggests that OS of +6 for iridium can be attained even under rather mild conditions (in solution), which indicates that treatment of solu-

tions of hydroxo complexes with oxidants under more drastic conditions has considerable promise.

V. Matrix oxidation state stabilisation

Recently, the so-called method of matrix OS stabilisation has been developed. This method is based on the fact that the tracer atoms incorporated into the crystalline matrix are interchangeable with the metal atoms of the base upon heating. Thermal treatment is apparently one of a few procedures used in this case because the mechanism of transfer of the atoms is obviously of a diffusion character and the diffusion is enhanced at higher temperatures. The efficiency of the exchange reaction is associated with the possibility of the change in the size of tracer atoms or of a change in the electronic configuration (and, consequently, in OS) of the above-mentioned atoms, *i.e.*, with the lability of the corresponding electron cloud. The crystal field of the matrix ‘forces’ the doping ions to behave as the electron cloud in the crystal lattice, which is in some cases accompanied by charge transfer from one metal atom to another,²²⁰ *i.e.*, by a change in OS.

The geometrical criteria (ionic radii, local symmetry, *etc.*) are of great importance because they reflect the effect of the thermodynamics of the mixed matrix–tracer system. The stability of OS should be determined to a large extent by the isomorphism rules because the geometry of the vacancy into which a transition metal ion is inserted plays a great role in the stabilisation of the latter.

The effect of the matrix on the properties of the doping ions can be illustrated by a change in the colour of Cr^{III} ions placed at the matrix nodes with different local symmetry. In corundum ($\alpha\text{-Al}_2\text{O}_3$), beryl ($\text{Al}_2\text{Be}_3\text{Si}_6\text{O}_{18}$) and kyanite (aluminosilicate, Al_2SiO_5), the Cr^{III} ions are red, green and blue, respectively.²²¹ Shifts of the absorption bands in energy depend on various factors, including the coordination number, and the absorption bands corresponding to the charge transfer depend on the valence transitions or on the stability of OS. For example, a change in OS of cerium in the same matrix, *viz.*, in ZrO_2 (fianites), leads to a change in the colour from bright red-claret (Ce^{IV}) to yellow-orange (Ce^{III}).²²²

Many researchers use the matrix stabilisation of the highest OS in spite of the fact that the lattice contributions to the total energy are insignificant. This method was used for preparing laser crystals doped with transition metal ions (see, for example, Refs 223 and 224). However, note that it is difficult to obtain metal ions in high OS in these subjects because of their specificity.

Table 5. Known oxidation states of heavy transition elements.

+10					– (see ^j)		

Note. The following notations are used: E, the highest OS, which is, apparently, the extreme one; ‘minus sign,’ this OS is absent.

^a Known, for example, in carbonyls and complex phosphines. ^b Known, for example, in halides and cyanides. ^c Known in many compounds. ^d Known in oxides and halides. ^e For fluorides. ^f For oxides. ^g Disproportionation occurs. ^h For hydroxo complexes. ⁱ A very unstable higher fluoride with an unknown composition formed upon heating of fluoro Au^{V} complexes. ^j See the discussion in the text. ^k The formation of this OS in a compound formed upon β -decay of $^{191}\text{OsO}_4$ was reported.

In matrices which are more suitable for stabilisation (for example, in $\text{BaM}^{\text{IV}}\text{O}_3$, where $\text{M} = \text{Ce, Th or Zr}$), Pr^{IV} , Tb^{IV} , Nd^{IV} and Dy^{IV} were obtained.^{128–130} Interestingly, it is possible to obtain Nd^{IV} in all the above-mentioned matrices, while Dy^{IV} was obtained only in $\text{BaCe}^{\text{IV}}\text{O}_3$. The Mn^{III} ,²²⁴ Cr^{IV} and Cr^{V} as well as Fe^{VI} ions^{225, 226} are stabilised in matrices of garnets, chromates and sulfates (the systems were prepared from solution) and Tb^{IV} ions are stabilised in $(\text{SrMgF}_4 : \text{Tb}^{\text{IV}})$ -phosphors (prepared in the solid phase).²²⁷

In studies of matrix oxide systems involving oxoferrates and oxoruthenates,^{33, 34, 228–236} the conditions for doping these matrices with Fe^{n+} and Co^{n+} ions (OS were established by Mössbauer spectroscopy with the use of ^{57}Fe and ^{57}Co isotopes) were found. Of the most interesting results, note the stabilisation of Co^{VI} ions in the ferrate $\text{Cs}_2\text{Fe}^{\text{VI}}\text{O}_4$ (see Refs 33 and 34) and the stabilisation of Fe^{VI} ions in the mixed-valence compound with composition $\text{Cs}_3(\text{Ru}_{1/2}^{\text{VI}}\text{Ru}_{1/2}^{\text{VII}}\text{O}_4)$.^{232, 235}

Attempts to attain the Fe^{VII} state are of particular interest. This OS can be realised for Fe. Thus it was concluded¹⁶⁵ that the disproportionation of FeO_4^{2-} ions (in alkaline media) occurs according to the following scheme:

Since a two-equivalent exchange occurs, the intermediate one-electron conversion with the participation of Fe^{VII} could be expected in accordance with Scheffer's principle. It was attempted to solve the problem of stabilisation of this OS by placing ^{57}Fe in the $\text{Cs}_3(\text{Ru}_{1/2}^{\text{VI}}\text{Ru}_{1/2}^{\text{VII}}\text{O}_4)$ matrix. In this ruthenate, the iron ion is stabilised primarily in the Fe^{VI} form. However, an unstable satellite was also observed in the slope of the intense line in the Mössbauer spectrum. The chemical shift value of this satellite corresponds to that expected for Fe^{VII} .^{232, 236} Unfortunately, there is no more convincing evidence for the presence of Fe^{VII} in this system. According to the data of Mössbauer spectroscopy (4 K),^{229, 237–241} the Fe^{VII} state can also be stabilised in the $\text{Na} - \text{Fe} - \text{O}$ system at a molar ratio $[\text{Na}]:[\text{Fe}] > 50:1$ (at lower ratios, only Fe^{IV} compounds are formed²⁴²).

Unlike other researchers, the authors of the publications^{229, 237–242} applied oxidation processes using sodium and cesium peroxides under rather mild conditions. The latter are suitable for the realisation of high OS if the strongest oxidants (Na_2O_2 and CsO_2) as well as an efficient stabilising agent (in particular, Cs^+ cations) are present in the reaction mixture.⁴³ In addition, peroxides as such can stabilise the highest OS of, for example, iron and cobalt on condition that their contents in the reaction mixtures are low.^{229, 241} Highly reactive reagents (precursors) which are formed, for example, upon ultrasonic treatment show promise. It is by this procedure that specimens of highly disperse Fe_2O_3 were prepared.²⁴³ The procedures for the preparation of the corresponding precursors have been summarised.²⁴⁴

VI. Valence possibilities of transition elements

It was hypothesised that the heaviest $5d$ elements can attain high OS,⁴⁸ which can be realised for Ir, Pt, Au and Hg in the tetrahedral oxo ions $\text{MO}_4^{\pm}$. Estimates of the energies of molecular orbitals which were obtained by the scattered wave X_α method for a series of tetraoxo anions $\text{M}^{\text{VII}}\text{O}_4^-$ of the third-row elements^{245, 246} indicate that rather stable compounds can be formed. Quantum-chemical and thermodynamic calculations were performed for the tetrahedral MO_4^q ions isoelectronic with OsO_4 ($\text{M} = \text{Ir, Pt, Au or Hg}$, $q = +1, +2, +3 \text{ or } +4$, respectively).⁴⁹ Quantum-chemical calculations were carried out with the use of quasirelativistic and relativistic pseudopotentials (*cf.* Ref. 247), which are believed to be very reliable.

Ab initio calculations for the $\text{Ir}^{\text{IX}}\text{O}_4^+$, $\text{Ir}^{\text{VII}}\text{O}_4^-$, $\text{Pt}^{\text{VIII}}\text{O}_4^0$ and $\text{Au}^{\text{VII}}\text{O}_4^-$ ions demonstrated⁴⁹ that the potential surfaces have minima. For the $\text{Pt}^{\text{IX}}\text{O}_4^{2+}$ and $\text{Au}^{\text{IX}}\text{O}_4^+$ cations, minima are also

observed but they are apparently too shallow to expect the formation of more or less stable compounds. An analogous conclusion can be drawn on the basis of the results of thermodynamic calculations. The main outcome of the study⁴⁹ was the conclusion that transition elements in very high OS (which have not yet been realised), up to $+10$ inclusive, can theoretically occur.

It was demonstrated⁴⁹ that the probability of the existence of $\text{Hg}^{\text{VIII}}\text{O}_4^0$ is distinct from zero because calculations gave a reasonable value for the internuclear $\text{Hg} - \text{O}$ distance of 2.12 Å (HgO_4^{2+} ions and all the more so, HgO_4^{4+} ions are unstable). Probably, mercury compounds in OS of lower than $+8$ are rather more stable.

For mercury and its analogues (Zn and Cd), $+2$ is still considered to be the highest OS. Note that the short-lived complex of trivalent mercury with composition $[\text{Hg}(\text{cyclam})](\text{BF}_4)_2$ was reported,²⁴⁸ although these data require additional proof. It was suggested that an unstable intermediate containing Hg^{III} is formed upon fluorination of organomercurials with xenon difluoride.^{249, 250} Based on the results of X-ray photoelectron spectroscopy of mercury copper–oxide superconductors with composition $\text{HgBa}_2(\text{Ca}_{0.86}\text{Sr}_{0.14})_2\text{Cu}_3\text{O}_{8+\delta}$, it was concluded that these superconductors contain Hg^{III} .^{251, 252} On the basis of the general regularities of the Periodic system, Jorgensen also believed that the possibility exists of attaining high OS for mercury.³⁷ He reasoned that the existence of $I(5d)$ of ~ 14 eV for mercury(II) fluoride may favour oxidation of Hg^{II} to Hg^{III} or Hg^{IV} , particularly taking into account that HgF_2 crystallises in the fluorite structure with a low lattice energy. The realisation of the $5d^8$ configuration and consequently of Hg^{IV} in the square-planar HgF_4 molecule is more probable than the $5d^9$ configuration and Hg^{III} .

In this connection, the publication³⁸ in which the molecular and electronic structure and the stability of HgF_4 , ZnF_4 and CdF_4 were compared is of fundamental importance. The possibility of stabilisation of HgF_4 upon anionic complexation was considered. Calculations were performed with the use of the same pseudopotentials as those used previously²⁴⁷ for HgF_2 . It was shown that the fluoride HgF_4 may well exist in the gaseous state.³⁸ To the contrary, the existence of CdF_4 and all the more ZnF_4 is highly improbable. In addition, it follows that complexation does not enhance stabilisation of Hg^{IV} with respect to Hg^{II} in anions.³⁸ The conclusion that complexation affects only slightly the stability of Hg^{IV} is unexpected because this is considered as one of the ways of stabilising the highest OS of f and d transition elements.^{39, 40} Since Hg^{IV} should exhibit the properties of d transition elements, the statement that the formation of the HgF_{4+x}^x anionic complexes has a favourable effect on the stability of Hg^{IV} should be fulfilled. The introduction of an equivalent amount of cations into the system containing anions decreases substantially the total energy of the system. In this case, the mutual cation–anion influence should occur and stabilisation should be realised through the electrostatic forces. In particular, this is consistent with the results of calculations of the electronic structures of the $\text{M}^{\text{V}}\text{F}_6^-$ ions ($\text{M} = \text{Hf, Ta, W, Re, Os, Ir, Pt, Au or Hg}$)²⁵³ by the spin-polarisation discrete variation X_α method. The change in electron affinity in the $\text{HfF}_6^- \rightarrow \text{HgF}_6^-$ series as well as the experimental data on the stability of the complex fluorides of Os^{V} , Ir^{V} , Pt^{V} and Au^{V} (compared to the data on the corresponding MF_5) indicate that the effect of complexation does exist. Thus the temperature of decomposition of complex fluoroaurates(V) is 100 °C higher than that of AuF_5 .^{45, 150, 192} Hence, the conclusion that coordination has no effect on the stability of higher mercury fluorides is questionable although it was not disproved (HgF_4 or other Hg^{IV} fluorides have not been obtained yet despite attempts, as can be judged from the published data,³⁸ aimed at their synthesis).

We emphasise that in the above-mentioned theoretical studies, only the presence of the minimum on the potential surface was noted, while the depth of this minimum can be determined only

experimentally. Thus derivatives of $\text{Cs}^{\text{III}}-\text{Cs}^{\text{IX}}$ and krypton oxides[‡] have not yet been obtained, although calculations predicted that they can exist.²⁵⁵ Apparently, this is also true for HgF_4 .

VII. Regularities of changes in the extreme oxidation states of transition elements

The highest OS of transition elements (according to the experimental data and results of quantum-chemical calculation)⁸⁹ are shown in Scheme 1. The extreme OS (E) are separated from the higher OS by a thick line, which assumes that the latter cannot be attained. It can be seen that the values of the extreme OS in the series of transition metals increase, reach a maximum and then decrease. This character of the change in the maximum OS is one of the main regularities of the Periodic system. For some OS, the experimental data are lacking but there is reason to hope that such information will be obtained. In relation to the aforesaid, it is necessary to make some comments.

For the first-row transition metals, the maximum OS is observed for iron (+8). The existence of Mn^{VIII} in tetraoxide MnO_4^0 , which is formed upon photodissociation of the MnO_4^- ion, is suggested on the basis of spectroscopic data.²⁵⁶ Probably, this conclusion is erroneous. For cobalt, +6 is the highest OS.^{33, 34} This state was identified by emission Mössbauer spectroscopy. The detection of OS by this method may indicate that it is highly unstable. In view of this fact, it is believed that +6 is the extreme OS for cobalt. For Ni, +4 is the highest OS attained. It is assumed that Ni^{VI} can be realised (handbooks even contain the E° value for the $\text{Ni}^{\text{VI}}/\text{Ni}^{\text{III}}$ pair). In our opinion, the existence of Ni^{VI} is still an open question. The preparation of Ni^{V} is more probable. Moreover, the identification of the OS in this case is a very complicated problem. The stability of Ni^{VI} and Ni^{V} derivatives should be rather low and probably the only suitable technique for observing OS is Mössbauer spectroscopy which can detect the chain of transformations $^{57}\text{Ni} \rightarrow ^{57}\text{Co} \rightarrow ^{57}\text{Fe}$.

The detection of particular OS in studies by emission Mössbauer spectroscopy [provided that radiative transitions (known as post-effects) are absent] is very revealing. In fact, for the $A \rightarrow B$ process where compound B has OS which can be observed by Mössbauer spectroscopy, $a_A \sim 1$ and $a_B = 10^{-8}$ (a is the activity). The latter value can readily be obtained on the assumption that the activity of the source was ~ 1 mCi (^{57}Co). Then $k_{\text{eq}} = a_B/a_A \sim 10^{-8}$ and $\Delta_r G^\circ = RT \ln k_{\text{eq}}$ is about 50 kJ mol^{-1} , i.e., it is impossible to obtain macroscopic amounts of a compound containing the desired OS.

For the second-row transition metals (see Scheme 1), the maximum OS is attained for Ru(+8). Compounds containing Rh^{VI} and Pd^{V} were described. On the basis of the published data,²⁴⁶ both states can hardly be assigned to the limiting states. In this connection, the question of whether higher OS are possible remains open. In the third-row transition elements, the maximum OS for iridium is +9^{48, 49} (apparently, this is the extreme OS), while OS +10 can be attained for platinum.⁴⁹ The probability of occurrence of the nona- and decavalent states for the elements is an open question.

According to Abegg's rule, each element may have a set of OS consisting of no more than 8 values. It is known³⁷ that this rule is fulfilled for the main-group elements and for the post-transition elements. Only four exceptions to this rule are known, namely, Mn, Ru, Re and Os, for which ten OS can be realised.³⁷ Assuming that OS of +10 and +9 can be attained for platinum and iridium, respectively, and thus postulating sets of 10 OS for these elements, we extend the series of the above 'exceptions.' Without consider-

Scheme 1

Metal	Oxidation state of the metal									
	2+	3+	4+	5+	6+	7+	8+	9+	10+	
Sc		E								
Ti			E							
V				E

Ir					H	??	??	?(see ^a)		
Pt					H		??	??	see ^b	
Au				H			see ^b	see ^b		
Hg	H	see ^c	see ^b				see ^b			

The following notations are used: H, the high OS is known, but it is unclear whether it is the extreme value; ??, the data are lacking, but there is the probability that this state can be attained.

^a The data were not confirmed. ^b According to the results of quantum-chemical calculations, this OS can be attained.⁴⁹ ^c The possibility of formation of derivatives upon fluorination of organomercurials at low temperature was reported.^{249, 250}

ing the nature of this phenomenon (which is, of course, governed not only by the electrostatics of metal–ligand interactions), we emphasise that the above 'exception' for transition elements is apparently the rule. Evidently, the presence of a particular set of OS for the element as well as the maximum valence are determined primarily by the principle of the arrangement of the Periodic system (the so-called 'Aufbau' principle; this follows from the ideology of the publication³⁷) which is based on thermodynamic factors, primarily on the energies of the detachment of electrons from the free atom. This can be judged, for example, from the values of the ionisation potentials^{257, 258} of atoms[§] realising that it is the differences between the ionisation potentials, which can characterise the tendency for OS stabilisation, rather than the absolute values of these potentials that are of importance. Analysis of the ionisation potentials demonstrated that it is necessary to overcome an energy barrier the value of which is

[‡] It was reported that a krypton compound with the orthotellurate ligand was presumably obtained though under cryogenic conditions.²⁵⁴ This compound exploded even under these conditions. More detailed data in support of the individuality of this compound and of the presence of the Kr–O bond are lacking.

[§] An analogous procedure was used in the analysis of the regularities of the changes in the ionisation potentials of atoms of the heavy transition elements.⁴⁸ Speculative conclusions obtained on this basis were subsequently confirmed by direct quantum-chemical calculations.⁴⁹

reflected in the stability of the OS, on going from one OS to another.

These barriers can be overcome in chemical (or in physical) processes. The latter is illustrated in the observation of a high OS for the metal atoms upon β -decay of ^{191}Os , ^{259}Am and ^{247}Bk in oxides,^{15, 16} which provides short-lived $\text{Ir}^{\text{IX}}\text{O}_4^+$, $\text{Cm}^{\text{VI}}\text{O}_2^{2+}$ and $\text{Cf}^{\text{VO}}\text{O}_2^+$ ions, respectively. In other words, the existence of OS +9 or +10 for some elements does not contradict the principles of construction of the Periodic system.

It was of interest to verify the regularities of the changes in the extreme OS and the observations of OS higher than the extreme values. On the one hand, the fundamental regularity as declared above seemingly does not allow for the formation of these OS. On the other hand, these OS are not theoretically forbidden and only energy barriers occur, which can be overcome in some cases, as demonstrated above.[¶] Presently, there is no point in going through all the details because the experimental data are lacking. However, attempts can, in principle, be undertaken to obtain this information, for example, in experiments on bombardment of solid and liquid targets with heavy highly charged ions. For example, calcium targets were bombarded with Ar^{12+} ions,^{262, 263} helium was treated with C^{6+} , N^{7+} , O^{8+} , Ar^{16+} , I^{16+} and Xe^{30+} ions²⁶⁴ and the recombination of Kr^{34+} ions on hydrogen molecules was considered.²⁶⁵ Evidently, the appearance of an almost bare nucleus in the matrix should cause a cascade of Auger electrons. These secondary processes are known and are being studied. For example, the manifestations of the secondary processes in the K_α spectra which were observed in experiments on bombardment of sulfur targets with Ar^{5+} and Xe^{8+} ions were analysed.²⁶⁶ Actually, the problem of OS stabilisation was not solved in the papers cited because ions and targets evidently were not optimum (in this context, the above-discussed studies on the matrix OS stabilisation are of importance). The questions are how long these superhigh OS live and whether these states can be detected by the available physical methods.

To summarise, the present review considers the state-of-the-art of the problem of the existence and stabilisation of the highest and extreme valent forms of transition elements. In the discussion of these problems, many authors (see, for example, Refs 23 and 29) attempted to reveal the relationship between the electronic structures of the atoms and the properties of the compounds. Evidently, this relationship can be also revealed in the present review. However, d transition elements (particularly, heavy elements) are characterised by a high degree of covalence, which makes these correlations poorly informative. Hence, we restrict ourselves to the discussion of the chemical evidence and the statement of empirical regularities. The advantage of the empirical method is its independence from the electronic structure and the inherent nature of the subjects under consideration. This is of particular importance when the data are scarce as in the case of elements in the highest unstable OS which are few in number. At the same time, the discussion of the general situation on the basis of the available reliable quantum-chemical and experimental data allows us to offer the hypothesis that superhigh and short-lived OS exist and to suggest the procedure for its verification.

The review has been written with the financial support of the Program 'Russian Universities' and the Russian Foundation for Basic Research (Projects Nos 96-03-33285 and 99-03-32488)

[¶] This question for main-group elements was considered by Sidorov,²⁶⁰ who has suggested that BeF_3 and AlF_4 can be obtained. However, more recent studies demonstrated²⁶¹ that attempts to obtain the above compounds and, consequently, OS higher than the extreme values (+2 for Be and +3 for Al) in chemical processes failed.

VIII. Conclusion	391

Abstract. The results of studies on the electrochemistry of diamond carried out during the last decade are reviewed. Methods for the preparation, the crystalline structure and the main electrophysical properties of diamond thin films are considered. Depending on the doping conditions, the diamond behaves as a superwide-gap semiconductor or as a semimetal. It is shown that the 'metal-like' diamond is corrosion-resistant and can be used advantageously as an electrode in the electrosynthesis (in particular, for the electroreduction of compounds that are difficult to reduce) and electroanalysis. Kinetic characteristics of some redox reactions and the impedance parameters for diamond electrodes are presented. The results of comparative studies of the electrodes made of diamond single crystals, polycrystalline diamond and amorphous diamond-like carbon, which reveal the effect of the crystalline structure (*e.g.*, the influence of intercrystallite boundaries) on the electrochemical properties of diamond, are presented. The bibliography includes 99 references.

I. Introduction

Diamond is a material endowed with unique properties: it is a perfect dielectric characterised by extremely high atomic density and hardness. Historical records of intensive electrophysical, physicochemical and optical studies of diamond is only several-decade long.^{1,2} Its practical uses have diversified and embrace nowadays such fields as materials technology,³ microelectronics⁴ and other.

Depending on the doping level, diamond behaves as a superwide-gap semiconductor or as a semimetal. Owing to its exceptional chemical stability, semiconductor diamond is undoubtedly promising as an electrode material. However, in contrast with other carbon materials of long-standing use (graphite, glassy carbon and other), electrochemical studies of diamond were initiated approximately a decade ago. Until recently, such investigations have been seriously hampered by two circumstances: firstly, diamond remained an exotic, difficultly accessible mate-

rial; secondly, by its nature, diamond is an insulator and hence is unsuitable material for electrodes.

The situation has radically changed in connection with the achievements in the technology of manufacture of diamond thin films from the gas phase under subatmospheric pressure. Highly efficient methods have been developed for the growing of polycrystalline diamond films on non-diamond substrates; such films are relatively inexpensive when manufactured on a large scale. Doping with boron, as an acceptor admixture, allowed one to synthesise semiconductor films with good conductivity, while high doping levels led to quasimetallic films.⁵

The first studies on diamond electrodes have opened a new branch of electrochemistry of semiconductor materials⁶ known now as electrochemistry of diamond.

Formally, the first publication on diamond electrochemistry was that describing attempts to make an electrode from a dielectric diamond crystal.⁷ In order to make electroconducting at least the thin outer layer of the specimen, the authors implanted Ar^+ ions into the diamond crystal. Argon is not a doping impurity for the diamond and does not change its conductivity, but as the result of such an ion implantation the external diamond layer becomes amorphous (*e.g.*, see Refs 8, 9). A noticeable conductivity arises because of the destruction of the diamond crystalline lattice and the appearance of a large number of carbon atoms with the sp^2 -hybridisation of their orbitals.¹⁰ For this reason, strictly speaking, the study of Iwaki *et al.*⁷ dealt with the electrochemistry of non-diamond (amorphous) carbon and not with the diamond proper.

In fact, the electrochemistry of diamond was started with the study reported in Ref. 11. In this work, the $I-V$ characteristic was derived for the first time and the differential capacitance at the diamond/electrolyte solution interface was measured; photosensitivity of diamond electrodes was also revealed and related to the semiconductor properties of diamond. A few years later, these investigations of Russian researchers were followed by studies carried out by electrochemists in Japan, Israel, France, USA and other countries. For the last three years the number of publications devoted to diamond electrodes has increased dramatically.

This review generalises the most important results from studies of electrochemical properties of synthetic semiconductor diamond and application of electrochemical methods for the determination of characteristics of diamond films and outlines perspectives of the development of this new branch of electrochemistry.

II. Preparation of diamond thin-film electrodes

Since the work reported in Ref. 11 until now the subjects of virtually all studies have been diamond films prepared by the method of chemical vapour deposition (CVD). The studies by Derjaguin *et al.*¹² carried out in the 1970s were an important stage in the development of this method. The CVD method relies on the deposition under subatmospheric pressure from an activated gas phase consisting of a volatile organic substance and hydrogen.^{3, 13} The gas phase activation is required in order to create sufficiently high concentration of active carbon-containing species. These particles, by colliding against the surface of a heated substrate, disintegrate and release carbon atoms from which the crystalline lattice of diamond is formed. In the temperature and pressure ranges used, the diamond is metastable; the stable form is another allotropic carbon modification known as graphite. The gas phase activation should lead to the appearance of a reagent suppressing the deposition of non-diamond forms, *viz.*, graphite and amorphous carbon. Atomic hydrogen is such a reagent; in its atmosphere graphite 'burns out', while diamond remains unaltered.

Current practices rely basically on the use of thermal and electric (sometimes, chemical and photochemical) methods of gas activation. In the case of thermal activation, a reactor for vapour deposition of diamond films is used (Fig. 1). Above the substrate, on which diamond is supposed to grow, an activator is suspended in the form of wire made of a high-melting metal (W, Ta). This wire is heated to incandescence ($\sim 2000^\circ\text{C}$) at which temperature the H_2 molecules dissociate at a sufficiently high rate. The gas phase is a mixture of carbon-containing gases (methane, acetone or methanol vapour, *etc.*, usually at concentrations of up to 5%) with hydrogen. Their contacts with the activator surface yield, along with the hydrogen atoms, excited carbon-containing molecules and radicals that are transferred towards the substrate surface, where deposition of diamond film takes place.

Figure 1. Scheme of a reactor for the chemical vapour deposition of diamond films under thermal activation;³

(1) reactor body; (2) substrate; (3) substrate heater; (4) thermocouple; (5) heated tungsten wire; (6) gas input; (7) diffuser; (8) pipe-line to a vacuum pump; (9) pipe-line to a manometer.

Electrical activation is induced using various forms of electric (arc, glow) discharge with the use of constant and alternating current (high frequency, ultra-high frequency, pulse mode). Each version of the electric method has its own advantages and disadvantages. For example, the electric arc discharge permits high deposition rates ranging from tens to hundreds of micrometers per hour. Under the ultra-high-frequency activation, the plasma ensures homogeneous conditions for the deposition over a large surface area of the substrate.

Depending on the aim of particular studies, the role of the substrate is played by metals (W, Mo), silicon (wafers with a mirror-polished surface that are frequently used in microelectronics), glassy carbon, *etc.* Crystallisation is primed by diamond microcrystals seeded on the support surface. Later, the silicon substrate can be easily etched to obtain the so-called free-standing films. If the substrate is a diamond single crystal (natural or synthetic), then epitaxial growth takes place: the growing film repeats the crystalline structure of the substrate and forms a single crystal (such films are called homoepitaxial). Usually, the film thickness is a few micrometers, but in some cases it may reach several millimetres. The area covered with a diamond film reaches 10×10 cm and more, though the electrochemical studies usually use electrodes $\sim 1 \times 1$ cm in size.

As noted above, in order to make a diamond film electroconducting, one should dope it (usually in the process of its growth) with boron. For this purpose, the gas phase is supplemented with a volatile boron compound, *e.g.*, trimethyl borate, in the concentration ranging from 10 to 10 000 ppm. Alternatively, a solid source of boron is placed near the activator and the substrate. In the latter case, the boron is transferred into the gas phase as a result of the activation. It has been established empirically that the content of boron in the growing film is approximately proportional to its content in the gas phase.¹⁴ The specific resistance of diamond depends on the content of boron in the film: it can vary, *e.g.*, from 10^4 Ohm cm (at a content of boron atoms in diamond of $\sim 10^{18} \text{ cm}^{-3}$) to tenth and even thousandth fractions of Ohm cm (at a content of boron atoms in diamond $\sim 10^{21} \text{ cm}^{-3}$). As its resistivity decreases, the dielectric diamond acquires successively the properties of a semiconductor, a degenerate semiconductor and then of a semimetal.

The energy of boron ionisation in diamond is great compared with the thermal energy (kT). At room temperature, the activation energy is 0.37 eV and decreases appreciably at high boron concentrations.¹⁵ Hence, the concentration of the majority charge carriers (holes) is 2–3 orders of magnitude lower than that of the boron atoms (acceptors).

It should be pointed out that the methods of chemical and physical vapour deposition are widely used for the preparation of not only crystalline (diamond) films but also films of amorphous hydrogenated carbon a-C:H¹⁰ in which there is no long-range ordering of the C–C bonds (hence, there is no crystalline structure), but the short-range ordering exists. Of a wide diversity of amorphous carbon films, one can conditionally distinguish graphite- and diamond-like films. Hybridisation of the carbon atom orbitals is predominantly of the sp^2 -type in the former and of the sp^3 -type in the latter. The graphite-like films are characterised by a small width (< 1 eV) of the gap and have high electric conductivity. The diamond-like films have a wider (2–4 eV) gap and are appreciably less conductive; certain properties of these films are similar to those of diamond (and this explains their name).

In addition to thin films, individual diamond crystals grown at high temperature and high pressure can also be used as electrodes. Such crystals are obtained from a carbon solution in molten metals (*e.g.*, Ni–Fe–Mn) in the pressure and temperature ranges corresponding to the region of thermodynamic stability of diamond; diamond crystals are doped with boron during their growth.

III. Crystal structure and basic electrophysical characteristics of diamond films

1. Crystal structure

Polycrystalline films consist of crystallites the size of which increases with the film growth approximately proportionally to its thickness and reaches a few micrometers. Facets of crystallites usually form a characteristic faceted morphology of the film surface.

The perfection of the crystalline structure of deposited films is monitored by recording their Raman spectra. A typical spectrum of a diamond film is shown in Fig. 2. The crystalline diamond is characterised by a narrow peak at 1332 cm^{-1} due to the first-order scattering on the crystal lattice. Two blurred bands at ~ 1350 and $\sim 1550\text{ cm}^{-1}$ correspond to the non-diamond carbon form with the predominant sp^2 -hybridisation. When comparing the diamond peak and the maximum determined by the sp^2 -carbon in the spectrum, one should bear in mind that the magnitude of Raman signal on the ordinate (Fig. 2) is 50 times more sensitive to the non-diamond carbon form than to the crystalline diamond.¹⁶ In the best specimens employed as electrodes, the admixture of the non-diamond form did not exceed 1% (as confirmed by independent electrochemical measurements). According to Hashimoto *et al.*,¹⁷ the admixture content decreases in the film substrate surface direction. Nevertheless, modern physical techniques (Raman and Auger spectroscopy, atomic-force microscopy) do not provide sufficiently exhaustive characterisation of non-diamond carbon inclusions in polycrystalline diamond films. It is by electrochemical measurements that these inclusions are revealed.¹⁸

Figure 2. Raman spectrum of a polycrystalline diamond film.

In polycrystalline diamond films, the non-diamond form is represented primarily by a disordered carbon of intercrystallite boundaries, the outcrops of which on the diamond surface were observed using high-resolution electron microscopy.¹⁹ The thickness of the intercrystallite boundaries in diamond films reaches a few nanometers. In addition, the crystal lattice of films has various defects. In some instances, a thin (about several nanometers) non-diamond layer coating the diamond film was revealed. This layer is often formed in the latest (poorly controlled) stages of film growth after cessation of the gaseous phase activation. To remove it, samples are heated in air to $520\text{ }^{\circ}\text{C}$ or boiled in concentrated HClO_4 , dichromate-sulfuric acid mixture or solutions of other strong oxidants. Such a treatment of the non-diamond carbon form results in its oxidation to CO_2 .

2. Electroconductivity of films

Specific resistance of diamond films is determined not only by the concentration but also by the mobility of free charge carriers. Usually, the mobility of the holes in polycrystalline films is not high; it is lower than that in natural single crystals (usually, of the magnitude of $1\text{ cm}^2\text{ V}^{-1}\text{ s}^{-1}$).^{20–22} although in some cases it reaches tens and hundreds of $\text{cm}^2\text{ V}^{-1}\text{ s}^{-1}$ (see, *e.g.*, Refs 23 and 24). The mobility of the holes in single-crystal (homoepitaxial) films is 1–2 orders of magnitude higher than that in polycrystalline films grown under the same conditions.²² In films of amorphous diamond-like carbon, the mobility is several orders of magnitude lower than that in crystalline diamond.²⁰

The character of conductivity of doped polycrystalline films and its relation to the crystal structure were studied by the method of impedance spectroscopy.²⁵ The results obtained have made it

possible to describe a conducting polycrystalline film using a simple model of a heterogeneous medium. According to this model, the medium consists of regularly distributed well-conducting crystallites of the same size separated by poorly conducting intercrystallite boundaries, which form a continuous matrix. Undoubtedly, such a model simplifies the structure of a real film in which crystallites are distributed over its thickness with regard to their size, while individual acicular crystallites penetrate through the entire film thickness. Nevertheless, this model is applicable in the studies of moderately doped diamond films. The theory of complex conductivity of a heterogeneous medium²⁶ developed for the model described has made it possible to determine the bulk proportion of the boundary phase in the film ($\sim 5\%$, which in order of magnitude correlates with the above-mentioned results of Raman spectroscopy) and to estimate conductivities of crystallites[†] and intercrystallite boundaries as 10^{-4} and $10^{-7}\text{ Ohm}^{-1}\text{ cm}^{-1}$, respectively.

Similar conclusions about the character of conductivity of polycrystalline films were made by Sokolina *et al.*²⁷ Subsequent studies devoted to thorough investigation of the frequency dependence of the impedance of polycrystalline films^{28–30} have shown that at high temperatures the electric conductivity due to the motion of free holes in the valence band should be supplemented with a component determined by the jump-over of holes between localised traps (possibly, associated with the intercrystallite boundaries).

IV. Synthetic diamond films as electrodes: resistance to corrosion and background current – potential curves

In the assessment of novel electrode materials used in electrolysis, electroanalysis and manufacture of electrochemical sensors and other devices, the main attention is paid to the magnitude of background current and the width of the potential range in which this current remains sufficiently low and does not interfere with measurements as well as to the corrosion resistance and stability of materials. The diamond electrode meets all of these criteria.

Let us consider the current-potential curves in solutions of indifferent electrolytes as the initial characteristic of the electrode behaviour of diamond.^{31–33} It is these curves that form the ‘background’ against which the kinetic, impedance, photoelectrochemical and electroanalytical characteristics of diamond electrodes are manifested.

An advantage of diamond electrodes is a wide potential range of weak background currents, which is sometimes called the range of ideal polarisability. It is obvious in comparison with other materials, which are widely used as electrodes (platinum, glassy carbon, graphite, *etc.*).

Figure 3 shows characteristic polarisation curves recorded using a solution of an indifferent electrolyte ($0.5\text{ M H}_2\text{SO}_4$) in the potentiodynamic mode of potential cycling on the polycrystalline diamond thin-film electrodes and the electrodes from platinum and highly oriented pyrographite which are traditionally applied in electrochemistry.

According to Martin *et al.*,³² all the diamond films used as electrodes may be divided into ‘good’ and ‘bad’ films, depending on the width of the ideal polarisability range. For the ‘good’ films, this range reaches $\sim 3\text{ V}$ at the current density j of several mA cm^{-2} and at least about 1.5 V for the j values making up a few decimal fractions of $1\text{ }\mu\text{A cm}^{-2}$ (Fig. 3a). For the ‘bad’ films, the range of ideal polarisability is appreciably narrower (Fig. 3b); there is a noticeable hysteresis, which naturally restricts their

[†] In the studies reported in Refs 11 and 25, the conductivity of diamond films was associated not with the boron incorporation but rather with the presence of unidentified admixtures and/or defects due to specific conditions of deposition (in particular, an elevated temperature of the substrate).

Figure 3. Polarisation curves of the electrodes made of polycrystalline diamond (*a*, *b*), platinum (*c*) and highly oriented pyrographite (basal plane) (*d*) in 0.5 M H₂SO₄.³³ (*a*) 'good' film; (*b*) 'bad' film; potential was measured relative to the normal hydrogen electrode (NHE).

applicability as electrodes. Martin *et al.*³² did not give any accurate definition of 'good' films but indicated that they were obtained at a low content ($\sim 1\%$) of a carbon-containing gas (methane) in the reaction system (the 'bad' films are formed at a methane content of $\sim 4\%$).

Comparison of the background currents for diamond and glassy carbon has shown that this current is 10 times as low on diamond.³⁴

As regards its resistance to corrosion in aggressive media and under extreme potentials, the diamond demonstrates it in full measure. Multiple cycles of potential variation on the diamond electrode from the potential of hydrogen evolution on the cathode to the potential of oxygen evolution on the anode in the aggressive solution 1 M HNO₃ + 0.1 M HF had no effect on either the surface morphology of diamond (according to electron microscopy data) or the ratio of diamond and non-diamond carbon forms on the electrode surface (according to Raman spectra). Under the same conditions, the electrodes from glassy carbon and pyrographite underwent strong degradation.³⁵ A similar study was conducted in the solution 1 M HNO₃ + 0.1 M NaCl under the potentials of the chlorine evolution on the anode.³⁶ But in this case too, X-ray photoelectron spectroscopy showed that neither the morphology of the diamond surface nor the content of admixtures on it were altered.

On the other hand, prolonged 'cycling' of the diamond electrode potential in concentrated (15%) KOH solution can lead to corrosive degradation of the diamond surface. The extent and character of this degradation depend on the conditions of diamond growth, although this dependence has not been clearly established. The intercrystallite boundaries composed of the non-diamond carbon undergo the strongest degradation.³⁷

In some cases (probably, in the presence of latent flaws in the film), prolonged polarisation of the diamond electrode in solution leads to the appearance in it of pinholes through which the electrolyte penetrates to the substrate.^{38–40} On the electrode surface, some inactive sites may appear⁴¹ as the result of local detachment of diamond films from the substrate or possibly because of a non-uniform doping of diamond with boron. The well-prepared films prove to be not only resistant to corrosion themselves but also to protect the metal substrate.^{39, 42, 43}

If a diamond film was obtained in a hydrogen atmosphere, its surface is covered by a hydrogen monolayer and displays hydrophobic properties. This type of surface is also obtained after treatment of diamond in a hydrogen plasma.⁴⁴ On the contrary, an oxidised diamond surface contains the hydroxy groups and hence is hydrophilic.^{32, 45} These two types of surface can also be obtained by electrochemical treatment consisting, respectively, in the cathodic or anodic polarisation in an aqueous electrolyte solution.⁴⁶

In conclusion, let us consider properties of the electrodes made of diamond-like carbon. Here, the data are scarce and are somewhat contradictory. For example, Howe⁴⁷ has reported that even thin films (50-nm thick) are well resistant to corrosion, while Sakharova *et al.*^{48, 49} have pointed out that such films proved to be permeable to the electrolyte, which by penetrating to the metal substrate resulted in its corrosion and led eventually to the film peeling. Films from diamond-like carbon of submicron thickness were found to be more resistant. Their background current – potential curves resemble analogous curves for the diamond electrode (Fig. 3*a, b*) but have a narrower range of ideal polarisability.⁵⁰

V. Impedance spectroscopy and semiconductor properties of diamond electrodes

1. Linear impedance. Equivalent circuits

Measurement of frequency characteristics of electrochemical systems makes it possible to derive information on their microscopic structure, as well as on the nature and kinetics of the charge transfer processes that occur in them. Linear impedance can be measured if a harmonic electrical signal with the frequency f is applied to the cell and then the real (Re Z) and imaginary (Im Z) components of the impedance Z are determined by analysing the spectrum of the system response with an appropriate device.

In studies of the impedance of diamond electrodes, the greatest attention is paid to the following peculiarities: the semiconductor character of diamond (for moderately doped films) and a special type of the frequency dependence of the impedance characteristic of the overwhelming majority of films.

In its general form, the impedance of a thin-film electrode may be represented by the three equivalent circuits shown in Fig. 4. The circuit depicted in Fig. 4*a* includes two RC -chains, one of which belongs to the diamond film itself and the other relates to the diamond/electrolyte solution interface. In the first chain, R_s is the ohmic resistance of the diamond film and C_g is the geometrical capacitance of the film; in the second chain, C_{sc} is the differential capacitance of the space charge region at the diamond/solution interface and R_F is the differential resistance to the process of charge transfer at this interface (the so-called Faraday resistance).

The geometrical capacitance of most films is low (of the order of 10^{-9} F cm⁻²); as regards the order of magnitude, the corresponding impedance is larger than the film resistance R_s (except for very lightly doped films), and hence the latter may be neglected. In this case, we obtain a simple equivalent circuit with three elements (Fig. 4*b*) which is known as the Randles – Ershler circuit.⁵¹ It is essential that all the elements of the above circuits are independent of signal frequency. The circuit represented by Fig. 4*c* includes a frequency-dependent, constant phase-shift element (CPE) (see below).

Figure 4. Equivalent circuits of the impedance (see text).

Figure 5. The Mott–Schottky plot for a boron-doped polycrystalline electrode with frequency-independent capacitance in 0.5 M H₂SO₄.⁵²

In certain cases, the impedance spectra of diamond electrodes are well described by the equivalent circuit (Fig. 4b) with a virtually frequency-independent (in the range of 1–10⁵ Hz) capacitance.⁵² Figure 5 presents the Mott–Schottky plot, which expresses the dependence of the squared reciprocal capacitance C_{sc} on the polycrystalline diamond electrode potential E in 0.5 M H₂SO₄. Physically, it reflects the dependence of the space charge layer thickness in a semiconductor on potential.⁶ The space charge arises because the near-surface region of semiconductors is depleted in mobile charge carriers (the so-called depletion layer). Extrapolation of the linear segment until its intersection with the abscissa provides the value of flat-band potential of the electrode E_{fb} , while the slope of this line can be used for calculating the concentration of non-compensated acceptors in a semiconductor by the formula

$$N_a = -\frac{2}{e\epsilon_0\epsilon} \left[\frac{d(C_{sc}^{-2})}{dE} \right]^{-1}, \quad (1)$$

where e is the electron charge, ϵ and ϵ_0 are the dielectric constants of diamond and vacuum, respectively. Formula (1) was derived under assumptions that, first, the potential drop during polarisation takes place in the space charge region (and, *e.g.*, not in the Helmholtz layer at the interface); second, there is no ionisation of ‘deep’ acceptors; third, the measured capacitance is that of the space charge region C_{sc} (and does not include, *e.g.*, the capacitance of surface states, adsorption capacitance, *etc.*). For the electrode under discussion (see Fig. 5), $N_a \approx 3.1 \times 10^{18} \text{ cm}^{-3}$.

The depletion layer is usually formed in a doped wide-bandgap semiconductor which is in contact with another phase (metal, electrolyte solution or vacuum). The potential barrier associated with the depletion layer formation (in particular, upon contact with the conducting phase) is called the Schottky barrier. The contact of polycrystalline diamond films with certain metals (Au, Pt, Pd) manifests a rectifying effect (see, *e.g.*, Refs 53 and 54), while its capacitance characteristics resemble those of the diamond/indifferent electrolyte contact.

However, specimens with a frequency-independent capacitance represent an exception rather than the rule. Usually, the capacitance of diamond films depends on frequency. Figure 6 features a characteristic electrode impedance spectrum presentation on a complex plane.⁵⁵ At high frequencies (1–100 kHz), the complex-plane plot forms a straight line that does not pass through the origin of coordinates (see Fig. 6a). A similar impedance feature was observed in a series of studies (see, *e.g.*, Refs 56–59). At low frequencies, the $-\text{Im}Z$ vs. $\text{Re}Z$ plot is curved due to the presence of the Faraday resistance in the equivalent circuit (Fig. 6). Under the anodic or cathodic polarisation, the curvature becomes more appreciable due to the decrease in R_F , and the shape of the low-frequency segment of the curve approaches a semicircle.

Figure 6. High-frequency (a) and low-frequency (b) segments of the complex-plane plot of the impedance of a single-crystal electrode in 0.5 M H₂SO₄ under a steady-state potential.³⁵ Numerals at the curves indicate the signal frequencies /kHz.

Such a characteristic type of the frequency dependence suggests that the equivalent circuit of the electrode includes the so-called constant phase element (CPE) with its impedance equal to

$$Z_{CPE} = \sigma^{-1}(i\omega)^{-a}, \quad (2)$$

where the frequency-independent parameter σ has the dimensionality $\text{F}^a \text{ Ohm}^{a-1} \text{ cm}^{-2}$, the index a determines the character of the frequency dependence, i is the imaginary unity, $\omega = 2\pi f$ is the angular frequency of the alternating current. Analysis of the impedance spectra is based on the equivalent circuit (Fig. 4c) derived from the Randles–Ershler circuit by replacing the frequency-independent capacitance with CPE. The elements of the equivalent circuit are usually calculated by the least-squares method with minimisation of the standard deviation of the logarithm of the impedance modulus measured at different frequencies from the logarithm of the impedance modulus calculated for the equivalent circuit using the corresponding computer programme.⁶⁰

Typical σ and a values, film resistance R_s , calculated diamond resistivity ρ and the Faraday resistance R_F are listed in Table 1 for the polycrystalline and single-crystal (thin-film and compact) diamond electrodes and the electrode made of amorphous diamond-like carbon.^{50,61} Comparison of the data presented in

Table 1. Parameters a , R_s (Ohm cm²), σ ($\mu\text{F}^a \text{ Ohm}^{a-1} \text{ cm}^{-2}$), ρ (Ohm cm) and R_F (Ohm cm²) found in the studies of the impedance of polycrystalline and single-crystal diamond films in 0.5 M H₂SO₄ solution.

Electrode	Substrate	Film thickness /μm	a	R_s	σ	ρ	R_F
Polycrystalline film	W	2.4	0.92	1.5	1–1.5	0.7×10^4	10^4 – 10^7
Single-crystal film	synthetic diamond single crystal	10	0.96	32	2.7	0.1	10^6 – 10^8
Single crystal ^a	—	—	0.92	2.8	2.5	30	10^6
Amorphous diamond-like film	glassy carbon	0.07	0.9	—	0.05	0.8×10^5	10^6

^a A single crystal grown under high pressure and high temperature.

Table 1 suggests that in both the qualitative respect (the equivalent circuit form and the presence of CPE in it) and the quantitative respect (typical a and σ values) the polycrystalline and single-crystal electrodes are virtually the same: a varies within a narrow range 0.9–0.96, $\sigma \approx 1\text{--}3 \mu\text{F}^{a-1} \text{ Ohm}^{a-1} \text{ cm}^{-2}$, $R_F \approx 10^4\text{--}10^8 \text{ Ohm cm}^2$ (in an indifferent electrolyte solution under a stationary potential). Assuming that the measured integral impedance parameters a and σ characterise the double electrical layer on diamond electrodes, it may be concluded that the structure of this layer is approximately the same in the polycrystalline and single-crystal specimens. Furthermore, on the whole, the structure of the double electrical layer is identical in the diamond and wide-bandgap diamond-like carbon electrodes.

Rather high values of the Faraday resistance R_F reflect the above-mentioned low background currents and the negligibly small corrosion of diamond in aqueous solutions. Larger values of σ in comparison with those in other semiconductor electrodes are indicative of a relatively high doping level of the diamond films studied (the acceptor concentration $N_a \geq 10^{18} \text{ cm}^{-3}$).

Note that according to different authors, the flat-band potential (E_{fb}) values determined by the extrapolation of the Mott–Schottky plots are in the range from 0.5 V (Ref. 52) to 1.2 V (Ref. 55) [relative to the saturated calomel electrode (SCE)]. Such a spread of data can in part be explained by different degrees of diamond surface oxidation (resulting from pretreatment of samples). It is known⁶ that the anodic and cathodic oxidation of numerous semiconductors shifts their flat-band potentials toward positive and negative regions, respectively. This is largely due to an appreciable extent to the dipolar potential drop associated with the oxygen monolayer adsorbed on the electrode surface and determined by the polarity of the C–O bonds.

Note in conclusion that in the CPE-containing equivalent circuit of the electrode, no separate frequency-independent capacitance was revealed that could be attributed to the space charge region in diamond.⁶² This means that it is the CPE [with its dependence on potential which is characteristic of semiconductor electrodes (see Section V.2 for more detail)] that describes the properties of the space charge region.⁶²

Recently, the diamond crystals grown under high pressure and high temperature have been used for the first time as electrodes. Their impedance characteristics proved to be close to those of thin-film electrodes (see Table 1).^{63, 64}

2. On the nature of the frequency dependence of the differential capacitance of diamond electrodes

Naturally, the dependence of capacitance on frequency that follows from the impedance complex-plane plot (see Fig. 6) determines the slope of the straight line in the Mott–Schottky plot.⁶⁵ The researchers investigating the frequency dependence of the differential capacitance of diamond electrodes must answer two major questions, *viz.*, what processes lead to the appearance of this dependence and what is the most convenient manner of its formal presentation.

The nature of the frequency dependence of the slope of the Mott–Schottky plot for the semiconductor electrodes has been subject to discussion for over three decades (see, *e.g.*, Refs 6 and 66). Possible reasons for its appearance are believed to be the dependence of dielectric relaxation on frequency in the space charge region,⁶⁷ roughness of the electrode surface,⁶⁶ slow ionisation of deep donors (acceptors) in the space charge region of semiconductors⁶⁸ and the influence of the surface states.

Evstefeeva *et al.*⁶⁹ investigated the dependence of capacitance on frequency in its application to the diamond electrode assuming that the electrode surface roughness should not necessarily lead to the appearance of CPE in its impedance.⁷⁰ The hypothesis⁵⁹ of slow ionisation of atoms with a deep-lying energy level (*e.g.*, boron) in the space charge region of diamond crystals has been assumed for a tentative explanation of the frequency dispersion of the Mott–Schottky plots of diamond electrodes. This explanation is supported by the fact that the magnitude of σ varies regularly

with changes in the thickness of the space charge layer (in conformity with Schottky's theory), whereas the magnitude of a is virtually independent of both the potential and the solution dilution, *i.e.*, the factors influencing the electrode surface state. Therefore, it has been concluded that the observed dependence of capacitance on frequency is not associated with the surface states but is determined by the process occurring in the space-charge region of diamond.[‡]

Let us consider different forms of the Mott–Schottky plots when they are frequency-dependent using the diamond electrode as an example. As noted above, this situation is typical of the electrochemistry of various semiconductor electrodes. Figures 7 and 8 illustrate three ways of presentation of such plots. The first pattern is a 'sheaf' of C^{-2} – E straight lines plotted from the capacitance values measured directly at a given frequency (a series of frequencies) and potential (see Fig. 7). The second one is the plot C_{calc}^{-2} – E (see Fig. 8, curve 2). When plotting this curve, the real equivalent electrode circuit (see Fig. 4c) was replaced by a simpler circuit (see Fig. 4b) including the frequency-independent capacitance instead of CPE. In its essence, the C_{calc} is the capacitance C_{sc} averaged over the entire range of the alternating current frequencies studied. As this step uses the body of experimental data for the whole frequency range, the value of C_{calc} obtained may be regarded formally as the frequency-independent one. Finally, the third pattern (for the cases where the equivalent circuit contains CPE) is the σ^{-2} – E plot (see Fig. 8, curve 1). Note that $\sigma \rightarrow C_{\text{calc}}$ at $a \rightarrow 1$.

Figure 7. The Mott–Schottky plot for a boron-doped single-crystal electrode with a frequency-dependent capacitance in 0.5 M H_2SO_4 . Frequency/Hz: (1) 21 544; (2) 10 000; (4) 4642; (5) 2154; (6) 1000; (7) 215; (3) the curve is calculated for C_{calc} ;⁶⁹ the potential values were measured relative to the Ag/AgCl electrode.

When comparing the above-listed patterns, one should pay attention to the fact that the plot σ^{-2} vs. E is frequency-independent, since σ is the frequency-independent parameter by definition [see formula (2)]. It may be considered as the most general case and be used for comparing results of different experiments, since in this case the contribution from the intrinsic frequency-dependent element is ruled out. However, taking into

[‡] It is unclear until now why the differential capacitance of some diamond electrodes is independent of frequency.

Figure 8. Dependence of $(\sigma/\sigma_{E=0.4\text{ V}})^{-2}$ (1), $(C_{\text{calc}}/C_{\text{calc},E=0.4\text{ V}})^{-2}$ (2) and a (3) on potential for a single-crystal electrode (calculated using the data of Fig. 7).⁶⁹ Potentials were measured relative to the Ag/AgCl electrode.

account the dimensionality of σ , correct comparison of the calculated data with the published results of direct capacitance measurement on diamond electrodes seems questionable.

The use of the $C_{\text{calc}}^{-2}-E$ dependence removes the dimensionality problems, although a somewhat formal character of the C_{calc} parameter is a disadvantage of this form of the Mott–Schottky plot presentation.

The sheaf of $C^{-2}-E$ straight lines may be interpreted as manifestation of a slow process (e.g., the above-mentioned ionisation of the deep acceptor) occurring in the space charge region of a semiconductor. Unfortunately, the nature of the dependence of differential capacitance on frequency is unknown; therefore, one should consider as approximate the literature data on the concentration of acceptors in diamond calculated on the basis of Schottky's theory for an arbitrary frequency of the measured signal. Nonetheless, it appears more convenient to use the dependence $\sigma^{-2}-E$ (especially for the cases when the exponent a is close to 1) or $C_{\text{calc}}^{-2}-E$ for qualitative comparison of electrodes made of the same semiconductor material.

VI. Kinetics of the electrode reactions

1. Kinetics of outer-sphere reactions. Metal-like diamond electrodes

It is common practice to divide electrochemical reactions into outer-sphere (occurring without cleavage of interatomic bonds in the reacting molecule) and inner-sphere ones (occurring with the cleavage or formation of such bonds). An example of outer-sphere reactions is the electron transfer in the $\text{Fe}(\text{CN})_6^{3-/4-}$ system, while the inner-sphere reactions may be exemplified by the oxidation and reduction of water molecules with the evolution of O_2 and H_2 , respectively. Let us start discussion of the kinetics of reactions on the diamond electrode with the former type of reactions.

A number of outer-sphere reactions were investigated by the method of potentiodynamic curves with a linear potential sweep. This method proved to be convenient for both qualitative and quantitative characterisation of the electrode behaviour. The theory of this method has been considered in textbooks.^{71, 72}

Typical cyclic voltammograms recorded for four redox systems are presented in Fig. 9. The outer-sphere reactions occur in solutions of $\text{Fe}(\text{CN})_6^{3-/4-}$, $\text{Ru}(\text{NH}_3)_6^{2+/3+}$ and $\text{IrCl}_6^{2-/3-}$, while the inner-sphere reaction occurs in the quinone/hydroquinone system. A characteristic shape of all curves with peaks of anodic and cathodic currents demonstrates that in all cases the stage of charge transfer at the interface is rather fast; the reaction is hampered due to the insufficiently rapid reagent mass transfer in solution toward the electrode surface. Similar curves were

Figure 9. Cyclic voltammograms in 10^{-4} M solutions of $\text{Fe}(\text{CN})_6^{3-/4-}$ (a), $\text{Ru}(\text{NH}_3)_6^{2+/3+}$ (b), $\text{IrCl}_6^{2-/3-}$ (c) against the background of 0.1 M KCl and quinone/hydroquinone (d) against the background of 0.1 M HClO_4 .⁷³ Potentials were measured relative to the SCE.

obtained in a series of studies of the ferrocyanide/ferricyanide⁷⁴ and quinone/hydroquinone systems,⁷⁵ Ce^{3+} ions (see Ref. 76), etc.

Analysis of these curves makes it possible to determine the following characteristics of the diffusion and interphase charge transfer: diffusion coefficient, transfer coefficients of the cathodic (α) and anodic (β) reactions and the rate constant (k^0). Quantitatively, the larger the difference between the potentials of the cathodic and anodic peaks the less reversible the electrode reaction. According to the theory of electrode kinetics,^{71, 72} for a reversible one-electron reaction at room temperature, $\Delta E_p = 56$ mV irrespective of the reagent concentration and the rate of potential sweep. For the systems, the voltammograms of which are shown in Fig. 9a–c, the values of ΔE_p are 88, 72 and 65 mV, respectively.⁷³ Consequently, on a relatively strongly doped polycrystalline electrode, the processes under consideration occur in the mode of a quasi-reversible reaction. On the contrary, the electrode reaction is markedly irreversible in the quinone/hydroquinone system: $\Delta E_p = 560$ mV. These qualitative estimates correlate with the values of rate constants determined for the above-listed redox systems.⁷⁷

Reagent	$\text{Fe}(\text{CN})_6^{3-/4-}$	$\text{Ru}(\text{NH}_3)_6^{2+/3+}$	$\text{IrCl}_6^{2-/3-}$	quinone/hydroquinone
$k^0/\text{cm s}^{-1}$	9×10^{-4}	3×10^{-3}	4×10^{-3}	$< 10^{-6}$

The rate constants strongly depend on both the level of diamond doping with boron (see below) and the prior preparation of the electrode surface; these data are presented here for the purpose of illustration. On the whole, based on the studies of a series of systems [including methyl viologen; $\text{FeL}_3(\text{ClO}_4)_2$, where L is *o*-phenanthroline; 1,1'-dimethoxyferrocene, etc.], the following qualitative inferences have been made:^{78, 79} the outer-sphere reactions are closer to reversible reactions than the inner-sphere ones; the reactions in the systems with a positive equilibrium potential are closer to reversible reactions than those in the systems with a negative potential;[§] on the heavily doped metal-like diamond the reaction rate is higher than on the moderately doped electrodes characterised by semiconductor properties. But even on the metal-like diamond electrodes the reaction rate is appreciably lower than that on the metal electrodes with high electrocatalytic activity, e.g., platinum. Consequently, upgrading

[§] This regularity is invalid for the $\text{Ce}^{3+/4+}$ system (see Ref. 75) which is discussed in more detail in the next section.

of electrocatalytic properties of diamond electrodes intended for practical applications is a topical problem. First experiments have shown^{80,81} that the deposition of microquantities of platinum onto the diamond electrode surface reduces the overvoltage of the cathode reactions.

2. Semiconductor properties of diamond and the electrode kinetics

The systems $\text{Fe}(\text{CN})_6^{3-/4-}$, quinone/hydroquinone[¶] and $\text{Ce}^{3+/4+}$ have been investigated quantitatively.^{75, 80, 82} The dependences of the potentials of the anodic and cathodic current peaks E_p in the potentiodynamic curves on the logarithm of the rate of potential sweep v were determined experimentally; the data characterising the quinone/hydroquinone system are shown in Fig. 10.⁷⁵ The transfer coefficients of the anode and cathode reactions were calculated from the slope of the straight line (Fig. 10 c) using the theory of the method of potentiodynamic curves.⁷²

Figure 10. Potentiodynamic curves recorded during the linear potential sweep in the course of hydroquinone (0.01 M) oxidation (a) and quinone (0.01 M) reduction (b) in 0.5 M H_2SO_4 on a polycrystalline diamond electrode, and dependences of the potentials of the cathodic ($E_{p,c}$) and anodic ($E_{p,a}$) current peaks on the logarithm of the sweep rate (c).⁷⁵ The rate of potential sweep $v/\text{V s}^{-1}$: (1) 0.005; (2) 0.01; (3) 0.02; (4) 0.05; (5) 0.1. Potentials were measured relative to the Ag/AgCl electrode.

Table 2 presents the measured α and β values typical of the single-crystal and polycrystalline thin-film electrodes and a single crystal (grown under high pressure and high temperature) in Ce^{3+} and Ce^{4+} solutions. For the $\text{Ce}^{3+/4+}$ system (as for the two other systems, viz., $\text{Fe}(\text{CN})_6^{3-/4-}$ and quinone/hydroquinone), the transfer coefficients are less than 0.5, especially for the cathodic reaction, and the sum $\alpha + \beta$ proves to be less than unity. According to the theory of the electrochemical kinetics on semiconductors,⁶ in the case of an 'ideal' p -type semiconductor electrode, the transfer coefficients for the reactions occurring with the participation of holes should be as follows: $\alpha = 0$, $\beta = 1$; $\alpha + \beta = 1$. In practice, however, the ideal case is extremely rare even for single-crystal semiconductor materials (silicon, gallium arsenide, etc.) that are prepared using much more advanced technologies than the technology for the preparation of polycrystalline CVD-diamond. The reason for the deviation from 'the ideal situation'

Table 2. Kinetic characteristics of diamond electrodes in a 0.01 M Ce^{3+} (or Ce^{4+}) + 0.5 M H_2SO_4 solution.

Electrode	α	β	$k^0/\text{cm s}^{-1}$
Polycrystalline film ⁵⁵	0.16	0.46	6×10^{-9}
Single-crystal film ⁵⁵	0.2	0.43	6.5×10^{-7}
Single crystal grown under high pressure and high temperature ⁶³	0.33	0.27	4.4×10^{-6}

appears to lie in the fact that during the electrode polarisation, part of the interphase potential drop is lost in the Helmholtz layer (e.g., due to a high density of the surface states). As a result, the transfer coefficients α and β have the values intermediate between those characteristic of semiconductors (0 or 1) and metals (~ 0.5).

Extrapolation of the impedance complex-plane plot until its intersection with the $\text{Re}Z$ axis (Fig 6a) gives the diamond film resistance R_s from which the diamond resistivity ρ can be calculated. The dependences of R_F on ρ for two redox systems are presented in Fig. 11. It is seen that, first, the reaction rate in the $\text{Fe}(\text{CN})_6^{3-/4-}$ system is approximately three orders of magnitude higher than that in the quinone/hydroquinone system, which is consistent with the above-cited rate constants; second, R_F is observed to be directly proportional to ρ over a wide range of diamond resistivity. The existence of such a dependence for diamond electrodes was first reported by Modestov *et al.*⁸⁰ It reflects the fundamental law of the kinetics of reactions on semiconductor electrodes: the rate of an electrochemical reaction is proportional to the concentration of free carriers on the electrode surface. Indeed, the concentration of holes in the diamond bulk p_0 is inversely proportional to its resistivity ρ .[†] The concentration of holes on the electrode surface p_s is related to p_0 by the Boltzmann equation⁶

$$p_s = p_0 \exp\left(-\frac{e\phi_{sc}}{kT}\right),$$

where ϕ_{sc} is the potential drop in the space charge layer.

If the chemical interaction of diamond with the solution and hence the potential distribution over the diamond/solution interface is assumed to be independent of the level of diamond doping with boron, then at the given electrode potential which is set by the redox system the value of $e\phi_{sc}$ is the same for all electrodes. Consequently, the reaction rate ($\sim 1/R_F$) should be proportional

Figure 11. Dependence of the Faraday resistance under equilibrium potential in the $\text{Fe}(\text{CN})_6^{3-/4-}$ (1) and quinone/hydroquinone (2) systems on the film resistivity.⁸³

¶ Note that the reactions occurring in the quinone/hydroquinone system are inner-sphere ones.

† In the discussion of the relation between the concentration of holes in specimens and their resistivity, it is assumed that the mobility of holes is independent of the boron concentration in specimens.

to the diamond conductivity, which is in fact observed in experiments.

3. Crystal structure and the electrode kinetics: comparison of electrodes from single-crystal and polycrystalline diamond and amorphous carbon

Polycrystalline diamond films are heterogeneous systems consisting of diamond crystallites and disordered carbon of intercrystallite boundaries (see Section III. 1). In this context, the following question arises: to what extent do the intercrystallite boundaries influence the electrochemical properties of polycrystalline diamond electrodes? In order to answer this question, one should compare the electrochemical behaviour of crystalline diamond with that of diamond-like carbon, which may be arbitrarily regarded as a model for the material of intercrystallite boundaries in the polycrystalline diamond.

Such a comparison shows that the kinetic characteristics (α and β) of single-crystal and polycrystalline diamond electrodes are similar. In solutions of redox systems, both types of diamond electrodes possess electrocatalytic activity (though not very great, which is characteristic of semiconductor electrodes).

The properties of amorphous carbon vary within very wide limits. In their electrode properties, the 'graphite-like' thin-film electrodes resemble conventional carbonaceous materials (*e.g.*, glassy carbon); redox reactions occur on them at high rates. On the contrary, in the case of 'diamond-like' electrodes there are no peaks of oxidation and reduction currents in such systems as $\text{Ce}^{3+/4+}$, $\text{Fe}(\text{CN})_6^{3-/4-}$ and quinone/hydroquinone; the currents measured do not differ from the background current. The fact that the diamond-like carbon proved to be electrochemically inactive suggests that the intercrystallite boundaries make no practical contribution to the electrode behaviour of polycrystalline diamond; it is totally determined by diamond crystallites. This conclusion relies on the results of comparison of the impedance (Table 1) and kinetic (Table 2) characteristics of polycrystalline and single-crystal diamond films and seems to be valid at least in the range of moderate electrode polarisation.⁵⁵

On the other hand, at high anode potentials (+1.7 V relative to the NHE, just before the beginning of oxygen evolution) a small peak is observed in the polarisation curve of a polycrystalline electrode in an indifferent electrolyte solution (similar to that shown in Fig. 3a).³² Its height is as small as $\sim 1 \mu\text{A cm}^{-2}$; therefore, it can hardly be seen in Fig. 3a (and other similar graphs). As to the quantity of electricity passed corresponding to this current peak, it may be concluded that within one such 'passage' of the curve, $\sim 0.05\%$ of the monolayer substance of the electrode surface takes part in the reaction. This current peak is better expressed for the diamond films with a relatively high content of non-diamond carbon, but it is not observed on single-crystal electrodes. According to Martin *et al.*,³² this peak is due to the oxidation of the non-diamond carbon of the intercrystallite boundaries, which is less resistant to oxidation than the crystalline diamond. No other peculiarities of the electrode behaviour of diamond, which could be attributed to the intercrystallite boundaries, have been revealed.

Note in conclusion that the wide-bandgap diamond-like carbon a-C:H which is usually electrochemically inactive acquires an electrode activity after the incorporation of a sufficiently large quantity ($\sim 10\%$) of platinum into the bulk of film (in the course of its deposition). In the shape of their potentiodynamic curves and the values of kinetic parameters, the a-C:H/Pt electrodes thus obtained resemble qualitatively the polycrystalline (boron-doped) diamond electrodes. For example, in the redox system $\text{Ce}^{3+/4+}$ no current peaks in the curves are observed at the Pt level ranging from traces to 1%, but they become well expressed at 12% of platinum; coefficients α and β being equal to 0.13 and 0.18, respectively. The redox reactions are irreversible; they occur under a mixed diffusion-kinetic control and have a moderate overvoltage.⁶¹

The results obtained point to the possibility of creation of fairly active electrodes from corrosion-resistant carbonaceous materials, *viz.*, synthetic diamond and diamond-like carbon, by incorporating into their bulk rather small quantities of metal catalysts such as platinum.

Platinum can be distributed in a carbon material in the form of individual atoms or clusters depending on the mode of its incorporation.⁸² An essential feature is that platinum is not a doping admixture in a-C:H in the sense of this term as used in the physics of semiconductors. Impedance measurements have shown that the Pt admixture does not virtually change the material resistivity. Therefore, it may be suggested that the effect of platinum is of a purely catalytic nature: its atoms on the electrode surface play the role of active sites on which the adsorption and the electrode reaction proceed at high rates.^{50, 61}

4. Kinetics of inner-sphere reactions. Diamond electrodes in preparative electrolysis and electroanalysis

The evolution of oxygen from water on the anode and hydrogen on the cathode are regarded as the inner-sphere processes. Potentials of these processes restrict the region of 'ideal polarisability' in aqueous solutions of electrolytes (see Fig. 3a,b). Overvoltage of these reactions increases with higher quality of electrode films. For the anodic evolution of oxygen, the exchange current is $5 \times 10^{-11} \text{ A cm}^{-2}$, transfer coefficient $\beta = 0.25$; for the hydrogen evolution on the cathode the exchange current is $10^{-10} \text{ A cm}^{-2}$ and $\alpha = 0.30$ (see Ref. 32).

The region of 'ideal polarisability' may be restricted by decomposition potentials of not only the solvent but also dissolved electrolyte, *e.g.*, halides. The reactions of anodic oxidation of Cl^- , Br^- and I^- ions with the evolution of the corresponding halogens proceed irreversibly and are accompanied by a much higher (by 1 V for Cl^-) overvoltage than on the platinum or graphite electrodes. Most probably, this is associated with low adsorbability of intermediate products (chlorine, bromine and iodine atoms) on the diamond surface, which thus proves to be passive.⁷⁸ (The outer-sphere reactions discussed in Section VI.1 occur without adsorption of reagents or intermediate products on the electrode; for this reason, they are insensitive to the poor adsorption capacity of the diamond surface.)

In addition to the above-mentioned processes, the inner-sphere reactions also include oxidations of numerous organic compounds, in which the interphase charge transfer is accompanied by transformations of organic molecules. Polycrystalline diamond electrodes have been used to investigate the anodic oxidation of chlorpromazine,⁴¹ ascorbic acid,⁸⁴ anthraquinone-2,6-disulfonate⁸⁵ and several amines.⁸⁶

One of the most efficient and promising applications of the diamond electrodes is their use for the electroreduction of compounds that are difficult to reduce. For example, the reduction of nitrate and nitrite ions to ammonium has been investigated.^{87–89} In an alkaline solution of NO_3^- , the following reaction takes place on a heavily doped electrode (with N_a up to 10^{21} cm^{-3}) under anodic polarisation:

At a potential of -5 V , the current density reaches 300 mA cm^{-2} but no corrosion of diamond is observed even after a few days of continuous electrolysis.

The most striking feature of this process is that the anodic current efficiency exceeds several-fold the theoretical limit calculated by the equation for the reaction! Attempts were undertaken to rationalise this fact by the occurrence of the conjugated oxidation of silicon (the diamond film was prepared by deposition on a silicon substrate), *e.g.*, through pinholes in the film. However, special experiments on a free-standing diamond film (see Section II) have shown that the current efficiency, though being somewhat decreased, still remained higher than its theoretical level. The reason of this effect is still unclear.

The electrodeposition of metals (Li, Ag, Cu, Pb, Pt, Hg) leading to the formation of a new phase stands somewhat apart. Data on such processes are scanty and rather contradictory. Lead and mercury are deposited as islets a few micrometers in diameter predominantly over the intercrystallite boundaries.⁸¹ According to Li *et al.*,^{18,90} lithium is deposited in the same mode with concomitant intercalation into the non-diamond carbon. Observation of the lithium intercalation–deintercalation may be used as a technique for revealing non-diamond inclusions on the surface of diamond films. Finally, there is indirect evidence that the electrodeposition of copper, the first stages of which follow the ‘underpotential deposition’ mechanism, also takes place on the intercrystallite boundaries.⁸

Electroanalytical methods have been developed on the basis of certain electrochemical reactions on diamond electrodes. Judging from the results of relevant studies,^{8,81} the diamond electrode is well-suited for use in the commonly accepted anodic-stripping analysis of solutions for low concentrations of metal ions, which consists in the cathodic deposition of small quantities of metals on an inert working electrode with their subsequent anodic dissolution.

A flow-type thin-layer cell with a diamond electrode has been devised^{85,91,92} for the determination of ethylamine, ethylenediamine and other amines, as well as azide ion N_3^- . Such determinations are carried out by injecting a microportion of the solution under study into the electrolyte flow with subsequent recording of the current jump induced by the oxidation of the compound under analysis (Fig. 12). The electrode function is linear in the concentration range of 10^{-2} – 10^{-5} M; the detection limit, *e.g.*, of azide ion, is 8 nmol l^{-1} (see Ref. 92).

Figure 12. Chronoamperogram in the determination of ethylamine concentration by injecting an aliquot (20 μl of 0.25 mM solution) into a flow-type cell with 0.1 M carbonate buffer; solution flow rate, 0.5 ml min^{-1} (see Ref. 91).

VII. Photoelectrochemistry of diamond

Like any other semiconductor, the diamond demonstrates a photoelectric effect due to photogeneration of free charge carriers upon illumination. An increase in the concentration of charge carriers affects the current across the diamond contact with another conducting phase or the interface charge. In the potentiostatic regime, a photocurrent is recorded and a photopotential is recorded in the galvanostatic and coulombostatic regimes.

Starting from the first study,¹¹ the photoelectrochemistry of diamond has been investigated by illuminating electrodes with light with quanta energy $h\nu$ smaller than the bandgap ($E_g \approx 5.5 \text{ eV}$); this energy is insufficient for the transition of excited electrons from the valence band to the conduction band. Free carriers were apparently formed due to ionisation of some unidentified photosensitive sites in the bandgap of diamond, *viz.*, admixtures or structural defects (the so-called extrinsic or impurity photosensitivity). Curves of photocurrent in the diamond electrode elicited by band-to-band electron transitions (the so-

Figure 13. Dependence of dark current (1) and photocurrent (2) upon illumination of a polycrystalline diamond electrode in 0.1 M KH_2PO_4 under intrinsic (a) and impurity-related (b) photoexcitation. The quanta energies were 6.4 eV (a) and 5 eV (b). Density of illumination power was 80 mW cm^{-2} (Ref. 93); the potential values were measured relative to the SCE.

called intrinsic photosensitivity⁹³) have been derived quite recently using an excimer laser with a wavelength of 193 nm (which corresponds to quantum energy $h\nu = 6.4 \text{ eV}$) as the high-energy light source. Figure 13 illustrates well the differences in the photocurrent density j_{ph} in the intrinsic and impurity-related photoexcitations. In the impurity-related excitation the quantum yield of photocurrent was $\sim 0.01\%$,⁹⁴ whereas in the intrinsic excitation it reached 34%.⁹³

The absolute magnitude of photocurrent is increased with increase in cathodic polarisation. This effect may be understood by examining Fig. 14 showing the square of photocurrent as a function of the potential.¹¹ This plot is equivalent to the Mott–Schottky plot (see Fig. 5) because, like the latter, it reflects the variation of the width of the space charge layer in the semiconductor diamond as a function of the potential. Upon illumination of this semiconductor, the light-generated charge carriers with opposite signs are separated by an electric field in the space charge region. The minority carriers drift in the electric field

Figure 14. Dependence of the squared photocurrent on the diamond electrode potential in 1 M KCl;¹¹ the potential values were measured relative to the SCE.

toward the interface, where they are 'captured' by the electrochemical reaction or they charge (in the coulombostatic regime) the electrode, whereas the majority carriers migrate into the bulk of diamond and then, through the ohmic contact, to the external circuit of the electrochemical cell. Therefore, the thicker the space charge layer from which the minority carriers are 'harvested' the stronger the photocurrent. By extrapolating the straight line in Fig. 14 until its intersection with the potential axis, one can determine the flat-band potential in the same way as when using the Mott–Schottky plot; both methods give consistent values for the same electrode (see Section V.1).

In a series of studies^{11,93,95} the photocurrent was measured in the steady-state mode upon illumination of the electrode with light of constant intensity. Later,^{94,96,97} pulsed illumination was used; the photopotential and dynamics of its decay were measured after the application of a light pulse. The current of photogenerated minority charge carriers charges the electrode capacitance and thereby determines the potential shift. The analysis conducted with the aid of a somewhat more complex version of the Randles–Ershler circuit (see Fig. 4b)[‡] afforded a satisfactory description of the dynamics of photopotential decay.

A typical spectrum of the cathodic photocurrent I_{ph} of a diamond electrode is shown in Fig. 15a. Processing of such spectra in the coordinates $(I_{ph}h\nu)^{1/2}$ vs. $h\nu$ (see Fig. 15b) provided values of threshold energies of indirect electron transitions that determine the photogeneration of charge carriers (for more details, see Ref. 6). In some cases, the spectra include two regions and give, respectively, two values of threshold energy. The problem of the elucidation of the physical nature of the energy levels in the bandgap of diamond which participate in such transitions is still far from its solution. Some transitions with a threshold energy close to 4 eV have been identified with the photoexcitation of electrons of the valence band on the energy levels of N^+ ions in the bandgap of diamond localised ~ 1.7 eV below the conduction band.⁹⁴

Figure 15. Spectrum of the cathodic photocurrent of a boron-doped polycrystalline diamond electrode in 0.5 M H_2SO_4 under a potential of 0.05 V (relative to NHE) (a) and its presentation in the $(I_{ph}h\nu)^{1/2}$ vs. $h\nu$ coordinates, which is convenient for the spectrum processing for the threshold energy determination.⁹⁴

The photocurrent–potential curves and the photocurrent spectra were also recorded for the films of amorphous diamond-like carbon.^{48,49,98} Processing of the spectra similar to that described above has made it possible to determine the width of the mobility gap in the disordered structure of this material. Upon illumination, the diamond-like carbon displays properties characteristic of intrinsic semiconductors.

Photoelectrochemical measurements make it possible to derive certain characteristics of the semiconductor diamond. Thus comparison of the spectra of light absorption coefficient and open-circuit photopotential allowed determination of the

diffusion length ($2-4\ \mu m$) of the minority carriers in polycrystalline diamond films.⁹⁹

VIII. Conclusion

About ten years have passed since the first studies in the field of diamond electrochemistry. This decade has witnessed the development of a somewhat schematic but rather comprehensive system of concepts of diamond as a novel electrode material. Investigations of diamond electrodes have afforded better understanding of the relationship between the crystal structure of solids and their electrode behaviour.

It is most likely that further studies on diamond electrochemistry will develop both extensively (a wider range of studied reactions, search for new applications of diamond electrodes in fundamental and applied electrochemistry) and intensively (a deeper insight into the relationship between the semiconductor and structural properties of carbon allotropes and their electrochemical behaviour). In the near future, the corrosion-resistant diamond film electrodes may be expected to replace (at least in part) the conventional dimension-stable electrodes based on the platinum group metals, which are used nowadays for the electrochemical synthesis and analysis.

Preparation of this review was supported by the Russian Foundation for Basic Research (Project No. 98-03-32057).

Abstract. The main factors affecting the pathways of multistep cationic molecular rearrangements of natural terpenes and their analogues are considered. Methods for predicting the most probable pathways of cationic rearrangements are proposed. The bibliography includes 85 references.

I. Introduction

Carbocationic reactions play a prominent role in molecular rearrangements of organic compounds. The regularities of these reactions are most efficiently studied by modelling methods based on 'direct visualisation' of ion conversions in hypernon-nucleophilic superacidic media at superlow temperatures. Specially synthesised simple organic compounds are normally used as subjects for the investigation. The use of this approach in a particular field of organic chemistry in which cationic molecular rearrangements play a central role (*e.g.*, terpene chemistry) seems to be highly efficient. The study of regularities of carbocationic reactions of terpenoids and their analogues pursues three main goals:

1. Elucidation of regularities of molecular rearrangements of complex polycyclic cations.
2. Broadening of the range of available natural compounds suitable for the preparation of novel substances.
3. Chemical proof of validity of biogenetic schemes.

II. Conformational control of reactions

Polyfunctionality and conformational mobility are the most characteristic features of terpenes. Studies of conformational mobility and its effect on the reactivity of terpenes at low temperatures have generated an entirely new field of research, *viz.*, the

chemistry of conformationally controlled carbocationic reactions. In synthetic organic chemistry, conformational control is usually restricted to deamination of aliphatic amines and related compounds, but it plays a prominent role in biogenetic reactions of carbocationic cyclisation. The discovery of conformationally controlled reactions of stable ions derived from terpenes at low temperatures has made it possible to fill the gap between the biogenetic and chemical processes and provided a way for experimental realisation of biogenetic reactions.

Conformational control can be manifested both in initial steps of reactions and in subsequent transformations of the intermediate carbocations. The former can be exemplified in rearrangements of a sesquiterpene diene, *viz.*, caryophyllene (**1**). According to ^{13}C NMR spectral data, which are consistent with the molecular mechanics (MM2) calculations, compound **1** may exist in four stable conformations, *viz.*, $\beta\alpha$, $\alpha\alpha$, $\alpha\beta$ and $\beta\beta$.^{1,2}

Con- former				
	$\beta\alpha$ - 1	$\alpha\alpha$ - 1	$\alpha\beta$ - 1	$\beta\beta$ - 1
ΔH_f° (MM2), /kcal mol ⁻¹	12.6	14.2	17.3	12.4
Content (MM2) (%)	39	3	0	58

The experimental barrier to the transition between the pairs $\beta\alpha \rightleftharpoons \alpha\alpha$ and $\alpha\beta \rightleftharpoons \beta\beta$ (16.25 kcal mol⁻¹) cannot be virtually overcome at temperatures employed for the ion generation ($\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$, from -120 to -100 °C). Indeed, the ratio of reaction pathways of two conformers, *viz.*, $\alpha\alpha$ and $\beta\beta$, the transannular cyclisation of which gives radically different intermediate carbocations and different reaction products, correlates with the ratio of the above conformers.

Uspekhi Khimii 68 (5) 430–453 (1999); translated by R L Birnova

Heating of the diene **1** in $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$ to $-30\text{ }^\circ\text{C}$ and its subsequent neutralisation yield a mixture of enantiomeric dienes **6** and **7** in which the diene **6** with a clovane backbone [judging from optical rotation dispersion (ORD) curves] is predominant. The reaction proceeds *via* the intermediate allylic ions **4** and **5**. The ratio of dienes **6** and **7** corresponds to the ratio of the conformers $\alpha\alpha\text{-1}$ and $\beta\beta\text{-1}$ in SO_2FCl at $-120\text{ }^\circ\text{C}$.

The stable ions derived from conformers $\alpha\alpha$ and $\beta\beta$ can be generated separately from clovene **2** and 1-substituted caryolanones **3** *via* ions **8** and **9**.

The conformational control can be effected after the carbocation has been formed and be manifested in different ways. The conformationally controlled molecular rearrangements of $4\beta,5\beta$ -(**10**) and $4\alpha,5\alpha$ -epoxides (**11**) of isocaryophyllene in superacids occur enantioselectively and result in the formation of the enantiomeric carbocations **12** and **13** from an epimeric pair of epoxides.³

Presumably, such enantioselective rearrangements take place when the opening of the epimeric monoepoxides generated from an optically active and conformationally flexible cyclic polyene occurs in acidic media with the participation of σ - and π -bonds. The direction of skeletal shifts is determined by the spatial structure of the epoxide. The optically active diene ultimately gives two enantiomeric products without recourse to any optically active reagents, *i.e.*, 'partial asymmetric synthesis' takes place.

The reaction which is controlled by the conformation of the intermediate carbocation may proceed in a structurally selective manner, as is the case with the low-temperature cyclisation of *trans*-5,6- (**14**) and *cis*-5,6- ϕ -ionones (**15**) in a superacidic medium. It was reported previously^{4,5} that the structural direction of cyclisation of isoprenoids containing a conjugated 5,6-double bond does not depend on its configuration. This was explained by decreased nucleophilicity of the double bond as a result of conjugation and, ultimately, a decrease in the cyclisation rate.

More recent studies have shown⁶ that protonation of the ketones **14** and **15** in $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$ at $-130\text{ }^\circ\text{C}$ yields conformers **16** and **17** of the same dication. Quenching of an acidic solution of the conformer **16** leads to elimination of the axial proton from the tertiary carbon atom linked with the side chain to give β -ionone (**18**). The conformer **17** eliminates the axial proton from the secondary carbon atom of the ring (in conformity with the ionic elimination rules) and is converted into α -ionone (**19**).

$$k_3, k_4 > k_1, k_2$$

Thus, in this case the conformational stability of intermediate monocyclic carbocations at low temperatures ensures conformational control and, as a result, the structural selectivity of the rearrangement.

A more complex situation is observed in the protonation of *cis*- (**20**) and *trans*- ϕ -ionones (**21**).⁷

Protonation of the ketone **20** in $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$ ($-130\text{ }^\circ\text{C}$) gives the dication **22** in which the methyl group at C(6) is in the *trans*-position relative to the side chain at C(2). The elimination of the axial proton from the secondary carbon atom in the dication **22** is accompanied by its conversion into the 'apparent' ion **23**; 'quenching' of the latter gives *trans*- α -irone (**24**). Heating of an acidic solution of the ion **23** to $-20\text{ }^\circ\text{C}$ results in pentadienyl ions **25** and **26**; their 'quenching' yields β -irone (**27**). Protonation of the latter at $-100\text{ }^\circ\text{C}$ gives a mixture of ions **25** and **26**. It is noteworthy that the ion **23** is not generated in the temperature range from -100 to $-10\text{ }^\circ\text{C}$. Structurally selective and stereo-selective transformation of the ketone **20** in $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$ is probably due to the lack of conformational transitions at $-130\text{ }^\circ\text{C}$ (Scheme 1).

Scheme 1

The transformation of the *trans*-isomer **21** in $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$ occurs differently. At -130°C , it gives a mixture of dication **22** and **28**. The latter exists as a mixture with the dication **29** due to conformational transitions of the *chair* $\rightleftharpoons$ *chair* type. 'Quenching' of the reaction mixture gives ketones **24** and **27** and *cis*- α -irone (**30**).

Generation of an ion, which exists in two different conformations that are more rapidly stabilised by intramolecular interactions than by interconversions, from different conformational isomers is yet another typical example of conformational control. However, in contrast with the above examples, this process ensures not only structural selectivity but also stereospecificity of cyclisation reactions. Thus the cyclisation of *trans*- (**31**) and *cis*-geranylacetone (**32**) in 100% sulfuric or fluorosulfonic acids is stereospecific and yields *trans*- (**33**) and *cis*-chromenes (**34**), respectively.^{8,9} It has been suggested¹⁰⁻¹² that the stereospecificity of cyclisation of dienones **31** and **32** is due to the formation of stable conformers **35** and **36**. However, it has been found⁶ that monocyclic ions **35** and **36** were not detected in the NMR spectra after dissolution of dienones **31** and **32** in $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$ even at -120°C because of their rapid cyclisation into carboxonium ions **37** and **38**. It should be noted that the methylcyclohexyl cation is a rather stable species.¹³

(a) $\text{HSO}_3\text{F}, \text{SO}_2\text{FCl}, -130^\circ\text{C}$.

^1H and ^{13}C NMR spectral data point to the formation of carboxonium ions **37** and **38**, which have not been considered previously at all as intermediates in the cyclisation of dienones **31** and **32** into chromenes **33** and **34**.¹⁰⁻¹² Presumably, the stereospecificity of these reactions is determined not by the conformational stability of monocyclic ions **35** and **36** as such, but rather by the ratio of rate constants of their conformational transitions as well as by the ratio of rate constants for the formation of bicyclic ions ($k_3, k_4 \gg k_1, k_2$).⁶ In this case, we are dealing with conformational control, since the ratio of the reaction products is approximately the same as the conformer ratio.¹⁴ The formation of conformationally isomeric monocyclic ions **35** and **36** from dienones **31** and **32** seems to be due to the fact that they react in the most stable conformations **31a** and **32a**.¹⁰ This conclusion is confirmed by the strain energies (*E*) of the conformations of dienones **31** and **32** calculated by the molecular mechanics method using parametrisation described in Ref. 15. It was found⁶ that the majority of geranylacetone atoms in conformations **31a** and **32a** fall into the attraction field of non-valent (van-der-Waals) interactions. Therefore, the energies of these conformations are by 6–8 kcal mol⁻¹ lower than those of non-valent interactions in other conformations, e.g., **31b** and **32b**.

	31b	32a	31b	32b
Conformation	31a	32a	31b	32b
<i>E</i> /kcal mol ⁻¹	218.6	219.5	226.7	225.5

The calculations of the barriers $\Delta H^\ddagger$ to the conformational ion transitions **35** $\rightleftharpoons$ **36** (MMX) and the opening of heterocycles **37** and **38** (PM3)¹⁶ corroborate the conclusion⁶ that $k_3, k_4 \gg k_1, k_2$.

The stepwise mechanism of generation of ions **37** and **38** proposed by Gavrilyuk *et al.*⁶ agrees well with the transition state energies of cyclisation of *cis*- and *trans*-undeca-6,10-dien-2-yl cations into decalin derivatives calculated by the MINDO/3 method. These calculations showed that the activation energies of synchronous processes are by 23–24 kcal mol⁻¹ higher than those of stepwise processes.¹⁷ In addition, experimental data suggest that biogenetic cyclisation of isoprenoids occurs in a stepwise manner.¹⁸

The formation of conformational isomers of cyclic ions as the manifestation of conformational control in the cyclisation of 2,6-dienes stereoisomeric with respect to the 4,5-double bond having a carbonyl or a hydroxy oxygen atom at C(1) is of general character¹⁹ and is observed in the cyclisation of stereoisomeric 2,6,9,9-tetramethyl-2,6-decadien-10-ols.

In the above examples, the interaction of the cationic centre in the conformers of monocyclic carbocations containing sufficiently nucleophilic carbonyl or hydroxy groups occurs faster than conformational transitions. In the cyclisation of *trans*, *trans*- (**39**) and *cis*, *trans*-farnesols (**40**), which are isomeric at the 6,7-double bond, the configuration of this double bond does not influence the steric direction of the reaction. Both isomers yield a

product with *trans*-fused rings. Apparently, this is due to decreased nucleophilicity of the 2,3-double bond caused by the $-I$ -effect of the hydroxy group.²⁰

Conformational control is also effected in the stage of formation of intermediate carbocations where the same ion exists in different conformations which give rise to different (but not isomeric) ions.²¹ Thus protonation of methyl 2,3-*trans*- (**41**) and *cis*-geranate (**42**) in $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$ at -120°C gives dication **43** and **44**, which are conformers but are not practically inter-converted at temperatures below -70°C . In the dication **43**, the 1,2-hydride shift prevails, so that the cationic centres become more remote. Subsequent addition of the fluorosulfonyloxy group results in the ion **45**. In the dication **44**, the axial proton is eliminated exclusively from the secondary carbon atom to give the ion **46**. It is interesting that 'quenching' of acidic solutions of ions **45** and **46** yields the same compound, *viz.*, methyl α -cyclogeranate (**47**). Thus, the studies of intermediate carbocations generated at low temperatures under 'long-life' conditions allowed Gavriluk *et al.*²¹ to conclude that it is the configuration of the 2,3-double bond that determines the structure of primary cyclisation products (*viz.*, intermediate carbocations) in the cyclisation of acyclic isoprenoids containing an ester group conjugated with the double bond.

It has been shown²² that conformational control can influence the ratio of intra- and intermolecular reaction products in the stage of generation of an intermediate carbocation. Thus stable

(a) $\text{HSO}_3\text{F}, \text{SO}_2\text{FCl}, -120^\circ\text{C}$; (b) $\text{OSO}_2\text{F}^-, \sim\text{H}$; (c) MeOH .

diastereomeric allylic ions **49–51** generated from (–)- α -murolene (**48**) differ only in the configuration of the asymmetric centre at C(6) or C(10).²³

This, in turn, affects the conformation of the corresponding ion and, ultimately, the dihedral angle between the vacant *p*-orbital of the cationic centre and the C(10)–C(9) σ -bond. This angle determines the probability of intramolecular rearrangements in these ions with a 'turnover' of a six-membered ring relative to another. Thus one of the epimers (ion **49**) undergoes intramolecular ring 'turnover' at 50°C to give the diene **52** (Scheme 2), while the other epimer (cation **50**) is converted into the ion **49** at -70°C . In the case of the ion **51**, only intermolecular rearrangement into the ion **54** is realised even upon heating to 70°C ; its 'quenching' gives compound **55** (see Scheme 2).

Scheme 2

Intramolecular rearrangement of the ion **49** may occur in two pathways, *a* or *b*. Which of them is realised in each concrete case can be established by comparing the ORD curves of dienes **55** and **56** mimicking compounds **52** and **53**, respectively.

The experimental results²¹ suggest that the rearrangement follows pathway *a*. This is probably due to the fact that of the two secondary spirocations **A** and **B** only the former can be stabilised by homoallylic conjugation. In the case of pathway *b*, such an efficient interaction is impossible due to the perpendicular position of the *p*-orbitals of the cationic centre and the double bond.

It should be noted that superacidic media favour profound molecular rearrangements that cannot be achieved in 'ordinary' media even under most drastic conditions. Since solutions of stable ion salts can be heated up to 100 °C and above, direct observation of 'cation–cation' rearrangements with an activation barrier of ~ 30 kcal mol⁻¹ and higher can be observed. Molecular cationic rearrangements which occur in superacidic media with an activation barrier of ~ 20 kcal mol⁻¹ cannot be reproduced under conditions of an ordinary acid catalysis (*cf.* Ref. 24).

The possibility of intermediate formation of the spirocyclic carbocation **58** in the previously discovered²² rearrangement of allylic cations of the type **49** with the cadalene skeleton has been demonstrated with a sesquiterpenoid hydrocarbon β -alaskene (**57**) having a spiro[4.5]decane backbone as an example.²⁵

Steric factors have a profound influence on the ratios of intra- and inter-molecular transformations of stable carbocations. They can also affect the regio- and stereoselectivity of these rearrangements as can be exemplified in the isomerisation of *cis*- (**59**) and *trans*-caranes (**60**) in HSO₃F–SO₂FCl (–120 °C) resulting in the formation of apparent ions **61** and **62**, respectively.²⁶

The opening of the cyclopropane rings in epimers **59** and **60** is accompanied by seeming inversion of configuration. This is due to the fact that in the case of long-living cations the conversions of initially formed ions **63** and **64** into thermodynamically more stable cations **61** and **62** occur through hydride shifts as can be judged from the molecular mechanics calculations.²⁷ The calculations of the geometry of the ground states of compounds **59** and **60** made with the use of the parameters described in Ref. 28 suggest certain elongation of the C(1)–C(7) bond relative to the C(6)–C(7) bond in the *cis*-isomer **59** and of the C(6)–C(7) bond relative to the C(1)–C(7) bond in the *trans*-isomer **60**. These data are in good agreement with the results of conversions of compounds **59** and **60** in superacids.

III. The effect of polyfunctionality of the original substrates

Yet another essential feature of terpenes as starting compounds in the generation of stable ions is their polyfunctionality. Thus terpenes may serve first as potential precursors of both mono- and dications with identical skeletons. The pathways of molecular rearrangements of mono- and dications often differ, which largely increases the diversity of terpene transformations. Thus it has been shown²³ that molecular rearrangements of mono- (**65**) and dications (**66**) generated from the same natural diene **48** give rise to diastereomeric allylic ions **49** and **67**.

(a) HSO₃F, SO₂FCl, –70 °C; (b) HSO₃F, SO₂FCl, –120 °C.

Second, a polyfunctional terpenoid molecule contains groups that can be both converted into an electrophile and simultaneously act as an internal nucleophile. The direction of a reaction often depends on the structural peculiarities of the original terpenoid. Minor structural changes in such strongly internally interrelated multicentre systems can result in dramatic changes in relative reactivities of different groups, in relative stabilities of intermediate carbocations and, ultimately, in the cyclisation pathway. The results of cyclisation of analogous acyclic terpenoids, *viz.*, citral (**68**), citronellal (**69**) and methyl geranate **41**, were compared under identical conditions (HSO₃F–SO₂FCl, –110 °C).²⁹

In the citral molecule (**68**), the proton is added to the most nucleophilic 6,7-double bond. The oxygen atom of the carbonyl group, which attacks the cationic centre to give rise to cyclic allylic ions, acts as a nucleophile; quenching of allylic ions with alcohols gives 7-alkoxy-substituted 6,7-dihydrocitral in good yields.

In contrast, in the aldehyde **69** the proton is added to the oxygen atom of the carbonyl group. The carbon atom in the latter attacks the 6,7-double bond to generate an allylic ion. Its 'quenching' gives 7-methoxymenthene.

Finally, similarly to the aldehyde **68**, protonation of the ester **41** results in the addition of a proton to the 6,7-double bond. However, in this case the role of a nucleophile is played not by the oxygen atom of the carbonyl group but by the 2,3-double bond, eventually resulting in the ester **47** after 'quenching'.

It has been shown³⁰ that isomeric bicyclic labdane diterpenoids **70** and **72**, which differ in the position of the allylic hydroxy group in the side chain undergo radically different conversions under identical conditions ($\text{HSO}_3\text{F} - \text{SO}_2\text{FCl}$, -100°C).

Thus the protonation of the terpene **70** involves the exocyclic double bond to yield a cyclic carbocation; the role of the internal nucleophile is played by the double bond in the side chain. This structurally selective and stereoselective rearrangement gives rise to the bifunctionalised isoagatane **71**.

The generation of the cationic centre in the tertiary alcohol **72** is of by the solvolytic type and is accompanied by elimination of the allylic hydroxy group from the side chain. In this case, the exocyclic double bond plays the role of the internal nucleophile, eventually resulting in the tetracyclic hydrocarbon **73**.

If a cationic centre is formed in a terpenoid molecule, it significantly affects the appearance of the second cationic centre in the same molecule (if this does take place) and its further behaviour. Thus the opening of a three-membered ring in carane (**59**) occurs through proton attack at C(1) of the cyclopropane ring.²⁶

In α -trans-3,4-epoxycarane (**74**), the initial opening of the epoxide ring ($\text{HSO}_3\text{F} - \text{SO}_2\text{FCl}$, -100°C) is followed by β -cyclopropylmethyl rearrangement and results ultimately in the formation of the ketone **75**.³¹

IV. Factors affecting the pathway of cationic rearrangements

The behaviour of stable π -conjugated carbocations is largely determined by charge delocalisation and the relative capacity to migration of substituents in 1,2-shifts.³² If ions are generated from terpenes or their analogues, the crucial role will be played by other factors, e.g., the nature of the acidic medium, the mode of generation of the cationic centre (solvolysis or electrophilic addition to the double bond) and the temperatures at which cations are generated and the acidic solutions are defrosted. The 1,2-shifts toward the cationic site are controlled by the competitive (rather than relative) migration capacity of the adjacent groups.

1. The nature of the acidic medium

Elucidation of the relationship between the chemical behaviour of stable carbocations generated in superacidic media and transformations of these original substrates under conditions of acidic catalysis is an important problem. Its solution will allow the use of regularities established in the studies of stable carbocations in prediction of the most probable pathways of multistep carbocationic rearrangements under conditions of conventional acidic catalysis. The solution of this problem is also important for designing organic syntheses in general and syntheses of terpene compounds in particular. However, the publications devoted to this problem are scarce and the conclusions made therein are

rather controversial. Thus Olah, who was a pioneer in the studies of the behaviour of cations generated in superacidic media, considers the chemistry of stable ions as an entirely independent field and conducts even applied investigations under extremely 'hypernon-nucleophilic' conditions.³³ In 1975, Sorensen *et al.*³⁴ generalised the data on carbocationic rearrangements of several monoterpenes in media of different acidities. According to these authors, the increase in the $\Delta G^\ddagger$ barrier to 'ion-to-ion' rearrangements is of the same order both in superacids and under conditions of acidic catalysis, while the stability of alkenes parallels that of the corresponding cations. It was thus concluded that the pathways of carbocationic rearrangements in acidic catalysis can be predicted from the results of direct observation of their rearrangements in superacids. No exceptions were reported.³⁴ In our opinion, this can be due to the limited choice of experimental objects investigated in this study³⁴ (as a rule, compounds with a norbornane skeleton were used). We have found several substantial limitations of Sorensen's statements. Thus in a more recent study, Brown³⁵ has shown that the chemical behaviour of stable ions and the pathway of solvolysis are in rather poor agreement with each other. In 1983, Arnett and Hofelich³⁶ established a correlation between the rate constants of solvolysis of certain chlorides in ethanol and enthalpies of ionisation of these chlorides in superacids and thus confirmed the formation of intermediate short-living carbocations in solvolysis that are analogous to stable ions generated in superacids. However, further multistep conversions of the initially formed ions have not been investigated.³⁶

We believe that the data obtained in the studies of molecular rearrangements in superacids can be used for predicting the most probable pathways of their transformations in ordinary acids with allowance made for possible changes in the nature of the medium, *e.g.*, the site of generation of the cationic centre, the nature of the internal nucleophile, the 'qualitative' changes in the ratio of rates of intra- or inter-molecular rearrangements, the non-correspondence of changes in the relative stabilities of alkenes and the cations derived from them, *etc.* This must be taken into consideration altogether in designing isoprenoid syntheses.

We have studied the effect of the nature of medium on the pathway of terpenoid rearrangements. Thus in the case of *trans*, *trans*-farnesol (**39**), the site of formation of the cationic centre has been shown to depend on the nature of the medium.³⁷

Protonation of the double bond takes place in superacids endowed with high protonating capacity and results in drimenol (**76**). Formic acid, characterised by high ionising capacity, favours solvolysis with the formation of an allylic ion. Its subsequent cyclisation gives bisabolol (**77**).

The medium acidity affects the behaviour of labdanoids **70** and **72** (see above) in different ways. Cyclisation of compound **72** containing a tertiary allylic group in the side chain in both superacids and ordinary acids gives the tetracyclic product **73**. Compound **70** containing a primary allylic group generates the tricyclic diol **71** in superacids and the tetracycle **73** in ordinary acids.³⁰

A study of transformations of nerolidol (**78**) in various acidic media has shown³⁷ that carbocyclisation reactions involving different π -bonds can take place even in the presence of a good leaving group (*e.g.*, a tertiary allylic hydroxy group) and in the case where a cationic centre at the same carbon atom is formed in different media. For example, conformational control favours the approaching of the chain termini in superacids at low temperatures to give the secondary ion **79**. In weak acids and at room temperature, this reaction proceeds with the formation of a more stable tertiary bisabolyl ion **80**.

(a) HSO_3F , SO_2FCl , -100°C ; (b) $[\text{H}^+]$, 20°C .

It has been shown³⁸ that cyclisation of chrysanthemyl alcohol (**81**) occurs differently in different media, since the medium determines the mode of reaction of a particular internal nucleophile with the cationic centre. This, in turn, significantly affects the ratio between carbo- and heterocyclisation reactions. Heterocyclisation in ordinary acids and carbocyclisation in superacids give cations **82** and **83**, which have identical stability ($\Delta H_f^\circ = 114.9$ and $114.6 \text{ kcal mol}^{-1}$, respectively, calculated by the MINDO/3 method). In other words, the reaction pathway is not determined by thermodynamic factors but is rather due to a lesser contribution of heterocyclisation because of the protonation of the heteroatom in superacids. In the study by Baig *et al.*,³⁹ the effect of the medium was neglected and the structure **84** was ascribed to the ion generated from the alcohol **81** in a superacid. As a matter of fact, this ion has the structure **82**³⁸ (Scheme 3, see Ref. 40).

Scheme 3

The direction of a reaction can be affected not only by the nature of the medium but also by changes in the superacid:substrate ratio. Thus cyclisation of the alcohol **78** in the presence of a large (20:1) excess of a superacid results predominantly in carbocyclisation with the formation of the ion **79**, whereas heterocyclisation resulting in the cation **85** occurs at the $\text{HSO}_3\text{F} : \text{78}$ ratio = 5:1.³⁷

A similar effect of the excess of an acid on the carbo- to heterocyclisation ratio was observed with the diol **86**.⁴¹

(a) $\text{HSO}_3\text{F} : \mathbf{86} = 2.5 : 1$; (b) $\text{HSO}_3\text{F} : \mathbf{86} = 5 : 1$.

In the above examples, the ratio of carbo- and heterocyclisation reactions changed with variations in the excess of an acid as the result of translocation of the cationic centre and the internal nucleophile. The effect of the medium can also be manifested in a different way. By varying medium acidity and excess of acid with respect to the substrate, one can generate structurally different mono- or dications from the same substrate. Thus by conducting the cyclisation of the ketone **14** in acids of various strengths, one can generate allylic ions (pathway *a*) or dications (pathway *b*) at the same temperature.⁶

(a) $\text{HSO}_3\text{F}, \text{SO}_2\text{FCl}$; (b) $\text{HSO}_3\text{F} : \text{SbF}_5 = 1 : 1, \text{SO}_2\text{FCl}, \sim \text{H}, \sim \text{Me}$.

A significant effect can be produced by varying only the excess of an acid relative to the substrate without changing medium acidity and reaction temperature. Thus by varying the excess of an acid in the cyclisation of the ketone **31**, one can generate either the bicyclic carboxonium ion **37** or monocyclic dications with six- or five-membered rings.⁶

(a) $\text{HSO}_3\text{F} : \text{SbF}_5 = 1 : 1, \text{SO}_2\text{FCl}$; (b) $\text{HSO}_3\text{F} : \mathbf{31} = 3 : 1$;
(c) $\text{HSO}_3\text{F} : \mathbf{31} = 8 : 1$.

Probably, the first example of a change in the ratio of the rates for intramolecular rearrangements upon transition from a superacid to ordinary acidic catalysis, which may alter both the stereo-isomeric composition and the structure of reaction products, was described in 1981.⁴² Thus the difference in the optical activities of isolongifolene (**88**) specimens ($[\alpha]_{\text{D}}^{20} = 0^\circ$ and -83°) obtained by isomerisation of longifolene (**87**) in HSO_3F and AcOH can be attributed to the change in the ratio of the rates for intramolecular rearrangements upon transition from a superacid to a degenerate (pathway *a*, racemisation) or non-degenerate acetic acid (pathway *b*, retention of optical activity). On going to a more nucleophilic solvent (AcOH), the degree of solvation of ion **89** increases, while the 'requirement' of the cationic centre formed at C(1) for the σ -bond decreases. As a result, the orientation of the vacant *p*-orbital of the cationic site relative to the σ -orbitals of the migrating groups and atoms changes, which affects the rate of their migration (sp^2 -alignment factor).

(a) HSO_3F ; (b) AcOH .

In the studies by Sorensen *et al.*,³⁴ it was shown that the rearrangements in mono- and polymethylnorbornyl cations formed as intermediate species independently of the medium gave 2-norbornyl ions; their further transformations occurred only by intramolecular pathways. In other cases, the contribution of intermolecular reactions can influence the comparability of rearrangement processes that occur in different media.

The change in the ratio of rates of intermolecular rearrangements of an isocaryofyllene isomer, *viz.*, the diene (**90**) (Scheme 4), has been established.⁴³ In superacids (pathway *a*), the double bond from position 3,4 migrates to position 4,5 faster than from position 8,12 to position 8,9. An opposite ratio is observed in ordinary acids (pathway *b*). This finding cannot be explained by thermodynamic factors as can be seen from the calculation of enthalpies of formation of the final ions and alkenes (hereinafter ΔH_f° and $\Delta\Delta H_f^\circ$ values are expressed in kcal mol^{-1}).

The pathways of neoclovene (**91**) conversions in superacids and ordinary acids differ drastically despite the similar character

Scheme 4

(a) HSO_3F ; (b) $[\text{H}^+]$.

of stabilities of the final ions and alkenes.⁴⁴ Calculations of the enthalpies of formation of ions and alkenes were carried out using the parameters described in Refs 45 and 46. According to NMR spectral data, pathway *b* is predominant in superacids and yields the ion **94**, which is more stable than the ion **93** formed from the ion **92** by pathway *a*. It is still unclear, however, why in sulfuric acid this reaction gives the alkene **95**, which is less stable than the alkene **96** generated by pathway *b*.

(a) H_2SO_4 ; (b) HSO_3F .

In conversions of the intermediate ion **97** in various acidic media, the changes in relative stabilities of carbocations are opposite to those of the corresponding alkenes (NMR data and calculations). In ordinary acids, the direction of these rearrangements is determined by relative stabilities of intermediate alkenes.

As can be seen from ΔH_f° and $\Delta\Delta H_f^\circ$ values, the Sorensen principle of parallelism of relative stabilities of carbocations and the corresponding alkenes³⁴ is violated in this case. It may be assumed that if several alternative pathways of rearrangements resulting in generation of ions with different skeletons (bridged,

open, monocyclic or fused structures) do exist, the trends of changes in relative stabilities of ions and the corresponding alkenes form opposite series. Thus bridged structures can give rise to stable non-classical ions and the corresponding unstable 'anti-Bredt' alkenes. Stable 'Bredt' alkenes corresponding to unstable classical ions are generated from open, monocyclic and fused compounds.

2. The mode of generation of the cationic centre

A difference in the stereochemical results of solvolysis of an acyloxy derivative and of protonation of the corresponding alkene in identical weakly acidic media has been established.^{47,48} According to Brown,⁴⁷ this effect is due to the fact that more 'loose' carbocations formed upon protonation are trapped by the nucleophile prior to complete establishment of an equilibrium between the ions. An alternative hypothesis⁴⁸ rests on the formation of isomeric non-classical (solvolysis) and classical ions (protonation). However, according to literature data, stable carbocations generated upon protonation of alkenes or upon solvolysis of esters (halides) normally yield identical species irrespective of the reaction type (e.g., see Ref. 49).

In a more recent study,⁵⁰ models were selected for the first time in such a way that isomeric stable ions could be generated upon alkene protonation and ester solvolysis. Their formation was confirmed by NMR spectroscopy.

(a) HSO_3F , SO_2FCl , -100°C .

On transition from these model compounds to terpenes, the problem of elucidating the dependence of the main pathway of

cationic rearrangements on the mode of generation of the cationic centre becomes more complicated. First of all, this is due to polyfunctionality and conformational mobility of terpenes. In the following, we will compare the behaviours of an alkene in the protonation and its monoepoxide in the solvolysis. This is of interest for both physical organic chemistry (studies of solvolysis) and terpene chemistry. The opening of epoxides can initiate biomimetic processes.

Two cases should be taken into consideration in comparing the behaviours of an alkene and the corresponding monoepoxide, *viz.*, the coincidence or non-coincidence of the charge localisation sites. However, further rearrangements of the carbocation may occur according to different pathways even in the former case. For example, the conversions of α -humulene (**98**) and its 6,7-epoxide **99**⁵¹ with the identical localisation of the initially formed cationic centre occur by different routes, *viz.*, by concerted, conformationally controlled pathway *a* (epoxide) or by barrier-free conversion of the alkene into the cation **101** (pathway *b*) and then into the ion **102**. The configuration of all the chiral centres in the ion **100** formed by pathway *a* was confirmed by X-ray analysis of the 'quenching' product. The original epoxide **99** seems to have the most stable CT-conformation. Analysis of the ¹³C NMR spectra of compound **99** at -120 to -70 °C revealed the absence of conformational transitions at these low temperatures.

Isocaryophyllene⁴³ and epimeric epoxides **10** and **11**³ derived from it generate different stable ions in superacidic media at all temperatures.

In isocaryophyllene, the energy barriers between individual conformers analogous to those of caryophyllene **1** are rather low, as a result of which it generates only one ion, **103**. The transition to epimeric monoepoxides **10** and **11** is accompanied by stabilisation of individual conformations which further generate enantiomeric ions **12** and **13** (see Section II).

Caryophyllene (**1**)² gives rise to a mixture of carbocations corresponding to the original mixture of conformers (HSO_3F-SO_2FCl , -120 °C). Since diene **1** conformers cannot be isolated in the individual state, the structure of the ion generated from one or another conformation cannot be established experimentally. Epimeric 4,5-monoepoxides **104** and **105**, which may be regarded as 'fixed' conformers, were used to generate one ion each (**106** and **107**) corresponding to those derived from the diene **1**.³

Naturally, the mode of formation of the carbocationic centre is affected by other parameters of cationic rearrangements. Studies with the epoxide **105** have shown³ that a change in temperature alters the position of the cationic centre. This, in turn, changes the composition of the reaction products formed from the monoepoxide **105** at different temperatures and, correspondingly, the pathways of rearrangements in the original diene **1** and its monoepoxide **105** occurring under identical conditions. Obviously, it is the ratio of epoxide **105** conformers that is changed with a change in temperature. As the barriers to the conformational transitions $105a \rightleftharpoons 105b$ and to the reactions of the primary ions are comparable, a change in temperature results in the change in the rearrangement pathways.

The epoxide transformations described above are concerted processes. However, they can be realised only for such relative arrangement of the epoxide ring that is opened and the part of the molecule where hydride and alkyl shifts toward the cationic site formed occur without difficulty. In other cases, non-concerted epoxide conversions may take place. The latter case has been described⁵² where stable ions **110** and **111**, differing in configuration of the carbon atom containing a hydroxy group, were generated in superacids from neoclovene epoxides **108** and **109**. The stereochemical result of this reaction suggests that conversions of epoxides **108** and **109** into the corresponding alcohols **110** and **111** occur in a non-concerted way.

The non-coincidence of pathways of rearrangements of an alkene and the derived epoxide may reflect the differences in the behaviour of mono- and dications with identical skeletons. For example, different stable ions were obtained from neoclovene (**91**) and epimeric epoxides **108** and **109** with identical backbones and identical sites of formation of the cationic centres under the action of a superacid. The epoxide opening generates a dication with charges on the carbon atom and the oxygen atom of the hydroxy group. Spatial separation of the charges is the driving force for the rearrangement of such a dication. It thus follows that a rearrangement of a cyclic alkene and the derived epoxide will yield the same ion only in the case where the rearrangement of an ion generated from the alkene is accompanied by translocation of the positive charge away from the site of proton addition.

The mode of generation of the cationic centre is also reflected in the structure of carbocations generated from dienes and the corresponding hydrogen chloride addition products. Stable isomeric carbocations **66** and **113** were generated from α -murolene **48** and the dichloride **112** with identical backbones and identical position of the cationic centres formed under identical conditions ($\text{SbF}_5\text{--HSO}_3\text{F--SO}_2\text{FCl}$, -120°C).⁵³

As has been noted earlier, isomeric stable ions were obtained upon changes in the mode of their generation.⁵⁰ The difference in the reaction routes was ascribed⁵⁰ to the formation of non-classical ions upon ester solvolysis and of classical ions upon

alkene protonation. However, non-classical ions are formed mainly in reactions of bridged polycyclic systems.⁵⁴ If the conversion of the dichloride **112** into the dication **113** occurs through a scheme involving a 1,5-hydride shift from C(11) to C(1), the quenching product should possess the structure **114a**. If this process involves only 1,2-hydride shifts, the diene formed should have the structure **114b**. It has been established⁵³ that ionisation of the dichloride **112** gives the diene **114b** and, correspondingly, translocation of the positive charge from C(1) to C(11) occurs as consecutive 1,2-hydride shifts.

In the dichloride **112**, elimination of the chlorine anion from C(7) is followed by translocation of the positive charge to C(11) through 1,2-hydride shifts and only after this process has been completed, the second chlorine anion is split off from C(1) giving rise to the dication **113**. Protonation of the diene **48** results in immediate generation of the dication **66** in which translocation of the positive charge through 1,2-hydride shifts from C(1) to C(11) does not occur, since the barriers to transition from a classical tertiary carbocation to a classical secondary isomeric carbocation usually exceed 14 kcal mol^{-1} at -120°C (see Ref. 55). Further translocation of the positive charge from C(1) to C(10) is hampered due to the presence of a cationic centre at C(7).

Thus, depending on the mode of cation generation, the difference in reaction routes can be caused by: (i) intermediate formation of classical and non-classical isomeric ions; (ii) concerted epoxide rearrangement and non-concerted rearrangement upon alkene protonation; (iii) change in the site of formation of the cationic centre; (iv) non-coincidence of pathways of rearrangement of mono- and dications having identical backbones and (v) peculiarities of the spatial structure of the original compounds including the ratios between the conformation barriers and barriers to reactions of the primary ions.

The effect of spatial structure of original compounds, *i.e.*, configuration and the nature of the leaving group, on the direction of a cationic rearrangement can be well illustrated by the following reactions:⁵⁶

3. Cation generation temperature

The temperature at which carbocations are generated is a crucial factor which determines the pathways of multistep cationic rearrangements. It is assumed that ions generated at low temperatures are not converted upon heating into cations that are formed at higher temperatures. In some cases, a change in cation generation temperature influences the position of the cationic

centre. Thus the diene **114b** predominantly generates the ion **115** at $-80\text{ }^{\circ}\text{C}$ and the ion **67** at $-50\text{ }^{\circ}\text{C}$ in $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$:⁵³

A change in the conformational composition of the original diene **114b** does not account for the temperature-dependent generation of allylic ions, since the ^{13}C NMR spectra of this diene in CD_2Cl_2 are not changed in the temperature range from -85 to $+10\text{ }^{\circ}\text{C}$. Rather, a change in temperature may affect the direction (the exo- or the endocyclic double bond) of primary protonation.

A temperature-dependent change in the ratio of protonation rates of two endocyclic double bonds has been described.²³ Thus ions **66** and **49** are generated upon protonation of the diene **48** at $-120\text{ }^{\circ}\text{C}$ in $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$, whereas heating to $-50\text{ }^{\circ}\text{C}$ yields ions **67** and **49** in a $\sim 2.5:1$ ratio. If the ions are generated at $-70\text{ }^{\circ}\text{C}$, the ion **49** is predominantly formed (see Section II). Thus, the ratio of diastereomeric ions can be altered by varying the temperature at which these ions are generated.

The effect of temperature on the ratio of bi- and tricyclic ions formed has been observed.⁵⁷ Thus a mixture of bicyclic (**49**) and tricyclic (**116**) ions is formed from the diene **48** ($\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$, $-30\text{ }^{\circ}\text{C}$) in a $\sim 2:1$ ratio (data from ^1H NMR spectroscopy).

Since the temperature at which ions are generated does not influence the conformational composition of the original diene **48** (the ^{13}C NMR spectra are not changed at temperatures from $-90\text{ }^{\circ}\text{C}$ to $+10\text{ }^{\circ}\text{C}$), it may be supposed that its protonation at -120 to $-70\text{ }^{\circ}\text{C}$ will yield the cation **65a** in the most stable *half-chair-chair* conformation (according to calculations carried out by the MM2 method). 1,2-Hydride shifts in the ion **65a** result in the allylic ion **49**. In the conformation **65c**, the reaction centres are at the shortest distance favourable for transannular cyclisation. The conformation of the ion **65a** is more favourable for transannular cyclisation than that of the ion **65b** as can be judged from

the formation of the ion **116** (in addition to the ion **49**) from γ -murelone (**117**) ($\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$, $-30\text{ }^{\circ}\text{C}$). At $-120\text{ }^{\circ}\text{C}$, the protonation of the diene **117** in $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$ gives the ion **49**;²³ at lower temperatures, it is the monocation **65a** that is exclusively formed due to the greater ease of protonation of the exocyclic double bond. γ -Cadinene (**118**), the isomer with a *trans*-fusion of the rings, does not generate either the ion **116** or any other tricyclic cations in $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$ at $-30\text{ }^{\circ}\text{C}$.

Obviously, the $\Delta H^\ddagger$ value calculated by the MM2 method for the conformational transition **65a** $\rightarrow$ **65c** ($10.9\text{ kcal mol}^{-1}$) significantly exceeds the barriers to 1,2-hydride shifts in the ion **65a** in the conversion of one tertiary ion into another ($< 4\text{ kcal mol}^{-1}$).⁵⁸ This explains the effect of the conformational composition of the ion **65** on the ratio of ions **49** and **116** at -120 to $-70\text{ }^{\circ}\text{C}$. The rise in ion generation temperature (but not in defrosting temperature) favours the conformational transitions **65a** $\rightarrow$ **65c** and increases the contribution of transannular interaction of the carbocationic centre with the double bond, resulting in the initial generation of ions **119** and **120**. Taking into account the difference in ΔH_f° values for these ions ($22.9\text{ kcal mol}^{-1}$) and the short C(3)–C(9) and C(4)–C(9) distances in the conformation **65c**, it may be supposed that the cyclisation of the ion **65c** gives a more stable ion **119**. The latter is further rearranged into the ion **116** according to the schemes⁵⁷ suggested on the basis of estimation of free energies of activation.⁵⁹

According to ^1H NMR spectral data, dissolution of α -copaene (**120**) in $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$ at $-115\text{ }^{\circ}\text{C}$ and subsequent heating to $-30\text{ }^{\circ}\text{C}$ yield a mixture of ions **49** and **116** ($\sim 3:1$). Hydrocarbon **120** is a direct precursor of the ion **119**; which rearranges further into the ion **121**. The observed rearrangement corroborates the pathway proposed for generation of the ion **116**.

An interesting example of the effect of ion generation temperature on the pathway of a cationic rearrangement has been described.⁵⁶

X is fluorosulfonate residue.

The hydroxy group at the C(9) atom in the diol **122** is the first to be eliminated under the action of HSO_3F . Subsequent 1,2- and 1,3-hydride shifts in the cation formed give the ion **123**. The latter is subject either to a 1,2-shift of the methyl group with subsequent elimination of an HX species (its nature is unknown) to give the ion **124** or to elimination of a proton and the HX species⁴ to give ultimately the ion **4**. The ratio of the pathways of ion **123** conversions is determined by the temperature of its generation from the diol **122**. Thus, the ion **124** is predominantly formed at -100°C , while the ion **4** is generated at 20°C .

4. Defrosting temperature

Yet another factor which controls cationic rearrangements is the temperature at which an acidic solution is defrosted.

First, the reaction mixture obtained following treatment with superacids (HSO_3F , $\text{HSO}_3\text{F}-\text{SbF}_5-\text{SO}_2\text{FCl}$ in a solvent or without it) can be heated from -130°C to $+100^\circ\text{C}$. This temperature range allows one to overcome the barriers to ion-to-ion transitions of up to 30 kcal mol^{-1} . Second, these 'hypernon-nucleophilic' media favour profound molecular rearrangements which have no analogues in acid-catalysed reactions. Thus cyclisation of dehydrolinalool (**125**) in 'ordinary' acidic media gives a mixture of compounds **126** and **127**.⁶⁰

In superacids, the rearrangements resulting in the formation of stable ions **128**–**133** are much more diverse.⁶¹

According to literature data,⁶² acid-catalysed cyclisation of isolone (**134**) gives exclusively florione (**135**). Ketone **134** generates the ion **136** in $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$ at -110°C . Heating of the

resulting acidic solution to -10°C yields a mixture of carboxonium ions **137** and **138**.⁶³

(a) $[\text{H}^+]$; (b) HSO_3F , SO_2FCl , -110°C .

The ketone **134** generates the dication **139** ($\text{HSO}_3\text{F}-\text{SbF}_5-\text{SO}_2\text{FCl}$, -90°C); heating to -60°C results in the dication **140**.

Longifolene **87** is predominantly converted into isolongifolene **88b** in acidic media.⁶⁴ Four carbocations (**89** and **141**–**143**) were generated in $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$ by varying the defrosting temperature;⁴² these carbocations were successively interconverted with the rise in temperature.

(a) $[\text{H}^+]$; (b) HSO_3F , SO_2FCl , -120°C .

The effect of defrosting temperature on the structure of carbocations formed has been observed.⁵⁶ It has been shown that ditosylate **144** generates the ion **145** in $\text{HSO}_3\text{F}-\text{SbF}_5-\text{SO}_2\text{FCl}$ at -90°C . Heating of the mixture to -50°C leads to its rearrangement into the ion **146**, which is further isomerised into the ion **4** with the rise in temperature to -20°C .

V. Selection rules

Irrespective of the complex structure of the original substrates, high selectivity of rearrangements of stable ions generated from terpenes is a very important factor which determines their behaviour in superacidic media. This selectivity is provided by a combination of regio- and stereocontrol.

Thus studies of diene **48** conversions in $\text{HSO}_3\text{F}-\text{SbF}_5--\text{SO}_2\text{FCl}$ have shown²³ that at temperatures from -120 to -50 °C all ionic isomerisations occur exclusively as 1,2-hydride shifts and deprotonation-protonation, but not as C–C shifts. Although the theoretically possible protonation–deprotonation reactions and 1,2-hydride shifts in the diene **48** can lead to an extremely complex mixture, this gives rise to a limited number of stable ions that are generated by several relatively short pathways. The selection rules realised in this case can be formulated as follows:

1. Protonation of double bonds and further rearrangements occur predominantly through the formation of both intermediate and final tertiary carbocations; secondary ions are not normally formed.

2. In superacidic media, 1,2-hydride shifts occur more easily than deprotonation reactions, if tertiary and allylic ions are formed.

3. Allylic ions in which all three carbon atoms are incorporated in a single ring and which do not involve two carbon atoms of the bond common to both rings are the most stable.

4. Protonation and deprotonation occur regio- and stereo-selectively. This may be due to both inherent steric hindrances for approaching a protonating reagent or a base (the conformational transitions are strongly hampered at -120 to -50 °C) and stereoelectronic factors in the deprotonation. These peculiarities distinguish the compounds under study from more simple, monocyclic or aliphatic models, *e.g.*, those in which protonation is non-selective as a rule.

The conversions of the dication **66** into the allylic ion **67** described above may occur through stereoselective addition of protons to the double bonds of intermediate dienes. An alternative scheme implies that under kinetically controlled conditions the protonation occurs non-selectively, whereas under thermodynamically controlled conditions the equilibrium between diastereomeric ions is practically completely shifted toward the ion **67**. This suggestion seems unlikely, since diastereomeric ions **49–51** generated separately are stable and are not interconverted under these conditions.²³

VI. Computational methods for predicting the most probable pathways of multistep cationic rearrangements

The 'selection rules' are valid in small groups of related compounds²³ and allow one to predict qualitatively the most probable pathways of multistep carbocationic rearrangements. Several approaches to quantitative estimations have been proposed.¹⁶ An original computer programme 'ICARUS' was used to investigate plausible mechanisms of multistep carbocationic rearrange-

ments.⁶⁵ This programme entails generation of the whole variety of multistep rearrangements of a definite chemical structure and control over realisation of the generated routes. All the cationic rearrangements can be divided into six main groups:

- (1) 1,2-shift of the σ -bond

- (2) addition at the multiple bond

- (3) β -fragmentation

- (4) allylic rearrangement

- (5) β -cyclopropyl–carbinyl rearrangement

- (6) α -cyclopropyl–carbinyl rearrangement

Validation of the pathways proposed by the programme is carried out using an empiric data base on the peculiarities of carbocationic rearrangements. In particular, the ICARUS data base involves the following selection rules:

1. Only the rearrangements occurring as 1,2-shifts of the C–C and C–H bonds fall under investigation; more distant 1,3-, 1,4-shifts, *etc.*, are not analysed.

2. Only intramolecular rearrangements (*i.e.*, those not resulting in degradation of the original structure into two independent species, *e.g.*, proton elimination followed by generation of an alkene) are subject to analysis.

3. Reactions resulting in generation of unstable intermediates (primary cations, structures containing strained small rings, *etc.*) are excluded from consideration. Also excluded are β -fragmentation reactions, since they produce high-energy intermediates: the formation of a double bond significantly increases the enthalpy of the reaction.

4. 1,2-Shifts of the σ -bonds in allylic ions are excluded from consideration.

However, estimation of the probability of such rearrangements on the basis of qualitative speculations alone does not always permit one to rule out improbable mechanisms. Quantitative estimations require calculation of thermodynamic characteristics of the intermediates by molecular mechanical or quantum mechanical methods. The enthalpy of a reaction can be calculated using a set of special force field parameters of the MM2 programme and bond increments for carbocations.⁶⁶ Estimation of the energy barriers demands simultaneous account of thermo-

dynamic and orbital factors, since their separate consideration often gives contradictory predictions. The enthalpies of formation of primary and final ions can be used as a thermodynamic factor. The orbital factor is associated with the value of the dihedral angle between the vacant p -orbital and the neighbouring migrating bond. It was assumed⁵⁹ that in the first approximation the internal barrier to the 1,2-shift (A) of a degenerate rearrangement is connected with the interorbital angle (φ) by equation (1):

$$A = A_0/\cos \varphi, \quad (1)$$

where A_0 is the internal barrier at $\varphi = 0^\circ$.

For a non-degenerate process, the thermodynamic factor was calculated by the Marcus equation (2) (in isoentropic approximation):

$$\Delta G^\ddagger = \left(1 + \frac{\Delta\Delta H}{4}\right)^2 \quad (2)$$

or in its linear Polanyi–Semenov approximation (3):

$$\Delta G^\ddagger = A + b\Delta\Delta H, \quad (3)$$

where $\Delta\Delta H$ is the difference between the ΔH_f° values of the generated and rearranged ions; $b = 0.25$ (for $-4A < \Delta\Delta H < 0$), 0.75 (for $0 < \Delta\Delta H < 4A$), $\Delta G^\ddagger = 0$ (for $\Delta\Delta H < -4A$), $\Delta\Delta H$ (for $\Delta\Delta H > 4A$).

The internal barriers, A_0 , for the orbitally optimum situation of a 1,2-shift were estimated according to Sorensen²⁴ from the values of barriers to 1,2-shifts of the C–C bond and the hydrogen atom in polymethylnorbornyl ions.

Degenerate 1,2-shifts can be estimated from equation (4):

$$A_0 = \Delta G_S^\ddagger \cos \varphi_S, \quad (4)$$

where $\Delta G_S^\ddagger$ is the barrier to the shift according to Sorensen and φ_S is the orbital factor in a norbornyl cation.

Since according to Sorensen's data the difference in the enthalpies of formation of secondary and tertiary isomeric norbornyl cations (in $\Delta\Delta H$) is equal to $5.5 \text{ kcal mol}^{-1}$, non-degenerate processes can be estimated from equation (5):

$$A_0 = (\Delta G_S^\ddagger + 5.5b) \cos \varphi_S. \quad (5)$$

The above equations allow one to predict the most probable pathways for the rearrangements of 1-chlorocaryolane,⁵⁹ clovene (2),² α -copaene (120)⁵⁷ and neoclovene (91)⁴⁴ in superacidic media.

Thus calculations have shown⁴⁴ that the ion 92 generated initially from neoclovene (91) is further converted into a mixture of two carbocations 94 and 147 with an energy gain, $\Delta\Delta H_f^\circ$, -13.0 and $-10.7 \text{ kcal mol}^{-1}$, respectively. This result was confirmed in experiments on protonation of the alkene 91 in $\text{HSO}_3\text{F} - \text{SO}_2\text{FCl}$ at -120°C .⁴⁴

Thus, the relatively simple technique for estimating the barriers to 1,2-shifts for the migrating ion⁵⁹ can efficiently be used for predicting rearrangements in alicyclic carbocations. However, this approach has some drawbacks. For example, the angle φ is not an unambiguous characteristic of the transition state strain. The internal barriers, A_0 , were estimated⁵⁹ on the basis of kinetic data for rearrangements of σ -delocalised 2-norbornyl ions. The choice of such specific models has led to overestimated barriers for open and monocyclic ions.

The correlation ratios (6) and (7) for estimating $\Delta G^\ddagger$ for 1,2-shifts of the hydrogen atom and the methyl group in aliphatic and alicyclic carbocations which actually determine the barrier to a degenerate rearrangement have been proposed.⁶⁷

$$\Delta G_H^\ddagger = 15.33 - 10.79q_{\pi_x} + 0.232 \log K_i, \quad r = 0.986, s = 0.9, n = 8, \quad (6)$$

$$\Delta G_{\text{CH}_3}^\ddagger = 25.74 - 21.48q_{\pi_x} + 0.303 \log K_i, \quad r = 0.995, s = 0.8, n = 7, \quad (7)$$

where q_{π_x} is the value of the Hückel charge on the atom toward which the migrating group is displaced and K_i is the basicity constant of the i th position formed upon migrant detachment.

In this approach, the alkene formed upon elimination of the migrating group from the original cation serves as a model of the transition state of a 1,2-shift. The non-degeneracy of this process can be estimated by the Marcus equation (2). An advantage of this approach is the possibility of indirect estimation of the orbital factor and 'olefin strain',⁶⁸ since both these factors are included in the proton affinity value. However, the correlation ratios (6) and (7) are inapplicable to the Wagner–Meerwein rearrangement; in this case, $\Delta G^\ddagger$ can be determined only as described in Ref. 59.

The use of the above approaches^{59,67} for estimating ΔH_f° and $\Delta G^\ddagger$ has made it possible to propose the most probable pathway for α -cedrene (148) rearrangement in superacids resulting in the ion 149.⁶⁹ The latter could be obtained experimentally (the figures under the structures refer to the $\Delta\Delta H_f^\circ$ values; the figures above the arrows indicate the values of the barrier to 1,2-shift in kcal mol^{-1}).

The primary site at which the cationic centre is formed in the alkene 148 having a trisubstituted double bond leaves no doubt. The primary proton attack in ledene (150) may involve both the double bond and the cyclopropane ring. Estimation of the proton affinity of the double bond and the three-carbon ring by the molecular mechanics method (MMX programme) revealed that the protonation of the double bond is much more preferable (by $3.5 \text{ kcal mol}^{-1}$).⁶⁹ As for the regio- and stereoselectivity of proton addition to the double bond, it has been found⁶⁹ that the protonation of the double bond at the carbon atom containing a

methyl group is more preferable for both α - and β -attack (by 9.2 and 8.3 kcal mol⁻¹, respectively) (MMX).

The isomeric ions **151** and **152** formed ($\Delta H_f^\circ = 157.4$ kcal mol⁻¹) have identical stability. Therefore, the stereodirection of their protonation was established with the use of additional data, viz., analysis of the Dreiding models of the alkene **150**, estimation of stability of epimeric epoxides prepared therefrom and estimation of steric accessibility of the double bond of the alkene **152** by the method described in Ref. 70. These data altogether suggest that the proton attack will occur largely from the α -side to yield the ion **152**.⁶⁹ The use of these approaches permits one to predict the rearrangement into the ion **153** and then into the ion **154** as the most probable pathway for alkene **150** transformations in 'long-living' ions; this conclusion was confirmed by the results of the reaction carried out in HSO₃F–SO₂Cl at –110 °C. The calculations predicted a gain in energy for the conversion of the ion **152** into the ion **154** (10.7 kcal mol⁻¹) (MMX).

It should be noted that neglect of calculation methods in predicting the most probable pathways of multistep carbocation rearrangements may lead to serious misinterpretations of experimental data. Thus analysis of ¹³C NMR data has led to a conclusion that dissolution of the epoxide **155** in HSO₃F–SO₂ at –70 °C yields the ion **158** according to the following scheme:⁷¹

The CH₂ group in the ion **157** undergoes a shift, although it is migration of the Me₂C group that should occur in this type of ions. To overcome this controversy, an alternative scheme has been proposed where the ion **156** is not converted into the ion **157** but

undergoes an unusual for epoxides cleavage of the C–C bond in a three-membered ring.⁷¹ This is followed by a hydride shift to the tertiary carbon atom with generation of the ion **159** and then into the ion **158**.

Later it was shown⁷² that this scheme of epoxide ring cleavage contradicts both the experimental and calculated data. According to the calculations performed by the AM1 method, the ion **156** is converted into the ion **157** (but not into the ion **159**) without a barrier. Further rearrangements of the ion **157** occur predominantly by pathway *a* resulting in the ion **160** ($\Delta H_f^\circ = 145.1$ kcal mol⁻¹) but not by pathway *b* (the ion **161**, $\Delta H_f^\circ = 150.3$ kcal mol⁻¹), which is attributed to the greater stability of the ion **160**.

(a) $\Delta G^\ddagger = 5.9$ kcal mol⁻¹; (b) $\Delta G^\ddagger = 6.5$ kcal mol⁻¹.

In addition, it has been shown⁷² that dissolution of the epoxide **155** in HSO₃F–SO₂Cl at –110 °C and subsequent 'quenching' with methanol yield acetal **162** as the main reaction product. The carboxonium ion **163** generated from the ion **158** by a standard route with a 1,2-shift of the Me₂C group is its immediate precursor.

We can cite another example of an error resulting from disregard of calculation methods. As has been noted above, the structure **84** was ascribed to the ion generated from the alcohol **81**.³⁹ However, quantum-chemical calculations by the MINDO/3 method (AMPAC programme) revealed that the cation **84** was converted into the ion **164** without a barrier. This suggests that the ion **84** could not be regarded as a stable species.

VII. A system of 'blocks' for aliphatic models

The synthesis of complex organic compounds from renewable plant material, particularly from widely accessible aliphatic monoterpenes by cationoid cyclisation acquires increasing importance (see Section VIII). Therefore, prediction of the most probable pathways of these processes becomes especially urgent. Unfortunately, pathways of structure-dependent cyclisation of acyclic compounds cannot be predicted either by quantum chemistry or molecular mechanics methods. By virtue of its 'non-rigid' geometry, the original compound can exist in different, relatively stable and energetically close conformations. Therefore, its cyclisation may occur by several different pathways; their choice is hampered by imperfection of the methods used.

An alternative approach to the experimental proof of the cyclisation schemes consists in fixation of intermediate cations in the rearrangement of aliphatic monoterpenes and establishment of a correlation between their generation and the presence of definite structural 'blocks' in the molecule of the original compound.⁷³

Systematic studies of the behaviour of terpenoids with identical carbon skeletons [e.g., citral (**68**), ionone (**14**) and methyl geranate (**41**)] in superacidic media have made it possible to propose three main pathways of primary cyclisation,^{73,74} viz., proton attack at the terminal double bond resulting in generation of a tertiary carbocation and its subsequent addition to the carbon (pathway *a*) or oxygen atom (pathway *b*); addition of a proton to the oxygen atom and subsequent attack of the cationic centre at the terminal double bond (pathway *c*, Scheme 5).

However, the cyclisation of citral (**68**) and citronellal (**69**), i.e., two aldehydes with identical skeletons, occurs by totally different pathways.²⁹

In some cases, compounds under study contain a common structural block which determines the pathway of cyclisation. This structural block is not necessarily identical with the carbon skeleton commonly used for classification of terpene compounds. For example, cyclisation in $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$ of ϕ -damascone (**165**) and methyl geranate (**41**) having different skeletons and belonging to different classes of organic compounds occurs by a similar route (pathway *a*, Scheme 5).²¹

Studies with *trans*-(**166**) and *cis*-4,8-dimethylnona-3,7-dien-2-ones (**168**) have shown that reactions of isomeric acyclic isoprenoids with a conjugated 3,4-double bond can occur in $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$ in a stereospecific way (pathway *b*, Scheme 5) both in the stage of generation of intermediate ions and the formation of 'quenching' products from acid solutions. Hence, the structural direction and stereochemical result of cyclisation of α,β -unsaturated carbonyl compounds of the terpene series depend on the configuration of the 3,4-double bond.

At first glance, ketones **166** and **168** share a common structural block with compounds **41** and **165** but the pathways of their primary cyclisation are totally different. Comparison of these models allows one to conclude that carbocyclisation requires that the structural fragment, $\text{Me}_2\text{C}=\text{CH}(\text{CH}_2)_2\text{C}(\text{Me})=\text{CHCO}$, was linked with a substituent X able to stabilise the positive charge by a mesomeric effect (OMe, $\text{CH}=\text{CHMe}$); otherwise heterocyclisation will take place.

Substitution of the hydrogen atom for the methyl group at C(4) in the ketone **166** ($\rightarrow$ **169**) changes substantially the pathways of cyclisation of compound **166** (Scheme 5, pathway *b*) and compound **169** (Scheme 5, pathway *c*) due to secondary conversions of the homologous carbocations **167** and **170**.

Varying the conditions of ion generation, particularly the acidity of the medium and temperature, makes it possible to carry out directed multistep rearrangements, *e.g.*, carbo- or heterocyclisation of ketones **166** and **168**.⁷³ In this case, heterocyclisation strongly depends on the configuration of the conjugated 3,4-double bond. Cyclisations of the 'ionone' type are independent of the spatial structure of the original substrate.

It is of note that compound **171** is the main product formed from the ketone **166** in dilute sulfuric acid.⁷³ In this case, the main pathways of cyclisation in superacids and 'ordinary' acids are different, since in the latter case intramolecular rearrangements prevail, which is not the case with superacids.

It was shown^{21,73,74} that many acyclic terpenoids (compounds **14**, **15**, **41**, **165**, **166**, **168**) undergo similar conversions in $\text{SbF}_5 - \text{HSO}_3\text{F} - \text{SO}_2\text{FCl}$ according to the following scheme:

$\text{R} = \text{COCH}=\text{CHMe}, \text{COMe}, \text{CH}=\text{CHCOMe}, \text{COOMe}.$

Electrostatic repulsion of positive charges in the primary dication **172** is the reason for its rearrangement into the dication **173** (from ketones **14** and **15**) or a bridged ion of the type **174** (from the ester **41** and ketones **166** and **168**). Erroneous structures were ascribed to the conversion products of geraniol (**175**) and nerol (**176**) in superacids.^{75,76} We assumed⁷⁷ that rearrangements of

aliphatic alcohols **175** and **176** proceeded in accordance with the above scheme and gave the ion **177** and the ester **178**, since they have a common structural block with compounds **165**, **166** and **168**. This hypothesis was confirmed experimentally.

The type of rearrangements of alcohols **175** and **176** depends on reaction conditions. Thus the cyclic oxonium ion **179** was obtained in $\text{HSO}_3\text{F} - \text{SO}_2\text{FCl}$ at -110°C , while the tetracyclic ion **182** was formed from intermediates **180** and **181** upon heating of the reaction mixture to -90°C . Deprotonation of the ion **182** gives the ether **183**. Such a conversion of a monoterpene into a diterpene has no analogues either among cyclisation reactions of acyclic isoprenoids occurring in superacids or among monoterpene reactions realised in ordinary acidic media.⁷⁸

The outcome of rearrangements of stereoisomeric alcohols **175** and **176** is independent of the configuration of the 2,3-double bond,⁷⁷ while reactions of geranyl (**184**) and neryl acetates (**185**) gave different products. In $\text{HSO}_3\text{F} - \text{SO}_2\text{FCl}$ (-120°C), these compounds are predominantly converted into acyloxonium ions **186** and **187**, respectively. 'Quenching' of acidic solutions of ions **186** and **187** results in diastereomeric hydroxy acetates **188** and **189**.

VIII. Synthetic aspects of terpene reactions in superacidic media

One of the goals of studies of behaviour of terpenoids in superacids is to extend the range of new synthetic substances that can be prepared from accessible natural compounds and their analogues. Structural features of these compounds and the use of superlow temperatures and hypernon-nucleophilic media in the reactions ensure great diversity of molecular rearrangements. In contrast with acid-catalysed processes, the use of superacids allows for: (a) multistep conversions due to hypernon-nucleophilicity of the medium; (b) the possibility to obtain dications, which has no analogues in acid-catalysed reactions; (c) rapid conversion of original substrates into carbocations, which prevents cationic polymerisation due to high acidity; (d) high structural and stereochemical selectivity owing to the use of superlow temperature.

The preparation of 19 stable carbocations (which represent optical isomers) from an optically active diene, *viz.*, (–)- α -murelone (**48**), serves as an illustrative example of synthesis of different compounds from terpenes in superacids.⁵³ The direction of reaction was changed by varying the mode of ion generation (protonation of the diene or solvolysis of the corresponding dichloride), the acidity of the reaction system and the temperature at which ions were generated or ‘defrosted’. Reactions of these ions with nucleophiles gave rise to different dienes, *viz.*, natural terpenes or previously unknown isomers.

The conversions of compounds **14**, **15**, **31**, **32** and **125** considered in this review demonstrate the possibility of synthesis of various compounds through intermediate generation of di- and monocations having identical skeletons.

Conducting reactions in superacidic media provides greater possibilities for varying the structure of reaction products in comparison with ordinary acidic media.^{72, 79} Thus treatment of the epoxide **74** with proton acids usually gives products with retention of a carane skeleton and few compounds with a bicyclo[3.1.0]hexane skeleton.⁸⁰ In $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$ at

-110°C , this epoxide generates a mixture of compounds **190–195**.

Compounds **190–195** have not been previously obtained upon acid-catalysed cleavage of the epoxide **74**. Their formation can be ascribed to the initial opening of the epoxide ring, subsequent rearrangements with cleavage of the cyclopropane ring and stabilisation of cations by virtue of reactions with internal or external nucleophiles or elimination of a proton.

The behaviour of the epoxide **155** in $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$ (-110°C) has been studied.⁷² The three main reaction products were acetal **162** and esters **196** and **197**.

(a) HSO_3F , SO_2FCl , -100°C ; (b) MeOH .

These compounds have also not been isolated earlier upon acid-catalysed cleavage of the epoxide **155**.

6-Methyl-3-(3-methylbut-2-enyl)hept-5-en-2-one **198** does not yield monomeric products under acid-catalysed conditions but is resinified. However, it gives a mixture of compounds **199** and **200** (yield 80%) upon treatment with $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$ (-110°C) with subsequent ‘quenching’.²⁹

(a) HSO_3F , SO_2FCl , -110°C ; (b) MeOH .

As has been noted above, the use of liquid superacidic media allows one to obtain a more complete set of substrate transformation products. If the problem is to prepare a specific compound, it is necessary to choose an appropriate solid catalyst, *e.g.*, a solid superacid. The role of such catalysts may be played by sulfates of transition metal oxides, which, according to literature data, have not been used previously as acid catalysts in terpene reactions. It has been shown⁷⁹ that the use of $\text{TiO}_2/\text{SO}_4^{2-}$ as an acid catalyst in isomerisation of the epoxide **74** allows one to obtain a mixture of reaction products in which the aldehyde **201** and the ketone **202** predominate, which is different from the results obtained with liquid superacids. Earlier, compounds **201** and **202** were considered to be intermediate products in the preparation of the acetal **190** and the ketone **195** in liquid superacids.

The pathways of conversions of conformationally flexible substrates in both liquid and solid superacids can be different. Thus the isomerisation of the epoxide **99** in a liquid superacid ($\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$) differs from that on a solid catalyst ($\text{Al}_2\text{O}_3/\text{SO}_4^{2-}$) and alcohols **203** and **204** are formed, respectively.⁸¹

(a) HSO_3F , $-80\text{ }^\circ\text{C}$; (b) $\text{Al}_2\text{O}_3/\text{SO}_4^{2-}$, $20\text{ }^\circ\text{C}$.

This phenomenon can be explained by the difference in conformational control due to low temperature and epoxide binding on the catalyst surface.

IX. Biogenetic aspects of terpene reactions in superacidic media

The biogenetic aspect is the last to be considered in this review. A question then arises about the relationship between the processes occurring under natural conditions and in superacidic media. According to Nishizawa *et al.*,¹⁸ biomimetic cyclisation of terpene alkenes is a 'stepwise' process which involves intermediate formation of cationic species. Their properties are best studied by modelling the behaviour of carbocationic salts under 'long-life' conditions. Low temperatures favour regio- and chemoselectivity of the reactions and conformational control, whereas hypernon-nucleophilic media are beneficial for more profound conversions. An example of such a conversion is cyclisation of isomanool (**205**) in $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$ ($-110\text{ }^\circ\text{C}$) into tetracyclic compound **73**, which occurs in nine steps.³⁰

The conditions of acid catalysis are much more distant from those of biogenetic reactions because they occur in accordance with the Curtin–Hammett hypothesis, *i.e.*, in the absence of conformational control, and the reactions do not involve profound rearrangements and are often stopped due to interactions with nucleophiles. Thus, superacidic media favour biomimetic reactions 'mimicking' natural processes and provide chemical evidence for practicability of various biogenetic schemes.

Thus it has been shown³⁰ that cyclisation in superacids ($\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$, $-100\text{ }^\circ\text{C}$) of labdane diterpenes **206** and **207** with primary allylic oxygen-containing groups in the side chain can be used for stereoselective syntheses of bifunctional compounds of the isoagatane series of specific structures. The ease of their cyclisation at low temperatures suggests that bicyclic labdanes might be biogenetic precursors of isoagatane compounds. Cyclisation of these compounds in ordinary acids yields a very complex mixture of reaction products in which the content of isoagatanes does not exceed 10%.

A similar mechanism has earlier been proposed for biogenetic cyclisation by Nishizawa *et al.*¹⁸

A key role in biogenetic schemes of sesquiterpenes has been ascribed to the diene **48**, which is considered as a precursor of tricyclic compounds with cubebane, copabornane and copaane skeletons. However, attempts to synthesise tricyclic products from the diene **48** and the alkene **120** by acid-catalysed reactions have failed. In contrast, tricyclic compounds **208** and **209** were obtained in $\text{HSO}_3\text{F}-\text{SO}_2\text{FCl}$.⁵⁷

(a) HSO_3F , SO_2FCl , -30°C ; (b) MeOH ; (c) HSO_3F , SO_2FCl , -110°C .

Wenkert⁸² has hypothesised that tetracyclic diterpenoids with different skeletons are formed from bicyclic diterpenoids according to the following scheme:

However, the attempts at *in vitro* synthesis of tetracyclic diterpenes from tricyclic ones have not met with success.⁸³ Thus treatment of pimaradienes with ordinary acids resulted merely in their isomerisation. It was therefore concluded that in contrast with the Wenkert scheme, pimaradienes are not biogenetic precursors of tetracyclic compounds. However, the use of superacidic media allowed, for the first time, cyclisation of pimaradienes into the tetracyclic compound **211**.⁸⁴ The failure to effect

(a) $[\text{H}^+]$; (b) HSO_3F , SO_2FCl , -100°C .

this cyclisation under conditions of acid catalysis was due to the higher rate of cation deprotonation at C(8) (compound **210**) resulting in the formation of a sterically hindered tetra-substituted double bond in comparison with the rate of cyclisation involving the vinyl group.

The skeleton of compound **211** is similar to that of stemarine **212** isolated recently from a natural source.⁸⁵

It is assumed that the latter is biosynthesised from pimaradienes. The preparation of the same stemarane-type stereoisomers from compounds of the pimaric and isopimaric series that are diastereomeric at the C(13) atom⁸⁴ provides evidence for the practicability of the Wenkert scheme postulating intermediate generation of a non-classical ion.

X. Conclusion

Thus, the main factors that control multistep multiroute cationic molecular rearrangements in superacidic media at superlow temperatures are the following: the nature of the acidic medium, the mode of generation of the cationic centre (solvolysis or proton addition to the alkene double bond), the temperature at which the cationic centre is generated and the temperature at which the acidic solution is 'defrosted'. The most probable pathways of multistep cationic rearrangements can thus be predicted with due regard to the orbital and thermodynamic factors. In practical syntheses of products of multistep cationic rearrangements, preference should be given to solid acidic (particularly superacidic) catalysts rather than to liquid superacids.

III. Complexes with organic derivatives of dicoordinated tellurium	422
IV. Conclusion	431

Abstract. Published data on the synthesis, reactivity and structure of complexes formed in the reactions of organic derivatives of tellurium with metal carbonyls and cyclopentadienyl carbonyls are described systematically and generalised. The bibliography includes 142 references.

I. Introduction

The substantial progress achieved in synthetic organotellurium chemistry has stimulated studies dealing with metal complexes with organotellurium ligands.^{1–11} In recent years, considerable attention has been paid to metal complexes, in particular, complexes of metal carbonyls and cyclopentadienyl carbonyls with organochalcogens, including organotellurium, ligands. Study of these complexes has allowed researchers to elucidate the influence of the nature of donor atoms (sulfur, selenium and tellurium) on the reactivity and structural and spectral features of compounds of the same type containing these atoms. Compounds prepared by the reactions of metal carbonyls with phosphine tellurides^{12–14} and diphenyl ditelluride¹⁵ and of tetracarbonylmanganese complexes with tellurium-containing ligands^{16,17} are convenient precursors of metal tellurides, the synthesis of which can be performed at relatively low temperatures.

This review is concerned with the synthesis, structures and reactivity of complexes formed by metal carbonyls and cyclopentadienyl carbonyls with organotellurium ligands. Various tellurium-containing clusters which contain either telluride (–Te–) or ditelluride (–Te–Te–) bridges have been considered in earlier reviews;^{2–4,18} therefore, we do not dwell on them here.

II. Complexes with organic derivatives of monocoordinated tellurium

This Section contains data on the reactions of metal carbonyls and cyclopentadienyl carbonyls with organic derivatives of monocoordinated tellurium. This type of derivative includes phosphine tellurides $R_3P=Te$ and compounds with $C=Te$ bonds. Since organytellurolate anions RTe^- can also be formally classified as

derivatives of monocoordinated tellurium, this Section also presents data concerning complexes with bridging and terminal RTe groups.

1. Phosphine tellurides

Methods for the synthesis and some reactions of complexes of phosphine tellurides with metal carbonyls and cyclopentadienyl carbonyls have been considered fairly comprehensively in a review.¹⁹ Therefore, here we present only recent data concerning the structure, synthesis and transformations of some of these compounds (Table 1). Spectral characteristics of complexes **1a–c** are listed in Table 2.

Table 1. Some complexes of phosphine tellurides with metal carbonyls and cyclopentadienyl carbonyls.

Initial compounds		Reaction products	Ref.
R ₃ P=Te	Metal complexes		
Bu ₃ P ^t =Te	M(CO) ₆ (M = Cr, Mo, W)	(CO) ₅ M–Te=PBu ₃ ^t (1a–c) ^a (M = Cr (a), Mo (b), W (c))	20

^a With respect to Me₂Te. ^b The chemical shifts for the free ligand are given in parentheses.

According to X-ray diffraction analysis,²⁰ complex **1c** has an octahedral structure, the P–Te bond length being equal to 2.439 Å. Comparison of this value with the lengths of the P = Te bonds in phosphine tellurides, which range from 2.305 to 2.371 Å,^{25–31} shows that the P–Te bond in the complex **1c** is mainly a single bond. This finding was explained²⁰ by assuming that the bipolar ionic structure Bu₃P–Te = M²⁺(CO)₅ makes the predominant contribution to the ground electronic state of the complex **1**.

The structures of clusters **2–5** have been studied by X-ray diffraction analysis. Here we shall briefly describe only the structures of the compounds **2**¹⁴ and **5**¹² closest to compounds that constitute the subject of this review. The molecules of the clusters **2** and **5** contain ditelluride bridges, Te–Te, the tellurium atoms of these bridges being bound to the Co and Mn atoms, respectively. The Te–Te bonds (2.765 Å in the cluster **2** and 2.763 Å in the compound **5**) are somewhat longer than those in diaryl ditellurides [2.697 Å in di(4-methylphenyl) ditelluride,³² 2.702 Å in di(4-chlorophenyl) ditelluride,³³ 2.710 Å in di(4-methoxyphenyl) ditelluride³⁴ and 2.712 Å in diphenyl ditelluride³⁵]. The Co–Te–Te and Mn–Te–Te bond angles (101.7° and 105.5°, respectively) are also somewhat greater than the C–Te–Te angle in diaryl ditellurides [for example, in di(4-methoxyphenyl) ditelluride, this angle is 99.8°]. The coordination polyhe-

dron about the Co atom is a distorted trigonal bipyramid in which the apical positions are occupied by the Et₃P groups; the environment of the Mn atoms is a distorted octahedron with *trans*-arranged phosphine ligands.

According to X-ray diffraction data,^{16,17} the crystal unit cell in the complex BnTeMn(CO)₃(PEt₃)₂ **6a** contains two crystallographically independent molecules, which differ in the conformation of the ethyl groups at the phosphorus atoms. The bond geometry about the manganese atom is a slightly distorted octahedron with *trans*-arrangement of the Et₃P groups. The Mn–Te bond length (2.702 Å) is close to the bond length in the cluster **5** (2.763 Å),¹² and the C–Te bond length is within the range normal for this type of bond.³⁶

2. Tellurocarbonyl compounds

Synthesis and reactions of complexes of metal carbonyls with tellurocarbonyl compounds have been described in detail in a review.¹⁹ Here we present only some examples of these complexes for which X-ray diffraction data have been obtained or chemical reactions have been studied (Tables 3, 4).

The bond lengths in the complex **17**, determined by X-ray diffraction analysis,⁴² point to the presence of a weak coordination bond W–Te, the length of which (2.808 Å) is close to the upper limit of the lengths of single W–Te bonds (2.88 Å).⁴⁶ The C=Te bond length amounts to 1.987 Å, which is close to the length of this bond in S=C=Te (1.904 Å⁴⁷). This indicates that the carbon–tellurium bond in the complex **17** is close to a double bond. The fact that upon heating of the complex **17** in a MeCN solution, the solvent displaces the telluroketone **16c** to give the complex (CO)₅W·MeCN confirms the conclusion that the coordination in this complex is weak.⁴²

The molecular and crystal structures of the complex **19a** were studied by X-ray diffraction analysis.⁴³ The geometry of bonds about the chromium atom corresponds to a distorted octahedron. The C–Te bond length (2.12 Å) falls into the range of lengths typical of single C–Te bonds,³⁶ while the Cr–Te–C bond angle is 96.1°. The Cr–Te bond length (2.765 Å) differs only slightly from

those in other complexes containing chromium and tellurium. The C–Te bond in the complex **19a** is much longer than the carbon–tellurium bond in the compound **17** (1.987 Å), which is due to the predominant contribution of polar resonance structures to the ground state of the molecule.⁴³

3. Organyltelluroate complexes

An important method for the synthesis of the complexes **24**, containing metal carbonyl fragments and organyltelluroate (mainly, aryltelluroate) bridging groups is based on reactions of various metal carbonyls **25** with diaryl ditellurides.^{48–54}

Dodecacarbonyltriiron,^{48–51} dodecacarbonyltriruthenium,⁴⁹ dodecacarbonyldimanganese^{53,54} and hexacarbonylmolybdenum⁵² enter into this reaction. The number of diaryl ditellurides that have been involved in this reaction is quite limited. The use of diphenyl ditelluride,^{49,52–54} bis(pentafluorophenyl) ditelluride^{50,51} and di(4-methoxyphenyl) ditelluride⁴⁸ has been reported.

M _x (CO) _y	[M(CO) _z TeAr] ₂	Ref.
Fe ₃ (CO) ₁₂ (25a)	[Fe(CO) ₅ TeC ₆ F ₅] ₂ (24a)	50, 51
	[Fe(CO) ₅ TePh] ₂ (24b)	49
	[Fe(CO) ₅ TeC ₆ H ₄ OMe-4] ₂ (24c)	48
Ru ₃ (CO) ₁₂ (25b)	[Ru(CO) ₃ TePh] ₂ (24d)	49
Mo(CO) ₆ (25c)	[Mo(CO) ₄ TePh] ₂ (24e)	52
Mn ₂ (CO) ₁₀ (25d)	[Mn(CO) ₄ TePh] ₂ (24f)	53, 54

These reactions occur under relatively mild conditions. Whereas in the case of Fe₃(CO)₁₂ **25a**, the complexes **24a–c** are the only reaction products, the reaction of ruthenium carbonyl **25b** with diphenyl ditelluride yields, depending on the ratio of the reactants, either a mixture of **24d** and [Ru(CO)₂(TePh)₂]_n (*n* = 6, 7, 12) **26** or only the latter compound.⁴⁹ When a molar excess of diphenyl ditelluride is used, only the complex **26** is formed, whereas with a **25b**:Ph₂Te₂ ratio of 3:2, a mixture containing the compound **26** (~90%) and the complex **24d** (~10%) is produced.⁴⁹

Variation of the reaction temperature has a substantial influence on the composition of manganese complexes. Indeed, UV irradiation of a tetrahydrofuran solution of Mn₂(CO)₁₀ **25d** and diphenyl ditelluride at room temperature affords the bis-bridged complex **24f**,⁵³ whereas refluxing of the initial solution yields paramagnetic compound **27**, containing three bridging PhTe groups.⁵³

Unlike other carbonyls, Co₂(CO)₈ reacts with diaryl ditellurides in an atmosphere of CO (pressure 10–100 atm) to give telluroesters.^{55,56} It was assumed⁵⁶ that these reactions yield complexes **28** as intermediates.

Ar = Ph, 4-MeOC₆H₄.

In the case of dialkyl ditellurides, no telluroesters are formed, the corresponding dialkyl tellurides being the only reaction products.⁵⁶

Diaryl tellurides can be used instead of diaryl ditellurides as the sources of bridging ArTe ligands in the preparation of complexes of the type **24**. Thus the complex **24f** is formed when a mixture of manganese carbonyl **25d** and diphenyl telluride is heated under rigorous conditions.⁴⁸

Yet another approach to the synthesis of binuclear manganese complexes of type **24**, containing various bridging ligands TeR [R = Ph, Alk, (Me₃Si)₃Si] is based on the nucleophilic replacement of the bromine atom in bromo(pentacarbonyl)manganese by lithium organyltelluroates.^{17,53} The reaction products **29** formed initially are quite unstable; they eliminate a CO molecule being thus converted into the binuclear complexes **24** in 10%–52% yields.¹⁷ The attempts to stabilise the mononuclear complexes **29** by introducing the bulky tris(trimethylsilyl)silyl group failed.¹⁶

R = Ph (f), Me (g), Et (h), Prⁱ (i), CH₂SiMe₃ (j), (Me₃Si)₃Si (k).

The reductive thermolysis of the complexes **24g, h** carried out by heating them under a hydrogen atmosphere at 300 and 200 °C, respectively, affords films containing manganese telluride in addition to manganese and tellurium.¹⁷

The attempts to convert the complexes **24** into the complexes **6** (*cf.* Section II.1) by substituting triorganylphosphines for the CO groups were unsuccessful.¹⁷ At room temperature, the reaction proceeded very slowly, while at an elevated temperature, it gave a complex mixture of non-identified products.

Nucleophilic substitution of chlorine in iridium complex **30** occurring on treatment of this complex with relatively stable lithium 2,4,6-tris(*tert*-butylphenyl)telluroate has been used to prepare complex **31** the structure of which was studied by X-ray diffraction analysis.⁵⁷

Recently the complex **24g** was synthesised⁵⁸ by virtue of a new tellurium-containing reagent, dimethyl(methyltelluro)tellurium tetrafluoroborate **32** (which was prepared by alkylation of dimethyl ditelluride by trimethyloxonium tetrafluoroborate in acetonitrile). Treatment of a THF solution of the compound **32** with salt **33** gives initially, like the reaction of bromo(pentacarbonyl)manganese with lithium methyltelluroate described

above,¹⁷ the mononuclear complex **29** (R = Me), the existence of which in solution at 0 °C was proved by spectroscopy (IR, ¹H NMR). This product rapidly dimerises with abstraction of CO to give the complex **24g**.

Since the natures of both components can be varied, this reaction can become a convenient method for the synthesis of binuclear complexes of type **24**. The prospects for using the salt **32** and its analogues in preparative organic chemistry are not less important. Sulfonium salts with similar structures containing alkyl and aryl radicals at the disulfide bridge^{59–61} and also dimethyl(phenylseleno)sulfonium tetrafluoroborate⁶² are used in the synthesis of episulfonium salts, S-arylation (alkylation) of alkenes, phenylselenation of aromatic compounds and in other reactions.

Manganese complexes of the type **24** have also been obtained using tellurium-containing anionic compounds **34a,b** (their synthesis is described below).⁶³ Treatment of the salt **34a** with triphenylmethyl tetrafluoroborate gave the complex **24f** in 34% yield. The same complex was isolated in 30% yield together with anionic complex **35** when salt **36a** (M = Te) was made to react with 'pentacarbonyl(bromo)manganese'.⁵⁸

Now we shall briefly describe two other reactions resulting in the formation of complexes with bridging aryltelluroate groups. Thus the compound **24f** has been synthesised by refluxing complexes **37**, prepared by the reaction of octacarbonyldihalomanganes (for details, see Section III.2) with diphenyl ditelluride, in heptane⁶⁴ or benzene.⁵³

Osmium complex **38** (yield 7%) has been obtained, together with non-identified compounds, on treatment of complex **39** with di(4-methoxyphenyl)tellurium dichloride at room temperature.⁶⁵ Thermolysis of the complex **38** (refluxing in octane for 2 h) affords cluster **40** (yields 6%). The mechanism of transformation of the compound **39** into **38** has not been discussed.

The molecular and crystal structures of the complexes **24e**,⁵² **24f**,^{53, 63} and **24g**⁵⁸ have been studied by X-ray diffraction analysis (Fig. 1). The structure of the molecules **24e–g** is a planar rhombus M_2Te_2 , in which the methyl groups occupy *syn*-positions;⁵⁸ the phenyl groups in the complex **24f** occupy *trans*-positions. The most important bond lengths and bond angles in the complexes **24e–g** are presented in Table 5.

The ¹H, ¹³C and ¹²⁵Te NMR spectra of the complex **24g** indicate the presence of two different TeMe groups, which is

Figure 1. Molecular geometry of **24e–g**; **A** is the *syn*-isomer, **B** is the *anti*-isomer.

Table 5. Bond lengths and bond angles in the complexes **24e–g**.⁵⁸

Complex	Bond lengths/ Å		Bond angles/ deg.	
	M–Te	C–Te	M–Te–M	Te–M–Te
[Mo(CO) ₄ TePh] ₂ 24e	2.756	2.133	68.8	111.2
[Mn(CO) ₄ TePh] ₂ 24f	2.661	2.129	95.96	84.04
[Mn(CO) ₄ TeMe] ₂ 24g	2.661	2.183	95.71	83.66

consistent with the finding that two conformers (**A** and **B**, see Fig. 1) exist in solution in a ratio of 4 : 5.¹⁷ The signals of the two TeMe groups in this complex coalesce at 361 K, and those for **24j** coalesce at 343 K, although the ¹²⁵Te NMR spectrum of the latter compound exhibits only one ¹²⁵Te signal. The data of multinuclear NMR spectroscopy for solutions of the complexes **24h,i** also point to the presence of two isomers. Judging by the fact that ¹²⁵Te NMR spectra of the complexes **24f,k** exhibit singlet ¹²⁵Te signals, these complexes exist as a single, more stable, isomer due to fast interconversion of the isomers.¹⁷

The binuclear manganese complex **27**,⁵³ which contains three bridging PhTe groups, has been described above. Recently,^{63, 66} trinuclear complexes containing either five PhTe bridges (**42a**, M = Te) or two PhTe bridges and three PhSe bridges (**42b**, M = Se) have been prepared. The complex **42a** was synthesised by the reaction of cobalt perchlorate hexahydrate with diphenyl ditelluride in the presence of the anionic complex **36a**; the reaction is accompanied by oxidation of Co²⁺ to Co³⁺.⁶³ The mixed selenium-and-tellurium complex was prepared from cobalt perchlorate hexahydrate, diphenyl diselenide and the anionic complexes **36a** and **36b**.⁶⁶ Evidently, the compounds **42a,b** result from rearrangement of the complexes **41a,b** formed intermediately.

M = Te (a), Se (b).

According to X-ray diffraction data,^{63,66} the complexes **42a,b** contain linear chains of atoms Mn–Co–Mn. The Co(III) ion is bound either to five PhTe bridging ligands and a terminal CO group (**42a**) or to two PhTe bridging groups, three PhSe bridging groups and a carbonyl group (**42b**). Thus, the coordination environment of the Co(III) atom in both complexes is a distorted octahedron. One Mn atom in **42a,b** is coordinated to two PhTe bridging ligands and four terminal carbonyl groups; the other manganese atom is linked to three carbonyls and three PhTe (**42a**) or PhSe (**42b**) bridges. Thus, the coordination polyhedron formed about each manganese is also a distorted octahedron. The Te–metal bond lengths in **42a** are the following: Co–Te (Mn–Te) 2.657 Å;⁶² in **42b**, they are 2.576 and 2.654 Å, respectively; the Co–Se bond length is 2.450 Å.⁶⁶

Unlike octacarbonyldihalo-manganese⁶⁴ and -rhenium,⁶⁷ which react with diphenyl ditelluride with retention of the Te–Te bond (for details, see Section III.2), oxidative addition of diaryl ditellurides to the carbonyl chloro iridium complex **43** occurs with rupture of the Te–Te bond and gives complexes **44** containing terminal ArTe ligands. Spectral characteristics of the complexes (shift of the singlet signal in the ³¹P NMR spectrum by ~100 ppm in relation to that in the spectrum of the initial complex **43** and the ¹²⁵Te chemical shifts) are consistent with the structure **44**; however, the exact geometry of these complexes is unknown. During the reaction, a broad EPR signal typical of tellurium-centred radicals was observed; based on this fact, a reaction mechanism was proposed which includes the initial addition of the ditelluride to the Ir(I) complex **43** followed by homolytic cleavage of the Te–Te bond to give the Ir(III) complexes **44**.⁶⁸

Ar = 4-EtOC₆H₄, 4-MeC₆H₄, Ph, 4-ClC₆H₄.

Among other halo carbonyl complexes containing ArTe ligands, rhodium complex **45** should be noted. It was synthesised in a yield of more than 50% by passing CO through a benzene solution of complex **46**.⁶⁹

In addition to the neutral carbonyl and halo carbonyl complexes described above, anionic carbonyl complexes with terminal RTe ligands have been reported. The synthesis of these compounds is based on a reaction typical of diorganyl ditellurides, namely, cleavage of the Te–Te bond by various nucleophiles: organolithium and organomagnesium compounds, alkalis, cyanide anion, *etc.*⁷⁰ When anionic metal carbonyls such as [Mn(CO)₅][–] (see Refs 58, 63) and [HFe(CO)₄][–] (see Refs 71–74) are used as nucleophiles, the reactions with diorganyl ditellurides result in the synthesis of the anionic tellurium-containing complexes **36a**, **47a,b**,^{58,63} and **48**,^{71–74} the yields of the complexes being higher than 90%. The reactions occur under mild conditions (THF, room temperature) at a reactant molar ratio of 1:1. Dimethyl ditelluride reacts with [Mn(CO)₅][–] similarly to diphenyl ditelluride but the reaction occurs more slowly. The formation of an intermediate complex of the type **36b** was judged only by the IR spectra of the reaction mixture; the reaction with dimethyl ditelluride yields the complex **34b** as the final product.⁶³

X = PPN: R = Ph (**36a**), Me (**47a**); X = Na-18-C-6, R = Ph (**47b**).

The complexes **36a**, **47a,b**, and **48** are crystalline compounds, stable in the absence of air and readily soluble in polar solvents.

The molecular and crystal structures of the complexes **47b**⁶³ and **48**⁷² were studied by X-ray diffraction analysis. The crystal lattice of the former compound contains separate [Na⁺ 18-C-6 · 2 THF] cations and *cis*-[Mn(CO)₄(TePh)₂][–] anions. As was to be expected, the manganese ion has an octahedral configuration of bonds; the average Mn–Te bond length is 2.673 Å.

The complex **48**⁷² has a trigonal-bipyramidal configuration of bonds about the Fe atom; the TePh group occupies the axial position. The Fe–Te bond length is 2.630 Å. The Fe–CO_{ax} bond (1.83 Å) is substantially longer than the Fe–CO_{eq} bond (1.73 Å).

The transformation of the compounds **36a** and **47a** on refluxing in a THF solution and the transformation of the complex **47b** at room temperature afford the complexes **34a,b** and **49** in high yields.⁶³

X = PPN: R = Ph (**34a**), Me (**34b**); X = Na-18-C-6, R = Ph (**49**).

According to X-ray diffraction data,⁶³ the crystals of **34a,b** consist of discrete cations and anions with slightly distorted octahedral configurations of bonds about each manganese atom (three bridging RTe ligands and three terminal carbonyl groups). The Mn–Te bond lengths are 2.674 Å in **34a** and 2.688 Å in **34b**.⁶³

It is noteworthy that the Mn–Te bond in the neutral binuclear triply bridged compound **27** (2.638 Å)⁵³ is on the average somewhat shorter than the corresponding bonds in the anionic complexes **34a,b**. The Mn–Te–Mn bond angles (average values) are also appreciably different; in the neutral derivative **27**, this angle (70.9°)⁵³ is much smaller than those in the anionic complexes **34a** and **34b** (82.8° and 81.0°, respectively).⁶³

The complex **36a** is detellurated upon the reaction with iodine⁵⁸ or NOPF₆ in acetonitrile⁶³ to give complexes **50** and *cis*-**51**.

The reaction of the complex **34a** with Ph₃C⁺ BF₄[–] giving rise to the complex **24f**⁶³ and the reaction of the complex **36a** with pentacarbonyl(bromo)manganese giving a mixture of **24f** and **35**⁵⁸ have been described previously.

The anionic iron complex **52**, containing three terminal PhTe groups, is formed in the reaction of the anionic iron carbonyl derivative with two moles of Ph₂Te₂ in THF at room temperature.⁷¹ The reaction rate markedly increases when the amount of Ph₂Te₂ in the reaction mixture increases. The complex **48** is formed as the intermediate compound.

It should be noted that the complex **52** is formed in the reaction of (PPN)[HFe(CO)₃PPh₃] with diphenyl ditelluride instead of the expected complex (PPN)[Fe(CO)₂PPh₃(TePh)₃], *i.e.* in this case, the triphenylphosphine ligand rather than CO is replaced.⁷¹

The crystal structure of the solvate **52** · 0.5THF is formed from separate cations and anions.⁷¹ The coordination polyhedron around the iron atom is a distorted octahedron with a Fe–Te bond length of 2.630 Å.

The complex **48** is a convenient starting compound for the synthesis of both new and known neutral^{72,73} and anionic

tellurium-containing metal carbonyl complexes.⁷⁴ Thus its alkylation with methyl iodide gives rise to an oily telluride complex **53**,^{72,73} while the reaction with HBF₄ affords the binuclear compound **24b**, described above.⁷²

It follows from published data^{71,74} that the complex **48** undergoes oxidative addition to diphenyl ditelluride to give the complex **52**. The reaction of the complex **48** with Ph₂Se₂ follows a similar pattern and gives rise to complex **54**.⁷⁴ Diphenyl disulfide does not react with **48**.

Thus, the ability of diphenyl chalcogenides to enter into oxidative addition reactions with the complex **48** decreases in the sequence Ph₂Te₂ > Ph₂Se₂ > Ph₂S₂ due to the decrease in the nucleophilicity of the chalcogens.

Complex **55**, in which the ratio of PhTe to PhSe groups is the opposite to that in the complex **54**, was prepared by the reaction of the selenium analogue of the complex **48** with diphenyl ditelluride.⁷⁴

The molecular and crystal structures of the complexes **54** and **55** were studied by X-ray diffraction analysis.⁷⁴

The reactions of diaryl ditellurides with metal cyclopentadienyl carbonyls are mostly accompanied by rupture of the Te–Te bonds and give complexes containing terminal or bridging ArTe ligands. Depending on the conditions (temperature, solvent, the presence or absence of UV radiation), the reactions of diaryl ditellurides with molybdenum,^{75–77} chromium⁷⁸ and iron^{79,80} cyclopentadienyl carbonyls give rise to complexes of four types. Under relatively mild conditions (room temperature or short-term refluxing in benzene), mononuclear complexes **56** with terminal ArTe ligands are formed.

Compound 56	<i>n</i>	R	M	Ar	Ref.
a	3	H	Mo	Ph	75
b	3	H	Cr	Ph	78
c	3	Me	Mo	Ph	76
d	2	H	Fe	Ph	79
e	2	H	Fe	4-EtOC ₆ H ₄	80

An X-ray diffraction study showed that the Te–C and Te–Cr bond lengths in the complex **56b** are 2.117 and 2.763 Å, respectively; the C–Te–Cr bond angle is 105.4°.⁷⁸

In some cases, in addition to the complexes **56**, binuclear complexes **57** with bridging ArTe groups were also isolated. They become the major products when the reaction is carried out under more drastic conditions (many-hour heating in toluene at 60 °C or under reflux for chromium and molybdenum complexes or

refluxing in benzene for iron compounds). The complexes **57** can also be obtained on heating or exposure to UV radiation of solutions of the compounds **56**.

The complex **57a** is formed in 50% yield when [CpMo(CO)₂]₂ is made to react with diphenyl ditelluride in toluene at room temperature.⁷⁷

Refluxing of bis(tricarbonylcyclopentadienyl)molybdenum with diphenyl ditelluride in xylene results in the formation of completely decarbonylated complex **58**.⁷⁵ When bis(tricarbonylcyclopentadienyl)chromium reacts with diphenyl ditelluride in toluene at 80 °C, complex [CpCr(TePh)₂]₂Te **59**, containing three telluride bridges, is produced.⁷⁸

It should be noted that the reaction of tricarbonyl(cyclopentadienyl)molybdenum with diphenyl diselenide occurs under milder conditions than that with diphenyl ditelluride.⁷⁵ In this case, the complexes CpMo(CO)₃SePh and [CpMo(SePh)₂]_x were isolated, although judging by the IR spectra, the solution contained the selenium analogue of the complex **57**. The reaction with diphenyl disulfide gave the completely decarbonylated complex of the type **58** as the only product.⁷⁵ Thus, the capability of ArE groups (E = S, Te, Se) of stabilising mono- and binuclear complexes decreases in the series Te > Se > S.⁷⁵ The same series of the stability of complexes as a function of the chalcogen nature holds for iron mononuclear complexes **56**.⁷⁹

Several geometric isomers are possible for the complexes **57a,c**. However, the ¹H NMR spectrum of the complex **57a** contains only one set of signals of cyclopentadienyl protons, indicating that only one isomer is present in the solution.⁷⁵ The binuclear complexes of iron **57d,e** can exist as five geometric isomers (A–E, Fig. 2).

Judging by the ¹H NMR spectra, the complex **57d** exists in solution as a mixture of two isomers; the attempts to separate the mixture into components failed.⁷⁹

Figure 2. Geometric isomers of the complexes **57d,e**. The given nomenclature is proposed in Ref. 80.

In the case of **57e**, crystals of two isomers (**A** and **D**, see Fig. 2) have been isolated in < 5% yields.⁸⁰ The molecular structures of these isomers were studied by X-ray diffraction analysis.⁸⁰ Both isomers contain Fe₂Te₂ rings, which are slightly bent along the axis connecting the iron atoms. The Te–Fe bond lengths (average) are 2.541 Å for isomer **A** and 2.547 Å for isomer **D**; the Fe–Te–Fe angles are 82.88° and 94.16°, respectively. The environments of the iron and tellurium atoms in both isomers are approximately the same. Each iron atom is situated at the centre of a distorted tetrahedron and the tellurium atoms are at a vertex of a trigonal pyramid. The difference between the isomers is that identical substituents (cyclopentadienyl, *p*-ethoxyphenyl, and carbonyl groups) in isomer **A** (Ar = *p*-EtOC₆H₄) occupy *cis*-positions with respect to each other, whereas in isomer **D** (Ar = *p*-EtOC₆H₄), they are *trans*-arranged. According to a proposed nomenclature,⁸⁰ the former compound is defined as the *cis*-I isomer and the latter one is referred to as *trans*-I.

The molecular structures of binuclear molybdenum (**57a**)⁸¹ and chromium (**57b**)⁷⁸ complexes have also been studied by X-ray diffraction analysis.

The structure of the complexes **57a,b** is close to the structure of the corresponding sulfur derivatives. Both compounds incorporate non-planar four-membered M₂Te₂ rings with Mo–Te distances of 2.822 Å and Cr–Te distances of 2.721 Å. The Te–Mo–Te and Mo–Te–Mo bond angles are 70.18° and 97.05°, respectively, and Te–Cr–Te and Cr–Te–Cr, are 70.39° and 98.12°. The Te–Te distance in the complex **57a** is 3.24 Å, while that in **57b** is 3.14 Å. Taking into account the fact that the sum of the van der Waals radii of tellurium atoms is 4.4 Å,⁸² it can be considered that there exist weak bonds between the tellurium atoms in these complexes. In the molybdenum complex **57a**, the phenyl groups, the cyclopentadienyl rings, and the carbonyl groups occupy *trans*-positions with respect to each other.⁸¹

The bond lengths and bond angles in compound **59** (X-ray diffraction data⁷⁸) are listed in Table 6.

Table 6. Average bond lengths and angles in the complex **59**.⁷⁸

Bond	Length/ Å	Bond angle	Size/ deg
Te ² –C	2.15	Cr–Te ¹ –Cr	68.47
Te ³ –C	2.13	Cr–Te ² –Cr	67.06
Te ¹ –Cr	2.609	Cr–Te ³ –Cr	67.34
Te ² –Cr	2.65		
Te ³ –Cr	2.647		

The heteronuclear cyclopentadienyl carbonyl complexes **60** and **61** with bridging PhE ligands (E = S, Se, Te) have been synthesised by the reaction of bis(phenylchalcogeno)niobocenes with nitrosyl carbonyl mercury complexes.⁸³

E = S, Se, Te.

Niobium-and-cobalt-containing complexes **61** were prepared according to the following scheme:

E = S, Se, Te.

The rate of formation of the complexes **60** and **61** increases in the sequence S < Se < Te, which was attributed⁸³ to the increase in the nucleophilicity of chalcogens in the same series.

The complexes **60** and **61** are more stable than the initial cyclopentadienyl derivatives of niobium. They are stable in DMSO solutions under an inert atmosphere but rapidly decompose in air.⁸³

The IR spectra of the complexes **60** exhibit bands at 1610 (NO) and 1840 cm^{–1} (C=O). The complexes **61** are characterised by

two bands, 1850 and 1910 cm^{–1}. The ¹H NMR spectra of the compounds **61** (E = Se, Te)[‡] contain three singlets for the cyclopentadienyl protons, which was explained by *cis*–*trans* isomerism. The ¹H NMR spectra of the complexes **60** exhibit six singlets due to the cyclopentadienyl protons, which correspond to two *cis*- (**60a,b**) and one *trans*-isomer (**60c**).⁸³

Apart from the neutral complexes described above, which contain bridging and terminal RTe groups, several anionic and cationic cyclopentadienyl carbonyl complexes with organyl telluride ligands have been synthesised. Thus anionic complex **62** is formed when paramagnetic monomeric complex **63b**, which occurs in solution in equilibrium with diamagnetic dimer **63a**, is reduced by sodium borohydride.⁸⁴

The coordination polyhedron around the tellurium atom in the complex **62** is a pseudo-tetrahedron, the Mn–Te bond length being 2.556 Å.⁸⁴

Anionic complex **64**, containing a bridging MeTe ligand, is formed in 85% yield when complex **65**⁸⁵ is made to react with methyllithium.^{86, 87}

Oxidation of neutral cyclopentadienyl carbonyl complexes **63a** and **66** by silver hexafluorophosphate has given rise to cationic complexes **67a**⁸⁴ and **67b** (yield 56%).⁸⁸ In the cation **67a**, the tellurium atom forms a pyramidal configuration of bonds; the Mn–Te bond length is 2.513 Å.⁸⁴

R = H, Ar = Ph (**63a**, **67a**); R = Me, Ar = Mes (**66**, **67b**).

Cationic chromium complex **68** has been prepared in a nearly quantitative yield by methylation of the corresponding neutral complex with methyl trifluoromethanesulfonate followed by treatment of the reaction mixture with NH₄PF₆.⁸⁶

[‡] The spectrum of the sulfur analogue could not be recorded due to its low solubility.

III. Complexes with organic derivatives of dicoordinated tellurium

This Section surveys data on the synthesis, structure and reactions of carbonyl and cyclopentadienyl carbonyl complexes of transition metals containing as ligands organic derivatives of dicoordinated tellurium such as diorganyl tellurides R^1TeR^2 , tellurium-containing heterocycles, diorganyl ditellurides $\text{RTe}-\text{TeR}$ and organoelement compounds with $\text{C}-\text{Te}-\text{E}$ and $\text{E}-\text{Te}-\text{E}$ fragments (E is a Group IV or V element). For tellurols RTeH , tellurenyl halides RTeHal and tellurocyanates RTeCN , complexes of this type are unknown.

1. Complexes of diorganyl tellurides

Several types of complexes of metal carbonyls and cyclopentadienyl carbonyls with acyclic (tellurium-containing heterocycles) diorganyl tellurides have been obtained.

Thus heating or UV irradiation of solutions of diorganyl tellurides and hexacarbonyls of Group VI metals [or complexes $(\text{CO})_5\text{M} \cdot \text{THF}$, which can be readily prepared from them] results in the formation of pentacarbonyl complexes **69a**,⁸⁹ **70a,b**⁹⁰ and **69b**.⁹¹

M = Cr, R = 2-Me₂NCH₂C₆H₄ (**a**);

M = W, R = 2,4,4-tris(trimethylsilyl)cyclopenta-2,5-dien-1-yl (**b**).

R = Me (**a**), Ph (**b**).

The structure of the complexes **69a,b** was proved by X-ray diffraction analysis.^{90,91} However, in another study,⁹² the product of reaction between chromium hexacarbonyl and dimethyl telluride was identified as $[\text{Cr}(\text{CO})_5]_2\text{TeMe}_2$ (IR spectroscopy and elemental analysis data).

The results obtained by ¹H NMR spectroscopy indicate that in solutions of the compounds **70a,b** [in C₆D₆ or (CD₃)₂CO], an equilibrium between Te- and N-centered complexes exists, as in the case of metal carbonyl complexes of benzothiazoles and benzoselenazoles.⁹³

When examining the formation of benzotellurazole complexes of the type **70**, one can follow the influence of the nature of the metal carbonyl on the structure of the final product, which has been repeatedly noted for other ligands. Thus the reaction of 2-methylbenzotellurazole with Fe₃(CO)₁₂ in boiling toluene gives rise to a mixture, formed in a low yield (6%–13%), of detellurated complexes **71** and **72** and tellurium-containing cluster **73**.⁹⁴

The reaction of benzoisotellurazole with Fe₃(CO)₁₂ is also accompanied by the destruction of the heterocycle and gives complex **74** and the cluster **73**.⁹⁴

Whereas in **69a,b** and **70a,b** the metal is coordinated only by the tellurium atom, the reaction of tellurophene, possessing heteroaromatic properties, with the chromium acetonitrile complex affords a different type of product, namely, π -complex **75** (yield 80%).⁹⁵ Similar complexes are formed with thiophene and selenophene.⁹⁵

Recently,^{96,97} a new approach to the synthesis of the complexes **69c–e** has been proposed, which is based on the reaction of metal hexacarbonyls with diaryl telluroxides in THF. Presumably,⁹⁷ the reaction occurs *via* a four-membered transition state.

Compound 69	Ar	M	Yield (%)	Ref.
c	4-MeOC ₆ H ₄	Cr	50	96
d	4-MeOC ₆ H ₄	Mo	42	97
e	4-MeOC ₆ H ₄	W	29	97

It should be noted that in the presence of pyridine, chromium hexacarbonyl reacts with di(4-methoxyphenyl) telluroxide to give the corresponding telluride and a complex of pyridine with chromium pentacarbonyl.⁹⁶

The reaction of hexacarbonyls of Group VI metals and iron pentacarbonyl with organoelement oxides R_nEO ($n = 2, 3$; E = Se, Te, As, Sb) is a fairly general process. It has been reported⁹⁶ that the reactions of chromium hexacarbonyl with the oxides obey second-order kinetics and that their relative rates decrease in the sequence $\text{TeO} > \text{SeO} > \text{SbO} > \text{AsO}$. Meanwhile, the least basic compounds among Group V and VI element oxides — triphenylphosphine oxide and diphenyl sulfoxide — do not react with hexacarbonyls of chromium group metals at all. It has been shown⁹⁷ that the rates of reactions of di(4-methoxyphenyl) telluroxide with metal hexacarbonyls $\text{M}(\text{CO})_6$ decrease in the series $\text{W} > \text{Mo} > \text{Cr}$ (the relative rates are 9.4, 4.4 and 1.0, respectively).

It follows from the above data that in order to prepare complexes of the type **69**, metal carbonyls should be made to react with diorganyl tellurides. Diorganyl tellurides can arise as intermediates in the reactions of metal hexacarbonyls with other organotellurium compounds and then react with excess metal hexacarbonyls, present in the reaction mixture, to give complexes of the type **69**. This idea has been confirmed by the synthesis of complexes **76a,b**, containing a dimethyl telluride ligand, from an organic compound containing tetracoordinated tellurium (dimethyltellurium diiodide) and salts **77**.⁹⁸ However, these complexes exist only in solution and rapidly decompose when the solvent is removed *in vacuo*.⁹⁸

M = Co, $n = 4$ (**a**); M = Mn, $n = 5$ (**b**).

The vigorous reaction of octacarbonyldicobalt with dimethyltellurium diiodide affords polymeric complex **78**.⁹⁸ However, the mechanism of this reaction is unknown.

It is of interest that the photoinduced reaction of Me_2TeI_2 with decacarbonyl-dimanganese and -dirhenium affords iodo carbonyls **79** in 60%–80% yields.⁹⁸

M = Mn (**a**), Re (**b**).

The chromium complex **69f** has been synthesised using a specific method for the synthesis of diethyl telluride derivatives, namely, alkylation of anionic complex **80** with triethyloxonium tetrafluoroborate.⁹⁹

Another example in which alkylation has been used to prepare telluride complexes — the synthesis of the complex **53**^{72, 73} — is described in Section II.3. On treatment with iodine, the complex **53** is oxidised to give halo carbonyl complex **81a** (yield 94%), which was characterised by spectroscopy (¹H NMR, ¹³C NMR, IR, UV).⁷³

The diphenyl analogue of the compound **81a** — complex **81b** — has been synthesised from diphenyltellurium diiodide. This complex reacts with $(\text{CO})_5\text{W} \cdot \text{THF}$ to give the diphenyl telluride derivative **69g**.⁷³ The mechanism of formation of this product and the structures of other reaction products have not yet been elucidated.

The molecular and crystal structures of the complexes **69a–c,g** and **70b** were studied by X-ray diffraction analysis. The most important bond lengths and bond angles are listed in Table 7.

The coordination polyhedron about the metal atom in all the studied complexes is a distorted octahedron; the tellurium atom normally has a pyramidal environment. The secondary intramolecular coordination N → Te, occurring in the free ligand, is retained in the structure **69a**.⁸⁹ The N–Te distance (3.096 Å) in **69a** coincides almost completely with the average N–Te distance in the ligand.

In the complex **70b**, formed by a bidentate tellurium-containing heterocycle, 2-phenylbenzotellurazole, with tungsten hexacarbonyl, of the two possible sites of coordination, namely, the ‘hard’ nitrogen atom and the ‘soft’ tellurium atom, it is the latter that is involved in coordination with tungsten, in conformity with the principle of hard and soft acid and bases (see Table 7).¹⁰⁰ In all probability, the complex **70b** is the first structurally characterised

Table 7. Bond lengths and bond angles in the complexes $(\text{CO})_5\text{M} \cdot \text{TeR}_2$.

Com- po- und	M	R	Bond lengths / Å		C–Te–C bond angle / deg	Ref.
			M–Te	C–Te ^a

70b	W		2.809	2.17	78.0	90

^a The average bond lengths and angles are given.

complex of a benzochalcogenazole with chalcogen–metal coordination.

The reactions of binuclear and trinuclear metal carbonyls with diorganyl tellurides give different products, depending on the nature of the substrate. The reaction of $\text{Mn}_2(\text{CO})_{10}$ with diphenyl telluride, accompanied by rupture of the C–Te bond and yielding the complex **24f** with bridging PhTe ligands,⁴⁸ has been described above (see Section II.3). The reaction of the trinuclear complex $\text{Fe}_3(\text{CO})_{12}$ with the same telluride gives complex **82** in a moderate yield (25%).⁴⁸

When dodecacarbonyltriiron is made to react with tellurophene in benzene, a mixture of FeTe, ferrole **83** and complex **84** is formed.¹⁰¹ Based on the mass spectra [molecular ion peak with $m/z = 459$ and peaks due to ions with $m/z = 459 - 28n$ ($n = 0 - 6$)] and the IR spectra (absorption bands for three terminal carbonyl groups in the range 1995–2064 cm^{-1}), a metallocene structure was ascribed to **84**.¹⁰¹ Tetraphenyltellurophene reacts with $\text{Fe}_3(\text{CO})_{12}$ to give complex **85** in a low yield.¹⁰²

According to the data of McWhinnie *et al.*,¹⁰¹ when conditions of the reaction of tellurophene with $\text{Fe}_3(\text{CO})_{12}$ are changed (refluxing in heptane, 2.5 h), this reaction yields ferrole **83** (45%) and FeTe, which appears to arise upon elimination of CO and $\text{Fe}(\text{CO})_5$ molecules from ferrole **83**.

Under the same conditions, dibenzotellurophene is converted into dibenzoferrole in 28% yield, FeTe being formed simultaneously.¹⁰¹

The reaction of telluroindan follows a different route. Refluxing a mixture of telluroindan with $\text{Fe}_3(\text{CO})_{12}$ gives rise to new

complex **86** (yield 15%) and the cluster **73**. The structure of the compound **86** was confirmed by X-ray diffraction analysis.¹⁰¹

The reaction of $\text{Co}_2(\text{CO})_8$ with diphenyl telluride is accompanied by rupture of both C–Te bonds, binuclear complex **87** being the final reaction product.⁴⁸ Heating of a mixture of diethyl telluride, $\text{Co}_2(\text{CO})_8$ and $\text{Fe}_3(\text{CO})_{12}$ affords cluster **88** in 30% yield.¹⁰³

Aryl ethynyl telluride **89** reacts with octacarbonyldicobalt in a different way.¹⁰⁴ The reaction carried out in a 1:1 pentane–toluene mixture at 25 °C gives complex **90** in 45% yield. According to X-ray diffraction data,¹⁰⁴ in this complex, as in other alkynyl complexes, the cobalt atom is coordinated to the multiple-bond carbon atoms rather than to tellurium.

The lengths of the Co–Co, C–C, Ar–Te and C–Te bonds in the complex **90** are 2.465, 1.31, 2.311 and 2.066 Å, respectively.¹⁰⁴

The reaction of nickel carbonyl with diphenyl telluride, unlike the reactions of manganese and cobalt carbonyls, is accompanied by complete dearylation and decarbonylation, tellurium and nickel being the only reaction products.⁴⁸ It is noteworthy that nickel carbonyl reacts with derivatives of tetracoordinated tellurium, ArTeCl_3 and Ar_2TeCl_2 , to give (after hydrolysis of the reaction mixture) carboxylic acids.¹⁰⁵

The structure of complexes resulting from the reaction of the osmium carbonyl cluster **91** with five-membered aromatic heterocycles is determined by the nature of the heteroatom.^{106, 107} Thus when the complex **91** reacts with furan¹⁰⁷ or thiophene,¹⁰⁶ the corresponding hydrido furyl (**92a**) or hydrido thienyl (**92b**) complex is obtained. The complexes **92a, b** have similar spectral characteristics. According to the X-ray diffraction data obtained for **92a**,¹⁰⁷ the heterocyclic fragments in these compounds act as μ, η^1, η^2 -vinylid ligands. The ¹H NMR spectra imply that the thiophene complex **92b** exists in solution at –55 °C as a mixture of *exo*- and *endo*-isomers (ratio 4:1), which undergo fast interconversion at room temperature.¹⁰⁶

The reactions of the complex **91** with selenophene and tellurophene in cyclohexane give rise to complexes **93a, b**.¹⁰⁶ The spectral characteristics of these compounds are close to each other but sharply differ from those of the complexes **92**. The X-ray diffraction data obtained for the selenophene complex **93a** indicate that it has resulted from insertion of the Os atom into the Se–C rather than C–H bond.¹⁰⁶

E = O (**92a**, 46%), S (**92b**, 57%), Se (**93a**, 20%), Te (**93b**, 35%).

Carbonyl-containing complexes of various types are also formed in the reactions of diorganyl tellurides with alkyl and acyl manganese carbonyls and manganese, rhenium, ruthenium, rhodium and iridium halo carbonyls.

The reactions of pentacarbonyl(methyl)manganese **94a** with dialkyl tellurides in THF at room temperature occur in the same way as reactions with other Lewis bases, giving rise to (acetyl)tetra-carbonyl(dialkyl telluride)manganes **95a–c** in yields of more than 80%.¹⁰⁸ The reaction with diisopropyl telluride occurs very slowly; the complex **95c** has not been isolated in an analytically pure state. When dialkyl tellurides are made to react with benzyl(pentacarbonyl)manganese **94b**, the complexes **95d, e** are formed together with substantial amounts of decarbonylated products **96**. Thus the reaction of **94b** with dimethyl telluride affords an unseparable mixture consisting of the initial carbonyl (10%), the complex **95d** (80%) and the corresponding decarbonylated product **96a** (10%). The reaction of **94b** with diethyl telluride in boiling pentane yields the decarbonylated complex **96b** as the only product.¹⁰⁸

Compound	94a	94b	95a	95b	95c	95d	95e	96a	96b
R ¹	Me	Bn	Me	Me	Me	Bn	Bn	Bn	Bn
R ²			Me	Et	Pr ⁱ	Me	Et	Me	Et

¹H and ¹²⁵Te NMR spectra (singlets in the region of 153.0 to 688.6 ppm) and IR spectra indicate that the complexes **95a–e** exist in solutions as single isomers with *cis*-arrangement of the acetyl and dialkyl telluride ligands.¹⁰⁸

The complexes **95a–e** decompose when distilled *in vacuo* (0.5 mm Hg, 40–70 °C), the reaction pathway depending on the nature of the substituent at the tellurium atom.¹⁰⁸

The complexes **95f, g** have been synthesised by the reaction of pentacarbonyl(propionyl)manganese with dialkyl tellurides.¹⁰⁸

The reductive thermolysis of the complexes **95b, c, g** under a hydrogen atmosphere at 200 °C yields films containing manganese and tellurium.¹⁰⁸

The reactions of manganese^{48, 108–111} and rhenium^{111–113} halo carbonyls with dialkyl and diaryl tellurides have been studied. Dimethyl and diethyl tellurides react with bromo(pentacarbonyl)manganese **97a** giving rise to dialkyl telluride complexes **79c,d**, their yields exceeding 80%.¹⁰⁸ The reaction of pentacarbonylchloromanganese **97b** with dibutyl telluride affords the binuclear complex $[(\text{CO})_4\text{MnCl}]_2$.⁴⁸ When the complex **79d** is treated with a second mole of diethyl telluride, it is converted into bis(diethyl telluride) complex **98a**.¹⁰⁸ Compounds of this type are formed as the only products in reactions of diphenyl telluride^{48, 109, 110} and phenoxatellurine⁴⁸ with manganese⁴⁸ and rhenium¹¹¹ halo carbonyls. The complex **98b** also arises in the reaction of pentacarbonylchlororhenium **97c** with dibutyl telluride,¹¹² i.e. the rhenium and manganese compounds react in different ways. Evidently, this implies that the rhenium complexes **98** are more stable than the corresponding manganese analogues. Rhenium bis(dialkyl telluride) complexes **98c,d** were prepared by the reaction of di- μ -chlorobis[tetracarbonyl-rhenium(I)] **99b** with diethyl telluride under drastic conditions¹¹³ and by the reaction of complex **100** with dimethyl telluride at room temperature.¹¹¹

The reaction of the binuclear rhenium complex **99b** with dimethyl telluride¹¹³ gives the complexes **79e**, while the reaction of the similar manganese complex **99a** with dimethyl telluride performed under relatively mild conditions affords the complex **79c**. When carbon monoxide is passed through a toluene solution of the complex **98c** at room temperature, the complex **79f** is produced.¹¹¹

The rhenium complexes **79e,f** are much more stable than the manganese analogues. Thus it has been found¹⁰⁸ that the manganese complex **79c** exists only in solution, the attempted isolation resulting in its complete decomposition.

Study of the dimethyl chalcogenide ligand exchange in the rhenium complexes **98**¹¹¹ shows that the equilibrium in these reactions is shifted towards the formation of complexes containing heavier chalcogen atoms.¹¹¹

A new pathway to the iodo carbonyl complexes **79a,b** is based on the reaction of decacarbonyl-dimanganese and -dirhenium with dimethyltellurium diiodide.⁹⁸ The compounds **79a,b** were isolated by sublimation *in vacuo* at 60 °C. The reactions of other dialkyltellurium dihalides with the manganese and rhenium carbonyls have not been studied.

Passing NO through a benzene solution of the complex **98e** gives the nitrosyl complex **101**, which, however, has not been isolated in an analytically pure state.⁴⁸

The reaction of the manganese complex **98f** with nitrogen-containing ligands results in the replacement of either or both diphenyl telluride ligands, depending on the nature of the reagent used.¹¹⁰

Both Rh(I)- and Rh(III)-containing complexes have been synthesised from rhodium halo carbonyls. Compounds of the former type (**102a–d**) were prepared by the reaction of di- μ -chlorobis[dicarbonylrhodium(I)] **103** with diorganyl tellurides,^{69, 114} including tellurium-containing heterocycles,¹¹⁵ at room temperature in pentane, hexane or toluene. According to IR spectroscopy, after the isolation of the complex with telluroxanthene **102c** (ν_{CO} 1967 cm^{-1}), the mother liquor contains the intermediate dicarbonyl complex **104** (ν_{CO} 2080, 2033 cm^{-1}), which has resulted from cleavage of the chloride bridges in the complex **103** by the tellurium-containing ligand.¹¹⁵

$\text{R} = \text{Et (a), Ph (b)};$

The reactions of $[\text{Rh}(\text{CO})_2\text{Cl}]_2$ with tellurium-containing ligands generally resemble its reactions with triorganylphosphines. However, tellurium-containing ligands, in particular, telluroxanthene and 3,7-dimethyl-*N*-ethylphenotellurazine, are weaker donors than phosphines. Indeed, $\text{Rh}(\text{acac})(\text{CO})_2$ readily reacts with triphenylphosphine at room temperature to give $\text{Rh}(\text{acac})(\text{CO})\text{PPh}_3$ ^{116, 117} but does not react with telluroxanthene even at 80 °C.¹¹⁵ However, telluroxanthene and 3,7-dimethyl-*N*-ethylphenotellurazine replace the alkene ligand in the rhodium complex **105**, giving rise to complexes **106** with *trans*-arrangement of organic ligands.¹¹⁵

The weaker donor properties of diorganyl tellurides compared to those of tertiary phosphines account for the fact that telluride ligands in the complexes **102c,d** and **106** are readily substituted by triphenyl- and tributylphosphines.¹¹⁵

The rhodium carbonyl complexes **102a,b** undergo fast oxidative addition of halogens and thiocyanogen to give octahedral $\text{Rh}(\text{III})$ complexes **107a–c**,¹¹⁴ **107d–f**⁶⁹ and **107g,h**.¹¹⁵

$\text{R} = \text{Et}$: $\text{X} = \text{Cl}$ (**a**), Br (**b**), I (**c**); $\text{R} = \text{Ph}$: $\text{X} = \text{Br}$ (**d**), I (**e**), SCN (**f**);

The complex **107a** was also prepared by the reaction of the diethyl ditelluride complex **102a** with hydrogen chloride;¹¹⁴ **102a** also adds several other reagents to give $\text{Rh}(\text{III})$ complexes **108a,b**.¹¹⁴ It is noteworthy that the diphenyl telluride analogue **102b**, unlike the compound **102a**, does not react with methyl iodide.⁶⁹

$\text{XY} = \text{MeI}$ (**108a**), PhSO_2Cl (**108b**).

The complex **108a** easily reacts with carbon monoxide; the insertion of CO into the $\text{Rh}-\text{Me}$ bond gives rise to a rhodium(III) acyl derivative.¹¹⁴

On passing from the planar rhodium(I) complexes **102** to the octahedral rhodium(III) complexes **107** and **108**, the ν_{CO} value increases by $\sim 100 \text{ cm}^{-1}$.^{69, 114, 115}

The CO stretching vibration frequencies in the spectra of the complexes **102c** ($1956, 1946 \text{ cm}^{-1}$), **102d** (1962 cm^{-1}), and the analogue of **102d** containing phenothiazine as a ligand (1966 cm^{-1})¹¹⁵ indicate that the π -donative transfer of electron density from the central atom to a carbonyl group is less significant in the complex with phenothiazine than in the complexes with telluroxanthene and tellurazine. A similar effect, although less pronounced, noted for diethyl chalcogenide complexes **102**,¹¹⁴ may be due to the enhancement of the σ -donor properties of chalcogen atoms in the series $\text{S} < \text{Se} < \text{Te}$. The substantial increase in ν_{CO} following the transition from the complexes **102c,d** to the phenothiazine complex attests that the $\text{Rh}(\text{I})-\text{S}$ bond is weaker than $\text{Rh}(\text{I})-\text{Te}$.¹¹⁵

The complex **102a** not only enters into oxidative addition reactions but also reacts with tetracyanoethylene and fumaronitrile to give stable 1 : 1 adducts **109** in almost quantitative yields.¹¹⁸ In these complexes, the metal is coordinated to the double bond of the cyanoalkene. Similar complexes with acrylonitrile and cinnamitrile are not formed.¹¹⁸

The rhodium(III) complexes **107** have also been obtained by replacement of one tellurium-containing ligand in complexes **110** by CO, which is attained by passing carbon monoxide through solutions of the complexes **110** in chloroform or toluene.^{69, 119}

Data on halo carbonyl complexes of iridium with diorganyl tellurides can scarcely be found in the literature. The only representative of this class of compound, complex **111**, has been synthesised by the reaction of polymeric iridium chloro carbonyl with diethyl telluride.¹²⁰

Only few representatives of complexes of diorganyl tellurides with iron⁴⁸ and ruthenium^{121, 122} halo carbonyls are known. Iron diphenyl telluride complexes **112** were prepared by substituting diphenyl telluride for one carbonyl group in tetracarbonyldihaloirons. The structure of these products was not specially studied; they were identified by analogy with other complexes.⁴⁸

$\text{X} = \text{Br}, \text{I}$.

A mixed iron carbonyl nitrosyl complex was synthesised in a similar way.⁴⁸

Complexes **113a–d**, containing two telluride ligands, were prepared by the reactions of polymeric ruthenium halo carbonyls with diorganyl tellurides.^{121, 122} These reactions also give small amounts of tritelluride complexes **114a–d**.¹²¹ They were not isolated in a pure state and their existence in solution was confirmed by IR spectra.

$\text{X} = \text{Br}$: $\text{R} = \text{Bu}$ (**a**), Ph (**b**); $\text{X} = \text{I}$: $\text{R} = \text{Bu}$ (**c**), Ph (**d**).

The mixture of the compounds **113e** and **114e**, resulting from the reaction of a CO-saturated alcoholic solution of $\text{RhCl}_3 \cdot \text{H}_2\text{O}$ with Ph_2Te , was successfully separated by fractional crystallisation.¹²¹

The reactions of complexes of the type **113** with halogens lead to the rupture of the Te–Ru bonds, unlike similar reactions of analogous complexes containing nitrogen and phosphorus ligands, in which less active halogens are replaced by more active ones.¹²¹

R = Bu (**c**), Ph (**d**); X = Cl, Br.

Of complexes of metal cyclopentadienyl carbonyls with diorganyl tellurides, compounds of Group V elements, vanadium^{123,124} and niobium,¹²⁵ have been described. These complexes, having the composition $\text{CpM(CO)}_3\text{TeR}_2$ **115**, are prepared by exposure of a solution of tetracarbonyl(cyclopentadienyl)-vanadium or -niobium and a large excess of a diorganyl telluride to UV or visible light. Complexes of the type **115** with other diorganyl chalcogenides have also been synthesised.

Compound 115	M	R ₂ E	Ref.

g	Nb		125
h	Nb		125
i	Nb		125

When other solvents (toluene, heptane) are used instead of THF, the complexes **115g–i** substantially decompose and their yields diminish.¹²⁵ The low thermal stability of dimethyl chalcogenide complexes is the obstacle preventing large-scale preparation of these compounds.¹²⁴ Niobium complexes with tetrahydrochalcogenophenes are the most stable; they have been isolated as individual crystalline compounds. However, they are still fairly sensitive to air both in the crystalline state and especially in solutions.¹²⁵ All complexes of the type **115** tend to decompose in solution to give diorganyl chalcogenides and CpM(CO)_4 .^{124,125} The stability of the diorganyl chalcogenide complexes with the same metal increases in the series S < Se < Te.^{123–125} This stability series was attributed¹²⁵ to the increase in the σ-donor capacity on passing to heavier chalcogens. This is confirmed by IR spectra, which display a decrease in ν_{CO} in the order S > Se > Te both for the vanadium¹²⁴ and niobium¹²⁵ diorganyl chalcogenide complexes **115**.

The reaction of formation of the complexes **115a–c** is reversible, the equilibrium constant increasing in the order S < Se < Te (4.5×10^{-3} , 1.8×10^{-2} and 5.8×10^{-1} , respectively). The dimethyl sulfide ligand in the complex **115a** can be displaced by dimethyl selenide and dimethyl telluride ligands; the equilibrium constants for these reactions are 4.0 and 1.3×10^2 , respectively.¹²⁴

The reactions of tetracarbonyl(cyclopentadienyl)-vanadium and -niobium with diorganyl chalcogenides can occur by either dissociative (pathway *a*) or associative (pathway *b*) mechanism.¹²⁵

Kinetic measurements¹²⁵ indicate that the formation of the niobium complexes **115g–i** occurs according to both mechanisms.

The tetrahydrochalcogenophene ligands in the complexes **115g–i** are easily replaced by various phosphine ligands.¹²⁵ The reaction rate increases in the series Te < Se < S, thus confirming the fact that on passing to heavier chalcogens, the complex stability increases, which has been repeatedly noted above.

R² = Bu, Ph, OPh.

In addition to the neutral complexes of diorganyl tellurides with metal cyclopentadienyl carbonyls **115** described above, cationic cyclopentadienyl carbonyl complexes of iron^{126,127} and molybdenum¹²⁸ and anionic cyclopentadienyl carbonyl complexes of vanadium^{129,130} have been synthesised.

When dimethyl chalcogenides react with cationic complexes **116a–c** under mild conditions, they substitute the THF molecule, which results in the formation of cationic complexes **117a–c**, their yields exceeding 90%.¹²⁶ On UV irradiation of solutions containing the complexes **117a–c** and dimethyl chalcogenides, the latter replace a CO molecule to give cationic monocarbonyl complexes **118a–c** (yields 47%–82%).¹²⁶ The cationic complexes **117a–c** and **118a–c** react with salts containing nucleophilic anions (CN[–], I[–]) to give neutral complexes **119**, **120a–c**, in which X is cyano group or iodine.¹²⁶

E = S (**a**), Se (**b**), Te (**c**); X = CN, M = K; X = I, M = Li;
(a) MX, CH₂Cl₂, ~20 °C, Ar; (b) Me₂E, CH₂Cl₂, *hν*.

Exposure of solutions of the complexes **117a,b** and dimethyl chalcogenides containing a heavier chalcogen to UV radiation leads to the displacement of a CO molecule and the formation of compounds **121**, which incorporate two different dimethyl chalcogenide ligands.¹²⁷

E¹ = S; E² = Se, Te; E¹ = Se, E² = Te.

Treatment of the complex **117c** with organoelement compounds of Group V elements results in the replacement of one or more CO ligands giving rise to compounds **122–124**.¹²⁷

MR₃¹ = PMe₃, P(NMe₂)₃, PPh₃, AsPh₃, SbPh₃; R² = Me, OMe, OPh; X = Ph₂P(CH₂)_nPPh₂.

The molecular and crystal structures of the complex **117c** have been studied by X-ray diffraction analysis.¹³¹ In this compound, the iron atom is linked to two terminal carbonyl groups, one TeMe₂ ligand and one cyclopentadienyl ring, which form a pseudo-octahedral configuration. No tight contacts between the [CpFe(CO)₂TeMe₂]⁺ cations and the BF₄[−] anions were found in the crystals. The Fe–Te distance is 2.533 Å. The dimethyl telluride ligand occupies the *anti*-position in relation to the cyclopentadienyl ring, which minimises steric contacts. The Te–C bond length (2.107 Å) and the C–Te–C bond angle (93.1°) fall within the ranges of these values normal for organic tellurides.

The extended Hückel quantum-chemical calculations¹³¹ for the [CpFe(CO)₂EMe₂]⁺ cations confirmed the conclusion, based on the study of reactions of the cations **117**, that the stability of the Fe–E bond increases in the series S < Se << Te.

A different approach has been used to prepare molybdenum cyclopentadienyl carbonyl complexes **125**.¹²⁸ These monocarbonyl complexes were synthesised in 39%–91% yields by treatment of tricarbonyl(cyclopentadienyl)iodomolybdenum with silver tetrafluoroborate in the presence of the corresponding dimethyl chalcogenides (at a molar ratio of the reactants of 1 : 1 : 1).

Dicarbonyl molybdenum-containing cations **126** were obtained in 86%–93% yields by oxidation of the dimer of dicarbonyl(cyclopentadienyl)molybdenum with ferrocenium tetrafluoroborate in the presence of dimethyl chalcogenides.¹²⁸ These compounds are formed as mixtures of *cis*- and *trans*-isomers the latter being formed in substantially larger amount.¹²⁸

E = S, Se, Te.

Anionic vanadium pentacarbonyl complexes **127**, containing diorganyl chalcogenides as ligands, have been synthesised by ligand exchange, namely, by the replacement of the THF molecule in the anionic complexes of vanadium **128** by diorganyl chalcogenide.^{129, 130}

Compound 127	R ¹	R ²	E	Ref.
a	Ph	Ph	S	130
b	Ph	Ph	Se	129, 130
c	Ph	Ph	Te	129, 130
d	Me	Ph	S	129, 130

Among the synthesised compounds, only the tellurium complex **127c** is stable at room temperature.¹³⁰ The ⁵¹V NMR spectra

of the complexes **127a–c** demonstrate that the metal atom becomes more shielded with an increase in the size of the chalcogen atom. The δ_{51V} values for E = S, Se, Te are −1618, −1658 and −1753 ppm, respectively.¹³⁰

2. Complexes of diorganyl ditellurides

It has been shown in Section II that bi- and trinuclear iron, ruthenium and manganese carbonyls and molybdenum hexacarbonyl react with diaryl ditellurides with cleavage of the Te–Te bond to give complexes containing bridging ArTe ligands. However, when diphenyl ditelluride reacts with chromium and tungsten hexacarbonyls, the Te–Te bond is retained in the resulting complexes.^{15, 132} Depending on the ratio of the substrates, this gives either 1 : 1 (**129**)¹³² or 2 : 1 (**130**)¹⁵ complexes. Complexes of the former type are produced in 40%–60% yields on UV irradiation of tetrahydrofuran solutions of metal hexacarbonyls and diphenyl ditelluride at room temperature.¹³² The use of adducts of metal carbonyls with THF instead of hexacarbonyls makes it possible to prepare the complexes **129** in approximately the same yield without UV irradiation.¹³²

M = Cr (**a**), W (**b**).

The complexes **129a,b** are orange crystalline compounds, stable in air and readily soluble in organic solvents.¹³²

The structures of complexes of both types were studied by X-ray diffraction analysis.¹³² The metal atom is bound only to one tellurium atom; the coordination polyhedron is a slightly distorted octahedron. The Cr–Te and W–Te bond lengths are 2.679 and 2.810 Å, respectively. The complexation has only a slight effect on the Te–Te bond length in the ligand; in the complex **129a**, the length of this bond is 2.737 Å, and in **129b**, it is 2.718 Å (the Te–Te bond length in Ph₂Te₂ is 2.712 Å³²).

The ¹²⁵Te NMR spectra of the complexes **129** exhibit, in conformity with the structure proposed for them, two singlet signals due to ¹²⁵Te nuclei; for the chromium complex **129a**, they occur at 289 and 250 ppm (with respect to Ph₂Te₂), while for the tungsten complex, they are observed at 340 and 34 ppm.¹³² Since the positions and shapes of the ¹²⁵Te signals do not depend on the temperature, no exchange processes occur in solutions. It remains unknown why the difference between the chemical shifts of the two ¹²⁵Te nuclei in the tungsten complex **129b** (Δδ = 306 ppm) is much greater than that in the chromium derivative **129a** (Δδ = 39 ppm).

Heterometallic complexes **130a–c** have been prepared in 40%–55% yields by the reaction of equimolar amounts of **129a–c** with (CO)₅M²·THF.¹⁵

M¹ = M² = Cr (**a**), W (**b**); M¹ = Cr, M² = W (**c**).

The complexes **130a–c** can also be synthesised by UV irradiation of a mixture of metal hexacarbonyls and diphenyl ditelluride (taken in a molar ratio of 2 : 1) followed by evaporation of the reaction mixture *in vacuo*.¹⁵

The compounds **130** form dark lilac crystals, readily soluble in aromatic and chlorinated solvents. They are fairly stable in air but gradually decompose in solutions. In coordinating solvents (acetonitrile, THF), especially in the light or on exposure to UV radiation, they decompose to give the complexes **129**.¹⁵

According to X-ray diffraction data,¹⁵ each metal atom in the complex **130a–c** is linked to one Te atom. The coordination polyhedron is a distorted octahedron. The Cr–Te bond in **130a** (2.656 Å) and the W–Te bond in **130b** (2.779 Å) are somewhat shorter than the corresponding bonds in the complexes **129**. However, the Te–Te bond lengths in the complexes **130a–c** (2.812, 2.808 and 2.828 Å, respectively) are markedly longer than the corresponding bonds in the complexes **129** and diphenyl ditelluride. The C₂Te₂ fragment is planar, the M(CO)₅ groups occupying *trans*-positions with respect to the Te–Te bonds.¹⁵

This molecular geometry implies one signal in the ¹²⁵Te NMR spectrum. For the complex **130b**, δ₁₂₅Te is 417. However, for the complexes **130a,c**, no signals for the ¹²⁵Te nuclei were detected; this was attributed¹⁵ to weakening of the Te–Te bond and its possible dissociation to give paramagnetic monomers. However, no evidence for such a homolytic bond cleavage (which could be provided, *e.g.*, by EPR spectroscopy) is presented in this study.

Thermal decomposition of the complexes **129a,b** and **130a–c** was studied by differential scanning calorimetry.¹⁵ The complexes **129a,b** decompose at 185–192 °C to give inorganic ditellurides CrTe₂ and WTe₂. The binuclear complexes **130a–c** lose the carbonyl and phenyl groups at 180–234 °C to yield, depending on the composition of the initial compound, CrTe, WTe and CrWTe₂.

Metal halo carbonyls, similarly to metal carbonyls, can react with diorganyl ditellurides both with rupture and with retention of the Te–Te bond. The reaction of *trans*-chlorocarbonylbis(triphenylphosphine)iridium **43** with di(4-ethoxyphenyl) ditelluride, accompanied by Te–Te bond rupture and giving the complex **44** with bridging ArTe ligands, was described above (see Section II).⁶⁸ Meanwhile, the reactions of the dimeric rhenium bromo carbonyl **100** (PhMe, room temperature) or pentacarbonyl(halo)manganese **97a,d** (Et₂O, PrⁱO, Δ)⁶⁴ and -rhenium **97e,f** (PrⁱO, Δ)⁶⁷ with Ph₂Te₂ give the binuclear complexes **37a–d** in which the Te–Te bond is retained. The dimeric octacarbonyl halo derivatives Mn₂X₂(CO)₈ are formed as intermediate compounds in the reactions of manganese complexes.⁶⁴ An intermediate with the same composition has been postulated for the reaction involving pentacarbonyl(iodo)rhenium.⁶⁷

M = Mn: X = Br (**37a, 97a**), I (**37b, 97d**);

M = Re: X = Br (**37c, 97e, 100**), I (**37d, 97f**).

The complexes **37a–d** are red or red-brown crystalline compounds. The manganese complexes **37a,b** exist in air in the crystalline state only for several minutes; in solutions, they are fairly unstable thermally and photochemically unlike the rhenium complexes **37c,d**. Thermal decomposition of manganese complexes affords the complexes **24f** with bridging PhTe ligands (see Section II.3).

The molecular and crystal structures of the rhenium complex **37c** were studied by X-ray diffraction analysis.⁶⁷ The geometry of bonds about the rhenium atoms is a pseudo-octahedron, each rhenium atom being bound to three carbonyl groups, one tellurium atom of the ditelluride fragment and two bridging bromine atoms. The average length of the Te–Re bond is 2.760 Å, and the Te–Te bond length is equal to 2.794 Å, which is somewhat longer than this bond in diphenyl ditelluride (2.712 Å).³² The length of the bridging Re–Br bond is 2.642 Å; the Te···Br contact (3.674 Å) is almost 0.5 Å shorter than the sum of the van der Waals radii of the corresponding atoms (3.91 Å) and attests apparently to a weak interaction between them.⁸²

The fact that the IR spectra of the rhenium bromo carbonyl **37c** are similar to those of the iodo carbonyl **37d** suggests that they have similar structures.⁶⁷ The IR spectra of the complexes **37a–d**

and their sulfur and selenium analogues show a regular decrease in the ν_{CO} value following an increase in the atomic mass of the chalcogen. In the opinion of the researchers cited,⁶⁷ this regularity is largely due to the increase in the σ-donor capacity of chalcogens in the series S < Se < Te.

The diphenyl ditelluride ligand in the complexes **37a–d** can be substituted by other ligands under mild conditions. Thus, on dissolution in THF, the diphenyl ditelluride molecule is ejected to be replaced by a THF molecule.^{64,67} However, the adduct of bromo(tricarbonyl)manganese with THF, formed from the manganese complex **37a**, is unstable even at room temperature⁶⁴ and decomposes to give a mixture of non-identified products.

Dissolution of the rhenium complex **37c** and its S and Se analogues results in the equilibrium

E = S, Se, Te.

The equilibrium constants diminish in the series S (3.15) > Se (7.5 × 10^{–2}) > Te (5 × 10^{–4}).⁶⁴

The diphenyl ditelluride ligand in the complexes **37a,b** is replaced relatively easily at room temperature by carbon monoxide.⁶⁴

For the manganese complexes of diphenyl dichalcogenides Mn₂Br₂(CO)₆E₂Ph₂ (E = Se, Te), the rate of this reaction for E = Se is higher than that for E = Te, which reflects the increase in the bond strength in this series.⁶⁴

A ¹³C NMR study of the exchange of diphenyl dichalcogenide ligands in the reaction of rhenium complexes **37** enriched in ¹³C with diphenyl dichalcogenides showed that the strength of the Re–chalcogen bond increases on passing from Se to Te. The ligand containing a heavier chalcogen expels the ligand containing a lighter chalcogen from the complex.

E¹ = S, E² = Se; E¹ = Se, E² = Te.

Complexes of metal cyclopentadienyl carbonyls with diaryl ditellurides are relatively little studied.^{88,133} The dark lilac complex of diphenyl ditelluride with dicarbonyl(cyclopentadienyl)manganese **131** has been prepared in 70% yield by the reaction of tricarbonyl(cyclopentadienyl)manganese with diphenyl ditelluride in heptane on exposure to UV radiation.¹³³ This complex was also obtained by the reaction of diphenyl ditelluride with [CpMn(CO)₂]THF at room temperature.¹³³

The complex **131** is fairly sensitive to air. It is readily soluble in THF, CH₂Cl₂ and in aromatic hydrocarbons and poorly soluble in alkanes. Its solution in THF does not exhibit signals in the EPR spectrum, and a toluene solution produces no signal in the ¹²⁵Te NMR spectrum.¹³³

The complex [MeCp(CO)₂Mn]₂(MesTe)₂ with a similar structure has been synthesised in 33% yield by the reaction of the adduct [MeCp(CO)₂Mn]THF with Mes₂Te.⁸⁸ It follows from X-ray diffraction data¹³³ that each CpMn(CO)₂ fragment in complex **131** is linked to one tellurium atom. The Mn–Te bond length is 2.486 Å. The metal atoms are in the *trans*-positions

relative to the Te–Te bond, the atoms in the Mn–Te–Te–Mn fragment thus formed lying in one plane. The coordination to the metal scarcely influences the Te–C bond length (2.128 Å) but substantially influences the Te–Te bond length, which is equal to 2.884 Å in the complex **131** and 2.712 Å in diphenyl telluride. The Te–Te–C bond angle also considerably changes — it is 88.4° in **131** and 97.4° and 100.3° in free Ph₂Te₂.³² This was interpreted¹³³ as being due to the additional dative interaction of the lone electron pairs of manganese with vacant *d* orbitals of tellurium.

The Te–Te bond in diorganyl ditellurides is retained when they react with the cationic iron complex **116**. The reaction occurs under mild conditions (CH₂Cl₂, ~20 °C) and affords complexes **132a,b** in high yields (85%–98%).¹³⁴ The sulfur and selenium analogues of the complexes **132** were prepared in a similar way in 89%–98% yields.¹³⁴

R = Me (**a**), Ph (**b**).

When diphenyl ditelluride reacts with two equivalents of the salt **116** or when the complex **132b** is treated with one equivalent of **116**, complex **133** is formed in 81% yield. Obviously, in this compound, diphenyl ditelluride acts as a bridging ligand, both its Te atoms being linked to iron atoms.¹³⁴ The sulfur and selenium analogues of **133** were synthesised in a similar way in 84% and 87% yields, respectively.¹³⁴

It should be noted that the complex **133** and its chalcogen analogues react with MeCN to give mixtures of complexes **132b** and **134**.

Diphenyl dichalcogenide complexes of the type **132** behave differently on heating in (CD₃)₂CO. In the sulfur complex, the solvent displaces the disulfide ligand, which leads to complex **135**.¹³⁴

In the case of the selenium analogue, the data of ¹³C NMR spectroscopy indicate the occurrence of a dynamic process, which was interpreted as a 1,2-shift of the CpFe(CO)₂ fragment.¹³⁴

For the tellurium complex **132b**, no splitting of the ¹³C signals of the phenyl groups is observed even at 200 K.¹³¹

3. Complexes of metal carbonyls with compounds with tellurium – element bonds

The formation of complexes from metal carbonyls and compounds containing Te–element bonds can, in principle, involve coordination of the metal atom both to tellurium and to the other element.

The interaction of metal hexacarbonyls with compounds (Me₃E)₂Te (**136**, E = Ge, Sn, Pb) gives rise to complexes **137**, their yields being 17%–45%.^{135, 136} The reactions proceed in THF on exposure to UV radiation.

M = Cr, Mo, W; E = Ge, Sn, Pb.

The complexes **137** are rather sensitive to moisture and atmospheric oxygen. Complexes with similar compositions and structures are formed when Cr, Mo and W hexacarbonyls are made to react with bis-element-substituted sulfides¹³⁷ and selenides.¹³⁵

The reactions of Mn(CO)₅Br and Re(CO)₅Cl with (Me₃Sn)₂E (E = Se, Te) afford binuclear complexes **138a–d**, which contain apparently bridging (Me₃Sn)E ligands.¹³⁸ Unlike the selenium derivatives **138a,b**, which are formed in high yields, the yields of their tellurium analogues **138c,d** are quite low. Thus the manganese complex **138c** was isolated in a yield of only 11%, and the formation of the rhenium derivative **138d** was judged only from the IR spectra of the reaction mixture.¹³⁸

E = Se: M = Mn (**a**), Re (**b**); E = Te: M = Mn (**c**), Re (**d**).

The complexes **138** can be transformed *via* two routes giving either compounds **139** or **140**.¹³⁸ The thermal transformation of **138** into **139** can be accomplished only for selenium-containing derivatives **138a,b**; the tellurium analogue could not be synthesised. On treatment with HCl, the complexes **138a–c** undergo destannylation to give the compounds **140a–c**.

E = Se: M = Mn (**a**, 69%), Re (**b**, 66%); E = Te, M = Mn (**c**, 57%).

The proton signals of the EH groups in the ¹H NMR spectra of the complexes **140a–c** substantially shift upfield on passing from Se to Te. The chemical shifts of the SeH group in the spectra of **140a,b** are –6.20 and –4.13 ppm, respectively, whereas the signal for the TeH group in the spectrum of **140c** occurs at

–12.80 ppm.¹³⁸ For comparison, the chemical shifts of protons of the TeH groups in stable tellurols (Me₃Si)₃ETeH are –5.10 (E = C), –8.82 (E = Si), –9.02 (E = Ge).¹³⁹

Unlike complexes formed by metal carbonyls with compounds containing Te—E bonds with Group IV elements, in which the tellurium atom acts as the coordination site, in the case of complexes in which E is a Group V element, both tellurium and this element can be involved in coordination.

The complexes **141a–c** have been prepared in relatively low yields (14%–27%) by reactions of metal carbonyls with compounds **142a–c** at room temperature.^{140, 141}

$$M = \text{Cr}; E = P(\mathbf{a}), \text{As}(\mathbf{b}); M = \text{Mo}, E = P(\mathbf{c}).$$

The complexes **141a,c** with phosphorus ligands are relatively stable in the light both in the solid state and in solutions in the absence of atmospheric oxygen. The arsenic analogue **141b** decomposes in solution over a period of several days even in the dark and under an inert atmosphere. Based on the spectroscopy data,^{140, 141} it was concluded that in phosphorus complexes, the metal is coordinated only to the P atom, while the arsenic complex exists as two isomers in which the metal is coordinated to either As or Te.

The reaction of the complex **141a** with trimethyltin hydride occurs with rupture of the P–Te bond.¹⁴²

A common drawback of studies describing metal carbonyl complexes with tellurium-containing ligands with Te–element bonds is that no X-ray diffraction data are presented.

IV. Conclusion

In the last 10–15 years, substantial progress has been achieved in the synthesis and study of complexes of metal carbonyls and cyclopentadienyl carbonyls with organic derivatives of tellurium(II). This includes synthesis of the complexes of metal carbonyls and cyclopentadienyl carbonyls with tellurocarbonyl compounds and triorganylphosphine tellurides, the use of organic derivatives of tricoordinated (diaryl telluroxides) and tetracoordinated (σ -telluranes) tellurium for the synthesis of Te(II) complexes and the possibility of thermolytic synthesis of metal tellurides. The reactions of bidentate N,Te-containing organic ligands also present interest; in particular, this refers to the synthesis of the first structurally characterised complex of benzochalcogenazoles with metal–tellurium coordination. It is significant that many types of complexes of organotellurium compounds considered here are more stable than complexes containing structurally related organic compounds of sulfur and selenium.

Further research in this field should be directed apparently along the following lines: (1) systematic studies of complexes with broad variation of the electronic and spatial structures of organotellurium ligands and metal carbonyls; (2) the search for new preparative methods for the synthesis of complexes of Te(II) organic derivatives using various compounds of tricoordinated (telluronium ylides, tellurimides, telluronium salts) and tetracoordinated (organyltellurium trihalides, aryltellurinic acid derivatives) tellurium as well as organyltellurenyl halides, organyl tellurocyanates, and telluroesters; (3) elucidation of the relationship between the structural and spectral characteristics of complexes and the structures of both initial components and elucidation of the influence of the nature of the chalcogen atom on the structure and reactivity of complexes containing similarly constructed organochalcogen ligands; (4) synthesis of complexes with various ambidentate tellurium-containing ligands; (5) pre-

paration of complexes with organotellurium ligands of various types containing bulky organic substituents (Me_3Si)₃E (E = C, Si, Ge) and the use of these complexes as initial compounds for low-temperature synthesis of metal tellurides.

The review was financially supported by the Russian Foundation for Basic Research (Projects No. 96-03-32502a, No. 96-03-32026a) and by the INTAS (Grant 94-4675).

Methods for the synthesis of α,β -unsaturated trifluoromethyl ketones and their use in organic synthesis

V G Nenaidenko, A V Sanin, E S Balenkova

Contents

I. Introduction	437
II. Methods for the synthesis of α,β -unsaturated trifluoromethyl ketones	437
III. The use of α,β -unsaturated trifluoromethyl ketones in organic synthesis	445
IV. Conclusion	456

Abstract. Published data on the methods of synthesis and properties of α,β -unsaturated trifluoromethyl-containing ketones are surveyed and described systematically. Primary attention is devoted to the use of these compounds in organic synthesis as useful building blocks for the preparation of various compounds bearing a trifluoromethyl group. The bibliography includes 133 references.

I. Introduction

Organofluorine chemistry has been vigorously developing during the last two decades. A large number of studies have been devoted to modification of natural products by introduction of a fluorinated or perfluorinated substituent.^{1–3} These fluorinated derivatives often exhibit biological activities; some heterocyclic compounds containing a trifluoromethyl group have already found wide use as medicines (for example, triflazine, trifluorothymidine).⁴ α,β -Unsaturated trifluoromethyl ketones (trifluoromethyl α,β -enones) are fairly convenient building blocks for preparing heterocycles with a trifluoromethyl group. Most of the known approaches to the synthesis of these heterocycles suffer from serious drawbacks, associated either with the fact that the initial compounds are rather difficult to obtain or with the fact that they are fairly toxic and inconvenient to work with.^{1–3} Thus, development of methods for the synthesis and study of properties of trifluoromethyl α,β -enones present substantial interest and have been in the centre of attention of many researchers in recent years.

In this review, we survey methods for the synthesis of α,β -enones with a trifluoromethyl (perfluoroalkyl) substituent at the carbonyl group, because these enones are used in organic synthesis much more often than those containing a CF_3 group at other positions.^{5,6}

II. Methods for the synthesis of α,β -unsaturated trifluoromethyl ketones

Although the first α,β -unsaturated trifluoromethyl ketones were synthesised almost 40 years ago, the vigorous development of the methods for their synthesis has started only in the last decade. As a

rule, they cannot be prepared by the same procedures as non-fluorinated α,β -enones.

Five possible approaches to the construction of the carbon skeleton of trifluoromethyl α,β -enones can formally be proposed. Four approaches are based on the formation of $\text{C}(1)–\text{C}(2)$, $\text{C}(2)–\text{C}(3)$, $\text{C}(3)=\text{C}(4)$ and $\text{C}(4)–\text{R}^3$ bonds and one is based on transformations resulting in the appearance of a carbonyl group.

Analysis of published data shows that the following principal methods for the synthesis of trifluoromethyl α,β -enones exist.

— Trifluoroacetylation (for example, of alkenes, their organometallic derivatives or compounds generating alkenes *in situ*) to give a $\text{C}(2)–\text{C}(3)$ bond.

— Condensation of 1,1,1-trifluoroacetone and its derivatives with aldehydes and the formation of the $\text{C}(3)–\text{C}(4)$ double bond in an elimination reaction.

— Addition to alkynyl ketones (α,β -ynones) or to enones containing a β -substituent capable of being replaced (most often, an alkoxy group), and replacement of one carbonyl group in β -diketones containing a perfluoroalkyl substituent [formation of the $\text{C}(4)–\text{R}^3$ bond]. In this case, examples described in the literature include formation of both $\text{C}–\text{C}$ and $\text{C}–\text{heteroatom}$ bonds.

— Addition of perfluoroalkyl organolithium compounds to esters of acrylic acid to give the $\text{C}(1)–\text{C}(2)$ bond. This method is scarcely documented and has never been used for the preparation of trifluoromethyl α,β -enones. Apparently, this is due to the fact that synthesis of perfluorinated organolithium compounds requires the use of perfluoroalkyl iodides, which are toxic and difficult to work with (especially, trifluoromethyl iodide).³

— Oxidation of allyl alcohols, which are synthesised using perfluorinated or vinylic organometallic compounds, yielding a $\text{C}=\text{O}$ group. This approach also has not found wide use.

Below, we consider all the above methods for the synthesis of α,β -unsaturated trifluoromethyl ketones in the same order.

1. Trifluoroacetylation of alkenes

a. Trifluoroacetylation of electron-rich alkenes by trifluoroacetic anhydride

Trifluoromethyl α,β -enones are formed upon trifluoroacetylation of activated alkenes by trifluoroacetic anhydride (or other derivatives of trifluoroacetic acid) at room temperature or on

V G Nenaidenko, A V Sanin, E S Balenkova Department of Chemistry, Moscow State University, Leninskie Gory, 119899 Moscow, Russian Federation. Fax (7-095) 939 31 81. Tel. (7-095) 939 22 76 (Nenaidenko). E-mail: nen@acylium.chem.msu.ru

Uspekhi Khimii 68 (6) 483–505 (1999); translated by Z P Bobkova

cooling. The reaction is often carried out in the presence of pyridine, which increases the yield.

Y = H, Alk, Ar, SAR; X = O, S, Te, NSO₂R², NCOR³;
R¹, R², R³ = Alk, Ar.

Activated alkenes can be represented by vinyl ethers⁷ (including cyclic ones such as **1**),^{8,9} vinyl sulfides,¹⁰ ketene dithioacetals,¹⁰ vinyl tellurides,¹¹ vinylamides,⁷ cyclic enamines^{12,13} and activated dienes such as 1,1-bis(alkylthio)alka-1,3-dienes **2** or *N*-acetyl-*N*-isopropyl-1-aminobuta-1,3-diene **3**.¹⁴

R = H, Me; n = 1, 2.

R¹ = Alk; R² = H, Et.

Trifluoroacetylation of vinyl ethers, vinylamides and 1,1-bis(alkylthio)alka-1,3-dienes **2** occurs stereospecifically yielding thermodynamically more favourable *E*-isomers of trifluoromethyl α,β-enones. Trifluoroacetylation of vinyl tellurides gives rise to *Z*-isomers, because they are stabilised by an O–Te coordinate bond (X-ray diffraction data¹¹). Vinyl sulfides are trifluoroacetylated non-stereoselectively. According to the ¹H NMR spectra and data on the reaction kinetics,^{15,16} this process follows an addition–elimination mechanism. Trifluoroacetylation of vinyl ethyl ether gives polymers as side products.¹⁶ In the absence of pyridine, the highest yield (59%) was attained when the reaction was carried out in chloroform.

Trifluoroacetylation of cyclic enamines, for example, 1-morpholinocyclopent-1-ene (or 1-morpholinocyclohex-1-ene), affords a complex mixture of products. In the case of less reactive 1-morpholinocyclohept-1-ene, doubly trifluoroacetylated product **4** was isolated.¹²

Enamines **5**, derived from indene, dihydronaphthalene and benzocycloheptene, react ambiguously with trifluoroacetic anhydride. Depending on the structure of the initial enamine, either trifluoromethyl enamino ketones **6** or products of their cyclisation, oxazine derivatives **7**, can be isolated.

X = CH₂, (CH₂)₂, OCH₂; n = 1–3.

The reactions of vinyl ethers with a threefold excess of trifluoroacetic anhydride in the presence of pyridine result in the formation of 3-(alkoxymethylidene)-1,1,1,5,5,5-hexafluoropentane-1,3-diones in high yields.¹⁷

R = Et, Buⁱ.

Orthoacetates, acetals¹⁸ and trithioorthoacetates¹⁹ react with excess trifluoroacetic anhydride with elimination of alkyl or aryl trifluoroacetate (thioacetate) to give trifluoromethyl enones, *i.e.*, they are precursors of the corresponding activated alkenes. It should be noted that only trifluoroacetic and trichloroacetic anhydrides enter into this reaction, whereas acetic anhydride does not.

R¹ = Me, Ph; R² = Me, Et.

b. Trifluoroacetylation of tertiary amines

When trialkylamines are made to react with trifluoroacetic anhydride or trifluoroacetyl halides, β-dialkylamino-substituted trifluoromethyl enones are formed. The reaction of two equivalents of triethylamine with trifluoroacetyl chloride at –30 °C gives rise to 4-diethylamino-1,1,1-trifluorobut-3-en-2-one (in 18% yield based on the initial trifluoroacetyl chloride).²⁰ The reaction mechanism proposed in the study cited²⁰ includes oxidation of triethylamine by one equivalent of trifluoroacetyl chloride to give diethyl(vinyl)amine. Trifluoroacetyl chloride is reduced simultaneously to fluoral. The subsequent interaction of diethyl(vinyl)amine with a second equivalent of trifluoroacetyl chloride results in the formation of the corresponding enamino ketone.

It has been found²¹ that the reaction of triethylamine or ethyldiisopropylamine with an equimolar amount of trifluoroacetic anhydride at 0 °C gives rise to doubly trifluoroacetylated

products **8a,b** (yield $\sim 25\%$), in conformity with the reaction stoichiometry

R = Et (**a**), Prⁱ (**b**).

Cyclic amines react in a similar way. For example, *N*-methylpiperidine is converted into the corresponding enamine **9** in 96% yield (with allowance for the degree of conversion of the starting amine).

Some alkaloids containing tertiary nitrogen atoms enter into similar reactions with trifluoroacetic anhydride. They are oxidised and the resulting enamine fragment is then trifluoroacetylated.²²

c. Trifluoroacetylation of non-activated alkenes

The electrophilicity of trifluoroacetic anhydride and other derivatives of trifluoroacetic acid is insufficient for trifluoroacetylation of non-activated alkenes. The attempts to increase the reactivity of these reagents by complex formation with Lewis acids prove successful only for acylation of aromatic compounds. Unsaturated substrates undergo cationic polymerisation under these conditions. The use of acylium salts for the acylation of unsaturated compounds would permit conducting the reaction at low temperatures and thus diminish the probability of polymerisation and other side processes. Unfortunately, acylium salts with a perfluoroalkyl radical are unstable and decompose with decarbonylation during their attempted synthesis.^{23,24}

A new method for direct electrophilic trifluoroacetylation of non-activated alkenes has been proposed.²⁵ The method is based on the use of trifluoroacetic anhydride in the presence of a complex of dimethyl sulfide with boron trifluoride. This reagent is more electrophilic than trifluoroacetic anhydride, which reacts only with alkenes activated by a heteroatom at the double bond. However, the use of the complex $\text{BF}_3 \cdot \text{SMe}_2$ has a drawback; acylation of an equivalent of an alkene results in the liberation of protonated dimethyl sulfide, which then reacts with at least one more equivalent of the alkene to give sulfonium salt **10**. Consequently, the yield of vinyl trifluoromethyl ketones does not exceed 50%. This reaction proceeds with alkenes able to form benzylic, allylic or tertiary cations (of the type **11**); however, in the last-mentioned case, mixtures of α,β - and β,γ -enones are formed.^{26,27}

(a) $(\text{CF}_3\text{CO})_2\text{O}$, $\text{BF}_3 \cdot \text{SMe}_2$, -60 to -30°C .

Cyclopropyl-substituted alkenes enter into a similar reaction.^{28,29} The reaction of 2-cyclopropylpropene and 1,1-dicyclopropylethene with trifluoroacetic anhydride in the presence of $\text{BF}_3 \cdot \text{SMe}_2$ follows an unusual route and results in cyclopropane ring opening to give sulfonium salts **12**.²⁹ The salts **12**, which are β,γ -unsaturated ketones, rearrange spontaneously into α,β -enones **13** (2 months, $\sim 20^\circ\text{C}$) in a quantitative yield. In the presence of a base (KF, DMF), the sulfonium salts **12** undergo cyclisation in which the dimethylsulfonium group is intramolecularly substituted to give α,β -enones with a cyclopropyl substituent **14**.

R = Me, cyclo- C_3H_5 .

In the presence of the complex $\text{BF}_3 \cdot \text{SMe}_2$, trifluoroacetic anhydride trifluoroacetylates alkynes with a phenyl substituent at the triple bond. The reactions afford sulfonium salts **15** as a result of conjugate addition of the CF_3CO group and dimethyl sulfide to the alkyne molecule.³⁰ The demethylation of these salts upon the reaction with dimethyl sulfide results in the formation of trifluoromethyl α,β -enones **16**. Oxidation of the enones **16** by hydrogen peroxide makes it possible to synthesise unsaturated compounds with two electron-withdrawing substituents at the double bond, namely, sulfonyl and CF_3CO groups.

The reactions of pentafluoronitroacetone **17** with vinyl ethyl ether,³¹ ketene diethyl acetal³² or isobutylene³³ give rise to products similar to those formed upon trifluoroacetylation of alkenes with trifluoroacetic anhydride. The reaction with activated alkenes follows a cycloaddition pathway. Thus the compound **17** and vinyl ethyl ether react at $0-5^\circ\text{C}$ to give oxetane **18**. Opening of the oxetane ring and subsequent thermolysis of the resulting alcohols in the presence of catalytic amounts of K_2CO_3 affords 4-ethoxy-1,1,1-trifluorobut-3-en-2-one **19** (yield 96%). Ketene diethyl acetal enters into a similar reaction with the compound **17** (at -30°C), 4,4-diethoxy-1,1,1-trifluorobut-3-en-2-one being formed in 90% yield.

The reaction of pentafluoronitroacetone **17** with isobutylene yields an alcohol, which eliminates difluoronitromethane to give 4-methyl-1,1,1-trifluoropent-3-en-2-one.

d. Trifluoroacetylation of vinylic and allylic organometallic compounds

Trifluoroacetylated derivatives of non-activated alkenes can be prepared by acylation of vinylic organometallic compounds. The first trifluoromethyl-containing enone, 1,1,1-trifluoro-4-phenylbut-3-en-2-one **20**, was synthesised by the reaction of styrylmagnesium bromide with trifluoroacetic acid in 1959; however, the yield of the product was relatively low.³⁴ The subsequent studies showed that organolithium derivatives are better suited for the synthesis of trifluoromethyl enones; in this case, higher yields of the target products can be attained.³⁵ However, only one example of this type of synthesis is known to date; apparently, this is due to the fact that the corresponding vinyl lithium derivatives are difficult to obtain.

(a) Mg, Et₂O; CF₃COOH (yield 11%);

(b) Li, Et₂O; CF₃CON C_6H_{11} (yield 63%).

Trifluoromethyl α,β -enones can also be prepared from allylic organometallic compounds. For example, the reaction of allylmagnesium bromide with sodium trifluoroacetate gives a mixture of the corresponding α,β - and β,γ -enones (ratio ~1:1) in an overall yield of 37%.³⁶

When lithium diisopropylamide is made to react with *N*-ethylidene-*tert*-butylamine, a heteroallylic anion is formed; subsequent treatment of the anion with ethyl trifluoroacetate gives rise to 4-(*tert*-butylamino)-1,1,1-trifluorobut-3-en-2-one.³⁷

Reactions of other vinylic or allylic organometallic compounds with trifluoroacetic acid or its derivatives have not been studied.

Thus, trifluoroacetylation of alkenes is a convenient method for the synthesis of trifluoromethyl enones; however, it is applicable only to alkenes containing either an activating group (e.g., OR, SR, TeR, NR₂) or, at least, a phenyl, vinyl or

cyclopropyl substituent or two alkyl substituents (trifluoroacetylation in the presence of Me₂S·BF₃).

2. Condensation of 1,1,1-trifluoroacetone and its derivatives; construction of a double bond upon an elimination reaction

The condensation of 1,1,1-trifluoroacetone with aromatic or α,β -unsaturated aldehydes catalysed by the piperidine–acetic acid system in THF makes it possible to prepare trifluoromethyl-containing conjugated enones, dienones and polyenones (retinoids).^{38,39} The reaction is stereospecific and gives *E*-isomers of enones. A drawback of this method is self-condensation of 1,1,1-trifluoroacetone during the reaction; therefore, it should be taken in more than 10-fold excess.

α,β -Unsaturated ketones are often prepared by condensation of β -dicarbonyl compounds with aldehydes and ketones (Knoevenagel condensation). However, β -dicarbonyl compounds containing a perfluoroalkyl substituent enter into this reaction with difficulty. Thus the reaction of aromatic aldehydes with 1,1,1-trifluoroacetylacetone yields a mixture of products resulting from condensation at the methyl and methylene groups in a relatively low yield.⁴⁰ This fact was explained by assuming that the addition of amine, used as the catalyst, to the initial 1,1,1-trifluoroacetylacetone is the predominant reaction route.

The reactions of β -diketones having one or two perfluoroalkyl groups with polyfluorinated aldehydes have also been studied.⁴¹ In the case of β -diketones with one perfluoroalkyl group, the carbonyl group adjacent to the perfluoroalkyl substituent, being more active, participates in the formation of the cyclic intermediate. As a consequence, the elimination of a carboxylate anion gives rise to β -unsaturated ketones with a non-fluorinated substituent at the carbonyl group.

R¹ = CF₃, H(CF₂)_{*n*}; R² = Me, Ph, CF₃, H(CF₂)_{*n*}; R³ = H(CF₂)_{*n*}.

When esters of trifluoroacetic acid are made to condense with aldehydes in the presence of traditional catalysts such as piperidine–AcOH, the target products are formed in fairly low yields.⁴² Recently, it has been proposed to use functionalised silica gel [silica gel treated with (3-aminopropyl)triethoxysilane] as the catalyst with toluene-*p*-sulfonic acid being added subsequently to the reaction mixture. A mixture of *Z*- and *E*-isomers of alkoxy carbonyl-substituted trifluoromethyl α,β -enones was obtained in this way in a good yield.⁴²

$$\text{R}_\text{F}\text{CF}_2\text{COCl} \xrightarrow[0-20^\circ\text{C}, 2\text{ h}]{\text{P(OEt)}_3} \left[\text{R}_\text{F}\text{CF}_2\text{C}(\text{O})(\text{OEt})\text{P(OEt)}_2 \right] \xrightarrow{\text{P(OEt)}_3}$$

$$\rightarrow \text{R}_\text{F}\text{C}(\text{F})=\text{C}(\text{OP(O)(OEt)}_2)\text{P(O)(OEt)}_2 \xrightarrow[2. \text{NH}_4\text{Cl (sat.)}]{1. \text{BuLi, CuI, THF}} \xrightarrow[-78^\circ\text{C}, 15\text{ min}]{} \text{R}_\text{F}\text{C}(\text{F})=\text{C}(\text{H})\text{P(O)(OEt)}_2 \xrightarrow[20^\circ\text{C}, 2\text{ h}]{\text{MeNH}_2} \text{R}_\text{F}\text{C}(\text{NMe})=\text{C}(\text{H})\text{P(O)(OEt)}_2 \xrightarrow[2. \text{RCHO}]{1. \text{B}} \text{R}_\text{F}\text{C}(\text{NMe})=\text{C}(\text{H})\text{CH}=\text{CH}\text{R} \xrightarrow{\text{H}_3\text{O}^+} \text{R}_\text{F}\text{COCH}=\text{CH}\text{R}$$

β -Iminophosphonate anions can also be obtained from diethyl alkylphosphonates and trifluoroacetimidoyl chloride. The synthesis is carried out as a one-pot procedure; first, diethyl alkylphosphonates are treated with two equivalents of lithium diisopropylamide and then with trifluoroacetimidoyl chloride; after that, the required aldehyde is added to the resulting β -iminophosphonate anion.⁴⁴

A method for the synthesis of substituted trifluoromethyl dienyl ketones with a particular configuration at the double bond has been reported.⁴⁵ Thus sulfoxides **22** were prepared from 1-trifluoromethyl-2-phenylthioacetylene *via* a four-stage procedure (Claisen rearrangement is the key stage of the process). Subsequent elimination of sulfinic acid from the sulfoxides **22** gave trifluoromethyl dienyl ketones **23** and **24** in high yields.

Alkynyl trifluoromethyl ketones are easily available compounds, readily formed upon acylation of lithium or magnesium acetylides (Iotsitch reagents) with trifluoroacetic acid or its derivatives.^{46–50} The best yields were attained in the reaction of lithium acetylides with ethyl trifluoroacetate in the presence of boron trifluoride etherate.⁵⁰

A method for the synthesis of trifluoromethyl α,β -enones is based on 1,4-addition of dialkylcuprates to acetylenic ketones. This reaction is highly regioselective but it is not stereoselective and gives products in moderate yields.^{50, 51}

The use of cyanocuprates results in higher yields and in a nearly 100% regioselectivity of the reaction. However, in some cases (for example, in the case of 1,1,1-trifluoro-4-phenylbut-3-yn-2-one), cyanohydrins are produced.⁵¹

The reactions of alkynyl trifluoromethyl ketones with aromatic amines afford β -amino-substituted trifluoromethyl enones in good yields.⁵²

R = Alk, Ar.

Alkynyl trifluoromethyl ketones can act as dienophiles in the Diels–Alder reaction. 1,1,1-Trifluoro-4-phenylbut-3-yn-2-one reacts with cyclopentadiene to give bicyclic trifluoromethyl enone **25**, a norbornadiene derivative, which undergoes a reversible rearrangement to give compound **26** of the quadricyclane series.⁵³

4. Addition to enones containing a replaceable group in the β -position

A method for the synthesis of trifluoromethyl enones based on the reactions of various zinc dialkyl- and diaryl-cuprates with β -trifluoroacetylvinyl tellurides has been proposed.⁵⁴

R¹ = Buⁿ, Buⁱ, Ph; R² = Ar, Alk; X = (CN)(ZnCl)₂, ZnCl.

However, in the case of zinc dialkylcuprates, the reaction is accompanied by side formation of the double addition products, Alk₂CHCH₂COCF₃, in 11%–19% yields. The necessity of using organotellurium compounds is also an obvious drawback of this method.

A new procedure for the synthesis of trifluoromethyl enones from β -trifluoroacetylvinyl sulfones **27** has been reported quite recently. The compounds **27** are formed as stable diols upon oxidation of trifluoroacetylated vinyl sulfides.⁵⁵

Thus β -trifluoroacetylvinyl sulfone **27** (R = Ph) reacts with electron-rich aromatic compounds (furans, indoles and pyrroles) to liberate sulfinic acid and to give aryl- and hetaryl-substituted trifluoromethyl α,β -enones.⁵⁵ The reaction is stereospecific yielding *E*-isomers of the enones.

R = Me, Ph.

β -Alkoxy-substituted trifluoromethyl enones (most often, 4-ethoxy-1,1,1-trifluorobut-3-en-2-one) are used as the starting compounds in a large number of syntheses. These compounds can be readily prepared by trifluoroacetylation of vinyl ethers.⁵⁶ Several studies consider the reactions of the enone **19** with diverse nucleophiles — electron-rich aromatic compounds, organometallic and organoboron compounds and amines. This reaction in the presence of zinc chloride can be carried out only for reactive aromatic compounds such as indoles, pyrroles^{57,58} and *N,N*-dimethylaniline.⁵⁷

X = , , 4-Me₂NC₆H₄; R¹ = H, Me, Ph;

R² = H, Me.

Less reactive compounds such as anisole do not enter into this reaction, and the use of other Lewis acids (BF₃ or TiCl₄) results in resinification.⁵⁷ The reactions of the enone **19** with other heterocyclic compounds such as furan, 2-methylfuran and thiophene under the same conditions do not lead to the desired result either.⁵⁸

The reaction of 3-ethoxymethylidene-1,1,1,5,5,5-hexafluoropentane-1,3-dione with indoles and pyrroles occurs faster and gives products in higher yields.⁵⁸

R = , .

The enone **19** reacts with quaternary salts derived from nitrogenous heterocycles to give dienones — δ -trifluoromethylbutadienylmerocyanines **28** or **29**.⁵⁹

Z = S, Me₂C, CH = CH.

4-Butoxy-1,1,1-trifluorobut-3-en-2-one enters into a similar reaction. The enone **19** reacts with the phenylmagnesium bromide to give a mixture of β -trifluoroacetylstyrene **20** and allylic alcohol **30**, resulting from its reduction, in an overall yield of 40%–60%, the proportion of the alcohol **30** increasing with an increase in the reaction time.⁵⁷ The reaction of phenylmagnesium bromide with 4-diethylamino-1,1,1-trifluorobut-3-en-2-one, prepared from the enone **19**, occurs more unambiguously;⁵⁷ it gives only β -trifluoroacetylstyrene **20** in 53% yield.

Reaction time /h 2 20
The **20** : **30** ratio 1 : 1 1 : 7

Recently, a new convenient and fairly versatile method for the synthesis of unsaturated trifluoromethyl ketones has been developed; this method is based on the reactions of various organolithium compounds with 4-dimethylamino-1,1,1-trifluorobut-3-en-2-one **31** and 3-(*N,N*-dimethylaminomethylidene)-1,1,1,5,5,5-hexafluoropentane-2,4-dione **8c**. The compound **8c** can be easily prepared by acylation of the enaminone **31** with trifluoroacetic anhydride in the presence of pyridine.⁶⁰

The reactions of the trifluoromethyl enaminones **31** and **8c** with organolithium compounds afford trifluoromethyl enones; in

the case of the enaminone **31**, the reactions are stereospecific and give only *E*-isomers of the enones.⁶⁰

$\text{R}^1 = \text{Ar, Het}; \text{R}^2 = \text{H, COCF}_3$.

The reaction of enaminodione **8c** with 1-methyl-1*H*-2-indolyl lithium **32** gives rise to the corresponding enedione **33** but does not stop at this stage; the subsequent cyclisation yields cyclopenta[*b*]indole derivative **34**.⁶⁰

The same study⁶⁰ describes the reaction of the enaminone **31** with a mixture of lithiated ferrocenes, resulting in the formation of the corresponding mono- **35** and bis-enones **36**. In the case of the enaminodione **8c**, only the product of its interaction with monolithioferrocene, enedione **37**, was isolated.

In order to synthesise conjugated trifluoromethyl enones containing an acetylenic fragment (enynones), which are promising from the synthetic point of view, a method based on the reaction of lithium acetylides with the enone **31** has been developed.⁶¹ The reaction is stereospecific giving *E*-isomers of substituted trifluoromethyl enynones.

$\text{R} = \text{Alk, Ar, Me}_3\text{Si}$.

The reactions of various trifluoroacetylated vinyl ethers with organoboron compounds, which occur with high stereoselectivity (92% – 98%) to give the *E*-isomers of the corresponding dienones, have been studied.^{62, 63} Thus the reaction of alkenyldialkoxyboranes with substituted vinylic ethers in the presence of boron trifluoride etherate affords the corresponding trifluoromethyl dienones.⁶² Similarly, 6-butyl-1,1,1-trifluorohex-3-en-5-yn-2-one is formed in the reaction of alkynyldialkoxyborane **38** with the enone **19**.⁶³

$\text{R}^1 = \text{H, Me, Ph, Br}; \text{R}^2 = \text{H, Br}; \text{R}^3 = \text{Et, Pr}^i; \text{R}^4 = \text{H, Me, Ph}$.

β -(Thio)alkoxy-substituted trifluoromethyl enones react with ammonia and primary and secondary amines (including aromatic ones) at room temperature to give β -amino-substituted enones (enaminones) in high (sometimes quantitative) yields.^{64, 65}

$\text{X} = \text{O, S}; \text{R}^1 = \text{Alk}; \text{R}^2 = \text{H, Me, Ph}; \text{R}^3 = \text{H, Alk}; \text{R}^4 = \text{H, Alk, Ar}$.

Diamines enter into a similar reaction. Thus symmetrical enaminones have been synthesised by the reaction of ethylenediamine and *o*-phenylenediamine with two molecules of β -ethoxy trifluoromethyl enone **19**.⁶⁴ The route of transamination in the series of β -amino-substituted enones does not depend on the nature of the solvent, being determined by the ratio of the initial reactants and the basicities of both the entering and leaving amines. The highest yields are attained when the amine entering into the reaction is more basic than the leaving one (for example, an amino group can easily be replaced by a dimethylamino or methylamino group but not *vice versa*). The reactions occur at room temperature and do not require a large excess of the amine used.^{65, 66}

$\text{R}^1 = \text{H, Alk}; \text{R}^2, \text{R}^3 = \text{H, Alk, Ph}; \text{R}^4 = \text{H, Alk}; \text{R}^5 = \text{Alk}$.

5. Preparation of trifluoromethyl ketones from β -diketones

Trifluoromethyl enaminones can be synthesised by the reaction of amines with β -diketones. When fluorinated β -diketones are made to react with ammonia,⁶⁷ ammonium acetate, ammonium hydrogen carbonate,⁶⁸ alkylamines or dialkylamines, stable salts **39** are initially formed. Refluxing of the salts **39** obtained from β -diketones having one trifluoromethyl (or perfluoroalkyl) substituent in benzene or toluene with azeotropic distillation of water affords β -amino-substituted enones in 12% – 76% yields.⁶⁷

$\text{R}_F = \text{H}(\text{CF}_2)_n \text{ (} n = 2, 4\text{)}; \text{R}^1 = \text{Alk, Ar};$
 (a) $\text{R}^2\text{R}^3\text{NH} \text{ (} \text{R}^2, \text{R}^3 = \text{H, Alk} \text{), } 20^\circ\text{C};$ (b) PhH or PhMe, Δ ;
 (c) $\text{R}^2\text{R}^3\text{NH} \text{ (} \text{R}^2 = \text{Ph, R}^3 = \text{H} \text{), MeOH, } 20^\circ\text{C}.$

In the case of low-basicity aromatic amines (*e.g.*, aniline), salts are not formed and the corresponding enamines are obtained by prolonged keeping of the initial compounds in polar solvents such as methanol at room temperature (yields 70%–90%).⁶⁷

As a rule (or always if $R^1 = \text{Alk}$), this reaction gives enamines in which the amino group is removed from the perfluoroalkyl substituent. Apparently, the electron-withdrawing influence of this group stabilises the *gem*-amino-alcoholic fragment and hampers elimination of water in the case where the amine has added at the carbonyl group adjacent to the perfluoroalkyl substituent.

β -Diketones having two perfluoroalkyl substituents react with amines, including aromatic ones, to give stable salts, which cannot be converted into the corresponding amino-substituted enones.⁶⁹ However, these enones can be obtained by the reaction of ammonia or aliphatic amines with fluorine-containing β -chlorovinyl ketones **40**.^{70,71} The compounds **40** are formed in the reaction of polyfluorinated β -diketones with SOCl_2 in the presence of DMF as a catalyst or with the Vilsmeier reagents [$\text{DMF} - \text{POCl}_3$ or $\text{DMF} - (\text{COCl})_2$].^{71–74} This approach has also been used to synthesise hexafluoromonothioacetylacetone **41**, which exists in the enol form.⁷²

Similarly, treatment of hydroxytetrahydrofuranone **42** — the hemiketal form of a diketone — with ammonia is accompanied by opening of the furan ring and gives rise to the corresponding hydroxy enamino ketone **43**.⁷⁵

The structure and the stereochemistry of β -amino-substituted trifluoromethyl enones were studied by NMR and IR spectroscopy.^{64,76} The configuration of their molecules was found to depend on the nature of the amino substituent. Trifluoromethyl enamines with NH_2 , AlkNH or ArNH groups in non-polar solvents or neat exist entirely as *Z*-isomers, which is apparently due to the presence of an intramolecular hydrogen bond. In polar solvents such as acetonitrile, an equilibrium between the *Z*- and *E*-isomers is established.

β -Dialkylamino-substituted enones always exist as *E*-isomers. Their ^1H NMR spectra exhibit two pairs of signals corresponding

to the diethylamino group, which seems to be due to the hindrance of its rotation around the $\text{C}(4) - \text{N}$ bond caused by conjugation.⁶⁴

An attempt has been made⁷⁷ to prepare unsubstituted perfluoroalkyl enone — trifluoromethyl vinyl ketone — from ethyl trifluoroacetoacetate. The researchers found that this enone (like other unsubstituted perfluoroalkyl vinyl ketones) dimerises spontaneously at temperatures above -30°C to give dihydropyran derivative **44**.

When two moles of methylmagnesium bromide are made to react with one mole of trifluoroacetylacetone, methylmagnesium bromide adds to the trifluoroacetylacetone anion formed initially (mostly at the carbonyl group further removed from the CF_3 substituent). The resulting tertiary alcohol **45** is readily dehydrated (to a large extent, during the hydrolysis) to give 1,1,1-trifluoro-4,4-dimethylbut-3-en-2-one.⁷⁸

6. Addition of perfluoroalkyl organolithium compounds to acrylic esters

Perfluoroalkyl organolithium compounds, generated by the reaction of perfluoroalkyl iodides with methyl lithium (transmetalation reaction), react with methyl acrylate or methyl methacrylate to give perfluoroalkyl enones, which exist in the reaction medium as anions of the corresponding hemiacetals **46**. Perfluoroalkyl α,β -enones having no substituents at the β -position are unstable and readily dimerise to give dihydropyran derivatives. Therefore, the hemiacetals **46** were introduced without isolation in reactions with isothiuronium salts or amidines, giving 4-perfluoroalkyltetrahydropyrimidines **47** in good yields.⁷⁹

$R^1 = \text{H, Me; } R^2 = \text{AlkS, Me, Ph; } X = \text{I, Cl; } n = 2, 4, 6, 8.$

This method has not been used to prepare trifluoromethyl enones, probably, because trifluoromethyl iodide is a toxic gaseous compound, inconvenient to work with.³

7. Palladium-catalysed reactions

Imino-derivatives of alkenyl (**48**) and alkynyl (**49**) trifluoromethyl ketones can be synthesised by condensation of trifluoroacetimidoyl iodides **50** with various alkenes and alkynes in the presence of a palladium catalyst; no elimination of fluorine, typical of this type of reaction, occurs.⁸⁰ The reaction is carried out under mild conditions, alkynes reacting much faster and at lower temperatures than alkenes.

$R^1 = \text{CO}_2\text{Me}, \text{Ph}, \text{CN}, \text{SO}_2\text{Ph}, \text{C}_6\text{H}_{13}$;

$R^2 = \text{Ph}, \text{CO}_2\text{Me}, \text{CO}_2\text{Et}, \text{C}_6\text{H}_{13}, \text{CH}_2\text{OCOPh}$.

8. Oxidation of allyl alcohols

Perfluoroalkyl-containing allyl alcohols can be synthesised in two ways, namely, by the addition of vinyl-containing organometallic reagents to fluoral⁸¹ or to another perfluorinated aldehyde or by the addition of perfluoroalkyl organometallic compounds to α,β -unsaturated aldehydes.^{82,83} In both cases, the corresponding halide and the metal are directly introduced in the reaction, because perfluoroalkyl organometallic compounds are unstable and vinyl organometallic compounds are usually formed in low yields. To increase the yield of perfluoroalkyl-containing allylic alcohols, ultrasonic treatment (yield 40%–70%)^{82,83} and catalysis by palladium or nickel complexes (yield 19%–62%)⁸³ have been employed.

$R = \text{H}, \text{Me}, \text{Ph}, \text{Me}_3\text{Si}$; $R_\text{F} = \text{CF}_3, \text{C}_2\text{F}_5, \text{C}_3\text{F}_7$; $X = \text{Br}, \text{I}$;

(a) ultrasound, THF, 20 °C, 3 h; (b) ultrasound, DMF, 100 °C, 1 h;

(c) $(\text{Ph}_3\text{P})_2\text{PdCl}_2$ or $(\text{Ph}_3\text{P})_2\text{NiCl}_2$, DMF, 20 °C, 3–4 h.

In addition, trifluoromethyl-containing allylic alcohols have been prepared by the reduction of alkynyl ketones with lithium tetrahydroaluminate.⁸⁴ The reaction is stereospecific and gives the alcohols as *E*-isomers.

$R = \text{C}_n\text{H}_{2n+1}$ ($n = 4-16$), $\text{Ph}(\text{CH}_2)_2\text{CH}(\text{OSiMe}_2\text{Bu}^t)$.

Trifluoromethyl-containing allylic alcohols can be oxidised into the corresponding enones on treatment with the Dess–Martin reagent^{84–87} or Swern reagent⁸⁸ (DMSO–oxalyl chloride–triethylamine). Manganese dioxide in CH_2Cl_2 was also used for this purpose; however, in this case, the yield of the product was somewhat lower.⁸⁹

Thus, despite the high yields of the target enones, this method is limited due to the poor accessibility of the initial allylic alcohols and has not found wide use.

III. The use of α,β -unsaturated trifluoromethyl ketones in organic synthesis

The first example of using a trifluoromethyl enone (β -trifluoroacetylstyrene) for the synthesis of pyrazolines dates back to 1959;³⁴ however, vigorous studies along this line started in the last decade. Trifluoromethyl α,β -enones are usually employed to prepare heterocyclic compounds. Attempts to use them for other purposes, for example, as protective reagents in peptide synthesis, have also been made (see below). All trifluoromethyl enones can be divided into two main types: (a) enones containing a group capable of being substituted (*e.g.*, OR, SR, NR₂) in the β -position and (b) enones without such group. β -Alkoxy- and β -amino-substituted trifluoromethyl enones as well as alkynyl trifluoromethyl ketones (α,β -ynones) have found the widest application. Below we consider the use of these compounds in organic synthesis, except for their use to prepare trifluoromethyl-containing enones from acetylenic ketones and enones of type (a), which is described in Section II.3.

1. Reactions of β -alkoxy-substituted enones and acetylenic ketones

Enones containing a β -alkoxy group (trifluoroacetylated vinyl ethers) and alkynyl trifluoromethyl ketones are readily available reagents (see Sections II.1 and II.3). Their reactions with various nucleophiles are widely used to synthesise five-, six- and seven-membered heterocycles and other compounds containing a CF_3 group.

Hydrazine and methylhydrazine react with β -alkoxy-substituted trifluoromethyl enones to give trifluoromethyl-containing pyrazoles **50**.^{61,90} The reaction of trifluoromethyl enones with phenylhydrazine affords pyrazolines **51**. On treatment with sulfuric acid, the compounds **51** are not dehydrated.⁹⁰ Apparently, the conjugation of the nitrogen lone electron pair with the benzene ring hampers aromatisation. In addition, the electron-withdrawing influence of the CF_3 group stabilises the *gem*-amino-alcoholic fragment.

The reaction of alkynyl trifluoromethyl ketones with hydrazine at room temperature gives rise to a mixture of pyrazoles **52** and pyrazolines **53**. Subsequent refluxing of the reaction mixture in benzene with azeotropic distillation of water affords only pyrazoles **52** in good yields.⁹¹

tert-Butylhydrazones of aldehydes react with β -ethoxy enone **19** giving rise to 4-trifluoroacetylpyrazoles **54**. A possible mechanism of this reaction includes replacement of the ethoxy group by the hydrazone. The subsequent cyclisation affords pyrazoles **55**, which are oxidised to pyrazoles by atmospheric oxygen.⁹²

R = Et, Ar.

It is noteworthy that the reactions of aldehyde methylhydrazones do not give the corresponding pyrazoles. In all probability, the bulky *tert*-butyl group favours cyclisation resulting in the formation of intermediate **55**. When the pyrazoles **54** are heated with 90% sulfuric acid, the *tert*-butyl group is removed, which gives *N*-unsubstituted 4-trifluoroacetylpyrazoles in high yields.

The reactions of β -alkoxy-substituted enones with hydroxylamine follow different pathways, depending on the structure of the initial enone. Thus acyclic enones and enones containing no oxygen atom in the ring are converted into isoxazolines **56**,^{9,64,93} which are dehydrated on treatment with P_2O_5 (followed by distillation of the reaction mixture)⁶⁴ or concentrated H_2SO_4 ⁹³ to give the corresponding isoxazoles **57** or **58**.

R¹ = Me, Et; R², R³ = H, Me; R²–R³ = (CH₂)₄.

Cyclic enones prepared by trifluoroacetylation of 2,3-dihydrofuran and 3,4-dihydro-2*H*-pyran are converted in a similar way at 0–20 °C into isoxazolines **59**, which result from opening of the furan or pyran ring. However, when the reaction is carried out at higher temperatures, it gives rise to tetrahydrofuran and tetrahydropyran derivatives **60**, formed apparently upon dehydration of aldehyde oximes **61**, resulting from recyclisation of the starting enones.⁹

n = 1, 2; (a) $\text{H}_2\text{NOH}\cdot\text{HCl}$, H_2O , Py; (b) 0–20 °C, 5–170 h; (c) 65–85 °C, 30–170 h.

Isoxazolines and isoxazoles were also obtained in good yields in the reaction of alkynyl ketones with hydroxylamine, the regioselectivity of the reaction being dependent on the reaction conditions.⁹¹ Thus ketone **62** reacts with hydroxylamine in an alkaline medium to give isoxazoline **63**; on refluxing in benzene with azeotropic distillation of water, this product undergoes dehydration to give the corresponding isoxazole **64**.

This reaction performed in an acid medium gives initially oxime **65**, which cyclises on refluxing in benzene giving rise to isoxazole **66**, isomeric to the isoxazole **64**.

This reaction pathway may be due to the fact that in an acid medium, dehydration is possible, which shifts the equilibrium towards the oxime. In an alkaline medium, the formation of isoxazoline, which exists as the anion under these conditions, appears to be thermodynamically more favourable.

The reactions of some β -alkoxy-substituted trifluoromethyl enones with isocyanides have been studied.⁹⁴ β -Ethoxyvinyl trifluoromethyl ketone **19** reacts with cyclohexyl isocyanide to give 2,5-dihydrofuran derivative **67**, whereas β,β -diethoxyvinyl trifluoromethyl ketone isomerises under the same conditions to ester **68**.

When β -alkoxy-substituted enones are made to react with formamide in the presence of NH_4Cl , with compounds of the urea series⁹⁵ or with isothiuronium salts,⁹⁶ trifluoromethylpyrimidines are formed. In the last-named case, the reaction is carried out in the presence of an acid or a base.

(a) HCl , EtOH, 20 °C, 48 h (X = O, S); (b) PhH, Δ , 6 h (X = NH); (c) AcONa, AcOH, 100 °C, 2 h (X = *p*-NSO₂C₆H₄NHCOMe).

$R^1, R^2 = \text{H, Me; } R^3 = \text{Me, Et; } R^1-R^2 = (\text{CH}_2)_2, (\text{CH}_2)_3$.

The reactions of β -alkoxy-substituted enones with enamino nitriles **69** result in the formation of pyridine derivatives containing a CF₃ group. Acyclic adducts **70** are formed as intermediates. For $R^1 = \text{H}$, they can be isolated in good yields on cooling. At room temperature, mixtures of the adducts **70** and cyanopyridines **71** are formed; refluxing of initial compounds in acetonitrile leads to pyridines **71** in high yields.⁹⁷

$X = -\text{N}(\text{CH}_2)_2-, -\text{N}(\text{CH}_2)_3-, \text{Y} = \text{O, NMe, NCOOEt}$.

Unlike reactions of enamino nitriles with alkoxyenones, which give 2-trifluoromethylpyridines, the reaction of 1,1,1-trifluoro-4-methoxypent-3-en-2-one with cyanothioacetamide results in the regioselective formation of 4-trifluoromethylpyridinethione **72**, the structure of which was proved by X-ray diffraction analysis.⁹⁸ The alkylation of the pyridinethiones **72** obtained by *N*-arylchloro(iodo)acetamides followed by cyclisation of the resulting compounds **73** in an alkaline medium affords 3-amino-4-trifluoromethylthieno[2,3-*b*]pyridinecarboxamides **74**.

$X = \text{Cl, I; Ar} = \text{Ph, 4-MeC}_6\text{H}_4, 3\text{-BuOC}_6\text{H}_4$.

The reaction of the butoxy-substituted trifluoromethyl enone, prepared by trifluoroacetylation of vinyl isobutyl ether, with 1,2-diamines (*o*-phenylenediamine or 1,2-ethylenediamine) gives rise to 1,5-diazepine **75** or **76**, while the reactions with *o*-aminophenols or *o*-aminothiophenol yield 1,5-oxazepines or 1,5-thiazepines **77**, respectively. The bis(trifluoroacetyl) derivative was also introduced into this reaction. Good yields were attained by using microwave (MW) radiation, whereas conducting the reaction in boiling xylene resulted in a complex mixture of products (Scheme 1).^{99, 100}

$X = \text{H, COCF}_3; R^1 = \text{H, Me; } R^2 = \text{H, Me, Cl, NO}_2, \text{COPh; } R^3 = \text{H, Cl; Y} = \text{O, S}$.

3-Aminopyrazolo[3,4-*b*]pyridine derivatives **78** enter into a similar reaction as nucleophiles. On exposure to microwave radiation, trifluoromethyl-substituted derivatives of pyrido[2',3':3,4]pyrazolo[1,5-*a*]pyrimidine **79** are formed in 62%–78% yields (the yield in the thermal reaction is only 20%).¹⁰¹

$X = \text{H, COCF}_3; R^1 = \text{Me, CF}_3; R^2 = \text{Me, Ar}$.

4,4-Diethoxy-1,1,1-trifluorobut-3-en-2-one reacts with *o*-phenylenediamines, *o*-aminophenols and *o*-aminothiophenol to give five-membered heterocycles — benzimidazoles, benzoxazoles and benzothiazoles — in high yields, the reaction occurring both on refluxing in toluene and on exposure to microwave radiation.¹⁰⁰

$Y = \text{O, S; } R^1 = \text{H, Cl; } R^2 = \text{H; Y} = \text{NH; } R^1, R^2 = \text{H, Me}$.

The reaction of β -ethoxy(phenoxy)-substituted enones with vinyl ethers affords 3,4-dihydro-2*H*-pyrans in good yields; thus, these enones are efficient heterodienes in the hetero-Diels–Alder reaction.¹⁰²

This reaction proceeds especially easily for β -alkoxy-substituted bis(trifluoromethyl) enones. The presence of the second strong electron-withdrawing group, COCF_3 , increases the reactivity of trifluoromethyl enones as heterodienes. The reaction occurs at room temperature to give 5-trifluoroacetyl-3,4-dihydro-2H-pyrans in high yields.¹⁷

Aryl vinyl ethers react with trifluoroacetic anhydride to give the corresponding bis(trifluoroacetyl) derivatives. It was found¹⁷ that these compounds are unstable and cannot be isolated in a pure state; however, they can be introduced without isolation in the reaction with a second equivalent of aryl vinyl ether. Aryloxy-substituted 5-trifluoroacetyl-3,4-dihydro-2H-pyrans **80** were obtained in this way in 50%–68% yields. In some cases, these products are formed directly in trifluoroacetylation of aryl vinyl ethers.¹⁷

Ring opening in 5-trifluoroacetyl-3,4-dihydro-2H-pyrans **81** induced by secondary amines in acetonitrile gives rise to 1-amino-4,4-bis(trifluoroacetyl)buta-1,3-dienes **82**. The mechanism pro-

posed for this reaction includes elimination of isobutanol, electrocyclic ring opening and nucleophilic substitution of the amine for the ethoxy group. It is of interest that no reaction of this type occurs in the series of non-fluorinated analogues of pyrans **81**.¹⁰³

$R^1 = \text{Alk, Ph}; R^2 = \text{Alk.}$

One trifluoroacetyl group in bis(trifluoroacetyl)-substituted dienes **82** can be eliminated in an acid medium; this gives 1-amino-4-trifluoroacetylbuta-1,3-dienes, which can be acylated by trifluoroacetic anhydride in the presence of pyridine to give the initial compounds **82**.¹⁰³

3,4-Dihydro-2H-pyran **83**, prepared by hetero-Diels–Alder reaction of β -ethoxy trifluoromethyl enone with vinyl ethyl ether, enters into a similar reaction. The dihydropyran ring opening induced by thiols in an acid medium is stereospecific and gives (*E*)-1-alkylthio-4-trifluoroacetylbuta-1,3-dienes **84** in good yields.¹⁰⁴

The reactions of β -ethoxy enone **19** with semicarbazide and thiosemicarbazide result in the formation of 2-pyrazoline-1-carboxamide **85** and 5-(1-thiosemicarbazido)-2-pyrazoline-1-thiocarboxamide **86**, respectively.¹⁰⁵

(a) $\text{H}_2\text{NCXNHNH}_2$, EtONa, EtOH; NH_4Cl , H_2O .

Apart from the synthesis of heterocycles, β -alkoxy-substituted enones have been used to prepare acyclic compounds. Thus the reaction of the lithium salt of (*R*)-methyl 4-tolyl sulfoxide **87** with the enone **19** (or some other perfluoroalkyl-containing enone) gives a mixture of two diastereoisomers of β -hydroxy sulfoxides **88a,b** in a ratio of $\sim 1:1$. These diastereoisomers were separated by chromatography; their configurations were determined by

X-ray diffraction analysis. The subsequent reduction of the sulfoxide group permits the preparation of two enantiomers of chiral allylic alcohols **89a,b** with known absolute configurations in a pure state (overall yield 40%–94%).¹⁰⁶

(a) LiAlH_4 , $-78\text{ }^\circ\text{C}$; $\text{EtOCH}=\text{CHCOCF}_3$ (**19**).

Trifluoroacetylated vinyl ethers (including cyclic ones) readily undergo haloform cleavage induced by KOH in boiling benzene in the presence of a small quantity of water to give α,β -unsaturated acids.⁸

$\text{R} = \text{Et}, \text{Bu}^n, \text{Bu}^i, \text{Ph}$.

$n = 1, 2$.

The replacement of the alkoxy group in β -alkoxy enones on treatment with amines occurs with high yields and the resulting enaminones are readily hydrolysed. Therefore, these enones can be used as protective reagents in peptide synthesis. Thus the β -ethoxy enone **19** reacts with amino acids in the presence of an equivalent of a base at room temperature to give the corresponding enaminones. The amino acids protected in this way were used to synthesise dipeptides **90**. The protective group can be easily removed on treatment with 3 M HCl in dioxane at room temperature.¹⁰⁷

$\text{R}^1 = \text{Me}, \text{Pr}^i, (\text{CH}_2)_2\text{CO}_2\text{Me}, (\text{CH}_2)_2\text{CO}_2\text{Bu}^i, \text{PhCH}_2$; $\text{R}^2 = \text{H}, \text{Pr}^i, \text{PhCH}_2$; $\text{R}^3 = \text{Et}, \text{Bu}^i, \text{Me}$; DCC is dicyclohexylcarbodiimide.

2. Reactions of β -amino-substituted trifluoromethyl enones

In addition to β -alkoxy-substituted trifluoromethyl enones, their β -dialkylamino-substituted analogues, readily prepared by treatment of β -alkoxy enones with dialkylamines, are also used for the synthesis of various trifluoromethyl-containing heterocyclic compounds. Since enaminones are less reactive in nucleophilic substitution than β -alkoxy enones, they are activated by virtue of POCl_3 or trifluoromethanesulfonic anhydride. Thus the reactions of enaminones with POCl_3 afford iminium salts **91a,b**, vinylogues of the Vilsmeier complexes. Despite the fact that these salts are less reactive than the complex $\text{DMF} \cdot \text{POCl}_3$, they are still able to aminoformylate ($\sim 20\text{ }^\circ\text{C}$, 1 h), e.g., *N,N*-dimethylaniline or quaternary salts of nitrogenous heterocycles **92** and **93**. These reactions yield hemicyanines **94–96**, respectively, which are valuable intermediates in the synthesis of cyanine dyes.⁵⁹

$\text{R} = \text{Me}$ (a), Et (b).

When two equivalents of the quaternary salt **92** react with one equivalent of triethylamine and with the iminium salt **91**, dicarbo-cyanines **97** are formed.⁵⁹

$\text{Z} = \text{S}, \text{CM}_2, \text{CH}=\text{CH}$; (a) **91**, NEt_3 , NaClO_4 , $20\text{ }^\circ\text{C}$, 30 min.

The electrophilicity of iminium salts proves to be insufficient for them to react with aromatic compounds less reactive than *N,N*-dimethylaniline. Thus quenching with a solution of KHCO_3 of the reaction mixture obtained upon the reaction between the complex of 4-dimethylamino-1,1,1-trifluorobut-3-en-2-one with POCl_3 and 1,3-dimethoxybenzene gave α,β -unsaturated aldehyde **98** in 7%–12% yield,¹⁰⁸ more than 80% of the initial 1,3-dimethoxybenzene being recovered unchanged.

Due to the low electrophilicity of the iminium salts obtained by the reaction of enaminones with POCl_3 it has been proposed to

use more reactive salt **99**, formed from enaminone and trifluoromethanesulfonic anhydride and containing a better leaving group (OSO_2CF_3). The reactions of this compound with electron-donating aromatic or heteroaromatic compounds under mild conditions give rise to α,β -unsaturated trifluoromethyl-containing aldehydes.¹⁰⁸ The reaction is stereoselective giving mainly *E*-isomers of the aldehydes; it occurs for relatively reactive compounds such as indoles, pyrroles, furans and 1,3-dimethoxybenzene, whereas thiophene and anisole do not enter into this reaction, even when it is carried out under more rigorous conditions.

β -Arylamino-substituted trifluoromethyl enones cyclise on treatment with acids giving rise to 2-trifluoromethyl- (**100**) and 4-trifluoromethylquinolines (**101**).^{37, 52, 109, 110} As catalysts, POCl_3 , ZnCl_2 and polyphosphoric acid (PPA) were used. Quinolines **101** are the products of 'normal' cyclisation, while the mechanism of formation of 2-trifluoromethylquinolines **100** needs to be further investigated. The ratio of the reaction products depends on the acidic catalyst used and the structure of the initial enone. Cyclisation of enones with $\text{R}^2 = \text{H}$ gives only 2-trifluoromethylquinolines **100**,^{37, 52} and when $\text{R}^2 = \text{Alk}$ or Ph , 4-trifluoromethylquinolines **101** are formed predominantly.⁵² The presence of electron-donating substituents in the *meta*-positions of the aromatic amine substantially facilitates cyclisation and increases the total yield.

$\text{R}^1 = \text{Me}, \text{OMe}, \text{Hal}; \text{R}^2 = \text{H}, \text{Alk}, \text{Ph}; \text{PPA}$ is polyphosphoric acid.

The reactions of aniline derivatives with the iminium salt **99** afford 2-trifluoromethylquinolines and no 4-trifluoromethyl-derivatives.¹¹¹

$\text{R} = \text{Me}, \text{OMe}, \text{SMe}, \text{OCF}_3, \text{Cl}, \text{OH}.$

Enaminone **102** cyclises on refluxing in a high-boiling solvent to give substituted 3-fluoromethylpyrrole **103**.¹¹²

A detailed study of the mechanism of cyclisation of such enamino ketones in the presence of a base demonstrated that the transformations of trifluoromethyl-containing ketones include not only 5-*exo*-trigonal cyclisation to give 3-trifluoromethylpyrroles **104** but also previously unknown 3-*exo*-trigonal cyclisation, giving 2-trifluoromethylpyrroles **105**. Similarly, in the case of sulfide derivatives of enones, 3-trifluoromethylthiophenes were isolated in addition to 2-trifluoromethylthiophenes (Scheme 2).¹¹³

Meanwhile, enaminones **106** cyclise in the presence of trifluoroacetic acid to yield 3-trifluoroacetylpyrroles.^{112, 114}

$\text{R} = \text{H}, \text{Me}, \text{Ph}.$

Reactions of 3-(diethylaminomethylidene)-1,1,1,5,5,5-hexafluoropenta-2,5-dione **8a** (enaminodione, whose electrophilicity is enhanced by the presence of the second trifluoroacetyl group) with various nucleophiles have been studied.¹¹⁵ When the enaminodione **8a** reacts with aromatic amines in the presence of catalytic amounts of FeCl_3 , the diethylamino group is substituted to give *N*-aryl-substituted enaminodiones, which cyclise on treatment with PPA or TiCl_4 , the yields of the reaction products being substantially higher in the case of TiCl_4 .

Scheme 2

Ar(Het)NH	Cyclisation product	Yield (%)	
		PPA	TiCl ₄
		10	96
		0	90
		15	0
		—	100
		25	60
		0	25

The reactions of the enaminodione **8a** with bifunctional nucleophiles occur similarly to the reactions of β -alkoxy-substituted enones. Thus the reaction of the compound **8a** with hydrazine gives rise to trifluoromethyl-substituted pyrazole **107**, while its reaction with phenylhydrazine yields a mixture of regioisomers **108** and **109** in 1 : 3 ratio.¹¹⁵

The reactions of the enaminodione **8a** with α -aminocarbonyl compounds (or their acetals) — 2,2-dimethoxyethylamine or ethyl *N*-benzylglycinate — result in the corresponding pyrroles **110** and **111**.¹¹⁵ In the reaction with 2,2-dimethoxyethylamine, for aromatisation to occur one molecule of $\text{CF}_3\text{CO}_2\text{H}$ is eliminated; this is the pathway to 3-trifluoroacetylpyrrole **110**.¹¹⁴

The enaminodione **8a** has also been introduced in reactions with compounds of the urea series. The reaction of **8a** with guanidine affords pyrimidine **112** in a good yield.¹¹⁵ The reaction with *O*-methylisourea affords two products — 1-methoxypyrimidine **113** and 1-diethylaminopyrimidine **114** — because diethylamine formed in the reaction reacts with methoxypyrimidine **113**. Optimisation of the reaction conditions (MeCN, 65 °C, 4 h) makes it possible to prepare the target compound **113** in 65% yield.

Thus, the enaminodione **8a** is a readily available reagent, widely used for the synthesis of various heterocyclic compounds containing both trifluoromethyl and trifluoroacetyl groups.

3. Reactions of trifluoromethyl enones containing no replaceable group

Trifluoromethyl enones containing no β -substituents able to be replaced are less available compounds than β -alkoxy- or β -amino-substituted enones; therefore, their reactions have not been studied so extensively. However, in the early 1990s, new methods for the synthesis of these compounds were developed (*e.g.*, trifluoroacetylation of alkenes in the presence of the complex of dimethyl sulfide with boron trifluoride^{25,26}). This stimulated vigorous studies of their synthetic potential.

Trifluoromethyl enones containing no replaceable substituents readily react with various bifunctional nucleophiles. Thus the reactions of phenyl-, cyclobutyl- or adamantyl-substituted enones with hydrazine result in the formation of pyrazolidines **115**, which contain a *gem*-amino-alcoholic fragment, stabilised by the electron-withdrawing influence of the CF_3 group. Dehydration of the pyrazolidines **115**, which occurs either during the reaction, or on prolonged storage, or on refluxing in benzene in the presence of a catalytic amount of toluene-*p*-sulfonic acid (depending on the nature of substituents R^1 and R^2) gives the corresponding pyrazolines.¹¹⁶

β -Trifluoroacetylstyrene **20** reacts with substituted aryl- or alkyl-hydrazines. Thus the reaction with *p*-bromophenyl- and phenyl-hydrazines affords pyrazolines **116**. Oxidation of the compound **116** with $X = H$ by lead tetraacetate affords the corresponding pyrazole in a moderate yield.³¹ The reaction with *p*-nitrophenylhydrazine does not give pyrazoline; in this case, β -trifluoroacetylstyrene *p*-nitrophenylhydrazone **117** is formed in a low yield.

When β -trifluoroacetylstyrene **20** is made to react with methylhydrazine, a mixture of isomeric pyrazolines **118a,b** (in $\sim 1:3$ ratio) is formed, which is apparently due to the fact that the nucleophilicities of the nitrogen atoms in methyl hydrazine are close. The reaction with 1,2-dimethylhydrazine gives pyrazolidine **119**, apparently due to the fact that elimination of water yielding a $C=C$ bond is substantially hampered.¹¹⁶

The enone **20** reacts with semicarbazide or thiosemicarbazide in an acid medium to afford semicarbazone **120a** or thiosemicarbazone **120b**. These compounds are stable both in acid and alkaline media and do not tend to cyclise.¹⁰⁵

$X = O$ (**120a**, 91%), S (**120b**, 93%).

Conversely, the reaction with semicarbazide carried out in the presence of an equimolar amount of sodium ethoxide gives a cyclic compound, 5-trifluoromethylpyrazolidine-1-carboxamide **121**.¹⁰⁵

$R^1 = Ar, R^2 = H; R^1-R^2 = (CH_2)_3, \text{ bicyclic system}.$

The reaction occurs regio- and stereoselectively, yielding predominantly one diastereoisomer. The bulky substituents R^1 and R^2 occupy pseudo-equatorial positions, *i.e.* thermodynamically the most favourable isomers are produced.¹⁰⁵

When trifluoromethyl-containing enones react with thiosemicarbazide under the same conditions, either 3-trifluoromethyl-2-pyrazolinethiocarboxamides **122** or 5-trifluoromethyl-2-pyrazolinethiocarboxamides **123** are obtained, depending on the structure of the starting enone.¹⁰⁵

Unlike pyrazolidines **115**, pyrazolidine-1-carboxamides and -thiocarboxamides cannot be converted into the corresponding pyrazolines.¹⁰⁵

The reaction of β -trifluoroacetylstyrene **20** with hydroxylamine in an acid medium gives rise to oxime **124**, which does not tend to cyclise in either acid or alkaline medium.¹¹⁷

Meanwhile, the reactions of trifluoromethyl enones with hydroxylamine in the presence of an equimolar amount of sodium ethoxide give isoxazolidines **125** in good yields.¹¹⁷

$R^1, R^2 = Ar, \text{ Het, Alk}.$

The attempts to carry out dehydration of isoxazolidines **125** to isoxazoles were unsuccessful. Refluxing of these compounds in toluene with azeotropic distillation of water in the presence of toluene-*p*-sulfonic acid gives rise to the corresponding oxime, the initial enone being formed as a side product. At the same time, β -alkoxy enones or alkynyl ketones are converted into isoxazoles, which are dehydrated in an acid medium to give isoxazoles.^{63,93} Thus, the possibility of aromatisation has the crucial influence on the reaction route.

The isoxazolidines **125** are fairly interesting from the stereochemical viewpoint. They exist in solutions at room temperature as equilibrium mixtures ($\sim 1:1$) of diastereoisomers. The energy barrier to nitrogen inversion in the compound **125** is almost a half that in the isoxazolidines described previously by Kostyanovsky *et al.*,^{118,119} however, it is still high enough ($51-55 \text{ kJ mol}^{-1}$)¹¹⁷ to retard nitrogen inversion. Therefore, the signals in the ^1H and ^{13}C NMR spectra recorded at room temperature are broadened, and when the temperature decreases, the conformation becomes 'frozen' and signals for four diastereoisomers are observed (due to the chirality of the nitrogen atom).

The reactions of trifluoromethyl enones with compounds of the urea series afford tetrahydropyrimidines **126** in high yields.¹²⁰ The compounds **126** are easily dehydrated on refluxing in toluene in the presence of catalytic amounts of toluene-*p*-sulfonic acid

[unlike cyclohexane derivatives containing a $C(OH)CF_3$ fragment]¹²¹ giving rise to dihydropyrimidines **127**.¹²⁰

$R^1 = H, R^2 = Ph; R^1-R^2 = (CH_2)_3; X = O, S.$

In the case of β -trifluoroacetylstyrene **20**, the reaction occurs stereoselectively, yielding predominantly ($\geq 95\%$) one of the two possible diastereoisomers of **126**. The configuration of the major diastereoisomer was established by X-ray diffraction analysis. This was found to be the thermodynamically more favourable *trans*-isomer (regarding the arrangement of the Ph and OH groups), in which the bulkiest substituents, Ph and CF_3 , occupy equatorial positions.

It should be noted that such stereochemistry has also been observed for cyclohexane derivatives with the same substituents at the 3- and 5-positions;¹²¹ this may be due to the relatively large effective size of the trifluoromethyl group[†] and to the high electron density on this group.

The reaction of a sterically hindered trifluoromethyl enone having an adamantane fragment with thiourea gives dihydropyrimidine **128**.¹²⁰

The reactions of phenyl- and adamantyl-substituted trifluoromethyl enones with guanidine occur in a similar way giving rise to the corresponding aminopyrimidines **129** and **130**.

β -Trifluoroacetylstyrene **20** reacts with aminoguanidine to give compound **131**, resulting from addition of two enone molecules to an aminoguanidine molecule and containing two heterocyclic moieties (tetrahydropyrimidine and pyrazoline).¹²⁰

In this case, water is eliminated only from the five-membered ring, which is consistent with the general rule according to which trifluoro-substituted pyrazolidines are dehydrated more readily than tetrahydropyrimidines.^{116, 120}

The reactions of trifluoromethyl enones with thiourea and thioacetamide in an acid medium afford dihydrothiazines **132**.¹²³ Both reactions are regiospecific and give one isomer, formed upon the addition of sulfur at the double bond and nitrogen at the carbonyl group. This reaction route was interpreted¹²³ in terms of the principle of hard and soft acids and bases.

$R^1 = H, R^2 = Ph; R^1-R^2 = (CH_2)_3;$

(a) $(H_2N)_2CS, HCl, EtOH, \Delta$ ($R^3 = NH_2$);
(b) $MeC(S)NH_2, EtOH, \Delta$ ($R^3 = Me$).

The reactions of some trifluoromethyl enones with thiols have been studied. Thus 1,1,1-trifluorodec-3-en-2-one reacts with benzenethiol to give β -oxo sulfide **133**.^{86, 124}

As opposed to this, the reaction of the enone **20** with 4-methylthiophenol gives rise to two products, β -oxo sulfide **134** and pyran **135**. The compound **134** results from Michael addition, while the pyran **135** is formed upon interaction of two molecules of the ketone with one molecule of the thiol and one water molecule.¹²⁴

The reaction is stereospecific, the compound **135** being formed as one diastereoisomer of the 16 possible isomers (the molecule has five asymmetric centres); the bulkiest phenyl, trifluoromethyl, and (4-methylphenylthio)phenylmethyl substituents occupy equatorial positions. The relative configuration of the carbon atom located outside the ring and bearing the phenyl and 4-methylphenylthio substituents is also fixed. Thus, effective asymmetric 1,2-induction takes place.¹²⁴

The reactions of trifluoromethyl enones with ammonium hydrogen sulfide have been studied.¹²⁵ The reaction pathway depends on the structure of the initial enone. For instance, the

[†] The energy required for substituents to pass from an equatorial to an axial position (conformational energy) was reported¹²² to increase in the sequence $Me < Pr^i < CF_3 < Bu^i$.

enone **20** reacts stereospecifically yielding tetrahydropyran **136** as one diastereoisomer of the eight possible isomers.¹²⁵

The reaction of ammonium hydrogen sulfide with cyclobutyl-substituted enone affords a mixture of *cis*- and *trans*-diastereoisomers of tetrahydrothiopyran **137a,b** (total yield 90%) in 1 : 1 ratio.¹²⁵

(a) NH_4SH , EtOH, 20 °C, 3 min.

The tetrahydrothiopyrans **136** and **137a** are oxidised with retention of configuration, giving the corresponding sulfones **138** and **139** in almost quantitative yields.

$\text{R}^1 = \text{Ph}$, $\text{R}^2 = \text{H}$ (**136**, **138**); $\text{R}^1 - \text{R}^2 = (\text{CH}_2)_3$ (**137a**, **139**).

The reaction of ammonium hydrogen sulfide with adamantylidenemethyl ketone follows an unusual route and affords compound **140**, containing a four-membered thietane ring, as the only product. On treatment with hydrogen peroxide in acetone or acetic acid, this product is oxidised to give 1,3-sultine **141** as a mixture of diastereoisomers.¹²⁵

(a) H_2O_2 , Me_2CO , Δ , 24 h (92%); (b) H_2O_2 , AcOH, Δ , 1 min (61%).

1,1,1-Trifluoro-4-phenylpent-3-en-2-one with three substituents at the double bond reacts with ammonium hydrogen sulfide to yield β -sulfanyl ketone **142**.¹²⁵

Aryl-substituted trifluoromethyl enones were found to react with 2-sulfanylbenzaldehyde at room temperature in ethanol in the presence of a basic catalyst (triethylamine). This gives a mixture of two compounds, thiochromanes **143** and 2*H*-thiochromenes **144**, resulting from dehydration of **143**. When the reaction mixture is refluxed for 1 h, the compounds **144** are formed in good yields. The intermediate thiochromane **143** (Ar = Ph) can be isolated in 65% yield only when the starting enone is β -trifluoroacetylstyrene **20**.¹²⁴

The reactions of trifluoromethyl enones with malonodinitrile and cyanoacetamide in protic (ethanol, propan-2-ol) and aprotic (benzene) solvents in the presence of various basic catalysts (triethylamine, pyrrolidine, calcined potassium fluoride) have been studied.¹²⁶ The reaction route depends on the reaction conditions and on the structure of the initial ketone.¹²⁶ On refluxing in benzene with malonodinitrile in the presence of pyrrolidine as a catalyst, β -aryl-substituted enones are converted into pyrans **145**.¹²⁶

$\text{R} = \text{H}$, Me.

Under the same conditions, cyclobutylidenemethyl trifluoromethyl ketone is converted into cyclobutylidenemalonodinitrile, while adamantylidenemethyl trifluoromethyl ketone reacts in the presence of a stronger base (calcined potassium fluoride) to give adamantylidenemalonodinitrile. Apparently, in the case of ketones with an exocyclic double bond, the initial Michael addition of malononitrile is not followed by cyclisation to give pyran derivatives; instead, elimination of trifluoroacetone enolate occurs. The researchers cited suggest¹²⁶ that otherwise, cyclisation products would contain a spiro-fused fragment and, as a consequence, the ring would be more strained.

The reaction of malonodinitrile with two equivalents of β -trifluoroacetylstyrene **20** in the presence of potassium fluoride in isopropanol affords substituted cyclohexanol **146**, the product of addition of two molecules of the ketone to malonodinitrile and the subsequent intramolecular aldol condensation. The compound **146** is formed in a good yield as a single diastereoisomer of the eight possible isomers; the bulky substituents (Ph, CF_3 , COCF_3) occupy energetically more favourable equatorial positions.¹²⁶

The reactions of trifluoromethyl enones with malonodinitrile in the presence of ammonium acetate occur ambiguously. Only in the case of the enone **20**, was pyridine derivative **147**, resulting from oxidation of the corresponding dihydropyridine **148** with atmospheric oxygen, isolated in a low yield.

1,1-Dicyanobuta-1,3-dienes **149**¹²⁶ were synthesised by Knoevenagel condensation of trifluoromethyl enones with malonodinitrile in the presence of the complex $\text{TiCl}_4 \cdot 2\text{Py}$ in dichloromethane.

An attempt to carry out cyclisation of the compounds **149** in an acid medium was undertaken. When 1,1-dicyano-4-phenyl-2-trifluoromethylpenta-1,3-diene was treated with concentrated sulfuric acid, substituted benzonitrile **150** was obtained; in other cases, such cyclisation did not occur.

It was found that on refluxing of benzylidene- and cyclobutylidene-methyl trifluoromethyl ketones with cyanoacetamide in isopropanol in the presence of calcined KF, a stereospecific reaction occurs, giving piperidines **151a,b** in high yields.¹²⁶

Dehydration of the piperidines **151a** and **151b** gives dihydropyridines **152a,b** (a mixture of diastereoisomers in ~2:1 ratio) and spiro compound **153**, respectively.

Imino-derivatives of unsaturated trifluoromethyl-containing ketones **154** cyclise in the presence of palladium supported on carbon to give, depending on the reaction conditions, either 2-trifluoromethylquinoline derivative **155** or 5-trifluoromethylpyrrolidone derivatives **156**.⁸⁰

The reactions of trifluoromethyl enones with *o*-phenylenediamine afford 2,3-dihydro-1,5-benzodiazepines **157**.¹²⁷ The compounds **157** undergo spontaneous dehydration, apparently, due to the fact that this enables the energetically favourable conjugation of the resulting C=N bond with the benzene ring.

γ,δ -Unsaturated trifluoromethyl-containing ketones **160** and **161** have been prepared by the reactions of β -trifluoromethylstyrene **20** with alk-1-enyl- (**158**)¹²⁸ and alk-1-ynyl-diisopropoxyboranes (**159**)⁶² in the presence of boron trifluoride etherate.

α -Alkoxy carbonyl-substituted trifluoromethyl α,β -enones, prepared by condensation of ethyl trifluoroacetoacetate with aldehydes, react with enamino esters **162** to afford fairly stable hydroxypyridines **163**, whereas their non-fluorinated analogues are converted directly into 1,4-dihydropyridines. The hydroxypyridines **163** were dehydrated in the presence of a number of catalysts; the best yields were attained when the complex $\text{POCl}_3 \cdot \text{Py}$ adsorbed on silica gel was used.¹²⁹

The reaction of the enone **20** with β -aminocrotononitrile results in the formation of 6-trifluoromethylpyridine **165** in a low

yield; oxidation of this product leads to the corresponding aromatic derivative **166**.¹³⁰

The reactions of 1,1,1-trifluoro-4-methylpent-3-en-2-one with isocyanides occur at room temperature without catalysts to give stable 1,4-cycloaddition products, namely, substituted dihydrofurans **167**.¹³¹

R = Bu^t, cyclo-C₆H₁₁.

Treatment of perfluoroalkyl α,β -enones with reagents that are widely used for asymmetric reduction of non-fluorinated ketones (e.g., Binal-H, Darvon-red)¹³² results in racemic alcohols.¹³³ The microbial reduction of perfluoroalkyl enones by baker's yeast was studied; however, the corresponding saturated ketones rather than alcohols were formed as the major reaction products. The alcohols were formed with high enantioselectivities (*ee* 77%–85%) but in very low yields.

R_F = CF₃, C₂F₅, n-C₄F₉; R = Me, Ph.

The reaction of γ -hydroxy enone **168**, synthesised by oxidation of the corresponding protected allyl alcohol by the Dess–Martin reagent, with benzenethiol affords a tetrahydrofuran derivative — hemiacetal **169**. On refluxing in benzene in the presence of sulfuric acid with azeotropic distillation of water, the compound **169** eliminates water and benzenethiol being thus converted into the corresponding furan **170**.⁸⁴

IV. Conclusion

The data presented in this review can be summarised by stating that development of facile methods for the synthesis of trifluoromethyl α,β -enones remains a topical task. Trifluoromethyl enones containing no RO, RS or R₂N groups are not very easy to synthesise; nevertheless, they are highly reactive compounds possessing great synthetic potential.

A remarkable feature of trifluoromethyl enones is their high reactivity towards nucleophiles combined with regio- and stereoselectivity of the corresponding reactions. Similar reactions of their non-fluorinated analogues with nucleophiles occur non-selectively giving products in low yields or do not occur at all. Another significant feature that distinguishes trifluoromethyl α,β -enones from non-fluorinated enones is their ability to form

compounds incorporating a stable hemiacetal or hemiaminal fragment, CF₃C(OH)O or CF₃C(OH)NH.

Thus, α,β -unsaturated trifluoromethyl-containing ketones are fairly convenient 'building blocks' for the synthesis of diverse CF₃-derivatives; further research into their properties and the ways of using them in organic synthesis appears quite promising.

The review was financially supported by the Russian Foundation for Basic Research (Project No. 97-03-38959a).

V. Conclusion	479

Abstract. Data on the methods of preparation of bipyrroles and furyl-, thienyl- and selenienylpyrroles are summarised and described systematically. The reactivity and the prospects of application of these compounds are discussed. Particular attention is paid to a new convenient one-step method for the synthesis of hetaryl-substituted pyrroles starting from alkyl hetaryl ketoximes and acetylene. The bibliography includes 191 references.

I. Introduction

Derivatives of five-membered aromatic heterocycles (pyrrole, furan, thiophene and selenophene) are, as a rule, endowed with high biological activity and other useful properties and find ever-increasing uses in medicine, agriculture and technology.^{1–11}

Of five-membered aromatic heterocycles, pyrrole possesses the highest reactivity and most diverse chemical properties. It is not accidental that it is pyrrole that Nature has 'chosen' for constructing the 'vital pigments' chlorophylls and hemoglobin, as well as other vitally important supramolecular structures (various porphyrins, chlorins, prodigiosins, vitamin B₁₂, etc.). For this reason, amongst all five-membered aromatic heterocycles the molecules containing the pyrrole nucleus attract the greatest attention of researchers and are studied in most detail.

The chemistry of bipyrroles as well as of pyrroles with furan, thiophene and selenophene substituents is a very recent field in the chemistry of heterocyclic compounds. Until recently, no sufficiently efficient and general methods of their preparation existed; therefore, these compounds remained attractive but hard to access and little studied subjects. The development of this field began in the 1970s, when new methods for pyrrole synthesis appeared or the existing procedures were modified to allow for linking five-membered aromatic heterocycles to the pyrrole ring. A very simple and versatile method based on the reaction of ketoximes with acetylene (the Trofimov reaction) has been developed, which allows the synthesis not only of hetarylpyrroles non-substituted at the nitrogen atom but also their 1-vinyl derivatives from accessible alkyl hetaryl ketoximes. This also stimulated studies of

reactivity, structure, biological activity and of other useful properties of hetarylpyrroles.

Some aspects of the chemistry of pyrroles with furyl, thienyl and selenienyl substituents have been presented in monographs,^{4, 12} reviews,^{5, 6, 13–21} the US physical and technical encyclopedia (chapter 'Acetylene'),²² and Ph.D. and D.Sc. theses.^{23–27} Nevertheless, generalising papers that summarise the progress in the chemistry of hetaryl-substituted pyrroles are missing. We have attempted to fill this gap by generalising and systematising the currently available literature on the methods of synthesis, reactivity, biological and other properties of pyrroles linked to five-membered aromatic heterocycles.

II. Methods of synthesis

Conventional methods for the synthesis of pyrroles — the Knorr, Hantzsch, Piloty, Yuriev (except for the Paal–Knorr synthesis) reactions — have not found wide use for the preparation of pyrroles bound to other five-membered heterocycles. This goal can be reached most efficiently using the method based on the reaction of alkyl hetaryl ketoximes with acetylene (the Trofimov reaction), which is carried out in one step using accessible initial compounds.

New methods have been developed for the preparation of hetarylpyrroles based on activated acetylenes, *e.g.*, by condensation of hetarylacetylenes with trimethylsilyl cyanide, as well as those with the use of isocyanides, other cyano compounds, azides, *etc.*

1. Synthesis from ketoximes and acetylene (the Trofimov reaction)

In the early 1970s, heterocyclisation of ketoximes with acetylene in a superbasic system (strong base–polar aprotic solvent) was discovered, which yielded in one step 1*H*- and 1-vinylpyrroles (the Trofimov reaction).^{4, 5, 14–20, 23, 24, 26}

R¹ = Alk, Ar, Het; R² = H, Alk, Ar; R¹–R² = (CH₂)_n; n = 3–5; B = MOH, MOR, MON = $\langle$; M is alkali metal; R³ = H, CH = CH₂.

Uspekhi Khimii 68 (6) 506–531 (1999); translated by V D Gorokhov

Later it was established that this reaction is of a general character and embraces virtually all ketoximes that have at least

one CH₃ or CH₂ group in the α -position relative to the oxime function and contain no groups unstable in the presence of strong bases. This finding has led to successful syntheses of pyrroles and 1-vinylpyrroles with alkyl, alkenyl, cyclopropyl, aryl and hetaryl substituents in the ring; condensed pyrrole systems of the type of cycloheptano[*b*]pyrrole, dihydrobenzo[*g*]indole and 5-azaindoles including stable free radicals with the NO $\cdot$ group at position 5, *etc.*^{13–24, 26, 28–33}

Synthesis of hetarylpyrroles with furyl and thienyl substituents by this method was first described by Trofimov *et al.*^{34–36} 2-(2-Furyl)-3-methyl-1-vinyl- and 3-ethyl-2-(2-furyl)-1-vinylpyrroles were synthesised from the corresponding ketoximes and acetylene in yields up to 85%.³⁵ An analogous approach was used to prepare 2-(2-thienyl)- and 2-(2-thienyl)-1-vinylpyrroles in 60% and 50% yields, respectively.³⁶ The reactions were carried out in an autoclave under an initial pressure of acetylene from 6 to 16 atm.

R¹ = H, Me, Et; R² = H, CH=CH₂; X = O, S.

Subsequently, this method has successfully been used for the preparation of 3-alkyl-2-(2-furyl)pyrroles **1a–c** and their 1-vinyl derivatives **2a–f**.³⁷

Compound	R	Yield (%)	Compound	R	Yield (%)
1a	H	36	2c	Et	85
1b	Me	23	2d	Pr ⁿ	77
1c	Et	39	2e	Pr ⁱ	81
2a	H	80	2f	Bu ⁿ	76
2b	Me	92			

Under conditions close to those established⁴ earlier for aliphatic ketoximes [100 °C, ketoxime:KOH = 5:3 (w/w), excess of acetylene, pressure 10–16 atm.], the reaction of 2-furyl methyl ketoxime with acetylene produces a mixture consisting of 1*H*- (**1a**) and 1-vinyl-2-(2-furyl)pyrroles (**2a**) in the ratio of *ca* 1:4 and an overall yield of 71% (16% and 55%, respectively).³⁷

Under analogous conditions 2-(2-furyl)-3-methyl-1-vinylpyrrole (**2b**, 57% yield) and the corresponding pyrrole **1b** (8% yield) are formed from ethyl 2-furyl ketoxime. At a higher temperature (130 °C) and an equimolar ketoxime:KOH ratio this reaction proceeds selectively with the formation of vinylpyrrole alone (**2b**, 92% yield).

The yield of furylpyrroles **1a** and **2a** upon the reaction of 2-furyl methyl ketoxime and acetylene depends on the reaction temperature (Table 1). At temperatures below 100 °C, the rate of ketoxime cyclisation into pyrrole **1a** and vinylation of the latter to vinylpyrrole **2a** is too low (the ketoxime conversion does not exceed 40%). At 130–150 °C, one observes resinification that decreases the yield of 1-vinylpyrrole **2a**. In addition, at a high temperature the process of deoximation of the initial oxime to 2-acetylfuran becomes noticeable. The optimal conditions for the synthesis of 3-alkyl-2-(2-furyl)-1-vinylpyrroles are as follows: 110–130 °C, 3 h, excess of acetylene (initial pressure 10–14 atm) and equimolar ratio ketoxime:KOH).

It should be pointed out that lithium hydroxide, which catalyses selectively the stage of heterocyclisation in an analogous reaction with methyl phenyl and benzyl phenyl ketoximes,^{38,39} is

Table 1. Dependence of the yield of 2-(2-furyl)- (**1a**) and 2-(2-furyl)-1-vinylpyrroles (**2a**) on the reaction temperature (molar ratio ketoxime:KOH = 1:1, C₂H₂ pressure 10–14 atm, 3 h).³⁷

Temperature / °C	Yield of mixed products (%)	Composition of mixture (%) ^a			Ketoxime conversion (%)
		ket-oxime	compound 1a	compound 2a	
70	85	60	26	14	40
90	82	20	24	56	80
110	70	traces	39	71	~100
120	65	"	15	85	~100
130	46	undetected	traces	~100	~100
150	21	"	"	~100	~100

^a According to ¹H NMR data.

not selective in this case: even at 100 °C a mixture of 1*H*- (**1a**) and 1-vinylpyrroles (**2a**) is formed in the ratio 15:1, while the total yield of pyrroles is lower than with KOH (~50% instead of 72%, GLC).

The corresponding pyrrole is also readily formed from methyl (5-methyl-2-furyl) ketoxime and acetylene.⁴⁰

R = H (53%), CH=CH₂ (62%).

Under atmospheric pressure (100 °C, 5 h, equimolar ratio ketoxime:KOH) the yield of 2-(5-methyl-2-furyl)pyrrole is 53% and the conversion of ketoxime is 80%. Under these conditions 2-(5-methyl-2-furyl)-1-vinylpyrrole is formed in a rather low yield (15%). Under acetylene pressure of 12 atm (90 °C, 3 h, molar ratio ketoxime:KOH = 1:2), the same reaction produces vinylpyrrole in 62% yield, though being accompanied by resinification. According to GLC data, no more than ~3% of the corresponding 1*H*-pyrrole remains unconsumed under these conditions.⁴⁰

It is known that even at 50–60 °C and atmospheric pressure alkyl phenyl ketoximes react readily with acetylene to form the corresponding pyrroles in yields up to 83%.⁴¹ The reaction of ethyl 2-furyl ketoxime with acetylene under a pressure of 10 atm and 100 °C produces 2-(2-furyl)-3-methyl- and 2-(2-furyl)-3-methyl-1-vinylpyrroles in yields of 8% and 57%, respectively.³⁷ Quite unexpectedly, in the condensation of the oxime **3** with acetylene (10 atm, 100 °C) the conversion of oxime **3** was no more than 65%, while the yield of pyrrole **4a** was as low as 30%. The reaction is accompanied by considerable resinification.

R = H (**a**), CH=CH₂ (**b**).

A decrease in the reaction temperature to 75–80 °C did not lead to higher yield of compound **4a**, because even at this

temperature ketoxime **3** seems to undergo deoxygenation to the ketone **5**.

Vinylpyrrole **4b** was detected in the reaction mixture only by GLC.⁴⁰ Low yield of pyrroles **4a,b** was explained by the decrease in the reactivity of ketoxime **3** due to the presence of bulky phenyl and furyl groups preventing the approach of oximate anion to the triple bond. An intermediate formed from ketoxime **3** isomerises easily into a substituted vinylfuran **6**, which cannot undergo the [3,3]-sigmatropic shift and, consequently, the pyrrole formation.

These two side reactions seem to account for resinification and formation of by-products, which prevent isolation of pure pyrroles **4a,b**. Additional difficulties appear to be associated with oligomerisation of acetylene, which occurs in the NH_3 (amine)–KOH–DMSO systems.⁴²

Condensation of alkyl 2-thienyl ketoximes with acetylene catalysed by superbases (MOH–DMSO) produced 1*H*- (**7a–f**) (50%–60%) and 3-alkyl-2-(2-thienyl)-1-vinylpyrroles (**8a–f**) (in 60%–70% yields).^{43,44} The reaction proceeds smoothly at 100–130 °C and may be carried out under both elevated (10–16 atm) and atmospheric pressures of acetylene.

The effect of reaction conditions (temperature, acetylene concentration, addition of water, the nature of cation in the alkali metal hydroxide) on the ratio of pyrroles to their vinyl derivatives formed in the same synthesis was studied in the example of methyl 2-thienyl ketoxime.

R = H (**a**), Me (**b**), Et (**c**), Prⁿ (**d**), Buⁿ (**e**), n-C₆H₁₃ (**f**); M = Li, K.

Synthesis of 2-(2-thienyl)-1-vinylpyrrole (**8a**) is best carried out in an autoclave, at 120 °C for 3 h under elevated acetylene pressure, 17 mass.%–30 mass.% of KOH with respect to the ketoxime.^{26,37} The increase in the reaction time to 5 h and more as well as in the temperature to 140–150 °C lead to more pronounced resinification and a lower product yield. 2-(2-Thienyl)pyrrole (**7a**) free of its vinyl derivative is produced in > 60% yield with the use of a superbasic pair LiOH–DMSO (100 °C, 3 h, 10–16 atm) which, as in the case of condensation of methyl phenyl ketoxime with acetylene,^{38,39} catalyses the stage of pyrrole ring formation and is virtually inactive in the stage of vinylation. The amount of lithium hydroxide added is ~ 18 mass.% with respect to the ketoxime. The same pyrrole was obtained in 47% yield under atmospheric pressure (130–140 °C, 7 h, 30% LiOH). The addition of water to DMSO (10%–15%) and the use of KOH (equimolar ratio of KOH to the

oxime) inhibit the vinylation process and make possible the preparation of 2-thienylpyrrole (**7a**) in 53% yield. Heating of propyl 2-thienyl ketoxime with acetylene (100–120 °C, 0.8 mol KOH, 11% H₂O, 7 h) leads to the formation of 3-ethyl-2-(2-thienyl)pyrrole (**7c**) also in 53% yield.

The length of the carbon chain of the alkyl radical in the original alkyl 2-thienyl ketoxime does not exert any noticeable effect on the composition and yield of the final products.

The starting ketoximes are a mixture of *E*- and *Z*-isomers. It was established that only the *anti*-isomer participates in the reaction with acetylene, while the *syn*-isomer is recovered unaltered after the reaction. It could be supposed that the oximes with a large content of *anti*-isomer would give thienylpyrroles in higher yields. This is not the case because of easy *syn*–*anti*-isomerisation. This was demonstrated for methyl thienyl ketoximes, where pure *syn*- and *anti*-isomers isolated by preparative TLC were used in the reaction with acetylene.²⁶

Like in the case of alkyl methyl⁴⁵ and alkyl benzyl ketoximes,⁴⁶ the reaction of (*E*)-methyl 2-(5-methyl-2-thienyl)ethyl ketoxime with acetylene involves the methylene group in the *anti*-position relative to the hydroxy group.⁴⁰ At 95 °C and atmospheric pressure, the ratio of structurally isomeric pyrroles **9a** and **10a** is 33 : 1 [yields 46% and 1.4%, respectively (GLC)], whereas vinylpyrrole **10b** was detected in the reaction products only in trace amounts. Despite a rather high total yield of pyrroles **9** and **10** (61%), their isolation from the reaction mixture proved to be problematic due to the presence of a number of unidentified by-products. More drastic conditions (120 °C) favour the increased proportion of the reaction products formed with the participation of the methyl group and also the vinylation of pyrroles **9a** and **10a**; the ratios of pyrroles **9a** : **10a** and **9b** : **10b** become equal to 24 : 1 and 5 : 1, respectively.⁴⁰

R = H (**a**), CH=CH₂ (**b**).

2-(2-Thienyl)- and 2-(3-thienyl)pyrroles **11** were synthesised recently using a modification of the Trofimov reaction consisting in the addition of methyl 2-thienyl and methyl 3-thienyl ketoximes **12** to methyl propiolate and dimethyl acetylenedicarboxylate.⁴⁷

R = H, CO₂Me.

The reaction is conducted in two stages: intermediate *O*-vinylloximes **13** are transformed into thienylpyrroles **11** on boiling in xylene.

Selenienylpyrroles have remained virtually unstudied until now since no efficient methods for their synthesis had been developed. Mikhaleva *et al.*⁴⁸ have shown the possibility of preparing the corresponding pyrroles from methyl 2-selenienyl ketoxime (**14**) by its reaction with acetylene at 95–97 °C: 2-(2-selenienyl)pyrrole (**15a**) and -2-(2-selenienyl)-1-vinylpyrrole (**15b**) were produced in yields of 10% and 2%, respectively.

R = H (a), CH=CH₂ (b).

Ketoxime **14** was used in this reaction as a mixture of *E*- and *Z*-isomers (1 : 1). Under these conditions, the *Z*-isomer reacted predominantly (or exclusively), which correlates with the results of the analogous reaction with methyl 2-thienyl ketoxime⁴³ and 2-benzimidazolyl methyl ketoxime.⁴⁹

The low yield of pyrrole **15a** is explained by its instability in the KOH–DMSO system.⁴⁸ Further temperature increase to 110–120 °C results only in a lower yield and resinification. Apparently, the C–Se bond is less stable and more sensitive to the attack by a strong base compared with the C–O and C–S bonds (as mentioned above, under the same conditions the total yield of furyl and thienyl analogues reaches 80%–90%).

a. 1,2-Dichloroethane as an acetylene equivalent

The reaction of alkyl hetaryl ketoximes **16** with 1,2-dichloroethane (DCE), which is a synthetic equivalent of acetylene under the conditions of the Trofimov reaction, is a version of the synthesis of furyl- and thienylpyrroles.⁵⁰

The ratio of the reaction products [hetarylpyrroles **1** and **7**, 1-vinylhetarylpyrroles **2** and **8**, intermediate *O*-2-chloroethyl (**17**) and *O*-vinyl (**18**) hetaryl ketoximes] and by-products, *viz.* 1,2-bis(hetarylalkylideneiminoxy)ethanes (**19**), depends on many factors: reaction temperature and time, the nature of the hydroxide cation, its concentration and the presence of water in the catalytic system (Scheme 1).

An advantage of this version consists in the substitution of acetylene by a more accessible, safe and handling-convenient DCE. The synthesis can be performed in a trivial apparatus under atmospheric pressure and in the temperature range 100–135 °C.⁵⁰ The highest yields of furyl- and thienylpyrroles were attained at 120 °C (6–9 h, molar ratio ketoxime : NaOH : DCE = 1 : 2 : 7). When KOH was used as a base, better results were obtained upon addition of 5%–10% of water (120 °C, 7 h, molar ratio ketoxime : KOH : DCE = 1 : 2 : 10); however, in this version the yields of 2-(2-furyl)- and 2-(2-thienyl)-1-vinylpyrroles did not exceed 25%. In the presence of lithium hydroxide, the yields of pyrroles were lower (18%). In an NaOH–DMSO + 10% H₂O system, the reaction stops at the stage of intermediates **18**, *viz.*, *O*-methyl 2-thienyl *O*-vinylketox-

imes (R = H, yield 43%) or 2-furyl methyl *O*-vinylketoximes (R = H, yield 6%).⁵⁰

The detection of *O*-vinylketoximes **18** and methyl 2-thienyl *O*-(2-chloroethyl)ketoximes **17** (X = S, R = H, yield 24%) among the main reaction products has made it possible to suggest⁵⁰ that in the case of DCE, two alternative pathways of the formation of pyrroles and 1-vinylpyrroles are realised. According to the first pathway,⁴ in a strongly basic medium DCE serves as the source of acetylene, and the reaction proceeds as usual (see Section II.1). The second pathway consists in the nucleophilic substitution of one chlorine atom in DCE by the oximate anion with the formation of *O*-(2-chloroethyl)ketoximes **17** with subsequent elimination of HCl to afford *O*-vinylketoximes (**18**). Intermediates **18** undergo cyclisation into the corresponding pyrroles, which react with DCE to form, apparently, 1-(2-chloroethyl)pyrroles **20**. These are further transformed into *N*-vinylpyrroles upon elimination of HCl.⁵⁰ The possibility of formation of 1-(2-chloroethyl)pyrroles **20** under these conditions is in accord with the data reported in Ref. 51.

b. Vinyl chloride as an acetylene equivalent

A simple and industrially acceptable method of synthesis of furyl- and thienylpyrroles is based on the reaction of the corresponding ketoximes with vinyl chloride in a KOH–DMSO suspension.²⁶ The condensation is carried out at 120 °C with a sixfold excess of KOH relative to the ketoxime. This results in the formation of a mixture of pyrroles and their 1-vinyl derivatives. In this modification of the Trofimov reaction, vinyl chloride serves as the acetylene equivalent.

Compound	X	R	Yield (%)
1b	O	Me	40
2b	O	Me	36
7d	S	Pr ⁿ	46
8d	S	Pr ⁿ	26

c. Intermediates and the reaction mechanism

Systematic studies on the synthesis of pyrroles from hetaryl ketoximes and acetylene in the superbasic KOH–DMSO medium have allowed not only identification of the reaction intermediates, such as *O*-vinylketoximes or 3*H*-pyrroles, but also the development of methods for their preparation.^{43, 50, 52–55} For instance, 2-furyl methyl (**18a**) and methyl 2-thienyl (**18b**) *O*-vinylketoximes were obtained in yields of 38% and 32%, respectively, by the reaction of 2-furyl methyl (**16a**) and methyl 2-thienyl ketoximes (**16b**) with acetylene in the KOH–DMSO system (initial pressure 12 atm, 3 h, 50–60 °C).^{52–54}

Scheme 1

X = O, S; R = H, Me, Et, Buⁿ; M = Li, Na, K.

X = O (a), S (b); (a) $\text{HC}\equiv\text{CH}$, MOH , DMSO , H_2O ; (b) $\text{Cl}(\text{CH}_2)_2\text{Cl}$, MOH , DMSO , H_2O ; M = K, Li.

Upon addition of 4% of water to the KOH – DMSO system, the yield of *O*-vinylketoxime **18b** increased to 44%.⁵⁴ Under similar conditions, the yield of the corresponding furyl derivative **18a** did not exceed 13%.⁵⁴ Under atmospheric pressure of acetylene, the synthesis of *O*-vinylketoximes is less efficient. 1,2-Dichloroethane is also suitable for the preparation of ketoximes **18a,b**. The optimal conditions for the synthesis of compound **18b** are the use of LiOH – DMSO system and addition of 10% of water (100 °C, 4 h, yield 43%).⁵⁰ In the NaOH – DMSO system containing 10% of water, *O*-vinylketoxime **18b** is not formed, whereas the yield of *O*-vinylketoxime **18a** is as low as 6%.⁵⁰

Ketoximes **18a,b** are transformed upon thermolysis into the corresponding pyrroles as do alkyl aryl *O*-vinylketoximes,⁵⁶ methyl (1-methyl-2-pyrrolyl) *O*-vinylketoxime⁵⁷ or *O*-vinylketoximes formed upon heating of *O*-(2-iodoethyl)ketoximes with Bu^tOK in Bu^tOH .⁵⁸ Thus, heating of 2-furyl methyl and methyl 2-thienyl *O*-vinylketoximes (100 °C) in the KOH – DMSO system led to 2-(2-furyl)- and 2-(2-thienyl)pyrroles in yields of 60% and 50%, respectively.⁵⁶ 2-(2-Thienyl)- and 2-(3-thienyl)-4-methoxycarbonyl- and -4,5-di(methoxycarbonyl)pyrroles **13** were obtained by heating of the corresponding *O*-vinylketoximes **12** in xylene⁴⁷ (see Section II.1).

The reaction of isopropyl 2-thienyl ketoxime (**21**) with acetylene afforded 3,3-dimethyl-2-(2-thienyl)-3*H*-pyrrole (**23**), the yield of which depended on the reaction conditions and in the best case (addition of Al_2O_3 to the catalytic system) reached 43% with respect to the consumed ketoxime.⁵⁵

The formation of the pyrrole **23** from the oxime **21** indicates that the reaction pathway includes the stage of prototropic isomerisation of *O*-vinylketoxime **22a** into *O,N*-divinylhydroxyamine **22b**.

This scheme of the formation of pyrroles from oximes is also supported by the identification^{59,60} of other reaction intermediates (hydroxypyrrolines) and their transformation into the corresponding pyrroles upon condensation of alkyl aryl ketoximes with acetylene.⁴¹ The fact that pyrroles cannot be synthesised from *O*-alkyl ketoximes under the conditions of the Trofimov reaction,²⁴ as well as the predominant formation of β -phenylpyrroles in the case of phenylacetylene⁶¹ support the proposed reaction scheme.

2. The Paal–Knorr synthesis

The Paal–Knorr synthesis is widely used for the preparation of pyrrolyl-, furyl- and thienylpyrroles. As a rule, it is carried out under mild conditions and provides for high yields of the target

products in the final stage. However, the preparation of the initial 1,4-diketones and/or amines with furyl and thienyl substituents remains a challenge: their synthesis includes several stages which do not always give high yields, which restricts substantially the applicability of this method.

N,N',N''-Tris(*tert*-butoxycarbonyl)-5,5''-dibromo-2,2':5',2''-terpyrrole (**26**) was obtained from 2-formylpyrrole⁶² in several steps (Scheme 2). In the intermediate disulfone **24**, two sulfonyl groups were substituted by *tert*-butoxycarbonyl protective groups. Simultaneously, the third pyrrole ring was *N*-protected; the totally protected terpyrrole **25** was then selectively brominated with *N*-bromosuccinimide (NBS) to pyrrole **26**.

Scheme 2

(a) NaH , PhSO_2Cl , DMF , 20 °C; (b) SO_2 , EtOH , Δ ; (c) AcONH_4 , Ac_2O , EtCO_2H , 140 °C; (d) NaOH , MeOH , 20 °C; (e) $(\text{Bu}^t\text{O}_2\text{C})_2$, Bu^tOK , THF , Δ ; (f) NBS , THF , –70 °C.

In a Japanese patent⁶³ it was proposed to prepare 1-(2-thienyl)pyrroles **29** (yields up to 80%) by the reaction of 2-aminothiophenes **27** with 1,4-diketones **28** on boiling for 20 min in benzene in the presence of *p*-toluenesulfonic acid.

R ¹	R ²	R ³	R ⁴	R ⁵

2-Cl	Me	Me	Me	H
H	H	Me	Me	H
H	H	Et	Me	H
H	Me	Me	Me	Me

Furylpyrroles (**31a,b** and **32a**) were prepared from 1-(2-furyl)pentane-1,4-dione (**30a**) or 1-(2-furyl)-2,4-diphenylbutane-1,4-dione (**30b**) and ammonia (NH₄Cl, 180 °C, 20 h, yields of 40% and 50%, respectively) or 4-chlorophenylamine (AcOH, EtOH, 7 h, yield 85%) under atmospheric or elevated pressure.⁶⁴

R¹ = H, R² = Me (a); R¹ = R² = Ph (b).

If ammonia is replaced by ammonium carbonate and the reaction is carried out in ethanol in the presence of acetic acid, a twofold increase in the yield of pyrrole **31a** is achieved.⁶⁴ It should be noted that the reaction of diketone **30a** with ammonia is accompanied by the formation of pyrrole **33** (yield 8%), while 2,4,5-tri(2-furyl)imidazole and 2,3,5,6-tetra(2-furyl)pyrazine (5% yield of each) are formed from diketone **30b**.⁶⁴

1-(5-Chloro-2-thienyl)pentane-1,4-dione (**36**) obtained from 5-chlorothiophene (**34**) and 5-methyl-5-hydroxytetrahydrofuran-2-one (**35**) reacts with ammonium acetate in methanol at 25 °C for 3 h to give 2-(5-chloro-2-thienyl)-5-methylpyrrole **37** in 65% yield.⁶⁵

Pyrroles **39a–d** containing two thienyl substituents in the ring were obtained in high yields from the corresponding diketones **38a–d** and methylamine in boiling propanol containing methylamine hydrochloride.^{66, 67}

c	2-thienyl	3-thienyl	90
d	3-thienyl	3-thienyl	99

Synthesis of 2,5-bis(2-pyrrolyl)thiophenes **42** (yield 65%) was brought about^{62, 68} by cyclisation of symmetrical 1,4-diketones **40a,b** with Lawesson's reagent (**41**) upon boiling in toluene.

Diketones **40a,b** are obtained from pyrrole-2-carboxaldehydes in ethanol in the presence of NaOAc, divinyl sulfone and a thiazolium salt as the catalyst (yields 70% and 74%, respectively).

2,5-Bis[3,5-di(ethoxycarbonyl)-4-methyl-2-pyrrolyl]thiophene (**44**) was prepared in 76% yield from diketone **43** [synthesised by the reaction of 3,5-bis(ethoxycarbonyl)-4-methyl-2-formylpyrrole with divinyl sulfone in dioxane at 80 °C in the presence of triethylamine] and Lawesson's reagent **41**.⁶⁸

R = EtO₂C.

The reaction of 2-methylsulfinyl-1-phenyl-5-(2-thienyl)pentane-1,5-dione (**45**) with ammonium acetate in acetic acid (Δ, 10 min) leading to 2-(2-thienyl)pyrrole (**46**) with a yield of 19% may be regarded as a variant of the Paal–Knorr synthesis.⁶⁹

An elegant and efficient synthesis of 1-(2-thienyl)pyrroles **51–53** is based on the condensation of 2-aminothiophenes **47**, 2-amino-4,5-dihydrocyclopenta[*b*]thiophene **48** or 2-amino-4,5,6,7-tetrahydrobenzo[*b*]thiophenes **49** with 2,5-dimethoxytetrahydrofuran (**50**) in acetic acid.^{70, 71}

Compound 51	R ¹	R ²	R ³	Yield (%)
a	Me	Me	H	86
b	Me	Et	CO ₂ H	96
c	Me	Me	CO ₂ H	97
d	H	H	CO ₂ Et	72
e	Me	Me	CO ₂ Et	70

R = CO₂H (96%), CO₂Et (71%).

R = H (70%), CO₂H (97%), CN (86%), CO₂Et (59.5%).

The oxidation products of aminoacylfuran **54** are supposed to contain, along with the major compounds **55a–c**, insignificant amounts of furylpyrroles **56a,b**.⁷²

R = OH (**a**), NH(CH₂)₄CH(NH₂)CO₂H (**b**), CONH(CH₂)₄CH(NH₂)CO₂H (**c**).

The reaction of cyclopropyl ketones **57** with amines leads to the formation of hetarylpyrroles **58** in high yields.^{73,74} The presence of an electron-acceptor substituent X (OMe, OEt, Cl) in the cyclopropane ring facilitates its isomerisation leading to the formation of a carbonyl group equivalent.

R¹ = 2-furyl, 2-thienyl; R² = H; R³ = H, Alk, Ar; X = OMe, OEt, Cl.

3. Syntheses involving activated acetylenes

Oxazolium oxide **60** formed from *N*-methyl-*N*-thenoylamino acid **59** and acetic anhydride is transformed into 2-(2-thienyl)pyrrole **61** upon boiling in benzene with dimethyl acetylenedicarboxylate (yield 89%).⁷⁵

R = CO₂Me.

A general method for the synthesis of thienylpyrroles **64** has been developed, which is based on 1,3-dipolar cycloaddition of 2-(2-thienyl)aziridines **62** to activated acetylenes.^{76,77} The reaction proceeds on heating of the reagents in benzene with the formation of intermediate thienylpyrrolines **63**, which are readily dehydrogenated under the action of tetrachloro-1,4-benzoquinone to give pyrroles **64**, as a rule, in moderate yields.

R	Ar	Yield of 64 (%)	R	Ar	Yield of 64 (%)
H	Ph	32	H	2-naphthyl	36
H	4-MeC ₆ H ₄	26	CO ₂ Me	4-MeC ₆ H ₄	53
H	4-MeOC ₆ H ₄	39	CO ₂ Me	4-MeOC ₆ H ₄	65
H	3-NO ₂ C ₆ H ₄	25	CO ₂ Me	3-NO ₂ C ₆ H ₄	32

Heating of 1,4-di(2-thienyl)butadiyne (**65**) with aniline at 140–160 °C in the presence of cuprous chloride leads to the formation of 2,5-di(2-thienyl)-1-phenylpyrrole (**66**) in 68% yield.⁷⁸

This reaction has a general character. Asymmetrically substituted butadiynes **67** react with amines, which allows preparation of various 2-(2-thienyl)pyrroles **68**.⁷⁸ Ethanol, dioxane and DMF are used as solvents.

R¹ = H, Me, Et, Ph; R² = H, Me, Et, Buⁿ, Ph.

A new method has been developed for the synthesis of 2-(2-pyrrolyl)-, 2-(2-furyl)- and 2-(2-thienyl)pyrroles **69a–c** from the corresponding amines **70**, acetylenes **71** and carbon monoxide with the use of zirconium cyclopentadienyl complexes.⁷⁹

X = N, R = Prⁿ (**69a**, 68%); X = O, R = Ph (**69b**, 49%); X = S, R = Prⁿ (**69c**, 41%).

The reaction with CO leading to hetarylpyrroles may be realised both with and without isolation of metallocycles **72**. This reaction can be carried out in the presence of NH₄Cl, under CO pressure of ~ 100 atm, at ~ 20 °C, for 24 h (method A) or in the absence of NH₄Cl, at 80 °C, CO pressure of ~ 6 atm and for 36 h (method B). The former method is more efficient, though the role of NH₄Cl is still unclear.

The following mechanism of this reaction has been proposed:⁷⁹

Insertion of CO into the C–Zr bond gives metallocycle **73**. Migration of the nitrogen atom from zirconium to the acyl carbon (formally, reductive elimination) leads to the zirconium complex **74**. The intermediate **74** can undergo ring opening with the formation of a zwitter-ion **75**, which after migration of the trimethylsilyl group from nitrogen to zirconium gives compound **76**. Its hydrolysis yields intermediate **77**, which undergoes prototropic rearrangement into pyrrole **69**. An alternative pathway is possible: hydrolysis of the complex **74** to the alcohol **78**, which is dehydrated to give the intermediate **77** with subsequent formation of pyrrole **69**.⁷⁹

Synthesis of pyrroles⁸⁰ through carbocupration of *N,N*-bis(trimethylsilyl) derivatives of alkyl 4-aminobut-2-ynoates with subsequent treatment with acyl chlorides has opened a route to new polyheterocyclic compounds, including furyl- and thienylpyrroles and tetrapyrrole macrocycles. Thus, the reaction of lithium methyl(hexynyl)cuprate with methyl (**79a**) or ethyl 4-aminobut-2-ynoates (**79b**) with subsequent treatment with 2-furyl or 2-thienoyl chlorides leads to 2-furyl- (**80**) and 2-thienyl-pyrroles (**81a,b**).

R = Me (**81a**, 30%), Et (**81b**, 58%); (a) $(\text{Bu}^n\text{C}\equiv\text{C})\text{MeCuLi}$,

Et_2O , -40°C ; (b) ; (c) .

4. Synthesis involving isocyanides

Isocyanides are rather common components in the synthesis of hetarylpyrroles.^{81–87} 3-(2-Furyl)- (**84a,b**) and 3-(2-thienyl)pyrroles **84c** were synthesised by addition of 1-tosylalk-1-enyl isocyanides **82** to chalcone analogues **83** in the presence of

Bu^tOK .⁸¹ The initial isocyanides **82** can be easily obtained by the reaction of tosylmethyl isocyanide with carbonyl compounds.

Compound 84	X	n	R	Yield (%)
a	O	1	2-furyl	93
b	O	3	Ph	89
c	S	2	2-thienyl	85

It is presumed⁸¹ that the formation of pyrroles **84** occurs by the following mechanism:

The Michael addition of the allylic anion **85**, formed under the action of a base, to the vinyl ketone **83** and subsequent cyclisation of the enolate anion **86** and elimination of the tosylate anion yield the final reaction product.

Pyrroles **89a–c** were obtained from 2-cyano-3-(2-furyl)- and -(2-thienyl)acrylic acids **87a–c** and tosylmethyl isocyanide (**88**) in a superbasic system KOH–dimethoxyethane.⁸²

Compounds 87, 89	X	R	Yield of 89 (%)
a	O	H	92
b	S	H	97
c	S	Me	89

The addition of methyl isocyanoacetate (**90**) to thiophene-2-carbaldehyde in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in THF at $40–50^\circ\text{C}$ (15 h) leads to 3-(2-thienyl)-pyrrole (**91**) in 70% yield.^{85,87}

Sakai *et al.*⁸⁵ have obtained pyrrole **91** by a different scheme including intermediates **92** and **93**.

Phosphorylated 3-(2-furyl)pyrrole **95** was synthesised in 54% yield by the reaction of isocyanide **94** with 2-(2-nitroprop-1-enyl)furan in the presence of lithium diisopropylamide (LDA) (THF, -78°C , 3 h; $\sim 20^{\circ}\text{C}$, 72 h; reflux, 2 h) with subsequent treatment with ammonium chloride.⁸⁶

5. Syntheses from cyanides

A simple and efficient method for the synthesis of 2-(2-furyl)pyrroles **98**, **99** is based on the reaction of tetracyanoethane with azomethine **96** or azine **97**.^{88–92}

Pyrrole **98** is synthesised either by heating ($90\text{--}100^{\circ}\text{C}$) of tetracyanoethane and azomethine **96** in aqueous dioxane (yield $60\% \text{--} 65\%$)⁸⁸ or with the intermediate isolation of pyrroline **100**, which is transformed into pyrrole **98** in 98% yield upon heating for 5–25 min at $60\text{--}70^{\circ}\text{C}$ in DMF.⁸⁹

Similarly, upon gentle heating in an aqueous-ethanolic or ethanolic medium pyrroline **101** loses one molecule of hydrocyanic acid and is transformed into pyrrole **99**.⁹¹

Condensation of bis(2-thienyl)acetylene **102** with an excess of trimethylsilyl cyanide catalysed by palladium or nickel chloride in pyridine yields 3,4-bis(2-thienyl)pyrrole (**103**).⁹³

The reaction involves such a profound rearrangement of trimethylsilyl cyanide that it is hardly possible to propose any reasonable mechanism of this reaction.

6. Organometallic synthesis

Kaufmann and Lexy⁹⁴ have synthesised bipyrrole **104** by α -lithiation of *N*-methylpyrrole with subsequent oxidative coupling of the intermediate obtained. Bipyrrole **105** was used for the preparation of terpyrrole and then oligopyrrole.

TMEDA is tetramethylethylenediamine; $n = 6$.

3,3-Bipyrrole **106** was obtained⁹⁵ by a Wurtz-type reaction from 3-bromo-1-(triisopropylsilyl)pyrrole (**107**) upon treatment of the latter with *tert*-butyllithium in the presence of CuI.

(a) Bu^tLi , CuI, $n\text{-C}_5\text{H}_{12}$ –THF, -78°C , 10 min; (b) 20°C , 2 h.

Groenendaal *et al.*⁹⁶ have described dimerisation of 5-bromo-1-*tert*-butoxycarbonyl-2-phenylpyrrole according to Ullmann.

Under the same conditions,⁹⁶ 2,5-dibromo-1-*tert*-butoxycarbonylpyrrole afforded a dimer and other oligomers containing up to 24 pyrrole rings, which were isolated as individual products by preparative HPLC.

$\text{R} = \text{CO}_2\text{Bu}^t$; $n = 3\text{--}24$.

Gjøs and Gronowitz⁹⁷ have developed a method for the synthesis of thienylpyrroles **108** and **109** by reaction of 2-iodo-

thiophene **110** with 1-methyl-2-pyrrolylcopper (**111**) prepared by metallation of 1-methylpyrrole with butyllithium in a mixture of ether and tetramethylethylenediamine followed by treatment with cuprous bromide.

The course of the reaction and the ratio of the products formed are substantially influenced by its duration: when the reaction was conducted for 1 h, a mixture was obtained that contained, along with thiopyrrole **108**, the initial iodothiophene (**110**), iodopyrrole **112**, bipyrrrole **113** and bithiophene **114**; when the mixture was allowed to react for 4 h, a decrease in the concentration of bithiophene **114** and an increase in the content of thiopyrrole **108** and bipyrrrole **113** were observed. Trace amounts of 1-methyl-2-[5-(2,2'-bithienyl)]pyrrole **109** and terthiophene **115** were also formed. According to GLC data, the ratio of products **108**:**109**:**113**:**114**:**115** was 53:14:24:7:<1. The major product, viz., thiopyrrole **108**, was isolated in 40% yield, while the yield of compound **109** was 15%.⁹⁷ The formation of the latter product is explained by the following scheme:

The reaction of the copper intermediate **111** with 3-iodothiophene leads to a more complex mixture of products.⁹⁷

According to GLC data, bicyclic and tricyclic compounds constitute 7% and 30% of this mixture, respectively. Column chromatography with subsequent distillation and recrystallisation gave 1-methyl-2-(3-thienyl)pyrrole (**116**) (yield 72%), thiopyrrole **108** (yield 6%) and tricyclic compound **117** (yield 9%).

Thienylpyrrole **108** was obtained by the same authors⁹⁷ in three steps:

The reaction of 2-acetylthiophene with dimethylformamide and phosphorus oxychloride followed by treatment of the reaction mixture with HClO₄ yields perchlorate **118**. The reaction of salt **118** with dimethylamine gives perchlorate **119**; its heterocyclisation leads to thiopyrrole **108**, although in a low yield.⁹⁷

The use of the Stille reaction allowed one to synthesise oligoheterocyclic compounds containing pyrrole and thiophene units, e.g., *N-tert*-butoxycarbonyl-di-2-(5-*tert*-butoxycarbonyl-5-phenyl-2-pyrrolyl)thienylpyrrole (**123**).⁹⁸ Organotin derivative **120** is prepared by stannylation of a substituted pyrrole. Cross-coupling of compound **120** with bromobenzene according to Stille in the presence of palladium[tetrakis(triphenylphosphine)] followed by stannylation of the reaction product yields compound **121**. Pyrrole **122** is obtained by distannylation of *tert*-butyl 2,5-bis(2-thienyl)pyrrole-*N*-carboxylate with subsequent bromination of the reaction product with *N*-bromosuccinimide. Cross-coupling of compounds **121** and **122** according to the Stille method leads to the oligoheterocycle **123**.

(a) (Bu^tO₂C)₂, Bu^tOK, THF, Δ; (b) tetramethylpiperidine, BuⁿLi, THF, −70 °C; (c) Me₃SnCl, THF, Pd(PPh₃)₄, −70 °C; (d) PhBr, Pd(PPh₃)₄, PhMe, H₂O, Na₂CO₃; (e) NBS, THF; (f) Pd(PPh₃)₄, PhMe, Na₂CO₃, H₂O, Δ.

Cross-coupling according to Stille was also used to prepare the following compounds:⁹⁸

R = Bu^tO₂C.

Cross-coupling of *N*-methylpyrrolylmagnesium(zinc) halides with 3-halogenothiophenes in the presence of a palladium catalyst leads to 1-methyl-2-(3-thienyl)pyrrole (**116**) in high yield.^{99, 100}

M = Mg, Zn; X = Cl, Br, I; Y = Cl, Br;

[Pd] = PdCl₂, Ph₂P(CH₂)₄PPh₂ (2.5 mol %).

7. Synthesis from azides

Thermolysis of azidobutadienes **125a–d** containing a hetaryl substituent yields the corresponding 2-hetarylpyrroles **126a–d**. The starting compounds for the preparation of azides **125a–d** were β-2(3)furyl- and β-2(3)-thienylacroleins **124a–d** and methyl azidoacetate. Alkaline hydrolysis of compounds **126a–d** and subsequent decarboxylation of acids **127a–d** in quinoline (with barium-promoted copper chromite as a catalyst) lead to the corresponding 2-(2-furyl)- and 2-(2-thienyl)pyrroles (**128a,b**) or 2-(3-furyl)- and 2-(3-thienyl)pyrroles **128c,d**.¹⁰¹

Compound	Substituent position	X	Yield (%)		
			126	127	128
a	2	O	90	79	68
b	2	S	90	75	46
c	3	O	92	79	43
d	3	S	87	89	57

8. Synthesis from unsaturated aminocarbonyl compounds

Rapoport *et al.*^{102–106} have synthesised 2,2-bipyrrole (**130**) and 2,2':5',2''-terpyrrole (**131**) by the reaction of 2-pyrrolidone with phosphorus oxychloride and subsequent dehydrogenation of the intermediate product **129**.

R = H (**130**), 2-pyrrolyl (**131**).

2-(2-Furyl)- and 2-(2-thienyl)pyrroles have been synthesised in 86% yields by the reaction of *N*-allyl carboxamides **132** with phosgene followed by the elimination of HCl from the chloroimines **133**.¹⁰⁷

X = O, S.

The construction of the pyrrole ring is presumed¹⁰⁷ to result from the intramolecular 1,5-dipolar cyclisation of the intermediate nitrile ylides **134** to 3*H*-pyrroles **135**, which are further isomerised to 1*H*-pyrroles.

1-(2-Thienyl)pyrroles **139** were obtained in good yields in the reaction of sodium derivatives of cyanoamides **136** with vinyltriphenylphosphonium bromide (**137**) followed by the intramolecular cyclisation of the intermediate **138** under the action of a base with elimination of HCN and Ph₃PO.¹⁰⁸

$R^1 = 2\text{-thienyl}$; $R^2 = \text{Ph}, 4\text{-ClC}_6\text{H}_4$.

9. Miscellaneous methods

Boberg *et al.*¹⁰⁹ have proposed to obtain 3-(2-furyl)- (**140a**) and 3-(2-thienyl)pyrroles (**140b–e**) from nitronic acids **141** formed upon reaction of nitrovinylfurans or -thiophenes with alkyl acetoacetates. Heterocyclisation of compound **141** takes place at 60 °C in the presence of reducing agents, such as a mixture of sodium sulfide with ammonium chloride, aqueous ammonia with ammonium sulfide or Zn in HCl. This method does not have any preparative value because of low yields of pyrroles.

Compound 140	X	R^1	R^2	Yield (%)
a	O	Et	Et	1
b	S	Me	Et	17
c	S	Et	Et	14
d	S	Me	Bu ^t	10
e	S	Ph	Et	8

Synthesis of 1-(2-cyano-3-thienyl)pyrrole (**142**) and 1-(3-cyano-2-thienyl)pyrrole (**143**) by the reaction of 2,5-dimethoxytetrahydrofuran (**50**) with 3-amino-2-cyano- and 2-amino-3-cyanothiophenes, respectively, has been described.^{110–113}

Kresze *et al.*¹¹⁴ have carried out a multistep synthesis of 4-acetoxy-5-(methoxycarbonyl)-2-(2-thienyl)pyrrole (**149**) in which the key compound is a tetrahydropyridazine derivative **148**.

(a) NaH, THF, BuⁿLi, 0 °C, 3 h; (b) 1. *p*-TsCl, Py, 20 °C, 12 h; 2. 80 °C, 0.5 h; (c) MeCOCl, Py, 0 °C, 5 h; (d) RN=NR (R = Cl₃CCH₂OCO), Δ, PhH; (e) Zn, AcOH, MeOH, 55 °C, 3 h.

Condensation of 2-formylthiophene **144** with ethyl acetoacetate leads to hydroxy ketone **145** (yield of a crude product 93%) dehydration of which yields *E*-olefin **146**.¹¹⁴ Its *O*-acetylation affords a mixture of *E*- and *Z*-isomers of diene **147** from which the *Z*-isomer was isolated by crystallisation from ether (yield 31%). The Diels–Alder reaction of the *Z*-diene with trichloroethyl azo-*N,N'*-dicarboxylate results in a tetrahydropyridazine derivative **148** as an intermediate; its treatment with Zn powder in acetic acid yields thienylpyrrole **149**.¹¹⁴

1-Vinyltetrahydroisoquinoline (**150**) (obtained from 3,4-dihydroisoquinoline and vinylmagnesium bromide) reacts with 2-formylfuran (**151**) or 2-formylthiophene (**144**) to form polycyclic systems (**152a,b**) with 2-furyl or 2-thienyl substituents.¹¹⁵

X = O (**a**, 40%), S (**b**, 53%).

Pyrrolo[1,2-*a*]quinoxalines **154** containing a 2-(2-furyl)pyrrole fragment have been synthesised by the cyclisation of 2-(2-furfurylideneacetyl)quinoxalines **153** under the action of HCl or HClO₄.¹¹⁶

R = H, Me.

Corrole **156** is prepared by the oxidative cyclisation of a linear tetrapyrrole **155** in an alkaline medium.¹¹⁷

As expected, boiling of *meso*-thiaphlorin **157** in *o*-dichlorobenzene resulted in elimination of sulfur with the formation of

corrole **158** in 35%–40% yield.¹¹⁸ In the presence of triphenylphosphine, the yield of corrole **158** reaches 60%.

X = CO₂Et.

In the case of *meso*-dithia macrocycle **159**, the extrusion of sulfur occurs less readily (213 °C, 10 h, triphenylphosphine) and leads to two isomers of *meso*-thiacorrole **160a,b** in a total yield of 42% (ratio 1 : 1).¹¹⁸

X = CO₂Et.

III. Reactivity

Until recently, chemical properties of pyrroles bound to five-membered aromatic heterocycles have been very little studied because of the absence of reliable general methods for their synthesis. There were only fragmentary data on some reactions that included mostly interactions of their functional substituents (with the exception of formylation of the pyrrole fragment). The development of methods for the synthesis of hetaryl-substituted pyrroles in the last two decades has led to a considerable expansion of the array of preparatively accessible representatives of this group of compounds and to the appearance of real conditions for systematic studies of their reactivity and other properties.

1. Electrophilic substitution

a. Protonation

It is known^{1–3, 119–125} that the most characteristic reaction of the pyrrole ring is electrophilic substitution, which is also typical of substituted furans and thiophenes.^{121–125} The simplest reaction of this type is reversible protonation (degenerate electrophilic substitution of hydrogen).

Over the last decade, the ¹H NMR method was used for the systematic studies of protonation of the series of 2-(2-furyl)- and 2-(2-thienyl)pyrroles and their 1-vinyl derivatives.

Numerous studies^{21, 25, 27, 126–133} have shown that at –80 to –50 °C all pyrroles, regardless of the nature of the second heterocycle and the acid (except for the ‘magic’ acid HSO₃F–SbF₅), are protonated at the C(5) atom of the pyrrole ring; in the case of vinyl derivatives (R³ = CH=CH₂), the double bond is retained.

X = O, S; R¹ = H, Me; R² = H, Me, Prⁱ; R³ = H, CH=CH₂, Et;
A = Cl[–], Br[–], CF₃COO[–], FSO₃[–].

The reaction of furylpyrroles with hydrogen halides (HCl, HBr) at –30 °C yields a mixture of pyrrolium **161** and furanium **162** cations.^{21, 25, 128} An analogous mixture is also formed on gradual elevation of temperature from –80 to –30 °C.^{21, 25, 128}

Protonation of vinyl derivatives (–30 °C) is accompanied by the addition of HX to the 1-vinyl group.^{21, 25, 27, 126–131}

On warming from –80 to –30 °C, the cation in which both α -positions in the furan ring are occupied adds HX only to the double bond with the formation of the pyrrolium ion **163**.^{21, 25, 27, 128}

R = H, Me; X = Cl, Br.

As the temperature is increased to 0 °C, the reaction of furylpyrroles with HBr leads to 4-bromo-4,5-dihydro-2-(2-pyrrolyl)furanium bromides **164** as the result of addition of HBr to the protonated furan ring.^{21, 25, 27, 128}

R¹ = H; R² = H, CHBrMe, Et; R¹ = Me; R² = H, CHBrMe.

At 20 °C, dihydrofuranium cations **164** are completely transformed into 4-bromo-4,5-dihydro-2-(2-furyl)pyrrololium bromide **165** with the rearomatization of the furan moiety of the molecule.^{21, 25, 27, 128}

R¹ = H, Me; R² = CHBrMe.

In contrast to the furan ring, the thiophene ring is not involved in the reaction with HBr. In this case, the formation of only 4-bromo-4,5-dihydro-2-(2-thienyl)pyrrololium bromide (**166**) is observed.^{21, 25, 130, 131}

Unlike ordinary acids, the superacidic system $\text{HSO}_3\text{F} - \text{SbF}_5$ reacts with 2-(2-furyl)-1-vinylpyrrole at -70°C to give an equilibrium mixture of dications: 1-(1-ethanio)-2-(2-furyl)-5H-pyrrolium (**167**) and 1-(1-ethanio)-2-(2-furyl)-3H-pyrrolium (**168**) in the ratio 3 : 1.^{21,25}

In the reaction with the superacidic system $\text{HSO}_3\text{F} - \text{SbF}_5 - \text{SO}_2$, 2-(2-thienyl)-1-vinylpyrrole forms two cations: 1-(1-ethanio)-2-(2-thienyl)-5H-pyrrolium (**169**) and 2-[1-(1-ethanio)-2-pyrrolyl]-5H-thiophenium (**170**) in the ratio 2 : 1. Heating of the reaction mixture up to 10°C changes the ratio **169** : **170** to 1 : 2.^{21,25,130,131}

b. Formylation

Formylation of 2-(2-furyl)-, 2-(2-thienyl)-, 2-(3-furyl)- and 2-(3-thienyl)pyrroles and their α -methoxycarbonyl derivatives under conditions of the Vilsmeier reaction has been studied.^{101,134} Thienylpyrroles are formylated only at the α -position of the pyrrole ring with the formation of 2-thienyl- (**171**) (yield 75%) and 3-thienyl-2-formylpyrrole (**172**).

Formylation of furylpyrroles results in a mixture of mono- (**173, 175**) and diformyl derivatives (**174, 176**), the former being predominant.^{101,134}

In 2-(3-furyl)pyrrole (**128**), both α -positions of the furan ring are free. However, the formyl group enters the position 2 of the furan ring, which is in accord with the standard orientation rule.

5-Methoxycarbonyl-2-(2-thienyl)- (**126b**) and -2-(3-thienyl)pyrrole (**126d**) give a mixture of 3-formyl-substituted pyrroles (**177, 178**) and 2-(5-formyl-2-thienyl)- (**179**) and 2-(2-formyl-3-thienyl)-derivatives **180**, respectively.¹³⁴

Because of the orienting effect of the α -methoxycarbonyl group, formylation in pyrroles **126b,d** occurs mostly in the β -position of the pyrrole ring (95%); the formylation product in the α -position of the thiophene ring is formed in the yield not exceeding 5%.

Unlike its thienyl analogues, 2-(2-furyl)- (**126a**) and 2-(3-furyl)-5-methoxycarbonylpyrrole (**126c**) form in this case virtually only the products of formylation at positions 5 and 2 of the furan ring, viz., pyrroles **181, 182**.¹³⁴

Heating of 2,5-di(2-pyrrolyl)thiophene **183** with benzoyl chloride in DMF leads to the formation of 2,2-di(5-formyl-2-pyrrolyl)thiophene **184** in 47% yield.⁶²

c. Acylation

Acylation of bipyrroles, furyl- and thienylpyrroles devoid of functional substituents with carboxylic acid anhydrides and halides has not been studied, except for trifluoroacetylation.

Acylation of 1-(2-aminomethyl-3-thienyl)pyrrole **185** occurs exclusively at the amino group with the formation of 1-(2-aroyleamidomethyl-3-thienyl)pyrroles **186a-c**.¹¹¹

R = Ph (**a**, 82%), 4-ClC₆H₄ (**b**, 89%), 4-NO₂C₆H₄ (**c**, 74%).

Starting from an isomeric aminomethylthienylpyrrole **187**, thienylpyrrolodiazepines **188** were obtained.^{111, 113}

R = H, Me, Et, Ph, MeC₆H₄, 2-thienyl, NHPh.

Tricyclic compound **191** was obtained from 1-(3-cyano-2-thienyl)pyrrole (**143**) by a series of consecutive reactions, including the rearrangement of the azide **189** into an intermediate **190**.¹¹²

Similarly, isomeric tricyclic compound **193** was synthesised from thienylpyrrole **192**.¹¹²

Trifluoroacetyl derivatives of various pyrrole systems have been attracting attention of researchers since the 1960–1970s.^{135–145} Trifluoroacetylation was often used on many occasions for comparing reactivities of various pyrrole, furan and thiophene derivatives in electrophilic substitution reactions.^{121, 124, 135–137} The relative trifluoroacetylation rates of pyrrole, furan and thiophene with trifluoroacetic anhydride are 5.3×10^4 , 1.4×10^2 and 1, respectively.^{121, 124} This ratio of rates illustrates the well known fact that pyrrole, owing to the higher, compared to other five-membered aromatic heterocycles, ability of its nitrogen atom to delocalise the positive charge in cationic σ -complexes, is appreciably more reactive than furan and the more so thiophene in reactions of electrophilic substitution.¹²² It was thus believed¹⁴⁶ that 2-(2-furyl)- (**1a**) and 2-(2-thienyl)pyrroles (**7a**), as well as their 1-vinyl (**2a, b**, **8a–c**), 1-ethyl (**194a**) and 1-triethylsilylmethyl derivatives (**194b**), would be acylated with trifluoroacetic anhydride only at position 5 of the pyrrole ring.

Initial compound	X	R ¹	R ²	Reaction product	Yield of 195 (%)
1a	O	H	H	195a	41
7a	S	H	H	195b	75
2a	O	CH ₂ =CH	H	195c	18
2b	O	CH ₂ =CH	Me	195d	34
8a	S	CH ₂ =CH	H	195e	78
8b	S	CH ₂ =CH	Me	195f	76
8c	S	CH ₂ =CH	Et	195g	63
194a	S	Et	H	195h	54
194b	S	CH ₂ SiEt ₃	H	195i	75

It was shown^{146, 147} that it is compounds **195** that are formed upon trifluoroacetylation of furyl- and thienylpyrroles. In the case of 2-(2-furyl)pyrrole **1a**, the reaction mixture contains, in addition to the initial pyrrole and the final 2-(2-furyl)-5-trifluoroacetylpyrrole **195a**, an admixture of a third compound, presumably the product of trifluoroacetylation in the α -position of the furan ring or the β -position of the pyrrole ring. The latter is possible for activated pyrroles.¹²² In contrast to 2-phenylpyrrole,¹⁴⁵ under comparable conditions the trifluoroacetylation of 2-(2-furyl)- (**1a**) and 2-(2-thienyl)pyrroles (**7a**) is not complete: the degree of conversion is 50%–60%, and the yields of the corresponding 5-trifluoroacetylpyrroles **195a, b** are 40%–50% with respect to the initial pyrrole. The use of a twofold excess of anhydride relative to pyrrole and the increase in the reaction temperature to 50 °C do not change its direction, though the yield of compound **195b** increases to 75%.

2-(2-Thienyl)-1-vinylpyrrole **8a** is acylated with both the equimolar amount and the twofold excess of trifluoroacetic anhydride to give virtually only one compound **195e**, whereas the major route of trifluoroacetylation of 2-(2-furyl)-1-vinylpyrrole **2a** is the attack at the α -position of the furan ring with the formation of compound **196**. With the twofold excess of anhydride, the content of isomer **195c** increases to 40% along with the increase in the overall yield (62.5%).¹⁴⁶

R = H (**196**, 28%); Me (**197**, 27%).

Substitution of α -hydrogen in the pyrrole ring by the trifluoroacetyl group is facilitated with the increase in its basicity, as is the case with 2-(2-furyl)- and 2-(2-thienyl)-1-vinylpyrroles with alkyl substituents at position 3. In contrast to compound **2a**, the attack of 2-(2-furyl)-3-methyl-1-vinylpyrrole (**2b**) by the trifluoroacetyl cation is directed mostly not at the furan but at the pyrrole ring. Structurally isomeric trifluoroacetylpyrroles **195d** and **197** are formed in 34% and 27% yields, respectively.¹⁴⁸ 3-Alkyl-2-(2-thienyl)-1-vinylpyrroles **8b, c** form only α -trifluoroacetylpyrroles **195f, g**. Substitution of the vinyl group by the ethyl group at the nitrogen atom (compound **194a**) does not change the direction of trifluoroacetylation. It also occurs in the pyrrole ring of compound **194b** in which there is a rather bulky triethylsilylmethyl substituent.¹⁴⁸

In order to interpret the results obtained, Trofimov *et al.*¹⁴⁶ considered the following factors; (a) an appreciably larger nucleophilicity of the furan ring compared to that of thiophene; (b) a decrease in the electron density in the pyrrole ring due to competitive conjugation of the vinyl group with the unshared electron pair on nitrogen and also owing to its negative inductive effect; (c) possible steric hindrance due to the vinyl group for the

attack at the α -position of the pyrrole ring. The reactivity of the thiophene ring is so low compared to the furan ring, and the more so, the pyrrole ring, that the factors (a) and (b) seem to be insufficiently strong for changing the direction of trifluoroacetylation of 2-(2-thienyl)-1-vinylpyrrole. The absence of double acetylation products points to a very strong influence of the electron-acceptor trifluoroacetyl substituent that is transferred to the thiophene ring. The mechanism of such a transfer cannot be reduced solely to the inductive effect but should include formation of a common conjugation system.¹⁴⁶

It is known that trifluoroacetylation of 1-vinylamides,¹⁴⁹ ethyl iminoacetoacetate¹⁵⁰ and 9-alkenylcarbazoles¹⁵¹ can result in electrophilic substitution of hydrogen in the 1-vinyl group. This reaction route was not observed for 2-(2-furyl)- and 2-(2-thienyl)-1-vinylpyrroles.

d. Aminomethylation

The reaction 1-(4,5-dimethyl-2-thienyl)pyrrole (**51a**) with the aminomethylation system $\text{Me}_2\text{NH} - \text{HCl} - \text{CH}_2\text{O}$ in acetic acid results in a 2-dimethylaminomethyl derivative of this pyrrole (**198**).¹⁰⁹

4-Aryl-5,6-dihydro-4H-pyrrolo[1,2-a]thieno[2,3-f]-1,4-diazepines **202a–h** were synthesised by the reaction of 1-(2-benzylideneaminomethyl-3-thienyl)pyrroles **200**, obtained from 1-(2-aminomethyl-3-thienyl)pyrrole (**199**) and the corresponding aromatic aldehydes, with hydrogen chloride in dry ethanol (Δ , 45 min) with subsequent treatment of the hydrochlorides formed (**201**) with dilute NaOH.¹¹⁰

2. Nucleophilic addition to the triple bond

Vinylation of NH-heterocycles with acetylene is usually carried out under a pressure of 20–40 atm at 160–200 °C. This process has limited laboratory uses because of its explosion hazard and the need for special equipment, though several such technologies have been realised on the industrial scale.²²

The use of superbasic catalytic systems of the KOH–DMSO type allows vinylation of alkyl- and arylpyrroles at 100–200 °C and atmospheric pressure.¹⁵² Under these conditions, 2-(2-furyl)- (**1a**) and 2-(2-thienyl)pyrroles (**7a**) are successfully vinyated.¹⁵³ The results of vinylation of compounds **1a**, **7a** and 2-phenylpyrrole are presented in Table 2.

X = O (**1a**, **2a**), S (**7a**, **8a**).

Table 2. Effect of vinylation conditions on the yield of 2-(2-furyl)- (**2a**), 2-(2-thienyl)- (**8a**) and 2-phenyl-1-vinylpyrroles (**203**).¹⁵³

Temperature / °C	Time / h	Yield of the vinylation product ^{a, b}		
		2a	8a	203
110	4	(2:98)	(15:85)	—
110	4.5	98	(3:97)	(12:78)
110	5	—	98.5	(5:95)
110	5.5	—	—	(2:98)
110	6	—	—	(~0.1:99.9)
120	3	86	(5:95)	(7:93)
120	4	—	(~0.1:99.9)	87

^a The yield was calculated after distillation. ^b The ratio of the initial compound to the reaction product (according to GLC) is indicated in parentheses.

Acetylene was passed through the reaction mixture under atmospheric pressure. Vinylation was carried out at a fivefold molar excess of KOH. Virtually quantitative yields (96%–98.5%) of 1-vinylpyrroles were attained at 110 °C within 4.5–6 h (see Table 2). With increase in the temperature to 120 °C the duration of vinylation is reduced, although the yield of 1-vinylpyrroles drops by 9%–16% because of side processes.

When vinylation was conducted in an autoclave (initial acetylene pressure 10–14 atm, maximal pressure 20–30 atm, DMSO, threefold molar excess of KOH, 120 °C), the yield of vinylpyrroles did not exceed 80% due to resinification. Thus, vinylation of aryl- and hetarylpyrroles under atmospheric pressure is not only safe but also more efficient.

The vinylation rate of pyrroles increases in the sequence 2-phenylpyrrole < 2-(2-thienyl)pyrrole < 2-(2-furyl)pyrrole (see Table 2). Their NH acidity increases in the same order. (Jackson³ did not give the value of 2-(2-furyl)pyrrole acidity, but it can be estimated from the cited dependence of pK_a on induction constants of substituents in the pyrrole ring). The observed order of reactivity of pyrroles fully confirms the previously established general regularity^{153–157} that the rate of base-catalysed addition of structurally similar azoles to acetylene, including 2-furyl- and 2-thienylpyrroles, increases with their acidity. However, it was reported¹⁵³ that the yield of 1-vinyl derivatives of tetrahydro- γ -carbolines increases with the introduction into their molecule of a methyl group, which decreases the NH-acidity. Thus, the infor-

mation available at that time did not give any clear idea about the influence of NH-acidity (nucleophilicity) of azoles on the rate of their addition to acetylene.

In order to assess the influence of substituents on the vinylation rate of pyrroles, the kinetic curves of vinylation of the series of NH-pyrroles for which precise values of pK_a of relative acidity are known have been compared quantitatively¹⁵⁶ with the correlation equations relating these parameters to the substituent constants.^{4, 157, 158} Vinylation was carried out in a KOH–DMSO system at 100 °C under atmospheric pressure. The course of the process was monitored using GLC. It was found¹⁵⁶ that the vinylation rates of 2-benzyl-3-phenyl-, 3-hexyl-2-phenyl-, 2,3-diphenyl-, 2-(4-ethylphenyl)- and 2-(4-methoxyphenyl)pyrroles increase with the decrease in their acidity (increase in pK_a values¹⁵⁹). However, 2-(2-furyl)- and 2-(2-thienyl)pyrroles are vinylated more readily than expected from consideration only of the values of their acidity, *i.e.*, possessing a stronger acidity than that of 2-phenylpyrroles, they have higher vinylation rates. The observed deviation may be explained by the fact that the nucleophilicity of anions is determined not only by their basicity (pK_a values of conjugated acids) but also by their polarisability and ionisation potential. Therefore, furyl- and thienylpyrroles, which are more easily polarised and possess lower ionisation potentials (owing to the heteroatoms conjugated with the pyrrole moiety of the molecule), should form anions of increased nucleophilicity with concomitantly decreased basicity. Despite the fact that the acidity of pyrroles increases and the basicity of the corresponding anions decreases in the order: 2-phenylpyrrole < 2-(2-thienyl)pyrrole < 2-(2-furyl)pyrrole, the reaction rate increases in the same order since the ionisation potentials^{160, 161} decrease in the following order (eV): 2-phenylpyrrole (7.61) > 2-(2-thienyl)pyrrole (7.41) > 2-(2-furyl)pyrrole (7.29). Thus, the 2-(2-furyl)- and 2-(2-thienyl)pyrrole anions, while being less basic than the 2-phenylpyrrole anion, are superior to it in their nucleophilicity.

Yet another peculiarity of the vinylation reaction of pyrroles has been revealed:¹⁵⁶ all kinetic curves are clearly S-shaped, which is characteristic of autocatalytic reactions. In principle, autocatalysis should be characteristic of vinylation reactions in aprotic and especially superbasic media. Indeed, with the consumption of protogenic substrate (the NH group of pyrrole in this case) one observes an increase in both nucleophilicity of the remaining anions (due to lower solvation) and the degree of ionisation of the remaining substrate molecules (owing to increased medium basicity). At the same time, the chemical activity of acetylene molecules is enhanced owing to complexation with partially dehydrated molecules of the base serving as the catalyst (KOH). The presence of a one-electron route of nucleophilic addition to the triple bond can also contribute to the manifestation of this effect.¹⁵⁶ This reaction can occur by a chain mechanism and be inhibited by admixtures that quench radical and non-radical intermediates. Such a mechanism is highly probable for superbasic systems in which highly reactive, dehydrated anions are especially prone to electron transfer. This is also consistent with the reported¹⁵⁶ approximate correlation between the reaction rate and the ionisation potentials of the initial pyrroles. The presumed existence of a one-electron route in the vinylation reaction of pyrroles has been confirmed in later studies.^{162–164}

3. Cyclisation

Cyclisation of pyrroles linked to aromatic five-membered heterocycles leads to difficultly accessible polycyclic systems.

Porphyrin-like macrocycles **207–210** have been obtained by the reaction of 2,5-bis(5-formyl-4-n-propyl-2-pyrrolyl)furan **204** or dipyrroledicarbaldehyde **205** with 2,5-bis(5-formyl-4-n-propyl-2-pyrrolyl)thiophene **206**.¹⁶⁵

Oxidative photocyclisation of isomeric 2,3-dithienyl-5-phenylpyrroles **39a–d** resulted in a series of isomeric dithienoindoles **211a–d** in 28%–47% yields.⁶⁶

Photochemical electrocycloisalisation of 3-(2-furyl)- and 3-(2-thienyl)pyrroles **84b,c** with subsequent dehydrogenation with 2,3-dichloro-5,6-dicyanoquinone (DDQ) leads to indole derivatives **212a,b**.⁸¹ Irradiation was carried out with a high-pressure mercury lamp at room temperature for 12 h in cyclohexane.

Compound 212	X	n	R	Yield of 212 (%)
a	O	3	Ph	73
b	S	2	2-thienyl	78

Linear tetrapyrrole intermediates (**213**) form complexes (**214**) with transition metal salts ($M = Ni, Co$; $X = Cl, Br, ClO_4$) upon heating in *o*-dichlorobenzene (100 °C, 14 h). These complexes are oxidised by atmospheric oxygen to corrole-like macrocycles **215** containing the bipyrrrole fragment. Subsequent reduction of the latter under drastic conditions (100 °C, 100 atm) leads to corrins. Their structural element forms the basis of numerous vitally important compounds, including vitamin B₁₂.^{166, 167}

$R^1, R^2 = Me, Et$; $M = Ni, Co$; $X = Cl, Br, ClO_4$.

4. Hydrolysis, decarboxylation, oxidation and other reactions of substituents

Hetaryl-substituted pyrroles often contain alkoxy-carbonyl groups. These can be eliminated by hydrolysis and decarboxylation (200 °C) (see Section II.7, synthesis of compounds **1a**, **7a**, **128**, **129**).¹⁰¹ 3-(2-Thienyl)pyrrole (**217**) was obtained in this way from the diester **91**.⁸⁵

Alkaline hydrolysis of the ester **218** leading to thienylpyrrole **219** has been described.⁷⁶

When di(pyrrolyl)thiophene **44** with four ethoxycarbonyl groups in the α - and β -positions of the pyrrole rings was boiled in methanolic NaOH, only the α -positions were selectively liberated with the formation of di(pyrrolyl)thiophene **220**.⁶⁸

$R = CO_2Et$.

Esters of 4-(2-thienyl)pyrrole-3-carboxylic acids **222** were synthesised by decarboxylation of 3-(2-thienyl)-2,4-pyrroledicarboxylic acid derivatives **221**.¹⁶⁸

$R^1 = H, Alk$; $R^2 = Alk$.

Solvolysis of thienylpyrrole **149** results in its deacetylation and formation of 4-hydroxy-5-methoxycarbonyl-2-(2-thienyl)pyrrole (**223**).¹¹⁴ Its methylation with dimethyl sulfate gives pyrrole **224**.¹¹⁴

(a) 5N NaOMe, MeOH, 3 h; (b) Me₂SO₄, NaH, THF.

Pyrrole-2-carbaldehydes **225**, **226** form prodigiosin analogues **227**, **228** upon reaction with the pyrrole **224** (yields up to 95%).¹¹⁴

The *N*-sulfonyl protective groups in dipyrrolylthiophenes **42a,b** are removed by boiling with methanolic NaOH.⁶⁸

R = Me (a), Ph (b).

Treatment of 2-(2-thienyl)-5-trifluoroacetyl-1-vinylpyrrole **195e** with boiling ethanolic NaOH gave 2-(2-thienyl)pyrrole-carboxylic acid (yield 88%), which is decarboxylated to vinylpyrrole **8a** upon heating (150–175 °C).¹⁶⁹

α -Formyl derivative of 2-(5-chloro-2-thienyl)pyrrole **229** was synthesised in 45% yield by the oxidation of pyrrole **37** with MnO₂ in dioxane.⁶⁵

The aldehyde **229** reacts with 2,4-pyrrolophane **230** in ethanol in the presence of concentrated HCl (8 °C, 15 min; 0 °C, 24 h) to give pyrrolophane **231**.⁶⁵

5. Reactions of the *N*-vinyl group

Systematic studies of the reactivity of 2-(2-furyl)- and 2-(thienyl)-1-vinylpyrroles became possible after the development of a

convenient and efficient method for their synthesis.⁴ Before that, there were virtually no data on the *N*-vinylpyrroles linked to five-membered aromatic heterocycles. Studies of reactions involving the *N*-vinyl groups of furyl- and thienylpyrroles open wide possibilities for the synthesis of new hetaryl-substituted pyrroles.

a. Hydrogenation

Hydrogenation of substituted pyrroles is a rather well-studied reaction,^{1,2} which allows one to synthesise pyrrolines and pyrrolidines in high yields. Platinum, ruthenium and nickel catalysts are most often used for catalytic hydrogenation of pyrroles.^{1,2,170} Depending on the nature of the substituent and its position in the ring, it is possible to bring about selective hydrogenation of either the pyrrole ring or the side chain.^{1,2} Electron-acceptor substituents in the α - and β -positions of the ring impede its reduction, whereas substituents at the nitrogen atom facilitate this process.^{1,2}

Hydrogenation of 2-(2-furyl)-1-vinyl- and 2-(2-thienyl)-1-vinylpyrroles in the presence of catalysts such as Raney nickel, platinum black, palladium chloride was first studied by Korostova *et al.*¹⁴⁸ It was shown that hydrogenation on Raney nickel (80 °C, 60 atm) results in the reduction of the vinyl group in 2-(2-furyl)-1-vinylpyrrole (**2a**) to the ethyl group which occurs as easily and selectively as in 2-alkyl(aryl)-1-vinylpyrroles,¹⁷¹ giving 1-ethyl-2-(2-furyl)pyrrole **194c** in 94% yield.¹⁴⁸

X = O (**2a**, **194c**); S (**8a**, **194a**).

In the hydrogenation over Raney nickel, a decrease in the hydrogen pressure to 10–12 atm (all other conditions remaining the same) leads to a sharp deceleration of the reaction and a decrease in the yield of ethylpyrrole **194c** to 65%. In the hydrogenation over palladium chloride (15 mass. % with respect to vinylpyrrole, 80 °C, 40 atm) the yield of ethylpyrrole **194c** amounts to 75%. In contrast with the data reported by Lunn,¹⁷² who succeeded in reducing pyrrole to pyrrolidine in the presence of a nickel–aluminium alloy, the pyrrole and furan rings of compound **2a** remain intact under the described conditions.¹⁴⁸ The presence of the thiophene ring complicates hydrogenation of 2-(2-thienyl)-1-vinylpyrrole (**8a**) over nickel catalyst (50 °C, 48 atm) due to poisoning of the catalyst. Only the use of a very large amount of the catalyst (50 mass. % with respect to vinylpyrrole) has allowed preparation of ethylpyrrole **194a** in 46% yield; in this case, hydrogenolysis resulted in the formation of low-boiling products. When PdCl₂ was used at room temperature, the yield of ethylpyrrole **194a** was as low as 7%. In the presence of palladium black (80 °C, 40 atm), 2-(2-thienyl)-1-vinylpyrrole is not hydrogenated.

b. Addition of alcohols

Electrophilic addition of alcohols to 2-(2-furyl)- and 2-(2-thienyl)-1-vinylpyrroles was studied in the example of reaction with propargyl alcohol in the presence of perfluorobutyric acid (PFBA).^{148,173,174} This reaction is conducted at 96 °C. Higher temperature and longer reaction time enhance resinification. The yield of adducts **232a–c** depends on the catalyst's concentration and the ratio of reagents: the optimum conditions are 1.5-fold excess of propargyl alcohol and 1.5%–2% of PFBA relative to the substrate.

R = H: X = O (**232a**, 55%), S (**232b**, 71%); R = Me, X = S (**232c**, 56%).

c. Addition of thiols

Free-radical thiylation of 2-(2-furyl)- and 2-(2-thienyl)-1-vinylpyrroles initiated by azobis(isobutyronitrile) (AIBN) gives *anti*-Markovnikov formation of solely β -adducts **233**.¹⁴⁸

Substrate	X	R ¹	R ²	Product	Yield (%)
2a	O	H	Et	233a	84
8a	S	H	Et	233b	78
8d	S	Pr ⁿ	Et	233c	95
8d	S	Pr ⁿ	Pr ⁿ	233d	80

At 70–80 °C, the reaction is completed within 18–25 h (the yield of adducts **233a–d** is 80%–95%). Under comparable conditions without initiator, the yield drops to 15%–20%.¹⁴⁸ This reaction has been successfully used for purification of 2-(2-thienyl)pyrroles from their 1-vinyl derivatives.⁴³

d. Hydrosilylation

Kopylova *et al.*¹⁷⁵ performed hydrosilylation of 2-(2-furyl)- and 2-(2-thienyl)-1-vinylpyrroles in the presence of different catalysts; they also used various hydrosilylation agents.

The highest yields of silyl derivatives were reached upon hydrosilylation with triethylsilane at an equimolar ratio of reagents in the presence of 0.05 M solution of $\text{H}_2\text{PtCl}_6 \cdot 6\text{H}_2\text{O}$ in THF (140 °C, 5 h). The reaction proceeded regiospecifically with the formation of β -adducts **234a–e**. (The yields were calculated relative to the consumed vinylpyrrole).¹⁷⁵

Compound 234	X	R ¹	R ²	Yield (%)
a	O	H	H	40
b	S	H	H	70
c	S	Me	H	65
d	S	Et	H	44
e	S	H	COCF_3	10

The Wilkinson complex $[(\text{Ph}_3\text{P})_3\text{RhCl}]$ also catalyses this reaction. Longer reaction time and the use of polar solvents (THF, dioxane) favour an increase in yields of the adducts. No positive results have been reported for the reactions involving trichloro-, triethoxy- and alkylchlorosilanes. Only upon reaction of methylchlorosilane with 2-(2-thienyl)-1-vinylpyrrole, the

formation of the corresponding adduct in ~7% yield was observed. In the absence of catalysts, the reaction does not take place under UV-initiation. The yield of adducts depends not only on the nature of the silane but also on the substituents in the pyrrole ring. Thus the yield of the pyrrole **234b** was 70%; upon introduction of an electron-acceptor substituent ($\text{R}^2 = \text{COCF}_3$) into the pyrrole ring, the yield of the corresponding pyrrole **234e** drops to 10%.¹⁷⁵

e. Cyclisation

7,8-Dicyano-5-methoxy-3-(2-thienyl)-5,6-dihydroindolizine (**235**) was synthesised from 2-(2-thienyl)-1-vinylpyrrole (**8a**), tetracyanoethylene and methanol.¹⁷⁶

f. 2-(2-Furyl)-1-vinylpyrroles as protected pyrroles

Protection of the NH group of the pyrrole fragment is often the key stage in the synthesis of complex pyrrole derivatives. In this case, not only the acidity of the NH group is temporarily blocked, but the reactivity of different positions of the pyrrole ring is substantially changed due to steric and electronic effects of the protective groups. The role of protective group is played by, *e.g.*, trialkylsilyl, tosyl, pyridylethyl, phenylsulfonyl or *N*- β -alkylthioethyl groups. The *N*-vinyl group may also be rather successfully used for the protection of the NH group.^{51, 95, 177–180} In this case, deprotection can be effected by acid hydrolysis in the presence of hydroxylamine hydrochloride¹⁸¹ or by mercuration with mercuric acetate followed by treatment with sodium borohydride.⁵¹ 2-(2-Furyl)- and 2-(5-methyl-2-furyl)-1-vinylpyrroles have thus been transformed into the corresponding 1*H*-pyrroles in 93% and 83% yields, respectively (relative to the consumed vinylpyrrole).¹⁸²

R = H, Me.

Mercuration is carried out at room temperature until disappearance of the initial 1-vinylpyrrole with subsequent *in situ* reduction of the intermediate mercuric acetate **236** with sodium borohydride.

Despite complete disappearance of the starting vinylpyrrole in the mercuration stage, it appears again in small amount after the reduction with sodium borohydride. It is presumed that the intermediate **236** is preceded by a complex of vinylpyrrole with the mercury cation, the reduction of which leads to regeneration of 1-vinylpyrrole.¹⁸²

g. Polymerisation

Polymerisation of furyl- and thienylpyrroles and their vinyl derivatives has been little studied so far. Electrochemical polymer-

isation of 2-(2-thienyl)pyrrole yielded poly(thienylpyrrole), apparently with alternating thienyl and pyrrole rings.¹⁸³

Under the conditions of radical initiation, *i.e.*, under the action of azobis(isobutyronitrile), 2-(2-thienyl)-1-vinylpyrrole forms homopolymers **237** with a molecular mass of 3700 Da.¹⁸⁴

The formation of polymers with involvement of only the *N*-vinyl group was proved by spectral data (IR, ¹H NMR) and turbidimetric titration data in different solvent–precipitant systems. It was suggested¹⁸⁴ that poly(1-vinylpyrroles) **237** form complexes upon contact with atmospheric oxygen; this suggestion is supported by intense EPR signals in polymers following their prolonged exposure in air.

Free-radical copolymerisation of 2-(2-thienyl)-1-vinylpyrrole **8a** with vinylpyrrolidone **238** yielded a copolymer **239** enriched in the vinylpyrrolidone units.^{185, 186} The molecular mass and the yield of the copolymer depend directly on the concentration of vinylpyrrolidone.

IV. Prospects for the use

The chemistry of pyrroles linked to five-membered aromatic heterocycles is still in its infancy. Nonetheless, the currently available data on their properties allow one to consider them and their derivatives as promising compounds for medicine, agriculture and some industrial fields.

This concerns primarily the 1-vinyl derivatives of furyl- and thienylpyrroles. Reactions of electrophilic substitution in the pyrrole ring and addition reactions to the vinyl group occur highly selectively making it possible to use these compounds as building blocks for the synthesis of various derivatives.

The potentialities of furyl- and thienylpyrroles are still far from being fully disclosed. Poly(furylpyrroles) and poly(thienylpyrroles) with regularly alternating rings can differ appreciably in their electrophysical properties¹⁸⁴ from polypyrroles — organic metals, which are already applied in novel technologies.^{187–190} Indolizines with thienyl substituents have been recommended as efficient photosensitisers.¹⁷⁶

The antiviral activity of a series of 2-(2-furyl)- and 2-(2-thienyl)-1-vinylpyrroles has been investigated. 2-(2-Thienyl)-1-vinylpyrrole was found to be moderately active against the herpes virus, whereas 3-ethyl-2-(2-thienyl)-1-vinylpyrrole proved to be active against the pox virus.²⁶ It should be pointed out that furylvinyl- and thienylvinylpyrroles are as a rule moderately or weakly toxic compounds^{23, 24, 26} (Table 3).

Table 3. Toxicity of 1-vinyl-2-(2-hetaryl)pyrroles, some of their precursors and derivatives.

Compound	LD ₅₀ /mg kg ^{−1} (see ^a)
3-Ethyl-2-(2-furyl)-1-vinylpyrrole	760
2-(2-Furyl)-3-isopropyl-1-vinylpyrrole	1300
3-Butyl-2-(2-furyl)-1-vinylpyrrole	270
2-(2-Thienyl)pyrrole	260
2-(2-Thienyl)-1-vinylpyrrole	630
3-Methyl-2-(2-thienyl)-1-vinylpyrrole	30
3-Ethyl-2-(2-thienyl)-1-vinylpyrrole	830
3-Propyl-2-(2-thienyl)-1-vinylpyrrole	1370
3-Butyl-2-(2-thienyl)-1-vinylpyrrole	620
3-Hexyl-2-(2-thienyl)-1-vinylpyrrole	1500
2-(2-Thienyl)-5-trifluoroacetylpyrrole	3900
2-(2-Thienyl)-5-trifluoroacetyl-1-vinylpyrrole	1870
2-(2-Thienyl)-1-vinyl-5-pyrrolecarboxylic acid	270

^a Approximate values.

The activity of a series of 2-(2-furyl)- and 2-(2-thienyl)pyrroles towards 11 strains of different bacterial and fungal species has been assayed. 2-(2-Thienyl)-1-vinylpyrrole proved to be the most active against staphylococci and candidas as well as against the anthracoid bacilli.²⁶

Investigation into the repellent and insecticidal activity of furylvinyl- and thienylvinylpyrroles has revealed that 2-(2-furyl)-1-vinylpyrrole is a highly active and selective repellent for forest pests (black coniferous longhorn beetle) and is non-toxic for warm-blooded animals and the ichthiofauna of rivers; 3-ethyl-2-(2-thienyl)-1-vinylpyrrole was also found to manifest weak repellent activity.^{4, 24, 26} The same vinylpyrroles proved to be moderately toxic for the larvae of the coniferous longhorn beetle.^{4, 26}

The assay of insecticidal activity of a series of 2-(2-furyl)- and 2-(2-thienyl)pyrroles has revealed moderate activity of 3-propyl-2-(2-thienyl)-1-vinylpyrrole against sugar-beet root aphid and high activity of 2-(2-thienyl)-, 3-ethyl- and 3-propyl-1-vinylpyrroles against larvae of the domestic fly.²⁶ 3-Propyl-2-(2-thienyl)-1-vinylpyrrole possesses high herbicidal activity, while 2-(2-thienyl)-1-vinylpyrrole and its copolymer with *N*-vinylpyrrolidone exhibit the growth-regulating activity.^{26, 186, 191}

A number of 4-cyano-3-furyl- and 3-thienylpyrroles were recommended as starting compounds for the synthesis of medicinal substances and pesticides,⁸² while esters of 4-(2-thienyl)-3-pyrrolecarboxylic acids seem to be appropriate drugs for the therapy of cardiac insufficiency.¹⁶⁸

V. Conclusion

The data discussed in this review demonstrate appreciable progress in the field of the synthesis of pyrroles linked to other heterocycles, *viz.*, bipyrroles, furyl-, thienyl- and selenienylpyrroles and their derivatives.

Broad synthetic potential of hetarylpyrroles and especially of their *N*-vinyl derivatives in various reactions, such as electrophilic substitution, nucleophilic addition to the triple bond, cyclisation, hydrogenation, thiylation, hydrosilylation, polymerisation, as well as useful properties inherent in certain compounds of this series open up broad prospects for their use in fine organic synthesis, medicine, agriculture and some technological fields.

The preparation of this review was supported by the Russian Foundation for Basic Research (Project No. 96-03-33263a).

II. Alkenylation of organoelement nucleoside derivatives and their analogues	484
III. Alkenylation of C-halogeno derivatives and triflates of nucleosides and their analogues	493
IV. Alkenylation of non-substituted nucleosides and their analogues	501
V. Conclusion	502

Abstract. Methods for C-alkenylation of heterocycle moieties of pyrimidine nucleosides and their analogues are generalised. The methods employing both organoelement nucleoside derivatives (organomercury, -tin, -boron and -lithium) and organoelement alkene derivatives (organomagnesium, -boron, -aluminium, -tin and -silicon) as well as palladium-catalysed oxidative coupling and photochemical reactions are considered. The reaction conditions (the role of solvents, catalysts and co-catalysts, temperature and time modes) are discussed. The advantages and the drawbacks of different approaches for introduction of alkenyl groups are discussed. Examples of practical applications of alkenylated nucleoside derivatives and their analogues are given. The bibliography includes 92 references.

I. Introduction

Derivatives of pyrimidine nucleosides with substituents at positions 5 and 6 have been the permanent focus of attention of investigators. The number of papers devoted to the synthesis and application of these compounds is rapidly increasing. This interest is largely associated with antiviral and antitumour properties of these nucleosides and the possibility of using them as probes for studying the interactions between biomolecules^{1,2} or as fluorescent probes for DNA sequencing.

Very often these properties are exhibited by nucleosides containing a C—C bond with various substituents at positions 5 and 6 (alkyl, alkenyl, alkynyl, aryl, hydroxyalkyl, acyl, *etc.*). In this context, systematisation of methods used for the synthesis of such compounds is especially important. A review³ on C-alkylation of nucleosides which is devoted to problems of synthesis of the majority of derivatives with the above substituents was published in 1990. A detailed study⁴ describing the synthesis of alkynyl derivatives of nucleosides and their analogues has appeared more recently.

Alkenyl-substituted nucleosides seem to play the most crucial role among other nucleosides under consideration; these are extensively used in practically all the fields mentioned above. Thus 5-(*E*)-bromovinyluridine and its carbocyclic analogues, 5-(*E*)-(propen-1-yl)uridine and 5-(*E*)-(3,3,3-trifluoropropen-1-yl)uridine, are known as efficient antiviral agents. Many alkenyl derivatives, particularly those containing a porphyrin fragment,⁵ manifest an antitumour activity. The extensively investigated reactions between certain alkenes and nucleosides are used to prepare probes to study biomolecules. These reactions allow both direct incorporation of a label into a biomolecule and its addition through an alkenyl linker. As an illustration, we can refer to biotin-containing probes,⁶ photoactivated labels^{7,8} and fluorescent probes⁹ used in DNA sequencing. Evidently, alkenyl linkers can also be used for other purposes. An interesting example is the addition of carborane-containing fragments¹⁰ used in anticancer boron neutron capture therapy (BNCT).

It can be mentioned that the synthesis of alkenyl derivatives of pyrimidine nucleosides and their analogues has a number of special features and often presents a more complicated task than the alkenylation of classical aromatic compounds, *e.g.*, benzene. Such complications can be associated with both the preparation of the starting activated nucleosides and the conducting of the alkenylation reaction. They result from the presence of several reactive functional groups in the nucleoside molecule and the complex behaviour of the quasi-aromatic system of pyrimidine nucleic bases. For example, alkenylation of mercury derivatives of nucleosides with non-activated alkenes in methanol yields predominantly α -methoxyalkyl derivatives, which are not typical of the analogous reactions for the benzene series.

One can say that generalised information on these reactions has not been adequately addressed in the literature, especially when one takes into consideration that all the presently known methods of C-alkenylation of pyrimidine nucleosides are extremely diverse. The reviews^{11,12} describing the synthesis of alkenyl-substituted nucleosides point to the exclusive use of 5-mercurionucleoside derivatives. It is of note that the first of them¹¹ was published as long ago as in 1982, while the second one¹² is rather a summary of results obtained by the authors in the preceding period. Even since the publication of the review by Krečmerová,³ several novel alkenyl nucleoside analogues and methods of their synthesis have appeared, which necessitates generalisation and critical evaluation of the vast body of experimental data concerning the methods of synthesis of pyrimidine nucleosides with C-alkenylated heterocycles.

All the currently known methods used for the synthesis of alkenylated pyrimidine nucleosides can be conventionally divided

into two groups. The most efficient (Group 1) methods consist in the direct formation of the C—C bond of a nucleoside with an alkenyl substituent. In contrast, Group 2 methods in which the pyrimidine ring is formed in the first step with subsequent glycosylation, have serious drawbacks. These include the necessity for preliminary preparation of reagents for cyclisation and the formation of a mixture of α - and β -anomers in the glycosylation step. The present review deals with the description of Group 1 methods, *viz.*, direct alkenylation of the pyrimidine ring of nucleosides and their analogues at position 5 or 6.

From our standpoint, the methods of direct alkenylation should best be classified according to the structural features of nucleosides and alkenylating agents involved in the reaction. The choice of compounds to be introduced in the reaction is determined, among other factors, by the ease of their synthesis. In many respects, this factor is crucial for a synthesis-oriented chemist. Thus 5-chloromercury derivatives of nucleosides formed under mild conditions are widely employed in the coupling with alkenes; examples of 'reversed' coupling of nucleosides by this reaction are unknown. The readers who are interested in the mechanisms of the reactions discussed below can be referred to the monograph.¹³ According to the structure of reagents (alkenylating reagents) and substrates (nucleosides), the methods used for alkenylation of pyrimidine nucleosides can be classified as follows:

1. *Alkenylation of nucleosides containing a C—E bond (E is the electropositive element, viz., Hg, B, Sn and Li).* Coupling of organomercury nucleoside derivatives with alkenes and cross-coupling of organoboron and organotin nucleoside derivatives with alkenyl halides are catalysed by palladium compounds. Nucleoside organolithium derivatives and their analogues as nucleophiles substitute the fluorine atom in perfluoro- or fluoro-chloroalkenes.

2. *Alkenylation of nucleosides with a C—Hal or a C—OTf bond.* The methods referred to this group can be additionally divided into four subgroups:

- a. Reactions of halogeno derivatives of nucleosides with alkenes in which carbon atoms at the double bond are not linked to heteroelements.

- b. Reactions of halogeno derivatives of nucleosides with vinyl acetate.

- c. Reactions of halogeno derivatives or triflates of nucleosides with organoelement derivatives of alkenes [Group III (B, Al) or Group IV elements (Si, Sn, Zr)].

- d. Photochemical introduction of alkenyl groups into nucleosides.

The reactions related to the first three groups are catalysed by palladium compounds.

3. *Coupling of non-substituted nucleosides with alkenes.* These include addition of nucleosides to activated alkenes, cross-coupling with triflate derivatives of alkenes and addition to alkenyl organomagnesium compounds. The first two reactions are catalysed by palladium complexes.

II. Alkenylation of organoelement nucleoside derivatives and their analogues

1. Coupling of organomercury derivatives of pyrimidine nucleosides and their analogues with alkenes

Coupling of 5-mercury derivatives of pyrimidine nucleosides with alkenes was the first reaction¹⁴ used in the synthesis of alkenylated nucleosides by direct formation of the C—C bond between the substituent being introduced and the heterocycle. It is also the first reaction which has a versatile preparative significance for C-alkylation of nucleosides in general, since the alkenyl group being introduced can be further (or directly, in the course of the reaction) subjected to easy modification. Reduction of vinyl groups with hydrogen over a platinum catalyst and decarboxylation of carboxyvinyl groups are typical examples of such modifications. The regio- and stereoselectivity of addition of certain substituents is an important feature of the alkenylation reaction.

As a matter of fact, this coupling represents the Heck reaction,^{15, 16} although its application to nucleosides has a number of specific features (see below). Its mechanism^{13, 15, 16} can be presented as a sequence of transmetallation reactions (Hg is replaced by Pd), insertion of an alkene and reductive elimination, and for the sake of simplicity can be represented as follows:

This reaction occurs easily for all types of nucleic acid components (nucleic bases, nucleosides and nucleotides). 5-Chloromercurio-, 5-acetoxymmercurio- and 5-trifluoroacetoxymmercurio-pyrimidine nucleosides are normally used.^{17, 18} Depending on the solubility of the starting compounds and reaction products, the reaction is carried out in methanol, dimethylformamide, acetonitrile or aqueous-organic media. Li_2PdCl_4 , Na_2PdCl_4 , K_2PdCl_4 and $\text{Li}_2\text{Pd}(\text{OAc})_2\text{Cl}_2$ are most commonly used as catalysts (Table 1).

In the alkenylation of 5-mercurionucleoside derivatives, Pd(II) is irreversibly reduced to Pd(0); therefore, the catalyst has to be used in at least equimolar amounts. To avoid this, an agent which oxidises Pd(0) to Pd(II) (as a rule, CuCl_2) is added to the reaction mixture. This allows the use of palladium in catalytic quantities (~ 0.2 mol. %), but the yield of the target product is slightly lower (Table 1, entries 12, 27 and 30). The mechanism of such coupling has been described in the original study by Heck¹⁵ as well as in the review¹¹ devoted to the behaviour of nucleosides and their analogues in this reaction. As can be seen from Table 1 (entries 1 and 5), significant differences from the classical Heck reaction are observed when the reaction is carried out in methanol: with ethylene and propylene devoid of M-effects, methoxyalkyl nucleoside derivatives are formed predominantly. Moreover, the reaction with propylene gives all types of alkenyl isomers, *viz.*, *cis*-, *trans*- and isopropenyl isomers. These regularities are observed with all simple vinyl compounds of the type $\text{H}_2\text{C}=\text{CHR}$ ($\text{R} = \text{Me, OMe, OAc, Hal}$). In principle, the formation of α -methoxyalkyl derivatives in the reaction of nucleoside 5-mercury derivatives with ethylene and certain alkenes that react regioselectively (Table 1, entries 2–4, 8 and 9) is not important, since methoxy derivatives, as alkenes, are reduced with hydrogen over 10% Pd/C to the corresponding saturated derivatives in overall yields of about 60%–80%. The double bond C(5)=C(6) in the pyrimidine ring is unaffected by this process. Much better results are achieved in reactions with activated alkenes, particularly with styrene derivatives, esters, amides and nitriles of acrylic, metacrylic and crotonic acids. Here, the reaction usually proceeds regio- and stereoselectively (the β -carbon atom of the double bond is linked to the heterocycle, exclusively *E*-isomers are formed). The product yields vary from 10% to 80%, being, on the average, $\sim 40\%$ – 60% .

A typical synthetic procedure consists in the following. An appropriate mercurionucleoside (mercury derivatives of nucleosides are insoluble in any known solvent, although a recent report³⁸ describes the synthesis of water-soluble mercury derivatives) is suspended in an excess of an alkene (1.2–11.0 moles per mole of nucleoside) or the substrate is stirred under the pressure of the corresponding gaseous alkene in the presence of 1 equiv. of a palladium catalyst or of 0.1–0.2 equiv. of a Pd catalyst and 2–4 equiv. of CuCl_2 at room temperature or with heating to 50–60 °C. After termination of the reaction, Pd is separated by filtration and mercury salts are precipitated by passing hydrogen sulfide through the reaction mixture or by reduction with sodium borohydride. The latter is used, in particular, for subsequent hydrogenation over Pd/C. In some cases, after removal of

enes in $\text{H}_2\text{O}-\text{MeOH}-\text{Et}_2\text{O}$ are comparable (59% and 66%, respectively) (Table 1, entries 21 and 22).

Reactions of nucleotides with alkenes in aqueous-organic media give rise to several valuable compounds. Thus the reaction of 5-acetoxymercuro-2'-deoxyuridine 5'-phosphate with 3-azidostyrene gave a photoactivated uridine derivative which inhibits thymidylate synthase (Table 1, entry 24). Coupling of 5-chloromercuriuridine 5'-triphosphate with allylamine (Table 1, entries 52 and 53) results in the formation of a linker useful for labelling studies.

Organomercury derivatives of nucleic bases can also react with alkenes. For example, two 5-substituted 1,3-dimethyluracils are formed from 5-acetoxymercuro-1,3-dimethyluracil and 3,4-dihydro-2*H*-pyran (Table 1, entry 46). An attempt has been made to use this reaction in the synthesis of C-nucleosides;³¹ however, in this case cyclic derivatives are predominantly formed.

In addition to the above-mentioned compounds, allyl chlorides were introduced into the reaction with 5-mercuro-nucleosides and their derivatives (Table 1, entries 50 and 51).^{33,39} The allylation of mercury derivatives of aromatic compounds in the presence of a Pd catalyst was described for the first time by Heck.⁴⁰ Strictly speaking, this reaction is irrelevant to the material described in this Section, but 5-allylated nucleosides obtained by this method are easily isomerised into the corresponding 5-(alk-1-enyl)pyrimidine nucleosides to give exclusively *trans*-isomers in the presence of rhodium complexes.

It should be remembered that direct coupling of non-activated alkenes with mercury derivatives of nucleosides normally gives complex mixtures of products.

This method (*i.e.*, coupling with alkenes) was used to obtain a series of substituted nucleosides that were further used as antiviral agents. An example is 5-(*E*)-bromovinyluridine and its carbocyclic analogues, 5-(*E*)-(prop-1-enyl)uridine¹⁹ and 5-(*E*)-(3,3,3-trifluoroprop-1-enyl)uridine.²¹

Of definite interest are the attempts to use nucleoside derivatives containing a porphyrin fragment as antitumour agents.^{33,39} A covalent binding of vinylporphyrins at position 5 of uridine has been carried out recently.⁵ Thus porphyrin **A** (Scheme 1) was

introduced into the reaction with an excess (3.3 equiv.) of acetylated 5-chloromercuriuridine in the presence of 1 equiv. (with respect to uridine) of a Pd catalyst. This reaction gave a mixture of *trans*- (**B**, 16.5%) and *gem*-isomers (**C**, 19.6%) irrespective of the fact that the vinyl group of porphyrin was conjugated with an aromatic system.

However, in the presence of a styryl group in the porphyrin fragment, this coupling occurs regio- and stereoselectively. It is noteworthy that this reaction is accompanied by partial substitution of Pd for Zn in the porphyrin fragment of the reaction product (Scheme 2).⁵

Scheme 2

Yet another rapidly developing field of the application of alkenylated nucleosides is their use for probing biological molecules in structural and functional studies. To this end, labels are introduced into nucleosides that are directly linked to the pyrimidine ring (Table 1, entries 36 and 37) or separated from it by a linker (Table 1, entry 54). Aminoallyl, aminoalkylacrylamide and acrylate groups at position 5 are the linkers of choice.

2. Cross-coupling of organotin pyrimidine derivatives of nucleosides with alkenyl halides

One of approaches to the synthesis of 6-alkenylated pyrimidine derivatives of nucleosides is based on the reaction of 6-tributylstannyl derivatives of nucleosides **34** with alkenyl halides (the Stille reaction).⁴¹ An alternative approach consists in the reaction of 6-iodo-substituted pyrimidine nucleosides and their analogues with organoelement derivatives of alkenes (see below). Organotin derivatives of pyrimidine nucleosides are prepared from the corresponding lithium derivatives (6-iodopyrimidine nucleosides and their analogues are synthesised in a similar way) according to the following scheme:

It should be noted that despite the data⁴² on the synthesis of the 5-trimethylstannyl derivative of a pyrimidine nucleoside and its arylation, we are not aware of its application for the incorporation of alkenyl groups. The mechanism of this conversion,¹³ similar to the mechanisms of other cross-coupling reactions of organometallic compounds with alkyl halides in the presence of transition metal complexes, represents a sequence of reactions of oxidative addition of a transition metal with a low oxidation number [most often, Pd(0) or Ni(0); complexes of low-valent metals can be formed *in situ*] to aryl or vinyl halides with subsequent transmetalation (substitution of R' for the halogen atom) and reductive elimination.

Alkenylation of 6-tributylstannyl nucleosides has made it possible to obtain the corresponding alkenyl derivatives the yields of which vary from moderate to high (Table 2).⁴³ Depending on the reagent's structure, one can synthesise *cis*-, *trans*- and *gem*-isomers. As can be seen from the reaction scheme, transition metal complexes are required exclusively in catalytic amounts in

Table 2. Alkenylation of the organotin nucleoside derivative **34**.⁴³

^a The corresponding organolithium derivatives are prepared by treatment of the substrate with BuⁿLi. ^b Overall yield. ^c Prior to coupling, the hydroxy groups of the substrate were protected by the action of (Me₃Si)₂NH–Me₃SiCl–Py.

this case. It should be noted that in some syntheses the presence of copper(I) iodide permits one to increase the product yields more than twofold. Presumably, the role of CuI is connected with the formation of an organocopper intermediate in the transmetallation of Pd for Sn.

3. Cross-coupling of organoboron derivatives of nucleoside analogues with alkenyl halides

Only one example of such a coupling is known (Scheme 3). Transmetallation of organoboron compounds was extensively studied by Suzuki⁴⁴ who was the first to establish that this reaction requires the presence of a base. Organoboron compounds are prepared from the corresponding organolithium derivatives. In the above example, the target product is formed in 72% yield (Scheme 3).⁴⁵

Scheme 3

Reagents and conditions: Pd(PPh₃)₄, 1 M NaHCO₃, MeO(CH₂)₂OMe, N₂, 4 h.

It should be remembered that this type of product cannot be obtained by coupling of organomercury derivatives with alkenes.

4. Reactions of organolithium derivatives of pyrimidine nucleosides and their analogues with fluoroalkenes

Alkenyl derivatives of pyrimidine bases and nucleosides can also be obtained by nucleophilic substitution of polyfluoroalkenes with the corresponding organolithium derivatives. The reaction of 5-bromo-2,4-dimethoxypyrimidine (37) and 5-iodo-3',5'-di-*O*-trimethylsilyl-2'-deoxyuridine with butyllithium was carried out in an atmosphere of nitrogen at -70 °C. After addition of an excess (5 equiv.) of the fluorinated alkene, the reaction mixture was kept at a temperature of solid carbon dioxide for 4 days (Table 3). The product yields were small, as a rule, but higher with nucleic bases (42%–55%) than with nucleosides (6%–24%). In addition, the reaction is not stereoselective (*Z*- and *E*-isomers are formed). Perfluorocycloalkenes could be added at position 5 of deoxyuridine, but the yields of the products were as low as a few per cent.⁴⁶

III. Alkenylation of C-halogeno derivatives and triflates of nucleosides and their analogues

1. The Heck-type coupling of idonucleosides with alkenes

Yet another example of the Heck-type coupling⁴⁷ is the reaction of idonucleosides and their analogues with alkenes in the presence of palladium compounds, which has found wide use in nucleoside chemistry. Its application in organic synthesis has been described in several reviews.^{48,49} This reaction was discovered independently by Heck⁴⁷ and a group of Japanese investigators.⁵⁰ Its mechanism consists in oxidative addition of vinyl or aryl halides to Pd(0) with subsequent insertion of an alkene at the aryl(vinyl)–palladium bond and elimination of PdHX with regeneration of Pd(0).

The reaction of alkenes with both nucleosides and nucleic bases has been described. Depending on the position of the iodine in the pyrimidine ring, one can obtain 5- and 6-substituted derivatives. Most often, activated alkenes of the acrylic ester type are introduced into the reaction; arylvinyl ketones and

terminal aliphatic alkenes are also used. Of special interest is the synthesis of 5- and 6-vinyl derivatives of pyrimidine nucleosides from the corresponding idonucleosides and 1-arylpropynols in the presence of CuI as the co-catalyst and the synthesis of 5-vinyl derivatives of nucleosides and nucleic bases from the corresponding iodo derivatives and vinyl acetate.

The coupling is carried out in dioxane, DMF, acetonitrile or aqueous-organic mixtures. Pd(OAc)₂ in the presence of Et₃N and PPh₃ or Pd(PPh₃)₂Cl₂/Et₃N are used as catalysts. In the latter case, small amounts of CuI are added. In contrast with the reaction of mercurionucleosides with alkenes, this type of the Heck reaction requires catalytic (but not equimolar) amounts of palladium (most often, as small as 0.05–0.15 equiv.). Depending on the reaction conditions and the nature of nucleosides and reagents used, the yields of the products vary from 8% to 90%. In general, the yields are higher than those in analogous reactions of mercurionucleosides with alkenes. The literature data concerning the synthesis of alkenylated nucleosides by the Heck reaction are summarised in Table 4.

These examples demonstrate that pretreatment of the catalyst significantly increases the yield of the product (Table 4, entries 1 and 2). When contemplating the influence of reaction conditions, one cannot but note the recently established increase in the product yield in the coupling of 5-iodo-2,4-dimethoxypyrimidine with methyl acrylate in water (Table 4, entry 29) rather than in organic solvents (the heterogenous Heck reaction⁶⁴). It is interesting to note that under these conditions the coupling occurs at room temperature, while the classical Heck reaction requires heating to 70–90 °C, which slightly restricts its application. An increase in temperature to 50 °C in the heterogenous reaction results in deiodination of the original pyrimidine and decreases the yield from 90% to 79%. It should be noted that deiodination of nucleosides and their analogues is also the main side reaction in other types of the Heck coupling reaction.⁶⁵ Presumably, milder conditions of the heterogenous reaction favour the inhibition of side reactions and increase the yields of the target products.

High yields of the target compounds in this particular reaction are achieved with alkyl acrylates and arylvinyl ketones as alkenylating reagents. In contrast, the use of terminal alkenes with alkyl substituents results in low yields (Table 4, entries 5–7). Low yields are also characteristic of coupling of vinyl acetate with uridine (the yield of 5-vinyluridine is 37%) and cytidine (8%), although vinyl acetate reacts readily with derivatives of nucleic bases under different conditions in ~60% yields (Table 4, entries 27 and 28). Alkynylation of the corresponding 6-iodo-substituted uracils with 1-arylpropynols occurs through intermediate formation of allenic alcohols, which are further isomerised into aroylalkenyl derivatives of nucleic bases (Table 4, entries 20–26).⁶⁰ Obviously, a mixture of *cis*- and *trans*-isomers is formed in this case, although this aspect has not been specially discussed.⁶⁰

The first alkynylation of aryl iodides was described simultaneously by Heck⁶⁶ and Cassar.⁶⁷ The Sonogashira reaction⁶⁸ (addition of CuI) in the Robins and Barr⁶⁹ modification (Et₃N as the base) is used in the synthesis of the corresponding nucleosides. A detailed description of this reaction is given in the review.⁴

Of note is a recently published paper⁷⁰ devoted to the synthesis of a porphyrin derivative of deoxyuridine (reaction of acrylamidoporphyrin with 5-iodo-2'-deoxyuridine, 5-IdU) (Scheme 4) used to investigate the reactions of porphyrins with the DNA double helix.

Coupling of a 5-iodo-substituted nucleoside or its analogue with methyl or ethyl acrylates followed by decarboxylation–bromination of the resulting product with *N*-bromosuccinimide is used in the synthesis of antiviral analogues of nucleosides containing the *E*-bromovinyl group at position 5 of the pyrimidine ring more often (due to higher yields) than other alkenylation reactions.

^a The catalyst was prepared beforehand by heating $\text{Pd}(\text{OAc})_2$, PPh_3 and Et_3N in dioxane or DMF up to the appearance of deep red colouring (10–20 min) at 70–75 °C.

The addition of carborane-containing fragments¹⁰ to 5-alkenyl nucleosides (Scheme 5) is an illustrative example of the application of alkenyl fragments as linkers; this reaction is used in cancer boron neutron capture therapy (for a review, see Ref. 71).

2. Cross-coupling of nucleoside halogeno derivatives and triflates with organoelement derivatives of alkenes

Recently, coupling of 5-halogeno derivatives and 5-triflates of nucleosides with organoelement derivatives of alkenes has acquired growing popularity for the synthesis of the corresponding 5-alkenyl derivatives of nucleosides.^{72–84} As mentioned above, in this case alkene derivatives with Group III (boron and aluminium) and Group IV elements (silicon, tin, zirconium) of the Periodic system are used as the starting compounds. The literature data on alkenylation of 5-halogeno derivatives and 5-triflates of nucleosides are summarised in Table 5. The mechanisms of the corresponding reactions are considered in Section II.2 exemplified in the cross-coupling of organotin nucleoside derivatives with alkenyl halides.

An essential advantage of this method is the possibility of performing the reaction with non-activated alkenes to obtain the corresponding 5-alkenyl-substituted nucleosides (particularly, 5-vinyl-substituted ones) (Table 5, entries 3, 13, 18, 26, 29–31, 33 and 35) in good yields.

It should be remembered that of all 5-mercurionucleosides only the 5-mercuriuridine derivative reacts with ethylene in DMF under conditions of the Heck reaction (Table 1, entry 44); 5-vinyluridine undergoes polymerisation under these condi-

tions.²⁹ In the reaction of vinyl acetate with 5-iodouridine, the yield of the target product is as low as 37% (Table 4, entry 31), while the yield of vinylcytidine is even lower (8%) (Table 4, entry 32).⁶³

As can be seen from the results presented in Table 5, there are only a few examples of nucleoside alkenylation with organoboron and organoaluminium compounds and the yields of reaction products are low. Thus styrylboronic acid reacts with 5-iododeoxyuridine in the presence of $\text{Pd}(m\text{-Ph}_2\text{PC}_6\text{H}_4\text{SO}_3\text{M})_3$ ($\text{M} = \text{K}, \text{Na}$) even in aqueous-organic media, the yield of the target product is 47% (Table 5, entry 1).⁷² The possibility of carrying out the reaction in the presence of water is important, particularly for modification of oligonucleotides. In the coupling of organoaluminium alkene derivatives with nucleosides, the product yields are significantly lower (Table 5, entry 2).⁷³ However, the use of organozirconium alkene derivatives and $\text{Pd}(\text{PhCN})_2\text{Cl}_2$ as a catalyst makes it possible to obtain a broad spectrum of 5-alkenyl nucleoside derivatives, including vinyl (Table 5, entry 3), alkylvinyl (Table 5, entries 4 and 5), containing a second multiple bond in the chain introduced (Table 5, entries 8 and 12), styryl (Table 5, entries 6 and 7) and other derivatives. It is of note that the reaction (*e.g.*, with 5-iodo-2'-deoxy-3',5'-di-*O*-trimethylsilyluridine in THF) occurs even at room temperature.^{74,75} The zirconium-containing alkenyl reagent is synthesised from the corresponding alkyne and the Schwartz reagent.

Organotin compounds are most often used for C-alkenylation of nucleosides. Alkenyltributyltin is normally employed for this purpose; alkenyltrimethyltin (Table 5, entry 24) and tetraalkenyltin (Table 5, entry 33) are used less often. The amounts of the alkenylating reagent vary from 1 to 5 equiv. 5-Iodo-substituted nucleosides and nucleoside 5-triflates (as a rule, with protected

hydroxy groups) serve as substrates. The reactions are conducted in acetonitrile, dioxane, THF, *N*-methylpyrrolidone, hexametapoll and DMF. $\text{Pd}(\text{PPh}_3)_2\text{Cl}_2$, $\text{Pd}(\text{PPh}_3)_4$, $\text{Pd}(\text{PPh}_3)_4$ in the presence of LiCl and $\text{Pd}_2(\text{dba})_3$ in the presence of TFurP serve as catalysts. The yields of the target compounds obtained by this method vary from 28% to 98%. Depending on the reagent's structure, one can obtain *trans*-, *cis*- (Table 5, entry 28) and *gem*-products (Table 5, entries 23 and 24).

The reaction of alkenylfluoro- and alkenylchlorosilanes with 5-iodouracil and 5-iodo-2'-deoxyuridine derivatives, which gives target products in high yields, has been studied recently.⁸⁴ To obvious merits of organosilicon reagents one can relate their low toxicity, moisture resistance and low cost. This reaction was carried out in the presence of 0.025 equiv. of $[(\eta^3\text{-C}_3\text{H}_5)\text{PdCl}]_2$ and 2 equiv. of Bu_4NF . This method allows the modification of the pyrimidine ring with alkenyl radicals of various structure, *e.g.*, vinyl (Table 5, entry 35), styryl (Table 5, entries 36, 37, 40, 43 and 45), alkylvinyl (Table 5, entries 38, 41, 44 and 46), *etc.* As a rule, protected substrates are used; non-protected halogeno derivatives of nucleosides react with organosilicon compounds less readily. Thus 5-iodouracil does not react with alkenylfluoro- and alkenylchlorosilanes and 5-iododeoxyuridine forms a mixture of *trans*- and *gem*-isomers.

3. Photochemical alkenylation of nucleosides

The advantages of the photochemical reaction of activated alkenes with 5-iodopyrimidine nucleosides are technologically simple and versatile procedures used for the synthesis and isolation. However, the yields of the target products are small, varying from low (12%) to moderate (41%) (the literature data on photochemical coupling of nucleosides with alkenes are presented in Table 6). In addition, alkenes are linked non-stereoselectively to give a mixture of *cis*- and *trans*-isomers. Therefore, it is reasonable to use this reaction exclusively for the synthesis of the corresponding alkyl derivatives by hydrogenation of the alkenyl-

ated product over Pd/C. Alkenyl fragments are added to the trimethylsilylated 5-iodonucleoside upon irradiation of the reaction mixture with light of the wavelength of 254 nm in deoxygenated and dry acetonitrile for 24 h.

IV. Alkenylation of non-substituted nucleosides and their analogues

Pyrimidine nucleosides and their analogues that are not substituted at positions 5 and 6 of the heterocycle can also enter into the alkenylation reaction. Three versions of this reaction are known, *viz.*, oxidative coupling of alkenes (predominantly, activated ones), cross-coupling with vinyl triflates (both reactions are carried out in the presence of Pd compounds) and nucleophilic addition of alkenylmagnesium derivatives at position 6 of the pyrimidine ring.

1. Oxidative coupling of activated alkenes

Oxidative coupling of alkenes (the Fujiwara reaction⁸⁷) is carried out in the presence of 1 equiv. of Pd(OAc)₂ on boiling in acetonitrile or at room temperature (Table 7). The mechanism of this reaction seems to consist in the formation of an arylpalladium

hydride intermediate followed by insertion of the alkene at the Ar–Pd bond and reductive elimination of PdHX to give Pd(0).⁸⁸

Reactions of 1,3-dimethyluracil with activated alkenes (methyl acrylate, acrylamide, methyl vinyl ketone and styrene) give uracil derivatives substituted at position 5 in good yields; all these reactions result in *trans*-isomers. In the case of non-activated alkenes, *gem*-isomers are formed as admixtures. It is of note that acrolein diethyl acetal also enters into the reaction, which permits one to introduce an alkenyl substituent with a terminal aldehyde group into the pyrimidine base (Table 7, entry 13). It should be remembered that this reaction cannot be realised with mercurio-nucleosides. The products of coupling nucleosides with acrolein diethyl acetal could not be obtained thus far. In general, nucleosides add alkenes less readily in this reaction (Table 7, entries 6, 7 and 14). Only in the case of 2',3'-*O*-isopropylidene-protected nucleosides could the methyl acrylate group be introduced at

position 5 of the pyrimidine ring (Table 7, entry 8); the target product was obtained in good yield (74%).

2. Oxidative coupling with vinyl triflates

Vinyl triflates react with non-substituted nucleosides in the presence of a catalyst [(Pd(PPh₃)₄) (~0.05 equiv.)] and an excess of LiCl in THF to give the corresponding alkenyl derivatives in moderate yields (Table 8). This reaction, as the coupling with organoelement alkene derivatives, permits one to introduce non-activated alkenyl substituents into position 5 of the pyrimidine

ring. Depending on the structure of the vinyl triflate reagent, one can obtain various regio- and stereoisomers.

3. Addition of alkenylmagnesium derivatives

Vinylmagnesium bromide and chloride are added at position 6 of the pyrimidine ring of the protected nucleosides; this reaction gives 6-alkenyldihydropyrimidine derivatives of nucleosides in good yields. Thus reaction of protected uridine **75** with vinylmagnesium chloride^{83,92} and reaction of the 5-bromo derivative **76** with vinylmagnesium bromide (Ar, 1 h) give their 6-vinyldihydro derivatives **77** and **78** (yields 61% and 96%, respectively).

R = H (**75, 77**), Br (**76, 78**).

The attempts⁸³ to oxidise reaction products to pyrimidine derivatives of nucleosides were unsuccessful.

V. Conclusion

Numerous methods for C-alkenylation of nucleosides and their analogues are currently known, which differ in complexity, reaction conditions and the possibility of obtaining substituted nucleosides with a predetermined structure. In our opinion, the most promising approaches involve reactions of organoelement alkene derivatives, in particular, organotin (in non-aqueous

solvents) and organoboron derivatives (in H₂O or aqueous-organic media). Organosilicon derivatives of alkenes seem to be promising reagents that might replace toxic organotin compounds in future, although their cross-coupling is insufficiently developed yet. Mercury derivatives of nucleosides used to introduce alkenyl substituents will hardly lose their significance by virtue of their availability, which can be attributed to the ease of their preparation and the presence of a large body of experimental material that helps selecting the conditions for a specific synthesis. However, in more distant future this method will most likely be replaced by analogous procedures, e.g., the Heck-type coupling of iodonucleosides with alkenes, which affords higher yields of the target products and precludes the use of toxic substrates. The methods of oxidative coupling of nucleosides with activated alkenes and alkenyl triflates also attract attention owing to their experimental simplicity. At the same time, literature data concerning these methods are scarce, which makes difficult their application in the synthesis of novel compounds and long-range prognoses. And finally, the use of photochemical alkenylation of nucleosides for preparative purposes will, most probably, hardly have any practical significance.

Abstract. The current state of description of molecular structure in computer-aided molecular design of biologically active compounds by means of descriptors is analysed. The information contents of descriptors increases in the following sequence: element-level descriptors—structural formulae descriptors—electronic structure descriptors—molecular shape descriptors—intermolecular interaction descriptors. Each subsequent class of descriptors normally covers information contained in the previous-level ones. It is emphasised that it is practically impossible to describe all the features of a molecular structure in terms of any single class of descriptors. It is recommended to optimise the number of descriptors used by means of appropriate statistical procedures and characteristics of structure–property models based on these descriptors. The bibliography includes 371 references.

I. Introduction

The empirical regularities in the variation of properties of compounds as functions of their structure established by the middle of the XIX century underlay the concept of the structure–property relationship for chemical compounds. The Periodic Law discovered by D I Mendeleev can be considered as the scientific base of the structure–property concept, and the prediction of physical properties and existence of new elements, unknown at that time, is the first stable predictive model based on this relationship.¹

Systematic studies on the relationship between the structure and the biological activity of organic compounds started at the end of the XIX century^{2–4} and by now, they have become widespread. The recognised founder of the research on the

quantitative structure–activity relationship (QSAR) carried out nowadays is C Hansch, who reported in 1964, together with T Fujita, a relation that has found the most extensive use in the studies on the structure–biological activity correlations.² However, whilst acknowledging the merits of this scientist, one should also remember his numerous predecessors. In particular, it was noted³ that as early as 1944, N V Lazarev proposed⁴ that the partition coefficients of chemical compounds in oil–water systems be used to establish the quantitative structure–activity relationships. The intense progress in computational hardware and its adoption for research practice, including that in the field of science in question, promoted the formation of a border line of research — computer-aided design of biologically active compounds. Many concepts of this rapidly progressing field are being modified and improved. Therefore, it is necessary to analyse at intervals the current state of studies dealing with this subject. The previous review on this topic⁵ was published in this journal in 1988.

With allowance for the structure–activity relationship concept, three main stages can be distinguished in the computer-aided design of biologically active compounds.

(1) Formation of a trial set of compounds having a specified property (activity) or a set of properties;

(2) description of the molecular structure of compounds in this set;

(3) elucidation of the structure–biological activity relationship followed by creation of a stable prognostic model suitable for predicting the properties of new compounds.

This review analyses the modern approaches to the quantitative description of molecular structures of chemical compounds within the framework of computer-aided design of biologically active compounds in terms of independent variables characterising structural features of molecules or their parts (substituents, fragments). These variables are called descriptors.

The progress in computational hardware has a crucial influence on the development of this line of research. It should be noted that computer-aided molecular design faces the problem of processing the data on molecular structures in a unified form with their information content being retained as fully as possible after the data have been entered in the computer.

Uspekhi Khimii 67 (6) 555–576 (1998); translated by Z P Bobkova

Complex natural processes are studied by developing their models. Advantages of these models over the original are that they are easier to investigate, can be better manipulated and monitored and that the investigations are cheaper.⁶ The models can be classified into iconic (ensuring similarity regarding the form), analog (ensuring similarity regarding the form and functions) and abstract (symbolic, conceptual) models, which provide the correlation with the original by virtue of symbols.

The modern views on the molecular structure are certainly not exhaustive and, in the future, they will be improved with the aid of various models. Here, it is pertinent to quote M Dewar, who said that we don't know and, perhaps, shall never know what molecules actually are. Our understanding of molecules is based on models, which reproduce their properties sufficiently well to be useful.⁶

Description of models, which are used in chemical research, can be found in the literature.^{6–8} In this review, molecular structure descriptors are considered briefly with allowance for the above classification of models.

II. Classification of descriptors

Various types of classification of descriptors are possible. Three types of classification are considered in a paper by Charton.⁹ According to the first type, descriptors are classified into simple (describing one effect of interatomic interactions) and composite ones (describing two or more effects). Composite descriptors, in turn, can be divided into unicomposite (describing effects of the same type) and multicomposite descriptors (reflecting the sum of effects of various types).

The second classification is based on the way in which descriptors are estimated, *i.e.*, experimental and theoretical ones.

The third classification takes into account the sort of effect described by a given descriptor. Three sorts of effects are distinguished — electronic (electric), steric and intermolecular effects. A specific case of using this type of classification is provided by the classical Hansch equation,^{2,10–14} which represents biological activity as a function of Hammett constants (electronic effects), Taft constants (steric effects) and hydrophobicity constants (transport effects arising due to intermolecular interactions).

For visualisation of the description of chemical structures, Testa and Kier¹⁵ used geometrical figures corresponding to the level of structure being considered: element level → two-dimensional structure → three-dimensional structure → bulk properties → stereodynamic structure → stereoelectronic structure → interactions with the environment. The information content of each subsequent level embraces the information content of the preceding one. Apparently, a similar approach in a somewhat different form could be used in this review to discuss descriptors. Figure 1 shows a chart for several levels of descriptors in which each subsequent level covers the information content of the preceding one. In this representation, it is assumed that structural formula descriptors carry the whole body of information contained in the element-level descriptors; electronic structure descriptors carry the information contained in the structural formula descriptors and descriptors of intermolecular interactions cover the whole body of information provided by all of the preceding levels. In some cases, descriptors do not bear the information of the previous level (*e.g.*, some descriptors of intermolecular interactions such as polarisability and hydrophobicity are often calculated without allowance for the three-dimensional structure), but in general, this approach to the classification of descriptors is visual and reflects the degree of their complexity and, thus, it is convenient for the analysis. In this review, each class of descriptors is considered. It should be noted that a descriptor of any level can characterise both a molecule as a whole and its part (fragment, screen, functional group, substituent).

Figure 1. Information contents of molecular structure descriptors.

III. Element-level descriptors

The gross formula bears the information about sorts of atoms that make up the molecule and the number of atoms of each sort. The only property that can be predicted precisely based on the gross formula is molecular weight (MW), which can be regarded as an element-level descriptor. The number of atoms of a particular sort is sometimes taken as another descriptor of this level.¹⁶ An example of using such descriptors can be found in the Appendix [see Eqn (A.1)].

A legitimate construction of the structure–property correlation should be carried out for related compounds. Therefore, the structure variation within a series of compounds being considered reduces to variation of substituents. Hence, the properties of substituents can be regarded as structural descriptors. In particular, the atomic weights of substituents can also be considered to be element-level descriptors. Generally, descriptors of this level carry too little information on the molecular structure and, hence, they cannot be used alone for elucidation of the real structure–property relationships.

IV. Structural formula descriptors

The structural formula of a molecule is the most widespread way of describing a chemical compound. As a model of molecular structure, this formula contains elements of iconic, analog and abstract models⁶ and provides the basis for the construction of many types of descriptors, most of all, topological descriptors (Fig. 2).

1. Topological indices

Topological descriptors (indices) are calculated based on the description of a structural formula of a compound by a molecular graph G , which is a two-dimensional representation of the molecule (the vertices correspond to atoms and the edges match the chemical bonds).¹⁷ Normally, the skeleton atoms and the bonds between them are considered, hydrogen atoms being erased. The matrix form of the graph is used to estimate the topological indices. The adjacency matrix $A(G)$ and the distance matrix $D(G)$ are used most often. The adjacency matrix elements a_{ij} are equal to either unity or zero depending on whether or not vertex i of graph G is incident to vertex j . The number of units in an i th line or j th column of the matrix is equal to the vertex degree.

Figure 2. Elements of molecular structure description based on the structural formula.

Each element in the distance matrix $D(G)$ represents the number of edges connecting vertex i to vertex j via the shortest route and is denoted by d_{ij} . The adjacency and distance matrices for pentane, 2-methylpentane, cyclopentane and furan are shown in Scheme 1. Note that the adjacency and distance matrices for the two last-mentioned compounds are identical because the molecular graphs are identical.

Scheme 1

Compound	Molecular graph	Adjacency matrix	Distance matrix
<chem>CH3(CH2)3CH3</chem>		$\begin{array}{c ccccc} & 1 & 2 & 3 & 4 & 5 \\ \hline 1 & 0 & 1 & 0 & 0 & 0 \\ 2 & 1 & 0 & 1 & 0 & 0 \\ 3 & 0 & 1 & 0 & 1 & 0 \\ 4 & 0 & 0 & 1 & 0 & 1 \\ 5 & 0 & 0 & 0 & 1 & 0 \end{array}$	$\begin{array}{c ccccc} & 1 & 2 & 3 & 4 & 5 \\ \hline 1 & 0 & 1 & 2 & 3 & 4 \\ 2 & 1 & 0 & 1 & 2 & 3 \\ 3 & 2 & 1 & 0 & 1 & 2 \\ 4 & 3 & 2 & 1 & 0 & 1 \\ 5 & 4 & 3 & 2 & 1 & 0 \end{array}$
<chem>CH3CH(CH3)(CH2)2CH3</chem>		$\begin{array}{c cccccc} & 1 & 2 & 3 & 4 & 5 & 6 \\ \hline 1 & 0 & 1 & 0 & 0 & 0 & 0 \\ 2 & 1 & 0 & 1 & 0 & 0 & 1 \\ 3 & 0 & 1 & 0 & 1 & 0 & 0 \\ 4 & 0 & 0 & 1 & 0 & 1 & 0 \\ 5 & 0 & 0 & 0 & 1 & 0 & 1 \\ 6 & 0 & 1 & 0 & 0 & 1 & 0 \end{array}$	$\begin{array}{c cccccc} & 1 & 2 & 3 & 4 & 5 & 6 \\ \hline 1 & 0 & 1 & 2 & 3 & 4 & 2 \\ 2 & 1 & 0 & 1 & 2 & 3 & 1 \\ 3 & 2 & 1 & 0 & 1 & 2 & 2 \\ 4 & 3 & 2 & 1 & 0 & 1 & 3 \\ 5 & 4 & 3 & 2 & 1 & 0 & 4 \\ 6 & 2 & 1 & 2 & 3 & 4 & 0 \end{array}$
Cyclopentane		$\begin{array}{c ccccc} & 1 & 2 & 3 & 4 & 5 \\ \hline 1 & 0 & 1 & 0 & 0 & 1 \\ 2 & 1 & 0 & 1 & 0 & 0 \\ 3 & 0 & 1 & 0 & 1 & 0 \\ 4 & 0 & 0 & 1 & 0 & 1 \\ 5 & 1 & 0 & 0 & 1 & 0 \end{array}$	$\begin{array}{c ccccc} & 1 & 2 & 3 & 4 & 5 \\ \hline 1 & 0 & 1 & 2 & 2 & 1 \\ 2 & 1 & 0 & 1 & 2 & 2 \\ 3 & 2 & 1 & 0 & 1 & 2 \\ 4 & 2 & 2 & 1 & 0 & 1 \\ 5 & 1 & 2 & 2 & 1 & 0 \end{array}$
<chem>c1ccoc1</chem>		$\begin{array}{c ccccc} & 1 & 2 & 3 & 4 & 5 \\ \hline 1 & 0 & 1 & 0 & 0 & 1 \\ 2 & 1 & 0 & 1 & 0 & 0 \\ 3 & 0 & 1 & 0 & 1 & 0 \\ 4 & 0 & 0 & 1 & 0 & 1 \\ 5 & 1 & 0 & 0 & 1 & 0 \end{array}$	$\begin{array}{c ccccc} & 1 & 2 & 3 & 4 & 5 \\ \hline 1 & 0 & 1 & 2 & 2 & 1 \\ 2 & 1 & 0 & 1 & 2 & 2 \\ 3 & 2 & 1 & 0 & 1 & 2 \\ 4 & 2 & 2 & 1 & 0 & 1 \\ 5 & 1 & 2 & 2 & 1 & 0 \end{array}$

The most commonly used topological indices calculated from the adjacency matrix are the Platt index $F(G)$ (the sum of degrees of each edge in graph G); the Gordon–Scantlebury index $Y(G)$ (the number of paths of length 2); the full adjacency index $A'(G)$ (the sum of all the non-zero elements in the adjacency matrix); the Randic connectivity index $\chi(G)$ (it will be discussed below); and the Zagreb group indices $M_1(G)$ and $M_2(G)$. The indices that should be mentioned as the descriptors calculated from the distance matrix are the Wiener index $W(G)$, the Hosoya index $Z(G)$, the polarity number $P(G)$, the distance sum index $S(G)$ and the index of distances between the vertices $VDI(G)$. The formulae for the calculation of these widely used descriptors and other topological indices estimated based on the adjacency and distance matrices as well as examples of using these descriptors in the

structure–property correlations can be found in original publications.^{18–20}

The above matrices and topological indices reflect only topological features of molecules without allowance for the types of atoms and the real distances between them. The imperfection of this description of the structures of compounds becomes clear if one recalls that the adjacency and distance matrices (and, hence, all the topological indices mentioned above) for cyclopentane and furan coincide.

In addition to the adjacency and distance matrices described above, the extended distance matrix E ,²¹ connectivity matrix C ²² and Wiener matrix W ²³ are used.

Many researchers use various descriptors estimated based on connectivity matrix C ; therefore, we shall briefly consider them here. In 1975, Randic proposed that the connectivity index $\chi(G)$ be determined in the following way:²⁴

$$\chi(G) = \sum (v_i v_j)^{-1/2}, \quad (1)$$

where v_i and v_j are the degrees of vertices i and j in graph G , respectively. Summation is carried out over all edges of graph G .

Kier and Hall²⁵ have employed the Randic scheme as the basis for the development of a general method for the description of structures of organic compounds and proposed the concept of molecular connectivity for this purpose.²⁵ The first equation for a topological index was as follows:

$${}^1X = \sum (\delta_i \delta_j)^{-1/2}, \quad (2)$$

where δ corresponds to the number of neighbouring atoms (with hydrogen atoms being omitted). This equation is identical to Eqn (1). However, the researchers made this approach more versatile by extending it not only to bonds but also to atoms (${}^0X = \sum (\delta)^{-1/2}$) and to fragments with several bonds. For example, when a molecular graph is cut into two-bond fragments, the index ${}^2X = \sum (\delta_i \delta_j \delta_k)^{-1/2}$ is estimated, when it is cut into three-bond fragments, the index ${}^3X = \sum (\delta_i \delta_j \delta_k \delta_l)^{-1/2}$ is determined and so on. In addition, calculation of these indices for molecules containing heteroatoms was started. The hydrogen atoms attached to heteroatoms were ignored (like those attached to carbon).

Later, Kier and Hall²⁶ proposed a general equation for the estimation of δ for any atom

$$\delta_v = Z_v - h, \quad (3)$$

where Z_v is the number of valence electrons with allowance for the electrons of lone electron pairs and h is the number of hydrogen atoms attached to the given atom (which are present in the structural formula but lacking in the molecular graph). Thus the δ_v value for a carbon atom of benzene is equal to three (the atom has four valence electrons and is linked to one hydrogen atom); the δ_v value for the oxygen atom in alcohols is equal to five (the atom

has six valence electrons and is linked to one hydrogen atom) and that for the oxygen atom in ethers is six (the same number of valence electrons but no hydrogens at the heteroatom).

In the subsequent studies, Kier and Hall^{27–30} proposed using electronic state indices (S) to describe quantitatively the mutual influence of atoms. The S value for any atom is estimated by the formula

$$S = I + \Delta I, \quad (4)$$

where $I = (\delta_v + 1)/\delta$ and $\Delta I = (I_i - I_j)/r_{ij}^2$ (r is the number of bonds between the two atoms considered). The indices of the electronic topological state for some substituted amines are presented below (Scheme 2).

Scheme 2

The Kier and Hall indices have been used rather widely in the search for quantitative structure–property relationships [see, for example, the Appendix, Eqns (A.2) and (A.3)]. These indices became very popular because they can be easily calculated and provide clear representation of the structural formulae of compounds. Several recent publications should be noted.^{31–39}

However, description of the electronic structure by the number of valence electrons and description of interatomic distances by the number of bonds between the atoms are too simplified to ensure elucidation of the true molecular structure. This accounts for the criticism levelled at the attempt of using these indices for establishing the real structure–biological activity correlations.⁴⁰

A commonly used index calculated from the distance matrix is the Wiener index $W(G)$, which is the first topological index used in chemistry. It is defined as the half-sum of the elements of the distance matrix D . The Wiener index and related topological indices are often used in the structure–property studies to characterise the compactness of a molecule.^{41–43} However, it should be borne in mind that in matrix D , the distance between atoms is expressed as the number of bonds separating these atoms. In order to bring the structure description in terms of the distance matrix closer to the real situation, it has been proposed to use averaged (typical) distances between atoms in molecules placed in a three-dimensional grid^{44–47} or distances found from experimental data or by quantum-chemical calculations^{48,49} as the off-diagonal matrix elements.

Molecular graphs serve as the source of diverse topological indices. Thus Kier^{50–54} proposed various kappa-indices for coding the shape or configuration of molecules. Description of some other new indices can be found in several publications.^{55–64} Particular correlations of these topological indices with various physical properties and biological activity have been considered.^{65–72}

Information topological indices have also been used for structure description. The estimation of these indices is based on the separation of the set of graph vertices into equivalence classes taking account of the closest environment of the vertices.^{18,73} Within the framework of this approach, a number of topological indices of the theoretical-information type have been devised, namely, ${}^1\text{IC}$ (information content), ${}^1\text{SIC}$ (structural information content), ${}^1\text{BIC}$ (binding information content) and ${}^1\text{CIC}$ (complementary information content), which are calculated from the following equations:

$${}^1\text{IC} = - \sum \frac{n_i}{n} \log_2 \frac{n_i}{n}, \quad (5)$$

$${}^1\text{SIC} = \frac{{}^1\text{IC}}{\log_2 n}, \quad (6)$$

$${}^1\text{BIC} = \frac{{}^1\text{IC}}{\log_2 q}, \quad (7)$$

$${}^1\text{CIC} = \log_2 n - {}^1\text{IC}, \quad (8)$$

where n_i is the number of vertices in the i th equivalency class, n is the number of graph vertices for the molecule and q is the number of graph edges. Examples of using the information topological indices for describing structures of organic compounds in elucidation of structure–property correlations including structure–biological activity correlations have been reported.^{74–80}

2. Encoding of structural formulae by linear nomenclatures and bond matrices

The necessity of automating the processing of information on the structures of chemical compounds, the amount of which has sharply increased in recent years, initiated the development of some new methods for representation of the structural formulae of chemical compounds, namely, various linear nomenclatures and bond matrices, which can be regarded as abstract models of molecules.⁶

According to the linear nomenclature, a structural formula is encoded by a string of characters, which, in turn, encode particular fragments of the structure. Each linear nomenclature is characterised by a definitely specified sequence of characters. The character set of a linear notation usually includes standard characters. The initial stage of development of linear nomenclatures is associated with the name of Wiswesser. As an example, we present the Wiswesser codes for the structures of some compounds:

The Wiswesser linear nomenclature has been described in detail.¹⁶

In Russia, a similar approach is practised by Avidon,^{82,83} who uses the SSFC language (substructure superposition fragmental code).

At present, the most widespread linear nomenclature used to represent structural formulae of organic compounds is contained in the SMILES system,^{84–86} which is used, in particular, to reveal the structural similarity of compounds.⁸⁷ A linear nomenclature suitable for the description of not only the structural formula but also the stereoisomerism also deserves attention.⁸⁸ In this nomenclature, a compound is represented by a canonical line code consisting of two parts; the first part describes the structural formula and the second part characterises the stereochemical features of the molecule.

When a structural formula is described using a connectivity matrix, each atom, each bond and each type of atoms are coded directly. Connectivity matrices are similar to adjacency matrices and distance matrices. The main diagonal of a connectivity matrix normally includes codes for the atoms in the structural formula, while off-diagonal elements are the codes for the types of bonds. These matrices were used rather widely in the 1970s and 1980s; they have been described in a monograph.¹⁶ A connectivity matrix of descriptor centres (CMDC) has been proposed;⁸⁹ in this matrix, the codes of atoms are replaced by codes of functional groups (descriptor centres) and the off-diagonal elements correspond to the numbers of bonds between the descriptors instead of the bond codes. In order to perfect the language of structure description in terms of CMDC, later it has been proposed to use computable distances between the descriptor centres.⁹⁰

3. Structural fragments as descriptors

The topological indices and various matrices described above provide certain information on a chemical compound as a whole. However, the crucial role in the interaction of a compound with other chemical and biological objects is sometimes played by separate fragments of molecules; therefore, in the elucidation of the structure–property and structure–biological activity correlations, the structures of compounds of a given series are often described fragment-by-fragment. A structural fragment can comprise one atom, a substituent, a functional group or a particular combination of atoms (with indication of the hybridisation types).⁹¹ Each structural fragment can be used as an independent descriptor. Further detailing can be attained by specifying the local characteristics of atoms forming the fragment (see, e.g., classification of the descriptor centres in terms of their donor–acceptor properties).^{92,93} Numerous approaches to the computer-aided construction of new substances based on structural fragments of compounds having a common property have been developed. Various substructure analysis descriptors,^{94–97} topological pharmacophores in the LOGANA programme package procedure,^{98–100} substructure descriptors,^{101,102} descriptors of the structural language of the DARC system,^{103,104} chemical functionality descriptors¹⁰⁵ and *de novo* design descriptors¹⁰⁶ can be cited as examples.

V. Descriptors of the electronic structure of molecules

Quantum-chemical calculations for complex molecules make use of atomic and molecular quantum-chemical descriptors. The methods for calculation, the potential and limitations of these descriptors have been described in detail in a review.¹⁰⁷ In this Section, we consider briefly only quantum-chemical descriptors related to intramolecular electronic properties.

Atomic charges are quantum-chemical descriptors used most often to elucidate the structure–property correlations. If chemical interactions are divided into electrostatic and covalent components, atomic charges characterise the electrostatic component. The full charge on an atom can be regarded as a non-directional descriptor, whereas the σ - and π -electron densities characterise the possible orientation of chemical interactions; therefore, they can be regarded as directional descriptors.¹⁰⁸ Examples of successful use of these descriptors can be found in the literature.^{109–111} When the charges on atoms are known, a new set of descriptors of this type can be used in each particular study.

The energies of the highest occupied (E_{HOMO}) and lowest unoccupied (E_{LUMO}) molecular orbitals are descriptors that are frequently used in calculations of electronic structures of molecules.^{112–114} It was found that in some cases, the E_{HOMO} values are directly correlated with the ionisation potential (I) and characterise the susceptibility of the molecule to electrophilic attack. The E_{LUMO} values correlate with the electron affinity (A) and characterise the susceptibility of the molecule to nucleophilic attack. Note that I and A are also used as independent electronic structure descriptors.^{115,116} The $E_{\text{HOMO}} - E_{\text{LUMO}}$ difference is believed to reflect the molecule's stability.¹¹⁷ The notions of softness and hardness of molecules are associated with exactly these electronic structure descriptors.¹¹⁸ The molecular hardness descriptor (η)

$$\eta = \frac{I - A}{2} \quad (9)$$

has also found use in the structure–property correlations (see, for example, Ref. 119).[†]

[†] Hardness as a measure of energy stabilisation has been defined by some researchers as the half-sum of the E_{HOMO} and E_{LUMO} values¹²⁰ or as the difference between E_{HOMO} and E_{LUMO} taken with a minus.^{121,122}

Dipole moment and related descriptors. The polarity of a molecule is described by its dipole moment (μ). The magnitude of this descriptor can be determined experimentally or calculated using a quantum-chemical method. This descriptor is used rather widely in elucidation of structure–property correlations.^{12,112,123–125} However, the vector summation of the dipole moments of several polar groups in a molecule can result in a small value. Therefore, in addition to μ , the greatest difference between the charges of two atoms, the topological electronic index, the local dipole index, the quadrupole moment tensor, *etc.* are sometimes used as polarity descriptors.¹⁰⁷

Examples of using electronic structure descriptors in structure–biological activity relationships are given in the Appendix [Eqns (A.4) and (A.5)].

VI. Molecular shape descriptors

It is now obvious that features of the three-dimensional structure of molecules need to be taken into account in elucidating the structure–property relationships. Suffice it to say that almost all of the modern automated systems for the search for new compounds contain, as obligatory elements, various procedures for comparison of the spatial structures of molecules.^{126,127}

The description of the three-dimensional structure of a molecule by a single quantitative descriptor (or a set of descriptors) is a fairly complicated task. Let us consider the simplest situation when the compounds under consideration have the same framework and different substituents at the same position. In 1976, Verloop and coworkers proposed a set consisting of five steric constants (STERIMOL parameters) for 243 different substituents; the constants were calculated based on standard bond lengths and bond angles.¹²⁸ These simple parameters have found fairly wide use in structure–property studies.^{129–131} A similar approach based on estimation of shape parameters of substituents has been proposed in another study.¹³²

Amoore¹³³ was the first to analyse the projections of molecular structures onto the three orthogonal planes in a study dealing with the relationship between the structure and odour of compounds. An approach describing the shape of a molecule in terms of six descriptors $S_1 - S_6$ has been proposed.¹³⁴

The main problem arising in the comparison of 3D structure parameters of various molecules is associated with conformational mobility. The appearance of an additional internal rotation axis results in an exponentially increased number of possible conformations; therefore, certain restrictions are required as well as special procedures for selecting real conformations and comparing their shapes.

Several methods for the estimation of molecular shape descriptors currently exist. These methods are briefly described below.

The distance geometry approach has been developed since the late 1970s, being constantly modified by Crippen *et al.*^{135–141} The consecutive steps of the procedure used to compare the 3D molecular shapes can be outlined as follows.

1. Generation of 3D structures for the compounds considered; the initial structure is based on the bond lengths and angles found in an X-ray diffraction experiment.

2. Ascribing of definite physico-chemical properties to atoms in the molecules.

3. Elucidation of low-energy regions in the conformational space for each of the compounds.

4. Determination of the geometrically possible superpositions of molecules onto the reference structure. First, all combinations of three atoms in the reference structure and in the molecule being analysed are considered. After the best correspondence of distances between some three-atom groups in the pair of compounds being compared has been found, superposition of these three pairs of atoms is fixed and the process of spatial superposition is continued for other atoms.

5. Analysis of a great number of 'good' superpositions of compounds on the reference structure makes it possible to compare the molecular shapes of the compounds; as this is done, the concept of the molecular shape descriptors is visualised and the shape of the binding site in a potential receptor is evaluated.

The binding site approach.^{142–144} This approach represents the binding sites of a potential receptor as non-overlapping areas covering the whole space rather than as points (as in the previous method). With such representation of a spatial structure, each atom should be located in one (and only one) area and the binding site model should include the list of areas (descriptors) in which each atom is located. Fig. 3a shows the binding site model calculated for compounds exhibiting competitive properties in relation to the protein isolated from mouse liver,¹⁴⁵ and Fig. 3b presents the optimum binding model for benzopyrene.

Figure 3. Binding site model for compounds exhibiting competitive properties towards a protein (a) and optimum binding model for benzopyrene (b).¹⁴⁵

Molecular shape analysis. This approach has been developed during the last 15 years in the studies of Hopfinger *et al.*^{146–155} The procedure for the quantitative comparison of the spatial structures of the molecules of various compounds includes six consecutive stages.

1. Conformational analysis with allowance for the internal rotation about all the single bonds and calculation of the energy for each 10° increment. This is done using methods of molecular mechanics with a force field comprising contributions of dispersion, steric and electrostatic interactions and, whenever possible, hydrogen bonds.

2. Selection of individual conformations. The real set of possible conformations for each compound is determined by the chosen difference between the conformation considered and the global energy minimum.

3. The choice of the reference compound and the active conformation by pairwise comparison of the molecular shapes in the series of compounds under consideration.

4. Superposition of each molecule in the series of compounds under consideration onto the molecule of the reference compound.

5. Quantitative comparison of molecular shapes. The following descriptors characterising the molecular shape similarity have been proposed:

the common overlap steric volume (V_0) determined from the following equation

$$V_0 = V_u \cap V_v, \quad (10)$$

where V_u and V_v are the space occupancy by the molecules of the compound considered and the reference compound, respectively;

the relative measure of the degree of similarity defined as the function

$$f_0 = \frac{V_u \cap V_v}{V_u}. \quad (11)$$

These descriptors do not contain information regarding the intramolecular stability of each conformation of the pair of compounds. Therefore, one more descriptor, the shape commonality index (I_c), has been proposed:

$$I_c = S_{(u,v,w)} - \frac{\Delta E_u}{[\Delta E_u^*(\Delta E_u^* + \Delta E_v^* + \varepsilon)]^{1/2}} + \frac{\Delta E_v}{[\Delta E_v(\Delta E_u^* + \Delta E_v^* + \varepsilon)]^{1/2}}, \quad (12)$$

where $S_{(u,v,w)}$ is wV_0 or wf_0 , w is the shape similarity parameter, ΔE is the difference between the conformation energies, $\Delta E_v^* = 1 \text{ kcal mol}^{-1}$, ΔE_u^* is taken to be 1, 3 and 6 kcal mol^{-1} in three separate calculations and ε is a correction factor.

The hypothetical active site lattice.^{156–160} This method is based on the assumption that a molecule can be described by descriptors characterising the space that it occupies and the nature of atoms that occupy this space. Three-dimensional space is defined as a set of regularly arranged points in a three-dimensional lattice. Translation of the molecule to the set of these points occurs with retention of those points of the lattice that fall within the van der Waals radius of each atom in the molecule. The resulting molecular lattice consisting of points carries information on the type and properties of atoms in the molecule. The type of atoms is defined simply: the value +1 is attributed to atoms rich in electrons, the value –1 is attributed to atoms poor in electrons and electrically neutral atoms are denoted by 0.

Estimation of molecular positions.^{161–163} In this approach, the comparison of spatial shapes of molecules also starts with the search for low-energy conformations and selection of energetically stable shapes for each compound in the series under consideration. Molecular position is defined as a specific conformation associated with the activity exhibited by this compound. The molecular position is described by several descriptors.

The weighted holistic invariant (WHIM) molecular descriptors are constructed in such a way as to cover the information on the three-dimensional structure as fully as possible including the size, shape and symmetry of molecules and the distribution of atoms in them.^{164–169} The calculation algorithm includes the analysis of the main components of the centred molecular coordinates using the weighted covariant matrix derived from various weighted schemes for atoms.

Different covariance matrices and principal axes are obtained depending on the type of the weighted scheme used. For example, when the atomic weights are used as the weighted scheme, the directions of the three principal axes coincide with the principal inertia axes.

For each weighted scheme, a set of statistical indices of atoms projected onto each principal component t_m ($m = 1, 2, 3$) is calculated. The invariance of the calculated parameters with respect to translation is attained by the procedure of centring the atomic coordinates, while the invariance with respect to rotation is ensured by using the principal components.

The directional WHIM descriptors are statistical indices calculated based on each individual principal component (1, 2, 3). The non-directional WHIM descriptors are found directly from directional descriptors. The latter type of descriptors characterise the overall shape of the molecule, any information related to the principal axes being lost in this case.

Eleven directional descriptors ($\lambda_1, \lambda_2, \lambda_3, \vartheta_1, \vartheta_2, \gamma_1, \gamma_2, \gamma_3, \eta_1, \eta_2, \eta_3$) characterising the molecular properties within each weighted scheme have been proposed.^{164–169} Thus, the total number of directional WHIM descriptors is 66. In the case of planar structures, only eight directional ($\lambda_1, \lambda_2, \vartheta_1, \vartheta_2, \gamma_1, \gamma_2, \eta_1, \eta_2$) and

five non-directional descriptors (T , A , V , K , D) should be taken into account for each weighted scheme.

Analysis of the shape of electron cloud.^{170–174} This method is based on the assumption that the shape of the electron cloud carries the whole body of information on the properties of compounds. This approach was used primarily to analyse molecular surfaces. The surface of a molecule is cut into areas according to the local curvature properties. Convex D_2 , saddle-like D_1 and concave D_0 local areas are distinguished. The ratios of these descriptors determine groups of molecular shapes, which include two- one- and zero-dimensional truncated surfaces obtained from the initial surface by removing all areas of a given type (D_2 , D_1 or D_0). The quantitative measure for the similarity of shapes of 3D molecules can be found by comparing the numerical codes of shapes. This procedure is performed automatically using a computer without subjective visual comparison of the shapes of objects.

Examples of using molecular shape descriptors in structure–biological activity correlations are given in the Appendix [Eqns (A.9) and (A.12)].

VII. Intermolecular interaction descriptors

Quantitative description of the intermolecular interactions in the elucidation of structure–biological activity correlations can be accomplished using the free energy difference (ΔG).^{175, 176}

$$\Delta G = G_f - G_i, \quad (13)$$

where G_f and G_i are the free energies of the final and initial states, respectively.

A more detailed quantitative description of intermolecular interactions is provided by using the enthalpy (ΔH) and entropy (ΔS) differences, which are related to ΔG as follows:

$$\Delta G = \Delta H - T\Delta S, \quad (14)$$

where T is the reaction temperature. By measuring experimentally the equilibrium constant (K), one can determine ΔG

$$\Delta G = \Delta G^\circ - RT \ln K, \quad (15)$$

where ΔG° is the free energy change for a reaction under standard conditions.

The ΔG , K , ΔH and ΔS values for a reaction or interaction can be regarded as descriptors of intermolecular interactions. For example, dissociation constants of acids and bases (pK_a) are used fairly frequently in the modelling of structure–activity correlations.^{177–180}

A large group of intermolecular interaction descriptors estimated from experimental data on reactivity comprises various constants describing the electronic influence of substituents on the reactivity of chemical compounds. This line of studies was initiated by Hammett who defined the parameter σ (Hammett constant) based on the relation¹⁸¹

$$\sigma_X = \log K_X - \log K_H, \quad (16)$$

where K_X is the corresponding constant for *meta*- (σ_m) or *para*-substituted (σ_p) benzoic acid, K_H is the ionisation constant for benzoic acid in water at 25 °C. By now, a great number of constants have been proposed to describe the electronic effects of substituents. For example, the inductive (σ_i) and resonance (σ_r , σ^+ , σ^-) constants, the inductive Taft constant (σ^*) and the Swain and Lupton constants^{182–184} are widely used as descriptors of intra- and inter-molecular interactions.

The reactivity descriptors, calculated by quantum-chemical methods, constitute an important group of intermolecular interaction descriptors. First of all, mention should be made of indices of electrophilic (S_e) and nucleophilic (S_n) superdelocalisabilities on a reaction centre (r), which are estimated from the equations

$$S_e(r) = 2 \sum_k^{\text{vac}} \sum_{\sigma(r)} \frac{(C_{\sigma k})^2}{0.5(E_{\text{HOMO}} + E_{\text{LUMO}}) - E_k}, \quad (17)$$

$$S_n(r) = 2 \sum_i^{\text{occ}} \sum_{\sigma(r)} \frac{(C_{\sigma i})^2}{E_i - 0.5(E_{\text{HOMO}} + E_{\text{LUMO}})}, \quad (18)$$

where the numerators contain coefficients for the atomic orbitals and denominators contain the energies of the corresponding molecular orbitals.

Some other descriptors such as self-atom polarisability $\pi(r)$,¹⁸⁵ reflecting the influence of the variation of electronegativity of atomic orbitals on the charge of the same atom

$$\pi(r) = 4 \sum_i^{\text{occ}} \sum_k^{\text{vac}} \sum_{\sigma(r)} \frac{C_{\sigma i}^2 C_{\sigma k}^2}{E_k - E_i}, \quad (19)$$

and atom–atom polarisability $\pi(\text{AB})$,¹⁰⁷ reflecting the effect of a perturbation at one atom (A) on the charge of another atom (B)

$$\pi(\text{AB}) = 4 \sum_i \sum_a \sum_p \sum_r \frac{C_{\pi}^A C_{pa}^A C_{ri}^B C_a^B}{E_i - E_a}, \quad (20)$$

can be used as well to describe intermolecular interactions.

These descriptors have also found application in the description of structure.^{107, 186–188}

Molecular refraction and polarisability. When a molecule is placed in an external electrostatic field, the charge distribution in it changes. The resultant dipole moment is determined from the relation

$$\mu = \alpha E, \quad (21)$$

where α is the molecular polarisability and E is the electric field intensity. The polarisability can be estimated experimentally based on the expression relating it to the molecular refraction (MR)

$$\text{MR} = \frac{4\pi N_A \alpha}{3}, \quad (22)$$

(N_A is the Avogadro number) and the relation of the molecular refraction to the refractive index (n)

$$\text{MR} = MV \frac{n^2 - 1}{n^2 + 2}, \quad (23)$$

where MV is the molecular volume. The MR and α values are estimated either based on the additivity of the experimentally determined contributions of separate atoms and fragments¹⁸⁹ or by quantum-chemical calculations.^{191–194}

Lipophilicity. The group of intermolecular interaction descriptors used most commonly to analyse the structure–activity correlations is related to the notion of lipophilicity, which characterises the transport properties of compounds in biological objects. In the vast majority of cases lipophilicity is described quantitatively in terms of the partition coefficients (P) of compounds in the model octanol–water system. The $\log P$ value for the neutral form of the compound is used as the descriptor for this system. The corresponding descriptors for the cationic, anionic and zwitter-ion forms are designated by $\log P^+$, $\log P^-$ and $\log P^{+/-}$.¹⁹⁵ The partition of ionised compounds between octanol and water depends on pK_a of the compound itself and pH of the medium. The distribution of substances in biological media is characterised by the index $\log D$ with indication of the pH, instead of $\log P$. In the vast majority of publications, $\log D$ refers to a physiological medium with pH 7.4.

The relationship between the descriptors $\log D$, $\log P$, $\log P^+$, $\log P^-$ and pK_a is given by the following expressions:¹⁹⁶ for the equilibrium $\text{XH} \rightleftharpoons \text{X}^- + \text{H}^+$,

$$\log D = \log P_{\text{XH}} - \log(1 + 10^{-pK_a - \text{pH}}); \quad (24)$$

for the equilibrium $\text{X} + \text{H}^+ \rightleftharpoons \text{XH}^+$,

$$\log D = \log P_{\text{X}} - \log(1 + 10^{-pK_a - \text{pH}}); \quad (25)$$

for the equilibria $X^- + H^+ \rightleftharpoons XH + H^+ \rightleftharpoons XH_2^+$,

$$\log D = \log(A_0 + A_1 + A_2), \quad (26)$$

where

$$A_0 = \frac{P_{X^-}}{1 + 10^{pK_{a2}-pH} + 10^{pK_{a1}+pK_{a2}-2pH}}, \quad (27)$$

$$A_1 = \frac{P_{XH}}{1 + 10^{pH-pK_{a2}} + 10^{pK_{a1}-pH}}, \quad (28)$$

$$A_2 = \frac{P_{XH_2^+}}{1 + 10^{pH-pK_{a1}} + 10^{2pH-pK_{a2}-pK_{a1}}}. \quad (29)$$

The experimental methods used to estimate the lipophilicity parameters have been described in detail in reviews.^{197–199}

Lipophilicity can be calculated using several schemes, for example, based on the additivity of the contributions of lipophilic constants of atoms²⁰⁰ or fragments^{202, 202} or using conformationally dependent approaches,^{203, 204} molecular descriptors²⁰⁵ and various solvatochromic parameters.²⁰⁶ The octanol–water partition of compounds is mainly governed by two factors — the molecular volume and the capacity of molecules to form hydrogen bonds.^{207, 208}

The contribution of the molecular volume to the lipophilicity has been described quantitatively^{209, 210} using several descriptors such as molecular weight MW, molecular volume MV, total molecular surface area SA, the integral of the van der Waals interaction spectra VWI, molecular refraction MR and molecular polarisability α . To describe quantitatively the contribution of hydrogen bonds, free energy factors for hydrogen bond donors and acceptors C_d and C_a were employed, which are considered in greater detail below. Since the descriptors corresponding to the contribution of the molecular volume are correlated with one another, only one of them can be included in the regression equation. The best result was obtained by using the polarisability and the sum of the factors for the hydrogen bond acceptor capacity [see the Appendix, Eqn (A.14)]. This approach to the quantitative description of the lipophilicity makes it possible to estimate the contributions of polarisability and hydrogen bonding acting in the opposite directions and thus to modify the structure of compounds in order to optimise their properties. Table 1 presents the values for lipophilicity of some chemicals determined experimentally and calculated by Eqn (A.14) and the contributions to the lipophilicity of the two parameters mentioned above.

Analysis of numerous computer programmes meant for the calculation of $\log P$ (see^{211–213}) demonstrated that they provide satisfactory accuracy in the calculation of the lipophilicities of

simple neutral organic compounds but in the case of complex compounds, especially medicines, the accuracy is fairly low. This may be due to the fact that most of the calculations are based on the additivity of the logarithms of the contributions of atoms and fragments rather than on an accurate additive scheme for the contributions of the octanol (oct)–water partition coefficients of compounds. In addition, only a few experimentally determined lipophilicities of compounds containing several cationic and/or anionic groups have been published. Meanwhile it is these data that could provide the basis for precise calculations of the lipophilicities of complex ionised compounds.

The application of Eqn (A.14) to the calculation of $\log P_{oct}$ values for various neutral organic compounds has resulted in the following expression

$$\log P_{oct}(\text{exp.}) = 1.00 (\pm 0.02) \log P_{oct}(\text{calc.}), \quad (30)$$

$$N = 2781, R = 0.971, S = 0.32 \text{ (see } \S \text{)}.$$

Comparison of the lipophilicities calculated from Eqn (A.14) with those determined experimentally for compounds that had been tested with 14 appropriate commercial programmes gave the following results: for 90 simple organic compounds, $R = 0.993$; for 48 medicines, $R = 0.935$ and for all the 138 chemicals tested, $R = 0.971$. These statistical criteria are commensurable with those attained in the best of the programmes tested. This outcome, together with the possibility of calculating the full pH-dependent profile for ionised compounds, attests to the value of the above-mentioned physico-chemical approach to the estimation of lipophilicity.

In recent years, in addition to the above 'classical' descriptors, another descriptor called molecular lipophilicity potential (MLP),^{214–218} which quantitatively describes lipophilicity in three-dimensional space, has been widely used. The lipophilicity potential at a given point in space is a result of intermolecular interactions governed by the lipophilicity of all fragments of the molecule. Two components are needed to calculate the lipophilicity potential, namely, the fragment lipophilicities and a function of distance describing the variation of lipophilicity in space²¹⁴

$$MLP_k = \sum_{i=1}^N f_i f_{ct}(d_{ik}), \quad (31)$$

where k is the label for a given point in space, i is the label of the fragment, N is the total number of fragments in the molecule, f_i is the lipophilicity constant for fragment i , f_{ct} is the distance function and d_{ik} is the distance between fragment i and point k in space.

A large number of examples in which the lipophilicity parameters have been used successfully as intermolecular interaction descriptors in the elucidation of structure–property correlations have been reported in a book¹⁸⁴ and in papers.^{214–224} Examples of using $\log P_{oct}$ in structure–property (activity) regression equations are given in the Appendix [Eqns (A.14)–(A.16)].

It should be noted that the majority of procedures used to calculate both descriptors of intermolecular interactions and energies of reactions are based on the assumption of additivity of contributions of various types of intermolecular interactions¹⁷⁵

$$\Delta G = \Delta G_{\text{solvent}} + \Delta G_{\text{conf}} + \Delta G_{\text{int}} + \Delta G_{\text{motion}}, \quad (32)$$

where $\Delta G_{\text{solvent}}$ is the solvent contribution, ΔG_{conf} is the change in the free energy caused by conformational changes in the reacting molecules, ΔG_{int} is the change in the free energy due to specific interactions and ΔG_{motion} is the change in the free energy of the molecule caused by changes in the translational, rotational and vibrational constituents.

‡ From here on, N , S and R are statistical criteria of equations: N is the number of observations, S is the standard deviation and R is the correlation coefficient; the Fischer criterion F is also used.

Table 1. Experimental and calculated values for lipophilicity and polarisability and acceptor capacity contributions in the formation of hydrogen bonds.²¹⁰

Compound	$\sum C_a$	α	$\sum C_d$	α	$\log P$	
					calculation	experiment
Chloracetamide	3.80	8.00	−2.57	1.99	−0.59	−0.53

Specific interactions are calculated on the assumption that the contributions of various types of interaction obey the additivity principle. At present it is believed that the greatest contributions to the specific interactions are made by steric (st) and electrostatic (el) effects and hydrogen bonds (hb). Within the framework of this assumption, the free energy of specific interactions can be represented as follows:²²⁵

$$\Delta G_{\text{int}} = \Delta G_{\text{st}} + \Delta G_{\text{el}} + \Delta G_{\text{hb}}. \quad (33)$$

Below we consider the parametrisation of these three types of specific interactions, analyse the existing descriptors and describe computer programmes used to calculate the energies of these interactions.

1. Parametrisation of steric effects

The first steric parameter E_s was proposed by Taft.²²⁶ When studying the reactivity of esters, he obtained the following relation:

$$E_s = \log \frac{k_R}{k_{\text{Me}}}, \quad (34)$$

where k_R and k_{Me} are the rate constants for hydrolysis of the compounds R^1COOR^2 and MeCOOR^3 , respectively. It is assumed that the inductive and electronic effects have no influence on the system under consideration. Tables containing refined E_s values are presented in the study cited. Examples of successful use of this steric parameter can be found in the literature.^{15, 184}

In the simplest case, steric effects can be characterised by van der Waals radii. Empirical steric parameters based on these radii have been developed in greater detail by Charton.^{182, 227, 228} The one-parameter method, which is the simplest among those proposed by this researcher, uses steric parameter v , which depends on the van der Waals radii and expresses the steric effect of the first atom in the substituent. In the case of atomic groups having different substituents at the atoms through which the hindered internal rotation axis passes, it is proposed to describe steric effect either by sets of effective steric parameters for certain reactions or by branching equations, which are empirical in their character.

Note that the empirical approach developed by Charton involves many simplifications and requires introduction of additional empirical constants and coefficients when considering new sets of compounds.

The Lennard–Jones potential takes into account the steric constituent of the total energy of an interaction E_{1j} , which is represented as a combination of the attraction and repulsion forces²²⁵

$$E_{1j} = \frac{A}{d^{12}} - \frac{B}{d^6}, \quad (35)$$

where d is the distance between a pair of non-bonded atoms. When d is small, the term A/d^{12} accounts for the predominance of the repulsion forces and, as a consequence, positive E_{1j} values. When d is large, the term B/d^6 is greater. The minimum E_{1j} value corresponds to the optimum distance between a pair of non-bonded atoms. The Lennard–Jones potential can be used as a self-contained descriptor of intermolecular interactions and also as a measure of the contribution of steric interactions to the total interaction energy. In particular, it has been shown that for a series of substituted esters of acetic acid, a steric descriptor based on the Lennard–Jones potentials is well correlated with the Taft parameter E_s .

2. Description of electrostatic interactions

Electrostatic interactions are described using the Coulomb's law for point charges located on atoms and using standard molecular-mechanics approaches.¹⁷⁵

When comparing the capacity of molecules for electrostatic interactions $V(R_i)$, molecular electrostatic potential (MEP) is used

almost always; this parameter can be calculated at each point R of the space surrounding the molecule²³⁰

$$V(R_i) = - \int \frac{\delta(R)}{|R_i - R|} dr + \sum \frac{Z_l}{|R_i - R_l|}, \quad (36)$$

where $\delta(R)$ is the electron density, r is the distance, Z_l are the charges of the nuclei and R_l are the coordinates of the nuclei in the molecule. The results of the calculations of MEP can be represented graphically as maps. Comparison of the MEP maps for a number of compounds having the same type of activity (examples of these studies can be found in Refs 231–235) may prove useful for judging the character of specific electrostatic interactions of these compounds with a biological target exhibiting the given type of activity. However, it should be borne in mind that visual comparison is subjective.

In recent years, formal approaches based on comparison of quantum-chemical parameters related to electrostatic interactions have been vigorously developing. First of all, molecular quantum similarity measures (MQSM) should be mentioned.^{236–239} According to this approach, quantum-chemical similarity of two molecules is identified by considering the electron density functional $Z_{AB}(\Omega)$

$$Z_{AB}(\Omega) = \int \rho_A(\mathbf{r}_1) \Omega(\mathbf{r}_1, \mathbf{r}_2) \rho_B(\mathbf{r}_2) d\mathbf{r}_1 d\mathbf{r}_2, \quad (37)$$

where $\rho_A(\mathbf{r}_1)$ and $\rho_B(\mathbf{r}_2)$ are the electron densities of molecules A and B, and Ω is a positively defined operator. Various operators can be chosen. It is convenient to present the operator in the form

$$\Omega(\mathbf{r}_1, \mathbf{r}_2) = \delta(\mathbf{r}_1 - \mathbf{r}_2), \quad (38)$$

which transforms the integral in Eqn (37) into an integral of the product of density distributions in the given pair of molecules.

$$Z_{AB} = \int \rho_A(\mathbf{r}) \rho_B(\mathbf{r}) d\mathbf{r}. \quad (39)$$

If molecules A and B being compared are identical, we obtain a self-similarity measure

$$Z_{AA} = \int \rho_A^2(\mathbf{r}) d\mathbf{r}. \quad (40)$$

The self-similarity measure is used to construct similarity indices, which can be regarded as normalised values of MQSM. The Carbo index was the first similarity index to be proposed²⁴⁰

$$C_{AB} = \frac{Z_{AB}}{(Z_{AA} Z_{BB})^{1/2}}. \quad (41)$$

This value ranges from zero (for comparison of dissimilar molecules) to unity (when the molecules are identical). Examples of using the Carbo index for elucidation of similarity of electronic structures have been reported.^{241–244}

3. Quantitative description of the ability of compounds to form hydrogen bonds

Hydrogen bonding plays a crucial role in the formation of many molecular and ionic complexes in important chemical and biological processes including enzymic catalysis. The most glaring example demonstrating the significant role of hydrogen bonding in biological systems can be found in a monograph²⁴⁵ in the description of DNA replication. This process is accompanied by a new binding of purine and pyrimidine bases *via* the formation of two (binding of adenine with thymine) or three (binding of guanine with cytosine) hydrogen bonds. Even a rather rough calculation of the free energy difference for this complexation, carried out by Pauling (it was assumed that one hydrogen bond provides an energy benefit of 20 kJ mol^{−1}), demonstrated that this system of hydrogen bonds ensures a ratio of the numbers of 'correct' and 'false' recognitions equal to ten million to one!

Despite this important role of hydrogen binding in the formation of the properties of substances, until recently this intermolecular interaction has been taken into account mainly at the level of an indicator variable.^{12, 13, 246–248} Therefore, in this review it is pertinent to discuss the quantitative approaches to the description of hydrogen bonding in detail.

According to Eqn (14), full thermodynamic description of a hydrogen bond requires a pair of parameters, namely, enthalpy and entropy or enthalpy and free energy. Four combinations of the changes in the enthalpy (ΔH) and the entropy (ΔS) are possible.^{249–252} Note that in the majority of studies devoted to hydrogen bonding in complexes, the change in the entropy is either totally neglected or considered to be proportional to the enthalpy change. The roughness of this approach becomes clear from the examples given in a review.²⁵¹

The development of the empirical scales of hydrogen bonding based on the experimental values of thermodynamic parameters started in the 1960s. Let us consider two approaches, the additive-multiplicative and multiplicative ones. In the additive-multiplicative method, the enthalpy change accompanying the formation of a hydrogen bond is described by six parameters^{253–255}

$$-\Delta H_{\text{hb}} = e_A e_B + c_A c_B + t_A t_B, \quad (42)$$

where e is a parameter reflecting the electrostatic contribution, c is a parameter related to the covalent interaction, t is a parameter describing the charge transfer and indices A and B correspond to Lewis acids (hydrogen bond donors) and bases (hydrogen bond acceptors), respectively. Most of studies dealing with the structure–biological activity correlations present no exact data on the molecular structure of one partner of the interaction (*e.g.*, receptor, biological target). This fact hampers the use of Eqn (42). The method describing the thermodynamic parameters of hydrogen bonds based on the multiplicative approach is more widely distributed. The enthalpy of the hydrogen bond is described by the equation²⁵⁶

$$\Delta H_{ij} = \Delta H_{11} P_i E_j, \quad (43)$$

where ΔH_{11} is the enthalpy change upon the formation of a hydrogen bond between phenol and diethyl ether (standard hydrogen bond partners) in tetrachloromethane,[§] P_i is a dimensionless factor for an i th hydrogen bond donor and P_j is a factor for a j th hydrogen bond acceptor.

The change in ΔH_{ij} can also be described using the donor (E_d) and acceptor (E_a) factors for the enthalpy of a hydrogen bond, which have opposite signs^{92, 257}

$$\Delta H_{ij} = \Delta H_{11} E_d E_a. \quad (44)$$

The E_d and E_a values for various neutral and ionised compounds have been estimated.^{258–270}

Similar equations have been proposed to describe the change in the free energy (ΔG) upon the formation of a hydrogen bond^{271, 272}

$$\Delta G = a C_d C_a + a_0, \quad (45)$$

where a and a_0 are coefficients and C_d and C_a are the donor and acceptor factors for the free energy of the hydrogen bond; and to describe the complex formation constant for hydrogen bonding^{273–276}

$$\log K = b \alpha \beta + b', \quad (46)$$

where b and b' are coefficients and α and β are the donor and the acceptor factors for the hydrogen bond formation constants. Taft *et al.*²⁷⁷ have estimated a large number of β values for phosphoryl compounds based on the data of several publications.^{261–263} With

§ Most of the experiments on the thermodynamics of hydrogen bonding have been carried out in tetrachloromethane. This solvent is non-polar and therefore convenient for determining the values of the thermodynamic factors described below.

allowance for the relationship between the change in the free energy and the constants [see Eqn (15)], it is obvious that the difference between Eqns (45) and (46) reduces to the factor $2.302RT$. In the case where the same array of experimental data is considered and the same method is used to estimate the hydrogen bond parameters, there should be a strict correlation between C_d and α and between C_a and β . No general correlation has been found between E_d and C_d or between E_a and C_a ; however, these correlations do exist for separate groups of compounds.²⁷²

Development and successful use of the empirical approaches described above are possible only when the set of experimental data on the thermodynamics of hydrogen bonds is being extended. A detailed description of an extensive set of data of this type has been reported.²¹⁰ The C_a and C_d values were calculated by selecting 414 hydrogen bond donors and 1298 hydrogen bond acceptors for which experimental thermodynamic parameters for interaction with several partners were available.²⁵¹ The matrix generated consisted of 414 columns and 1298 rows. This permitted rigorous calculations of the C_a and C_d values.

The factors for the free energy of hydrogen bonding for some compounds are presented below

Compound	C_d	Compound	C_a
CF ₃ COOH	−4.78	CCl ₃ CN	0.55
CCl ₃ COOH	−4.75	C ₄ H ₉ Cl	0.60
CHCl ₂ COOH	−4.28	C ₆ H ₅ OCH ₃	1.07
3,5-(NO ₂) ₂ C ₆ H ₃ OH	−4.09	CH ₃ OH	1.76
C ₆ F ₅ COOH	−3.82	CH ₃ C(O)CH ₃	1.92
3-NO ₂ C ₆ H ₄ OH	−3.49	(CH ₃) ₂ SO ₂	2.01
(CF ₃) ₂ CHOH	−3.31	C ₃ H ₅ N	2.45
CF ₃ C(O)NHC(O)CF ₃	−2.98	(C ₂ H ₅) ₃ N	2.57
C ₆ H ₅ OH	−2.50	(CH ₃) ₂ NC(O)N(CH ₃) ₂	2.96
CH(CN) ₂ Br	−2.06	(CH ₃) ₂ SO	3.13
4-NO ₂ C ₆ H ₄ NH ₂	−1.82	(C ₆ H ₅) ₃ PO	3.65
CH ₃ C(O)SH	−1.62	[(CH ₃) ₂ N] ₃ PO	4.00
C ₂ H ₅ OH	−1.42	(C ₄ H ₉) ₂ NO	4.25
C ₆ H ₅ NH ₂	−1.04		
CHCl ₃	−0.81		
2-CH ₃ C ₆ H ₅ NH ₂	−0.50		
C ₂ H ₅ SH	−0.24		
C ₆ H ₅ ≡CH	−0.12		

It should be emphasised that the limits of variation of the factors for the free energy of hydrogen bonding for functional groups overlap (Table 2). This indicates that substituents at a donor or acceptor atom play an exceptionally important role in the formation of the capacity of these atoms for hydrogen bonding.

Comparison of the experimental values for enthalpy and free energy with the values calculated using Eqns (44) and (45) proves

Table 2. Minimum and maximum free energy factors for hydrogen bonds for various functional groups.

Hydrogen bond donors	$C_d^{\min}$	$C_d^{\max}$	Hydrogen bond acceptors	$C_a^{\min}$	$C_a^{\max}$
R ¹ R ² R ³ C—H	−2.06	−0.12	R—O—R	0.78	2.01
RS—H	−1.92	−0.24	R—S—R	0.57	1.51
R ¹ R ² N—H	−3.32	−0.50	R ¹ R ² R ³ N	0.58	3.65
PhO—H	−4.24	−0.76	RC≡N	0.55	2.77
AlkO—H	−3.50	−1.06	R ¹ R ² R ³ P=O	2.40	4.02
RC(O)O—H	−4.78	−2.50	R ¹ R ² S=O	1.16	3.25

the adequacy of the multiplicative approach to the quantitative description of the thermodynamics of hydrogen bonding²⁵¹

$$\Delta H(\text{calc.}) = -0.49 (\pm 0.29) + 0.99 (\pm 0.08) \Delta H(\text{exp.}), \quad (47)$$

$$N = 2787, R = 0.970, S = 2.40, F = 44350,$$

$$\Delta G(\text{calc.}) = -0.07 (\pm 0.12) + 1.04 (\pm 0.05) \Delta G(\text{exp.}), \quad (48)$$

$$N = 3301, R = 0.991, S = 1.12, F = 175000.$$

In the case where charge transfer makes a significant contribution to the hydrogen bond in a particular complex, the values calculated in this way may deviate from experimental results.²⁷⁸

Using the known C_d values for 414 hydrogen bond donors and C_a values for 1298 hydrogen bond acceptors, one can calculate ΔG_{hb} for 537 372 hydrogen-bonded complexes. When a similar approach was used to calculate the constants of formation of hydrogen bonds, the α values for 150 hydrogen bond donors and the β values for 500 hydrogen bond acceptors were determined; this permitted the calculation of K_{hb} for 75 000 complexes.²⁷⁹

A whole series of descriptors have been proposed for the multiplicative description of the thermodynamic parameters of a hydrogen bond, including the donor and acceptor factors for the hydrogen bond free energy and enthalpy for the strongest donor and acceptor sites in a molecule ($C_a^{\text{max}}, C_d^{\text{max}}, E_a^{\text{max}}, E_d^{\text{max}}$), the sum of the free energy and enthalpy factors over all the donor and acceptors sites in a molecule ($\sum C_a, \sum C_d, \sum E_a, \sum E_d$) and the four last-mentioned descriptors divided by the molecular weight ($\sum C_a/\text{MW}, \sum C_d/\text{MW}, \sum E_a/\text{MW}, \sum E_d/\text{MW}$).^{280, 281} These descriptors have been used to model the structure–property relationships in complex processes such as complex formation,^{91, 282–286} solubility in water,²¹⁰ lipophilicity,²¹⁰ inhibition of cholinesterase,^{287, 288} inhibition of dopamine back capture,²⁸⁹ determination of the boiling points of hydrocarbons and acids,²⁹⁰ insecticide activities of nitrogen and phosphorus organic compounds,²⁹¹ ionophoric activity of macrocycles,²⁹² fungicidal activity of phenols and β -adrenergic activity of alicyclic acids and phenols,²⁹³ toxicity against *Golden orfe fish*²⁹⁴ and permeability of biological membranes.^{210, 295} Descriptors based on α and β factors have been described in a review.²⁷⁹ Similar indices for hydrogen bonding have been reported in one more study.²⁹⁶

VIII. Indicator descriptors

Indicator descriptors (sometimes called *de novo* constants) have found fairly wide use in modelling the structure–property (activity) relationships. It is difficult to classify these descriptors into any particular class because they can encode in an implicit form various structural features of compounds (properties of hydrogen bond donors and acceptors, the presence or absence of hydrogen bonds within the molecules, *ortho*-effects, *cis*–*trans* isomerism, stereoisomerism, various fragments, *etc.*).

The expediency of using indicator variables in some cases has been demonstrated in a review.²⁹⁷ Thus for two sets of papain ligands, similar two-parameter relations were obtained [see the Appendix, Eqns (A.7) and (A.8)], having fairly close coefficients at MR and σ but substantially different constant terms. By combining these equations and by using the indicator variable I ($I = 1$ for mesylamides and $I = 0$ for benzamides), the researchers derived a common relation applicable to both series [see the Appendix, Eqn (A.24)].

Other examples of using indicator descriptors can also be found in the literature.^{298, 299}

Indicator descriptors are especially useful at initial stages of investigations. These descriptors can be used for tentative combinations of compounds to give various subsets of compounds with a particular property, which is needed to form a training set meant for the modelling of the structure–property relationship based on a more extensive structure description.

In analyses of the structure–biological activity relationships, various physico-chemical molecular properties or experimental

parameters obtained by various physical methods are often used as structure descriptors.¹⁵ The use of physicochemical properties as descriptors has been discussed in the preceding Sections. A more detailed discussion of these descriptors can be found in the literature.³⁰⁰

IX. Modern computer software for the calculation of descriptors

At present the market of computer software meant for chemistry and, in particular, for molecular design is filled by diversified programme products. Therefore, to be competitive, every new programme must have obvious novelty elements or obvious advantages over other programmes.

1. MOLSURF is a generator of chemical descriptors for QSAR.¹⁹³ This programme has three distinctive features.

Firstly, it is assumed that a researcher prefers describing molecules using chemical terms such as hydrogen bonds, nucleophiles, electrophiles, bases, acids, hydrophobicity, polarisability, π -interaction, *etc.* rather than using quantum-chemical terms (HOMO, LUMO, electrostatic potential, force fields, *etc.*). Therefore, the MOLSURF programme calculates the descriptors related the above chemical notions.

Secondly, the programme is based on correlations of the calculated values of descriptors with experimental data.

Thirdly, the programme prefers descriptors of substituents to molecular descriptors, because the former reflect more accurately the variation of properties upon structure modification and because their values can be calculated more precisely.

2. The calculations and the use of theoretical descriptors within the framework of the concept of linear correlations of free energy have been described in a number of publications.^{301–306} In this fairly simple approach, a property is described by regression equations containing descriptors related to steric interactions, polarisability and hydrogen bonding as independent variables. The steric interactions are estimated quantitatively using the van der Waals volumes V_{mc} . A descriptor called polarisability index (π) is defined as polarisability divided by volume. To describe hydrogen bonds, the researchers distinguish two constituents, the acidic and basic ones. Each constituent is divided in turn into covalent and electrostatic components. The covalent contribution is assumed to be determined by the energy of the highest occupied molecular orbital (HOMO). The electrostatic contribution to the basicity is characterised by the formally most negative atomic charge (q_-) in the molecule (it is assumed that the most negative atom should interact most efficiently with the proton in a neighbouring molecule). The covalent component in the acidic constituent (ϵ_a) is characterised by the energy of the lowest unoccupied molecular orbital (the difference between the LUMO energy of the compound and the HOMO energy of water divided by hundred). A smaller ϵ_a value points to a higher tendency to form hydrogen bonds (the ϵ_b component) with water. The contribution of the electrostatic component to the acidity is determined by the most positive charge of a hydrogen atom in the molecule (q_+).

According to this approach a property (P) can be described by the following six-parameter equation

$$\log P = \log P_0 + \frac{AV_{\text{mc}}}{100} + B\pi_1 + C\epsilon_b + Dq_- + E\epsilon_a + Fq_+. \quad (49)$$

where A, B, C, D, E and F are coefficients.

This method has been used to describe the properties and biological activity of chemical compounds and gave formally rather good results. Nevertheless, this approach seems to be based on a simplified physical model. In addition, when initialising sets are relatively small, multiparameter regression equations of this type are not stable and may lead to faulty results when used to predict the properties of compounds.

3. The CoMFA programme (Comparative Molecular Field Analysis) is currently the most widespread computer programme

used to calculate the energies of intermolecular interactions in terms of the corresponding descriptors establishing the structure–property relationships.³⁰⁷

The parameters calculated initially include the energies of steric and electrostatic interactions between the compound considered and a probe atom being placed into various points of a regular three-dimensional grid. The size of this grid should be sufficiently large to accommodate the largest molecule of the initialising set. The size of the cell in this grid is usually taken to be 2.0 Å and, in some cases, 1 Å (the smaller the grid dimensions, the larger the number of descriptors and the time it takes to calculate them). An sp^3 hybridised carbon atom with the charge +1.0 was used initially as the probe atom; later, various atoms and groups have been used (see, e.g. Ref. 308). It is clear that these calculations give an enormous number of descriptors, exceeding the number of compounds in the initialising set by a large factor. Most of the descriptors thus obtained are correlated with one another. Under these conditions, a stable model can be designed only by using a special procedure. The PLS (Partial Least Squares)³⁰⁹ method permits selection of orthogonal components. During the design of stable models, the number of these components can be optimised by calculating the correlation coefficients for predictive models, formed by the cross-validation procedure.

During the last decade, the CoMFA programme has been constantly improved. For example, several studies have been devoted to the methodological aspects of the programme development^{310, 311} (description of non-linear CoMFA, the use of various semiempirical methods for optimisation of the calculations of the geometry and the properties of compounds). The programme has been used to study many types of biological activity of various compounds, for example, the relationship between the structure of 2-hetarylquinoline-4-amines and their biological activity against HIV,³¹² the structures and steric and electronic effects of phosphorus ligands³¹³ and the structure–inhibitory activity correlations for various compounds,³¹⁴ steroid inhibitors,³¹⁵ melatonin receptor ligands³¹⁶ and calcium blocking agents.³¹⁷

However, the CoMFA programme is not free from drawbacks. First of all, it should be noted that until recently it had been unable to calculate the energies of hydrogen bonds, which play a crucial role in many biological processes. In addition, based on the parameters that act as independent variables in the final regression equation, it is hardly possible to construct any useful physical model for a structure–property relationship because these variables are linear combinations of many thousands of descriptors. Yet another drawback of this programme is that it cannot be run on a personal computer.

4. The GRID programme,²²⁵ having some common features with CoMFA, also uses atoms and functional groups of various natures as the probe atoms to estimate the intermolecular interactions with the macromolecules under study, which are put in a three-dimensional grid. It is significant that this programme, unlike CoMFA, takes into account not only steric and electrostatic interactions but also hydrogen bonds (E_{hb}). Initially this has been done using a direction-dependent 6–4 function with a broad energy minimum^{225, 318}

$$E_{hb} = \left(\frac{C}{d^6} - \frac{D}{d^4} \right) \cos^m Q, \quad (50)$$

where Q is the DHP angle (D is the donor atom of the protein, H is a hydrogen atom and P is the probe electron-withdrawing atom); m is usually taken to be 4.

If the interaction involves two identical atoms, the interatomic separation d_{min} is determined by tabulated values for C and D . If different atoms interact, the geometrical mean of their individual D values and the arithmetic mean of their separations (d_{min}) are used. Later, the 6–4 function has been replaced by a 8–6 function.^{319–320}

$$E_r = \frac{C}{r^8} - \frac{D}{r^6}, \quad (51)$$

where r is the distance between the probe atom and some atom in the compound considered. The hydrogen bond energy is represented by the following expression:

$$E_{hb} = E_r E_\tau E_p, \quad (52)$$

where E_τ and E_p are angle functions taking account of the mutual arrangement in space of the hydrogen atom and the lone electron pair of the hydrogen bond acceptor.

The GRID programme has been used successfully to design models of various biological receptors.^{321–327}

5. As an alternative to the CoMFA and GRID programmes, approaches reflecting a three-dimensional structure and the capacity for intermolecular interactions as a spectrum of interatomic distances or interatomic interactions can be considered.^{251, 270, 328–340} In these cases, a molecular structure is represented as a radial scattering curve, which can be constructed for a molecule of any complexity provided that its Cartesian coordinates are known. A similar approach is employed in gas phase electron diffraction studies of molecular structures. The radial distribution function $[M(s)]$ in the spherical approximation for atoms i and j and in the absence of intramolecular vibrations is a spectrum of interatomic distances, the intensity of the spectrum being determined by the natures of the atoms spaced at a given distance and by the dynamics of the variation of this distance during intramolecular vibrations

$$M(s) = \sum_{i=1}^N \sum_{j>i}^N C_{ij} \frac{\sin sr_{ij}}{sr_{ij}}, \quad (53)$$

where C_{ij} is a coefficient characterising the scattering capacity of this pair of atoms, s is an angle parameter: $s = (4\pi/\lambda)\sin(Q/2)$ (λ is the electron wavelength and Q is the scattering angle) and r_{ij} is the interatomic distance in the molecule.

It can be said that the radial distribution function obtained in an electron diffraction experiment is the pattern ‘seen’ by an electron interacting with the molecule in a scattering event. This analogy has been extended to the case where a receptor interacts with molecules of a substance administered into an organism.³²⁸ It is known that a receptor interacts with parts of the molecule that are complementary to the active sites of the receptor rather than with the whole molecule. The governing factors are the distances between the active sites and the susceptibility to intermolecular interactions of the atoms located at these distances from one another in the reagent molecules. A sort of scattering of the reagent molecules on the active sites of the receptor occurs, i.e. the receptor ‘sees’ the molecule as a radial distribution function. In this approach, the radial distribution function can be modified in such a way as to take into account quantitatively the ability of atoms of the reagent to undergo various intermolecular interactions. This approach was embodied in some studies^{251, 340} and in the MOLTRA (Molecular Transform Analysis) programme package, which can be used to calculate the spectra for the steric interactions of atoms; interactions of positively charged atoms with one another, negatively charged atoms with one another and positively charged atoms with negatively charged atoms; interactions of hydrogen bond donors with one another, hydrogen bond acceptors with one another and hydrogen bond donors with hydrogen bond acceptors. Each of these spectra is a superposition of bands corresponding to pairs of atoms in the molecule. The positions of the band maxima are matched by the equilibrium distances between these atoms and the areas below the band contours are proportional to the products of the given local properties for a given pair of atoms.

Figure 4 shows the spectra for the interactions of hydrogen bond acceptors in some macrocyclic polyethers. Each point in the spectra presented can be considered as a descriptor of intermolecular interactions describing the interaction of hydrogen bond

Figure 4. General view of the spectrum of interactions of hydrogen bond acceptors in some macrocyclic polyethers.

acceptors located at a given distance. For distances ranging from 1.1 to 20.0 Å and with a step of 0.1 Å, each spectral pattern provides 190 descriptors. Seven spectral patterns permit the description of the possible steric and Coulomb interactions and hydrogen bonds in terms of 1340 descriptors.

X. The necessary properties of descriptors

A great number of descriptors have been reported by now. It is clear that the extension of the views on molecular structure stimulates the design of new structure models and new descriptors reflecting these views. The attempts of developing new descriptors which, having been introduced in computer programmes, would preserve and utilise the information on the molecular structure better than the earlier descriptors are also justified.

Nevertheless, the introduction of new descriptors is expedient only in two cases — either when none of the existing descriptors or their combination provides the elucidation of stable structure–property correlations for the training set used or when the new descriptor ensures a substantial improvement of the statistical criteria of the model.⁹

New descriptors should be readily calculable, convenient to use and versatile; they should ensure comprehensive description of a given structural feature and be interpretable.³⁴¹

Unfortunately, the above requirements are by far not always taken into account.

The efficiency of descriptors of various classes used in establishing the structure–biological activity correlations becomes clear upon comparison of the statistical criteria of the models designed using these descriptors. For example, Raevsky *et*

al.^{290, 293} compared the models for classification of agonists and antagonists among substituted phenylethylamines based on a number of topological and physico-chemical descriptors using linear discriminant analysis, a discrete regression model²⁹⁰ and significant cluster analysis.³⁴² In all of these types of classification, the best results were attained by using hydrogen bond descriptors. Other examples can also be found in the literature.^{14–16, 337, 343, 344}

In this review, the descriptors were introduced in the order of increasing amount of information on the molecular structure contained in them. However, this does not mean that the use of a more informative descriptor guarantees better results in elucidation of the structure–property correlations. Indeed, there are many examples of successful employment of topological descriptors for the calculation of the melting and boiling points, evaporation enthalpies and other ‘simple’ physical properties within narrow series of related compounds, which differ, for example, in the length of the chain in the alkyl substituent. In these cases, the statistical criteria of regression equations containing more informative descriptors as independent variables prove sometimes to be inferior to those for equations based on simpler descriptors, because the magnitudes of more informative descriptors are estimated with lesser accuracy and because they carry ‘excessive’ information for the set considered. The foregoing leads to the following conclusions: it is expedient to use combinations of known descriptors with different information contents; it is useful to develop new descriptors and perfect the procedures to attain more precise calculations of all descriptors; well-founded selection of descriptors for a particular set of compounds is necessary.¹

Note that comprehensive description of a molecular structure cannot be attained in terms of any single descriptor. One descriptor can predominantly take into account one feature of

the electronic or steric structure or one type of intermolecular interactions. For this reason, description of a molecular structure using several descriptors and construction of structure–property models based on several independent variables appears expedient.

In the construction of structure–biological activity models, the modern views on the processes occurring in an organism with participation of chemical compounds play an important role in the selection of appropriate descriptors. For example, it is currently believed that the complex mechanism of action of a substance on an organism consists of three stages — pharmacologic, pharmacokinetic and pharmacodynamic stages.³⁴⁵ The pharmacologic stage is associated with the administration of a substance into an organism and includes disintegration of the preparation. The pharmacokinetic stage is determined by the transport of the substance from the administration site to the particular biological target and includes the processes of absorption, distribution, metabolism and excretion. At this stage, the reactivity of the initial compounds and their capacity for complex formation are important. The pharmacodynamic stage is characterised by the interaction of the initial substance or the products with biological targets responsible for the particular type of biological activity. At this stage, the three-dimensional structure of the interacting partners is the most important factor.

The exceptional popularity of the Hansch–Fujita three-parameter equation is due most of all to the fact that it uses descriptors of the electronic structure (Hammett constants), steric interactions (Taft steric constants), and transport properties (octanol–water partition coefficients). At present, similar models and the corresponding equations are also used successfully in the molecular design of biologically active substances.^{346–349} For example, for a series of bicyclic compounds, an equation describing their ability to bind the muscarinic receptor based on three descriptors has been derived²¹⁰ [see the Appendix, Eqn (A.23)]. One descriptor characterises the transporting properties of the compounds, the second descriptor is related to the solubility of the compounds in water and the ability to form hydrogen bonds with the donor sites of the receptor and the third one points to the important role of the distance between two particular hydrogen bond acceptors in the formation of the substrate–receptor complex.

The development of models requires the observance of formal criteria. From the statistical viewpoint, the number of compounds considered should exceed the number of descriptors by a large factor. The information contents of the descriptors must be sufficiently large and, simultaneously, they should not correlate with one another. This can be attained by several procedures including experimental design,³⁵⁰ the SIMCA/PLS method^{351,352} and the principal component and factor analyses.³⁵³

XI. Conclusion

At present, molecular structure descriptors constitute an integral part of the majority of studies dealing with structure–property (including biological activity) correlations; they are widely used to optimise characteristics of compounds in the molecular design. The Appendix to this review presents examples of successful application of various types of descriptors for quantitative description of diverse properties and types of biological action.

It should be emphasised that the molecular structure descriptors used should finally provide the design of structure–property models, which satisfy certain requirements. These models should be consistent with the laws of Nature, be relatively simple and have a clear physical meaning; in addition, they must be stable and hence possess predictive capacity and provide the possibility of identifying the relationships that were not specified in an explicit

form when the model was developed. All these points broach one more important section of the computer-aided molecular design, namely, modelling of the structure–property relationships, and require separate discussion.

XII. Appendix

Examples of successful application of molecular structure descriptors in structure–property (biological activity) correlations are presented below.

1. Element-level descriptors

Solubility of gases in water, $\log L^w$ (see³⁵⁴).

$$\log L^w = 42.37(\pm 1.11)\text{HDCA}(2) + 0.65(\pm 0.02)[2n(\text{N}) + m(\text{O})] - 0.16(\pm 0.02)\Delta E + 0.12(\pm 0.01)\text{PCWT}^E + 0.82(\pm 0.01)N_{\text{ring}} + 2.65(\pm 0.22), \quad (\text{A.1})$$

where HDCA(2) is a hydrogen bond descriptor, $[2n(\text{N}) + m(\text{O})]$ is a descriptor characterising the number of nitrogen and oxygen atoms in the molecules of compounds studied, $\Delta E = E_{\text{LUMO}} - E_{\text{HOMO}}$, PCWT^E is an electronic topological index, N_{ring} is the number of aromatic rings; $N = 406$, $R = 0.971$, $S = 0.52$, $F = 1300$.

2. Topological descriptors

Lipophilicity of organic compounds (based on topological and information topological indices), $\log P$ (see³⁵⁵)

$$\log P = 0.19P_{10} - 1.46\text{IC}_0 + 1.09\text{CIC}_2 - 0.77\text{CIC}_3 - 1.36^6X_b + 5.34^0X^V - 3.41^1X^V + 0.55^4X^V - 0.41^3X_C^V + 1.10X_w - 0.17W - 5.60, \quad (\text{A.2})$$

$N = 219$, $R = 0.955$, $S = 0.35$, $F = 194$.

β -Blocking activity of medicines, pLD_{50} (see³⁵⁶).

$$\text{pLD}_{50} = 1.79^1\chi - 1.81^1\chi^V + 0.36^2\chi + 2.37^4\chi_p^V - 2.76^4\chi_p + 1.56, \quad (\text{A.3})$$

where χ are Kier and Hall connectivity indices; $N = 17$, $R = 0.905$, $S = 0.208$, $F = 10.1$.

3. Descriptors of the electronic structure of molecules

Binding of an estrogen receptor, pEC_{50} (see³⁵⁷).

$$\text{pEC}_{50} = 3.38(\pm 0.12)D^2 + 3.22(\pm 0.20)\text{Gap} - 44.3(\pm 1.8) \quad (\text{A.4})$$

where D is the Balaban topological index, Gap is the $E_{\text{LUMO}} - E_{\text{HOMO}}$ difference; $N = 33$, $R = 0.99$, $S = 0.30$, $F = 595.0$.

Toxicity against Daphnia magna, EC_{50} (see³⁵⁸).

$$\text{EC}_{50} = -3.63 \frac{V_{\text{mc}}}{100} - 45.8\pi + 3.71q_- - 2.0q_+ + 11.4, \quad (\text{A.5})$$

where V_{mc} is the molecular volume, π is the polarisability index, q_- is the electrostatic basicity, q_+ is the electrostatic acidity; $N = 38$, $R = 0.977$, $S = 0.37$, $F = 176$.

Fungicide activity of phosphonates, pEC_{50} (see³⁵⁹).

$$\text{pEC}_{50} = 0.296(\pm 0.124)\sum \pi - 0.047(\pm 0.012)\text{MR}(\text{R}^2) + 0.543(\pm 0.331)\sum F' + 3.556(\pm 0.215), \quad (\text{A.6})$$

where π is the hydrophobicity constant, $\text{MR}(\text{R}^2)$ is the molar refraction of the second substituent, F' is the Swain–Lupton electronic parameter; $N = 57$, $R = 0.851$, $S = 0.290$, $F = 46.32$.

Binding of papain ligands by phenyl N-mesylglycinates (see²⁹⁷).

$$\log \frac{1}{K_m} = 0.529(\pm 0.230)\text{MR} + 0.379(\pm 0.200)\sigma + \quad (\text{A.7})$$

¶ An expert can rely not only on the generally recognised views on the mechanism of formation of the property being considered but also on the knowledge not yet formalised and even on intuition.

+ 1.877(±0.130),
where σ is an electronic constant; $N = 13$, $R = 0.935$, $S = 0.105$,
 $F = 34.51$.

Binding of papain ligands by phenyl N-benzoylglycinates (see²⁹⁷).

$$\log \frac{1}{K_m} = 0.771(\pm 0.670)MR + 0.728(\pm 0.370)\sigma + \quad (\text{A.8})$$

$$+ 3.623(\pm 0.340),$$

$N = 7$, $R = 0.971$, $S = 0.148$, $F = 32.85$.

4. Molecular shape descriptors

Inhibition of ligand binding, pIC₅₀ (see³⁶⁰).

$$\text{pIC}_{50} = 10.25(\pm 0.97)V + 1.43(\pm 0.56), \quad (\text{A.9})$$

where V is the shape index; $N = 26$, $R = 0.912$, $S = 0.462$,
 $F = 111.1$.

Sweetness of aniline derivatives, logRS (see³⁶¹).

$$\log RS = 0.52L - 1.37W1 + 3.71, \quad (\text{A.10})$$

where L and $W1$ are STERIMOL parameters; $N = 20$, $R = 0.90$,
 $S = 0.32$.

Psychomimetic activity of phenyl-2-aminopropane derivatives, logMU (see³⁶²).

$$\log MU = 1.99(\pm 0.13) - 1.78(\pm 0.17)MTD + \quad (\text{A.11})$$

$$+ 0.93(\pm 0.10)S_3 - 0.77(\pm 0.12)q_4,$$

where MTD is the minimum topological difference, S_3 is the
electron topological index for the atom with number 3 in the
benzene ring, q_4 is the charge on atom 4 of the benzene ring;
 $N = 49$, $R^2 = 0.885$, $S = 0.241$, $F = 84.7$.

Inhibition of hepatic receptors, pEC₅₀ (see¹⁶⁹).

$$\text{pEC}_{50} = 0.447Tm + 0.242Ts - 0.158Vu + 2.361, \quad (\text{A.12})$$

where Tm , Ts and Vu are WHIM descriptors; $N = 71$, $R = 0.914$,
 $S = 0.64$.

Inhibition of photosystem II, pIC₅₀ (see³⁶³).

$$\text{pIC}_{50} = 1.081 \log P - 0.57\sigma(Y, Al) + 0.29L(Y, Al) - \quad (\text{A.13})$$

$$- 0.95T(Y, Al) - 2.21T(Y, Ar) - 0.32W(X) +$$

$$+ 1.02I_u + 8.16,$$

where Y and X are substituents, Al is alkyl, Ar is aryl, L , W and T
are shape descriptors, I_u is an indicator variable (1 for urea
derivatives and 0 for all other compounds); $N = 69$, $R = 0.921$.

5. Intermolecular interaction descriptors

Lipophilicity of various compounds, logP (see²⁰⁹).

$$\log P = -0.01(\pm 0.08) + 0.249(\pm 0.005)\alpha - \quad (\text{A.14})$$

$$- 0.68(\pm 0.02)\sum C_a,$$

where α is the molecular polarisability, $\sum C_a$ is the sum of the
factors for the hydrogen bond acceptor capacity; $N = 234$,
 $R = 0.961$, $S = 0.34$, $F = 1383$.

Effect of protein binding, log HSAI (see³⁶⁴).

$$\log HSAI = 0.59(\pm 0.03)\log P + 0.27(\pm 0.08), \quad (\text{A.15})$$

$N = 57$, $R = 0.92$, $S = 0.28$, $F = 283$.

Toxicity against Daphnia, log(1/IC₅₀) (see³⁶⁵).

$$\log \frac{1}{IC_{50}} = 0.809 \log P + 1.64, \quad (\text{A.16})$$

$N = 23$, $R^2 = 0.84$, $S = 0.30$, $F = 118$.

Bactericidal activity, pMIC (see³⁶⁶).

$$\text{pMIC} = -0.35 \text{pK}_a + 0.68, \quad (\text{A.17})$$

$N = 8$, $R = 0.973$, $S = 0.063$.

Ligand-receptor binding, ΔG (see³⁶⁷).

$$\Delta G = 0.06(\pm 0.01)E_L - 0.05(\pm 0.02)\Delta E_{\text{solv}} + 7.74(\pm 0.57), \quad (\text{A.18})$$

where E_L is the change of the intramolecular energy of the ligand
upon binding, ΔE_{solv} is the change of the solvation upon binding;
 $N = 10$, $R = 0.92$, $F = 20.61$.

Inhibitory activity of aryl-substituted piperazine and piperylene, log(1/EC₅₀) (see³⁶⁸).

$$\log \frac{1}{EC_{50}} = 0.62(\pm 0.04)\log P - 0.39(\pm 0.05)\sum C_a - \quad (\text{A.19})$$

$$- 2.16(\pm 0.18),$$

$N = 17$, $R^2 = 0.90$.

Toxicity of carboxylic acids against Xenopus embryos, pLC₅₀
(see³⁵⁸).

$$\text{pLC}_{50} = 0.696 \log P - 0.358 \text{pK}_a - 0.541, \quad (\text{A.20})$$

$N = 44$, $R = 0.947$.

Membrane permeability (human red cell basal), logBP (see³⁶⁹).

$$\log BP = -0.70(\pm 0.64) + 1.08(\pm 0.16)\sum C_d, \quad (\text{A.21})$$

$N = 10$, $R = 0.983$, $S = 0.433$.

Membrane permeability (cells of the alga Chara ceratophylla), log Per (see³⁶⁹).

$$\log \text{Per} = 0.83(\pm 0.57) + 0.59(\pm 0.12)\sum C_d, \quad (\text{A.22})$$

$N = 27$, $R = 0.903$, $S = 0.49$.

Binding of the muscarinic receptor by bicyclic ligands, log K
(see²¹⁰).

$$\log K = 1.28(\pm 0.15)\log P - 0.09(\pm 0.06)\sum C_a + \quad (\text{A.23})$$

$$+ 0.27(\pm 0.08)\text{HBA5.3A} - 4.58(\pm 0.48),$$

where HBA5.3A is a descriptor characterising the interaction
between two hydrogen bond acceptors spaced 5.3 Å apart;
 $N = 27$, $R = 0.918$, $S = 0.38$, $F = 41.1$

6. Indicator descriptors

Binding of papain ligands by phenyl N-mesylglycinate and N-benzoylglycinate, log(1/K_m) (see²⁹⁷). (The combination of Eqns
(A.7) and (A.8) with the aid of an indicator variable I ($I = 1$ for
mesylamides and $I = 0$ for benzamides)).

$$\log \frac{1}{K_m} = 0.57(\pm 0.26)MR + 0.56(\pm 0.19)\sigma - \quad (\text{A.24})$$

$$- 1.92(\pm 0.15)I + 3.74(\pm 0.17),$$

$N = 20$, $R = 0.990$, $S = 0.148$, $F = 272.04$.

Inhibition of HIV-RT, pIC₅₀ (see³⁷⁰).

$$\text{pIC}_{50} = 1.47I + 0.41\mu + 2.69 \log MW - 4.36, \quad (\text{A.25})$$

where I is the indicator variable, MW is the molecular weight,
 $N = 14$, $R = 0.94$, $S = 0.42$, $F = 27.4$.

Cytotoxic activity, pIC₅₀ (see³⁷¹).

$$\text{pIC}_{50} = 0.73(\pm 0.46)I_2' + 1.14(\pm 0.38)I_5' + \quad (\text{A.26})$$

$$+ 1.12(\pm 0.43)I_{xy} + 3.15,$$

where I_2' , I_5' , and I_{xy} are indicator variables; $N = 22$, $R = 0.915$, $S = 0.32$, $F = 30.78$.

VII. Conclusion	545

Abstract. The state-of-the-art of the investigations aimed at creating expert systems for establishing the structure of organic molecules from IR, ^1H and ^{13}C NMR spectra is analysed. Computer methods used for identification of molecular fragments, generation of their structure and spectra prediction are considered. Principles of the creation of modern expert systems and general strategy of solving structural problems are discussed. The bibliography includes 174 references.

I. Introduction

More than 30 years have elapsed since the publications^{1–5} in which the problem of using mathematical methods and computers for establishing the structure of organic molecules from their spectra were first considered. Even in these articles it was shown that the structural-group analysis (SGA) can be formalised using methods of mathematical logic and performed on a computer,^{1,2} while application of graph theory and combinatorial analysis makes it possible to generate automatically (perform mathematical synthesis) structural formulae from fragment sets.³ In this time, many interdisciplinary sciences have united on the basis of mathematical algorithms as computer programs to form a new line of investigation, application of artificial intelligence (AI) to the determination of molecular structures from spectral data.

Since World War II, spectral methods have received wide acceptance in chemistry. It will not be an exaggeration if we say that IR, NMR spectroscopy and mass spectrometry revolutionised the methodology of chemical investigations and ‘chemical’ thinking and have become one of the main sources of structural information for chemists. Unquestionable are the advantages of spectral methods, *viz.*, their versatility, fast operation, ease of constructing a computer interface and the use of well developed theories (this particularly concerns IR and NMR spectroscopy). It is these features, as well as the accumulation of a great body of information on empirical spectrum – structure correlations (SSC),

that have stimulated investigations on the application of AI in chemistry.

To formalise the process of molecular structure determination, it was necessary to find mathematical tools adequate to the problem considered. Since a molecule has a discrete nature and its energy levels are discrete too, mathematical logic, graph theory and combinatorial analysis were chosen as appropriate mathematical tools. It is discrete mathematics which describes the models of the ‘black box’ type that has become one of the main instruments of mathematical chemistry, which has progressed intensively in the last decades.

At first, mathematical synthesis of the structures from the atoms and fragments seemed to be merely a stage in the identification process of organic compounds; however, soon it became clear that its importance goes far beyond the scope of the problem considered. In fact, innumerable sets of organic molecules designed by the structure generator can be interpreted as enumeration of logical implications from a system of axioms that form a basis of the theory of molecular structure. At the same time, knowing only the structural formula of a compound, one can predict a number of its important properties. This made it possible to pose a problem of the development of mathematical methods for predicting the structure of the compounds with desired properties and, *vice versa*, the properties of compounds from a structure given (studies of N S Zefirov’s scientific school in this line of investigation have gained world-wide acceptance). Rich experience accumulated by chemists shows that most predictions on the possibility for unknown compounds to exist in nature and to be synthesised, made on the basis of the classical theory of the structure of organic substances, were borne out, the percentage of wrong predictions being relatively small.⁶

Formalisation of chemical research based on integration of many sciences has become an important result of the studies on the application of AI in molecular spectroscopy.

By and large, the development of concepts and methodological approach in this new area of study was completed by the early 1980s, which was embodied in a number of monographs^{7–10} and reviews.^{11–15} The efforts of investigators from many countries have resulted in general principles for creating AI systems [currently, they are called expert systems (ES)] and in developing corresponding algorithms which were tested on a large number of problems.

About twenty ES for molecular spectroscopy have been documented. They differ in their possibilities, use different algorithms and instrumental tools and are aimed at the applica-

tion of different methods of spectral analysis. However, common to these systems is the fact that they simulate reasoning of an expert (spectroscopist) when solving an identification problem. This thinking process involves the following main stages:

- (1) structural-group analysis of an unknown compound;
- (2) generation of possible structural formulae from the fragment sets found;
- (3) test for the correlation between structural formulae and experimental spectra (and additional information) using spectra prediction of the assumed structures.

Each stage is simulated by a corresponding block of an expert system. The above-mentioned blocks are relatively independent and their functions are usually realised using different mathematical methods. Currently, methods for identification of the fragments, structure generation and prediction of their spectra have become almost independent divisions of computer spectroscopy and mathematical chemistry.

To come as close to solving actual problems using ES as possible, it was necessary to investigate the nature of the structure determination problem. Peculiarities of this problem were considered¹⁶ as an example of the inverse problem.¹⁷ As is known, the inverse problems belong to the so-called ill-posed problems: they do not have a unique solution unless *a priori* restrictions are imposed.¹⁸ Important conclusions were drawn that it is impossible to perform a structure determination without the attention of a chemist and that all problems should be solved in the interactive mode. At that time, it was also appreciated that information on the spectra–structure interrelations is usually ‘fuzzy’ (ambiguous). With this in mind it was suggested¹⁹ that methods of fuzzy mathematics²⁰ should be used for SGA formalisation and approximate spectra prediction. The results obtained by different research groups up to the early 1990s have been reported in reviews.^{21–23} At about the same time a considerable interest has been expressed by investigators in algorithms of artificial neural networks (ANN),^{24–27} the application of which in different areas of computer chemistry seems to be rather promising. The number of studies in this investigation line grows rapidly. It appeared to be so new for chemistry and chemometrics that no mention of ANN was made, *e.g.*, in a ‘Chemometrics’ monograph²⁸ published in 1986.

At the same time it became clear that ES have a chance to become an analytical tool of organic analysis only if they ‘learn’ to operate on large non-additive structures (*e.g.*, the structures of natural compounds) and possess a high degree of user-friendliness. The efforts of several research groups focussed on this line of investigation have led to the creation of new ES (see, *e.g.*, Refs 29–32).

In the present review, the experience mostly accumulated in the last decade in the area of creation of the ES oriented to the molecular structure determination from IR, ¹H and ¹³C NMR spectra is generalised. First, methods for identification of fragment sets, structure generation and prediction of their spectra are considered and then strategies of structure determination are analysed taking the most perfect ES as examples. Particular emphasis is placed on discussing the problems that arose in the course of ES operation and analysing possible ways of overcoming these problems.

II. Methods for identification of structural fragments

To identify the structural fragments, most ES use characteristic features of functional groups and other structural elements in the molecular spectra. Usually, the knowledge base of an ES consists of molecular fragments, ranges of changes in their characteristic features (frequencies in IR spectra and chemical shifts in NMR spectra) and the rules relating the spectra to the structure. In a number of systems, libraries of the structures and corresponding spectra are included in the knowledge bases in addition to molecular fragments. Depending on the type of the knowledge

base, different methods of structural information retrieval are used.

1. Formal logic method

It has been shown^{1,33} that the scheme of relations between the elements of molecular structure and their spectral features can be described by a discrete structural model, therefore application of mathematical logic in the studies of the spectrum–molecular structure interrelation naturally follows from the nature of the object studied. It is assumed that the molecule is additive or partially additive and each fragment A_i of a set A of fragments related to the problem given is characterised by one or several intervals of changes of characteristic features $\omega_i \in \Omega$ (Ω is a set of spectral features).

Boolean algebra was used as a mathematical tool of the theory of SGA. This made it possible to derive in the general form logical relations connecting structural elements to their characteristic spectral features and to construct a model of reasoning when identifying structural fragments.

Boolean algebra deals with elementary propositions and their combinations, which are called Boolean functions. Combinations of elementary propositions are constructed using ‘and’ (conjunction), ‘or’ (disjunction), negation and implication operations. The latter has a meaning of a complex proposition ‘if..., then ...’ and is denoted by an arrow ($\rightarrow$). For instance, the sentence ‘if a molecule contains a fragment A_i , then feature ω is observed in its spectrum’ is represented by the $A_i \rightarrow \omega$ implication. Elements of Boolean algebra and SGA theory are reported in the monograph.⁷

In the general case, reasoning of an expert who performs SGA seems to be as follows: if a Boolean function $T(A, \Omega)$ correctly reflects interrelation between the spectrum and molecular structure, then the presence in the spectrum of a combination of spectral features, which is described by a Boolean function $R(\Omega)$, indicates the presence in the molecule under study of at least one combination of the structural elements defined by a Boolean function $f(A)$, *i.e.*

$$T(A, \Omega) \rightarrow [R(\Omega) \rightarrow f(A)].$$

This expression is a general formulation of the problem of qualitative spectral analysis in terms of Boolean algebra, it is a logical equation with respect to function $f(A)$. Solution of the logical equation is reduced to calculating the function $f(A)$ using an algorithm which is based on the concept of designation numbers and reported in the monograph.⁷ Function $f(A)$ contains fragment sets, each of which can explain characteristic features in experimental spectra.

The approach described serves as the basis for the SGA block in several generations of the RASTR system^{34–36} and is used in the X-PERT,²⁹ CHEMICS,³⁷ EXPIRS^{38,39} and other systems. This makes it possible to select successively possible fragments for producing logically consistent sets appropriate for further structure generation. However, such an approach has a drawback consisting in too ‘rigid’ logical determinacy. For instance, a small deviation of a characteristic feature of the fragment in the experimental spectrum from the limits of a given interval leads to the loss of the corresponding fragment. In addition, the knowledge base of the algorithm remains to a great extent similar to correlation tables and, hence, vast information presented in terms of natural language in numerous monographs on molecular spectroscopy (regularities, empirical rules, *etc.*) is not used. In this connection attempts have been undertaken to create such an ES in which SSC are described in more detail.^{19,40}

2. Methods of predicate logic

To create an ES which operates on the knowledge presented in terms of a natural language with professional restrictions, it is necessary to find appropriate mathematical tools. The requirements placed on such mathematical tools are caused by the character of the knowledge formulated in terms of natural language. On the one hand, descriptive (declarative) knowledge,

in particular, in the field of IR spectroscopy (see, *e.g.*, Ref. 41), is characterised by some fuzziness and ambiguity. The statement that, usually, stretching vibrations of the C=C bond are observed in the IR spectrum in the region near 1650 cm^{-1} ; however, sometimes they are shifted to the region 1685 cm^{-1} can serve as an example.⁴¹ On the other hand, logical inferences in the course of solving qualitative problems are also performed in terms of a natural language with inherent ambiguity and hidden estimates of reliability (*e.g.*, 'often', 'rarely', 'sometimes', *etc.*). The man thinks using fuzzy concepts rather than numbers. Therefore, theoretical tools appropriate for adequate simulation of our knowledge and reasoning must meet the requirement figuratively formulated by L. Zadeh who initiated fuzzy mathematics:⁴² 'The theory of nature must reflect the fact that nature paints by arbitrary strokes rather than by a ball pen'.

To represent the knowledge on IR spectroscopy, applied logical calculus^{19,40} (ALC) based on the theory of first-order predicates⁴³ and theory of fuzzy sets^{20,42} was proposed. The basic principles of ALC are as follows.

A logical function $P(X_1, X_2, \dots, X_n)$, where $X_i \in M(X_i)$, which takes a 'true' or 'false' value on substituting the objects belonging to a certain object domain is called an n -place predicate. Most often, the predicate reflects properties of the objects and relations between them. For instance, let predicate $P(X)$ reflect the property of the substances to have a strong IR absorption band near 1700 cm^{-1} and let $X_1 = \{\text{acetone}\}$ and $X_2 = \{\text{propylene}\}$. Then, obviously, $P(X_1) = 1$ ('true') and $P(X_2) = 0$ ('false'). If $M(X_i)$ is a set, then a fuzzy subset F of the set $M(X_i)$ is defined as a set of ordered pairs $\{X_i, \mu_A(X_i)\}$, where $\mu_A(X_i)$ is a characteristic membership function, which varies from 0 to 1 and indicates to which degree the element X_i is a member of the subset F . For instance, the membership function of the proposition 'there is a band near 1710 cm^{-1} in the IR spectrum' will be written as follows: $\mu_A(1710\text{ cm}^{-1}) = 1$. In this case it is assumed that there exist certain bounds, *e.g.*, 1700 and 1720 cm^{-1} , and beyond them the function $\mu_A(X_i)$ is zero.

If predicate variables are assigned the meaning of the elements of fuzzy sets, then we get fuzzy predicates. Each n -place predicate symbol is associated with mapping M^n into a set of the values of a characteristic membership function, which in the case of ALC is called a truth function μ_p , $0 \leq \mu_p \leq 1$.

A system of predicates describing the IR spectrum–structure interrelation was developed to describe the spectrochemical knowledge. In particular, predicates characterising the IR spectrum ('there is a band of vibrations of the type ζ of a structural group g in the spectrum; the band is characterised by frequency X_i , intensity Y_i and halfwidth Z_i) and molecular structure ('the molecule contains a fragment R_1 ', 'the molecule contains a fragment R_1 separated by n_1 bonds from m_1 fragments R_2 ', 'the molecule contains a ring of size j , which includes a fragment R_3 ', *etc.*) were introduced. Specific predicates characterise the state of aggregation of the substance, solvent type, *etc.* To describe changes in the data, second-order predicates are introduced, and using them it is possible to indicate the direction of changes in the variables which appeared in the first-order predicates (*e.g.*, 'increases', 'decreases', 'disappears', 'becomes split into d components', *etc.*).

Using such a system of predicates and conventional logical operations, it is possible to formalise declarative knowledge to a great extent. For instance:

(1) 'stretching vibrations ν_s of compounds with one double C=C bond and alkyl substituents (Alk) absorb in the region $1640\text{--}1680\text{ cm}^{-1}$ '

$\text{STRUCT}(\text{C}=\text{C}, \text{Alk}) \rightarrow \text{SPECTR}(\nu_s, \text{C}=\text{C}, 1640, 1680);$

(2) 'conjugation of double bonds of two alkyl-substituted groups results in splitting of the band of stretching vibrations ν_s into two bands'

$\text{Q}_1[\text{STRUCT}, \text{C}=\text{C}, \text{Alk}(\text{C}=\text{C})] \rightarrow$
 $\rightarrow \text{Q}_2[\text{SPECTR}, \nu_s, \text{C}=\text{C}, X_1(\text{SPL}, 2)].$

The logical formula G and the predicate symbol P are associated with a set of outside values of the truth function μ_e , $0 \leq \mu_e \leq 1$. The external value of the function μ_e reflects the knowledge quantification ('often', 'sometimes', 'in some instances', *etc.*). For instance, the statement 'stretching vibrations of the C=C bond are often observed in the region $1640\text{--}1660\text{ cm}^{-1}$ ' is represented by elementary formula $[0.8]\text{SPECTR}(\nu_s, \text{C}=\text{C}, 1640, 1660\{10\})$, where $[0.8]$ is the external value of the truth function, $\{10\}$ is the segment length (in cm^{-1}) on both sides of the bounds of the region $1640\text{--}1660\text{ cm}^{-1}$, on which the trapezoidal membership function decreases to zero. To determine the value of the truth function μ_i appeared in the elementary formula, it is necessary to multiply the external value of μ_e by those of the membership functions of fuzzy constants and variables in this formula. In this case, taking into account the properties of a triangle, we get $\mu(X) = 0.5$ at $X = 1665\text{ cm}^{-1}$; at $\mu_e = 0.8$, the μ_i value will be equal to $0.5 \times 0.8 = 0.4$.

Spectrochemical knowledge can be divided into facts (expressions containing constants) and regularities (expressions containing at least one logical variable). It is convenient to operate on structured knowledge. To structure the knowledge, a class is specified of general regularities that are valid for most organic molecules (*e.g.*, 'there are no small rings containing a triple bond in organic chemistry'). Principal functional groups possessing characteristic spectral features (C=C, C $\equiv$ C, C=O, C $\equiv$ N, OH, *etc.*) are accepted as structuring units of other knowledge. The molecular fragment is described by its core (C=C, C $\equiv$ C, *etc.*) to which surrounding atoms are successively added, thus respectively forming first-, second-, third-level fragments, *etc.* The knowledge hierarchy thus formed is a tree graph called a declarative knowledge network. The description of a network node contains the fragment structure, possible types of its vibrations, regularities and facts for each type of vibrations and those characteristic of the given fragment.

If declarative knowledge is considered as a system of axioms of the theory used for solving an applied problem, the SGA problem is represented in terms of statements (theorems) that should be proved or rejected. It has been shown⁴³ that the classical resolution method adapted to the theory of fuzzy predicates can be used for automated proof of the theorems (automated SGA).

The formalism suggested makes it possible to solve SGA problems as well as those of structural interpretation of IR spectra. The results of interpretation can be used for self-learning of declarative knowledge, in the course of which the facts and regularities are tested, values of characteristic membership functions are changed and new facts and regularities are revealed.

The approach described was realised as a research prototype of an ES written in the Prolog algorithmic language.⁴⁴ The system reveals consistent fragment (network node) sets that explain the spectrum. Simultaneously, interpretation of the IR spectrum is performed: each frequency is assigned to a certain type of vibrations of corresponding fragments with an indication of the value of the truth function μ_p for the assignment given.

Predicate logic and Prolog algorithmic language were also used for structural interpretation of IR spectra in the EXPEC system.^{45–47} The knowledge base of the system includes a rule interpretation generator. As in the preceding system,⁴⁴ fragments included in the knowledge base are hierarchically structured in the form of a network of declarative knowledge. When interpreting the spectrum of unknown compound, the network is scanned to find the rule for each fragment, according to which the relation between the fragment and spectrum is analysed. Each result obtained is associated with its probability. Explanatory facilities make it possible to trace the reasoning process of the program.

The knowledge base of the system is formed on the basis of SSC known from the literature and is supplemented using the rule interpretation generator,⁴⁵ as well as due to input of expert's knowledge. To perform automated rule generation, a library of IR spectra of organic compounds belonging to the CHO class is used. The program generates a set of potential rules, selects the least correlated ones and minimises their number.

The presence of the rule generator⁴⁵ is an advantage of the EXPEC system. Automated rule generation involves four steps: (1) selection of structural fragments; (2) database retrieval to find all structures containing a S_i fragment; (3) search for the intervals of characteristic features for S_i and (4) selection of intervals appropriate for using interpretation rules. The problem of the knowledge base formation is of fundamental importance for creating an efficiently operating ES, therefore the above-mentioned approach to automatization of this process appears to be rather promising.

The interpreter (inference machine) selects only those network fragments for which the presence of groups in the network nodes was validated. For instance, the rules concerning detection of phenol compounds can be used only after the presence of benzene ring and hydroxy group was confirmed. For each substructure, the probability of its presence is calculated using a trapezoidal probability distribution function for a given interval (*e.g.*, this shape was chosen for the band membership function of the absorption region^{19,40}). Selected fragments are arranged in order of decreasing the probability of their presence.

The investigators from different research groups suggest different rules for selecting possible fragment sets (see, *e.g.*, Ref. 48). It seems that these studies will progress and make it possible to come right up to creating ES for the molecular spectral analysis that interact with a chemist in terms of a natural language with professional restrictions. However, on this way the investigators will inevitably face many difficulties. Overcoming them will require joint efforts of the experts who carries out interdisciplinary research such as, *e.g.*, mathematical linguistics, mathematical logic, knowledge technology, *etc.*

3. Application of artificial neural networks

Beginning in the early 1990s, the attention of chemists was drawn to the possibilities of new promising mathematical tools of computer chemistry, *viz.*, artificial neural networks (ANN). Particularly rapid is the increase in the number of studies on the application of ANN to interpretation and classification of spectral data.

A neural network is a simplified model of the human brain, consisting of several layers of neurons that send signals to other neurons depending on the input signals received. Such networks function according to the 'black box' type and possess a common ability to construct empirical models of the systems for which theoretical dependences between the input and output are too complicated or even unknown. Models are obtained as a result of the network training. In the course of training, the network is represented in the form of input–output pairs related by simulated transformation. A network trained on these examples is capable of predicting the output signals from the input signals not 'seen' at that instant. The training procedure may be time-consuming (tens of hours); however, a network once trained generates the answer or prediction almost instantaneously. For instance, a network can be trained to generate structural information (output) retrieved from a spectrum (input) or to predict a spectrum (output) from structural information (input). By applying this procedure to the spectra, it is possible to establish which functional groups can be present and absent in the specimen and to complement these data with reliability estimates of the results obtained.

Let us consider general principles of designing neural networks^{24,49} in more detail.

Strictly speaking, ANN is a computational structure consisting of a number of interconnected elementary units called nodes or neurons. In a simplified form, a neuron functions as follows.

The 'signal' values s_i ($i = 1 \rightarrow m$) at the neuron input (we will call them inputs) are multiplied by weighting factors w_i and summed up to give the function Net:

$$\text{Net} = s_1w_1 + s_2w_2 + \dots + s_mw_m.$$

Then, the Net value is transformed into the output signal of a neuron using a nonlinear transfer function. The sigmoid function

$$\text{sf} = \frac{1}{1 + \exp(-s_iw_i)}$$

is most often used as a transfer function.

This signal is then used as the input signal for other neurons and the organisation of the connections between neurons defines the network architecture. A large number of neurons and interrelations between them makes the network behaviour more complex. The network can be modified by 'adjustment' of its parameters, among which weighting factors are the main ones. Adjusting the network parameters in order to obtain a desired behaviour is called the network training. This process is carried out iteratively using a learning algorithm on a set of examples. At each iteration, the network outputs are compared with the reference values (examples) and, if they appear to be different, the program performs correction of weighting factors. The network is trained until coincidence of outputs with references.

In the first studies on structural interpretation of IR and NMR spectra, multilayer ANN trained using the back-propagation of errors (BPE) algorithm²⁴ were most often used. In these networks, each neuron is connected to all neurons in the preceding and succeeding layers. The first (input) layer receives the input data and distributes them over the succeeding layer. The last (output) layer, or decision layer, is responsible for outputs of the entire network. Other layers, if any, are called hidden layers (Fig. 1). Information is propagated from the input layer through hidden layer(s) to the output layer. For instance, an IR spectrum encoded as the intensity values taken at points uniformly distributed along the abscissa axis is used as the input vector. The output vector coordinates are certain numerical values (often, zeros and unities) indicating the presence or absence of particular structural features. The number of points used for encoding the spectrum defines the size (the number of nodes) of the input layer while the number of structural features (fragments) introduced determines the size of the output layer. There is no generally accepted rule for setting the number of nodes in hidden layers: it has to be large enough to provide correct data processing; however, increasing the number of nodes increases both the learning time and risk of the network 'over-training'. The latter consists in decreasing the network performance after a certain

Figure 1. A scheme of neural network.

number of iterations (they are called cycles or epochs) in the course of training.

After random initialisation of the initial values of weighting factors w_i , the network training is performed on a set of spectra of the compounds containing fragments associated with desired outputs. (This set is called the training set.) There are numerous variants of this algorithm; however, all of them are based on the same principle, a steepest-descent minimisation of the total error, calculated as the sum of differences (or the squared differences) between the network outputs and desired results.

To determine the network performance (efficiency), a set of examples (the test set) is used. This set should differ from the training set in order to measure the network capacity for generalisation instead of learning.

The size and composition of the training set strongly affects the learning efficiency. For instance, increasing the number of examples increases the overall performance of the network, but only up to a certain point.⁵⁰ The effect of the composition of the training set appears to be much more complicated. The effect of presents/absents balance for structural features in the molecules, *i.e.*, the proportion of compounds presenting a structural feature to those not presenting it in the training set has been studied.^{49, 51, 52} In particular, it has been found⁴⁹ that increase in the proportion of presents in the training set increases the probability of recognising these fragments in the compound analysed to the detriment of the absents. At the same time, it was found that there is a certain limit of presence under which the network is unable to perform correct classification. The setting of a well-balanced and diversified training set can be difficult, especially if the network to be trained has many outputs.

The number of network outputs is of great significance: according to the reported data,^{50, 53} mono-output networks perform better than the networks with many outputs; moreover, large networks are more difficult to optimise than small ones (networks with smaller number of outputs). Since the best result for each output may occur at a different training time, the ANN training is stopped at a stage where the averaged (but not for each output) network performance will be optimum. The use of many mono-output networks for the determination of a large number of structural features is much more time-consuming than the use of a single network. Therefore, advantages and drawbacks of using a single multi-output network are opposite to those of using several mono-output networks.

A hierarchical system for spectrochemical studies, which should retain the best of both approaches, was proposed.⁵⁴ In such a system, a multi-output top-level network performs a rough classification of the spectra. Depending on the structural feature considered, the hierarchy is extended to deeper levels where further refinement is performed.

The top-level network outputs activate the first-level networks and so forth through the whole hierarchy. The design of a hierarchical system of neural networks can be considered as a compromise between one multi-output network and many mono-output networks. Its main characteristics are also intermediate. It was found that it is easier to balance the components of the training set for each network of the hierarchy than for a single large network (in some sense, as simple as for a mono-output network). In addition, optimisation of the learning time is easier for a smaller number of outputs, and the modular conception makes it possible to modify the system without the entire reconstruction.

A hierarchical system gives information on structural features on different levels: from general characteristics ('a compound contains a CO group') to more specific ones ('a compound contains an acidic group'), the number of networks to be activated in each particular case remaining small. For instance, there is no need to find out whether a compound is a primary or tertiary alcohol if the OH group has not been recognised by the top-level network. However, mention has been made⁴⁹ that the adjustment of a hierarchical network is a complex task and

requires *a priori* knowledge and consideration of the dependence of sub-level networks on upper-level network performance.

Let us consider the results of studying a hierarchical system as an analytical tool for determination of the fragments using IR spectra.⁴⁹ The experiments were carried out using a set of 8620 compounds and their IR spectra taken from the Sadtler Bio-Rad library. Calculations were performed on an IBM RS6000 workstation. The system was trained to recognise 33 structural groups whose hierarchy is shown in Fig. 2. As can be seen, recognition of carbonyl group was carried out using two specially designed networks, one for wide-spread structural features (carboxyl, ketone, ester and amide) and another for rare structural features (acid chloride, anhydride and aldehyde).

The following network parameters were used.

Input vector. The IR spectrum in the region 500–3596 cm^{-1} was represented as a set of 259 points separated by increments of 12 cm^{-1} . The weighted mean of absorbance in the vicinity of each point was scaled to a 0 to 1 range and used as input.

Hidden nodes. Networks contained only one hidden layer, and the number of hidden nodes was set to 30 for all networks.

Transfer function. The classical sigmoid function was used.

Structure encoding: 0 and 1 were respectively used to encode the absence and presence of a structural feature.

Learning algorithm. All networks were trained using the BPE algorithm with a learning rate $\alpha = 0.05$ and a momentum $\mu = 0.90$ (Ref. 24).

Decision making. Since the network outputs were real values from the 0–1 range, two thresholds were necessary for decision about the presence or absence of each structural feature f in the molecule: accept level (presence threshold) AL_f and reject level (absence threshold) RL_f of a structural feature. If the output number is between RL_f and AL_f , the answer is considered ambiguous and the fragment is reported as 'not classified'. These decision thresholds were optimised individually for each network.

Training and test sets elaboration. The sets of examples required to train 10 networks constituting a hierarchical system were built by random selection from initial population with the constraints to reach a prescribed proportion of compounds containing preset structural features. For the top-level network,

Figure 2. Hierarchical organisation of networks. The numbers of activated networks are given in parentheses.

the whole collection of spectra was used. Sub-level networks were trained using specially designed protocols.

As was mentioned above, in hierarchical structures the network dedicated to recognition of the fragments belonging to a specific class is activated only if it recognised the example as a member of this class. For a structural feature, two types of misclassification are possible: (1) the fragment was identified in the compound in which it does not occur; this case is called false present (AdP); and (2) the fragment was not identified in the compound containing it; this case is called false absent (PdA). False absents are not propagated through the hierarchy, since the structural feature is considered as absent. However, false presents raise a new problem: sub-level networks must refine classification of the fragment which actually is not contained in the compound.

Special experiments showed that the hierarchical system is robust and bears the change of networks without losing the global capability of the hierarchy. The best training was found to occur for the training sets of 1000 examples and the number of cycles was between 5 and 20. The best results were obtained for C=O and OH groups that are easily recognised in the IR spectra.

The following indices were suggested for measuring the performance of the entire hierarchical system:⁴⁹

Ptf — a general characteristic of the presence of a structural feature (the total present found); it is defined as the ratio of the number of compounds in which the presence of the fragment was correctly identified to the total number of compounds containing the given structural feature;

Atf — the same as above, as applied to the absent structural features (the total absent found);

Pte — the total error of decision of the presence of the structural feature (the total present error), which is defined as the ratio of the number of compounds containing the feature but identified as absent to the total number of the compounds containing the given structural feature;

Ate — the total error of decision of the absence of a structural feature (the total absent error), which is defined analogously to the preceding index.

The results of testing the system using the criteria introduced are shown in Table 1. Comparison with the reported data⁵⁵ shows that, on the whole, the hierarchical system performs better than multi-output network; however, the results qualitatively rank below those obtained using well optimised mono-output networks.

Currently, a few studies dedicated to application of ANN to the selection of molecular fragments has been reported; however, investigations in this area are gathering force. Thus, analyses of IR spectra using ANN were reported.^{52–61} An ANN was used to identify amino acid residues in proteins from their 'fingerprints' in 2D NMR spectra.⁶² Adjustment of the networks in the case of joint application of different spectral methods to elucidation of structural fragments was reported.^{51,63} This investigation line seems to be of particular interest; therefore, let us consider the results reported in the last two articles in detail.

A study⁵¹ was carried out in which IR and ¹³C NMR spectra and molecular formulae of organic substances served as input signals for a neural network preliminarily trained to recognise molecular fragments. The ANN containing 512 inputs, 85 outputs and ~ 50 neurons in the hidden layer was used. The training set comprised 1560 compounds for which IR and ¹³C NMR spectra were known. A total of 128, 294 and 90 inputs were respectively specified for IR spectra, NMR spectra and molecular formulae. Such a distribution was chosen taking into account the estimate of the amount of information contained in each data type. IR spectra were encoded in the same way as in the study by Cleva *et al.*⁴⁹ ¹³C NMR spectra were encoded by present/absent indicators of signals at intervals of 2 ppm. The indicators for signals of different multiplicity were stored in prescribed positions of the input vector (*e.g.*, encoding the chemical shifts of quartets in the spectral range 0–64 ppm was performed using 32 intervals to which positions 128–159 of the input vector corresponded). The molecular

formula was encoded by the numbers of present types of atoms, the degree of unsaturation and molecular weight. Structural formulae were encoded by 0 or 1 depending on the presence or absence in the molecule of each of 85 fixed structural elements including functional groups ($-\text{O}-\text{C}=\text{O}$, $\text{C}\equiv\text{N}$, $\text{H}_2\text{C}=\text{CH}$, *etc.*)

and chemical classes (steroids, terpenes, pyridines, *etc.*). Optimisation of parameters and the network training using the BPE procedure were carried out on HP 9000 RISC and other workstations. Performance of the system was studied for different combinations of input data.

It was established that performance of the system in the case of using NMR spectra only is higher than that reached using IR spectra only; the inclusion of molecular formula increases performance of the system for any combination of IR and NMR spectral data; simultaneous use of both types of spectra leads to a substantial increase in performance of the system (*i.e.*, the number of reliably identified groups increases appreciably).

These conclusions were not unexpected; however, the importance of this study⁵¹ is that the procedure for identification of fragments by joint use of IR and ¹³C NMR spectra, based on ANN application was first proposed. This approach can be realised with ease in a fragment selection block of an ES.

Application of ANN to joint interpretation of IR and mass spectra (MS) of gases has been described.⁶³ The network was trained to identify 26 functional groups. The proportion of correctly identified present groups was 86.4% when using com-

bined data; this index was respectively 88.4% and 78.2% when IR spectroscopy and mass spectrometry data were used separately. Among 26 groups, only for 8 did the use of MS lead to improving the recognition quality; the results of determination for the C—Cl bond have been considerably improved. This confirms the known fact that IR spectroscopy is more appropriate for identification of functional groups than mass spectrometry. Absent functional groups were predicted to an accuracy of 95.5% using combined data and IR spectroscopy data only and to an accuracy of 87% using mass spectrometry data only. The results of this study⁶³ show that principles of combining the data obtained by different spectral methods, as applied to ANN, require special investigations to find optimum variants.

It should be noted that, as a rule, different groups of researchers use different indices of network performance, therefore comparison of the results obtained in their studies is difficult. In this connection the problem of the selection of generally accepted indices and standard test sets, which would make it possible to easily compare the efficiency of different classification methods, appears to be topical.

Despite improved capability of ANN to identify fragments, successful application of the networks is to a great extent dependent on the user's skill in adjusting the network parameters (decision thresholds, composition of the training set, *etc.*) to meet specific requirements when solving any problem. Currently, there is no information on the use of ANN in any actual ES dedicated to identification of the molecular structure and the number of structural features that can be recognised using an ANN is unclear (for comparison, it should be noted that spectral libraries of known ES contain hundreds of fragments). Therefore an estimate of actual possibilities of this approach is still ahead. However, it can be stated with certainty that application of ANN to the determination of individual classes of chemical compounds is rather efficient.

4. Methods for recognition of large fragments

To solve the problem of identification of large molecules, an ES must have adequate analytical tools for determination of large fragments. Attempts to create libraries containing large fragments and ranges of variations of their characteristic spectral features are of no promise because of imminent combinatorial explosion and the virtual impossibility to predict the ranges. An actual way of solving the problem is using modern databases containing structural formulae and spectra of substances. The basis of the method is a hypothesis that similar spectra (subspectra) correspond to similar structures (substructures).

Two approaches to identification of large fragments using IR, NMR and mass spectra databases have been described. The algorithm suggested to this end in the first approach is reduced to three main operations:^{64–72} (1) search for structures whose spectra are similar to a given experimental spectrum and ordering the former according to decrease in similarity; (2) selection of a number of structures in the beginning of the list that, according to the basic hypothesis, have the highest resemblance to the structure of the analysed compound; and (3) selection (among these structures) of largest common fragments that can be plausible constituents of the structure of the unknown compound. The probability of correct identification of the fragment increases if the database retrieval system selects the data using several types of spectra and the selected fragments are tested on the basis of coincidence of the predicted subspectra (the latter can be most easily done using ¹³C NMR spectra).

Realisation of the above algorithm requires reliable quantitative criteria for structural and spectral similarity, as well as methods for revealing the largest common subgraph in a set of chemical graphs. Studies on the development of such methods gave rise to an independent investigation line in graph theory and numerous studies on the subject have been reported.

The other method for recognising large fragments found a wide application in practice due to the appearance of large

¹³C NMR spectra databases. In these types of databases the structures are described by 'spherical' code⁷³ while the signals in the spectra are assigned to corresponding carbon atoms. This made it possible (see, *e.g.*, Refs 30, 31, 74) to develop algorithms which can automatically create the subspectrum–substructure correlation libraries used for solving the problem raised. First, the program compares all subspectra of library fragments with the experimental NMR spectrum of the analysed substance. In this case it is necessary that the signal intensity (*i.e.*, the number of carbon atoms) be also indicated in addition to the chemical shifts and signal multiplicities. As a result, only those substructures (fragments) are selected to which subspectra coinciding (within the limits of prescribed deviations) with the query subspectra correspond. Further, the most probable fragments are selected by a detailed analysis of spectral information and ranked in descending order with respect to the number of carbon atoms and skeletal atoms. Thus, the largest fragments appear in the beginning of the list (the use of the described procedure in ES is considered below).

III. Generation of structural formulae of isomers

No more than two dozen of publications concerning the search for ways of increasing the software performance and methods of more efficient use of structural constraints have appeared after the first generators of isomers^{3, 75–78} were developed. This relatively small number indicates stubbornness of the problem rather than a loss of its actuality or interest. The numbers of possible structural formulae and the CPU time grow exponentially as the number of skeletal atoms and fragments involved in the generation process [they are called discrete units of structure (DUS)]⁷ increase. Therefore, all the efforts were aimed at using structural constraints even in the course of rather than after structure generation and at developing new algorithms that make possible improving the efficiency of generation.

This interesting and ambitious problem drew the attention of mathematicians, specialists in the field of graph theory and combinatorial analysis, which resulted in the development of new approaches and appearance of efficient software (COCOA,⁷⁹ MOLGEN,^{80–82} and GENM^{83–86} programs). Parallel to the search for efficient generation algorithms, computer performance has increased swiftly. On the whole, this has led to appreciable increase in dimensionality of the problems which can be solved using modern generators of isomers. Currently, the number of DUS used in the structure generation that takes a 'reasonable' time lies in the range from 10 to 16 depending on the valence of the atoms considered as DUS, the number of free bonds in the fragments, the unsaturation degree of the molecule and several other factors (*cf.* with 7–8 DUS in the 1970s). For instance, it took 3420 s to generate 4347 isomers of composition C₁₅H₃₂ using (the first in the USSR) program generator written by V V Raznikov in codes of an M-20 computer,⁷⁵ whereas a modern GENM program installed on a personal computer equipped with a Pentium CPU solves this problem in a matter of seconds. One more example can be given: generation of 217 isomers of composition C₆H₆ using the MAISS program written in Fortran algorithmic language and installed on a Minsk-32 computer took ~30 min;⁷⁷ the GENM program performs this task for a fraction of a second, which means that the actual rate of structure generation has increased by several orders of magnitude. However, since recognition of the structures of large molecules is of prime interest for practice, the generation stage remains a bottleneck for all ES despite the advances achieved.

Basic requirements for the structure generators have been formulated and realised as long ago as 1970s. The results of these studies were generalised.^{7, 8} The most important requirement is that, irrespective of generation algorithm used, the software suitable for practical use must contain flexible tools for imposing structural constraints among which the following are typical.

1. Fragments — DUS identified at the SGA stage. It is usually assumed that they have no overlapping atoms and the number of

free valence bonds of terminal atoms in such fragments is fixed. Therefore such fragments are also called macroatoms and they participate in structure generation along with free atoms. The DUS sets are designed of atoms and macroatoms and the total number of DUS in the set determines the dimensionality of the problem. Some programs, *e.g.*, GENOA⁸⁷ admit partial overlap of the macroatoms; however, this makes the algorithm more complicated and increases the generation time.

2. Obligatory and forbidden fragments (GOODLIST and BADLIST, respectively). These are structural constraints imposed by a chemist and each structure must meet these requirements. This type of constraint is imposed on the basis of *a priori* knowledge of the compound under study (the origin of the specimen, data of non-spectral experiments, *etc.*). These fragments have a peculiarity consisting in the possibility for their structures to overlap and superimpose on the DUS structure.

3. Constraints associated with the ring size and bond multiplicities make it possible to formulate general requirements for generated structures with consideration of specificity of the DUS set and *a priori* information (the presence of multiple bonds in macroatoms, rings, the inclusion of the unsaturation degree of the molecule, *etc.*).

4. Fragments which are unlikely in organic chemistry. These include small rings containing triple bonds, structures that contradict the Bredt rule, certain strained fused structures with small rings, fragments of the $-O-O-O-$ type, *etc.*

Since 'construction of generators' has become an individual division of mathematical chemistry and combinatorial mathematics, we will restrict ourselves to mentioning some new programs that are of prime interest for the ES creation. Detailed information concerning modern structure generation algorithms can be found in the theses.^{88,89}

The CONGEN generator developed in 1970s⁹⁰ is based on the algorithm generation by building up a chemical graph from its centre. As a result of improving this algorithm, the MOLGRAPH⁸⁰ and MOLGEN⁸¹⁻⁸³ programs have been developed. The MOLGEN program generates structures using nonoverlapping fragments. It has a high performance and is capable of generating stereoisomers. Currently, this generator has received wide acceptance in Europe.

A GENM program^{84-86,88} for generation of structural isomers was developed in the Russian Federation. The parameters of the program are at least as good as and in some instances superior to those of the MOLGEN program. The algorithm used has a number of unique features that make it possible to rule out 'hopeless' branches of the solution in the course of generation in accordance with the constraints imposed. Operating experience of the GENM generator at the Institute of Organic Chemistry (the Siberian Branch of the Russian Academy of Sciences, Novosibirsk, Russian Federation) and in the RASTR³⁶ and X-PERT²⁹ systems has shown its high reliability and fast operation.

The SMOG program^{89,91} allows a chemist to analyse different structural hypotheses in the course of investigations of chemical reactions. This program can generate structures containing atoms in unusual oxidation states or carrying formal charges, generate the molecules using both non-overlapping and overlapping fragments and recognise different resonance forms of the same aromatic molecule among the results of generation. The SMOG program can serve as a basis for the development of software tools designed to operate on a special-purpose workstation used in the chemical laboratory; however, the program operates not so fast to be used as a 'conveyer-type' structure generator in ES.

In some instances where the fragments are elucidated independently by using different methods of investigation (IR, NMR, MS, *etc.*) it may appear that the structures of particular fragments have common atomic groups (*e.g.*, $-\text{CH}=\text{CH}-\text{C}=\text{O}$ and $\text{>C}=\text{C}-\text{CH}_3$). In this connection the GENOA program⁸⁷

capable of generating the structures using overlapping fragments was developed to extend the potentialities of the CONGEN program. At the same time, structure generation using overlapping atoms belonging to different fragments is the major condition for operation of a number of recently developed programs.^{30,31,74} This type of algorithm was developed to provide structure generation using a set of fragments identified by means of ¹³C NMR spectra (see Section II.4). The program tries to match the atoms belonging to different fragments and predict the subspectrum of a new, enlarged fragment. If the predicted subspectrum does not contradict the experimental spectrum within the limits of prescribed admissible deviation, an attempt is made to add one more fragment, *etc.*

Thus, structure generation is a successive assembly accompanied by verification of the correctness of all possible combinations of the fragments. Structure generation using this approach does not require knowledge of an empirical formula and even the molecular weight. However, it should be compensated for the absence of empirical formula by ascribing a certain number of carbon atoms to each signal in the experimental NMR spectrum (this cannot be done in all cases, especially for symmetric molecules). This algorithm implicitly uses the $\text{C}_n\text{H}_{(m-k)}$ part of the empirical formula, where k is the number of hydrogen atoms bonded to hetero-atoms. Information on the latter is retrieved in the course of structure generation. However, if the set of selected fragments is not exhaustive with respect to the structure of the entire molecule, the generation fails. Application of this type of generator is considered in detail below.

Mention may be made of a number of studies (*e.g.*, Refs 92-97) in which different principles of structure generation were evaluated. However, their actual efficiency and performance can be assessed only by solving the test problems on clone-type computers, which seems to be difficult.

In some instances, structure recognition is not restricted to determination of the structural formula of the compound, but also involves the establishment of the spatial model of the molecule. To this end, algorithms and programs for generation of stereoisomers,^{83,98,99} and building of spatial models of the molecules⁹⁹⁻¹⁰³ were developed. They use structural formulae of organic compounds as the input information. Building spatial structures can appear to be necessary for prediction of the spectra of candidate structures, thus becoming an important stage of elucidation of the true structural formula of the compound analysed. It should be noted that one of the most efficient 3D-generators, CORINA,¹⁰¹ can be accessed *via* the Internet (the webpage URL is <http://www2.ccc.uni-erlangen.de/services/3d.html>).

IV. Prediction of spectra of probable structures

Prediction of the spectra of isomers to reveal plausible structures is the final stage of the ES operation. In practice, depending on how hard are structural constraints imposed, the answer file may contain tens, hundreds or even thousands of structural formulae that cannot be distinguished taking into account the ranges of changes in characteristic spectral features. This requires prediction of complete molecular spectra. Time-consuming quantum-chemical calculations are inapplicable in this case, so only fast approximate spectra prediction using various empirical correlations, rules and parameters, as well as spectral databases can be used. Numerous studies concerning this problem have been reported. Because of its prime importance for the methodology of the development of ES, let us consider the approaches to prediction of IR, ¹H and ¹³C NMR spectra.

1. Simulation of ¹³C NMR spectra

¹³C NMR spectroscopy is one of the most powerful methods for elucidation of the structure of organic molecules and testing structural hypotheses. Among all types of molecular spectra, it is the ¹³C NMR spectra that can be simulated most easily since in the case of off-resonance they consist of singlets, doublets, triplets and

quartets ($^1\text{H}-^{13}\text{C}$ spin-spin coupling through one bond) and each anisochronal (magnetically equivalent) carbon atom is ascribed a signal with specific chemical shift and multiplicity. Usually, 2D DEPT NMR experiments make possible reliable determination of signal multiplicities even in the case of strong overlap. Prediction of ^{13}C NMR spectra can be performed with different degree of detailisation.

a. Prediction of the number of signals with different multiplicity

Shelley and Munk¹⁰⁴ were the first who suggested use of prediction of the number of signals with different multiplicity for selecting candidate structures. The method is based on the topological analysis of a multigraph on which the structural formula of the molecule is mapped. All skeletal atoms are divided into groups of topologically equivalent atoms. Where all carbon atoms in the structure appear to be unique, the predicted number of signals in the spectrum is equal to the number of carbon atoms in the molecule; in this case the number of different types of multiplets is predicted automatically. If the structure contains several groups of equivalent carbon atoms, the expected number of signals in the spectrum is equal to the number of groups. The authors¹⁰⁴ analysed how stereochemical factors affect the correctness of prediction and suggested a number of rules which make it possible to take into account splitting of the signals of dimethyl groups located near a chiral centre. A simple comparison of predicted and experimental numbers of different types of multiplets allows one to reduce appreciably the number of candidates. However, it should be noted that accidental coincidence of inequivalent signals can occur or unexpected splittings can appear in the spectra. To improve this approach, it was suggested²⁹ that the number of signals with different multiplicity in characteristic spectral regions be predicted, which increased the resolving ability of the method used.

b. Prediction of chemical shifts

Simulation of ^{13}C NMR spectra is based on the prediction of chemical shifts of carbon atoms in the structure under consideration. The model spectrum obtained is compared with the experimental one and the structural hypothesis is accepted or rejected on the basis of calculated mean or standard deviations. There are two most widely used procedures for predicting NMR spectra, based on construction of empirical models¹⁰⁵⁻¹¹⁰ and on application of spectral databases.¹¹¹⁻¹¹⁵ Recently developed software¹¹⁶⁻¹¹⁸ uses both approaches. Attempts to simulate ^{13}C NMR spectra using ANN are also documented.¹¹⁹⁻¹²⁸

Grant and Paul¹²⁹ suggested the first additive linear model for calculating the chemical shifts of carbon atoms in aliphatic hydrocarbons using increments with consideration of the effects of environment up to δ -atoms. Later, linear models were constructed for alkanes, cyclohexanes, alcohols, amines, chlorine-containing compounds, *etc.* The formulae derived and tables of increments were collected in a number of monographs (see, *e.g.*, Refs 130, 131). The approach described provides a rather high quality of prediction, which stimulated the development of software for analysing the candidate structural formula, selecting a corresponding additive model for each carbon atom and calculating the chemical shift. This type of software is of limited utility since chemical shifts can be predicted only for sp^3 -hybridised carbon atoms and the increment values cannot be modified.

Fürst and Pretsch¹¹⁰ removed these restrictions. Using large databases containing structural information and assigned ^{13}C NMR spectra, the authors of this study succeeded in constructing linear models which can be applied to many classes of chemical compounds. The models contain configuration- and conformation-dependent parameters and take into consideration the configuration of C=C bonds and the presence of axial and equatorial substituents in the cyclohexane ring. The software developed allows modification of parameters (reference values and increments) and input of new additive rules. A test of the

program on the set of 170 000 known chemical shifts showed that the rules derived are fulfilled for 97% of the cases. The standard deviation of predicted chemical shifts from experimental values was 5.5 ppm; our experience has shown that calculations of the spectrum of medium size molecules ($\text{C}_{12}-\text{C}_{16}$) on a modern personal computer take no more than a second. Obviously, this program can be used for filtration of the answer files created by an ES.

In another approach,¹¹¹⁻¹¹⁵ databases containing structural information and chemical shifts of carbon atoms are used. For all carbon atoms of each reference compound contained in the database, atom-centred fragments (ACF) with a prescribed number of concentric layers are generated. These fragments and the corresponding chemical shifts are stored as an ordered list. To predict the spectrum of a candidate structure, the program selects all possible ACF existing in the structure, performs a search for their analogues in the database and ascribes the chemical shifts taken from the reference fragments to carbon atoms. If an ACF was not found in the database, the program usually performs 'interpolation' using the available 'most similar' structures. The results obtained using this approach are in very good agreement with experimental ones when using a large database containing a diversified set of structures (see, *e.g.*, Ref. 73). Usually, the difference between predicted and experimental chemical shifts lies within the limits of 1 ppm, which means that the prediction accuracy is rather high.

However, despite its indubitable advantages, the approach described has some drawbacks. The absence of stereochemical information in the database (only structural formulae are available) may strongly affect the prediction quality. As has been shown,¹³² neglect of stereochemical effects may increase the difference between predicted and experimental chemical shifts by more than 10 ppm. Spectral properties of the reference fragments used for extrapolation may appear to be not the closest to those of the fragments of the hypothetical structure. Additionally, the fact that the effect of an atom equally distant from another atom can be different in different compounds is ignored at the encoding stage. Finally, prediction of a spectrum takes a rather long time (tens of seconds and even minutes) depending on complexity of the molecule.

A method is described,¹¹⁷ which is a combination of both above-mentioned approaches. At the first stage, the environments of carbon atom in the reference and target (verified) structures are represented as vectors and the Euclidean distance between these vectors is calculated. After repeated application of this procedure, a test set of carbon atoms whose chemical environment is similar to that of carbon atoms in the target molecule is generated. If the degree of similarity of the chemical environment of the target atom appears to be high, the chemical shift characteristic of its 'twin' in the reference structure is ascribed to this atom in the target structure. Otherwise a linear model is constructed using the test set. To this end, descriptors describing topological, geometric and electronic properties of the environment are introduced. Models are constructed using multiple linear regression (MLR), partial least squares (PLS) method^{28, 133} and principal component analysis.²⁸ The test of the combined approach on the set of 38 500 atoms has shown that the mean deviation is 1.69 ppm, whereas this value was 1.85 ppm in the case of straightforward database retrieval procedure.

It was mentioned above that ANN can be used not only for structural interpretation of the spectra, but also for prediction of spectral pattern corresponding to a particular structure. Attempts to apply ANN for prediction of chemical shifts in NMR spectra have been undertaken taking methyl-substituted cyclohexanes,¹²¹ mono-substituted benzenes,¹²² monosaccharides,¹²⁵ ribonucleosides,¹²⁶ sp^2 - and sp^3 -hybridised α -atoms in acyclic alkenes^{127, 128} *etc* as examples.

Artificial neural networks are trained to predict spectra of compounds belonging to prescribed classes on a training set which includes structures encoded analogously to the procedure

described in Section II.3. In the course of training, the network uses encoded reference structures as input information and the output signals are compared with the ^{13}C NMR spectra of these structures. Training is completed if the deviations of predicted spectra from the reference ones take appropriate values. Let us consider the results of computational experiments¹²⁸ as an example.

The authors trained a network to predict the chemical shifts of sp^3 -hybridised carbon atoms in the α -position with respect to the double bond in acyclic alkenes. Parallel with the training, a MLR-based model was developed. Testing both models showed that the standard deviation lay within the limits from 1.3 to 1.5 ppm for ANN and was 3 ppm for the MLR model, which means that ANN can predict the spectra more correctly than linear models.

Artificial neural networks can be applied only to predict the spectra of compounds belonging to those classes on which the network was trained, whereas the structures included in the answer (output) files created by the ES may contain diversified and unexpected atomic fragments. We believe that the optimum strategy of applying prediction of ^{13}C NMR spectra must include two steps, *viz.*, screening of structures (using fast approximate prediction methods, *e.g.*, linear models¹¹⁰) followed by more accurate (oriented to chemical classes) prediction applied to those structures for which the mean or standard deviation lies within the limits of error of the computational method used and, hence, further refinement is required.

2. Prediction of ^1H NMR spectra

As was mentioned above, relative simplicity of prediction of ^{13}C NMR spectra is associated with the fact that they consist of clearly defined multiplets. It is a much more complicated problem to predict ^1H NMR spectra, because they contain both first-order signals and higher-order multiplets. This is also the reason for difficulties encountered when trying to compare automatically experimental and predicted spectra. That is why information on the methods for prediction of ^1H NMR spectra is scarce.

The Proton Shift program developed¹³⁴ to predict the chemical shifts in ^1H NMR spectra on the basis of simple linear models¹³¹ automatically determines the substructures for which certain rules are applicable and considers the rest part of the molecule as a set of substituents at each of the substructures selected. To extend the area of application of the program, different extrapolation procedures were used, including division of large substructures and replacement of missing substituents by related substructures. The program takes into account *cis-trans*-isomerism of double bonds as well as axial and equatorial positions of substituents in six-membered rings. Linear models are based on a large set of increments and the total number of parameters that can be used in calculations approaches 3000. A test on the set of 583 chemical shifts showed that the mean deviation of predicted values from the measured ones was 0.06 ppm (the standard deviation was 0.18 ppm).

The authors of another study¹³⁵ on evaluation of the quality of the Proton Shift system using a large test set found that the standard deviation of chemical shifts was 0.3 ppm, which is closer to actual values. Using the ASSEMBLE structure generator,¹³⁶ 24 308 isomers with 111 605 different proton environments were generated. The chemical shifts were assessed in 89% of the cases, which can be considered satisfactory. The mean time taken to predict the chemical shifts for one structure on a Macintosh Quadra 650 computer was 0.30 s. When comparing the predicted and experimental spectra, the input of the latter is performed manually as a set of chemical shifts of CH , CH_2 and CH_3 groups. The program compares each experimental chemical shift with the closest value of corresponding chemical shift in the predicted spectrum. Then the standard deviations are calculated to rank the isomers generated. The procedure for comparing the chemical shifts in high-order spectra used in the study cited¹³⁵ remains unclear. Most likely, the approach described can be used only for

preliminary rough selection of structures in the answer file ranked after predicting the ^{13}C NMR spectra.

The ACD/HNMR Predictor program¹³⁷ is designed to calculate automatically the absorbance curve in the ^1H NMR spectrum from the structural formula of the molecule. The program has an internal database containing 180 000 experimental chemical shifts and 25 000 experimental spin-spin coupling constants (SSCC). The algorithm of quantification of spin-spin interactions in organic compounds used by the system is based on parameters found for more than 3000 structural fragments. Each δ_{H} value in the database is assigned to a particular structural fragment and each $J_{\text{H-H}}$ constant is assigned to a pair of interacting structural fragments taking into account the skeleton bonding them. The internal database of assigned δ_{H} and $J_{\text{H-H}}$ values is based on the results of analysis of 48 000 experimental ^1H NMR spectra. The δ_{H} and $J_{\text{H-H}}$ values for fragments not found in the database are calculated using special-purpose algorithms.

Calculations of the spectrum are performed for the basic frequency of the spectrometer, which is considered as a parameter. Calculated chemical shifts and constants are provided with 95% confidence intervals to indicate the reliability of the calculated values. The spectrum is calculated with consideration of second-order interactions and long-range SSCC, which allows simulation of the spectra of strongly coupled spin systems containing up to eight magnetically inequivalent nuclei (if there are magnetically equivalent nuclei, then a larger number of interacting spins can be taken into account). The program recognises *cis-trans*-isomers of alkenes and *syn-anti*-isomers of amides, oximes, hydrazones and nitrosamines.

After input of the query structure whose spectrum should be predicted, the program automatically 'splits' the molecule into a set of unique fragments that are compared with the fragments contained in the internal database. If any structural fragment coincides with a fragment from the database, its experimental δ_{H} values are included into the set of chemical shifts of the structure. If some fragments are not found in the database, the chemical shifts are extrapolated using the parameters of similar fragments.

After composing the final lists of chemical shifts and SSCC, the program composes and diagonalises the spin Hamiltonian matrix to calculate the number of lines, their positions and intensities and to assign the δ_{H} values to the hydrogen atoms of candidate structure. The program generates the spectrum plot (including digitising of positions of the lines and the integrated curve). Calculations of chemical shifts, spectral contour, integrated curve and digitising of maxima take from several seconds to tens of seconds CPU time on a computer with a Pentium type CPU.

The ACD/HNMR Predictor program was developed to interpret experimental spectra and test hypotheses. However, where preliminary ranking of the structures in the answer file created by the ES was already done on the basis of ^{13}C NMR spectra prediction, only 5–10 structures placed at the beginning of the final list require additional testing. Hence, comparison of the calculated spectra with the experimental ones to select the most probable structures can be done with ease by a chemist.

The author of this review has assured himself that the approach used in this program is highly efficient when analysing the answer (output) files for many problems solved using ES.³¹ In all the cases considered, it has been possible either to elucidate the true structure or to reduce drastically the number of alternative structures.

3. Prediction of IR spectra

The nature of IR spectra is such that, in principle, they can be used for selecting candidate structures. This is due to the fact that IR spectrum depends not only on which groups constitute a molecule, but also on their arrangement; in other words, the IR spectrum reflects properties of the entire molecule. Therefore, considerable

efforts of many investigators were aimed at developing methods for prediction of IR spectra of organic molecules.

Semiempirical calculations of an IR spectrum using a computer database of molecular parameters (the geometry, force constants, electrooptical parameters) can be considered as an efficient method for predicting the spectra. A corresponding database as well as computational techniques and software were developed under the supervision of L A Gribov.¹³⁸ The IR spectrum is calculated in the harmonic valence-force field approximation using a semiempirical computational procedure for calculating the band intensities.¹³⁹ The force constants and electrooptical parameters to be stored in the database are found from quantum-chemical calculations followed by solving mechanical and electrooptical inverse spectral problems. Calculated spectra are represented as spectral distributions of the absorption coefficient and can be immediately compared with the experimental curves. Calculations of the IR spectrum of a medium-size molecule take several minutes of CPU time; however, preparation of input data may take from 15 min to several hours depending on the problem complexity. Our experience shows that this approach can be successfully used not only to select preferable isomeric structures, but also to elucidate plausible stereoisomers and conformers.¹⁴⁰

However, the advantages of this method for prediction of IR spectra have their counterpart consisting of at least three drawbacks: the method is not so fast as those used for prediction of NMR spectra and, hence, it cannot be used for 'conveyor-type' calculations of dozens of structures (to say nothing of hundreds and thousands of them); prediction of the spectrum cannot be performed automatically without attention of a chemist; and the method can be applied to recognise small- and medium-size molecules only.

The first two drawbacks are obvious and their influence will gradually decrease with improving the algorithms and increasing the computer performance. The third one is of crucial importance, since it is due to the nature of molecular vibrations rather than to limitations of the software performance imposed by the size of molecules (*e.g.*, a program¹³⁸ makes it possible to operate with the structures containing over 100 atoms). In the general case, the larger the molecule, the more rich its IR spectrum. This statement has a consequence consisting in a nearly uniform distribution of absorption bands of rather large molecules over the 'fingerprint' region, which makes it senseless to compare the calculated spectra of candidate structures with experimental ones. Therefore, it is appropriate to use straightforward calculations of IR spectra in those cases where it is impossible to make unambiguous decision using fast prediction methods.

Prediction of IR spectra of three isomers with closely related structures, for which standard deviations of predicted ¹³C NMR spectra appeared to be within the limits of admissible errors of computational procedure, is illustrated in Fig. 3. The structures are ordered in accordance with decreasing similarity between the predicted and experimental NMR spectra. Comparison of calculated and experimental IR spectra shows that the calculated spectrum of the structure shown in Fig. 3*b* is closer to the experimental spectrum than the calculated spectra of the other structures (see the region from 10 to 14 μm). The same result was obtained using the ACD/HNMR software package¹³⁷ developed for prediction of ¹H NMR spectra. Thus, three methods for prediction of spectra indicate the priority of the first structure (2,4-dimethylanisole).

Impossibility of using semiempirical methods for fast automated prediction of IR spectra has stimulated the search for another approaches. Dubois *et al.*¹⁴² suggested the simplest procedure for simulating the IR absorbance curve. A database containing 700 substructures with fixed expected absorbance regions in the IR spectra was created within the framework of the DARC system. The expected intensities and band shapes are indicated for each interval. The prediction method includes the search for reference fragments in the candidate structure and

Figure 3. Experimental (a) and calculated (b–d) IR spectra of candidate structures.¹⁴¹

graphical representation of the spectrum of the molecule as superposition of the bands on the intervals corresponding to the fragments found. It is obvious that this approach leads to inevitable loss of many bands of skeletal vibrations in the 'fingerprint' region, as well as overtones and combination bands, and that the influence of molecular symmetry on the band intensities in the region of functional groups is ignored. It is also clear that the fragment library is far from exhausting all possible atomic combinations.

It should be kept in mind that, as a rule, characteristic spectral features of isomers included in the answer (output) file of ES correspond to experimental spectra. However, structurally similar isomers can be recognised first of all using noncharacteristic IR bands containing encoded structural information and observed in the 'fingerprint' region'. In practice, the most likely structure is chosen on the basis of careful comparison of frequencies and intensities of no more than five bands in the experimental and predicted IR spectra (see Fig. 3). Therefore the approach suggested¹⁴² should be considered unacceptable for the analysis of the answer structural files.

An attempt to use ANN for predicting the IR absorbance curves of organic compounds from numerically encoded structural formulae has been undertaken.¹⁴³ It has been possible to predict satisfactorily absorbance in the regions characteristic of functional groups; however, this approach appeared to be unacceptable for prediction of the 'fingerprint' region. It is likely that the failure can be explained by application of too rough a coding procedure, which, in particular, completely ignores the spatial structure of the molecules.

An analogous conclusion was also drawn by Weigel and Herges¹⁴⁴ who attempted to simulate IR spectra using an ANN trained on a set of spectra obtained from experiments and semiempirical quantum-chemical calculations.

In contrast to the above-mentioned failures, a new approach^{145, 146} seems to be encouraging. Taking into account

that IR spectra are strongly dependent on the spatial structure of molecules, the authors attempted to train the ANN on a training set composed of three-dimensional models of organic molecules. Since all models should be described by vectors of equal dimensionality, the impossibility of using Cartesian atomic coordinates in this case is obvious. To describe the spatial structure of molecules with different numbers of atoms using the same number of descriptors, it was subjected to a transformation based on the equation used for analysing experimental data on electron diffraction. This made it possible to find a procedure for coding any spatial structure by a vector with 32 or 64 coordinates (the 3D MoRSE code). Using the CORINA program¹⁰¹ for fast transformation of structural formulae into three-dimensional models, the authors studied the spatial structure–IR spectra correlations using ANN. The structural formulae from the training set and the target structures were first transformed into spatial models and then encoded using the 3D MoRSE code.

Experiments show that this methodology makes it possible to simulate adequately the IR spectra of specified classes of compounds throughout the absorption region including the region of ‘fingerprints’. The experimental and predicted IR spectra of a quinoline derivative are shown in Fig. 4 as an example (in this case, the ANN used for prediction was trained by the BPE method on a set of more than 50 quinoline and isoquinoline derivatives). The similarity of experimental and calculated spectral curves for this non-additive complex molecule shows that the approach has a chance to become an analytical tool for choosing plausible structures. However, it should be kept in mind that in this case successful results were obtained after training the network on the set of related compounds.

Figure 4. IR spectra of trisubstituted quinoline: experimental (1) and predicted using ANN (2).¹⁴⁶

It is noteworthy that, in principle, this approach also makes possible solving the ‘inverse’ problem, *viz.*, construction of the spatial model of a molecule using its IR spectrum. This was illustrated taking 1-phenylbutan-1-ol¹⁴⁶ and cholesterol¹⁴⁷ molecules as examples (in the latter case, the model found from the IR spectrum appeared to be fairly close to the structure obtained from semiempirical quantum-chemical calculations).

Yet another method¹⁴⁸ for prediction of IR spectra seems to be promising. On the basis of the search for nearest neighbours of a target molecule in the library containing structures and corresponding IR spectra the authors proposed to develop a method for simulation of IR spectra in the region 2250–550 cm^{−1}. The prediction mechanism is based on a reasonable assumption that similar IR spectra correspond to similar structural features. Thus, it is assumed that it is highly probable for compounds assigned the highest similarity rank to have IR spectra similar to that of the target molecule. The predicted spectrum is composed of the spectra of the neighbours (the nearest neighbours in the structure space) if they meet specific requirements for structural similarity.

The structures and spectra are considered as such, *i.e.*, no substructure–subspectrum correlations are used. This approach is most likely to retain noncharacteristic skeletal vibrations, overtones and combination bands, as well as the bands that are changed depending on the molecular symmetry (usually, these bands are in correlation tables). This method of nearest neighbours has also the advantages that it requires no preliminary classification of reference substances and allows easy elucidation of the target molecules that have no analogues in the reference set, thus indicating impossibility to simulate the spectrum.

Implementation of this idea required choice of such procedures for coding fragments, structures and spectra that would make it possible to introduce quantitative measures of structural and spectral similarity. Two methods of structure representation used in the study cited¹⁴⁸ were the method of ACF with one atomic layer¹⁴⁹ and a method which employs a modified graph-theoretical descriptor designated as the ES vector.¹⁵⁰

The ACF code is a reasonable compromise between the undue increase in the number of fragments and comprehensive description of the molecule. In this case, each atom is characterised by its own type (C, O, *etc.*) and by the types of the atoms and bonds of its nearest neighbours (hydrogen atoms are ignored). The fragment size varies from two atoms and one bond (a terminal group) to five atoms and four bonds for the atoms with four valence bonds. The fragments are ordered in the same way as the coordinates of the *n*-dimensional vector and each molecule is characterised by its own vector. The presence or absence of a fragment in the molecule is represented as a binary 1 or 0, respectively, and the occurrence number of the given fragment in the structure is indicated.

The program selected 180 different fragments in the set of about 9000 compounds for which the IR spectra were known. The structures were coded as vectors with *n* = 180. The molecules consisting of C, N, O, Br and Cl atoms and containing ordinary, double, triple and other bonds were selected. On the average, the structure was described by eight different fragments while the reference molecules were polyfunctional.

Using the ACF code, it is possible to exactly describe various functional groups and, at the same time, impossible to distinguish the variants of mutual orientation of functional groups within the same molecule (*e.g.*, substitution types in benzene ring). Therefore, the ES vector¹⁵⁰ was used as an additional descriptor to simulate the structure in more detail. It is less sensitive to changes in the atomic groups than the ACF code; however, both codes well complement each other. The ES vector code is based on the counting statistics of the number of routes in the coloured molecular graph mapped onto the coded compound. It provides a way for performing a detailed (though highly redundant) description; therefore the principal component analysis²⁸ of encoded data was applied in the next stage. To characterise each molecule, the contributions from the first eight principal components responsible for 99% of changes of complete code were used. Experiments have shown that the structure encoding system¹⁴⁸ is rather well suited in this case.

Various procedures for estimating the degree of structural similarity have been considered.¹⁵¹ In particular, similarity of structures X and Y characterised by vectors $\mathbf{X} = \{x_1, \dots, x_i, \dots, x_n\}$ and $\mathbf{Y} = \{y_1, \dots, y_i, \dots, y_n\}$ can be described using the Tanimoto coefficient

$$S_T = \frac{\sum_i x_i y_i}{\sum_i x_i^2 + \sum_i y_i^2 - \sum_i x_i y_i}.$$

The X and Y vectors can be composed of zeros and unities representing the presence or absence of the fragment, respectively, or of integers representing the occurrence number of the fragment in the structure. As applied to IR spectra, the 0/1 representation is more informative than the integer representation, since the absence of any fragment often changes the entire IR spectrum, whereas the difference in the number of the same structural

fragments usually results in a gradual change in the spectral pattern. Therefore, the structures to be sorted are selected using 0,1 vectors and ranked in accordance with the similarity criterion calculated on the basis of the occurrence number. Ranking of molecules using ES vectors is based on calculations of Euclidean distances from the vector of the target molecule.

Experiments were carried out using the IR spectra recorded in the region $2250\text{--}550\text{ cm}^{-1}$ with a resolution of 2 cm^{-1} and represented as sets of 128 points separated by 13.5 cm^{-1} (this corresponded to the same spectral resolution); at each of the 128 points, the value was averaged over seven points in the experimental spectrum covering the 13.5 cm^{-1} interval. Spectral intensities were normalised so that the absorbance of the most intense band was taken as 1.0.

Reliable estimate of similarity in the IR spectra is by no means easy problem. The spectral pattern seen by a spectroscopist's eye is hard to digitise. To solve this problem, the Pearson rank correlation coefficient and Spearman rank correlation coefficient (the strongest, medium intensity and weakest peaks are respectively characterised by the highest, mean and lowest ranks) were used.¹⁴⁸

The spectrum prediction algorithm was as follows.

1. Search for the nearest neighbours in the structure space. Compare the target structure with all reference structures in the collection and select k nearest neighbours for each of three models of structural similarity (the Tanimoto coefficients for both the 0,1 and integer vectors and the Euclidean distances for ES vectors). Get three lists of coincidences, containing information on k structures each.

2. Rank the selected molecules in accordance with the three measures of similarity. Search for the same structures in the three lists and sum up the individual ranks. If some molecules were found in one or two lists only, then ascribe rank $k + 1$ to these molecules in those lists in which they were not found. Sort molecules in ascending order of complete ranks and generate the final list.

3. Select those molecules whose characteristics either exceed the structural similarity threshold or are below the distance threshold.

4. If the final list contains information on less than two molecules, then terminate the procedure and display the results. Go to step 6.

5. Check the IR spectra of selected molecules for spectral homogeneity using correlation coefficients. If more than 50% of the spectra (*e.g.*, 2 out of 2, 2 out of 3, 3 out of 4, *etc.*) are much alike (*i.e.*, the correlation coefficient value exceeds a certain threshold value), then use the averaged spectrum for prediction. If the checking for homogeneity fails, then return control to the chemist. Go to step 6. In any case, display all available information.

6. Reject automated prediction since no or only one molecule is available. Prompt the chemist to assess the situation and decide between continuation and termination of the program. If a decision to predict the spectrum is made, then prompt the chemist to specify the molecules that were ascribed the highest rank and whose spectra should be used.

Thus, prediction can be performed either automatically or manually. If the chemist makes final decision, the result of prediction is characterised by higher quality. The CPU time is dependent on the number of fragments in the structure and takes several seconds on a personal computer with a Pentium CPU operated at 75 MHz, which is well suited.

Unfortunately, the authors restricted themselves to demonstration of a unique example (Fig. 5), which shows that the predicted and experimental spectra are similar. However, no attempts were made to test the method by sorting actual answer files of the ES, which makes impossible to obtain a statistically justified estimate. In our opinion, this approach has the advantage that its algorithm is free from the 'black box' type elements; therefore, the spectroscopist can easily establish the reasons for change in the prediction quality.

Figure 5. IR spectra: experimental (1) and predicted on the basis of search for the nearest neighbours of the target molecule (2).

V. Pathways of development of expert systems

Among the expert systems created in 1970–1980s, the best known is the DENDRAL system⁸ referred to as a 'classical' example of ES in numerous publications on chemistry and books on AI. Popularity of the DENDRAL system is, on the one hand, to a great extent associated with the fact that this project was worked out under supervision of the Nobel Prize winner J Lederberg and noted scientists in the field of AI. On the other hand, the authors of the project have reported about 40 articles collectively called 'Application of artificial intelligence in chemistry', which could not but draw the attention of many specialists. However, Gray¹⁵² critically analysed the idea behind the DENDRAL system and concluded that this artificial intelligence system is far from being perfect. This problem was hotly debated^{153, 154} with participation of the directors of the project. In contrast to a widespread opinion that the CONGEN program has found extensive application, Gray stated that it used rarely (he knows 8 articles in which application of the system was reported). One of the reasons for not-too-high popularity of the system is probably that it is not user-friendly.

In this review the emphasis is placed on the modern ES appeared in the 1990s. The potentialities of modern ES and those belonging to earlier generations were compared.¹⁵⁵ In the last decade, the efforts of researchers were aimed to improve the methods for retrieval of structural information from the spectra, to search for optimum strategies of computer-assisted structure recognition and to increase the user-friendliness of the systems. Our experience has shown that non-user-friendly ES have no chances to become an analytical tool for the chemist. A user-friendly system must:

- (1) have convenient and operationally simple tools for information interchange with the user, which allows the chemist control over any step of the solution of the problem;
- (2) offer the chemist the possibility of getting explanation of each decision made by the program;
- (3) inform the chemist in case of 'emergency' at any solution step and display messages adequate to the situation;
- (4) have advanced graphical tools for representing spectral and structural information to allow a chemist to quickly assess current status of the program operation and make corresponding decision.

In this review we consider certain ES, which, in our opinion, reflect modern tendencies and new approaches. However, let us first define basic concepts to be used later. Let the empirical formula of an unknown compound be determined and the number of isomers corresponding to the empirical formula be N . In principle, the N value can be found by structure generation using appropriate software. We say that a set of n structures ($1 \leq n \leq N$)

selected after the ES operation is a solution of the problem. The solution is correct if it contains a proper structure, otherwise it is incorrect. A correct solution and proper structure can be found only by checking each structure from the answer file using prediction of its spectra and additional experiments. If the answer file is empty ($n = 0$), the problem has no solution consistent with experimental data, information stored in the knowledge base and system options.

A description of the RASTR expert system created to elucidate the molecular structure using IR and NMR spectra is available (see, e.g., Ref. 22). This system is capable not only of revealing possible structures, but also of generating, constructing and depicting spatial models of all stereoisomers corresponding to a given structural formula. The RASTR system was used as a prototype and basis for a user-friendly X-PERT system²⁹ which operates under MS WINDOWS. Let us consider the most important elements of this ES, which in one form or another are incorporated into several other systems.

1. The X-PERT system

The X-PERT system was created to elucidate the structure of organic molecules containing up to 30–35 skeletal atoms (C, N, O, P, S, B, Si, Hal) using IR, ¹H and ¹³C NMR spectra. The knowledge base of the system comprises a set of libraries of molecular fragments and ranges of changes in their characteristic spectral features. The libraries are composed taking into account that the fragments belong to different classes of chemical compounds and respond specifically toward different types of spectroscopic techniques. Libraries belonging to different categories play different roles. The first category comprises universal libraries used for both fragment selection and structure filtration. Libraries belonging to the second category are adjusted to different types of spectroscopic techniques and are mainly used as filters for structure verification. Each fragment in every library is associated with its characteristic features in IR and NMR spectra, which are also stored in the knowledge base.

There are four hierarchically organised universal libraries.

1. Library of principal functional groups (LPF), e.g., C=O, C≡N, etc. The widest ranges of changes in characteristic spectral features are used for these groups irrespective of the nearest environment of a fragment. These libraries are mainly used for preliminary evaluation of a specimen to assign it to a particular class of chemical compounds and for recognition of the structure of non-additive compounds.

2. Library for structural-group analysis contains functional groups and information on the admissible nearest environment,

e.g., $\begin{array}{c} | \\ -C-CO-C \\ | \end{array}$, $\begin{array}{c} | \\ -C-O-C=O \\ | \end{array}$, $-CH_2-OH$, etc. The library

is used for SGA and structure filtration.

3. Library of aromatic fragments (AROM) contains 12 types of benzene ring substitution.

4. Library of phosphorus-containing fragments.

There are the following specialised libraries:

A library of ¹³C NMR data; three libraries of ¹H NMR data to reveal CH₃, CH₂ and CH groups with consideration of the nearest environment; a library containing fragments (mostly cyclic) characterised by strong specific absorption bands (e.g., four- and five-membered cyclic ketones, lactones, lactams, etc.); and a library of fragments containing an OH group.

For each fragment, the system generates a 'visit card' containing the following information: the fragment structure; ranges of changes in the characteristic features in IR (frequencies, halfwidths and intensities of absorption bands) and NMR spectra (chemical shifts, SSCC, signal multiplicities and corresponding numbers of C or H atoms); structural descriptors used to set the requirements for the fragment environment (additivity conditions) and provide retention of its spectral features on going from one molecule to another. Descriptors characterise the frag-

ment atoms with free valence bonds. The descriptor indicates the possibility of adding a hydrogen atom, hetero-atoms (they can be enumerated), aromatic cycles and multiple bonds to a given atom. The possibility (or impossibility) of the formation of a multiple bond and incorporation of the fragment into cyclic structures of specified size is also indicated.

The descriptor can have three types of meanings: 'possible' (P), 'forbidden' (F) and 'obligatory' (O). The program finds classes of topologically equivalent atoms with free bonds in the fragment structure and colours them using individual colours. Each coloured atom is associated with a column of corresponding colour in the table of descriptors. This makes it possible easily to form, interpret and correct the values of descriptors characterising equivalent atoms. The total number of fragments in the libraries is 450.

Experimental data (the empirical formula or molecular weight and available spectra) can be input manually or imported using the OPUS and WIN-NMR programs. The system checks the data for consistency and prompts the chemist to double-check the reliability of the data in questionable situations. If the empirical formula is unknown or questionable, the program generates all possible molecular formulae corresponding to the specified molecular weight taking into account the constraints imposed on the qualitative and quantitative composition of the substance. In this case the most probable molecular formula is chosen using a recently developed method.^{156†}

From this time on, the system operates in the interactive mode. This makes it possible to use the experience and intuition of the chemist and the capability of computer to perform fast search for necessary information and complex logic-combinatorial calculations. In this case, the basic requirement for ES is also met: at any step in the solution the program can explain the reasons for one or another decision and the user can be prompted to activate a corresponding option.

Prior to starting the operation, the program assesses complexity of the problem and displays messages concerning the method of its solution. If the problem can be solved automatically, the program generates all structural isomers and selects possible structures by passing them through a system of filters.

The first stage of the standard method for solution is generation of fragment sets. First, possible fragments are selected with consideration for their empirical formulae, spectral intervals and the unsaturation degree. In this case, necessary libraries of fragments are chosen by the user. The fragments are selected taking into account that the reliability of finding a fragment is 100% if the experimental band falls into the middle of the characteristic interval. It (reliability) linearly decreases as the interval bounds are approached and decreases to zero on both sides of the bounds. A trapezoidal membership function¹⁹ of the interval is chosen so that the decrease in the reliability near the bounds with increasing the length of the interval be more gradual.

The fragments selected and their reliability indices are displayed. The 'Show Spectra' procedure makes it possible to represent experimental spectra and characteristic intervals for selected fragments in clear graphical form to allow the chemist to assess the reliability of the fragments and to edit the list by adding (if needed) his own fragments. Then the table with interpretation data of all available experimental spectra is displayed. The chemist can analyse logical relations between the fragments and correct the 'reasoning' of the program using his experience and *a priori* information. The final set of consistent logical equations is used as input information for the 'inference machine'. The result of the solution of the logical equations [function f(A), see Section II.1] is displayed as a set or several sets of fragments consistent with the spectra, empirical formula and the unsaturation degree of the compound analysed. The program automatically adds sets of

† See also a recent study by M E Elyashberg, Yu Z Karasev and E R Martirosian *Anal. Chim. Acta* **388** 353 (1999).

microfragments such as CH_3 , CH_2 , *etc.*, which were not included as constituents of the structures of selected fragments. The chemist can also correct the selected fragment sets or compose his own sets. The special-purpose 'Multiple Fragments' procedure allows for the inclusion of a fragment appearing repeatedly in the structure, which reduces dimensionality of the problem.

Structure generation using fragment sets is the next step of the program operation. In this stage, the possibility of imposing structural constraints listed in Section III (GOODLIST, BADLIST, constraints associated with the ring size, bond multiplicities, *etc.*) is provided. There is an additional option which enables or cancels the descriptor control in the course of structure generation. The descriptor control is useful to preclude generation of a large number of wrong (bad) structures. Cancellation of the descriptor control can appear to be useful in the case of repeated solution of the problem if the structures found are questionable. The structure generation is carried out by the program based on the known algorithms.^{84,85} The structure counters allow the chemist to monitor the process and assess the efficiency of the constraints imposed.

Structure generation using fragment sets and free atoms can lead to such substructures whose presence contradicts the spectra and/or concepts of organic chemistry, therefore all generated structures are verified using the following six filters (see Section IV).

1. Checking for consistency with characteristic spectral features.
2. Rough simulation of ^{13}C NMR spectra (see Section IV.1.a).
3. Checking for consistency with principles of structural chemistry and stereochemistry (unlikely fragments, Bredt's rule).
4. Checking each isomer for its appropriateness to be used in interpreting experimental spectra.
5. Search for and exclusion of identical structures.
6. Prediction of chemical shifts in ^{13}C NMR spectra to reveal the most probable structures.

The system chooses necessary libraries on the basis of generalised 'portrait' of the answer file to perform a two-stage check. In the first stage, the list of fragments that contradict the spectra is generated. In the second stage, only contradictory fragments are sifted using structural formulae to save time and reject those structures in which at least one of these fragments is found. Options used in the filtration stage allow the user to specify the parameters determining hardness of constraints imposed (*i.e.*, the degree of fuzziness of the interval bounds).

Structure verification using the first and second filters can be performed in both the standard and supervised modes. The first of them provides automated filtration (the so-called 'blind' filtration). In this case, only messages on the current status of program operation and the running number of 'good' and 'bad' structures are displayed. In the second mode, the filtration process is visualised and the user can control over it as well as get all information necessary to explain the decisions made by the system. Each structural formula to be checked is displayed. If no contradictory fragments are found in the structure (it should be kept in mind that only these are sifted), the structure is indicated as good. Otherwise contradictory fragments found in the structural formula are coloured and information on characteristic spectral features (frequencies, chemical shifts, parameters of bands or signals) not confirmed by the spectra is displayed in the form of a 'visit card' of the fragment.

Depending on the number and type of contradictory fragments found in the structure, the user decides to reject the structure as unlikely or accept it for further checking. Structure filtration using this user-friendly mode of the program operation is visualised, fully controllable and understandable.

Checking the number of signals with different multiplicity in ^{13}C NMR spectra in the supervised mode is accompanied by displaying the data on the differences between the number of predicted and observed signals.

After passing the data through the first five filters the system automatically uses the answer file as input data for the SpekEdit program which predicts the chemical shifts in ^{13}C NMR spectra. Then the standard deviations (*S*) of calculated spectra from experimental ones are calculated and the structures are ranked in ascending order of *S*.

The potentialities of the system will be assessed below; here we consider only one example to illustrate the operation of the program.²⁹

Let an unknown compound have a molecular weight of 295 and possible composition $\text{C}_{1-50} \text{H}_{0-120} \text{N}_{0-30} \text{O}_{0-30}$; 197 different molecular formulae correspond to this set of parameters. Using IR and NMR spectral data, the program found the only molecular formula $\text{C}_{17}\text{H}_{13}\text{N}_1\text{O}_4$ and created the fragment sets (1) $\text{C}=\text{O}$, C_6H_5 , 1,2- C_6H_4 and (2) $\text{C}=\text{O}$, C_6H_5 , 1,3- C_6H_4 . These sets were used to generate 6995 structures. The proper structure

was elucidated using spectral and structural filtration.

2. The SpecSolv system

The SpecSolv system[‡] is a new module of the well known SpecInfo system¹⁵⁷ designed for storage and structural interpretation of NMR, IR and mass spectra. In particular, the SpecInfo knowledge base consists of over 200 000 assigned ^{13}C NMR spectra which serve as a basis for the development of the program.

The SpecSolv system is designed to elucidate the molecular structure using the ^{13}C NMR spectrum only and does not require the knowledge of the molecular weight and molecular formula. It uses parameters of ^{13}C NMR spectra [the chemical shifts, signal multiplicities and intensities (the latter as the number of carbon atoms)] as input data. The knowledge base of the system is a library of fragments and their subspectra. The library was created by automated 'cutting off' fragments from the structures stored in the SpecInfo database and contains more than 400 000 fragments encoded by the three-sphere HOSE code⁷³ and more than 100 000 fragments encoded by the two-sphere HOSE code with respect to the central carbon atom. The library is carefully checked by experts.

Information on a fragment includes the connectivity matrix, HOSE codes of all heavy atoms and the subspectrum. Parameters of ^{13}C NMR spectrum (chemical shift, multiplicity, intensity and root-mean-square deviation *R* of the chemical shift) are stored for each carbon atom. The *R* values were calculated for the sets of equivalent substructures in the SpecInfo database. All fragments are completely defined including ring closures in the outer sphere.

The first step of structure elucidation with the program is the fragment search. All subspectra in the library of fragments are compared with the experimental spectrum and the fragments whose subspectra match corresponding regions in the experimental spectrum are selected. A typical case is selection of ~ 500 fragments for a molecule containing ~ 25 heavy atoms.

Fragment search includes three stages: preliminary (pre-search), main and fine search. After the first stage the subspectra are coded as strings encoding the presence of signals with a certain multiplicity within discrete regions of the ^{13}C NMR spectrum. At the second stage it is tested as to whether the number of signals in the regions selected after presearch has a matching number of lines in the experimental spectrum. The fine search includes checking for exact deviations of the chemical shifts in both spectra.

[‡] The first article contained the description of the SpecSolv system³⁰ appeared in 1996 and had an intriguing title 'Fully Automated Structure Elucidation — A Spectroscopist's Dream Comes True'.

Typically, the deviation is 2 to 5 ppm. The selected fragments are then ranked in descending order of match factor, which is defined as the mean deviation of the chemical shift of each atom from the signals in the experimental spectrum.

Despite the fact that the program can operate without knowledge of the molecular formula, it is necessary to specify possible types of atoms (especially, hetero-atoms) since they cannot be immediately revealed by ^{13}C NMR spectroscopy.

It is essential that there is no need for a chemist to analyse all selected fragments, since bad fragments should be excluded at the stage of structure generation. However, if *a priori* information is available (most often, such is indeed the case), it can be expected that analysing the list will make it possible to exclude the bad fragments to save the working time. The main feature of the generation algorithm used in the SpecSolv system is that the fragments are linked by overlapping common atoms. The largest fragment whose subspectrum best matches a particular region of the experimental spectrum is taken as the first one and the program tries to add successively any other fragment to this fragment. If the new fragment passes the plausibility test, it is accepted and the enlarged fragment is considered as starting structure. Before adding the next fragment, the program predicts the ^{13}C NMR spectrum of the enlarged fragment. This is achieved by simple combination of the subspectra, which provides a high performance of prediction. Intermediate structures for which the deviations of the chemical shifts exceed a prescribed value are excluded. In this fashion the final structure is being assembled at the same time with cross-validation of intermediate structures. The absence of such a verification tool in structure generators that admit assembly of structures from overlapping fragments (e.g., GENOA⁸⁷) is a grave drawback.

The assembly continues until all chemical shifts in the experimental spectrum are assigned and free bonds in the resulting structure are absent. Usually, 10 generation cycles based on the first 10 best (the largest with minimum deviation of the chemical shifts) fragments are sufficient to elucidate the answer structure. This is possible since the selected fragments are ranked by match factor of their subspectra with the experimental spectrum. Most often, only one structure is found after exhaustive search in the entire fragment space, though several isomers of similar structure can also be obtained (in general, if no empirical formula is given, generation of nonisomeric structures is also possible).

Will, Fachinger and Richert³⁰ reported recognition of rather large molecules, e.g., such as **1**.

However, it is obvious that structure generation is possible only if the fragment library contains large overlapping fragments of such molecules. Hence successful identification requires the presence of a rather large number of large molecules related to the molecule to be recognised in the system database. However, even if the database contains appropriate fragments, the absence of common atoms will make generation of the proper structure impossible, which means a strong dependence of the result on the diversity and quality of the database. The program is also very 'sensitive' to the solvent in which the experimental spectrum is recorded and, in addition (this is a grave drawback) does not recognise stereoisomeric forms. These factors can have a determining effect on the results of comparison of predicted subspectra of intermediate substructures and the overall model spectrum with the experimental one. It is reported that the system elucidated the

structure of 80% of all compounds analysed in the laboratory. The system was adapted for exploitation on a VAX 6610 minicomputer.

As can be seen, at present 'a spectroscopist's dream' does not come true with the aid of the SpecSolv system since 20% of all problems remain unsolved. If the system cannot solve the problem, a corresponding message is generated and the program is terminated. Therefore new approaches are required which make it possible to resume the analysis in those cases where the program reaches a deadlock. A procedure for overcoming a deadlock has been implemented in the ACD/Structure Elucidator system.³¹

3. The ACD/Structure Elucidator system

The ACD/Structure Elucidator system integrates the recognition strategy developed by the authors of the SpecSolv system³⁰ and conventional methodology used in the RASTR,²² X-PERT,²⁹ CHEMICS³⁷ and other systems.

Two structure elucidation modes, a standard mode and the classical ES mode are permitted. The first mode is to a great extent based on the known general strategy.³⁰ As in the SpecSolv system, the set of experimental data includes a ^{13}C NMR spectrum, chemical shifts, signal multiplicities and intensities. If it is difficult to indicate the exact number of carbon atoms assigned to a signal, their minimum and maximum values are specified. To facilitate measurements of signal intensities, it is appropriate to record a ^{13}C NMR spectrum with an admixture of a paramagnetic reagent, e.g., $\text{Cr}(\text{acac})_2$, which shortens and equalises the spin-lattice relaxation time T_1 for all carbon atoms including quaternary ones. The experimental spectrum can be imported directly from the spectrometer or the user can input spectral parameters manually. Usually, only an NMR spectrum is required for structure elucidation; however, it is helpful to have IR and ^1H NMR spectral data to facilitate the solution of the problem. The database of the system is a library consisting of more than 400 000 fragments and their ^{13}C NMR subspectra that were derived from 135 000 structures with assigned ^{13}C NMR spectra (the structural database). This ES has an appreciably smaller knowledge base than the SpecSolv system has.

The operation of the program begins with the search for ^{13}C NMR spectrum in the knowledge base. Once a spectrum is found, a corresponding structure is displayed and the program is completed. Otherwise the structure is reconstructed from fragments.

At first, the program selects fragments whose subspectra do not contradict the experimental spectrum. The fragments found are sorted in descending order of the number of skeletal atoms and mean deviations of their subspectra from corresponding signals in the experimental spectrum. Since it is impossible to accept or reject the presence of, e.g., OH, NH and $\text{C}\equiv\text{N}$ groups or to differentiate between δ_{C} of the $\text{O}=\text{C}-\text{N}$ group and aromatic ring signal (150–160 ppm) using the ^{13}C NMR spectrum, then, if the IR spectrum is available, filtration of selected substructures is performed using a library of functional groups having the most characteristic features in the IR spectra. Analogous filtration can be performed using fragments having clearly defined characteristic features in the ^1H NMR spectra. After filtration the number of selected fragments is reduced (in some instances, it becomes halved), which favours placing good fragments at the beginning of the list. Then, beginning with the first fragment, the fragments are checked for the possibility of linking by common atoms to perform successive assembly of the structure. As in the SpecSolv system, linking the fragments is accompanied by prediction of the ^{13}C NMR subspectrum of the enlarged fragment to verify the correctness of the assembly.

The problem is considered solved if after checking of all possible combinations of the fragments the program generates one or several structures. The most promising fragments (*i.e.*, the largest ones whose subspectra match well the experimental spectrum) are placed at the beginning of the list; therefore the answer structure is often generated within minutes after starting

the operation of the program. In the case of good correspondence between the ^{13}C NMR spectrum predicted for the answer structure and the experimental spectrum the process can be terminated before completion of exhaustive search for all combinations of the fragments.

If the attempt to assemble the structure fails (the knowledge base contains no appropriate fragments having common atoms or good fragments were not selected), the program automatically switches on the classical ES mode to operate with DUS.

As was mentioned in Section III, operation in this mode requires knowledge of the molecular formula or at least the molecular weight. If the molecular formula is unknown, the program first selects functional groups that would be present in the molecule analysed. To this end, a library containing a small number of the most characteristic functional groups and their spectral features is used. Then search for selected functional groups in the structure of previously selected fragments is performed. The elemental composition and unsaturation degrees of the verified functional groups, as well as the numbers of carbon and hydrogen atoms counted from NMR spectral data are used by the program for automated determination of structural constraints for the generator of empirical formulae. One or several possible empirical formulae established by this generator are passed to the structure generator for verification.

This structure generator operates with the atoms and fragments having no common atoms. It is based on the known algorithms.^{84–86} The fragment sets are composed as follows.

The first N (reference) fragments in the primary list of selected and filtered fragments (usually, the chemist varies the N value from 10 to 30 on his own) are chosen. Obviously, these are the largest fragments and this set almost always includes those fragments that are constituents of the structural formula of analysed compound. Then, the fact is used that, according to the ranking algorithm, small fragments (most often functional groups with their nearest environment) are placed at the end of the primary list.

The subspectrum of the first reference fragment is compared with the experimental spectrum to select the unmatched chemical shifts in the latter. Then, small fragments appropriate for interpreting these chemical shifts are chosen. Only those combinations of small fragments are added to the first reference fragment that provide the highest degree of interpretation of the experimental spectrum. If thereafter certain signals in the query ^{13}C NMR spectrum remain uninterpreted, the program adds corresponding microfragments (CH_3 , CH_2 , CH , $\text{C}=\text{O}$, *etc.*) to the set. Each of the sets obtained is checked for consistency with the current empirical formula of the molecule. The sets corresponding to the second, third, *etc.* reference fragment are generated analogously. If no small fragments appropriate for composing the sets were found, the latter are formed using microfragments so that the number of sets becomes equal N .

The chemist can add his own fragments to the sets, compose the sets based on one of the reference fragments and use all types of constraints described in Section III. To facilitate this, the program displays a 'generalised portrait' of the molecule under study, *i.e.*, the distribution of typical functional groups over frequency of meeting them in the selected fragments. High frequency of meeting indicates that the group is, probably, a constituent of the molecule, whereas the absent groups are used to generate the BADLIST.

Before starting the structure generation using the current fragment set the program assesses the working time (to this end, the percentage of the job done in a time set using system options, *e.g.*, 20 s, is measured) and, if it appears to be longer than a reasonable time, this set is skipped during the first program run and the program begins testing the next fragment set. All structures resulting from the structure generation process are checked for consistency with the available spectra and principles of organic chemistry and stereochemistry. A special program developed to search for tautomeric structures excludes unstable

forms from the list, which often substantially reduces the size of the answer file.

Then the structures automatically arrive at the input of the program for prediction of ^{13}C NMR spectra (the ACD/CNMR Predictor program¹¹⁸). When prediction is completed, the structures are ranked in ascending order of mean deviations of the predicted spectra from the experimental spectrum. Our experience shows that calculations of the spectrum using a personal computer equipped with a Pentium CPU operating at 133 MHz take from 0.5 to 1 s, so prediction of the spectra of 1000 structures takes only 5 to 15 min depending on the number of carbon atoms. Testing of the system showed that in the majority of cases the proper structure is ranked 1st or 2nd from the beginning of the answer file or is at least placed among the first dozen of the structures. However, if the difference between the chemical shift deviations of the preferred structure and the succeeding structure lies within the accuracy of the calculation of the ^{13}C NMR spectrum, further verification of the solution is required.

To this end, automated prediction of ^1H NMR spectra is performed using the ACD/HNMR Predictor program¹³⁷ (see Section IV.2). As a rule, only the spectra of the first dozen of structures are predicted, so the CPU working time is relatively short (~ 10 – 60 s per structure depending on the complexity of the spin systems calculated). Experimental and calculated ^1H NMR spectra are compared by a chemist who makes the final choice of the preferred structure or makes a decision on the necessity of additional experiments. The calculated spectra, integral curve and δ_{H} values for all lines are displayed. If the predicted spectra of several structures appear to be equally close to the experimental spectrum, the proper choice may be made by using the ΔCH_3 values for the δ_{CH_3} singlets

$$\Delta\text{CH}_3 = |\delta_{\text{CH}_3, \text{exp}} - \delta_{\text{CH}_3, \text{calc}}|$$

and comparing the integrals for all multiplets. In most cases, at $\Delta\text{CH}_3 \geq 0.2$ – 0.3 ppm the structure can be rejected. Resolving of questionable situations requires additional experiments, in particular, using 2D NMR spectroscopy.

Thus, the ACD/Structure Elucidator system differs from other systems in the possibility of using two interacting strategies for solving the problem, each of them being based on corresponding structure generator. If in both operating modes the program cannot automatically find an adequate solution, the possibility is provided of solving the problem in the step-by-step mode under the supervision of a chemist who has considerable opportunities to interfere in the 'reasoning' of the program. Testing of the system on a test set of 220 problems showed that correct solution can be found in 90% of cases.

4. 2D NMR spectroscopy in expert systems

The systems created have progressively been developing. In addition to improving the algorithms and extending the knowledge bases, attempts are made to use 2D NMR spectroscopic data in ES, since methods employed in this area of NMR spectroscopy have received wide acceptance and, actually, became routine.

For instance, instrumental tools for using 2D NMR spectroscopy data were incorporated into the CHEMICS system to extend its capabilities.^{158, 159} Methods of processing the data obtained in 2D-INADEQUATE ($\text{C}-\text{C}$ correlations through one bond) and $^1\text{H}-^{13}\text{C}$ NMR COSY ($\text{C}-\text{H}$ correlations through one bond)/ $^1\text{H}-^1\text{H}$ NMR COSY ($\text{H}-\text{H}$ correlations through three bonds) spectroscopic experiments were developed. Using the data of 2D NMR experiments, it is possible to reveal CH_n groups ($n = 0-3$) bonded by chemical bonds and to correlate this additional information with the library fragments selected by the system, thus testing the possibility of the formation of a bond between the fragments. The data obtained are used for controlling the process of structure generation from the fragments.

A new SESAMI system¹⁶¹ was created as a result of improving the CASE system.¹⁶⁰ The library of ^{13}C NMR spectra containing 5100 ACF with one-layer environment is used as the

database in this system. First, SESAMI generates an exhaustive list of fragments, which then is made more 'sparse' using a special-purpose subprogram. Another subroutine adds extra constraints imposed on the structures. The reduced list of fragments and the constraints are used as input data by the COCOA structure generator.⁷⁹ Preliminary selection of the structures generated is performed on the basis of prediction of their ¹³C NMR spectra and an expert makes the final decision.

Enhancement of potentialities of the SESAMI system is attained by incorporating the software¹⁶² developed for processing the data of 2D NMR experiments. The system receives information on correlations between signals and builds fragments consistent with these data. The structures are generated using the COCOA program. Further improvement of the system is performed to develop a module based on application of ANN and designed to elucidate the fragments in the case of simultaneous use of IR and ¹³C NMR spectra.

In parallel with improving the known ES by incorporating tools for processing 2D NMR data, investigations on creation of computer systems designed to retrieve and efficiently use structural information 'hidden' in 2D NMR spectra for molecular structure generation began in the last decade. The demand for the development of such systems is caused by the necessity of establishing the structures of very large molecules of natural products containing up to 50–60 skeletal atoms. Of interest is a recently developed approach.^{32, 163, 164} The authors started from a rather logical position that if once enormous efforts were made to isolate a natural product, carrying out a number of rather labour-consuming 2D NMR experiments seems to be entirely justified. Fragments designed immediately in the course of experiments are mostly used for structure elucidation. As a result, a CISOC-SES expert system was created whose operation requires the data of 1D (¹H and ¹³C) and 2D DEPT, DQF-COSY, HMQC, HMBC, HETCOR, COLOC and 2D-INADEQUATE NMR experiments. In this approach, structural data obtained from 2D NMR experiments are mostly used (the structure is reconstructed as if by applying 'the first principles'), therefore the authors called this approach 'ab initio'.

Obtaining information from 2D NMR experiments requires a skilful choice of procedures (pulse sequences) and correct use of data. Hence the efficiency of such systems will be to a great extent determined by the success in implementing the man–computer 'symbiosis'. Since the systems based on fragment selection retrieve valuable structural information, one should expect that both approaches will eventually integrate.

VI. Strategy of molecular structure elucidation

Since the requirements for the ES architecture are, on the whole, already formulated, the development of an optimum strategy of the ES application is topical. This problem can hardly be solved

theoretically because it is impossible to imagine the whole versatility of situations that may arise in the course of structure elucidation. Efficient approaches can be found only after analysis of the solution protocols of a rather large number of problems.

An attempt to develop the methodology of the molecular structure elucidation using ES was made.¹⁴¹ Particular emphasis was placed on the study of difficulties and contradictions that arise when solving the problems and on the development of procedures for overcoming them. The authors carried out a large-scale computational experiment using the X-PERT system.²⁹ About 200 structural problems taken mostly from monographs^{165–168} or spectral databases and analytical practice were solved. The molecules analysed contained from 10 to 23 skeletal atoms, which is characteristic of the compounds commonly used in industrial laboratories. Most of empirical formulae contained hetero-atoms (from 1 to 10). Over 80% of the total number of compounds belonged to the cyclic ones and about 45% of them contained benzene rings.

As a rule, experimental data included IR, ¹H and ¹³C NMR spectra, as well as the empirical formula or the molecular weight of the substance. To find possible ways of solving the problems, each of them was repeatedly solved using different methods and strategies. Particular emphasis was placed on elucidation of the reasons for difficulties and failures. To facilitate the logic-statistical analysis of the data obtained, the system automatically stored the solution protocols as text files incorporated into the active database. Plausible structures were elucidated on the basis of prediction of chemical shifts in the ¹³C NMR spectra using specially developed software.¹⁶⁹ Computational experiments were carried out on an AT 486 personal computer operated at 66 MHz.

Analysis of the protocols has shown that it is possible to find a correct solution in virtually all the cases considered using the interactive mode. The percentage of unambiguous solutions was 40% and the number *n* of candidate structures did not exceed 5 for 70% of the problems. The *n* value exceeded 10 for 15% of the problems. Prediction of ¹³C NMR spectra of ambiguously solved structures increased the total percentage of unambiguous and right answers from 40% to 75%, i.e., the proper structure was ranked 1st and placed at the beginning of the file.

For instance, the answer structures of molecules **2–9** were obtained with indication of *n* values, reduced size of the answer file after prediction of ¹³C NMR spectrum (*n*^p) and the number of the proper structure in the ranked answer file *n*^t. The *n*^p value was defined as the number of structures for which the root-mean-square deviation *s* does not exceed 5.5 ppm (the accuracy of the program¹⁶⁹).

About 60% of problems were solved automatically by using SGA or straightforward structure generation (SSG) from empirical formulae. In those cases where the structure was unambiguously elucidated by means of SSG followed by structure filtration, exhaustive information on the molecular structure was obtained

using characteristic features not observed in the experimental spectra. Moreover, filtration has led to recognition of certain structures containing fragments that were absent in the database.

In essence, the strategy of solving a problem is a set of methods for overcoming various difficulties. The authors¹⁴¹ analysed typical difficulties encountered when using ES.

1. Examples of difficult situations

Mixed-valence atoms. Depending on the valence state, mixed-valence chemical elements can form various functional groups (e.g., SH, >S=O , >SO_2 , >PH , >P=O). Each functional group generates its own family of isomers. Therefore, strictly speaking, structural problems should be repeatedly resolved until all valence states of atoms present in the empirical formula have been searched through. The problem is appreciably simplified if available information on the origin of a specimen or data of independent experiments make it possible to determine the valences of all elements in the empirical formula.

Specific character of IR spectrum. It is known that IR spectrum is extremely sensitive to slight changes in the molecular structure and electron density. This makes it possible to reveal even minor changes in the molecular structure. However, frequencies or intensities can be interpreted only if the structural formula of the molecule is known. This is impossible until the molecular structure has been recognised. For this reason, rearrangements of functional groups in the isomers, which have little effect on the additivity of the molecule, can cause the characteristic frequencies and band intensities to go beyond the limits indicated in the fragment libraries.

For instance, in some instances the bands at 3000, 1600 and 1500 cm^{-1} characteristic of benzene derivatives appear to be inactive or too weak to be detected in the spectrum. However, if the NMR spectra of such a compound contain signals in the aromatic region, the X-PERT system assesses the situation and prompts the chemist to accept or reject the presence of an aromatic fragment (in other words, to decide between 'yes' and 'no', respectively). Another problem arises if a compound is dissolved in a solvent of the CCl_4 or CHCl_3 type. In this case diagnostically important aromatic bands in the region 700–800 cm^{-1} cannot be used for determination of the types of benzene substitution, which results in increasing the size of the answer file.

The IR spectral pattern in the region of stretching vibrations of the OH group is dependent on many factors (the presence of neighbouring atoms and functional groups, solvent properties, etc.). Because of a very strong effect of the intramolecular $\text{O-H}\cdots\text{X}$ hydrogen bond, the parameters of some IR bands [$\nu_s(\text{OH})$, $\nu_s(\text{C=O})$, etc.] are shifted beyond the limits of characteristic intervals. Therefore, deciding between the presence and absence of the OH group often requires the interference of a chemist (the X-PERT system generates a corresponding message).

It turned out that joint use of IR and NMR spectra often leads to the loss of right fragments whose characteristic features were not confirmed because of unusual IR spectral pattern. Therefore, the IR spectrum should sometimes be 'switched off' during the first program session. Of course, it does not mean that the ES can exclude IR spectra from its 'reasoning', since there is a rather large number of functional groups which contain no C and H atoms (e.g., NO_2 , SO, SO_2 , NO, ONO, P=O , P=S , etc.) and cannot be immediately detected by NMR technique without using the IR spectral bands for confirmation.

The influence of structural peculiarities on the complexity of the problem. At first glance, it may appear that the larger the molecule, the larger the expected n value. Actually, the n value is a very complex function of different structural parameters. Therefore it is quite possible that a large molecule will be identified unambiguously, whereas the answer file created when recognising a relatively small molecule will contain a large number of structures. Let us consider the most important structural factors affecting the problem solution.

If the symmetry of the structure of analysed compound is higher than C_1 , the solution of the problem becomes easier, since a large number of wrong structures are often rejected after comparing the predicted number of signals and their multiplicities in the ^{13}C NMR spectrum with the experimental data. For instance, unique and proper answer structures were found for molecules 10–17. It should be noted that structure 12 containing the O=C-N-C=O fragment was unambiguously recognised despite the fact of the absence of this fragment in the knowledge base.

Symmetry of the structure also allows the chemist to use more efficiently the 'Multiple Fragments' procedure²⁹ to generate sets containing admissible (from the viewpoint of the empirical formula) numbers of identical fragments, which makes possible generation of large structures. For instance, a set containing four ester groups and four ethyl groups was created for the empirical formula $\text{C}_{14}\text{H}_{22}\text{O}_8$ and the unique structure 17 was recognised after the filtration procedure.

As is known, the number of signals in a ^{13}C NMR spectrum calculated as the number of groups of topologically equivalent carbon atoms does not always correspond to experimental data. For instance, only three signals are observed in the ^{13}C NMR spectrum of molecule 18 instead of the six expected. In this case the proper structure was unambiguously elucidated using prediction of ^{13}C NMR spectrum.

Accidental degeneracy of signals in the NMR spectrum or splitting of signals of carbon atoms of *gem*-dimethyl, isopropyl and other groups near the stereocentres makes computer-assisted structure recognition more difficult and requires interference by a chemist. If there are several stereocentres in the molecule, the answer file often contains a larger number of structures than usually. This is explained by complexity of ^1H NMR spectra (a small number or even the absence of the first-order signals, different δ_{H} values of geminal protons) and additional splittings of signals in the ^{13}C NMR spectra. For instance, in the case of compound 19 having three stereocentres the program for δ_{C} prediction ranked the proper structure 3rd from the beginning of the answer file containing 31 structures in the structural similarity criterion.

Large number of candidate structures in the answer file is also characteristic of hetero- and carbocyclic compounds, e.g., for 18–25. This is associated with a large number of rearrangements

possible in heterocyclic structures with several substituents. Compound **20** can serve as an example. The set including all fragments of this structure, 3(>N-CH_3), 2(>C=O), >C=C< , >C=N- , was created manually. The program generated 181 structures which were subjected to filtration to select 40 structures containing five- and six-membered rings.

The S value of 11.6 ppm was obtained for the predicted ^{13}C NMR spectrum of the proper structure **20** (the maximum deviation was 25.6 ppm.). As a result, the proper structure was ranked 14th from the beginning of the list of structures in the structural similarity criterion. Thus, we get a 'fuzzy' solution even if the fragment set used is *a priori* suitable for recognition of the proper structure; therefore, elucidation of a proper structure requires additional information (obtained, *e.g.*, from 2D NMR experiments) and application of more reliable methods for spectra prediction.

Analysis of the ways of overcoming difficult situations made it possible to propose methodology resulting in correct solutions of the problems.

2. Strategies of problem solution

To obtain a correct solution of a problem using an ES, *i.e.*, to find a proper structure in the answer file containing a minimum number of possible structures (ideally, one structure), it is necessary (but not sufficient) to provide the possibility of selecting as many fragments constituting the analysed structure as possible. To this end, a large knowledge base should be incorporated into the system and characteristic spectral ranges of the fragments should be rather wide lest the correct fragments be lost.

When these conditions are met, it appears that the number of selected fragments is too large since many superfluous (wrong) fragments are also selected. This requires finding and excluding superfluous fragments. Editing the list of selected fragments is hardly possible without participation of a chemist. This procedure can be excluded only if all logically admissible fragment sets and generation of structural formulae are created automatically. As a result, the number of generated structures will be too large, structure generation and filtration will take a long time and the problem even may appear to be virtually unsolvable. In addition, the answer file can contain the structures that contradict *a priori* information. Hence, in any case checking the list of selected fragments by a chemist seems to be virtually unavoidable rather than desirable.

Thus, meeting the requirement for the presence of the largest possible number of right fragments in the list of selected substructures results in increasing the total number of fragments and, as a consequence, in increasing the size of the answer file. In this case the solution will likely be right, but 'fuzzy'. This should be considered as a pay for correctness.

The selectivity of fragment selection is strongly dependent on the environment descriptors of the fragments. The stiffer the requirements for the fragment environment, the narrower the intervals of characteristic spectral features and, hence, the higher the SGA selectivity. At the same time, the narrowing of the intervals increases the probability of the loss of correct fragments because of the deviation of an experimental feature beyond the bounds of the characteristic interval.

There is also a clear dependence between the size of the structural file and the rigour of definition of descriptors describing the fragment environment. The point is that only those structures which meet all the requirements imposed by the environment descriptors are stored in the course of structure generation. This drastically reduces the number of structures to be checked later. On the one hand, there are problems which cannot be solved at all without descriptor control over structures during the structure generation stage (calculations take too long a time). On the other hand, there is a possibility of losing a proper structure in the case of too rigorous descriptor control. For instance, if the O=C-C=C fragment defined in the library as acyclic (whereas the proper structure contains the C=C bond in the ring) was selected at the SGA stage, all structures containing this fragment in the ring (including the proper structure) are rejected in the course of structure generation. This leads to an incorrect solution. Ideally, it is desired to have an ES characterised by high selectivity at SGA stage and, at the same time, by the capability to generate unambiguous and correct solutions. It is hardly probable to meet both requirements, therefore a compromise should be found.

Since the basic requirement for the solution is that it should be correct, it is possible to put up with its ambiguity. Therefore, the optimum strategy of structure elucidation can be formulated as follows: the problem should be solved in the interactive mode, which is a sequence of iterations followed by increasing the hardness of imposed constraints. For instance, if dimensionality of the problem is not very large, the library of principal functional groups (LPF, see Section V.1) should be used to select the fragments in the first stage. This provides the possibility of using softest structural constraints to generate a maximum number of fragment environments. Recognition of a large molecule requires additional use of the SGA and AROM libraries.

To control the hardness of imposed constraints at the stages of fragment selection and structure generation, the chemist can switch on (or off) the following options: the use of any type of spectra from the available experimental data; the use of signal multiplicities and SSCC in NMR spectra; the use of band intensities and halfwidths in IR spectra; the environment descriptor control over structures in the course of structure generation; the environment descriptor control over structures in the course of structure filtration; setting of various tolerances for the predicted number of signals with different multiplicity in the ^{13}C NMR spectrum; the use of structural constraints at the stages of structure generation and filtration (the limiting size of the ring, the maximum bond multiplicity, satisfying Bredt's rule, GOODLIST, BADLIST, list of unlikely fragments, *etc.*).

If no solution was obtained during the first program run which, as a rule, is carried out automatically, rational use of the above-mentioned switchable parameters in the course of iterative (trial-and-error) procedure usually makes it possible to establish the reasons for contradictions, thus facilitating the search for a correct solution. The search for contradictions is particularly efficient when using the controlled filtration mode (see Section V.1). Storing all intermediate results in the active database allows the user to return to the solution of the problem at any step.

Fast operation of programs for prediction of ^{13}C NMR spectra (0.5–1 s per spectrum) makes possible effective employment of the strategy outlined above. Thus, to attain a correct solution, the initial constraints may sometimes be slacked to such a degree that the answer file will contain thousands of structures. Prediction of the chemical shifts and the maximum likelihood ranking of the structures are carried out automatically; therefore CPU time taken can be considered justified and admissible.

The choice of appropriate strategy of solving a certain problem depends on optimum combination of two basic modes of operation of the system, which can be called the 'Archaeologist' mode and the 'Sculptor' mode. The 'Archaeologist' mode is used to perform SGA and structure generation (to 'glue' fragments and atoms). Then the 'Sculptor' mode should be switched on to carry out structure filtration and reject wrong structures (in this mode, the strategy is to cut off all superfluous structures).

Analysis of a large number of solutions made it possible to divide all problems into the following categories:

(1) problems solved automatically using SSG from molecular formulae followed by application of the 'Sculptor' mode strategy;

(2) problems solved automatically using strategies of the 'Archaeologist' and 'Sculptor' modes;

(3) problems solved using elements of the interactive mode (a chemist edits the 'reasoning' of the program using diversified information easily obtained from experimental data); and

(4) problems which can be solved only in the interactive mode (manual creation of fragment sets, imposing various constraints due to the origin of a specimen, etc.).

Rating a problem in a particular category depends on different factors (e.g., the size of the molecule, the presence of large fragments with characteristic spectral features, symmetry, etc.) and, first of all, on the number of skeletal atoms in the empirical formula. In many instances, SGA can be performed automatically; however, the appearance of at least one contradiction between the axioms of the SGA theory and experimental data makes the interference of an expert virtually inevitable. It should be kept in mind that even coincidence of predicted spectra with experimental ones does not guarantee against incorrect choice of the structure. Additional experiments can appear to be necessary, in particular, an X-ray study or structure confirmation by INADEQUATE 2D NMR technique. Despite carrying out additional labour-consuming procedures, the expenses are incommensurate with the cost of independent synthesis, isolation and purification of the product.

Thus, AI programs must be considered as powerful tools of extending the intellectual potentialities of the investigator rather than those of a method designed to exclude a chemist from the structure elucidation process. This idea was clearly expressed by the authors of monograph:¹⁷⁰ 'Computer-based automated or interactive versions of similar approaches have also been devised for structural elucidation of complex natural products, such as the SESAMI (Systematic Elucidation of Structures by using Artificial Machine Intelligence), but there is no substitute for the hard work, experience and intuition of the chemist.' We cannot but agree with this.

VII. Conclusion

The first studies reported 30 years ago laid the foundations of an independent line of investigation, the development of ES for elucidation of the molecular structure of organic compounds by spectral methods. It is closely related to many branches of chemistry (organic, physical, analytical, quantum chemistry, stereochemistry, molecular spectroscopy, molecular mechanics), mathematics (theory of graphs, combinatorial analysis, mathematical logic, theory of fuzzy sets, mathematical statistics), cybernetics (AI, programming, information theory, pattern recognition, ANN theory, computer graphics, mathematical linguistics), psychology (the man–computer interface) and philosophy of science (the role of the complementarity principle in studying

the structure of matter).¹⁷¹ Therefore rapid progress in the development of ES that absorbs new achievements of interdisciplinary sciences should be expected.

Three major stages of the process of structure recognition, viz., the SGA, structure generation and prediction of the spectra of candidate structures, have been transformed into independently developing investigation lines. It has been possible to computerise the structure generation and prediction of NMR spectra to a greater extent than SGA. Several methods were developed to reveal molecular fragments; however, this stage remains the most vulnerable and dependent on the *a priori* information. Recently, intensive studies on the application of ANN to revealing the fragments have begun.

Up to now, all attempts to develop a fast and reliable method for the prediction of IR spectra have failed. Solving this problem requires investigation of the potentialities of ANN (encouraging results have already been obtained) and development of new approaches. The known methods of calculation of IR spectra must be essentially improved to accelerate calculations. It has been shown^{172–174} that calculations of IR spectra can also be used for quantitative spectral analysis of organic compounds without any calibration. Therefore incorporation of databases (e.g., such as it was made by Gribov and Zinoviyev¹³⁸) into ES will allow one to create systems for both qualitative and quantitative spectral analysis of organic substances.

Taking into account the accumulated experience in solving many structural problems, the general strategy of elucidation of the molecular structure using ES was established. It consists of performing a number of successive iterations followed by a gradual increase in the hardness of constraints imposed. The use of this strategy makes it possible to obtain correct solutions.

Currently, most of ES are capable of recognising small and medium size (up to 20–25 skeletal atoms) molecules; however, this does not mean that ES have limited area of application. Millions of organic structures can correspond to a relatively simple molecular formula (e.g., about 48.5 mln of structures correspond to the empirical formula $\text{C}_9\text{H}_{10}\text{O}_3$); since 'only' ~ 14 mln of compounds are known currently, it is easy to conclude that the area of application of ES is very wide.

Since at present the structures generated by the use of the most sophisticated structure generators contain no more than 10–12 molecular fragments, the ES capable of revealing large fragments are rather promising for recognition of large molecules. Rapid progress of ES in which 2D NMR spectroscopy data are used should also be expected.

Three-body ion – molecule processes

G V Karachevtsev (deceased), P S Vinogradov

Contents

I. Introduction	549
II. Theoretical models for three-body reactions	550
III. Experimental methods for the study of three-body ion – molecule reactions	554
IV. Temperature dependences of association rate constants	556
V. Some results of studies	556
VI. Conclusion	559

Abstract. Theoretical models used in the studies of three-body ion – molecule reactions are considered and the experimental methods for the study of these processes are described. The results of experimental studies are presented, including those for gas phase reactions at ultra-low temperatures and for the kinetic isotope effect induced by the symmetry of the species. The bibliography includes 130 references.

I. Introduction

Three-body ion – molecule processes of the type

where A^+ is an atomic or polyatomic ion (in this case, positively charged) and B and M are neutral species, constitute an important class of reactions which can affect substantially the composition and electrophysical properties of the low-temperature plasma.

In gas-phase chemical kinetics, the term ‘three-body reactions’ denotes reactions the rates of which depend on the concentrations of the components A^+ , B and M . The rate of a third-order reaction is represented as

$$W = k_t[A^+][B][M],$$

where k_t is the rate constant independent of the component concentrations, these reactions may be regarded as a special case. Such a reaction order is characteristic, for example, of the association reaction at sufficiently low pressure.

The dependence of the reaction rate on the concentrations of the components over a wide pressure range is more complex. This dependence is determined by a combination of several processes: the formation of transition states (with a definite dispersion of lifetimes), decomposition of these states through different channels (into different quantum states with account of the conservation laws), as well as energy exchange between the species and its intramolecular conversion. It should be noted that the rates and

branching ratios between the channels for some exothermic reactions which are formally represented as second-order reactions

can depend on the buffer gas pressure. For some of the ion – molecule processes, this dependence can be noticeable even at a pressure of several Torr.

The majority of studies regarding three-body ion – molecule processes are devoted to the investigation of association reactions. The pressure range in which quantitative measurements of the rate constants have been carried out[†] usually does not exceed 10 Torr. The most reliable values of the rate constants are obtained by the mass spectrometric method where reactions occur in a flow or ion drift in an electrical field at a buffer gas pressure of ~ 1 Torr. Under these conditions, a third order reaction is observed for the majority of systems studied involving a small number of atoms. As the number of atoms is increased (for some systems, starting from seven or eight), a transition mode is established, which corresponds to a change from a third to a second order reaction.

The importance of the association processes is due to the fact that it is the composition of the positive ions that largely determines the loss rate of free electrons, *i.e.*, one of the basic parameters characterising the properties of an ionised gas. The recombination coefficients of various types of positive ions with electrons can differ by several orders of magnitude. This can be seen from two examples.

In the inert gas plasma, three-body association results in the formation of molecular ions such as He_2^+ , Ne_2^+ , Ar_2^+ , which recombine with electrons much more efficiently (in dissociative recombination processes) than the corresponding atomic ions that have different neutralisation mechanisms.

In the atmosphere of Earth, as the altitude decreases, three-body association affects essentially the kinetics of ionic processes starting from the *D*-layer (height range 75–90 km). Rocket-based *in situ* measurements detected complex ions in the *D*-layer.^{1,2} The formation of complex (cluster) positive ions results in a decrease in the concentration of free electrons, as the dissociative recombination coefficients for these ions are about two orders greater than those for non-cluster primary ions. In the Earth stratosphere, where the high-energy intergalactic species are the major ionisa-

[†] Or rather, effective rate constants, since such processes are not elementary in the strict sense.

tion source, the ion chemistry is completely determined by transformations of positive and negative cluster ions.^{3,4}

Three-body processes play an important role in high-pressure analytical mass spectrometry,^{5,6} for example, where chemical ionisation and ionisation at atmospheric pressure are used, as well as in plasma chromatography.^{7,8} Termolecular reactions can compete with some slow bimolecular reactions of species exchange^{9–17} and with energy exchange processes.^{11, 18–20}

In this review, we discuss the specific features of three-body ion–molecule reactions and the application of the developed theories to processes involving ions; the theories based on statistical approaches occupy a special place among them. The experimental methods for the study of termolecular reactions are described. A separate section deals with the analysis of results of studies of the processes occurring at very low temperatures.

II. Theoretical models for three-body reactions

Three-body reactions involve several steps. The Lindemann scheme of three-body association is rather simplified, however, it gives a qualitative idea of the multistage character of the process. The first step implies the formation of an excited complex in a bimolecular collision; the complex can then undergo a spontaneous decay into the original species

where k_f is the rate constant for the formation of the collisional complex,

where k_d is the rate constant for the spontaneous decay of the collisional complex.

In parallel with the decay, stabilisation of the excited complex can occur upon collision with the third species M

where k_s is the rate constant for the collisional stabilisation of the excited complex. Assuming the concentration of AB^{+*} to be quasi-steady, the rate of, *e.g.*, the association process can be presented as

$$W_a = \frac{d[AB^+]}{dt} = k_s[M][AB^{+*}] = k_f k_s \frac{[A][B][M]}{k_d + k_s[M]}.$$

The rate constant for a three-body reaction k_t (which is of the third order and a dimensionality of $\text{cm}^6 \text{s}^{-1}$) equals

$$k_t = \frac{k_f k_s}{k_d + k_s[M]}. \quad (2)$$

At the low pressure limit, where

$$[M] \ll \frac{k_d}{k_s},$$

k_t does not depend on $[M]$

$$k_t = \frac{k_f k_s}{k_d}.$$

If the equality (2) does not hold, the association rate constant is usually represented as an apparent rate constant of a quasi-bimolecular second-order reaction (dimensionality $\text{cm}^3 \text{s}^{-1}$) which depends on $[M]$:

$$k_{\text{ef}} = \frac{k_f k_s [M]}{k_d + k_s [M]}.$$

The dependence on $[M]$ disappears only at the high pressure limit; in this case, $k_{\text{ef}} = k_{\infty} = k_f$.

Some authors supplement the scheme with the formally possible decomposition of the AB^{+*} complex upon collisions with M

Note that the scheme does not take radiative stabilisation into account

This process does not require stabilisation by a third species and can compete with the stabilisation only at very small concentrations of M ($[M] \leq k_r/k_s$).

The Lindemann model is based on formal kinetics concepts. Nevertheless, the model shows the key role of the intermediate excited complex AB^{+*} . It is the formation of this complex with an energy sufficient for its decay that allows one to consider three-body association using various approaches developed in the studies on unimolecular decomposition.^{21–25}

An important role in the transformations of the AB^{+*} complex belongs to energy exchange, including both intramolecular energy conversion of the highly excited species AB^{+*} ('reactive molecule' in terms of the unimolecular decomposition theory) and energy exchange with the buffer gas (collisional relaxation—activation). The contemporary theoretical approaches used for the description of the energy exchange and reactions of highly excited polyatomic molecules, as well as the results of optical experimental studies of these processes, are described in sufficient detail elsewhere.²⁶

1. Association of atomic species

In the simplest case, where A^+ and B are atomic species, the rate constants can be calculated using the method of trajectories. It is also useful to consider other ways of estimating that give a qualitative idea of the magnitudes of the rate constants for this type of reactions.

For ion–atom processes at low energies, the ion–neutral species interactions are determined by the long-range potential and k_f and k_s have a typical value of $10^{-9} \text{cm}^3 \text{s}^{-1}$. The minimum lifetime of a collisional complex $\tau_c = 1/k_d$ can approximately be estimated as the time during which one species is located near another one, *i.e.*, as the ratio of several characteristic sizes of the atoms to the velocity of their relative motion. Such an estimation yields a value of the order of $k_d \simeq 10^{13} \text{s}^{-1}$ and an association rate constant of atomic species of the order of $k_t \simeq 10^{-31} \text{cm}^6 \text{s}^{-1}$ (see Refs 21 and 27).

Let us note an interesting approach to the estimation of the rate constant for ion-atom association based on the data on the mobility of ions and polarisability of atoms. The rate constant for the process can be calculated using the formula²⁸

$$k = 3.27 \times 10^{-27} \frac{Z^{5/2} (\alpha_M m / T m_A)^{3/4}}{\mu_0 (m_A + m_B)} \quad (\text{cm}^6 \text{s}^{-1}), \quad (3)$$

where Z is the ion charge in elementary charge units; m is the reduced mass

$$m = \frac{m_A m_M}{m_A + m_M},$$

m_A , m_B and m_M are the masses of species A, B and M in atomic mass units, respectively; T is the temperature in K; μ_0 is the reduced mobility of the ion in $\text{cm}^2 (\text{V s})^{-1}$ estimated using the Langevin formula (which is valid if the species A and M are different)

$$\mu_0 = 13.8 \frac{\alpha_B m_A m_B}{m_A + m_B},$$

α_B and α_M are the polarisabilities of B and M in 10^{-23}cm^3 . The experimentally measured mobilities μ_0 are used in the calculations. This approach is based on the fact that the mobility is determined

by the cross-section and kinematics of collisions, *i.e.*, the averaged characteristics of energy transfer in collisions are used.

Formula (3) provides a fairly good description of the experimental data for the association of atomic species and can be used for reliable estimates of the association rate constants at temperatures from 70 K to 300 K. Similar calculated values of rate constants are obtained using an approach suggested elsewhere.²⁹

A quantum-mechanical calculation with account of species tunnelling through a centrifugal barrier (*i.e.*, with account of resonance quasi-bound states) yields a correction (less than 20% at ambient temperature) to the data of a classical calculation even for the reaction of light species,³⁰ for example,

Considerable discrepancies arise at very low temperatures. Experimental results for a flow cooled to 1 K after gas expansion through a nozzle^{31–34} do not correlate with the temperature dependence which follows from formula (3). The reasons for this discrepancy are not known yet. Probably, one has to take the quantum effects in scattering processes into account in order to provide agreement between the experimental results and the calculation.³⁵ The importance of these effects has been noted, *e.g.*, in studies of the ion mobility in a gas at low temperatures.^{36–38} In addition, the dynamics of the collisional complex at very low gas temperatures can be affected by thermal infrared radiation of the relatively ‘hot’ walls.³⁹ This radiation affects the energy redistribution in the system, which affects the lifetime of the intermediate complex.

The approach described above is of interest for the estimation of the association rate constants of electronically excited atomic ions. It is known that the mobility of such ions can differ from the mobility of ions in the ground state.⁴⁰ The difference is due to partial electron density transfer from the neutral species to the ion in collision. The transfer is possible over rather long distances (10 Å). This results in a decrease in the effective polarisability of the neutral species and should affect the collision cross-section and the association rate constant.

An analysis⁴¹ showed that the available experimental results on the association rate constants involving polyatomic species are poorly described by the formula (3). Nevertheless, the following qualitative conclusions may be made from comparison of the experimental results and those of calculations presented in Fig. 1: the points above the straight line, which characterises the equality between the measured rate constants and those calculated using the formula (3), correspond to the formation of complexes with high bond energy (more than 1.5 eV); the points below the straight line correspond to the formation of weakly bound complexes. This correlation is related to the characteristic features of the energy exchange processes in polyatomic systems and may be explained

based on more rigorous theoretical approaches with the use of the statistical theory.

Qualitatively, the divergence between the calculations and experimental results can be explained by the fact that the characteristic lifetime of a complex is longer than that determined by the kinematics of collisions of ‘point’ species having no molecular structure. An increase in the lifetime of the complex in molecular systems virtually does not affect its mobility but results in an increase in the association rate constant.

For weakly bound complexes, the overestimated calculated rate constants for the processes involving molecular species may be explained by a decrease in the efficiency of the complex stabilisation. Upon a collision with the third body, the latter takes away a rather small fraction of the excess internal energy of the complex ($\sim kT$). Therefore, even after collision, the energy in the internal degrees of freedom of the complex is sufficient for its decomposition.

2. Characteristic features of ion–molecule interactions

Close similarities exist between the termolecular reactions involving only neutral species^{42,43} and ion–molecule reactions. On the other hand, there are also differences caused by the specific character of interaction between ions and neutral species. They are characterised by longer-range interactions than colliding neutral species. In addition, there are also certain specific features in the interactions at short distances.

The peculiarity of long-range interactions results in the cross-sections of ion–molecule collisions, and hence the rate constants for collisions, being much greater than the corresponding values for neutral species. The formation of a collisional complex occurs in the first step of three-body processes, and this is one of the reasons why the overall rate for ion–molecule interaction is greater than that for neutral–neutral species.

The typical rate constants for collisions between ions and molecules at room temperature are of the order of $10^{-9} \text{ cm}^3 \text{ s}^{-1}$. Therefore, the rate constants for three-body reactions of ions may be expected to be ~ 2 – 3 orders greater than similar reactions of neutral species at the low pressure limit due to the greater values of $k_{\text{tr}}k_{\text{s}}$.

The dependence of the collision rate constant on the translational energy of species is determined mainly by the polarisation interaction (*i.e.*, the interaction of an ion with an induced dipole) and the ion–permanent dipole interaction if the neutral species has a permanent dipole moment μ_{d} . If one assumes that the dipole is always directed along the radius-vector $\mathbf{r}$ connecting the colliding species regarded as point masses, the corresponding effective potential has the form

$$U_{\text{ef}} = \frac{L^2}{2\mu r^2} - \frac{\alpha q^2}{2r^4} - \frac{\mu_{\text{d}} q}{r^2}, \quad (4)$$

where L is the orbital angular momentum, μ is the reduced mass, α is the polarisability of the neutral species, and q is the ion charge. The first term, *i.e.*, the centrifugal potential, considers the fact that the relative motion occurs in the central ion. If the molecule is non-polar ($\mu_{\text{d}} = 0$, the Langevin model), the collision rate constant is determined by the expression⁴⁴

$$k_{\text{L}} = 2\pi q \sqrt{\frac{\alpha}{\mu}}. \quad (5)$$

If the neutral species has a permanent dipole moment, the dynamics of the collision process becomes much more complex. Formula (4) describes the so-called locked dipole model, while the dipole rotation, which is the closer to the free rotation the greater is r , is not taken into account. One of the coordinates of the potential energy surface of species interacting over long distances, $U(\mathbf{r}, 0)$, is the angle θ between the direction of the dipole axis and the radius-vector

Figure 1. Correlation between the experimental rate constants for molecular ion association and those calculated using the formula (3).⁴¹

$$U(\mathbf{r}, 0) = -\frac{\alpha q^2}{2r^4} - \mu_d \frac{q}{r^2} \cos \theta.$$

The effect of the ion–dipole interaction on the collision rate constants has been studied in sufficient detail^{45–47} and procedures have been developed for the calculation of these constants.^{45, 48}

In spite of the fact that the ion–dipole interaction is long-ranged ($\sim 1/r^2$), its contribution to the overall collision cross-section is not great as compared to the contribution in the case of a locked dipole model. Because of the dipole rotation, the time phases of attraction ($\cos \theta > 0$) and repulsion ($\cos \theta < 0$) are averaged to some extent, and the total effect is comparable with the contribution from the polarisation interaction; however, dependence of the collision rate constant on temperature appears in this case.

For some molecules, the polarisability α can be anisotropic, *i.e.*, it can depend on the molecular orientation in an electrical field. However, taking into account the relationship (5) and the averaging effect described above, it may be noted that the contribution of this anisotropy is insignificant (usually $< 10\%$). If the molecule has a quadrupole moment Q , α is also anisotropic. The corresponding contribution to the interaction potential is determined by the equation

$$U_Q(r, \theta) = \frac{1}{2} \frac{Qq(3 \cos^2 \theta - 1)}{r^3}.$$

Estimates show that the contribution to the collision rate constant due to ion–quadrupole interaction ($\propto Q^{2/3}/\alpha^{1/2}$) is not very large in comparison with the Langevin constant ($\sim 10\%$). The contributions due to other types of interactions proportional to $-1/r^N$ (the exponent N depends on the interaction type) are also relatively small.⁴⁵

To summarise the above considerations, it should be noted that long-range interactions of ions with molecules and atoms are mostly determined by electrostatic forces represented as a sum of terms with different exponents N . The main contribution to the collision rate constant is given by the almost isotropic polarisation interaction ($\propto -1/r^4$). For polar molecules, the rotation of dipoles is not ‘frozen’ at long distances, and the contribution to the collision rate constant due to the ion–dipole interaction can be comparable with the Langevin constant only for a sufficiently large dipole moment (> 3 Debye units).

The Langevin model provides rather precise estimates of actual collision rate constants at translational energies of species from 0.01 to 1 eV. For a typical value of $k_L = 10^{-9} \text{ cm}^3 \text{ s}^{-1}$, the cross-section $\sigma(v) = k_L/v = 3.3 \times 10^{-14} \text{ cm}^2$ at the initial ($r = \infty$) velocity of the relative motion of species $v = 3 \times 10^{-14} \text{ cm s}^{-1}$. In this case, the maximum value of the aiming parameter $b^*(v)$ allowing a collision to occur is

$$b^*(v) = \left[\frac{\sigma(v)}{\pi} \right]^{1/2} = 10.5 \text{ \AA},$$

while the ‘orbiting’ radius $r_c(v)$ defined from a condition where $U_{\text{eff}}(r, v)$ is a maximum (or the top of the ‘centrifugal hump’), is

$$r_c(v) = \sqrt{2}b^*(v) = 7.4 \text{ \AA}.$$

This value is much larger than the characteristic sizes of atoms and small molecules. A criterion for the collision to occur is that the initial translational energy exceeded $U_{\text{eff}}(r_c)$, *i.e.*, the image point passed above the ‘centrifugal hump’ into the region of short distances.

The value of r_c may be regarded as an arbitrary border dividing the regions of interaction at short and long distances. The value of r_c enables an approximate estimate of the position of the ‘critical’ surface (transition state) in the theoretical analysis of the processes with the use of statistical and quasi-equilibrium approaches. The actual position of this surface should be

determined by the more precise variational methods. The corresponding criteria are found, for example, from the condition

$$\frac{\partial [W_{s-1}(E - U(r), r)]}{\partial r} = 0,$$

where $W_{s-1}(E - U(r), r)$ is the sum of the allowed states for all degrees of freedom, except for the reaction coordinate r , in the energy range $E - U(r)$; E is the total energy.

At short distances, the interaction between the species cannot be represented as a sum of electrostatic interactions. In this case, one has to use various quantum-chemical methods (*ab initio* and modifications of the semiempirical methods). Nowadays, it is possible to calculate the optimum geometry of stable ionic complexes, their dissociation energies, frequencies of normal vibrational modes and rotational constants with sufficient precision using computer programmes. In turn, these data allow one to find equilibrium constants and other kinetic characteristics.

When comparing ion–molecule processes with those involving neutral species, it should be noted that the bond energy of the complexes A^+B , *i.e.*, products of association of a molecular ion formed from a stable molecule A and a stable molecule B, is often much higher than the bond energy of neutral van der Waals clusters AB. At short distances, charge delocalisation is typical; distribution of the effective charge between the species can be represented as $A^{+(1-\delta)} - B^{\delta+}$.

It is noteworthy that some stable complex ions, such as $(O_2)_2^+$, $(CO)_2^+$ and $(NO)_2^+$, have a zigzag structure, *i.e.*, the axes of the molecules O_2 , CO and NO are not collinear but are parallel to each other and are coplanar. Let us also note that the multiplicity of the ground state of the $(O_2)_2^+$ complex equals four, which means that this state is formed with parallel spins of the ion (doublet) and the O_2 molecule (triplet).

The reactions of organic molecular ions with the precursor neutral molecules ($A^+ + A$) most commonly result in protonated ions AH^+ as the main products. In the association products of such ions (protonated dimers AH^+A), the species A appear non-equivalent, *i.e.*, they have different structures and effective charges. The structure of the complex ion should be represented as $A-H^+-A$, where one of the bonds is longer than the other by 40%–60%.

Thus, ion–molecule interactions are characterised by greater collision cross-sections than interactions of neutral species and wider ‘potential wells’ in the interactions at short distances. However, despite these features, the fundamental ideas of the theories used for three-body ion–molecule processes and those involving neutral species are alike. Still, the purely technical details can differ essentially in the calculations for particular systems.

3. Statistical methods for the calculation of the rate constants of three-body reactions

The statistical approaches have already been used for theoretical calculations of chemical reaction rates for nearly 70 years. The best known among them are the activated complex theory, the RRKM method (the quasi-equilibrium theory) and the statistical theory (phase space theory) taking the conservation of angular momentum into account. To date, these methods have been described in sufficient detail (see, *e.g.*, Refs 21–26).

The wide application of statistical methods to ionic processes started in the early 1950s after the statistical theory of mass spectra had appeared; this theory was used for the calculation of the energy distribution of fragmentation products (decomposition pathways) in the ionisation of molecules by electrons with different energies. Later, they found use in ion–molecule reactions.

The simplest form of the formula from transition state theory is

$$k(T) = \frac{k_B T}{h} \frac{Q^\ddagger}{Q} \exp\left(\frac{-E_a}{k_B T}\right),$$

where k_B is the Boltzmann constant, h is the Planck constant, T is the temperature, E_a is the activation energy, $Q^\#$ is the partition function for the transition state, and $Q = Q_A Q_B Q_{tr}$ is the product of the partition functions for the reacting species A and B and the translational statistical sum of their relative motion. The microcanonical equation of the RRKM theory has the form

$$k(E) = \frac{W^\#(E - E_0)}{h\rho},$$

where $W^\#(E - E_0)$ is the number of states (vibrational and rotational) in the energy range $(E - E_0)$, E is the total energy, E_0 is the dissociation energy and ρ is the total density of vibrational-rotational states of the reagents.

The most reliable results are obtained in the calculations of the rate constants with the use of phase space statistical theory that takes conservation of the total angular momentum (J) into account. This approach was used for calculations of the rate constants of three-body ion–molecule reactions (see, *e.g.*, Refs 49–51). An analogue of the Lindemann scheme of the association process is presented by the following scheme within the framework of the statistical model:⁵²

The rate constants of the reactions are presented in a microcanonical form, but a two-dimensional one,

$$k(E - E_0, J) = \frac{W^\#(E - E_0, J)}{h\rho}$$

and then used in this form in the expression for the overall reaction rate. For example, the association rate constant at small pressures is represented as:⁵²

$$k_t = k_f \beta k_c \int_0^\infty dE \int_0^{J^*(E-E_0)} \frac{F(E - E_0, J)}{k_d + k_c \beta [M]} dJ, \quad (6)$$

where β is the stabilisation probability, k_c is the rate constant for the corresponding collision, $F(E - E_0, J)$ is the function of distribution over the states taking the conservation of the angular momentum of the AB^{+*} complex into account, and J^* corresponds to the greatest possible angular momentum for the current value of E .

For the sake of clarity, the stabilisation rate constant in the formula (6) is presented not in the microcanonical, but in a simplified form $k_s = \beta k_c$, *i.e.*, as the product of the stabilisation efficiency per collision of the AB^{+*} complex with the species M by the rate constant for the corresponding collision. The relationships for the calculation of $F(E - E_0, J)$, $k_d(E - E_0, J)$ and the effective constant are reported in Ref. 52. Formula (6) is a stricter analogue of the expression (4).

The statistical approach was used to obtain the temperature dependence of the association rate constant at the low pressures limit. This constant was found to be mainly determined by the difference in the rotational degrees of freedom of the complex and the reagents (S)

$$k_t \simeq T^{-S/2}.$$

A correction (X) is introduced in order to take the contribution of vibrations into account, which depends on temperature and is estimated from the ratio of the statistical vibrational partition functions

$$k_t \simeq T^{-(S/2+X)}.$$

The effect of X becomes noticeable at rather high temperatures.

The use of the statistical theory requires detailed data on the activated complex and rather complicated calculations. The success of its application for particular systems often depends on how successfully the parameters of the complex are chosen and how meticulously the distribution functions are calculated.

It should be noted that even rather simple approaches can sometimes be used successfully for the interpretation of the experimental results. For example, the simplified statistical approach has been used⁵³ for the reaction

Statistical methods were used to find the boundaries of the area of experimental results processing where the dependences should conform to the behaviour at the low pressure limit for the ion–induced dipole⁵⁴ and ion–dipolar molecule association reactions.⁵⁵

A stricter description of the three-body association process involving complex molecules is based on the solution of the two-dimensional master equation [such as equation (6)]. The corresponding approaches have been considered in detail;⁵⁶ the methods of its solution with account of the specificity of the ion–molecule interaction can be found in Refs 57–59.

The approach with the use of the master equation allows one to take into account the contribution of weak stabilising collisions, where the third body M accepts a relatively small fraction of energy from AB^{+*} . The remaining energy is sufficient for the decomposition of the complex, while complete stabilisation requires several collisions of this kind.^{56–59}

For unimolecular decomposition of the AB^{+*} complex with the characteristics $E - E_0$ and J , the two-dimensional master equation taking into account both the change in the internal state of the complex and its decomposition into the original species, has the following form at any pressure:

$$\begin{aligned} k_{uni}g(\varepsilon, J) = \omega \int \int [P_{2D}(\varepsilon, J \rightarrow \varepsilon_1, J_1)g(\varepsilon_1, J_1) - \\ - P_{2D}(\varepsilon_1, J_1 \rightarrow \varepsilon, J)g(\varepsilon, J)]d\varepsilon_1 dJ_1 - k_d(\varepsilon, J)g(\varepsilon, J), \end{aligned} \quad (7)$$

where k_{uni} is the rate constant of the process, $\varepsilon = E - E_0$, ω is the frequency of collisions between AB^{+*} and the species M, $P_{2D}(\varepsilon, J \rightarrow \varepsilon_1, J_1)$ are the probabilities of transitions between the states $(\varepsilon, J \rightarrow \varepsilon_1, J_1)$ induced by collisions, and $g(\varepsilon, J)$ and $g(\varepsilon_1, J_1)$ are the populations of the states with a given energy and angular momentum. The separation of variables method was used to simplify equation (7):⁵⁷

$$P_{2D}(\varepsilon, J \rightarrow \varepsilon_1, J_1) = P_\varepsilon(\varepsilon, \varepsilon_1)P_J(J, J_1),$$

and present the functions in a form convenient for calculations.

Let us note some features of the use of the statistical theory for ion–molecule association. One of them concerns taking into account rotational freezing if the species B is a dipole. At long distances between A^+ and B, the species B is considered as a rotor, while at a distance shorter than some critical value r_{cr} estimated from the relationship

$$\frac{\mu_d q \cos \theta}{r_{cr}^2} \leq k_B T,$$

where μ_d is the dipole moment, it becomes an oscillator. For example, $r_{cr} = 13$ Å for the HCN molecule, and $r_{cr} = 23$ Å for acetonitrile. The expressions for the partition functions of the oscillator and the rotor are different. There is an approach which takes the ‘hidden rotor’ into account.⁵⁷

Yet another specific feature is the rather large moment of inertia of the transition state (J^*). Many of the methods for the calculation of the association rate constants from approximate solutions of the two-dimensional microcanonical master equation, which are used for the calculation of the association rate

constants of neutral species, can give wrong results when applied to ion–molecule processes. The approaches used for neutral systems are valid if the ratio of the moments of inertia of the transition state and the reagent is $I^*/I < 6$. This inequality usually holds for reactions of neutral species. If the inequality is not valid, the role of weak collisions increases. This factor can be taken into account using the reported procedures.⁵⁷

III. Experimental methods for the study of three-body ion–molecule reactions

Mass spectrometric methods are the most popular and convenient ones for the study of three-body ion–molecule reactions. The ratio of the number of three-body collisions (Z_3) to the number of two-body ones (Z_2) is proportional to the concentration of the species M in the reactor

$$\frac{Z_3}{Z_2} = \frac{k_t[M]}{k_f}.$$

Therefore, one has to increase the pressure in the region where these processes occur to increase the yield of the products. At a pressure of 10^{-8} Torr in the mass spectrometer, the effective time of formation of, e.g., a neon molecular ion in the reaction

is $\sim 10^3$ years.⁶⁰

The contribution of two-body ion–molecule reactions to the mass spectra obtained with mass spectrometers with conventional ion sources becomes appreciable at pressures of $\sim 10^{-6}$ Torr and a characteristic reaction time of *ca.* several microseconds. The study of three-body processes requires much higher pressures, *viz.*, at least 10^{-2} Torr. This implies that the reaction zone and the zone where ion separation according to their masses occurs should be separated, and in the second area the vacuum required for the analysis (no less than 10^{-6} Torr) should be provided.

In ordinary mass spectrometers, small ionisation chambers (with a characteristic size of 1 cm and even smaller) with rather narrow diaphragms (to minimise the gas flow into the high-vacuum zone) are used as a reactor.

Primary ions are usually formed under the action of a fast-electron beam. Diffusion of primary ions to the ionisation chamber walls is accompanied by various reactions. In the vicinity of the diaphragm, the ions are carried away by the gas flow into the high-vacuum zone, separated according to their masses by the mass analyser and detected. The processes occurring in the ionisation chambers at higher pressures have been considered elsewhere.^{7, 61, 62}

The ratio between the current of secondary ions I_2 formed in three-body reactions [see reaction (1)] to the current of primary ions I_1 at low degree of conversion is determined by the expression

$$\frac{I_2}{I_1} = k_t[\text{B}][\text{M}]\tau,$$

where k_t is the reaction rate constant (with the assumption of the low pressure limit) and τ is the lifetime of ions in the ionisation chamber. If $\text{B} = \text{M}$ (it is for such systems that ordinary mass spectrometric methods are most commonly used), then

$$\frac{I_2}{I_1} = k_t[\text{B}]^2\tau.$$

This formula is used to determine the rate constants of three-body reactions from the experimental results. Of greatest difficulty is the determination of τ , as the residence time of ions in the ionisation chamber is determined by many factors: diffusion, drift in the field of the space charge of ions, ‘penetration’ of the extracting field into the chamber, gas flow and geometric parameters of the chamber.

The problem can be simplified by using the pulse method suggested by Tal’roze and Frankevich.⁶³ These methods are

mainly used for the study of ion–molecule reactions at elevated pressures in the ionisation chamber.^{64–67}

Ionisation is carried out by a short pulse of electrons. The time dependences of the intensity of ion currents with different masses (over a sufficiently long time period) are studied with the use of a multichannel pulse analyser.^{64–66} Ionisation pulses are repeated with a certain frequency, and acquisition of data on the time dependence of the current for each type of ions is performed. This is necessary to obtain reliable results as regards the signal-to-noise ratio. Processing of the kinetic dependences of the ion mass spectra obtained in such a way enables one to find the reaction rate constants.

However, the pulse method suffers a number of drawbacks, the main one of which is that a large excess of the buffer gas is not allowed. If $\text{B} = \text{M}$, the mechanism of stabilisation of the complex is much more complicated, as the substitution of the species B, *i.e.*,

can contribute to certain extent.

Instead of the actual reaction time, the kinetic dependences include its analogue which is averaged in a rather complicated way.

The flow and drift mass spectrometry methods are the most reliable. The use of these methods for the study of the ion–molecule reaction kinetics has been reviewed rather thoroughly (see Refs 68 and 69).

The flow method (this is also called the flowing after glow method) makes it possible to study the reactions of ions thermolysed in the excess of a buffer gas (He, Ar, N₂, *etc.*) at temperatures from 80 K to several hundred degrees (Kelvin scale) and pressures from tenths of a Torr to several Torr.^{70–73}

In this method, the region where the primary ions are formed is spatially separated from the reaction zone, which begins where the neutral reagent is added to the flow of the buffer gas containing primary ions that had already been thermolysed. The reaction zone is ended by a nose cone with an orifice in the top, which withdraws a part of the flow for the ionic composition analysis. The time period during which the reactions are studied is determined by the flow rate and the place of injection of the neutral reagent and amounts to several milliseconds.

A useful modification of this method is the injection of ions, which have previously been separated by mass with another mass spectrometer, into the flow [the so-called SIFT (selected ion flow tube) technique]. The main drawback of the SIFT technique is that the conditions of injection from the low pressure zone into the reactor do not allow increasing the pressure in the latter above 1 Torr. Thus, despite the main advantage that only one type of primary ions is considered, the procedure for the processing of the kinetic result is simplified and the reliability is enhanced, the possibility of monitoring the changes in the reaction order occurring at pressures above 1 Torr for many three-body reactions is lost.

A similar principle for studying ion–molecule reactions underlies the drift methods. The motion of ions along the reactor is determined by the rate of the ion drift in an electrical field ($v_d \gg v_T$) generated by a potential difference between the guard rings located along the drift tube rather than by the gas flow rate. The drift methods allow one to study the dependences of the reaction rates on the energy of the relative translational motion of the colliding partners^{74–76} which can vary over a wide range (from the value close to that of ambient-temperature motion to several electron-volts in the centre-of-mass system) by varying the electrical field. At present, drift methods make use of the injection of mass-selected ions into the drift tube. This method is known as selected ion flow-drift tube (SIFDT) method.

In the drift methods, there are nonequilibrium distributions of species according to their energies. These can be characterised as the translational collision temperature of an ion and a molecule, the effective temperature of the internal degrees of freedom of an ion (the relevant formulas can be found in Refs 74 and 77) and the

Figure 2. Dependence of the effective rate constant for the process (8) on pressure at different values of E .

E / meV: (1) 41; (2) 42; (3) 47; (4) and (5) 49; (6) 59; (7) 61; (8) 75; (9) 87; (10) 100.

temperature of the neutral reactant, which is equal to the temperature of the reactor walls.

If the translational energy (E) in collisions of rather heavy species (≥ 28 amu) is less than 0.1 eV and helium is used as the buffer gas, the effective temperature of the internal degrees of freedom of an ion does not differ much from the ambient temperature. This allows one to study correctly enough the dependences of the association rate constants on E in the range from 0.04 to 0.1 eV.⁷⁸ Figure 2 can be regarded as an example, it presents the dependences of the effective rate constant for the reaction

on the helium pressure, and Fig. 3 presents the dependence of the ratio of the rate constants for stabilisation in collisions of the complex with helium to the spontaneous reverse decay rate constant of the collisional complex at different E values.

Figure 3. Dependence of the ratio of the rate constant for collisional stabilisation to the rate constant for the collisional complex decay on E for the process (8).

The drift method allows one to study, over a wide energy range, the competition of the association channel with other channels, for example, endothermic charge transfer,⁷⁹ or with reactions accompanied by species rearrangement.⁸⁰

At sufficiently high energy of species relative translational motion in the centre-of-mass system, the SIFDT method is very helpful for the studies of the collision-induced dissociation of stable ionic complexes AB^+ , since the reaction zone contains no neutral reagent B and the reverse process, *viz.*, association, does not occur there. The dissociation of a series of complex ions has been studied in detail.⁷⁷

A procedure with a modified flow reactor has been developed for the measurement of the rate constants for ion–molecule reactions at low temperatures in which the reactions were studied

Figure 4. A scheme of an experimental set-up for low-temperature studies of ion-molecule reactions:⁸⁹

(1) gas-dynamic nozzle with a pulse valve for gas flooding; (2) focus of ionising laser irradiation; (3) a plate for the deflection of ions to the input of the mass spectrometer; (4) time-of-flight mass spectrometer; (5) micro-channel plates; (6) collector of secondary electrons.

in a cooled supersonic flow.^{31,81–86} A strongly cooled flow is obtained by adiabatic gas expansion following its discharge through a nozzle or an orifice in a thin wall.

A scheme of this type of experimental set-up is shown in Fig. 4. The gas expands through a pulse nozzle. The ionising laser radiation is focused on the axis of the supersonic flow at a point located sufficiently close to the nozzle. The ions moving together with the supersonic flow react with molecules. When the ions reach the level of the repeller plate, the pulse electrical field directs them into the time-of-flight mass-spectrometer moved along the flow; the mass-spectrometer records the ion composition of the beam.

The yield of secondary ions in reactions can be increased not only by increasing the gas pressure, but also by increasing the time of ion residence in the reactor under low pressure conditions. Various types of ionic traps are widely used for this purpose in mass spectrometry.^{87–93} In the flow and drift methods, the order of characteristic reaction time is 10^{-3} s, while in ionic traps this time can be many orders longer. In ion cyclotron resonance (ICR) spectrometers, the cell retention time for an ion can amount to several hours at a very high vacuum. However, kinetic measurements require higher pressures, but under these conditions the reaction time is usually less than a minute.

In radio frequency traps, such as QISTOR, effective retention of ions requires the presence of a buffer gas (usually, helium) at a pressure of 10^{-3} Torr. However, the ion translational energy in these traps is rather high (> 1 eV), hence, they can be used only for studying the dissociation of complex ions that have been previously injected into them.

Yet more promising are multipole radio-frequency traps (of the ‘ion guide’ type)⁹³ in which the energy of ions is not high. The ionic-trap and ICR methods, like the drift method, allow variation of the translational energy of the reacting ions.

The ICR method is limited to small pressures. Therefore, it can be used for studying the association reactions of relatively complex species, with rather long complex lifetimes (of about a microsecond and more). Only the reagent can act as the stabilising species in this case. However, this method proved to be convenient for radiation stabilisation studies. This can be clearly demonstrated using the Lindemann scheme with allowance for radiative stabilisation with the rate constant

$$k_r = \frac{1}{\tau_r},$$

where τ_r is the radiation lifetime of the species.

The effective rate constant of association (represented as a second-order reaction) has the form

$$k_{\text{ef}} = \frac{k_f k_s [\text{M}]}{k_d + k_r + k_s [\text{M}]} + \frac{k_f k_r}{k_d + k_r + k_s [\text{M}]} \quad (9)$$

and has a nonzero value when $[\text{M}]$ is extrapolated to zero. Experimental studies of the processes taking into account the competition between the collisional and radiative stabilisation are described in Refs 94–100. A more perfect statistical model for data interpretation [in comparison with that used to derive formula (9)] is reported elsewhere.^{101, 102}

The results of the rate constant measurements for three-body ion–molecule reactions using the methods described above are tabulated in reference books.^{103, 104}

IV. Temperature dependences of association rate constants

As noted above, the temperature dependence of the association reaction is a negative power function

$$k \approx T^{-n}. \quad (10)$$

At relatively low temperatures, where the energy difference between the vibrational levels is much greater than the thermal energy ($h\nu \gg k_B T$) for simple molecules, the contribution of the relative vibrational partition functions to the rate constant can be neglected. Under nonequilibrium conditions where the effective temperatures of the internal degrees of freedom for ions (T_i), neutral molecules (T_m) and collisional complexes (T_c) differ (as in the case of ion drift), the temperature dependence of the association rate constant at the low pressure limit has the form⁷⁶

$$k \propto \frac{T_c^{r_c/2}}{T_{\text{tr}}^{3/2} T_i^{r_i/2} T_m^{r_m/2}},$$

where T_{tr} is the temperature that characterises the energy of the relative motion of the colliding molecules; r_c , r_i and r_m are the numbers of the rotational degrees of freedom of a complex, an ion and a neutral molecule, respectively. It should be noted that the electrical field can affect the translational temperature of ions and their internal energy but not the temperature of neutral species. The validity of this formula was confirmed experimentally in studies of ion drift in an electrostatic field.

In the case of equilibrium temperature, the exponent n is determined by the relationship

$$n = \frac{3 - r_c + r_i + r_m}{2}. \quad (11)$$

It should be noted that both the statistical theory, which takes conservation of the angular momentum into account, and the simplified theory, which disregards this, give identical expressions for n .¹⁰⁵

It should be noted that the statistical theory is applicable only to the reactions occurring with the formation of an intermediate complex with a sufficiently ‘deep potential well’, which is the reason for its long lifetime necessary for the efficient energy exchange between the degrees of freedom. For example, the temperature dependence of the rate constant for the process

is rather well described by the statistical theory, $n = 2$, whereas for a similar process

$n = 4$.

For complexes with a small bond energy, a transition from statistical to dynamic control of the lifetime of the intermediate complex takes place.^{105, 106} In this case, the lifetime of the complex is given by the effective time of collision, *i.e.*, the time during which the species remain sufficiently close to each other. This value is estimated by numeric calculation of trajectories. The large exponent n for the formation of the intermediate complex

$(\text{NO}^+ \text{N}_2)^*$ is a consequence of dynamic restrictions for the total rotational energy of the colliding species (at fixed energy, collisions are possible only at small values of the total orbital momentum).

As the molecules become more complex and/or the temperature increases, it is necessary to take the contribution of the vibrational partition functions of the colliding species and the intermediate complex into account. Relatively simple models of harmonic oscillators are used for the estimation of this contribution. The corresponding correction of the parameter n in the formula (10) gives results which agree satisfactorily with the experiment.^{107, 108}

The contribution of the aforementioned radiative processes to the stabilisation of complex molecules, *viz.*, association products, can increase considerably. The competition between the channels for complicated hydrocarbon ion–molecule complexes was considered in detail;^{94, 109} it was shown that their ratio evaluated using the approach mentioned above agrees satisfactorily with the experiment. For very complicated systems, the assumption of the uniform energy distribution between the degrees of freedom of a collisional complex may no longer agree with the experimental results.¹¹⁰

V. Some results of studies

A new type of isotope effect related to the involvement of several potential energy surfaces with different symmetry types in one process has been discovered in three-body ion–molecule association processes. The simplest of the processes studied is the association in helium¹¹¹

In a mixture with approximately equal concentrations of ^3He and ^4He , the molecular ions with the isotope composition $^3\text{He}^4\text{He}^+$ are formed with a higher efficiency than the $^3\text{He}^3\text{He}^+$ and $^4\text{He}^4\text{He}^+$ ions. The relative concentration of the mixed molecular helium ions [$^3\text{He}^4\text{He}^+$] exceeded approximately 2.5 times the statistical value, which would be observed if equal association rate constants independent of the isotope composition were assumed.

This isotope effect was rationalised as follows. Only for a half of collisions between the species of identical isotope composition is the interaction potential defined by the term $^2\Sigma_u^+$ of the ion He_2^+ , which corresponds to attraction and passes through a minimum; for the other half of the collisions, the potential interaction energy corresponds only to the repulsive term $^2\Sigma_g^+$, and the species cannot approach for short distances where the formation of a bound state becomes possible (Fig. 5a).

Figure 5. Dependences of the potential energy on the internuclear distance for the system $\text{He}^+ + \text{He}$.¹¹¹ (a) the $^4\text{He}^+ + ^4\text{He}$ system, (1) $^2\Sigma_g^+$, (2) $^2\Sigma_u^+$; (b) the $^3\text{He}^+ + ^4\text{He}$ (1) and $^4\text{He}^+ + ^3\text{He}$ (2) systems.

If the isotopes are different, at sufficiently long distances between the species, along with the term of the original species there is a term with a very small energy difference corresponding

to the charge transfer products, *i.e.*, there is a splitting of terms for the ${}^3\text{He}^+ + {}^4\text{He}$ and ${}^4\text{He}^+ + {}^3\text{He}$ systems (Fig. 5*b*). It is assumed that the binding state of the molecular ion becomes available in every collision, as the transition to the binding term occurs in a nonadiabatic transition in the area indicated in the Figure.

The quantum-mechanical restrictions for symmetry (more exactly, the restrictions due to the identity of species) forbid a transition into the ground state from the ${}^2\Sigma_g^+$ state for identical isotopes. Thus, the isotope effect depends not only on the masses of the species involved in the process, but also on this type of quantum-mechanical restrictions.

Let us compare, for example, the kinetic isotope effect related to the mass difference with the isotope effect due to the symmetry (identity or nonidentity) of the species for the process

This process has not been studied experimentally yet. The interest in it is due to the fact that the difference between the ionisation potentials of ${}^{20}\text{Ne}$ and ${}^{22}\text{Ne}$, which determines the energy difference of terms, is much smaller than that for helium. In addition, the hyperfine structure for ions is absent (its possible effect has not been discussed) because the nuclei of these isotopes have no magnetic moments.

The magnitude of the isotope effect due to the mass difference only is estimated as $\sim 3\%$. Assuming, as in the case of helium, that upon collision of homonuclear species the potential of interaction between them is determined with equal probability by the terms ${}^2\Sigma_u^+$ and ${}^2\Sigma_g^+$ and that for every collision of heteronuclear species the potential corresponds only to the binding term, we find that the ratio of the association rate constant k_{20-22} , estimated taking into account the mass difference and the nonidentity of the nuclei, to the rate constant k_{st} found ignoring these effects is

$$\frac{k_{20-22}}{k_{\text{st}}} = 2.06.$$

The even greater magnitude of the kinetic isotope effect for the ${}^3\text{He}-{}^4\text{He}$ mixture is due to the fact that the symmetry restrictions manifest themselves not only in the complex formation step but also in its stabilisation step.

Let us note that the isotopes formed in the three-body association can then participate in fast bimolecular switching reactions of the type

There are no symmetry restrictions for these reactions, and they can rapidly result in an equilibrium isotope distribution in the molecular ions. Therefore, the isotope effect described above is observable only at relatively small degrees of conversion determined by the ratio between the association and switching rate constants.

This type of kinetic isotope effect has been also found experimentally in three-body reactions involving molecular species. The theoretical explanation of the effect in this case is much more complicated than in the case of systems involving atomic species.

The enrichment in the ${}^{17}\text{O}$ and ${}^{18}\text{O}$ isotopes upon the formation of the O_4^+ ions in the reaction $\text{O}_4^+ + \text{O}_2 + \text{M}$ was studied.¹¹² It was found that the isotope effect strongly depends on the energy of the ionising electrons used for the formation of the primary O_2^+ ions. The relative enrichment of the dimers in the labelled molecules (in comparison with the statistical enrichment) was found to be ~ 10 at E_i close to the O_2 ionisation threshold (12.077 eV). However, the enrichment at an energy of the electrons above 40 eV decreases to a virtually statistical value.

In addition, the yield of ionic dimers O_4^+ from O_2^+ ions formed by electrons at E_i close to the ionisation threshold is much lower than that from ions obtained at higher electron energies. All this is explained¹¹² by the above-mentioned symmetry restriction upon the formation of a bound electronic state of O_4^+ in a collision of O_2^+

with O_2 (${}^3\Pi_g$). The restriction disappears if O_2^+ (or O_2) is a heteronuclear species.

The efficiency of the $(\text{CO}_2)_2^+$ formation in the $\text{CO}_2^+ + \text{CO}_2 + \text{M}$ reaction also increases as the energy of ionising electrons is increased.¹¹³ The symmetry-induced kinetic isotope effect was also studied for this process with the use of ${}^{13}\text{C}$ and ${}^{18}\text{O}$ labels. If the heavy oxygen label ${}^{18}\text{O}$ is used, an increase in the ionising electron energy from 25 to 100 eV results in a gradual decrease in the heavy isotope enrichment factor from 27 to 8. For ${}^{12}\text{C}$ and ${}^{18}\text{O}$, the heavy isotope enrichment factor is ~ 5 and virtually does not depend on the energy of the ionising electrons.

It is of note that the kinetic isotope effect is also manifested in the clusterisation of ions $(\text{CO}_2)_n^+$ where one of the CO_2 molecules is replaced by another species with a closed electron shell. For example, the isotope effect was observed in the formation of cluster ions in reactions of ArCO_2^+ complexes (see Ref. 114). It was shown that the CO_2 molecules containing heavy isotopes ${}^{17}\text{O}$ and ${}^{18}\text{O}$ are incorporated into the ArCO_2^+ clusters 20 times more efficiently than a statistical combinatorial estimate would predict. The studies of the symmetry-induced kinetic isotope effect in three-body ion–molecule reactions have been reviewed.¹¹⁵

Let us discuss the results of the experiments at ultralow temperatures in a cooled gas-dynamic flow. Figure 6 presents the temperature dependence of the rate constant for the reaction

In a wide range from moderate (~ 300 K) to low temperatures (~ 0.1 K), the rate constant cannot be described by the relationship (10) with an index n which does not depend on T . It was found that $n = 1.8$ at low temperatures, while at moderate temperatures n is much smaller. The average value $\langle n \rangle$ over the entire temperature range studied is equal to 1.2. It should be recalled that the theoretical n value for the association of monatomic species should be equal to 0.75.

Figure 6. Temperature dependence of the rate constant for reaction (14).¹¹⁶

Similar deviations from the theoretical dependence are also observed for other reactions involving monatomic species:

The values of n are given for $T \simeq 0.1$ K.

For the above process (12) involving molecular nitrogen in the same wide temperature range, the expression (10) at $n = 2$ describes well the experimental temperature dependence of the rate constant (Fig. 7). It would be interesting to study analogous temperature dependences for n at low T for the formation of weakly bound complexes, for example, for the reaction (13) for which n is anomalously high at moderate temperatures.

Figure 7. Temperature dependence of the rate constant for reaction (12).¹¹⁶

The points refer to the data from different authors.

The radio frequency ion trap method with cooled walls was used to measure the rate constants for clusterisation and fragmentation

at 10 K for odd i in normal hydrogen $n\text{-H}_2$ with an equilibrium ratio of the *ortho*- and *para*-isomers and in hydrogen enriched in the *para*-component, $p\text{-H}_2$.⁹² The data obtained are presented in Fig. 8. The difference between the curves for $n\text{-H}_2$ and $p\text{-H}_2$ is due to the rotational energy of the molecule with total nuclear momentum $J = 1$ in the *ortho*-modification of molecular hydrogen. The bond energy of the H_2 molecule with the H_i^+ cluster changes from several kcal mol⁻¹ at small i to a value comparable with the heat of evaporation of liquid hydrogen (0.2 kcal mol⁻¹).

Figure 8. Dependence of the rate constant for the formation of odd hydrogen ionic clusters in the reaction $\text{H}_i^+ + 2\text{H}_2$ on the relative size change $i/(i+2)$ of an ionic cluster H_i^+ at low temperatures.⁹² The points in the curve 1 were obtained in an experiment with an equilibrium concentration of the *para*- and *ortho*-modifications in H_2 , those in the curve 2, in hydrogen enriched with the *para*-component.

This example demonstrates a transition from clusters with sufficiently strong chemical bonds to clusters with van der Waals bonds with an increase in the number of species.

Experiments also give information on the cluster structure. For example, a decrease in the association rate constant with an increase in the cluster size at $i = 9$ is due to the beginning of formation of the second shell around the H_5^+ skeleton. The rate decrease at $i > 15$ is due to a decrease in the efficiency of stabilisation by the third body.^{41, 73}

The effect of the particular features of the complex structure on the association rate constant is demonstrated in Fig. 9, which

Figure 9. Dependence of the rate constant for reaction (15) on the number of atoms in an ionic copper cluster.⁷³

The points refer to the experiment; the curve gives the calculation in accordance with the RRKM theory under the assumption of a 'soft' transition state. The dotted line connects the calculated points obtained for a 'hard' transition state for $n = 1$ and 2.

shows the experimental dependence of the association rate constant for copper ionic clusters Cu_n^+ with CO molecules

on the magnitude of n .⁷³ On going from the Cu^+ ion to its dimer Cu_2^+ , the rate constant increases by about an order of magnitude. However, the rate constant decreases somewhat on going from Cu_2^+ to Cu_3^+ . This rather unexpected result is related to the specific features of the trimer electronic structure, which are unknown.[‡] The passage from Cu_3^+ to Cu_4^+ again results in an increase in the reaction rate constant by an order of magnitude.

Further increase in the cluster size results in a slower increase in the rate constant, which approaches a steady level at $n = 7$.

The agreement between the calculated and experimental points for the rate constants of the reactions of the Cu_n^+ ions with $n \geq 3$ is good, but the experimental points for Cu^+ and Cu_2^+ 'fall out'. If another type of transition states (so-called hard ones) are assumed for the $\text{Cu}^+ \text{CO}$ and $\text{Cu}_2^+ \text{CO}$ complexes, the agreement for these points with the calculated data is improved considerably.

The rates of three-body association processes usually decrease with an increase in the temperature and translational energy of ions. There is only a single publication¹¹⁷ where the effective rate constant for the reaction

is reported to be independent of the translational energy of the ions over a wide energy range. However, in this case it cannot be ruled out that the $\text{C}_{12}\text{H}_{12}^+$ ions are products of associative ionisation of highly excited benzene molecules¹¹⁸

the rate of this process is not affected by electrical fields that accelerate the ions.¹¹⁷

However, some data indicate that the efficiency of association in certain systems is increased with an increase in the translational energy of the colliding species. For example, it was found that collisions of accelerated fullerene ions with inert gas atoms produce long-lived excited complexes with a noble gas atom inside the molecular cage of the fullerene.^{119, 120} These are threshold processes that occur only at sufficiently high collision energies.

[‡] A semiempirical calculation by one of the authors suggests that for $\text{Cu}_2^+ \text{CO}$ the almost T-shaped structure of the $(\text{Cu}-\text{CO}-\text{Cu})^+$ complex in which the carbon atom is arranged between the two copper atoms has the lowest energy.

The formation of long-lived excited complexes in bimolecular processes also occurs in collisions of ions of large biological molecules with small molecules like NH_3 and CH_4 .¹¹⁸ Probably, association is possible in these systems, and its efficiency increases with an increase in the translational energy of ions.

Of the three-body ion–molecule processes, the association processes have been studied most thoroughly to date. However, three-body exchange reactions, which have been little studied thus far, are of considerable interest. There are reasons to believe that at higher gas pressures three-body reactions resulting in the same products as bimolecular ones

can compete successfully with some slow exothermic bimolecular reactions of the type

The reactions

(rate constant $3 \times 10^{-27} \text{ cm}^6 \text{ s}^{-1}$) and

with a rate constant less than $10^{-11} \text{ cm}^3 \text{ s}^{-1}$ can serve as examples.^{14, 121}

The detailed mechanisms of these processes have not been sufficiently studied yet. Studies of the dependence of the reaction rate on pressure^{122, 123} and temperature¹²⁴ revealed an abnormal behaviour of the $[\text{SF}_5 + \text{H}_2\text{O}]$ complex. This complex can probably exist in different configurations with considerably different reactivities.

VI. Conclusion

Intense studies on ion–molecule reactions in gases have already been continuing for almost half a century after V L Tal'roze discovered these reactions in mixtures of hydrocarbons in the early 1950's. About 15 years later, intense studies of three-body reactions began in parallel with bimolecular reactions; the contribution of the former becomes important upon increasing the pressure in the reaction region. At present, there is a rather extensive experimental data base on the rate constants for such reactions; however, its bulk is about 30 times smaller than that of a similar base for bimolecular ion–molecule reactions.

After the discovery of ion–molecule reactions, it was considered that all of them are fast if this is allowed by their thermochemistry. The main reason in favour of this was the assumption that the activation barriers appearing in the rearrangement of species (characteristic of reactions between neutral species) are already inside the 'potential well' arising due to strong electrostatic ion-dipole or polarisation attraction. In addition, it was shown that the majority of ion–molecule reactions result in an intermediate long-lived complex, and this mechanism is more typical than the 'direct' mechanisms.

It was thus concluded that exothermic ion–molecule reactions are a specific type of process different from similar reactions between neutral species. However, many exceptions from this concept were found later. The presence of energy barriers and the effect of various types of internal excitation on the reaction rates were observed. In view of this, it was concluded that there is no fundamental difference between the mechanisms of ion–molecule reactions and reactions of neutral species.

In fact, the energy barrier exists in the direction of the reaction coordinate, while the potential well originating from electrostatic attraction between an ion and a molecule corresponds to another coordinate describing the distance between the species. The effect of the electrostatic attraction can be demonstrated in a simplified form as a decrease in potential energy relative to the level of dissociation into the original species. The difference between the total energy and the energy barrier level (which, in rare cases, can

even be negative) for ion–molecule system is most commonly different from that for neutral species. However, this is most likely a quantitative parameter, and the theoretical approaches for the consideration of ion–molecule reactions do not differ fundamentally.

It is of note that the role of the ion–molecule attraction should not be overestimated. The electrostatic interactions cannot be extrapolated for the short distance range. When the reacting partners approach each other, considerable redistribution of the effective charge in a system of colliding species occurs, and the character of interaction alters.

However, owing to redistribution of the effective charge, which can occur even at rather long distances between the partners, the properties of the reagents (geometry, bond energies, vibration frequencies) also change. This charge redistribution is more typical of ion–molecule collisions than of collisions involving neutral species (except for the systems with a weakly bonded electron).

Activation is usually non-typical of ion–molecule association reactions. However, specific effects related to the presence of charge in the system manifest themselves in full measure. This corresponds to a deeper global minimum of the potential energy surface for the interaction between the reagents, *i.e.*, an increase in the dissociation energy. The potential well becomes much wider, which results in an increase in the number of internal energy levels. As a result, the rate constants for ion–molecule association appear to be much higher than those for similar systems of neutral species. Upon this is further superimposed the effect of larger collision cross-sections due to long-range interaction.

Despite the similarity of the theoretical approaches for three-body processes involving only neutral and ion-neutral species, the calculation details differ in the practical calculations, where it is necessary to use certain approximations. For ion–molecule association processes, anisotropic effects are essential (an example of their calculation within the framework of the statistical theory was described above). Calculations of potential energy surfaces (which commonly have local minima in addition to global ones in ion–molecule systems) and the corresponding trajectory calculations are also important.

Rather recently, a quasi-classical method has appeared, *viz.*, SACM (statistical adiabatic channel model), for the calculation of ion capture by molecules.¹²⁵ Rather accurate algorithms of trajectory calculations for these processes^{126–129} and three-body collisions¹³⁰ have also been developed. However, a strict theoretical consideration of low-temperature experiments requires the development of purely quantum models.

Abstract. The review surveys advances in high-resolution solid-state ¹H and ¹³C NMR spectroscopy applied to studies of conversions of hydrocarbons and alcohols on zeolite catalysts of an acidic nature. The potential of NMR spectroscopy in studies of mechanisms of chemical reactions and analysis of compounds formed *in situ* is considered. The bibliography includes 134 references.

I. Introduction

NMR spectroscopy has been used for studying solid heterogeneous catalysts and surface chemical reactions over several decades.¹ However, impressive progress in this field has been achieved only with the advent of special techniques for recording NMR spectra and with the development of superconducting magnets producing strong magnetic fields (7–18 T). Thus the application of the magic-angle-spinning (MAS) technique in which the sample is rotated rapidly about an axis subtending a magic angle (57°48'8'')^{2–4} with respect to the external magnetic field (2–35 kHz) leads to substantial narrowing of NMR signals for nuclei of both solid catalysts (¹H, ¹⁷O, ²⁷Al, ²⁹Si and ⁵¹V) and organic molecules adsorbed on the catalyst surface (¹H, ¹³C, ¹⁵N and ³¹P). The implementation of a technique for recording NMR spectra with the use of cross-polarisation simultaneously with high-power proton decoupling^{5–7} enhances the sensitivity of NMR spectroscopy a hundred times and makes possible observations of signals of molecules adsorbed on the catalyst surface.

Presently, high-resolution solid-state NMR spectroscopy is widely used for both characterising structures of heterogeneous catalysts^{1,8–13} and studying conversions of organic molecules on their surfaces.^{13–17} In many cases, NMR spectroscopy appears to be the unique physical method which provides data on reaction mechanisms and enables one to perform reliable analysis of

compounds formed *in situ*, to determine their compositions and structures and to make conclusions about chemical processes that occur on the catalyst surface. Hence, one can go from the hypothetical notion of reaction mechanisms to the understanding of their true mechanisms.

NMR spectroscopy is particularly helpful in studying catalytic conversions at low (as regards traditional organic catalysis) temperatures, for example, in studying low-temperature alkene conversions on zeolites. This field of potentially important low-temperature chemical conversions remains poorly studied due to problems associated with analysis of undesorbable compounds.

Recently, studies of conversions of hydrocarbons and alcohols on zeolites by NMR spectroscopy have attracted growing interest in connection with the solution of the following practical problems:

— a search for ways of enhancing the selectivity of the yields of C₄–C₅ alkenes in the course of catalytic cracking based on zeolite catalysts (HY, USY and HZSM-5);

— synthesis of a motor fuel from methanol on HZSM-5 zeolite.¹⁸

Discussion about the role of various intermediates, *viz.*, alkoxides and carbenium ions, in catalytic hydrocarbon conversions on solid acids (zeolites and amorphous aluminosilicates), which has lasted for the last decade, gave additional impetus to the application of NMR spectroscopy to the studies of hydrocarbon conversions.

The present review surveys the most interesting results of studies of conversions of various hydrocarbons on solid zeolite catalysts of acidic nature which have been performed in the leading world's laboratories with the use of NMR spectroscopy. The first results of studies of hydrocarbon (alkene) conversions are compared with the results obtained by various research groups within the last five years. The possibilities of other methods (primarily, of IR spectroscopy) in studies of hydrocarbon conversions are considered.

In the present review, the discussion is restricted to the results of chemical studies[‡] obtained by NMR spectroscopy.

[‡] Experimental details and discussion of various possibilities of the use of high-resolution solid-state NMR spectroscopy for characterisation of catalysts and processes that occur on their surfaces have been reported in the literature.^{10–13, 16, 19, 20}

II. Alkene oligomerisation

1. Adsorbed products of low-temperature alkene oligomerisation

Until recently, the nature of hydrocarbon products which were formed upon low-temperature oligomerisation of alkenes (ethylene, propene or isobutene) on acidic forms of zeolites (for example, on the HZSM-5 zeolite), remained unclear and was the subject of discussion.^{21–38} It was reasonable to suggest that alkene oligomerisation in the presence of an acidic catalyst should afford a long-chain alkene. However, signals at 1660–1670 [$\nu(\text{C}=\text{C})$] and 3020–3090 cm^{-1} [$\nu(\text{C}=\text{H})$] expected for the double bonds³⁹ were not observed in the IR spectra of adsorbed oligomeric products.^{21–24, 27–29, 31, 33} Signals with the chemical shifts at δ 110–140 typical of alkene double bonds⁴⁰ were absent in the ^{13}C NMR spectra as well.^{24–26, 30, 32, 34–38} The only identified signals were those of saturated hydrocarbon fragments of oligomeric products.^{21–38}

The absence of signals of alkene fragments in the IR and NMR spectra has been explained within the frameworks of two alternative hypotheses. According to the first hypothesis, adsorbed oligomers are hydrocarbon fragments covalently bonded to oxygen atoms of the zeolite lattice, *i.e.*, the hypothesis postulates that oligomeric alkoxides (alkyl silyl ethers), which do not contain double bonds, are formed.^{32–34, 38} According to the second hypothesis, adsorbed oligomers are oligomeric aliphatic carbenium ions,^{27, 28, 37} which do not contain double bonds as well. Unfortunately, both hypotheses are self-contradictory. Actually, if oligomers were alkoxides, the ^{13}C NMR spectra should have signals for the carbon atoms of the C–O–Si fragment at δ 70–90.^{40, 41} However, in a series of studies,^{24–26, 30, 32, 34–38} no mention of these signals was presented, while in other studies^{15, 35, 38, 42–48} these signals were observed only in the case of small hydrocarbon fragments (Me, Prⁱ, Bu^t and Buⁱ) bound to the zeolite framework.

The same is true for carbenium ions containing long-chain hydrocarbon fragments for which signals at δ 300–330 (a carbon atom that carries a positive charge)^{49–51} in the ^{13}C NMR spectra or bands at 1260–1295 cm^{-1} [$\nu(\text{C}^+-\text{C})$ stretching vibration]^{52, 53} in the IR spectra would be expected. However, neither the IR spectra nor the NMR spectra had these signals.

a. Alkoxide nature of the adsorbed oligomers

The ^{13}C CP/MAS NMR spectrum[§] of products of ethylene oligomerisation on the HZSM-5 zeolite at 296 K is shown in Fig. 1.⁵⁴ On the whole, this spectrum is identical with that obtained previously by van den Berg and co-workers for ethylene oligomers.³⁰ The signals at δ 14, 22 and 33 were assigned to the terminal CH_3 groups, to the adjacent CH_2 groups and to internal CH_2 groups of linear hydrocarbon fragments of oligomers, respectively.

The spectrum has no signals with noticeable intensities at δ 110–140 (for alkene fragments)⁴⁰ or at δ 300–330 (for carbenium ions).^{49–51} However, substantial enhancement of the spectrum made it possible to detect a weak broad signal at δ 89, which indicates that adsorbed oligomers contain carbon atoms bound to oxygen atoms of the zeolite framework, *i.e.*, is indicative of the presence of C–O–Si fragments.^{41–45} An analogous signal for C–O–Si fragments at δ 86, while substantially more intense, was observed for isobutene oligomers formed upon dehydration

Figure 1. The ^{13}C CP/MAS NMR spectrum of oligomerisation products of ethylene (40% $^{13}\text{CH}_2=\text{CH}_2$) on HZSM-5 zeolite at 296 K. Hereinafter, peaks due to the rotation of the sample are marked with asterisks.

of *tert*-butyl alcohol on HZSM-5 zeolite.^{35, 38} Therefore, evidence for the alkoxide nature of the adsorbed oligomers was obtained.[¶]

b. Carbenium-ion properties of the adsorbed oligomers

An interesting experiment, which gave a deeper insight into the nature of the adsorbed oligomers, was described in Ref. 37. Studies of a possible ethylene oligomerisation product, *viz.*, oct-1-ene containing the selectively ^{13}C -labelled terminal $=\text{CH}_2$ group, adsorbed on the HZSM-5 zeolite demonstrated that the terminal $=^{13}\text{CH}_2$ group of oct-1-ene was converted into the ^{13}C -labelled terminal methyl group immediately after adsorption (Fig. 2). Then the intensity of the signal for the carbon atom of the terminal $^{13}\text{CH}_3$ group at δ 14.3 decreased and the intensities of the signals of internal CH_2 groups of oct-1-ene at δ 30.0 increased with time. This is indicative of the transfer of the selective ^{13}C label from the methyl group of oct-1-ene to its CH_2 groups with the characteristic half-reaction time $\tau_{1/2} \sim 4$ h (at 290 K). The redistribution of the carbon label in the adsorbed oct-1-ene was completed in $t > 20$ h. It is known that the redistribution of

Figure 2. Change in the ^{13}C CP/MAS NMR spectrum of oct-1-ene (containing the ^{13}C -labelled terminal $=\text{CH}_2$ group) adsorbed on HZSM-5 zeolite ($T = 290$ K) with time.³⁷ Time/h: 0.17 (a), 2.83 (b), 6.17 (c), 12.83 (d), 53 (e).

§ The ^{13}C CP/MAS NMR spectrum was recorded with the use of the magic-angle-spinning (MAS) technique at the spinning frequency of 2500–5000 Hz using cross-polarisation (CP).

¶ An explanation of the reasons for the low intensity of the signal for the carbon atom of the COSi fragment in adsorbed ethylene oligomers is offered below, where the interpretation of the spectra is discussed.

carbon labels is typical only of carbenium ions existing as stable species in solutions of superacids.^{49–51, 55–57} Based on the afore-said, it was concluded that carbenium ions were formed upon adsorption of oct-1-ene on the HZSM-5 zeolite. The changes observed in the NMR spectrum are attributable to the following reactions (Scheme 1):

In the adsorption of oct-1-ene on zeolite, the proton of the acidic OH group of the zeolite is transferred to the oct-1-ene molecule. In this case, the terminal =CH₂ group is converted into the terminal CH₃ group simultaneously with the formation of a carbenium ion. In the cation formed, the ¹³C label is redistributed through the formation of protonated cyclopropane intermediates,^{49, 50, 55–57} which leads to a decrease in the intensity of the signal for the CH₃ group and to an increase in the intensities of the signals for the internal CH₂ groups with time (Fig. 2).

In spite of the label redistribution typical only of carbenium ions, signals at δ 300–330, which are indicative of the presence of carbenium ions in the system, were not observed in the spectrum. It was thus concluded that either the concentration of the cations formed was too low or these cations were short-lived transient species.

Later, the conclusion that carbenium ions exist in small amounts among adsorbed oligomers was confirmed by the chemical reaction at room temperature involving the adsorbed oligomers, which is characteristic of carbenium ions. It is known that carbenium ions readily react with carbon monoxide in solutions of strong acids^{58, 59} to form carboxylic acids. Consequently, carbenium ions formed among oligomeric products would be expected to react with CO and water to form carboxylic acids. Actually, simultaneous adsorption of CO and water on a zeolite specimen containing ethylene oligomers resulted in conversion of oligomers into a mixture of the corresponding oligomeric carboxylic acids (Scheme 2), which is evidenced by the signal of carboxyl groups at δ 189 in the ¹³C CP/MAS NMR spectrum (Fig. 3).^{60, 61}

The formation of carboxylic acids and the redistribution of the selective ¹³C label unambiguously suggest that carbenium ions were present among the adsorbed oligomers. In addition, after completion of the reaction of oligomers with CO and H₂O, signals for oligomeric alkoxides at δ 89 were no longer observed in the ¹³C NMR spectrum (*cf.* Figs 1 and 3), which is indicative of the conversion of alkoxides into acids. These results altogether allowed the conclusion that alkoxides existed in the equilibrium with oligomeric carbenium ions. Though the concentrations of the

Figure 3. The ¹³C CP/MAS NMR spectrum of products formed after additional adsorption of ¹³CO + H₂O on zeolite containing ethylene oligomers.

latter are too low to be detected by ¹³C CP/MAS NMR spectroscopy, the reactivities of the oligomers are determined by the reactivities of the equilibrium carbenium ions.

Taking into account that conversion of C₂–C₄ alkenes in a flow reactor at $T < 450$ K afforded C₆–C₁₈ alkenes,^{62, 63} *i.e.*, oligomeric products can be desorbed as alkenes under particular conditions,[†] it was concluded that alkenes were present in small amounts among the adsorbed oligomeric products. However, the concentrations of alkenes were so low that these compounds, like carbenium ions, were 'invisible' to NMR spectroscopy.

Hence, the NMR spectral data allow the conclusion that oligomeric products of low-temperature alkene conversions, which are adsorbed on acidic forms of zeolites, exist as three interconvertible forms, *viz.*, as alkoxides, carbenium ions and alkenes (Scheme 3).

Scheme 3

Oligomeric alkoxides present the major adsorbed form.

2. Compositions and structures of products of alkene oligomerisation on HZSM-5 zeolite

In the first studies devoted to oligomerisation of alkenes on HZSM-5 zeolite, qualitative conclusions about the formation of linear oligomers^{25, 26, 30, 34} which contain approximately 16 carbon atoms from alkenes (ethylene, propene or isobutene) were made based on the analysis of the positions of the signals for CH₃ and CH₂ groups in the ¹³C MAS NMR spectra.³⁰ However, signals for the CH₂ groups of linear fragments and signals for the CH₃ groups of branched fragments of oligomers are observed in the same region of the ¹³C NMR spectrum (at δ 20–30).⁴⁰ Consequently, one cannot infer the structures and lengths of hydrocarbon chains of oligomeric products exclusively from the chemical shifts of signals in the ¹³C NMR spectra.

It was suggested that 2D *J*-resolved ¹³C MAS NMR spectroscopy followed by GC-mass spectrometric analysis and traditional high-resolution ¹³C NMR spectroscopy (in solution) of oligomers which have been extracted from zeolite, be used for establishing the compositions and structures of oligomeric products formed from ethylene on HZSM-5 zeolite.⁵⁴

[†] Signals of double bonds are also absent in the NMR spectrum of the adsorbed oligomer.

a. 2D J -resolved ^{13}C MAS NMR spectroscopic data

Two-dimensional J -resolved MAS NMR spectroscopy offers advantages over 1D NMR spectroscopy because not only does it provide data on the chemical shifts of signals for carbon atoms of oligomers but it also allows the determination of the multiplicity of the signals that occurs due to spin-spin coupling between the ^{13}C nuclei and the adjacent protons [the spin-spin coupling constants $J(^{13}\text{C}-^1\text{H})$].^{64,65} In the 2D NMR spectrum, the assignment of the signal with a particular F2-dimension chemical shift to the CH_n group is made based on the calculation of the number of peaks of this signal on the F1 axis.^{36,38,64–66} As a result, the ambiguity of the assignment of the signals for carbon atoms is excluded and the true structure of oligomers in the adsorbed form can be determined.

The contour plot of the 2D J -resolved ^{13}C MAS NMR spectrum of ethylene oligomers on the HZSM-5 zeolite and the corresponding 1D NMR spectrum are shown in Fig. 4b. It can be seen that the signals at δ 30 and δ 34 exist as triplets with the constant $J(^{13}\text{C}-^1\text{H}) = 140 \pm 16$ Hz, which suggests that these signals belong to the CH_2 groups of oligomers. The signal at δ 22 is a singlet characteristic of the quaternary carbon atom. However, it is observed in the region typical of either the terminal CH_3 groups of branched oligomers (in this case, the signal should exist as a quartet on the F1 axis⁶⁶) or the CH_2 group (a triplet on the F1 axis⁶⁶) adjacent to the terminal CH_3 group of the linear fragment of the hydrocarbon chain rather than being located in the region of chemical shifts of the quaternary carbon atom of alkanes (at δ 30–40⁴⁰). The existence of a singlet rather than a doublet at δ 22 suggests that this signal is in fact a triplet for which only the most intense central component is distinct in the spectrum against a background of the noise level.^{35,67} Hence, it was concluded that the signal at δ 22 belongs to the CH_2 groups of oligomers. The existence of four peaks on the F1 axis for the signal at δ 14 indicates that the latter belongs to the terminal CH_3 groups of the oligomer.

To summarise, analysis of the multiplicities of signals of the adsorbed oligomers allowed the conclusion that signals in the

Figure 4. Spin-echo 1D ^{13}C MAS NMR spectrum (a) and the contour plot of the 2D J -resolved ^{13}C MAS NMR spectrum (b) of oligomerisation products of ethylene on HZSM-5 zeolite at 296 K. The observed value of the scalar spin-spin coupling constant $J(^{13}\text{C}-^1\text{H})$ on the F1 axis is half as large as the real value $J(^{13}\text{C}-^1\text{H})$ due to the use of a special technique for recording the 2D spectrum.⁶⁵

region from δ 22 to δ 34 belong to the CH_2 groups, *i.e.*, the oligomers formed are linear hydrocarbon fragments.

b. High-resolution solution ^{13}C NMR spectroscopic data

To confirm the conclusions about the structures of oligomers formed from ethylene, a sample of HZSM-5 zeolite with the adsorbed oligomers was dissolved in 10% NaOH⁶¹ and the liberated hydrocarbon products were extracted with diethyl ether, dissolved in benzene- d_6 and analysed by high-resolution ^{13}C NMR spectroscopy. The major characteristics (chemical shifts, the ratio of the intensities of the signals and the multiplicities of the major, most intense signals) of the spectrum of the products desorbed from the zeolite (Fig. 5) are identical with those of the adsorbed oligomers (see Fig. 1). The most intense signals at δ 22 and 33–34 exist as triplets with $J(^{13}\text{C}-^1\text{H}) = 125$ Hz and the signals at δ 10–14 exist as quartets with $J(^{13}\text{C}-^1\text{H}) = 125$ Hz.

Figure 5. The high-resolution ^{13}C NMR spectrum (in benzene- d_6) of ethylene oligomers extracted from HZSM-5 zeolite after dissolution of the zeolite in NaOH solution.

In the spectra of the extracted products, the intensities of the signals at δ 60–80 are as small as those of the adsorbed oligomers. The fact that the ratio of the signals of the adsorbed products is identical with that of the extracted products as well as the presence of signals for the carbon atoms of the CH_x-OH fragment of alcohols indicate that the oligomers are extracted from the zeolite as alcohols and the structures of the extracted alcohols are analogous to those of the adsorbed alkoxide oligomers. The estimation of the ratio of the signals at δ 14, 22 and 33 (Fig. 5) demonstrated that an average linear oligomeric chain consists of seven carbon atoms [$-(\text{CH}_2)_6\text{CH}_3$] bound to an oxygen atom of the zeolite framework.

From the spectrum shown in Fig. 5 it follows that not only linear but also branched oligomers are formed on the HZSM-5 zeolite, which is evidenced by the signals at δ 35–50 belonging to secondary and tertiary carbon atoms.^{30,68} However, linear oligomers predominate apparently due to the specific structure and the size of the channels in the HZSM-5 zeolite.⁶⁹ The fact that the ^{13}C NMR spectrum (see Fig. 5) has more than 20 signals from alcohols at δ 60–80 indicates that a mixture of no less than 20 oligomeric alkoxides containing predominantly linear fragments is formed upon adsorption of ethylene on the HZSM-5 zeolite. For a mixture of adsorbed oligomers, only one broad low-intensity signal at δ 89 (see Fig. 1) is observed, which is indicative of the alkoxide nature of the adsorbed oligomers.⁵⁴ Previously,^{30,32,34,70,71} attempts to identify this signal have failed for several reasons. First, the adsorbed oligomers exist as a mixture of oligomeric alkoxides (> 50 , according to GC-mass spectrometric analysis⁵³). Second, the signals for oligomeric alkoxides are broad

but their intensities are low. Third, chemical shifts of the signals vary within the range of > 15 ppm.

In some cases, signals at $\delta 87-89$ observed for various alkenes (Pr^i and Bu^i)^{35,45,48,72} were assigned to small hydrocarbon fragments bound to the oxygen atoms of the zeolite framework. However, the fact that the chemical shifts of the signals for alkoxides observed upon propene oligomerisation on HY zeolite^{45,73} or on HZSM-11 zeolite⁴⁸ are identical with those observed upon isobutene oligomerisation on HZSM-5 zeolite³⁵ allows the conclusion that the signals at $\delta 87-89$ (see Refs 35, 45 and 48) should be assigned to oligomeric alkoxides rather than to short hydrocarbon fragments.

c. Data of GC-mass spectrometric analysis

The compositions of ethylene oligomers formed were also determined by GC-mass spectrometric analysis. To do this, the adsorbed oligomers were first converted into a mixture of the corresponding carboxylic acids according to Scheme 2. Then, carboxylic acids were extracted from the zeolite by dissolving the latter in 10% alkali. Subsequent treatment of the mixture of acids with diazomethane⁶¹ made it possible to convert them into the corresponding methyl carboxylates, which were readily separated and analysed by GC-mass spectrometry. It was found that the mixture extracted was comprised of more than 50 different oligomeric products (C_5-C_{14}).

III. Dehydration of alcohols

1. Methyl alcohol

NMR studies of alcohol conversions on zeolites attracted interest immediately after 'Mobil' had discovered conversions of methanol into a motor fuel on HZSM-5 zeolite.^{74,75} The first NMR spectral study devoted to conversions of methanol⁷⁶ had already demonstrated the possibility of the application of ^{13}C MAS NMR spectroscopy in the analysis of intermediates and reaction products. Evidence was obtained for the conversion of methanol first into dimethyl ether and then into a mixture of hydrocarbons *via* intermediate carbenium ions rather than carbenes, as had been suggested previously by Chang and Silvestri.¹⁸ Anderson and Klinowski^{78,79} noted the difference in the composition of the products which were present in the gas phase and in zeolite pores. Thus in no case were C_{10} aromatic products observed among the desorbed products, but these compounds were found *in situ* in zeolite pores. It was thus concluded that products were formed within zeolite pores under conditions of the equilibrium reaction, the composition of the desorbed products being determined by the pore size of the zeolite. Hence, the effect of the internal specific size and the pore structure on the composition of the products desorbed was experimentally demonstrated.

In the study devoted to methanol conversions,⁷⁹ it was noted that ethylene was formed as an important intermediate. It was also reported that the reaction performed under conditions similar to those used in a flow reactor (small contact time) yielded intermediate C_4 alkenes and cyclopentenyl cations (CPC).⁸⁰ Below is given the scheme of conversions of methanol into a mixture of hydrocarbons on the HZSM-5 zeolite.

2. *tert*-Butyl alcohol

Conversions of aliphatic C_3-C_4 alcohols on acidic zeolites were studied with the aim of obtaining more detailed information on the mechanism of dehydration. The molecular sizes of these alcohols are comparable with the pore sizes of zeolites.

Dehydration of C_3-C_4 alcohols starts at substantially lower temperature (300–400 K) than that of methanol (550–700 K). This enables one to obtain more detailed information on the nature of intermediates based on the data of NMR spectroscopy and, consequently, to draw conclusions about the mechanism of these reactions. In addition, it becomes possible to reveal the effect of the pore size of a zeolite on the course of dehydration of isomeric alcohols and to analyse subsequent conversions of the products formed upon primary dehydration. In the present review, the results of studies of dehydration of isomeric butyl alcohols are considered in detail.

Dehydration of *tert*-butyl alcohol on HZSM-5 zeolite occurs at room temperature.⁸¹ NMR spectral studies of this reaction, which is not complicated by secondary processes of cracking of the products formed, are of considerable interest for the understanding of the mechanisms of dehydration and subsequent oligomerisation of isobutene formed upon dehydration.^{35,38,46,70} It was found⁴⁶ that the dehydration of Bu^iOH containing the ^{13}C -labelled tertiary carbon atom on HZSM-5 zeolite ($\text{Si}:\text{Al} = 36$) was accompanied by complete redistribution of the labels in the oligomeric products. It was thus concluded that carbenium-ion intermediates were involved in dehydration of the alcohol and that *tert*-butyl silyl ether (TBSE) was formed as a stable intermediate, *i.e.*, the *tert*-butyl fragment was covalently bound to the oxygen atom of the zeolite framework. The authors⁴⁶ believed that the formation of TBSE is evidenced by the signal at $\delta 77$ corresponding to the carbon atom bound to the oxygen atom of the zeolite[‡] as well as by the unusually large chemical shift of the carbon atom bound to the oxygen atom of the zeolite framework compared to that of the carbon atom in the initial Bu^iOH , which is generally observed in neat alcohol or in neutral solutions.

More recent studies^{33,35} demonstrated that the conclusion about the formation of TBSE as a stable intermediate^{46,70} was erroneous. A special NMR spectral study³⁵ showed that dehydration of Bu^iOH on an HZSM-5 zeolite with $\text{Si}:\text{Al} = 24$ at room temperature proceeded slowly and was completed in > 15 h (Figs 6 and 7). With an HZSM-5 zeolite in which $\text{Si}:\text{Al} = 36$, *i.e.*, the zeolite in which the concentration of reactive acidic OH groups is 1.5 times lower, the dehydration time could only increase. Hence, it was concluded that dehydration of alcohols cannot be completed in 1.5 h (the reaction time in the study⁴⁶) and, consequently, the signal at $\delta 77$ can be assigned only to the initial unconsumed alcohol.³⁵ The difference between the chemical shift of the carbon atom of the $\text{C}-\text{O}$ fragment in the adsorbed alcohol (at $\delta 82$ ^{35,70} or at $\delta 77$ ⁴⁶) and that of this carbon atom in the initial solution (at $\delta 68.97$ ⁴⁰) should be attributed to specific interactions between the alcohol and the centres of its adsorption (Brønsted acidic OH groups) as well as to a possible change in the geometry of the alcohol upon its adsorption in zeolite channels.⁸²

IR spectral studies³³ demonstrated that the rates of oligomerisation and isomerisation of isobutene liberated upon dehydration are substantially higher than that of its dehydration. Hence, the products observed in the NMR spectrum are isobutene oligomers.

The identity of the spectra of isobutene oligomers prepared from Bu^iOH containing selectively ^{13}C -labelled CH_3 or $\text{C}-\text{OH}$ groups suggests the complete redistribution of the selective ^{13}C labels (*cf.* Figs 6 and 7) and confirms the conclusions made by Aronson *et al.*⁴⁶ that carbenium-ion intermediates are involved in dehydration and oligomerisation of Bu^iOH .

The formation of the *tert*-butyl carbenium ion (TBCI) and isobutene as intermediates, which exist in equilibrium with the initial alcohol,³⁵ is evidenced by the experimental data on the incorporation of the deuterium label from D_2O into the methyl group of *tert*-butyl alcohol which had previously been adsorbed on zeolite (Fig. 8, Scheme 4).

‡ It was suggested that dehydration of the alcohol on HZSM-5 zeolite with the $\text{Si}:\text{Al}$ ratio of 36 was completed in 1.5 h.

Figure 6. Changes in the ^{13}C CP/MAS NMR spectra of *tert*-butyl alcohol (containing the selectively ^{13}C -labelled C–OH group) with time at 296 K (1–5), 373 K (6) and 448 K (7) after adsorption on HZSM-5 zeolite (Si : Al = 24). Spectra 1'–7' at δ 60–110 are given with a fourfold amplification.

Time /h: (1) 0.33; (2) 2.83; (3) 5.5; (4) 8.0; (5) 15.5; (6) 1; (7) 1. The signal at δ 82 belongs to the ^{13}C –OH group of the unconsumed initial alcohol.

Figure 7. Changes in the ^{13}C CP/MAS NMR spectra of *tert*-butyl alcohol (containing the selectively ^{13}C -labelled CH_3 group) with time at 296 K (1–4), 373 K (5) and 448 K (6) after adsorption on HZSM-5 zeolite (Si : Al = 24). Spectra 1'–6' at δ 60–110 are given with an eightfold amplification.

Time /h: (1) 0.33; (2) 2.83; (3) 5.5; (4) 15; (5) 1; (6) 1. The signal at δ 29.8 belongs to the $^{13}\text{CH}_3$ group of the initial alcohol.

Figure 8. The static ^2H NMR spectra observed after adsorption of D_2O on a HZSM-5 zeolite specimen with the previously adsorbed $\text{Bu}'\text{OH}$ recorded within 5 min (a) and 1 h (b) after adsorption of D_2O ($T = 296\text{ K}$). (a) the shape of the spectral line corresponds to deuterated water; (b) the shape of the spectral line corresponds to superposition of three signals, viz., a signal for the $(\text{CD}_3)_3\text{C}$ fragment of alcohol with the observed quadrupole splitting $Q_3 \approx 10\text{ kHz}$ and signals for the CD_3 and CD_2 groups (weak signals) of oligomers with $Q_2 \approx 38\text{ kHz}$ and $Q_1 \approx 123\text{ kHz}$, respectively.

Scheme 4

It was also demonstrated that if zeolite containing a smaller number of acidic OH groups was used, i.e., in the case of slower dehydration of the alcohol, the selective ^{13}C label from the C–O group of the alcohol was transferred to its CH_3 group (Fig. 9).³⁸ This redistribution of the ^{13}C label confirms that TBCI is formed as an intermediate, which exists in equilibrium with the initial alcohol, in the course of dehydration. An analogous redistribution of the carbon labels was also observed in the case of carbenium ions in superacid solutions (Scheme 5).^{49, 50}

In spite of the above-considered experimental evidence for the formation of TBCI, the signal at δ 330 characteristic of the carbenium ion was not observed.⁵¹ It was thus concluded that the cation formed in zeolite is either transient or present in an amount insufficient for detection by ^{13}C NMR spectroscopy.

The signal at δ 86, which was observed in the ^{13}C NMR spectrum in the course of dehydration of $\text{Bu}'\text{OH}$, was originally assigned to stable *tert*-butyl silyl ether formed in the reaction (see Figs 6 and 7).³⁵ However, it was found that this signal appeared simultaneously with signals of oligomers and persisted after completion of dehydration. This signal disappeared only at a temperature higher than 373 K at which cracking of oligomers

Figure 10. Changes in the ^{13}C NMR spectrum of isobutyl alcohol (containing the selectively ^{13}C -labelled CH_2 group) adsorbed on HZSM-5 zeolite (Si : Al = 24) upon successive heating of the specimen at different temperatures. Temperature /K (duration of heating, min): (a) 296 (without heating); (b) 343 (70); (c) 398 (40); (d) 413 (60); (e) 428 (60); (f) 448 (60).

Further increase in the temperature (Fig. 10 *d–f*) caused subsequent conversions of IBSE and TBSE into a mixture of alkanes (Fig. 10 *f*) and CPC (see Scheme 12 below) *via* butene oligomers.³⁸

IV. Reactions of alkenes and alcohols with carbon monoxide and acetonitrile

The experimental evidence for the involvement of carbenium ions in conversions of alkenes and alcohols on zeolites obtained in NMR studies was further confirmed by a series of chemical reactions which occurred on zeolites under mild conditions.^{49, 50, 86}

1. The Koch reaction

Selective conversions of isomeric butyl alcohols in the presence of carbon monoxide and of alkenes (ethylene, isobutene and oct-1-ene) in the presence of CO and water on the HZSM-5 zeolite to form carboxylic acids (the Koch reaction^{59, 87}), which were studied with the use of ^{13}C NMR spectroscopy,^{60, 61} were found to occur at lower temperatures (20–100 °C) compared to those (300–500 °C) normally used in catalytic reactions on zeolites. Actually, the use of labelled reagents (alcohols, alkenes and CO) for the analysis of products of their reactions on the HZSM-5 zeolite provided conclusive evidence of selective conversions of alcohols and alkenes into carboxylic acids. Thus the following changes in the ^{13}C NMR spectra (Fig. 11) were observed in the reaction of Bu^tOH with CO at room temperature: when Bu^tOH containing the ^{13}C -labelled tertiary carbon atom was used, a signal at δ 40.7 belonging to the tertiary carbon atom of trimethylacetic acid (TMAA) was observed (Fig. 11 *a*); when Bu^tOH containing the ^{13}C -labelled CH_3 group was used, a signal at δ 27.8 belonging to the methyl group of the acid was observed (Fig. 11 *b*); and when labelled carbon monoxide was used, a signal

at δ 186–194 belonging to the carboxyl group was observed (Fig. 11 *c*). The formation of TMAA from Bu^tOH and CO on a zeolite catalyst at room temperature agrees well with the general concepts of the mechanism of this reaction in solutions of acids and superacids.^{58, 59} In both cases, the carbenium ion is the key intermediate (Scheme 8).

Hereinafter, the chemical shifts for the carbon atoms are given above the corresponding atoms.

The special role of carbon monoxide in this reaction is to capture TBCI formed upon elimination of the water molecule from the alcohol and to hinder its rapid oligomerisation^{35, 38, 46} by converting it into the acylium cation, which reacts with water to form acid.

Trimethylacetic acid is also selectively formed from Bu^tOH and isobutene, which suggests the presence of TBCI. Ethylene is selectively converted into 2-ethyl-2-methylbutyric acid, which is indicative of rapid oligomerisation of ethylene to form the C_6

Figure 11. The ^{13}C CP/MAS NMR spectra of the product formed upon adsorption of Bu^tOH and CO on HZSM-5 zeolite at 296 K. Bu^tOH containing the ^{13}C -labelled tertiary carbon atom (a); Bu^tOH containing the ^{13}C -labelled methyl group (b) and labelled CO (c). The spectrum (d) is the spectrum (c) recorded without CP.

carbenium ion followed by termination of the growing oligomeric chain by carbon monoxide.

Subsequent NMR spectral studies demonstrated also that benzene can undergo carbonylation to form benzoic acid on HY zeolite⁸⁸ and sulfatized zirconia.⁸⁹

2. Friedel–Crafts-like acylation of alkenes

In the absence of water adsorbed on zeolite, the alkyl cation which is formed upon adsorption of alkenes on zeolite reacts with CO to give the acylium cation. The latter reacts with another alkene molecule to form unsaturated ketone. This represents the Friedel–Crafts-like acylation of alkenes,^{90–92} the acylating agent being formed *in situ* from the alkene and CO on the zeolite.

Actually, the ^{13}C NMR spectrum of the product formed in the case of simultaneous adsorption of isobutene and ^{13}CO on the HZSM-5 zeolite has two intense signals for the ^{13}C -labelled carbonyl group⁹³ at δ 225 and δ 250 (Fig. 12 a,b). The signal at δ 225 belongs to unsaturated ketones formed in the reaction and the signal at δ 250 belongs to stable cyclic five-membered carboxonium ions (Scheme 9).⁹⁴

The ^{13}C CP/MAS NMR spectra of the products formed after the adsorption of ^{13}C -labelled ethylene and CO on the HZSM-5 zeolite are shown in Fig. 12 c,d.

If a zeolite specimen was kept in air, *i.e.*, was exposed to atmospheric moisture, the signal for the carboxonium ion at δ 250 disappeared, the signal for unsaturated ketones was shifted downfield (to δ 217) and a signal belonging to carboxylic acids appeared at δ 186 (Fig. 12 e). It was thus concluded that carboxonium ions were decomposed in the presence of moisture and the

Figure 12. The ^{13}C CP/MAS NMR spectra of the products formed after adsorption of alkenes and CO on HZSM-5 zeolite in the absence of water at 296 K.

(a) $(\text{CH}_3)_2\text{C}=\text{CH}_2 + ^{13}\text{CO}$; (b) $(\text{CH}_3)_2\text{C}=\text{CH}_2 + \text{CO}$; (c) $\text{CH}_2=\text{CH}_2 + ^{13}\text{CO}$; (d) $^{13}\text{CH}_2=\text{CH}_2 + \text{CO}$; (e) $(\text{CH}_3)_2\text{C}=\text{CH}_2 + ^{13}\text{CO} + \text{H}_2\text{O}$. Curves (1–5) without amplification; (2') with a fivefold amplification; (4') with a twenty fold amplification.

equilibrium shown in Scheme 9 was shifted towards acylium cations, which reacted with water to form carboxylic acids.

Hydroxy ketones, which are the products of the reaction of unsaturated ketones or carboxonium ions with water, were not detected in the reaction under consideration.

3. The Ritter reaction

Since the discovery of the reactions of alcohols and alkenes with nitriles (the Ritter reaction) in 1948,^{95–98} it was believed that the formation of *N*-alkylamides occurs *via* an intermediate *N*-alkylnitrilium cation $\text{CH}_3\text{C}\equiv\text{N}^+\text{R}$.

However, the experimental spectral supporting evidence for the formation of *N*-alkylnitrilium cations was long absent, which has cast doubt on the existence of a cationic intermediate.⁹⁸ It was suggested that this reaction afforded a sulfate $\text{CH}_3\text{C}(\text{OSO}_3\text{H})=\text{NR}$ (the reaction was carried out in sulfuric acid) as an intermediate.^{95,98}

It was demonstrated^{99,100} by ^{13}C and ^{15}N MAS NMR spectroscopy that the Ritter reaction can be performed on zeolite catalysts. These studies provided the first experimental proof for the formation of *N*-alkylnitrilium cations as stable intermediates in the reactions of alkenes (or alcohols) with carbonitriles.

The ^{13}C NMR spectra of the intermediate *N*-*tert*-butylacetonitrilium cation and of the final *N*-*tert*-butylacetamide, which were formed in the reaction of Bu^tOH with CH_3CN on the

HZSM-5 zeolite, are shown in Fig. 13. It was found that *N*-alkylnitrilium cations are long-lived stable species in the absence of moisture.

Hence, the reaction mechanism proposed for the Ritter reaction⁹⁵ was additionally confirmed by the detection of stable *N*-alkylnitrilium cations on zeolites using NMR spectroscopy. The behaviour of the acetonitrile molecule in the Ritter reaction is analogous to that of the CO molecule in the Koch reaction, *i.e.*, acetonitrile acts as a trap for the alkylcarbenium ion thus stabilising the unstable alkyl cation (Scheme 10) and preventing secondary reactions involving highly reactive alkyl cations (oligomerisation and cracking).

Scheme 10

The identification of stable *N*-alkylnitrilium cations confirmed the suggestions made previously that alkylcarbenium cations can be stabilised on zeolite through their interactions with acetonitrile molecules^{101–103} and disproved the suggestion¹⁰⁴ that strong Lewis centres to which acetonitrile molecules are coordinated are formed on the zeolite.

V. Analysis of hydrocarbon products and intermediates formed from alkene oligomers

Adsorbed hydrocarbon products were analysed *in situ* by studying dehydration of Bu^tOH on HZSM-5 zeolite in a wide temperature range (296–637 K) as an example using ^{13}C CP/MAS NMR spectroscopy.³⁸ It was found that heating (448 K) of a zeolite specimen containing adsorbed alcohol resulted in the appearance of two groups of signals at *ca.* δ 10–40 and δ 150–250 in the ^{13}C NMR spectrum (Fig. 14). The signals at δ 10–40 correspond to a mixture of acyclic alkanes (Fig. 14*a*) and those at δ 100–450 correspond to stable cyclopentenyl cations (Fig. 14*d*). The simultaneous formation of alkanes and CPC from oligomers of isobutene, which is formed in the first stage of dehydration of *tert*-butyl alcohol, occurs as a result of cracking of oligomers (for example, of oct-1-ene; Scheme 11). The diene formed upon cracking of the alkene undergoes further dimerisation and cyclisation to form alkyl-substituted cyclopentadienes, which are stabilised within channels of the HZSM-5 zeolite as CPC.

Scheme 11

Figure 13. The ^{13}C NMR spectra of the products formed upon simultaneous adsorption of *tert*-butyl alcohol and acetonitrile on HZSM-5 zeolite at 296 K; (a) and (b) simultaneous adsorption of Bu^tOH containing the labelled tertiary carbon atom and CH_3CN ; (c) and (d) adsorption of labelled Bu^tOH (10% enrichment with the ^{13}C isotope) and CH_3CN (80% enrichment with the ^{13}C isotope); (a) and (c) the spectra were recorded within 4 h after the adsorption; (b) and (d) the spectra were recorded within 4 days after the adsorption.

Figure 14. The ^{13}C MAS NMR spectra of the conversion products of Bu'OH on HZSM-5 zeolite at 448 K at δ 10–60 (a–c) and at δ 100–450 (d). (a) experimental data; (b) a model spectrum obtained by superposition of 25 signals of the mixture of 11 hydrocarbons; (c) the spectrum of the cyclopentenyl cation (a 16-fold amplification of the intensities of the signals).

The simultaneous formation of acyclic alkanes and CPC on the HZSM-5 zeolite indicates that the mechanisms of conversions of alkenes on zeolites and in sulfuric acid are similar.

Actually, as early as 1936, Ipatieff and Pines^{105, 106} demonstrated that a mixture of alkanes and cycloalkenes was formed when isobutene was passed through concentrated sulfuric acid at 0 °C. Cycloalkenes, as was demonstrated by Deno and co-workers in the early 1960s using NMR spectroscopy,¹⁰⁷ exist in 96% H_2SO_4 as stable alkyl-substituted CPC.

The use of 2D J -resolved ^{13}C MAS NMR spectroscopy for the analysis of the multiplicities of signals at δ 10–40 corresponding to hydrocarbon products (Fig. 15) allowed the determination of the number of hydrogen atoms attached to the carbon atoms in the CH_n groups ($n = 0–3$).

Based on the analysis of the ^{13}C chemical shifts, the relative intensities of the signals (see Fig. 14) and the multiplicities (see Fig. 15), it was found that a mixture of hydrocarbons was formed

Figure 15. Contour plot of the 2D J -resolved ^{13}C MAS NMR spectrum of the products of Bu'OH conversion on HZSM-5 zeolite at 448 K (a). The 1D spin-echo ^{13}C NMR spectrum (b) corresponding to the spectrum of the standard one-pulse excitation (see Fig. 14a). The observed value of the spin-spin coupling constant $J(^{13}\text{C}–^1\text{H})$ on the F1 axis is half as large as the true value of $J(^{13}\text{C}–^1\text{H})$ due to the use of a special technique for recording the 2D NMR spectrum.^{35, 61, 63}

at 448 K and the relative amount of hydrocarbons that occurred in the adsorbed state (Table 1) was determined.

An increase in the reaction temperature to 573 K led to the redistribution of the intensities of signals for alkanes at δ 10–40 (Fig. 16). In this case, propane and butanes were prevailing

Figure 16. The ^{13}C CP/MAS NMR spectra of the conversion products of Bu'OH on HZSM-5 zeolite at 573 K [spectrum (b) is given with an eightfold amplification of the intensities of the signals at δ 40–240].

Table 1. Assignment of the signals in the ^{13}C NMR spectrum and the relative amounts of alkanes, isobutene oligomers and aromatic hydrocarbons formed upon conversion of Bu^tOH on HZSM-5 zeolite at 373–673 K.

Toluene + <i>m</i> -xylene	22.5 (32.3)					—	—	—	8.1 ^b

Note. The assignment was made relative to the total amount of hydrocarbons whose CH_n signals are observed at δ 10–40. ^a The chemical shifts of CH_n groups of the adsorbed hydrocarbons were taken from the spectra shown in Figs 14–17 (the accuracy of the determination was ± 0.5 ppm). The chemical shifts of the same hydrocarbons in a solution were taken from the literature⁴⁰ and are given in parentheses. ^b The values were determined only from the intensities of the CH_3 groups without considering the intensities of the carbon atoms of the benzene ring of toluene or xylenes.

alkanes (Table 1), signals for CPC at δ 150 and δ 250 disappeared and a signal at δ 128, which belongs to a mixture of monocyclic and fused aromatic hydrocarbons with the latter predominating, appeared. The changes in the ^{13}C NMR spectrum are indicative of cracking of alkanes formed at 448 K. When the temperature was further increased to 673 K, C₂–C₄ alkanes (with propane predominant) and aromatic hydrocarbons, *viz.*, toluene and xylene, were obtained as the major reaction products (Fig. 17).

**Figure 17.** The ^{13}C MAS NMR spectrum of the conversion products of Bu^tOH on HZSM-5 zeolite at 673 K.

At 373 and 296 K, alkanes were also formed from isobutene oligomers.³⁸ However, at these temperatures, isobutene oligomers covalently bound to the oxygen atoms of the zeolite framework, *viz.*, alkoxides, were obtained as the major conversion products of Bu^tOH on HZSM-5 zeolite, which is evidenced by the presence of a broad signal for the C–O groups at δ 89 in the spectrum of oligomeric products (Fig. 18).

The sequence of conversions (according to the ^{13}C MAS NMR spectral data) of alkene oligomers adsorbed on acidic zeolite in the temperature range of 296–637 K is shown in Scheme 12.³⁸

Scheme 12

VI. Activation of alkanes at low temperatures. Isotope (H/D) exchange between alkanes and acidic OH groups of zeolite

The results of the studies^{108–112} demonstrate that NMR spectroscopy is a particularly informative and unique method for investigating conversions of lower alkanes (propane and isobutane) on acidic zeolites at low (as regards traditional conversions of alkanes on zeolites) temperature (350–550 K). It was found¹⁰⁸ that the selective ¹³C label of the CH₂ group was incorporated into the CH₃ group of propane adsorbed on Ga/HZSM-5 zeolite at 573 K. According to the results of the studies,^{50,55–57} the redistribution of the selective carbon label indicates that the isopropylum ion which is responsible for this redistribution is formed as an intermediate on the zeolite, although Derouane and co-workers¹⁰⁸ believed that the label redistribution observed in the case of Ga/HZSM-5 zeolite proceeds with the participation of a transition complex of propane with the Ga atom,¹⁰⁸ while in the case of pure HZSM-5 zeolite,¹⁰⁹ the redistribution involves the C-ethylmethanum (carbonium) ion.¹¹³

The observed redistribution of the ¹³C label in propane indicates that propane is activated and can undergo subsequent chemical conversions (cracking and alkylation¹¹⁴).

Yet another example of the use of NMR spectroscopy for studying activation of alkanes at low temperature is investigation

of hydrogen isotope exchange^{110,111} and activation of alkanes in the presence of CO and H₂O.¹¹² The H/D isotope exchange between alkanes and acidic OH groups of zeolites proceeds at rather low temperatures (20–200 °C) at which the alkane does not undergo isomerisation and cracking.^{115–121} The isotope exchange involving stages of cleavage and formation of C–H bonds in alkane and O–H bonds in zeolite is indicative of activation of alkane. Hence, it is not surprising that a large number of experimental^{115–124} and theoretical^{121–124} studies were devoted to the elucidation of the mechanism of the hydrogen exchange. Recently, ¹H MAS NMR spectroscopy was used for investigating the kinetics and mechanism of the H/D exchange of alkanes.^{110,111}

1. Propane

In studies of the kinetics of the H/D isotope exchange between deuterated propane and acidic groups of HZSM-5 zeolite (150–250 °C), the simultaneous incorporation of protium from the acidic HO groups into the deuterated methyl and methylene groups of propane was observed. It was found that the intensities of the signals for the CH₃ and CH₂ groups of propane at δ 1.0 and δ 1.45, respectively, in the ¹H MAS NMR spectrum increased with time (Fig. 19). Analysis of the kinetics of the incorporation of protium into the methyl and methylene groups of propane

Figure 19. Changes in the intensities of the signals for the methyl (δ 1.0) and methylene (δ 1.45) groups with time at 519 K in the ¹H MAS NMR spectrum of propane C₃D₈ adsorbed on HZSM-5 zeolite. The first spectrum (at the bottom) and the last spectrum were recorded within 3 min and 5 h after the adsorption. The intervals at which the spectra were recorded were 5 min.

revealed a noticeable difference in the rates of hydrogen exchange for these groups (Fig. 20). The corresponding rates, which were

Figure 20. Kinetic curve of the transfer of the proton from acidic OH groups of zeolite to the methyl (curve 1) and methylene (curve 2) groups of propane C₃D₈ at 519 K.

calculated by the kinetic equation $I_t = I_\infty[1 - \exp(-Rt)]$ [I_t and I_∞ are the integral intensities of the signals for the CH_n groups ($n = 2$ or 3) in the ^1H MAS NMR spectrum at times t and $t = \infty$ (equilibrium)] are $R(\text{CH}_3) = 0.03816 \text{ min}^{-1}$ and $R(\text{CH}_2) = 0.0436 \text{ min}^{-1}$. The time $t = 0$ corresponds to the beginning of the experiment when the temperature was increased from room temperature to 519 K. The activation energies of hydrogen exchange for the methyl and methylene groups were determined ($E_{\text{CH}_3} = 118 \pm 2 \text{ kJ mol}^{-1}$ and $E_{\text{CH}_2} = 117 \pm 4 \text{ kJ mol}^{-1}$) from the temperature dependence of the reaction rate of hydrogen exchange (from the Arrhenius parameters; Fig. 21).¹¹⁰

Figure 21. Dependence of the rate of the H/D exchange for the methyl (1) and methylene (2) groups of propane on HZSM-5 zeolite in terms of the Arrhenius parameters.

Taking into account the absence of selective or predominant enrichment of the methyl groups with protium, the fact that the H/D exchange is not inhibited by carbon monoxide and the fact that the experimental activation energies are close to those theoretically calculated for methane and ethane,^{122–124} it was concluded that H/D exchange with the acidic OH protons occurs independently for each group (without the formation of a single carbenium ion intermediate or a transition state) *via* an intermediate pentavalent transition state in which the hydrogen atoms that are exchanged lie halfway between the carbon atom of the methyl (methylene) group and the oxygen atoms of the zeolite.

The data obtained do not also contradict the formation of the carbonium ion as a two-electron three-centre intermediate state involved in the hydrogen exchange in the propane–superacid $\text{DF} - \text{SbF}_5$ system.¹²⁵ The difference in the rate of exchange for the methyl and methylene groups was attributed to the difference in the σ -basicity of the C–H bonds of the primary (CH_3) and secondary (CH_2) groups of the alkane.¹²⁶

2. Isobutane

In the case of the hydrogen exchange in isobutane, the situation is different (Fig. 22). In this case, only methyl groups are subjected to H/D exchange,^{118–120,127} which is manifested in an increase in the intensity of the signal at $\delta 1.0$ (Fig. 22*b*).¹¹¹ The expected increase in the intensity of the signal for the CH group at $\delta 1.85$ (Fig. 22*c*) was not observed. Measurements of the rates of hydrogen exchange in the temperature range of 80–150 °C allowed the determination of the activation energy of the exchange ($50 \pm 2 \text{ kJ mol}^{-1}$) which is half as large as that of

Figure 22. The ^{13}C MAS NMR spectra of isobutane adsorbed on HZSM-5 zeolite at 295 K.

(a) the spectrum of isobutane- d_{10} before the temperature was increased to 425 K or of isobutane- d_{10} in the presence of CO after storage of the sample at 475 K for 10 h; (b) the spectrum of isobutane- d_{10} after storage of the sample at 425 K for 70 min; (c) the spectrum of nondeuterated isobutane.

propane. It was also found that carbon monoxide completely inhibits the regiospecific hydrogen exchange (Fig. 22*a*). The mechanism of the regiospecific hydrogen exchange for isobutane was explained within the framework of the catalytic cycle^{118,120} shown in Scheme 13.

Scheme 13

The regiospecificity of the H/D exchange is achieved due to formation of TBCI and isobutene as intermediates, which exist in equilibrium with each other. Carbon monoxide, which is present in the system, reacts with TBCI to give the oxocarbenium ion. The latter cannot undergo reversible deprotonation to form the alkene, which results in complete inhibition of the hydrogen exchange.

VII. Activation of alkanes at low temperatures. Carbonylation

In addition to the hydrogen exchange in alkanes at 20–200 °C, NMR spectral studies allowed observation of carbonylation at 100–200 °C,¹¹² which is also indicative of the possibility of activation of alkanes on acidic zeolites at low temperatures.

Based on the assumption that alkanes are formed from carbenium ions and alkenes^{118,119,127} as intermediates upon hydrogen exchange at low temperature and taking into account that alkenes (carbenium ions) can react with carbon monoxide and water on zeolites⁶¹ to form carboxylic acids, it was suggested that carboxylic acids can be formed from alkanes at low temperature¹¹² at which hydrogen exchange is observed but alkanes do not undergo cracking.

1. Propane

It was found that heating of a zeolite specimen containing adsorbed propane, CO and water at 373–473 K led to changes in the NMR spectra compared to those of the initial reagents. In the case of simultaneous adsorption of ¹³C-labelled propane, carbon monoxide and water, the ¹³C CP/MAS NMR spectrum has a signal at δ 191 for the carboxy group of isobutyric acid formed along with signals at δ 17.0 and δ 18.2 belonging to the initial propane (Fig. 23a). The ¹H MAS NMR spectrum of the same specimen has a signal for methane at δ 0.25, signals for the initial propane at δ 1.0 and δ 1.45 and a signal for water adsorbed on acidic OH groups of zeolite at δ 6.2 (Fig. 23c). In the case of adsorption of labelled propane-2-¹³C, the ¹³C MAS NMR spectrum has a signal for ethane-1-¹³C at δ 7.3, a signal for the carbon atom of the ¹³CH group of isobutyric acid at δ 36.4 and signals for unconsumed propane-2-¹³C and CO at δ 18.2 and δ 185, respectively (Fig. 23b). These changes agree well with

Figure 23. NMR spectra of propane, carbon monoxide and water adsorbed on HZSM-5 zeolite at 473 K. The samples were heated at 473 K for 3 h.

(a) the ¹³C CP/MAS NMR spectrum, simultaneous adsorption of propane, ¹³CO and water; (b) the ¹³C MAS NMR spectrum, simultaneous adsorption of propane-2-¹³C, CO and water; (c) the ¹³C MAS NMR spectrum, simultaneous adsorption of propane, ¹³CO and water.

activation of propane-2-¹³C on zeolite and protolytic cleavage of the C–C bond of propane to form ¹³CH₄, ¹³CH₃CH₃ and (CH₃)₂¹³CHCOOH according to Scheme 14. Actually, in the course of the reaction of ¹³C-labelled propane with CO and H₂O, the selectively ¹³C-labelled CH₂ group of propane was converted into the ¹³CH group of isobutyric acid (δ 36.4). Methane, which is observed only in the ¹H MAS NMR spectrum, is formed in the stage (1) due to the protolytic attack of the acidic group of zeolite on the C–C bond of propane. The ethyl cation formed in the same stage reacts with another molecule of labelled propane to give ethane and the isopropyl cation [stage (2)]. The latter reacts with CO and water to form isobutyric acid [stage (3)].

Scheme 14

2. Isobutane

The reaction of isobutane with carbon monoxide and water on zeolite proceeds analogously.¹¹² After heating of a zeolite specimen containing adsorbed isobutane, ¹³CO and water at 423 K for 3 h, the ¹³C CP/MAS NMR spectrum has four signals, viz., signals for TMAA at δ 193 and δ 27.7, a signal for the initial isobutane at δ 25.5 and a signal for the intermediate Si–C(OOH)–Al at δ 172 (Fig. 24). The ¹H MAS NMR spectrum of the same specimen has signals for the initial isobutane at δ 1.0 and δ 1.8, a signal for H₂O/Si–OH–Al at δ 6.6 and signals for the reaction products, viz., H₂ and TMAA, at δ 4.1 and δ 1.45, respectively (Scheme 15).

No conversion products were detected in a special NMR spectral study of conversions of propane and isobutane on HZSM-5 zeolite in the absence of CO and water in the same temperature range. However, cracking products of these alkanes,

Figure 24. NMR spectra of conversion products of isobutane, ¹³CO and water adsorbed on HZSM-5 zeolite.

(a) the ¹³C CP/MAS NMR spectrum; (b) the ¹³C MAS NMR spectrum.

Scheme 15

such as hydrogen (in the case of isobutane), ethane and methane (in the case of propane), were detected by gas-chromatographic analysis. The amounts of these compounds were so small that they could not be detected by NMR spectroscopy. It was concluded that in the presence of H_2O and CO (a trap of carbenium ions), the cracking equilibrium of alkanes was shifted to the corresponding acids formed from CO and carbenium ions. In this case, the reaction product, *viz.*, a carboxylic acid, was accumulated in amounts detectable by NMR spectroscopy. The low degrees of conversion of propane and isobutane into the corresponding acids at 373–423 K (1%–2%) are attributable to the presence of insignificant amounts of superacidic centres in the zeolite (no more than 1%–2% of the total amount of acidic protonic centres) on which cracking occurs at these low temperatures.

VIII. The nature of intermediates in conversions of alkanes, alkenes and alcohols

The nature of intermediates in the reactions of hydrocarbons and alcohols on heterogeneous catalysts of the acidic nature has long been the subject of discussion. According to the classical concepts of conversions of organic molecules in the presence of acids, alkyl-type carbenium ions represent reactive intermediates in these reactions. However, the absence of direct experimental evidence for the formation of alkyl-type carbenium ions on acidic centres of zeolites has cast doubt on the possibility of their formation as stable species.

The first results of quantum-chemical calculations^{128, 129} demonstrated that carbenium ions are not located in a local minimum on the potential energy surface and these ions can be formed on zeolites only as an unstable transition state. More recent studies^{130–132} demonstrated that alkoxides are key intermediates, while carbenium ions are formed upon thermal excitation of alkoxides where the C–O bond is elongated. Theoretical calculations¹³³ also indicated that acid catalysis on zeolites occurs with the involvement of alkoxide intermediates and without the participation of carbenium ions. Some NMR spectral data (for example, those obtained in studies of oligomerisation products of propene¹³⁴) were interpreted without regard for the participation of carbenium ions in the reaction.

Recently, considerable progress has been achieved in the identification of various intermediates (carbenium ions and alkoxides) by NMR spectroscopy and in the understanding of the role of these intermediates in conversions on solid acids. The reliable evidence was obtained for the formation of alkoxide intermediates in the case of lower hydrocarbons (MeO ,^{42–44} Pr^iO ¹³⁴ and Bu^iO ⁴⁷) and oligomeric alkoxides⁵⁴ and their role as intermediates was revealed. The methoxide (A) and isobutoxide intermediates (C) are stable species at 293–373 K, while the isopropoxide intermediate (B) oligomerises even at 200 K.¹³⁴

Apparently, this fact indicates that isopropoxide rather than the isopropylum ion is a reactive intermediate in the oligomerisation of propene.¹³⁴ However, these conclusions were drawn without considering the characteristic time of the ^{13}C -carbon redistribution in carbenium ions, which should be approximately

39 days at 230 K.¹³⁴ Taking into account that oligomerisation proceeds substantially faster (is completed in several hours), the formation of the carbenium ion, which rapidly undergoes oligomerisation, from isopropoxide must not be ruled out.

The redistribution of the selective ^{13}C label in oct-1-ene at room temperature, which is indicative of the formation of carbenium ions, as well as the alkoxide nature of adsorbed alkene oligomers⁵⁴ allow conclusions to be drawn about the existence of the equilibrium between the alkoxide and carbenium-ion intermediates, the latter being formed in small amounts undetectable by NMR spectroscopy.

The formation of carbenium ions on zeolites is additionally confirmed by the fact that chemical reactions typical of carbenium ions proceed under mild conditions (room temperature). It appeared that unstable carbenium ions undetectable by NMR spectroscopy can be stabilised by introducing these ions into the reaction with CO and CH_3CN to obtain cyclic carboxonium⁹³ and alkynitrilium^{99, 100} cations, respectively, which can be detected by NMR spectroscopy. The hydrogen H/D exchange between D_2O and the methyl groups of Bu^iOH ^{35, 81} and the transfer of the ^{13}C label from the tertiary carbon atom to the methyl group of Bu^iOH ³⁸ are also indicative of the formation of the carbenium ion upon dehydration of Bu^iOH on zeolite. Recent quantum-chemical calculations⁸⁵ of the stability of alkylcarbenium ions adsorbed on zeolite taking into account the stabilising effect of the zeolite lattice (it was believed that 16 oxygen atoms rather than two atoms, as was assumed in all the previous studies,^{128–133} are involved in stabilisation of the intermediate formed) revealed a local minimum for carbenium ions. It was found that the stability of alkyl carbenium ions is 10–20 kJ mol^{-1} lower than that of the corresponding π -complexes of alkenes. Taking into account the experimental data obtained by NMR spectroscopy, it may be concluded that alkylcarbenium ions exist in zeolites as real structures (although they are very unstable and highly reactive) along with more stable alkoxide intermediates.

Alkyl-substituted cyclopentenyl cations belong to another type of carbocationic intermediates that exist in zeolites.⁴⁵ Their formation from alkene oligomers on zeolites simultaneously with alkanes indicates that conversions of alkenes on zeolites and in a solution of concentrated sulfuric acid occur analogously.³⁸ These cations are intermediates, which form aromatic hydrocarbons at higher temperature.

IX. Conclusion

Recently, considerable progress has been made in the understanding of the mechanisms of hydrocarbon conversions on the surface of zeolites of acidic nature. This progress was achieved primarily due to the successful use of high-resolution solid-state NMR spectroscopy for the *in situ* analysis of intermediates and the final products of hydrocarbon conversions. In some cases where the expected intermediate was not observed due to its instability or low concentration (alkyl-type carbenium ions), this was identified from the characteristic reactions, *viz.*, from the redistribution of selective carbon labels or from the reactions with cation traps (CO or CH_3CN). Based on the NMR spectral data, possible pathways of conversions of alkenes and alcohols on zeolites at low temperature were suggested. Carbonylation of alkenes and alcohols (the Koch reaction), Friedel–Crafts-like acylation of alkenes where an acylating agent is formed directly from the alkene and CO on

zeolite and the reactions of alkenes with acetonitrile to form *N*-alkylamides (the Ritter reaction) were studied. Interestingly, the *N*-alkylnitrilium cation as a stable intermediate in the Ritter reaction was first detected and characterised by NMR spectroscopy on zeolite rather than in solution. Hence, presently not only does solid-state NMR spectroscopy confirm or refute the parallels between the mechanisms of conversions of hydrocarbons in solutions and on the surface of solid acidic catalysts, but it also enables one to obtain original data on the mechanisms of chemical conversions. The Friedel–Crafts-like reaction of alkenes with CO adsorbed on zeolite to form unsaturated ketones and carbonylation of alkanes (propane and isobutane) to form carboxylic acids are examples.

The use of NMR spectroscopy for the analysis of products formed *in situ* on zeolites provides a deeper insight into the effect of the internal structure of zeolite pores on the composition of the products, which was clearly exemplified by conversions of methanol on HZSM-5 zeolite. NMR spectroscopy is more informative than IR and UV spectroscopy in the analysis of the structures of adsorbed hydrocarbons. As a result, NMR spectral studies made it possible to identify stable alkyl-substituted cyclopentenyl cations, which were formed in zeolites as intermediates in the conversions of alkenes into aromatic compounds, and to establish their structures. *In situ* studies of the kinetics of the hydrogen exchange of alkanes by NMR spectroscopy allowed conclusions about the nature of intermediates of this exchange to be drawn.

It would be expected that the experimental data on hydrocarbon conversions obtained by NMR spectroscopy and conclusions about the mechanisms of these conversions will be rationally used in the development of new industrially important processes of hydrocarbon conversions, such as alkylation or isomerisation of alkenes and alkanes, and the data on the nature of intermediates will provide the basis for quantum-chemical calculations.

III. Structure of imines of polyhalogenated aldehydes and ketones: <i>syn</i> – <i>anti</i> isomerism; enamide–acylimine tautomerism	588
IV. Reactivity of <i>N</i> -acyl-, <i>N</i> -sulfonyl- and <i>N</i> -phosphorylimines of polyhalogenated aldehydes and ketones	589
V. Conclusion	601

Abstract. Published data on the synthesis, structure and chemical transformations of *N*-acyl-, *N*-alkoxy(aryloxy)carbonyl-, *N*-carbamoyl-, *N*-sulfonyl- and *N*-phosphoryl-imines of chlorine-(and bromine)-containing ketones and aldehydes are surveyed and described systematically. The influence of polyhaloalkyl and functional substituents at the azomethine bond on their properties is considered. The bibliography includes 198 references.

I. Introduction

The chemistry of imines presents interest for both theoretical and applied organic chemistry.^{1–21} On the one hand, azomethines are convenient models for the investigation of stereochemistry of organic compounds, tautomerism and isomerism phenomena, molecular rearrangements and mechanisms of radical, electrophilic and nucleophilic addition at the double bond and cycloaddition.^{1–5} On the other hand, imines are used as the starting compounds for organic synthesis,⁶ for the synthesis of biologically active^{7–10} and natural products,⁵ monomers¹ and various nitrogenous heterocycles.^{1–5,11} In addition, compounds containing an azomethine group are known to play an important role in living organisms.^{1,5}

N-Functionally substituted polyhalogenated aldimines and ketimines present special interest due to their enhanced reactivity imparted by electron-withdrawing polyhaloalkyl substituents and by acyl, alkoxy(or aryloxy)carbonyl-, -carbamoyl, sulfonyl or phosphoryl group at the N atom.

The chemistry of polyhalogenated *N*-acyl aldimines and ketimines started to develop in the last two or three decades, because it was not until the early 1960s that preparative methods for their synthesis appeared. Quite a large number of review papers devoted to these interesting compounds have been published. The synthesis and properties of *N*-fluoro-, *N*-acyl-, *N*-sulfonyl- and *N*-phosphoryl-imines of polyfluorinated ketones

and aldehydes have been considered in the literature fairly comprehensively;^{12–17} therefore, they will not be discussed here.

However, known reviews^{18–25} dealing with the corresponding polychloro(bromo)-containing derivatives do not cover adequately the chemistry of *N*-acyl-, *N*-carboxy-, *N*-carbamoyl-, *N*-sulfonyl- and *N*-phosphoryl-imines of polyhalogenated aldehydes and ketones.

Therefore, it appears pertinent to generalise and describe systematically the data concerning the methods of synthesis and chemical transformations of *N*-acyl-, *N*-alkoxy(aryloxy)carbonyl-, *N*-carbamoyl-, *N*-sulfonyl- and *N*-phosphoryl-imines of polychlorinated (brominated) aldehydes and ketones $R^1N=CXCHaI_nR^2$, where $R^1 = \text{Alk}(\text{Ar})\text{CO}$, $\text{Alk}(\text{Ar})\text{OCO}$, Alk_2NCO , NH_2CO , $\text{Alk}(\text{Ar})\text{NHCO}$, $\text{Alk}(\text{Ar})\text{SO}_2$, Alk_2NSO_2 , $(\text{AlkO})_2\text{P}(\text{O})$, $(\text{AlkO})_2\text{P}(\text{S})$, $\text{Ar}_2\text{P}(\text{O})$, $(\text{ArO})_2\text{P}(\text{O})$; $X = \text{H}$, Ar , COOR^3 , CCl_3 , $\text{OAlk}(\text{Ar})$, CN , NR^4R^5 , Cl , *etc.*; $n = 2, 3$; $\text{Hal} = \text{Cl}$, Br ; $R^2 = \text{Alk}$, ArAlk , *etc.*

II. Synthesis of polychlorinated (brominated) aldimines and ketimines *N*-substituted by carboxylic, carbamic, sulfonic and phosphoric acid residues

The known methods for the synthesis of acid *N*-polychloro(bromo)alkylideneamides can be divided into several groups differing in the approach to the formation of the azomethine bond.

1. Preparation of *N*-acylated ketimines and aldimines from carboxamides and polyhalogenated aldehydes and ketones.

2. Syntheses based on amide derivatives — *N*-sulfinylsulfonamides and *N*-sulfonyl isocyanates — and carbonyl compounds.

3. Successive transformation of α,β -polyhaloalkyl isocyanates into amides and azomethines upon reactions with nucleophiles.

4. Creation of an azomethine bond by a free radical reaction of *N,N*-dihaloamides with 1,2-polyhaloethenes and alkynes.

5. Photochemical halogenation of *N*-alkyl(or aryl)amides.

Other methods, which have not found wide application, are also known; they are considered at the end of this Section.

1. Preparation of polychlorinated (or brominated) aldimines and ketimines based on amides and carbonyl compounds

Condensation of carbonyl compounds with amines is a classical method used to introduce an azomethine bond into a molecule. This is a two-stage process involving the intermediate formation of an amino alcohol.

Received 24 July 1998

Uspekhi Khimii 68 (7) 638–662 (1999); translated by Z P Bobkova

However, in the general case, this reaction cannot be used to prepare imines of polyhalogenated compounds. The presence of electron-withdrawing groups in the molecule enhances the stability of the intermediate amino alcohol. Therefore, the rate of the synthesis of polyhalogenated aldimines and ketimines is limited by the second stage, that is, dehydration of hemiaminals. Thus it is known that condensation of carboxamides with aliphatic and aromatic aldehydes gives *N,N*-alkylidene- or *N,N*-arylidene-bis-amides,¹⁸ whereas polyhalogenated aldehydes and ketones react with amines and amides to give stable 1-hydroxyalkylamines.^{18,26} In the case of aliphatic and aromatic amines and chlorinated aldehydes and ketones, the problem of transformation of amino alcohols into imines was solved by using TiCl_4 .²⁷

For the synthesis of acyl-, alkoxy(or aryloxy)carbonyl- and -carbamoyl-, sulfonyl- and phosphoryl-imines of polyhalocarbonyl compounds, methods based both on dehydration and on other chemical transformations of 1-hydroxypolyhaloalkylamides have been devised.

a. Dehydration of *N*-(1-hydroxypolyhaloalkyl)amides

In the earliest studies^{28–30} devoted to *N*-trichloroethylidene-amides, it was found that treatment of *N*-(1-hydroxy-2,2,2-trichloroethyl)acetamide, *N*-(1-hydroxy-2,2,2-trichloroethyl)chloro-(bromo)benzamides and *N*-(1-methoxy-2,2,2-trichloroethyl)bromobenzamides with dehydrating agents gives bis(1-acylamino-2,2,2-trichloroethyl) ethers instead of the corresponding chloral imines.

An example of fairly easy thermal dehydration giving rise to the target imines has been reported. Chloroacetamide reacts with chloral and bromal³¹ yielding *N*-(2,2,2-trichloroethylidene)- and *N*-(2,2,2-tribromoethylidene)chloroacetamides **1a,b**.

X = Cl (**a**), Br (**b**).

Subsequently, synthetic expedients have been developed which permit dehydration of some chloral hemiaminals.

N-(2,2,2-Trichloroethylidene)-4-toluenesulfonamide **2a** has been prepared by dehydration of the corresponding *N*-(1-hydroxyalkyl) derivative induced by P_2O_5 at 200 °C in benzene or xylene.³²

In our opinion, the sulfonamide derivative is esterified in this reaction by phosphoric anhydride and then phosphoric acid splits off. However, phosphorylimines cannot be prepared by dehydration of *N*-(1-hydroxy-2,2,2-trichloroethyl) dialkyl phosphoramidates.³³ An attempt to dehydrate *N*-(1-hydroxy-2,2-dichloroalkyl)amides was also unsuccessful.³⁴

Apparently, the limited scope of the method for the synthesis of imines based on dehydration of hemiaminals of polyhalogenated aldehydes and ketones is due to the fact that these compounds are unstable in the presence of dehydrating agents and decompose to give the initial components or condensation products (esters) under the reaction conditions (see, for example, Refs 28–30).

b. Dehydrochlorination of chloro(bromo)polyhaloalkylamides

Dehydrochlorination of *N*-(1-haloalkyl)amides, which are prepared by chlorination of the corresponding hydroxy derivatives by SOCl_2 or PCl_5 , is a fairly general method for the synthesis of acyl-, alkoxy- and -carbamoylimines of polyhalogenated carbonyl compounds as well as their sulfonyl and phosphoryl analogues.

This synthetic route was first used³⁵ to prepare *N*-(2,2,2-trichloroethylidene)benzamide **3a** and *N*-(2,2,2-trichloroethylidene)-*N*-benzyloxycarbonylamine **3b**.

R = PhCO (**a**), PhCH₂OCO (**b**).

The same method, except that thionyl chloride has been used as the chlorinating agent, has been employed to prepare trichloromethyl- and tribromomethyl-ethylidene-*N*-(alkoxycarbonyl)amines,³⁶ including various acyl- and alkoxy(aryloxy)-carbonylimines of chloral^{37–41} and bromal,⁴² acylimines and alkoxycarbonylimines of bromodichloroacetaldehyde,^{43,44} and *N*-acetyl(benzoyl)imines and *N*-methoxycarbonylimines of 1,1,2-trichloro-2-phenylpropionaldehyde and 1,1,2-trichlorobutyraldehyde,⁴⁵ their yields ranging from 52% to 92%. Several *N*-(2,2,3-trichloropropylidene)amides and *N*-(2,2,3-trichloropropylidene)ethoxycarbonylamine have been prepared in the same way (yields 52%–72%).⁴⁶

$\text{R}_{\text{Hal}} = \text{CCl}_3, \text{CBr}_3, \text{CBrCl}_2, \text{PhCHClCCl}_2, \text{CH}_2\text{ClCCl}_2, \text{MeCHClCCl}_2, \text{AlkCCl}_2$; R = Alk, Ar, PhCH₂, OEt, OMe.

Synthesis of *N*-(2,2-dichloroalkylidene)acetamides by condensation of dichlorinated aldehydes with acetamide followed by chlorination and then dehydrochlorination of the resulting compounds has been reported.³⁴ In the same study,³⁴ dichloroethylidenebenzamide was prepared in a low yield and an attempt to prepare 2,2-dibromoalldimines failed, probably due to the instability of the intermediate hemiaminals formed from 2,2-dihaloaldehydes and amides.

The condensation of carboxamides with methyl trichloropyruvate gave the corresponding *N*-acylhemiaminals, which were then converted into methyl 2-acylimino- and 2-alkoxycarbonylimino-3,3,3-trichloropropionates **4a–d**.⁴⁷

R = Me (**a**), Et (**b**), OMe (**c**), OEt (**d**).

N-(2,2,2-Trichloroethylidene)-*N*',*N*'-dimethylaminosulfonamide has been synthesised by a traditional multistage procedure based on the condensation of chloral with *N,N*-dimethylaminosulfonamide followed by chlorination by PCl_5 . Dehydrochlorination of the intermediate compound was carried out on heating.⁴⁸

Preparation of the phosphoryl analogues of *N*-acylimines of halogenated aldehydes was first reported in 1965.⁴⁹ It was shown that the products of acidolysis of trichlorophosphazo com-

pounds — *N*-polychloroalkylaminophosphoryl dichlorides containing chlorine atoms at the α -position with respect to nitrogen — readily abstract an HCl molecule on treatment with triethylamine to give *N*-(2-chloro-2-methylpropylideneamino)- and *N*-(2,2-dichloro-3,3-dimethylbutylideneamino)phosphoryl dichlorides.⁴⁹

R = Me₂CCl (**a**), Bu^tCCl₂ (**b**).

Several dialkyl *N*-(2,2,2-trichloroethylidene) phosphoramidates have been prepared in 50%–76% yields from chloral and dialkyl phosphoramidates using chlorination and dehydrochlorination of intermediate products.^{33,50}

R = Me (**a**), Et (**b**), Prⁿ (**c**), Prⁱ (**d**), Buⁱ (**e**).

Dimethyl *N*-(2,2,2-trichloroethylidene) phosphoramidothioate has been synthesised in a similar way.⁵¹

It has been shown^{52,53} that some tetrachloroalkanesulfonamides can be dehydrochlorinated thermally without using dehydrochlorinating agents. For instance, *N*-trichloroethylidenemethane- and -propane-sulfonamides were synthesised in 73% and 93% yields on distillation of the corresponding tetrachloroethylalkanesulfonamides.

Thus, this method is fairly versatile and permits the preparation of various *N*-functionally substituted imines of polychlorinated (or brominated) aldehydes and ketones. The drawbacks of this method include the large number of stages, the use of corrosive reagents and also the facts that the intermediate hemiaminals are relatively unstable and haloaldehydes with different halogen atoms are inaccessible.

c. Condensation of *N*-sulfinylsulfonamides and *N*-sulfonyl isocyanates with haloaldehydes

Chloral *N*-4-tolylsulfonylimine **2a** has been prepared in 91% yield by the reaction of chloral with unstable *N*-sulfinyl-4-toluenesulfonamide in the presence of AlCl₃.^{32,54,55} The starting amide was synthesised by the reaction of 4-toluene sulfonamide with thionyl chloride in the presence of AlCl₃.⁵⁶ *N*-(Trichloroethylidene)benzenesulfonamide **2b** (yield 40%) and other chloral *N*-arylsulfonylimines (e.g., **2c,d**) were prepared in a similar way.⁵⁷

R = Me (**a**), H (**b**), Cl (**c**), MeO (**d**).

However, an attempt to prepare (*N*-2,2-dichloroethylidene)arenesulfonamides from *N*-sulfinyl-4-toluenesulfonamide and dichloroacetaldehyde³² resulted in the isolation of 1,1-bis-(4-tolylsulfonylamino)-2,2-dichloroethane.

An attempt to synthesise 1-chloroimines by condensation of *N*-sulfinylarenesulfonamides with acid chlorides was also unsuccessful because the condensation products proved to be unstable under the reaction conditions.⁵⁸

Thus, the applicability of this method is quite limited. For example, it is impossible to prepare *N*-trichloroethylidene dialkyl phosphoramidates by the condensation of the corresponding sulfinylamides with chloral.³³

A general method for the synthesis of chloral sulfonylimines consists in the interaction of chloral with sulfonyl isocyanates in the presence of amines and quaternary ammonium bases.⁵⁹

R = Cl (**e**), F (**g**), Alk(C₁–C₂₀), ArAlk(C₇–C₁₂), Ar(C₆–C₁₀).

The method for the synthesis of acyl-, X-carbonyl- and phosphoryl-imines of polyhalogenated aldehydes and ketones based on condensation of *N*-derivatives of amides with carbonyl compounds has not been further developed. However, a large number of sulfonylimines of aromatic and aliphatic aldehydes and ketones⁶⁰ and *N*-*tert*-butyl- and *N*-fluoroalkyl-imines of alkyl, aryl, polyfluoro and chloro aldehydes and ketones have been prepared from sulfinylamines.⁶¹

2. Preparation of imines of polychlorinated aldehydes and ketones from isocyanates

Methods for the synthesis of halo-containing imines based on 1-*R*-1,2,2,2-tetrahaloethyl isocyanates and perchlorinated isocyanates have found wide application.

Thus the reaction of 1-aryl-1,2,2,2-tetrachloroethyl isocyanates with alcohols, phenols, benzenethiols and amines taken in equimolar amounts affords *N*-(1-aryl-1,2,2,2-tetrachloroethyl)amides. These compounds are dehydrogenated on heating or on treatment with bases. *N*-*R*-Oxycarbonyl-, arylthiocarbonyl- and carbamoyl-imines of trichloromethyl phenyl ketone, *N*-*R*-oxycarbonylimines of trichloromethyl 4-methylphenyl ketone and phenoxy carbonylimines of trichloromethyl aryl ketones were prepared in this way.⁶²

Ar = Ph; X = MeO, PhO, 4-MeC₆H₄O, 3,5-Me₂C₆H₃O, 4-BrC₆H₄, O(CH₂CH₂)₂N, Ph₂N, PhNH, 3-CF₃-4-NO₂C₆H₃NH;
Ar = 4-MeC₆H₄; X = MeO, PhO;
X = PhO; Ar = 4-ClC₆H₄, 4-Cl₃CC₆H₄, 4-FC₆H₄.

Later,^{63,64} *N*-Alkyl(aryl)-*N'*-(perchloroethylidene)ureas **8a–d** were synthesised by the reaction of perchloroethyl isocyanate with primary amines at –20 °C.

R = Prⁱ (**a**), Bu^t (**b**), Ph (**c**), 2,4,6-Me₃C₆H₂ (**d**).

Tetrachloroethyl isocyanate was prepared by treatment of *N*-(1-hydroxy-2,2,2-trichloroethyl)alkoxycarbonylamide with PCl₅³⁹ and pentachloroethyl isocyanate was obtained by its photochemical chlorination.⁶³

The readily available ylide Ph₃P=CHCN easily adds to 1,2,2,2-tetrachloroethyl isocyanate giving rise to a new biphilic reagent, which contains the clearly electrophilic group CCINHCO[–], apart from the nucleophilic centre of the ylide fragment. This new reagent was used to create biphilic phosphonium ylide **9**.⁶⁵

The reactions of 1,2,2,2-tetrachloroethyl isocyanate with orthoesters of carboxylic acids and with benzaldehyde amins

result in the formation of chloral *N*-alkoxycarbonylimines **10a,b** and *N,N'*-substituted dialkoxyureas **11a,b**.⁶⁶

(a) $(\text{R}^1\text{O})_3\text{CR}^2$; (b) $\text{PhCH}(\text{NR}_2^3)_2$; $\text{R}^1 = \text{Me}$ (**10a**), Et (**10b**);
 $\text{R}^2 = \text{H}$, Ph, 4- ClC_6H_4 ; $\text{R}_2^3 = (\text{CH}_2)_2\text{O}(\text{CH}_2)_2$ (**11a**); $(\text{CH}_2)_5$ (**11b**).

It was found⁶⁶ that acetals do not enter into similar reactions with tetrachloroethyl isocyanate.

1,2,2,2-Tetrachloroethyl isocyanate reacts with (dialkylamino)alkoxymethanes and bis(dialkylamino)ethoxymethanes giving rise to the chloral *N*-alkoxycarbonylimines **10a,b** and the *N,N'*-substituted ureas **11c,d**.⁶⁷ The reactions with dimethylformamide acetals afford a mixture of chloral imines and 1-alkoxy-2,2,2-trichloroethyl isocyanates.

$\text{R}^3 = \text{Me}$ (**11c**), Et (**11d**).

Apart from tetrachloroethyl isocyanate, the products resulting from replacement of one chlorine by an aryloxy or alkoxy group are also employed in the synthesis of imines. Thus the reaction of 1,2,2,2-tetrachloroethyl isocyanate and 1-aryloxy-2,2,2-trichloroethyl isocyanate with trimethylsilylamines gives the *N,N'*-substituted ureas **11a,d**.⁶⁸

$\text{X} = \text{Cl}$, PhO, 4- $\text{ClC}_6\text{H}_4\text{O}$; $\text{R} = \text{Et}$, $\text{R}^2 = (\text{CH}_2)_2\text{O}(\text{CH}_2)_2$.

The compound **11a** was obtained in the reaction of diethyl(trimethylsilyl)amine with 1-alkoxytrichloroethyl isocyanates; the first stage of the reaction yields silylated ureas, which decompose on heating to give the imine **11d** and the corresponding alkoxy silanes.⁶⁹

$\text{X} = \text{Cl}_2\text{CH}$, $\text{H}(\text{CF}_2)_2$, $\text{H}(\text{CF}_2)_4$, COOMe.

This method was used to synthesise a large number of acyl-, alkoxy(aryloxy)(thio)carbonyl- and *N'*-substituted carbamoylimines of chloral and trichloromethyl aryl ketones.

In conclusion, we would like to note that, despite the fact that these imines are produced from polychloroethyl isocyanates in preparative yields, isocyanates themselves are synthesised from polyhalogenated amides, nitriles, *etc.*, using PCl_5 , COCl_2 and other similar reagents, which restricts the scope of application of this method.

3. Reactions of *N,N*-dihaloamides with 1,2-polyhaloethenes as a new pathway to azomethines

The reactions of 1,2-polyhaloethenes with sulfonic, carboxylic, alkoxy-carboxylic and phosphoric acid *N,N*-dichloroamides have been vigorously studied for about 20 years. These reactions were found to give azomethines rather than saturated adducts. They provide the basis for one-stage procedures for the preparation of polyhaloaldehyde imines and their derivatives. Studies dealing with the synthesis of acyl-, ethoxycarbonyl- and sulfonyl-imines of chloral and other haloaldehydes, *N*-(2-bromo-2,2-dichloroethylidene)benzenesulfonamide, *N*-(2,2-dibromo-2-chloroethylidene)benzenesulfonamide and *N*-(2,2-dichloroethylidene)arenesulfonamides from *N,N*-dichloro- and *N,N*-dibromo-amides and 1,2-polyhaloethenes (trichloro-, tribromo- and dichloro-ethenes) published before 1989 have been surveyed in several reviews.^{23–25} Here we consider the studies that have not been covered in these reviews.

For instance, when *N,N*-dichloronitrobenzenesulfonamide, aminobenzenesulfonamide and *N,N*-dichloroamides of perfluoroalkanesulfonic acids are made to react with trichloroethene (TCE), the chloral sulfonylimines **2a–h** are formed;^{70,71} the reaction of *N,N*-dichlorourethanes with TCE affords chloral *N*-alkoxycarbonylimines **10a–c** in preparative yields.^{72,73}

$\text{R} = 4\text{-MeOC}_6\text{H}_4$ (**a**), Ph (**b**), 4- ClC_6H_4 (**c**), 3- $\text{NO}_2\text{C}_6\text{H}_4$ (**e**), 4- $\text{NO}_2\text{C}_6\text{H}_4$ (**f**), 4- $\text{MeOCONHC}_6\text{H}_4$ (**g**), Alk_F (**h**).

$\text{R} = \text{Me}$ (**a**), Et (**b**), Bu (**c**).

The reactions of TCE with *N,N*-dichloroarenesulfonamides in the presence of Lewis acids (SnCl_4 , AlCl_3) also afford the sulfonylimines **2a–c**, which are formed, however, in lower yields (up to 47%); *N*-(1-arylsulfonylamino-2,2,2-trichloroethyl)arenesulfonamides are formed as side products.⁷⁴

It has been reported previously²³ that TCE reacts with *N,N*-dibromobenzenesulfamide or *N,N*-dibromourethane giving rise to the corresponding imines of 2-bromo-2,2-dichloroacetaldehyde $\text{BrCl}_2\text{CCH}=\text{NSO}_2\text{Ph}$ and $\text{BrCl}_2\text{CCH}=\text{NCOOMe}$.

The reaction of TCE with *N*-bromourethane, which is known to disproportionate to give amide and dibromoamide, results in the formation of 2-bromo-2,2-dichloro-1,1-di(ethoxycarbonyl)amino)ethane.⁷⁵

The reactions of *N,N*-dichlorourethane and *N,N*-dichlorobenzenesulfonamide with tribromoethene (TBE) follow a similar route. *N,N*-Dichlorourethane is converted into ethyl *N*-(2,2-dibromo-2-chloroethylidene)carbamate **12**.⁷⁶ The reaction is accompanied by evolution of chlorine, bromine and 1,1,2-tribromo-1,2-dichloroethane.

It has been reported in studies cited in a review²³ that *N,N*-dichloroarenesulfonamides react with 1,2-dichloroethene (DCE) to give *N*-(2,2-dichloroethylidene)arenesulfonamides **13a–c**; the formation of these products was proved by physico-chemical methods and by chemical transformations. In another study,⁷⁷ they were isolated and characterised for the first time. The relative

yields of the compounds **13**, **14** and **2** depend on the reaction conditions.^{76, 77}

13a–c

14a–c

2a–c

R = PhSO₂ (**a**), 4-MeC₆H₄SO₂ (**b**), 4-ClC₆H₄SO₂ (**c**).

The reaction of *N,N*-dichlorourethane with DCE was found⁷⁶ to afford highly reactive ethyl *N*-(2,2-dichloroethylidene)carbamate **15**. However, like the reaction of *N,N*-dichloroarenesulfonamides with DCE, this process yields the imine **10b** and the product of addition of dichlorourethane to the C=N bond of this imine, namely, 2,2,2-trichloro-1,1-bis(ethoxycarbonylamino)ethane **16**, together with the target imine **15**. This is due to the fact that the process is accompanied by the chlorination of DCE giving rise to trichloroethene, tetrachloroethane, tetrachloroethene and urethane.

N,N-Dichloroarenesulfonamides have been found to react readily with 1-bromo-1,2-dichloroethene yielding *N*-(2-bromo-2,2-dichloroethylidene)arenesulfonamides **17a,b**.⁷⁸

17a,b

Ar = Ph (**a**), 4-ClC₆H₄ (**b**).

Systematic studies dealing with the influence of the natures of the polyhaloethene and dihaloamide used on the structure of the imine RN=CHCCl_nBr_{3–n} made it possible to refine the scheme proposed previously²³ for this reaction. It was demonstrated that the radical adducts formed either from *N,N*-dibromoamides and polychloroethenes or from *N,N*-dichloroamides and TBE do not undergo 1,2-halotropic rearrangement because these reactions afford neither polychloroaldehyde imines nor bromal imines.^{23, 75–78}

The method for the synthesis of polyhaloaldehyde imines based on the reaction of amidyl radicals with polyhaloethenes permits polychlorinated (or polybrominated) azomethines including those with different halogen atoms to be prepared from available initial compounds and to be used subsequently without isolation for synthetic purposes. However, the process of the preparation of halo-containing acyl- and phosphoryl-imines requires optimisation. The applicability of this method to the preparation of carbamoylimines and fluorinated imines containing residues of various types of acids also has to be studied.

4. Synthesis of *N*-arylsulfonylimines of polyhaloaldehydes by the reaction of *N,N*-dihaloamides with acetylene derivatives

The method for the synthesis of imines from acid dichloroamides and acetylene derivatives was developed in the last decade.

It has been shown^{79, 80} that the reaction of *N,N*-dichloroarenesulfonamides with phenylacetylene occurs by a free radical mechanism and results in the formation of *N*-(2,2-dichloro-2-phenylethylidene)arenesulfonamides **18a,b**. A detailed study of the process⁸⁰ demonstrated that *N,N*-dichlorobenzenesulfonamide reacts with phenylacetylene giving rise to a mixture of compounds, the imine **18a** being the major product (yield up to 75%); adduct **19a**, resulting from the addition of benzenesulfonamide to the C=N bond of **18a**, is also formed in a noticeable amount.

Ar = Ph (**a**), 4-ClC₆H₄ (**b**).

The reaction of phenylacetylene with *N,N*-dibromoarenesulfonamides gives 2,2-dibromo-2-phenyl-1,1-di(phenylsulfonylamino)ethane and benzenesulfonamide.⁸⁰

The reactions of *N,N*-dichlorourethanes and *N,N*-dichloroamides with phenylacetylene have also been studied.^{81, 82} However, the results obtained are contradictory and require more precise determination of the structures and transformations of the reaction products.

The reaction of *N,N*-dichloroarenesulfonamides with propargyl alcohol and 3-chloroprop-1-yne^{83, 84} gave the products of the subsequent addition of arenesulfonamides to the imines formed, namely, 3-chloro- and 3-hydroxy-2,2-dichloro-1,1-di(phenylsulfonylamino)propanes or 1,1-di(4-chlorophenylsulfonylamino)propanes.

X = Cl, OH; Ar = Ph, 4-ClC₆H₄.

5. Chlorination and bromination of amide derivatives

Among the methods for the synthesis of polyhaloaldehyde imines, mention should be made of chlorination of *N*-alkyl(aryl)amides; however, this method has already been considered in several reviews.^{17–21} We would only like to emphasise that chlorination of *N*-acylamides has been shown⁸⁵ to give products resulting from chlorination of both the aldehyde and the amide fragments. Photochemical high-temperature chlorination of isopropylamides of benzoic and 4-chlorobenzoic acids affords the corresponding acylimines of hexachloroacetone.

The transformation of *N*-(1-phenyl-2,2,2-trichloroethyl)amides under conditions of photochemical chlorination⁸⁶ and the transformation of *N*-(1-diethoxyphosphoryl-2,2,2-trichloroethyl)benzamide on treatment with the chlorine complex of pyridine⁸⁷ yield *N*-(1-phenyltrichloroethylidene)trichloroacet(or benz)amides **19a,b**⁸⁶ and *N*-(1-diethoxyphosphoryltrichloroethylidene)benzamide **19c** (yield 68%).⁸⁷ It was shown⁸⁷ that the latter product is more convenient to prepare by the chlorination of the silyl derivative CCl₂=C[P(O)(OEt)₂].N(SiMe₃)COPh (yield 84%).

X = Ph, R = CCl₃ (**a**, 58%), Ph (**b**, 62%); X = (EtO)₂P(O), R = Ph (**c**).

Yet another study deserves special attention⁸⁸ in which it was reported that *N*-acetyl-(1-*tert*-butoxycarbonyl-2,2-dibromo)propan- and -butanimines **20a,b** are formed upon successive bromination of the corresponding enamides with *N*-bromosuccinimide (NBS).

Finally, some polyhalogenated ketimines have been prepared by halogenation of compounds with C=N bonds. Thus *N*-perchlorovinylcarboximidoyl chlorides were used to synthesise *N*-substituted imino esters with a perchlorovinyl group.⁸⁹ When these compounds are subjected to chlorination, the perchlorovinyl group is converted into a perchloroethyl group. Methyl *N*-perchloroethylbenzimidates eliminate chloromethane on heating to give *N*-(tetrachloroethylidene)benzamides **21a–c** in high yields. Bromination of esters of *N*-perchlorovinylimidic acids under mild conditions is accompanied by elimination of MeBr and gives rise to *N*-(2-bromotrichloroethylidene)benzamides **22a–c**.

R = 4-XC₆H₄; X = H (a), Cl (b), NO₂ (c).

Chlorination has been employed to prepare imines of cyclic halogen-containing ketones.⁹⁰ Thus chlorination of both *N,N'*-bis(arylsulfonyl)-1,4-benzoquinonediimines **23** and *N*-arylsulfonyl-substituted *p*-phenylenediamines **24** in dimethylformamide results in the isolation of the same products, 2,3,5,6-tetrachloro-*N,N'*-bis(arylsulfonyl)-1,4-phenylenediamines **25**. Further chlorination affords tetrachlorobis(arylsulfonyl)benzoquinonediimines **26**, which, in turn, add a chlorine molecule at a double bond of the quinone ring to give the final products, 1,4-bis(arylsulfonylimino)-2,3,5,6,6-hexachlorocyclohex-2-enes **27a–c**.⁹⁰

R = PhSO₂ (a), 4-MeC₆H₄SO₂ (b), 4-ClC₆H₄SO₂ (c).

Similarly, 4-arylsulfonylimino-2,3,5,5,6,6-hexachlorocyclohex-2-en-1-ones **28a–c**⁹¹ and 4-arylsulfonylimino-2,3,5,5,6,6-hexachloro-1-oxo-1,2,3,4-tetrahydronaphthalenes **29a–c**⁹² were obtained by chlorination of *N*-arylsulfonyl-1,4-aminophenols and *N*-arylsulfonyl-1,4-aminonaphthols.

Ar = Ph (a), 4-MeC₆H₄ (b), 4-ClC₆H₄ (c).

6. The use of organophosphorus compounds and PCl₅ for the synthesis of polyhalogenated imines

Several methods for the synthesis of *N*-functionally substituted polyhalogenated imines based on organophosphorus compounds and PCl₅ are known.

Dialkyl *N*-(1-amino-2,2-dichloroethylidene) phosphoramidates were prepared by the reaction of trichloroacetylaminides with trialkyl phosphites.⁹³

R¹ = H, R² = Me; R³ = Me (a), Et (b), Prⁿ (c), Prⁱ (d);
R¹ = H, R² = Bu^t, R³ = Et (e).

Diethyl *N*-(1-dimethylamino-2,2,2-trichloroethylidene) phosphoramidate **31** was synthesised from *N*-chloro-*N'*,*N'*-dimethyltrichloroacetylaminides and triethyl phosphite.⁹³

Trialkyl phosphites were shown⁹⁴ to react with polychloronitrosoethanes under mild conditions (–20°C) giving rise to the corresponding dialkyl *N*-chloroalkylidene phosphoramidates **32a–h**.

R¹ = CH₂Cl; R² = Prⁿ (a), Buⁿ (b), Buⁱ (c), C₅H₁₁ (d), ClCH₂CH₂ (e);
R¹ = CHCl₂; R² = Prⁿ (f), Buⁿ (g), C₅H₁₁ (h).

The reaction of *N*-trihaloacetyl diphenylphosphinic amide with PCl₅ affords a mixture of *N*-(tetrachloroethylidene) (**33a**) and *N*-(trifluoro-1-chloroethylidene) (**33b**) diphenylphosphinic amides (70%) and phosphazone compounds **34** (30%).⁹⁵ The rearrangement, which occurs presumably *via* a four-centre transition state, is facilitated by the presence of strong electron-withdrawing groups.

X = Cl (a), F (b).

However, trichloroacetamide reacts with excess PCl₅ to give *N*-dichlorophosphoryltetrachloroethanimine **35**.⁹⁶ This product reacts with sodium phenoxide giving rise to the products of substitution of phenoxyl residues for the halogen atoms — *N*-diphenoxyphosphoryl-2,2,2-trichloro-1-phenoxyethanimine **36**.⁹⁷

Imines of type **35** have also been used to prepare chlorinated and fluorinated imides of phosphorothioic acids **37a–d**.⁹⁸

R = CCl₃ (**a**), CH₂ClCCl₂ (**b**), MeCCl₂ (**c**), EtCCl₂ (**d**).

When the imines **37a,c** are made to react with alcohols and amines, the chlorine atoms at phosphorus and carbon are substituted to give compounds **38a–e** and **39a–f**.⁹⁸

R¹ = Cl₃C: NR²R³ = PhNH (**38a**), 4-ClC₆H₄NH (**38b**), N(CH₂CH₂)₂O (**38c**);

R¹ = Cl₂CMe: NR²R³ = 4-ClC₆H₄NH (**38d**), N(CH₂CH₂)₂O (**38e**);

R¹ = Cl₃C: R⁴ = Me (**39a**), Et (**39b**), Pr (**39c**), Bu (**39d**), Ph (**39e**);

R¹ = Cl₂CMe, R⁴ = Et (**39f**).

Several *N*-phosphorylimines have been synthesised using trichlorophosphorazoperchloroethane **40**,⁹⁹ which reacts with alcohols to yield imides of various structures depending on the reaction temperature and the reactant ratio. When an equimolar amount of an alcohol is employed, one chlorine atom is replaced giving rise to unstable alkyl *N*-(perchloroethyl)dichlorophosphorimidates, which decompose on heating with evolution of an alkyl chloride to give *N*-dichlorophosphoryltetrachloroethanimine **35**.

R = Me, Et, Pr, Bu, C₈H₁₇.

When a threefold excess of an alcohol is used, this reaction results in the formation of a mixture of dialkyl phosphoramidates **41a–h** and the corresponding alkoxy chloro derivatives **42a–h** in ~60 : 40 ratio.

R = Me (**a**), Et (**b**), Prⁿ (**c**), Buⁿ (**d**), Buⁱ (**e**), C₅H₁₁ (**f**), iso-C₅H₁₁ (**g**), C₈H₁₇ (**h**).

When the alcohol : imine **40** ratio is 4 : 1, dialkyl *N*-(1-alkoxy-2,2,2-trichloroethylidene) phosphoramidates **43** are produced in 65%–85% yields. These compounds can also be obtained by treatment of the compounds **35**, **41** or **42** with an alcohol.

The imine **41a** was converted into dimethyl *N*-trichloroacetyl phosphoramidate **44** using a procedure proposed by Kirsanov *et al.*⁹⁶ The product **44** can exist in solution as the imine tautomer **45**.¹⁰⁰

The compound **6a** can be prepared by treatment of *N*-(1,2-dichloro-2-methylpropylidene)aminophosphorus trichloride with sulfur dioxide.⁴⁹

Tetrachloroethylideneaminodioxaphospholane **48** was prepared by the reaction of 2-amino-2-trichloromethyl-5,6-dichlorobenzo-1,3-dioxolane **47** with PCl₅.¹⁰¹ Presumably, a phosphazo compound is formed initially and then it rearranges into the dioxaphospholane *via* a seven-membered intermediate.

7. Other methods of synthesis

It is worth noting that chlorovinylamides, structural isomers of chloroethylideneimines, can be used in some cases for the synthesis of imines. Thus bis(dialkoxyphosphoryl)trichlorovinylamines react with two equivalents of a dialkylamine to give dialkyl *N*-(1-dialkylamino-2,2-dichloroethylidene) phosphoramidates **49a,b**.¹⁰²

R = Me (**a**), Et (**b**).

It has been mentioned above that imines with a similar structure have also been prepared from trichloroacetamides.⁹³

(2,2-Dichloro-1-cyanovinyl)benzenesulfonamide **50** reacts with amines, in the opinion of the researchers cited,¹⁰³ in the imine form with replacement of the cyano group by an amino group; *N*-(1-dialkylamino-2,2-dichloroethylidene)arenesulfonamides **51a–e** were isolated in good yields.

NR¹R² = PhCH₂NH (**a**), PhNH (**b**), 4-MeC₆H₄NH (**c**), Me₂N (**d**), O(CH₂CH₂)₂N (**e**).

A quite promising method for the preparation of imines is that based on ethyl *N*-[trichloro-1-alkoxy(aryloxy)ethyl]carbamates and chlorotrimethylsilane. When ethyl *N*-(1-aryloxy-2,2,2-trichloroethyl)carbamates are silylated with chlorotrimethylsilane in the presence of triethylamine, the intermediate product decomposes to give *N*-(ethoxycarbonyl)chloral imine **10b**.⁶⁹

R = Ph, 2,4-Br₂C₆H₃.

It has been shown that 1-phenyl-2,2,2-trichloroethylideneureas **52** can be prepared from phenyl *N*-(1-phenyl-2,2,2-trichloroethylidene)carbamate **53**.⁶² Under rigorous conditions, the phenoxy group is replaced by the amine residue.⁶²

The reaction of *N,N*-dichlorobenzenesulfonamide with dichlorovinyl ketones followed by dechlorination of the resulting *N*-(1-acyl-2,2,2-trichloroethyl)benzenesulfonamides on treatment with alkali resulted in the formation of *N*-(1-acyl-2,2-dichloroethylidene)benzenesulfonamides **54a–c**. They can exist as two tautomers.¹⁰⁴

R = Me (**a**), Pr (**b**), CH₂Cl (**c**).

III. Structure of imines of polyhalogenated aldehydes and ketones: *syn*–*anti* isomerism; enamide–acylimine tautomerism

1. Structure of *N*-trichloroethylidenearenesulfonamides according to the data of ³⁵Cl NQR and NMR spectroscopy. *syn*–*anti* Isomerism of polyhaloaldehyde imines

Despite the considerable attention devoted to the chemistry of carboxylic, sulfonic and phosphoric acid *N*-polyhaloalkylideneamides, their structures certainly have not been adequately studied. Most often, these compounds have been characterised by IR and NMR data; the results of NQR studies of trichloroethylidenearenesulfonamides can be found only in two publications.^{105, 106}

The ³⁵Cl NQR spectra, as well as ¹H and ¹³C NMR spectra,⁷⁰ indicate that chloral arylsulfonylimines **2a–c** occur as one of the two possible isomers. According to quantum-chemical calculations, *anti*-isomer **A** is more favourable than *syn*-isomer **B**; this is confirmed by experimental and theoretical ³⁵Cl NQR data.¹⁰⁵

Ar = 4-MeC₆H₄, Ph, 4-ClC₆H₄.

It has been shown by NMR spectroscopy that the dibromoacetaldehyde imines **12** and **55** exist as mixtures of *syn*- and *anti*-isomers in 3 : 4¹⁰⁷ and 1 : 3⁷⁶ ratios, respectively. Indeed, the ¹H NMR spectrum of the imine **55** exhibits, in addition to the multiplet for the phenyl protons, two singlets at 8.30 and 8.40 ppm due to the protons at the double bond, the ratio of their intensities being 3 : 4. The ¹³C NMR spectrum contains two signals for the carbon atoms of the CH=N group (167.9 and 167.6 ppm) and the CClBr₂ group (135.7 and 135.6 ppm).¹⁰⁷ More evidence supporting the existence of *syn*- and *anti*-isomers of imines is provided by the fact that addition of nucleophiles at the C=N bond affords two enantiomers.¹⁰⁷

It should be noted that *syn*- and *anti*-isomers cannot be detected in the ¹H NMR spectra of chloral sulfonylimines **2a–c** or ethoxycarbonylimines **10b**,^{108, 73} dichloroacetaldehyde sulfonylimines **13a–c** or ethoxycarbonylimines **15**,^{76, 77} or bromodichloroacetaldehyde sulfonylimines **17a,b** or alkoxy carbonylimines.^{23, 78, 109}

The correlations between the experimental ³⁵Cl NQR frequencies and the C–Cl bond lengths proposed in Ref. 110 were used to calculate the bond lengths in the imines **2a–c**, which were estimated as ranging between 175.8 and 176.3 pm.¹⁰⁵ These values are typical of C–Cl bond lengths in compounds with a trichloromethyl group.

It has been noted that the three chlorine atoms in trichloroethylidene-benzenesulfonamide and -4-toluenesulfonamide **2a,b** are nonequivalent in the ³⁵Cl NQR spectra, whereas the ³⁵Cl NQR spectrum of the corresponding 4-chlorophenylsulfonylimine **2c** exhibits a single signal for the trichloromethyl group,^{105, 106} which is difficult to explain based on its molecular structure. Apparently, the electron environment of all the chlorine atoms in this imine becomes equivalent due to intermolecular contacts.

Unfortunately, no data of ³⁵Cl NQR spectra for imines that are known to exist as both *syn*- and *anti*-isomers can be found in the literature.

2. Enamide–acylimine tautomerism in dichloroethylideneimines

An interesting problem of theoretical chemistry is the question of the existence of enamide–acylimine tautomerism in haloalkylideneimines *N*-substituted by acid residues.

X = H, Hal.

It has been concluded in reviews^{20, 21} that, among *N*-acylimines of chloro(bromo)(fluoro)aldehydes and ketones, stable structures with the imine bond can be found for ald- and ketimines containing no β-hydrogen atoms in the haloalkyl groups.

However, now it is known that arylsulfonylimines of dichloroacetaldehyde ArSO₂N=CHCHCl₂ **13a–c**, Ar = Ph (**a**), 4-MeC₆H₄ (**b**), 4-ClC₆H₄ (**c**), which do have a hydrogen atom in the β-position with respect to the imine group, exist in the stable imine form, as indicated by the presence of characteristic absorption bands of the C=N bond in the IR and NMR spectra (the signal for the azomethine proton at δ 8.35–8.44 ppm and for the carbon atom of the CH=N group at δ 166 ppm).⁷⁷ Similarly, the dichloroethylidenecarbamate **15** (the signal of the azomethine proton at δ 8.06 ppm⁷⁶) and 1-alkylamino-substituted dialkyl 2,2-dichloroethylidene phosphoramidates also exist as stable imine forms.^{93, 102}

According to the data of IR and ¹H NMR spectra, *N*-dichlorovinylamides and *N*-dichlorovinylthioamides exist as stable enamide forms.^{111, 112} Nevertheless, they react with nucleophiles to give stable products of addition at the azomethine bond.^{112–114}

Some functional substituents, for example CN,^{103, 115, 116} CONH₂,¹¹⁷ POPh₂,¹¹⁸ PO(OEt)₂,^{119, 120} and P+Ph₃Cl[–],¹²¹ present in a dichloroalkyl group stabilise the enamide form Cl₂C=C(R¹)NHCOR², where R² = Alk, Ar, OMe, OPh. These amides react with primary and secondary amines in the enamide tautomeric form to give the products of replacement of chlorine atoms.

An exception is provided by *N*-(1-carbamoyl-2,2-dichlorovinyl)benzamide **56**, which reacts with methyl- and ethylamine giving rise to stable addition products **57**.¹¹⁷

R = Me, Et.

It has already been mentioned (see Section II.7) that *N*-(2,2-dichloro-1-cyanovinyl)benzenesulfonamide **50** reacts with amines with substitution of the cyano group to afford stable 1-amino-2,2-dichloroethylidenesulfonamides **51a–e**.¹⁰³

It has also been found that *N*-(1-acyl-2,2-dichloroethylidene)benzenesulfonamides **54a–c** can exist as two tautomers;¹⁰⁴ the amide form predominates in the solid state, whereas in solutions the equilibrium shifts towards the imine form. The facts that the equilibrium is established over a relatively long period and that the tautomers can be observed separately indicate that the energy barrier separating these forms is higher than 107 kJ mol^{−1}.¹⁰⁴

It should be emphasised that bromination of the NH group in *N*-(1-*tert*-butoxycarbonyl-2-methyl- and 2-ethylvinyl)acetamides yields unstable compounds which undergo a 1,3-halotropic rearrangement with migration of the halogen atom giving rise to the imines **20a,b** (see Section II.4). Similarly, *N*-chloro-*N*-(2-chloro-2-phenylvinyl)arenesulfonamides and *N*-bromo-*N*-(2-bromo-2-phenylvinyl)benzenesulfonamide, formed in the reaction of *N,N*-dichloro(bromo)arenesulfonamides with phenylacetylene (see Section II.4), are converted into the corresponding *N*-(2,2-dihalo-2-phenylethylidene)arenesulfonamides of the type **18** as a result of 1,3-halotropic rearrangement.^{79, 80}

Thus, the imine form of dichloroacetaldimines is stable in the case of arylsulfonylimines and alkoxy-carbonylimines and for *N*-dichlorovinyl phosphoric amides if the α -position of the vinyl group has electron-donating substituents. *N*-Dichlorovinyl-substituted dialkyl phosphoramidates, carboxamides and thiocarboxamides containing no substituents at the α -position of the vinyl group are stable in the enamide form; however, they react with nucleophiles in the imine form. The presence of electron-withdrawing substituents at the 1-position of the vinyl group of dichlorovinylamides stabilises the enamide tautomer. The introduction of a halogen atom in the NH group facilitates tautomerisation of enamides to give halogen-containing imines.

IV. Reactivity of *N*-acyl-, *N*-sulfonyl- and *N*-phosphorylimines of polyhalogenated aldehydes and ketones

The reactivity of N-functionally substituted polyhalogenated aldimines and ketimines is due to the presence of the highly electrophilic C=N bond. Electron-withdrawing substituents at this bond increase its reactivity towards nucleophiles and electron-rich species such as dienes, alkenes, alkynes or arenes.

1. Reactions of polychlorinated(brominated) aldimines and ketimines with nucleophiles

Acyl-, alkoxy(aryloxy)(amino)carbonyl-, sulfonyl- and phosphoryl-imines of polyhalogenated aldehydes and ketones have been studied in reactions with O-, N-, S- and P-nucleophiles and bifunctional nucleophiles. To elucidate the relationship between the structure of imines and their reactivity towards nucleophiles, the kinetics have been measured for the addition of ethanethiol and 2,4,6-trichloroaniline to chloral imines with various acyl residues, Cl₃CCH=NCOR, where R = Ph (**3a**), PhCH₂O (**3b**), Me (**3c**), Et (**3d**), Prⁱ (**3e**), Bu^t (**3f**), 4-MeC₆H₄ (**3g**), 4-MeOC₆H₄ (**3h**), 4-ClC₆H₄ (**3i**), 4-O₂NC₆H₄ (**3j**), 3-MeC₆H₄ (**3k**), 3-ClC₆H₄ (**3l**), and to the imines **10a,b**, **2a,b** and **7b**.^{41, 122} It was found that the reactions obey second-order kinetics, the reactivity of imines sharply decreasing in the series **3** > **10** > **7**.

Cl ₃ CCH=NR	3a	3d	10b	7b
R	PhCH ₂ CO	EtCO	EtOCO	(EtO) ₂ PO
<i>k</i> / litre mol ^{−1} h ^{−1}	226.0	77.0	14.6	4.7

The rate constants for the addition of ethanethiol diminish by factors of 20 to 52 on passing from the acylimines **3** and **10** to the phosphorylimine **7**. Evidently, this is due to the decrease in the

electronegativity of the acid residues, resulting in a higher electron density on the carbon atom of the azomethine group. The substantial decrease in the reactivity observed on passing from *N*-ethoxycarbonylchloral imine **10b** to *N*-propionylchloral imine **3d** is due to the decrease in the conjugation of the azomethine group with the carbonyl group involving the alkoxy residue. The considerable influence of conjugation is also supported by the fact that the reactivity of an imino group attached to a phosphonyl residue is even lower because in this case, conjugation is insignificant if at all present.¹²²

Study of the reactivity of the chloral aroylimines **3i–m** towards 2,4,6-trichloroaniline in benzene, dioxane and acetonitrile demonstrated that the rate of addition of the amine in acetonitrile depends on the substituents in the benzene nucleus.⁴¹ This reaction is accelerated by electron-withdrawing substituents and retarded by electron-donating ones.

Comparison of the reactivity of chloral imines towards 2,4,6-trichloroaniline⁴¹ demonstrated that the influence of the substituent at the nitrogen atom on the capacity of the C=N bond for the addition reactions decreases in the sequence COAr > COAlk > SO₂Ar and also in the sequence COAlk > PO(OAlk)₂ > COOAlk.

Although arylsulfonamide groups possess high electronegativity, they have a lesser influence on the reactivity of the C=N bond towards trichloroaniline. The addition of the amine to phosphoryl- and sulfonylimines is characterised by greater negative values of activation entropy than the addition to acylimines. This was interpreted⁴¹ by assuming that the reactions of the amine with the C=N–C=O, C=N–P=O and C=N–SO₂ systems occur *via* different cyclic transition states. In the case of acylimines, a six-membered transition complex is formed, whereas for phosphoryl- and sulfonylimines a four-membered transition state is involved. This assumption is confirmed by the known fact that acylimines enter into 1,4-cycloaddition reactions, whereas arylsulfonylimines tend to undergo 1,2-cycloaddition.

a. Reactions of imines with O-nucleophiles

The reactions of imines with oxygen-containing nucleophiles have been studied most extensively; it was shown that acyl-, alkoxy(aryloxy)carbonyl-, carbamoyl-, sulfonyl- and phosphoryl-imines of polyhaloaldehydes add water and alcohols with heat evolution to give stable hydroxy- **58** and alkoxy-substituted **59** haloalkylamides.

Allyl alcohol adds to chloral arylsulfonylimines under mild conditions without heating.¹²⁹

The addition of alcohols and ammonia at the C=N bond in trichloromethyl phenyl ketimines is accompanied by simultaneous replacement of the fragment X by an alcoholic residue or an amino group to give 1-[alkoxy(amino)carbonylamino]-2,2,2-trichloroethylbenzenes **60**.⁶²

X = OAlk, SAr, NAlk₂; Y = MeO, EtO, NH₂.

Reactions of acyl-, sulfonyl- and dialkoxyphosphoryl-trichloroethylideneamines with phenols and 1-naphthol have been studied. It was shown that phenol^{33, 36, 37, 50, 123, 124, 130} and *p*-chlorophenol^{33, 39, 130} add to almost all types of imines giving rise to aryloxy derivatives **61**.

Ar = Ph, 4-ClC₆H₄; X = Cl, CH₂Cl;

R = AlkCO, AlkOCO, (AlkO)₂PO, ArSO₂.

1-Naphthol readily adds to phosphorylimines.^{33, 50} However, these imines give no addition products with 2,6-dimethylphenol, 2,6-dinitrophenol or 2,4,6-trinitrophenol even on heating.³³ This is caused not only by steric reasons but also by the low nucleophilicity of nitrophenols.

Chloral arylsulfonylimines, which also react with phenol, do not react with chloro-substituted phenols.¹²³

2-Chloroalkanols vigorously react with chloral imines and dichloroacetaldehyde sulfonylimines yielding *N*-[(2,2-dichloro-2-X-1-(2-chloroalkoxy)ethyl)amides **62**, which cyclise on treatment with an alkali giving rise to 1-arylsulfonyl(ethoxycarbonyl)-2-trichloromethyl- and -dichloromethyloxazolidines.^{77, 131}

R¹ = PhSO₂ (**a**), 4-ClC₆H₄SO₂ (**b**), 4-MeC₆H₄SO₂ (**c**), EtOCO (**d**), R² = H, X = Cl; R¹ = PhSO₂, R² = CH₂OMe, X = Cl (**e**); R¹ = PhSO₂, R² = CH₂Cl, X = Cl (**f**); R¹ = PhSO₂, R² = H, X = H (**g**).

The reactions of imines with carboxylic acids have been studied extensively. Although carboxylic acids are weak nucleophiles, they add at the C=N bond of imines (sometimes on heating) to afford 1-acyloxy-2-polychloroethylalkylamides **64**.

The imine **2b** reacts with halocarboxylic acids to give addition products — sulfonamides **65a,b**. An attempt to dehydrohalogenate these products in order to prepare heterocyclic compounds **66a,b** failed.¹³¹

X = Cl, $n = 1$ (a); X = Br, $n = 2$ (b).

The sulfonylimine **2b** vigorously reacts with oximes of aliphatic, cycloaliphatic and aromatic ketones being thus converted into the addition products **67a–d**.^{8, 11, 124}

$\text{R}^1 = \text{Me}$; $\text{R}^2 = \text{Ph}$ (a), Bu^t (b), Me (c); $\text{R}^1-\text{R}^2 = (\text{CH}_2)_5$ (d).

An attempt was made to carry out addition of hydroxylamines to imines. Cyclic hydroxylamines, namely, 4-hydroxy-2*H*-1,4-benzoxazin-3(4*H*)-ones, were found to add to the acylimines **1** and **3**. Compounds **68** were patented as antimicrobial preparations.¹³²

$\text{R}^1 = \text{Alk}, \text{Ar}, \text{ArO}$; $\text{R}^2, \text{R}^3 = \text{H}, \text{Hal}, \text{AlkO}, \text{Alk}, \text{Ar}, \text{CN}, \text{NO}_2$.

b. Reactions of imines with NH-nucleophiles

Only two examples of addition of ammonia to the imines in question have been reported. The reaction of the benzoylimine **19b** with ammonia has resulted in the isolation of *N*-(1-amino-2,2,2-trichloro-1-phenylethyl)benzamide **69**.⁸⁶

It was shown⁶⁵ that biphilic phosphonium ylide **9** reacts with ammonia to give the product of addition to the C=N bond, $\text{Ph}_3\text{P}=\text{C}(\text{CN})\text{COCH}(\text{NH}_2)\text{CCl}_3$, in 95% yield, the cyano group and the C=P bond remaining intact. It was also reported that the reaction of ammonia with trichloromethyl phenyl ketimine affords 1-amino-1-phenyl-2,2,2-trichloroethylurea.⁶²

The reactions of N-functionally substituted imines of polyhalogenated aldehydes and ketones with amines, amides and imines have been studied in detail.

Acyl- and alkoxy(aryloxy)carbonyl-imines of polyhaloaldehydes add primary and secondary amines to give addition products **70** in good yields.^{34–37, 41, 43–45, 65}

$\text{R}^1 = \text{AlkCO}, \text{AlkOCO}, \text{ArCO}, \text{ArOCO}, \text{Ph}_3\text{P}=\text{C}(\text{CN})\text{CO}$;
 $\text{R}^2, \text{R}^3 = \text{H}, \text{Alk}, \text{Ar}$; $\text{R}^2-\text{R}^3 = (\text{CH}_2)_2\text{O}(\text{CH}_2)_2, (\text{CH}_2)_4$;

$\text{NR}^2\text{R}^3 =$; X = Cl, MeCHCl, PhCHCl, Br, Pr, Bu.

Trichloroethylideneureas show a similar behaviour in the reactions with amines. Thus the amides **11a–c** add diethylamine, morpholine or piperidine at 20 °C to give diethylamide, morpholide and piperidide, respectively, of 1-diethylamino- (**71a**), 1-morpholino- (**71b**) and 1-piperidino-2,2,2-trichloroethylcarbamic acid **71c**.^{66, 68}

$\text{R}^1 =$, Me_2N ; $\text{R}^2 = \text{Et}$ (a), $(\text{CH}_2)_2\text{O}(\text{CH}_2)_2$ (b), $(\text{CH}_2)_5$ (c).

Phenoxy- and methoxycarbonylimines of trichloromethyl aryl ketones also add amines at the C=N bond yielding compounds **72a–c**.⁶²

X = PhO, Ar = 4- $\text{Cl}_3\text{CC}_6\text{H}_4$, Y = PhCH_2NH (a);
X = MeO, Ar = Ph, Y = BuNH (b), PhCH_2NH (c).

However, it was found that the reaction between phenyl phenyltrichloroethylidene carbamate **53** and secondary amines, for example, morpholine or diphenylamine, can occur without participation of the C=N bond. Under rigorous conditions, the phenoxy group is replaced by an amine residue to give the imines **52**.⁶² (see Section II.7).

The reactions of dialkyl *N*-trichloroethylidene phosphoramidates **7** with amines have also been studied in detail. It was shown^{41, 133} that these imines and their sulfur-containing analogues⁵¹ readily react with primary aromatic amines to give stable addition products, *O,O*-dialkyl *N*-(1-amino-2,2,2-trichloroethyl) phosphoramidates and -phosphoramidothioates.

$\text{R}^1 = \text{PO}(\text{OAlk})_2$ (Alk = Me, Et, Prⁿ, Prⁱ, Buⁱ); $\text{PS}(\text{OMe})_2$;
 $\text{R}^2 = \text{H}$; $\text{R}^3 = \text{Ph}, \text{PhCH}_2, 4\text{-ClC}_6\text{H}_4, 4\text{-MeC}_6\text{H}_4, 2,4,5\text{-Cl}_3\text{C}_6\text{H}_2$;
 $\text{R}^2 = \text{R}^3 = \text{Et}$; $\text{R}^2-\text{R}^3 = (\text{CH}_2)_5$.

The imines **7** add aniline, 4-chloroaniline and 4-methylaniline at room temperature; the reaction with 2,4,6-trichloroaniline occurs at ~80 °C and that with the least nucleophilic 2,4,6-trinitroaniline does not occur even at 100 °C.¹³³

Whereas acyl-, phosphoryl-, alkoxy- and carbamoyl-imines of trichloro- and dichloroacetaldehydes, trichloropropionaldehyde and other aldehydes react to give the products of addition to the azomethine bond, the trichloroethylidenearene-sulfonamides **2** can either give the products of addition to the C=N bond or undergo haloform decomposition.

Aniline,^{32, 124} trichloroaniline,⁴¹ morpholine,¹²⁴ *N*-ethylaniline,¹³⁶ *N*-methylaniline¹³⁶ and primary amines (methylamine, *tert*-butylamine, allylamine¹²⁹) yield products of nucleophilic addition. Diphenylamine does not react with chloral arylsulfonylimine.⁷³

Meanwhile, highly basic dialkylamines induce haloform decomposition; this affords the products of substitution of the CCl_3 group, *N*-arylsulfonyl-*N'*,*N'*-dialkylformamides **73**,^{73, 134–136} in high yields.

Ar = Ph, 4-MeC₆H₄, 4-ClC₆H₄; R = Me, Et, Pr, Bu, C₆H₁₃;
R–R = (CH₂)₂O(CH₂)₂, (CH₂)₅.

In the case of sulfonylimines, this reaction pathway is explained⁷³ by the fact that the ArSO₂ group, unlike acyl or alkoxy- and carbamoyl groups, cannot participate in conjugation and, hence, it cannot ensure stabilisation of the transition state. Therefore, CHCl₃ is ejected from the intermediate to give the compound **73**.

The reaction scheme proposed in the literature¹³⁶ includes the addition of amine to the double carbon–nitrogen bond and the reaction of the intermediate with a second amine molecule to give ionic species **75**. Fragmentation of this product yields formamide and a trichloromethyl anion.

Imines add readily to the azomethine bond of the trichloroethylideneamides **1** and **7** giving rise to azomethines.^{37, 136}

X = MeCO, R¹ = R² = Ph; X = PO(OEt)₂; R¹ = R² = Ph;

R¹ = Ph, R² = 4-MeC₆H₄; R¹ = Me, R² = OEt.

When 2,2-dichloropentanal *N*-acetylamine **76**³⁴ or the phenylsulfonylimine **2b**¹²⁴ are made to react with hydrazines, the addition products, *N*¹-aryl-*N*²-[1-amido-2-(trichloroethyl)- and -(2,2-dichloropentyl)]hydrazines **77a–c**, are produced in good yields.¹²⁴

X = PhSO₂, R¹ = Cl, R² = Ph (**77a**); X = MeCO, R¹ = Pr,

R² = Ph (**77b**), 2,4-(NO₂)₂C₆H₃ (**77c**).

N-2,2,2-Trichloro-, bromodichloro-, dibromochloro- and 2,2-dichloro-ethylideneamides and 2-*R*-2,2-dichloroethylideneamides of carboxylic, carbamic and sulfonic acids and of dialkyl phosphates add acid amides and substituted ureas on moderate heating giving rise to polyhaloalkanedylbisamides **78** and **79** in good yields.

This reaction can be performed for amides of aliphatic and aromatic carboxylic acids unsubstituted at the nitrogen atom as well as phosphoric and phosphorothioic amides and thioamides; *N*-substituted amides do not react with acetylmines even on refluxing for several hours.^{34, 138}

Detailed investigation of the reactions of the imines **7** with amides has revealed several characteristic features.¹³³ The capacity of amides for the addition sharply changes on variation of the electronegativity in the acyl residue. Comparison of the reactivities of acetamide, trichloroacetamide and the amide of pivalic acid demonstrates that the steric factor is insignificant. When the reaction mixture is heated to ~90 °C, pivalamide and acetamide add quantitatively, whereas trichloroacetamide reacts only at 167 °C.¹³³

In a study of the addition of amides and thioamides of four-coordinate phosphorus to trichloroethylideneacetamide **3c**, it has been found that amides of phosphorus thioacids add more readily than the oxygen analogues to give the corresponding substituted acetamides **79a–d**.¹³⁸ *N*-Acylated amides and thioamides of phosphorus-containing acids do not enter into this reaction due to steric shielding and low nucleophilicity of the amide nitrogen atom. *N*-Thioacylamides of phosphorus acids, in which the sulfur atom of the C = S group possesses high nucleophilicity, undergo exothermic addition giving rise to carboximidothioates **80a–g**.¹³⁸ Addition at a sulfur atom also occurs in the reaction of the aldimine **3c** with bis(diphenylthiophosphinyl)amine; this affords phosphinimidothioate **81**.¹³⁸

The reactivity of amides and thioamides of phosphorus acids towards chloral acetylamine increases in the sequence $R^1R^2P(X)NHC(O)R^3 < R^1R^2P(O)NH_2 < R^1R^2P(S)NH_2 < R^1R^2P(S)NHP(S)R_2^3 < R^1R^2P(X)NHC(S)R^3$.

Promising complex-forming reagents and biologically active compounds **82** have been prepared by the reaction of diaza-18-crown-6 with two equivalents of the imine **3c**.¹⁴¹

These compounds are smectic liquid crystals with fan texture.¹⁴¹

c. Reactions with S-nucleophiles

Much attention has been devoted to the reactivity of polyhaloaldehyde imines *N*-substituted by functional groups towards sulfur-containing nucleophiles (hydrogen sulfide, thiols, benzene thiols and thioamides), which add to imines very easily.

The *N*-acetalimine **3c** and dialkyl phosphoramidates **7d,e** react with hydrogen sulfide at 20 °C (ratio 2 : 1) to give bis(1-amido-2,2,2-trichloroethyl) sulfides **83a–c**.^{33, 37}

R = MeCO (**3c**, **83a**), (PrⁱO)₂PO (**7d**, **83b**), (BuⁱO)₂PO (**7e**, **83c**).

Unlike the reaction of imines with water, which yields stable hydroxy derivatives, in this case, the corresponding product with a thiol group has not been isolated. Evidently, this difference is related to the higher reactivity of *N*-(2,2,2-trichloro-1-sulfanylethyl)amides, formed in the first stage, towards the addition to the C=N bond of the initial imine compared to that of the hydroxy analogue.

As has already been noted, the rate of the reaction of ethanethiol with chloral imines depends on the nature of the substituent at the nitrogen atom; the reaction gives *N*-(2,2,2-trichloro-1-ethylthioethyl)amides **84**.¹²² Later it has been shown that *O,O*-dimethyl *N*-(2,2,2-trichloroethylidene) phosphoramidothioate **85** also reacts with ethanethiol being thus converted into the compound **84e**.⁵¹

R = PhCH₂CO (**a**), EtCO (**b**), EtOCO (**c**), (EtO)₂PO (**d**), (MeO)₂PS (**e**).

Chloral arylsulfonylimines **2** add butanethiol and prop-2-ene-1-thiol.^{142, 143}

The reactions of the phosphorus-substituted imines of chloral **7** with thiols and diphenylphosphinothioic acid have been studied extensively.^{33, 50} These reactions occur on mixing the reactants without heating, the yields of *N*-(2,2,2-trichloro-1-*R*-thioethyl)amides **86** being quantitative.

R¹ = Me, Et, Prⁿ, Prⁱ, Buⁱ; R² = 4-ClC₆H₄, 4-NO₂C₆H₄, Et, Ph, Ph₂P(S).

The acylimine **3c**,³⁷ the imine **9**, functionally substituted in the acyl fragment,⁶⁵ methoxycarbonylimine **10a**³⁹ and 2,2-dichloroalkylideneacetamides **76**³⁴ also react with ethanethiol,³⁴ 4-nitrobenzenethiol,³⁹ benzenethiol^{34, 39} and 4-chlorobenzenethiol,⁶⁵ with heat evolution.

Imines **87** have been introduced *in situ* in the reaction with 4-chlorobenzenethiol; this gave *N*-[polychloroalkyl-1-(4-chlorophenylthio)]amides **88**.⁴⁵

X = MeCHCl, PhCHCl; R¹ = MeOCO, PhCO; R² = 4-ClC₆H₄.

d. Reactions of imines with bifunctional O,O-, O,N-, S,N- and N,N-nucleophiles

The reactions of trichloropropionaldehyde acetylamine with 4-aminophenol and *para*-phenylenediamine have been studied.¹³⁰ These reactions were found to involve the amino group of the aminophenol or both amino groups of phenylenediamine and to give 4-(1-acetamido-2,2,3-trichloropropyl)aminophenol **89** or bis(*N*-1-acetamido-2,2,3-trichloropropyl)-1,4-phenylenediamine **90**.

The sulfonylimine **2b** reacts with monoethanolamine at –20 °C giving compound **91** in a quantitative yield.¹⁴⁴

Treatment of the sulfonylimines **2** with triethanolamine or dimethylethanolamine induces only haloform decomposition of azomethines.⁷³ However, the ethoxycarbonylimine **10b** reacts with *N,N*-dimethylethanolamine giving rise to a stable addition product **92**.⁷³

Only decomposition products — sulfamides, chloroform and aminothiol hydrochloride — have been isolated upon the exothermic reaction of the imines **2** with aminoethanethiol.¹⁴⁴

The reaction of ethylene glycol with the imines **3** has given both mono- (**93**) and bis-O-amidoalkylation products, [1,2-bis(1-arylsulfonamido-2,2,2-trichloroethoxy)ethanes **94**.¹⁴⁴

The reactions of dialkyl *N*-tetrachloroethylidene phosphoramidates with trimethyl and triethyl phosphites occur in a similar way and result in the formation of trichlorovinylamides $\text{Cl}_2\text{C}=\text{CClN}[\text{P}(\text{O})(\text{OR}^1)_2]$ ($\text{R}^1 = \text{R}^2 = \text{Me, Et}$; $\text{R}^1 = \text{Me, R}^2 = \text{Et}$).¹⁰²

The reaction of benzoylchloral imine **3a** with triethyl phosphite follows a different pathway yielding a complex mixture of products, in which diethyl 1-benzamido-2,2-dichlorovinylphosphonate **100** and diethyl 1-benzamido-2,2,2-trichloroethylphosphonate **101** have been detected.¹⁴⁷

Trimethyl phosphite reacts with the imine **3a** giving only dimethyl 1-benzamido-2,2-dichlorovinylphosphonate **102**; the yield of this product is not given in the study cited.¹⁴⁸

$$\begin{array}{lcl}
 & \xrightarrow{(\text{EtO})_3\text{P}} & \text{Cl}_2\text{C}=\text{C}(\text{NHCOPh})\text{P}(\text{O})(\text{OEt})_2 \\
 & & \mathbf{100} \\
 \text{Cl}_3\text{CCH}=\text{NCOPh} & \xrightarrow{(\text{EtO})_3\text{P}} & \text{Cl}_3\text{CCH}(\text{NHCOPh})\text{P}(\text{O})(\text{OEt})_2 \\
 \mathbf{3a} & & \mathbf{101a} \\

 & & \text{CCl}_2 \quad \mathbf{102a}
 \end{array}$$

Detailed study of the reaction of the imine **3c** with trimethyl phosphite¹⁴⁸ showed that, depending on the reaction temperature, different products can be obtained.

The sulfonylimines **2** react with glycolic and sulfanylacetic acids under mild conditions to give nucleophilic addition products, *O*- or *S*-(2,2,2-trichloro-1-arylsulfonylamino)glycolic **96a** and -thioglycolic **96b** acids, respectively.^{124, 145} When these products are treated with thionyl chloride and then with triethylamine, intramolecular cyclisation occurs giving rise to 3-arylsulfonyl-2-trichloromethyl-1,3-oxazolidin-4-ones **97a** and -1,3-thiazolidin-4-ones **97b**.

At $-13\text{ }^{\circ}\text{C}$, a mixture of dimethyl α -(*N*-acetyl)amino-2,2,2-trichloroethylphosphonate **101b** and dimethyl α -(*N*-acetyl)amino-2,2-dichlorovinylphosphonate **102b** is formed. The same reaction carried out without cooling ($40\text{--}45\text{ }^{\circ}\text{C}$) affords 1,3-oxazine **103**, and at $-40\text{ }^{\circ}\text{C}$, 1,2,4-oxaphosphazole **104** is obtained.¹⁴⁹

Organophosphorus acids and thioacids react with imines to give addition products.^{36, 37, 150, 151} *N*-Acetyl-,³⁷ *N*-ethoxycarbonyl-³⁶ and perchloroalkylsulfonyl-trichloroacetaldimines⁷¹ readily add various organophosphorus reagents. In the case of dialkyl phosphites, dialkyl 1-acetyl-, 1-ethoxycarbonyl- and perchloroalkylsulfonyl-amino-2,2,2-trichloroethylphosphonates **105** are formed.

Ar = 4-MeC₆H₄ (**a**), Ph (**b**).

Dialkyl *N*-trichloroethylidene phosphoramidates react with trialkyl phosphites giving rise to bis(phosphorylated) compounds.^{99, 147}

The P-substituted imine **7b** also adds diethyl phosphite being thus converted into diethyl *N*-(1-diethoxyphosphoryl-2,2,2-trichloroethyl) phosphoramidate.⁵⁰

The reaction of diphenylphosphinic acid³⁷ with the acetyl-imine **3c** results in the formation of the O-addition product, 1-acetylaminotrichloroethyl diphenylphosphinate **106a**; in the case of phosphorothioic and -dithioic acids, S-addition products, namely, 1-acetyl-amino-2,2,2-trichloroethyl diphenylphosphino-dithioates and -thioates **106b,c** are produced.^{37, 150, 151}

R = Ph, X = Y = O (**a**); R = Ph, MeO, EtO, PrⁿO, PrⁱO, X = Y = S (**b**); R = EtO, PrⁿO, PrⁱO, X = S, Y = O (**c**).

Phosphorus pentachloride is widely used in the reactions with derivatives of alkyl- and alkoxy-carbonylimines of polyhaloaldehydes in order to prepare isocyanates.^{62, 63} However, heating of *N*-perchloroethylideneureas **8**^{63, 64} with PCl₅ yields highly reactive halo-substituted diazadienes **107a,b** in 41%–76% yields.

R = Prⁱ (**a**), Ph (**b**).

N-Mesityltrichloroethylideneurea reacts with phosphorus pentachloride to give a mixture of two isomers, carbodiimide and diazadiene.⁶³

An unusual reaction of *N*-*tert*-butyl-*N'*-perchloroethylideneurea with PCl₅ was discovered; in this case, phosphorus pentachloride acts simultaneously as a chlorinating and a phosphorylating agent.⁶⁴

When *N*-dichlorophosphorylimines of polychloroaldehydes are treated with phosphorus pentachloride, (dichlorophosphorylthio)polyhaloethylideneimines **37a–d** are formed (see Section II.6).⁹⁹

3. Reactions of acylimines with organometallic compounds and metals

Reactions of polyhaloaldehyde imines with organometallic compounds have been less studied. A review has been published¹⁹ dealing mainly with reactions with organomagnesium and -lithium compounds.

In the general case, alkoxy-carbonylimines of chloral **10a,b** are converted into nucleophilic addition products **108** upon reactions with non-branched Grignard reagents.^{39, 152}

R¹ = MeO, EtO; R² = Me, Et, Pr, Bu, Ph, PhCH₂, CH₂ = CHCH₂.

Branched organometallic compounds reduce the imine **10b** to the corresponding amine, which adds to the initial compound to give the aminal. This product cyclises giving rise to azetidine **109**.¹⁵²

R = Prⁱ, Buⁱ.

Acylimines of halogenated aldehydes, like other halogenated imines, react with lithium aluminium hydride yielding substituted aziridines.^{19, 153, 154} In particular, *N*-acetyl-*R*-2,2-dichloroacetal-dimines are converted into 1,2-substituted aziridines **110**, in which the acyl group has been reduced to an ethyl group.

R = Pr, Bu, C₅H₁₁.

The behaviour of trichloroethylideneacetamide **3c** in reactions with zinc and electrophilic reagents has been studied.¹⁵⁵ The interaction of the imine **3c** with zinc affords a zinc-containing intermediate, which is a polydentate reagent with three nucleophilic centres — the carbon, nitrogen and oxygen atoms. The reaction of this intermediate with α-chlorinated ethers or acyl halides gives *N*-addition products, namely, substituted amides and imides. The reaction with chlorotrimethylsilane affords the O-attack product, *N*-(2,2-dichlorovinyl)-*N*-(1-trimethylsilyloxyethylidene)amine.

R = Me, Prⁱ, Buⁿ, Bu^t, Ph.

4. Reactions of imines with inorganic acids

The reactions of imines with hydrogen chloride have been studied in the greatest detail; it has been shown that polyhaloalkylidene-amides of dialkylphosphinic, carboxylic and carbamic acids are converted into chloroalkyl derivatives.^{33, 35, 37, 39, 46, 50}

On treatment of the sulfonylimines **2a,b** with hydrogen cyanide in the presence of triethylamine, 1-(arylsulfonylamino)-2,2-dichloroacrylonitriles **111a,b** are readily formed.¹⁵⁶

Ar = 4-MeC₆H₄ (**a**), Ph (**b**).

Similarly, when the benzoylimine **3a** is treated *in situ* with hydrogen cyanide, *N*-(2,2-dichloro-1-cyanovinyl)benzamide is produced.³⁸

On the other hand, the methoxycarbonylimine of trichloromethyl phenyl ketone adds hydrogen cyanide to give the amide Ph(CCl₃)C(CN)NHCOOMe.⁶²

The reaction of chloral imines with hydrazoic acid has been carried out; this gave 1-amino-2,2,2-trichloroethyl azides **112**.⁴⁰

R = PO(OEt)₂, COEt, COPr, COCH₂Ph, COOEt.

5. Cycloaddition reactions involving alkoxy-carbonyl-, acyl- and sulfonyl-imines of polyhaloaldehydes

The capability of acylimines, including halogenated ones, of exhibiting the properties of both dienophiles and dienes has been discussed in reviews.^{157, 158} Sulfonylimines can act as dienophiles.¹⁵⁸ It should be noted that these reviews^{157, 158} are far from embracing all publications devoted to this topic.

The high reactivity of chloral sulfonylimine **2a** towards dienes (2,3-dimethylbutadiene and cyclopentadiene) was first reported in 1964.¹⁵⁹ Reactions of chloral sulfonylimines with a large number of dienes (piperylene,¹⁶⁰ butadiene,¹⁶¹ cyclopentadiene,^{57, 158–164} dimethylbutadiene^{161, 162, 165} and isoprene^{160, 161}) have been studied much later. The cycloaddition products, 1-arylsulfonyl- and 1-alkoxycarbonyl-2-trichloromethyl-1,2,3,6-tetrahydropyridines **113** and *N*-arylsulfonyl- and *N*-alkoxycarbonyl-2-azabicyclo[2.2.1]hept-5-enes **114** are formed in 50%–94% yields.

N-Ethoxycarbonyl-2-azanorbornenes have been synthesised and some of their reactions, for example, dehydrochlorination and bromination, have been studied.^{161, 162}

N-Ethoxycarbonyl-2-azabicyclo[2.2.2]oct-5-ene **115** has been prepared¹⁶³ by the reaction of the imine **10b** with cyclohexadiene. Chloral 4-tolylsulfonylimine **2a** does not enter into the cycloaddition reaction with cyclohexadiene either on heating or under acid catalysis.¹⁶³

R¹ = MeOCO, EtOCO, MeCO, 4-XC₆H₄SO₂ (X = H, Me, Cl, MeO); R², R³, R⁴ = H, Me.

Cycloaddition of halogenated azomethines to non-symmetrical dienes occurs regiospecifically giving only one of the two possible isomeric heterocycles.¹⁶⁰

Study of the ¹H NMR spectra of 4-tolylsulfonyl-, alkoxy-carbonyl-, and acetyl-substituted 2-azanorbornenes and bicyclooctenes, prepared by the reactions of chloral imines **2a**, **3c**, and **10a,b** with cyclopentadiene and cyclohexadiene, showed that these bicyclic systems are mixtures of two isomers with *exo*- and *endo*-arrangement of the trichloromethyl group, the isomer ratio being dependent on the reaction temperature and on whether or not a Lewis acid is present in the system.^{161–164}

Acylimines of polyhaloaldehydes are able to participate in reactions with dienes not only as dienophiles but as heterodienes.¹⁶²

R¹ = R² = Me (**a**); R¹ = Me, R² = H (**b**); R¹ = OMe, R² = H (**c**).

Thus the acetylimine **3c** reacts with 2,3-dimethyl-, 2-methyl- and 2-methoxybuta-1,3-dienes mainly as a diene to give mixtures of 5,6-dihydro-4*H*-1,3-oxazine derivatives **116a–c** and **117a–c**. When the acetylimine reacts with 2,3-dimethylbuta-1,3-diene, it acts as a dienophile; a compound of the type **113** was isolated.¹⁶⁵

The methoxycarbonylimine **10a** reacts with 1-alkoxydienes as a dienophile, the final reaction product, 1-methoxycarbonyl-2-trichloromethyl-1,2-dihydropyridine **119**, being formed in 84% yield upon elimination of an alcohol molecule with simultaneous migration of the double bond in the intermediate **118**.¹⁶⁶

R = Me, Et.

Chloral acylimines introduced in reactions with vinyl ethyl ether act as heterodienes, which leads to 2-alkyl-6-ethoxy-4-trichloromethyl-5,6-dihydro-4*H*-1,3-oxazines **120a–d**.¹⁶⁷

R = Me (**a**), Et (**b**), Pr (**c**), Ph (**d**).

Sulfonylimines are capable of forming [2 + 2]-cycloadducts. Thus the imine **2f** reacts with trimethylsilyl ketene or ketene at room temperature to afford 1-propylsulfonyl-4-trichloromethyl-azetidin-2-ones **121a,b**.^{168, 169}

R = H (**a**), SiMe₃ (**b**).

The reaction of the sulfonylimine **2f** with trimethylsilyl ketene diethylacetal gives 3-(*N*-trimethylsilylpropylsulfonylamino)-1,1-diethoxy-4,4,4-trichlorobut-1-ene **122** instead of a cyclic product. The compound **122** undergoes desilylation and hydrolysis yielding ethyl 3-(propylsulfonylamino)-4,4,4-trichlorobutanoate **123**.⁵³

The researchers⁵³ suggested that the reactions with trimethylsilyl ketene acetals occur *via* bipolar intermediate **A**, which is stabilised upon migration of the trimethylsilyl group. An alternative pathway in which the silyl group migrates in [2 + 2]-cycloadduct **124** formed from the intermediate **A** is also possible.

O-Silylated analogues of the compound **122**, 1 : 1 adducts **125**, have been isolated upon reactions of trimethylsilyl ketene dialkylacetals with the acetylimine **3c**. No desilylation was observed in this case.^{169, 170}

It is noteworthy that the reaction of the imine **3c** with ketene acetals occurs without heating and gives [2 + 4]-cycloadducts, 6,6-dialkoxy-2-methyl-4-trichloromethyl-5,6-dihydro-4*H*-1,3-oxazines **126**. Under hydrolysis conditions, they are converted into alkyl 3-(methylcarbonylamino)-4,4,4-trichlorobutanoates, for example, compound **127**.¹⁷⁰

$\text{R}^1 = \text{H}, \text{Me}_3\text{Si}; \text{R}^2 = \text{Me}, \text{Et}, \text{Pr}^i$.

No cyclic products have been isolated after the reactions of the imines **10a, b** with ketene diethyl- and dimethylacetals. However, the formation of these products was proved by spectroscopy and by isolation of esters **128**, resulting from their transformations, in quantitative yields.¹⁷¹

$\text{R}^1, \text{R}^2 = \text{Me}, \text{Et}$.

The reaction of chloral acetylimine **3c** with *O*-acetyl-*O*-ethyl-trimethylsilyl ketene acetal gives a 1 : 1 product **130**, which is an ester of substituted butyric acid containing a trimethylsilyl group at the α -position. Presumably, this product results from migration of the acetyl group in the intermediate **129**.¹⁷²

Meanwhile, 2-trimethylsilyloxy-3-trimethylsilylacrylonitrile reacts with the imine **3c** only in the presence of a catalyst, trimethylsilyl trifluoromethanesulfonate. The reaction involves the activated cyano group and results in [4 + 2]-cycloadduct, 4*H*-1,3,5-oxadiazine.¹⁷³

The reactions of imines with several acetylene derivatives have been studied. The chloral imine **3c** reacts with silicon- and germanium-substituted alkoxyacetylenes at room temperature without a catalyst to give a mixture of [4 + 2]-cycloadducts — 6-alkoxy-2-methyl-4-trichloromethyl-5-trialkylsilyl(trialkylgermyl)-4*H*-1,3-oxazines **131** — and *N*- and *O*-element-substituted acyclic compounds isomeric to them.¹⁷²

$\text{R}^1, \text{R}^2 = \text{Me}, \text{Et}; \text{M} = \text{Si}, \text{Ge}$.

It is noteworthy that the reactions of ethoxyacetylene and methoxymethylacetylene with the imine **3c** occur over a period of 20 h at room temperature and give [4 + 2]-cycloadducts of type **131**, 6-alkoxy-2-methyl-4-trichloromethyl-1,3-4*H*-oxazines.⁵²

The reactions of trialkylsilyl(germyl)ethoxyacetylenes with sulfonylimines follow the [2 + 2]-cycloaddition route. The resulting cycloadducts, 1-alkylsulfonyl-2-alkoxy-3-trialkylsilyl(germyl)-4-trichloromethyl-2-azetines, undergo ring opening under thermolysis conditions. The addition of water to the product of recyclisation of the triethylgermyl derivative of azetidine involves the C = C bond and gives compound **132**, the azomethine group remaining intact.⁵²

$\text{R}^1 = \text{Me}, \text{Pr}; \text{R}^2 = \text{Me}_3\text{Si}, \text{Et}_3\text{Si}, \text{Me}_3\text{Ge}, \text{Et}_3\text{Ge}; \text{R}^3 = \text{Me}, \text{Et}$.

Arylsulfonyl-, acetyl- and alkoxy-carbonyl-imines of chloral enter into cycloaddition reactions with azomethines and azadienes. Thus cycloaddition of diphenyl isocyanatophosphite to the imine **3c** yields cycloadducts, the dimerisation of which during the reaction leads to tricyclodecanes **133**.¹⁷⁴ When the imine **3c** reacts with dimethyl alkynylphosphonites, unstable cycloadducts are formed, which are hydrolysed to give linear derivatives **134**.

Chemical reaction scheme showing the synthesis of two phosphorus-containing heterocycles from a common starting material.

The starting material is $(\text{EtO})_2\text{P}(\text{O})\text{C}(\text{Cl})_3$ (trichloromethyl diethylphosphonate).

Reaction 1 (top): Reaction with R_3P yields a 5-membered heterocycle (phosphorinane derivative) containing a phenyl group, a trichloromethyl group, and a diethoxyphosphoryl group.

Reaction 2 (bottom): Reaction with a benzodioxane derivative (containing a PNEt_2 group) yields a 6-membered heterocycle (phosphorinane derivative) containing a phenyl group, a trichloromethyl group, and a diethoxyphosphoryl group, fused to a benzodioxane system.

Ar = Ph, 4-ClC₆H₄, 4-MeC₆H₄; X = H, Cl; R = H, Cl, Me;
Z = S, O, NH, NMe.

The sulfonylimines **2a–c** react with 1,8-bis(dimethylamino)naphthalene without heating or catalysts giving rise to 4-[1-(arylsulfonylamino)-2,2,2-trichloroethyl]-1,8-bis(dimethylamino)naphthalenes **139**.¹⁸⁶

Ar = 4-MeC₆H₄ (**a**), Ph (**b**), 4-ClC₆H₄ (**c**).

The sulfonylimines **2** react equally easily with indole and its substituted derivatives being thus converted in good yields into compounds **140**, resulting from C-amidoalkylation at the 3-position.¹⁸⁷

Ar = Ph, 4-ClC₆H₄; R¹, R² = H, Me.

The sulfonylimine **2b** C-amidoalkylates azines and hydrazones of aldehydes and ketones containing α-methylene and α-methine groups; this leads to 3-arylsulfonylamino-4,4,4-trichlorobutyl ketazines **141a,b**, aldazines **141c,d** and hydrazone **142**.¹⁷⁷

R¹ = R² = H; R³ = Me (**a**), Ph (**b**); R¹ = R² = Me, R³ = H (**c**);

R¹ = R³ = H, R² = Et (**d**).

The use of polyhaloaldehyde imines for C-amidoalkylation of heterocyclic compounds extends the capacity for the preparation of new derivatives. Thus chloral imines of carboxylic and carbamic acids have been used in C-amidoalkylation of pyrazolones. This resulted in the synthesis of 2-aryl(alkyl)-4-[1-acetyl(benzoyl)aminoethyl]-2,2,2-trichloro-3-alkyl(phenyl)-2-pyrazolones **143** in high yields.¹⁸⁸

R¹ = Me, Et, Bu^t, Ph; R² = Ph, 2,4,6-Cl₃C₆H₂, Me; R³ = Me, Ph, OEt.

The reactions of N-acyl-N-(2,2,2-trichloroethylidene)amines (which were prepared *in situ* from the corresponding 1,2,2,2-tetrachloroethylamides) with enamines **144** and **145** occur with high diastereo- and enantioselectivity yielding amidoalkylation products, which are hydrolysed to give chiral 2,2,2-trichloroethylamides **146**, **147**.¹⁸⁹

Reactions of various types of monohydroxypyrimidines with N-(benzoyl)trichloroacetalimine **3a** and other acylimines **3**, generated *in situ* from the corresponding tetrachloroethylamides have been studied.^{190,191} It was found that 2-hydroxypyrimidines and 4-hydroxypyrimidines containing no substituents at the 2-position form the products of amidoalkylation of the NH group — 1-(1-acylamino-2,2,2-trichloroethyl)-2- (**148**) and -4-hydroxypyrimidines **149**, respectively.¹⁹⁰

R = Ph, H, Bu^t,

R¹ = H; R² = Ph, H, Bu^t, , 4-ClC₆H₄;

R¹ = Me; R² = Ph, H, Bu^t, .

In the case of 2-alkyl-4-hydroxypyrimidines, the reaction involves the oxygen atom and gives O-(1-acylamino-2,2,2-trichloroethyl)-4-hydroxypyrimidines **150a-d**; in the opinion of the authors cited,¹⁹⁰ this is due to the steric shielding of both nucleophilic centres at the nitrogen atoms.

R¹ = H, R² = Me; R³ = H (**a**), Ph (**b**);

R¹ = Me, R² = Prⁱ; R³ = Ph (**c**), 4-ClC₆H₄ (**d**).

Long refluxing of the imine **3a** with 4-hydroxy-2-methylpyrimidine induces C-amidoalkylation involving the methyl group of the pyrimidine, which affords 2-(2-benzamido-3,3,3-trichloropropyl)-4-hydroxypyrimidine **151b**.¹⁹⁰ The product **151a** with a

similar structure was also isolated when the pyrimidine **150a** was heated in the presence of triethylamine.¹⁹⁰

C-Amidoalkylation of 4-hydroxy-6-methylpyrimidine does not proceed even under rigorous conditions.¹⁹⁰

When 4-methoxy-6-phenacylpyrimidine **152** reacts with *N*-(1,2,2,2-tetrachloroethyl)amide of 4-chlorobenzoic acid in the presence of Et₃N, monoamidoalkylation product **153** is formed. When **152** reacts with the imine **3j**, the activated methylene group in the side chain and the ring nitrogen atom may be amidoalkylated simultaneously giving rise to compound **154**.¹⁹¹

(a) Cl₃CCHClNHCO₂C₆H₄Cl-4, Et₃N, Δ; (b) Cl₃CCH=NCOC₆H₄Cl-4 (**3g**).

C-Amidoalkylation of the closest analogues of pyrimidine **152** — 4-dimethylamino-, 4-methyl-, 4-benzoylmethyl-6-(benzoylmethyl)-pyrimidines — has been accomplished by introducing these compounds into reactions with *N*-(1,2,2,2-tetrachloroethyl)amide of 4-chlorobenzoic acid in acetonitrile in the presence of triethylamine.¹⁹¹ The alkylation involves the benzoylmethylene group and affords compounds of the type **153** — 4-dimethylamino-, 4-methyl-, 4-benzoylmethyl-6-[3,3,3-trichloro-2-(4-chlorobenzoylamino)-1-benzoylpropyl]pyrimidines.¹⁹¹

Under similar conditions, amidoalkylation of some 5-R-uracils by tetrachloroethylamides of benzoic acids involves both nitrogen atoms and affords 1,3-bis[2,2,2-trichloro-1-(4-chlorobenzoylamino)ethyl]-5-R-pyrimidine-2,4-diones **155**.¹⁹²

R = H, Ph, OMe.

The reaction of 2-thiouracil with tetrachloroethylamides in the presence of triethylamine follows a more complex pathway, which includes not only amidoalkylation at the nitrogen and sulfur atoms but also dehydrochlorination; this gives 2-[(1-amido-2,2-dichlorovinyl)thio]-4-(1-amido-2,2,2-trichloroethoxy)pyrimidines **156**.¹⁹³

R = Bu^t, Ph, C₆H₄Cl-4, OMe.

7. Other reactions of polyhaloaldehyde imines

Reduction of imines presents interest as a method for the synthesis of amines. Only a single example of diastereoselective reduction of an azomethine group in cyclic dichlorocamphorsulfonylimine **157** to camphorsultam **158** (yield 93%–97%) was reported.¹⁹⁴ In the case of the corresponding bromo-derivative, debromination is the predominant reaction route.

It was found¹⁹⁵ that when benzylsulfonamide reacts with chloral in the presence of trifluoromethanesulfonic anhydride or another similar reagent, the chloral benzylsulfonylimine formed at the first stage undergoes intra- and intermolecular heterocyclization under the reaction conditions to afford 3,4-dihydro-1*H*-1,3-benzothiazine 2,2-dioxide **159** (yield 3%–58%) and 1,3,5-tribenzylsulfonylhexahydrotriazine **160** (yield 17%).

8. Reactivity of arylsulfonyliminopolychlorocyclohexenes

The reactions of bis(arylsulfonylimino)-2,3,5,5,6,6-hexachlorocyclohex-2-enes **27b,c** with reducing agents, organophosphorus and organosilicon compounds, alcohols, primary aromatic amines, secondary cyclic amines^{196, 197} and with hydrazoic acid¹⁹⁸ have been studied.

When the compounds **27b,c** react with Na₂S₂O₄, zinc in acetic acid or with dialkyl phosphites, elimination of two chlorine atoms from the 5- and 6-positions occurs to give the benzoid structure **161**.¹⁹⁶

The reactions with methanol give products **162** resulting from addition to one azomethine bond. It was shown that 1,4-bis(arylsulfonylimino)hexachlorocyclohex-2-enes **27b,c** do not react with any other alcohols.¹⁹⁶

The reactions of the bis(sulfonylimines) **27b,c** with aromatic amines containing no electron-withdrawing groups in the aromatic ring also involve the addition to the C=N bond and give rise to compounds **163**.¹⁹⁶

The reactions with morpholine and piperidine occur as nucleophilic substitution of the chlorine atom at the sp^2 -hybridised carbon atom of the bisimine and give products **164**.¹⁹⁶ Two processes — elimination of two chlorine atoms and 1,6-addition to the system of conjugated double bonds — occur simultaneously in the reactions of **27b,c** with trimethylsilyl diisopropyl phosphite. The addition products are subsequently hydrolysed with elimination of the trimethylsilyl group, which leads to compounds **165**.¹⁹⁶

When the bis(sulfonylimines) **27b,c** react with pyridine, this gives the products of substitution of the vinylic halogen atom, *N*-[3,6-di(arylsulfonylimino)-2,4,4,5,5-pentachlorocyclohex-1-en-yl]pyridinium chloride **166**; on exposure to UV radiation or under electron impact, these compounds eliminate two chlorine atoms to give quinone structures, *N*-[3,6-di(arylsulfonylimino)-2,4,5-trichlorocyclohex-1,4-dienyl]pyridinium chlorides **167**.¹⁹⁶

$\text{Ar} = 4\text{-MeC}_6\text{H}_4 \text{ (b)}, 4\text{-ClC}_6\text{H}_4 \text{ (c)}.$

The reaction of 4-arylsulfonyliminohexachlorocyclohex-2-en-1-ones **28b,d** with pyridine results in the isolation of arenesulfonamides and compounds **168**, formed upon the substitution of a pyridinium ion for the chlorine atom in the resulting 1,4-dioxo-2,3,5,5,6,6-hexachlorocyclohex-2-ene.¹⁹⁷

It is of interest that 4-arylsulfonylimino-2,2,3,3-tetrachloro-1-oxo-1,2,4,4-tetrahydronaphthalenes **29** do not react with pyridine.

$\text{Ar} = 4\text{-ClC}_6\text{H}_4 \text{ (b)}, 4\text{-MeC}_6\text{H}_4 \text{ (d)}.$

The reaction of the imines **28a–c** with hydrazoic acid occurs as nucleophilic replacement of the chlorine atom at the sp^2 -hybridised carbon atom located at the 2-position, accompanied by competing elimination of chlorine with restoration of the benzoid structure.¹⁹⁸

$\text{Ar} = \text{Ph} \text{ (a)}, 4\text{-MeC}_6\text{H}_4 \text{ (b)}, 4\text{-ClC}_6\text{H}_4 \text{ (c)}.$

V. Conclusion

Analysis of the published data indicates that *N*-functionally substituted halogenated imines are highly stable and can be prepared by reactions of *N,N*-dihaloamides with 1,2-polyhaloethenes, transformation of an isocyanate bond and by other non-trivial methods, which require further development.

Electronegative substituents at the $\text{C}=\text{N}$ bond account for the high reactivity of *N*-functionally substituted halogenated imines towards nucleophiles. A specific feature of these reactions is that nucleophiles attack the sp^2 -hybridised carbon atom of the $\text{C}=\text{N}$ bond. The enhanced electrophilicity of the $\text{C}=\text{N}$ bond in polyhaloaldimines permits the use of acyl- and sulfonyl-imines for *C*-amidoalkylation of aromatic and heterocyclic compounds. Search for conditions under which acyl- and phosphonyl-imines of polyhalogenated aldehydes and ketones could be involved in similar reactions appears to be topical task.

Chloral acyl- and alkoxycarbonyl-imines can enter into cycloaddition reactions as heterodienes but can also act as dienophiles. Unfortunately, imines of the largest class, polyhaloalkylphosphonylimines, have not been studied in cycloaddition reactions.

Halogen-containing imines are of interest regarding investigation of the enamide–imine tautomerism and *syn–anti* isomerism of azomethines and determination of the energy parameters of tautomerisation and isomerisation.

The synthetic potential of imines is now far from being completely utilised. The data on the reactivity of halogenated imines can serve as the basis for targeted design of required structures with important biogenic groups: acyl-, phosphonyl- and sulfonyl-amide groups and polyhalomethyl groups. It can be expected that more extensive studies along this line would permit the researchers to perform intra- and intermolecular heterocyclisation of imines, reactions involving haloalkyl groups, etc.

VI. Conclusion	613

Abstract. Chemical reactions occurring in the combustion and decomposition of char-forming polymeric systems and the effects of the nature of the polymer and additives on the reaction pathways are discussed. The thermal characteristics of the chars formed upon combustion are considered. The bibliography includes 86 references.

I. Introduction

The lowering of ignitability and flammability of polymers and the creation of fire retarding materials is an urgent problem which demands immediate solution. Regulation concerning the prohibition or limited use of flammable polymeric materials in industrial and civil engineering, construction of means of transportation (aircraft, automobiles, railway cars, ships), electrical and electronic engineering and production of special-purpose materials have been passed in many countries.

This circumstance has given a strong impetus to the studies aimed at elaboration and practical application of fire retarding polymeric materials. In the coming years, many commodities prepared on the basis of polymeric materials will be manufactured only in a fireproof form.

The production of fire retarding polymeric materials is following three main directions, *viz.*, synthesis of fire retarding polymeric materials, chemical and physical modification of polymers and the use of fire retardants.

The first trend, which holds especially great promise, consists in the synthesis of polymers of two types, *viz.*, polymers yielding incombustible gases upon decomposition and highly thermostable rigid-chain polymers. The first group of compounds includes fluorine- or nitrogen-containing polymers (*e.g.*, fluoroplastics,

nitroso and triazine elastomers)¹ and organoelement polymers (*e.g.*, polyphosphazenes, polysiloxanes and polycarboranes).^{2–4} The second group comprises polymers containing heterocyclic fragments, such as polysulfones (arylox, bakelite, radel, udel, *etc.*), polyphenylene sulfides, liquid-crystalline polyesters (vectra, econol, *etc.*), polyamides (phenilon, kevlar, polymers containing mesogenic groups), polyimides (kapton, epilex, ultem, torlon, *etc.*) and polyheterocycles, such as polypyrazoles, polyoxazoles, polybenzimidazoles, polybenzoxazoles, polyquinoxalines and polyimidazobenzophenanthrolines (the BBB polymer).⁵ Rigid-chain polymers combine low flammability and high thermostability with other valuable properties, *e.g.*, high chemical and radiation stability, high durability and dielectric characteristics.

Studies^{6–8} of effects of the chemical structure and conditions of preparation of polymers on their flammability and thermal characteristics have demonstrated a good correlation between the yields of non-volatile residues formed upon decomposition of the polymers and their flammability (oxygen index, OI). The yields of carbonised products depend on the chemical structures of polymers.^{6,7} The smaller the number of flexible 'hinge' groups in the polymer molecule the higher the char yield. It is of note that the flammability of poly(ester imides) depends on the method used for their synthesis.⁸ It was shown also that the thermal stability of a polymer is determined by the nature of its end groups and the presence of admixtures.

Unfortunately, the high cost of organoelement and high-performance polymers restricts the fields of application of materials based on them. Today, the production of low-cost polymers which employs less power-consuming synthetic procedures and less expensive monomers seems to have especially great potential.

Chemical and physical modification of polymers is the second trend in the production of fire retarding polymeric materials. In order to decrease the flammability of carbochain polymers, carbochain monomers are copolymerised with halogen- or phosphorus-containing monomers. In addition, chemical modification of synthetic polymeric products can be achieved by treating them with various reagents: this can be effected, *e.g.*, by bromination, chlorination, phosphorylation^{9–12} and polymer-analogous transformations aimed at incorporating halogen- and phosphorus-containing groups into polymers and copolymers.^{13–15} This approach was used to obtain brominated polystyrene¹⁶ and polyphenylene oxides,¹⁷ copolymers of vinyl acetate, ethylene and derivatives of halogen-containing acids¹⁸ and phosphorus-containing epoxy resins (PER).¹⁹

Received 4 August 1998

Uspekhi Khimii 68 (7) 663–673 (1999); translated by R L Birnova

Physical modification of polymers is based on the treatment of the polymer surface with various types of energy (plasma, thermal and laser beams, UV or IR irradiation, *etc.*). Using this approach, one can obtain fire retarding polymeric materials based on various polymers.²⁰ Unfortunately, modification very often induces significant changes in the properties of the polymers and cannot be used to decrease the flammability of industrial polymers.

The third approach to the preparation of fire retarding polymeric materials, which employs fire retardants, is the most popular and efficient way.

Polybrominated biphenyls and diphenyl oxides are the most widespread compounds endowed with the ability to decrease the flammability of industrial plastic materials. However, there is evidence that combustion and thermal degradation of polymeric materials based on them is accompanied by the formation of highly toxic products.^{21–23} Thus, the need arose for fire retarding materials devoid of low-molecular-weight polybrominated compounds. High-molecular-weight bromine-containing fire retardants meet this demand. It was established^{16, 17, 23} that thermal degradation of brominated polyphenylene oxides and polystyrene was not accompanied by the formation of highly toxic products either in the presence or in the absence of plastic materials. Fire retarding styrene-based plastics have been developed which contain high-molecular-weight fire retardants, their properties are comparable with those of styrene-based materials containing low-molecular-weight fire retardants.²⁴

II. Intumescent systems

The problem of formation of toxic compounds in the combustion of polymeric materials is completely eliminated if intumescent systems (IS) devoid of polybrominated diphenyls or diphenyl oxides are used. An IS represents a mixture of compounds which form foamed cokes on the polymer surface upon heating and thus prevent combustion. The fire-resistance due to foamed coke layers is associated with thermal insulation and barrier properties in mass transfer.^{25, 26}

The superficial foamed coke layer is formed as a result of complex physical and chemical processes, each contributing to the decrease in the polymer flammability. The factors affecting the flammability of IS-containing polymers can be classified as follows:

1. Reversal of the route of the polymer thermal degradation towards the formation of foamed cokes and incombustible volatile products.
2. A change in the heat balance of combustion due to the thermal effects of chemical reactions occurring on intumescence and dilution of fuels with incombustible gaseous products.
3. Thermal insulation of the polymer surface from reverse heat flows.
4. Prevention of fuel diffusion into the combustion zone.
5. Prevention of oxygen diffusion from the environment to the polymer surface.

The first two factors exert their influence on combustion through chemical reactions between individual components of the polymeric composition, while the rest are closely connected with the physical structure of the foamed coke.

III. Types of intumescent systems

1. The use of intumescent systems for decreasing the flammability of carbochain polymers

The following compounds can be used as IS components:^{27, 28} inorganic acids (in free form or as derivatives which generate acids on heating), polyhydroxy derivatives, nitrogen and halogen derivatives.

This classification is arbitrary, since any component may contain several functions. The presence of a nitrogen- or a halogen-containing compound is not always necessary. It is

believed that acids favour carbonisation of polyhydroxy derivatives (carbon source) due to dehydration, whereas nitrogen- or halogen-derivatives (foaming agents) facilitate intumescence of the system due to intense degradation associated with evolution of large quantities of gaseous compounds.

IS that are to be used in polymeric materials should meet the following requirements:²⁹

1. IS must be resistant to temperatures above 200 °C, which are often used in polymer processing.
2. Thermal degradation of polymers must not interfere with the foaming reaction.
3. IS should produce a protective foamed coke layer over the whole polymer surface despite the dilution of the additive with the polymer.
4. IS should not induce any significant changes in the physical and mechanical properties of the polymer or interact with other additives (pigments, stabilisers, *etc.*).
5. The mineral acid formed upon heating of the corresponding derivative used as IS should be high-boiling and should not be a strong oxidant.

Phosphoric acid derivatives (amides, esters, imides) meet these requirements most completely. Of these, high-molecular-weight ammonium polyphosphate (APP), $-\text{P}(\text{ONH}_4)(\text{O})\text{O}-$, where $n = 20-3000$, is the most popular fire retardant.³⁰

The IS containing APP used for decreasing the flammability of carbochain polymers are listed in Table 1. Several other compounds tested as fire retardants for various polymers are listed in Table 2.

These data suggest that efficient reduction of flammability demands a high degree of polymer filling, which inevitably increases its cost, deteriorates its physical and mechanical properties and impedes its processing.

The mechanisms of action of IS systems are different and depend on the structure of the polymer and the additives. The polymer can take part in the formation of the carbonised layer on the surface of the burning material, but the foamed coke layer can be also formed in the absence of the polymer.

2. The use of intumescent fire retardants for the preparation of polymeric materials based on polycondensation polymers

Polycarbonates are widely employed in electrical engineering, instrument making and automobile construction. These compounds are endowed with valuable and unique properties, such as higher thermal stability and lower flammability compared with polyalkenes and styrene-based plastic materials. Many branches of industry have a great demand for fire retarding polymeric materials based on polycarbonates (PC). The flammability of PC can be lowered if alkali metal salts of organic acids are used as additives. The preparation of materials with OI above 35% demands only small quantities of the additive ($\leq 3\%$).

The mechanism of action of these additives has been studied.^{48, 49} It is known that thermal degradation of polycarbonates occurs through two main routes. The first route consists in isomerisation followed by the formation of aryloxybenzoic acids **1**. Further thermal conversions of the thermal degradation products yield ethers, xanthenes and cross-linked structures:

The second route involves intramolecular transfer reactions, resulting in cyclic oligomers of type **2**. The reaction of product **2** with water and subsequent elimination of CO_2 yield phenols:

^a Designation: $X^+ =$ 

It has been found that the high efficacy of alkali metal salts of organic acids is determined by the fact that they accelerate thermal degradation of PC. This results in the increase in the amount of the char formed and evolution of CO_2 as one of the polymer decomposition products at lower temperatures. In addition, decomposition of PC in the presence of organic acid salts is

accompanied by the Fries rearrangement (migration of acyl groups of phenol esters to the *o*-position of the benzene ring), eventually resulting in the formation of cross-linked structures of the type 3:

Thermal decomposition of polycarbonates occurring along this route leads to the formation of a solid foamed coke layer on the polymer surface, which prevents further spreading of the flame. It was found⁴⁹ that foamed coke is made up of the polymer degradation products, *i.e.*, PC takes an active part in its formation, whereas the additive catalyses this process but is not directly involved in it.

It is known that the main drawback of PC is a drastic decrease in their impact strength at low temperatures.⁵⁰ Polymeric materials based on PC and an acrylonitrile–butadiene–styrene copolymer (ABS) and polyethylene terephthalate (PETP) are free from such defect. Some aromatic sulfonates as well as phosphorus- and bromine-containing compounds were tested as fire retardants for PETP–PC⁵¹ and ABS–PC mixtures.^{49, 52} It was found that aromatic sulfonates become less efficient after addition of ABS to PC.⁴⁹ The decrease in the fire retarding efficacy with the change in the composition of the polymeric matrix is due to the lowering (by 50 °C) of the temperature at which decomposition of PC containing ABS begins. As a result, the fire retardant does not affect the composition of PC pyrolysis products and the antipyr-rogenous effect of aromatic sulfonates on the PC–ABS mixture is not manifested.

Thus, IS prepared from aromatic sulfonates exert rather specific selective action and even minor alterations in the composition of the polymeric mixture may significantly decrease their efficiency.

Phosphorus-containing fire retardants can be recommended for the preparation of polymeric high-resistant materials based on a PC–ABS mixture. Although these compounds are less efficient than the bromine-containing ones, the materials based on them possess better mechanical properties.³⁹ The bromine- and phosphorus-containing fire retardant is especially efficient in PC–PETP and PC–ABS mixtures.^{51, 52}

The combustion of systems prepared from polyurethane and ammonium polyphosphate⁵³ or polyamide and ammonium polyphosphate⁵⁴ yields foamed cokes, predominantly due to the reaction of the polymer with the additive resulting in the formation of cross-linked products. Recently it was shown⁵⁵ that certain melamine salts are efficient as fire retardants for polycapramide, because these compounds also favour the formation of cross-linked products in the reaction of the additive with the polymer. The reactions resulting in the formation of foamed cokes have been considered.

Phosphoric acid is known to be an efficient fire retardant for cellulose.⁵⁶ Phosphoric acid reacts with the polymer, which alters the mechanism of thermal degradation of cellulose towards char formation; therefore, this system can be related to IS.⁵⁷

By virtue of their stability, adhesiveness, dielectric properties, thermal stability and technological efficiency, epoxy resins (ER) and phenol–formaldehyde resins (PFR) are widely employed as binding agents in preparation of reinforced plastic materials in many branches of technics. Fire retardants affecting the mechanism of their thermal degradation are the most efficient for these polymers. Thus the efficiency of some transition metal salts (*e.g.*, cobalt acetate) is due to their catalytic effect on dehydration and dehydrogenation of ER and PFR.^{58, 59} This significantly increases the char yield, while the yield of volatile flammable products formed in thermal degradation of ER decreases in the presence of organophosphorus compounds¹⁹ and certain phosphines.⁶⁰

The effects of the composition of ER on the mechanism of thermal degradation and the composition of the pyrolysis products responsible for the flammability of ER have been discussed.⁶¹ It was shown that enhanced char formation is the determining factor in this process.

Chemical reactions occurring in the presence of phosphoric acid used as IS for carbamide–formaldehyde resin (CFR) have been discussed in detail.⁶² It was shown that in the course of thermal conversions phosphoric acid reacts with the amide groups of CFR to give *N*-phosphorylated products, which lose water,

ammonia and carbon dioxide and eventually turn into foamed cokes

A viscous melt of poly(amidophosphates) favours the formation of a swollen carbonised layer and suppresses thermal oxidation of foamed cokes, which enhances the fire-proof effect.

Phosphorus-containing compounds, like phosphoric acid, react with functional groups of the polymer to yield foamed cokes which protect the polymer surface from the heat flow. It is the formation of foamed cokes that is responsible for the significant lowering of the flammability of the polymers to which a fire retardant has been added.

IV. Chemical reactions occurring in the intumescence

Chemical reactions occurring in the intumescence are most extensively studied for IS consisting of ammonium polyphosphate and pentaerythritol. The sequence of chemical and physical processes has been established: decomposition of ammonium polyphosphate at 215 °C, esterification of the alcoholic groups of pentaerythritol with liberation of H₂O, which results in the increase in the bulk of IS, solidification of the swollen carbon–phosphorus residue at 360 °C.³⁰

Studies using thermogravimetric analysis (TGA), thermovolumetric analysis and ³¹P NMR spectroscopy have shown^{63–69} that pentaerythritol is phosphorylated with APP at 210 °C with the scission of the main polyphosphate chain of APP and the formation of the –[P(O)OCH₂]– phosphate groups. This reaction does not yield volatile products.

This is followed by the formation of cyclic esters of polyphosphoric acid with elimination of ammonia and water.

Repetition of these reactions gives the structures of type 4.

The fact that the APP–pentaerythritol pyrolysis products are paramagnetic has led the authors to suppose that their formation occurs *via* an intermediate carbene **5**.⁶⁹

An alternative hypothesis suggests⁶³ that esterification of APP is preceded by the formation of a carbenium ion. The formation of cyclic structures as intermediates in thermal conversions of APP–pentaerythritol mixtures has made it possible to use bisphosphate of pentaerythritol as a model compound for investigation of a intumescence mechanism.^{63, 64} It was shown that condensation with elimination of water and formation of structures of type **4** is the first step in the degradation of this bisphosphate.

An analysis of ³¹P and ¹³C NMR spectra made it possible to propose the following mechanism for char formation. Its first step is the formation of the carbenium ion **6** owing to protonation and cleavage of the C–O bond. This ion can be rearranged into a stable tertiary carbocation **7**; deprotonation of the latter leads to the formation of the double bond. Subsequent pyrolysis of the ester **8** can occur with the elimination of phosphoric acid resulting in diene derivatives **9** which enter into the Diels–Alder reaction to give polycyclic compounds of the type **10**.

Repetition of these reactions yields conjugated aromatic structures.⁷⁰ The reactions can be accompanied by condensation of phosphoric acids and polymerisation; therefore, the reaction products possess irregular structures. Intumescence occurs within a narrow temperature range (300–350 °C) and results in the formation of a bulky carbonaceous residue containing admixtures of phosphoric acid.

The lack of a sufficient body of evidence does not allow any valid conclusion on the possibility of the interaction of polymers with IS. It was found^{63–68} that polypropylene (PP) has virtually no effect on the mechanisms of intumescence. In turn, IS do not influence the composition of products formed upon polymer decomposition. Experiments with TGA in air have shown^{38, 71} that the contribution of the polymer to char formation is insignificant. Presumably phosphoric acid reacts with alcohols formed in the oxidation of PP with atmospheric oxygen. Enhanced paramagnetic properties of the residue obtained upon pyrolysis of the polymeric composition in comparison with pure IS are attributed to the reaction of free radicals formed upon thermal degradation of the polymer with IS (APP + pentaerythritol).⁶⁹

This assumption was supported by the finding that the mass of the char residue diminishes in the presence of free radicals.

An analysis of the chemical composition of the chars formed upon thermal degradation of PP, polyethylene (PE) and polystyrene (PS) with IS (APP + pentaerythritol) has shown³⁹ that the chars formed at any temperature and with any polymer or without it are made up of identical chemical structures, which represent a combination of fragments containing quaternary carbon atoms with irregular aromatic and phosphorus–oxygen units.

However, there is conclusive evidence⁷² that the chemical structure of a comonomer and its content in the polymer strongly affect the interaction of IS based on APP and pentaerythritol with ethylene copolymers. It was found that butyl acrylate–ethylene and maleic anhydride–ethylene copolymers markedly increase the efficiency of IS due to their interaction in the condensed phase. It was also shown that aluminosilicate zeolites also significantly increase the efficiency of IS.⁷²

Reactions of ammonium polyphosphate with polyols (pentaerythritol, starch, polyvinyl alcohol, glycerol) have been studied in the search for the optimum ratio of reaction components to be used for the filling of polymers in order to decrease their flammability.⁴⁵

Irrespective of the polyol/APP ratio, all the systems examined displayed exothermic peaks of various intensities in the DPA curves. Presumably, this was due to the reaction of the polyol with APP with elimination of ammonia and water in this temperature range. The magnitude of the thermal effect was estimated on the assumption that the maximum thermal effect corresponds to the most complete reaction. It was established⁴⁵ that all the systems under study were characterised by identical mass loss and had identical masses of char residues, but differed in thermal effects.

The optimum APP/polyol ratio for all the systems tested was 7:3 (mass %) as can be judged from the identical mass loss in the reaction. However, no strict correlation between the char yield, mass loss upon esterification and maximum thermal effect was found for systems containing methylphosphonic acid and pentaerythritol.⁴⁵

V. Heat-insulating characteristics of foamed cokes formed upon combustion and thermal degradation of polymeric systems containing intumescent fire retardants

The efficiency of IS is determined primarily by heat-insulating characteristics of foamed cokes formed in the combustion of

Figure 1. The OI values for specimens burnt under ordinary conditions (1) and for specimens from which 'char caps' were removed during combustion (2).¹⁹

polymers. The role of 'char caps' in the lowering of flammability has been established¹⁹ by comparing OI of specimens burnt by routine methods with those where the foamed coke layer formed in the course of combustion was continuously removed (Fig. 1). The considerable difference in the characteristic curves and much greater values of OI in the former case (Fig. 1, curve 1) suggest that the presence of foamed cokes is the main factor decreasing flammability. Measurements of hydrodynamic resistances have shown⁷³ that foamed cokes cannot prevent the diffusion of degradation products to the combustion zone. It was concluded⁷³ that heat-insulating properties of 'char caps' play the crucial role in flammability reduction. These results are in good agreement with the finding⁷⁴ that the foamed coke layer is permeable by low-molecular-weight liquids. However, the results of microstructural analysis of foamed cokes formed in the combustion of IS-containing PP compositions by scanning electron microscopy led the authors to conclusion⁶² that diffusion of degradation products through the foamed coke layer plays an important role in combustion. The compositions with low OI displayed multiple fissures and breaks in the carbon structure, whereas foamed cokes formed from the compositions with high OI had closed pores.

Evidently, heat-insulating characteristics (HIC) of foamed cokes are responsible for the high efficiency of IS in PP. Model studies of forced combustion,^{36,75} where a polymer sample with a thermocouple inserted at a definite distance from its surface was flame-burnt, have demonstrated that the foamed coke layer formed significantly lowers the polymer temperature. Under these conditions, the rate of the polymer temperature changes, *i.e.*, HIC, of the foamed coke correlated with the OI. No such correlation was found for PP charged with various fillers (10%–30%) in addition to IS.³⁰

The HIC of foamed cokes formed from different compositions and polymeric matrices but containing the same amounts of IS have been investigated.⁷⁶ A great variety of compositions allowed the authors to establish a relationship between the flammability of polymer material and thermal characteristics of foamed cokes in a broad range of OI values. Thus it was found that a satisfactory correlation between OI and HIC was observed only for relatively low (< 25) OI values. In addition, it was shown that the flammability of IS-containing polymeric systems is determined not only by the HIC of 'char caps' but also by the rate of foamed coke layer formation.

Most authors believe that HIC of foamed cokes play the major role in flammability reduction, although no satisfactory correlation between these parameters has been found so far.

Various factors determining the HIC of foamed cokes formed upon combustion have been investigated.^{62,77} A unit used in these studies allows the registration of the light flux and the response in the sample's rear (Fig. 2a). The sample to be tested, which represents a disc (~ 1 mm thick) 10 mm in diameter (Fig. 2b) is mounted on a thin metal stage. The sample surface is irradiated with the light generated by a carbon dioxide laser. Part of the radiant flux is diverted to an ILD-24M irradiation meter by means of a semitransmitting mirror made of a chalcogenide glass. A

Figure 2. A schematic representation of a unit (a) and a stage (b) for studying heat-insulating characteristics of various materials; (1) carbon dioxide laser; (2) sample; (3) a thermocouple; (4) chalcogenide glass; (5) radiation meter; (6) interface; (7) computer; (8) the radiant flux; (9) asbestos support; (10) base.

chromel-copel thermocouple (0.08 mm thick) is placed on the sample's rear. Having passed through the mirror, the radiant flux reaches the sample and warms it up. The signal of the thermocouple response is passed to a computer. The experiments were carried out with both continuous and pulsating radiant fluxes (in the latter case, the ratio of the pulse length to the pause was equal to two) and ignition of the sample did not occur.

Figure 3 shows the temperature *vs* time curves for the combustion of PS, PP and PE containing IS prepared from APP and pentaerythritol.³⁹ Complete burn-out of polymers containing no fire retardants normally takes 15 s at temperatures ≤ 800 K and does not depend on their chemical nature. Comparison of experimental curves points to significant differences in the properties of foamed cokes at the moment of their formation. The shape of these curves is of complex type; each portion of the curve corresponds to a definite state of the system. A drastic increase in the temperature in the initial moment corresponds to the heating of the composition prior to foamed coke layer formation. Subsequent decline (curves 2 and 3) or a bend (curve 1) correspond to the formation and growth of the foamed coke layer on the polymer surface. The plateau corresponds to the intumescence of the sample in bulk and is associated with heat absorption upon intense degradation. A slow increase in temperature up to the steady-state level in the terminal steps indicates that the intumescence process is completed and the whole mass of the sample has been converted into foamed coke. The shape of the curve for the composition prepared from PE (curve 1) suggests that the

Figure 3. Heat-insulating characteristics of foamed cokes prepared from IS-containing polymeric compositions based on APP and pentaerythritol; (1) PE; (2) PP; (3) PS.

formation of foamed coke occurs at an extremely slow rate and it has low HIC. A small bend on the curve for the compositions prepared from PS (curve 3) points to a relatively high rate of foamed coke formation, which is followed by a decrease in the rate of warm-up for a short period. The shapes of the curves for the compositions prepared from PP and PS (curves 2 and 3) indicate that the formation of, and accumulation of, the foamed coke occur much faster than in the case of the compositions based on PE. These foamed cokes have enhanced HIC, but their shapes and the positions of their extrema point to differences in the kinetics of their intumescence. The sharp maximum on the curve for the composition based on PP (curve 2) suggests that the activation energy of the intumescence reaction is low, while the rate of intumescence and the HIC of foamed cokes formed even at insignificant heat fluxes are high. The maximum on the curve for the composition derived from PS (curve 3) points to the higher rate of intumescence and formation of foamed coke at higher temperature in comparison with the composition prepared from PP. In the final step, the rates at which the temperature changes occur and their limiting values for the compositions prepared from PP and PS coincide (curves 2 and 3), which testifies to identical properties of the 'char caps' formed. The differences in the HIC of 'char caps' at the moment of their formation and the similarity of their HIC in the case of IS-containing PS and PP compositions can be attributed to the differences in their internal structure, which is schematically presented in Fig. 4. In both cases, 'char caps' represent thick walls with large cavities inside. The walls of the 'caps' have porous structures, which differ in pore size and in wall thickness. The foamed coke formed from the composition based on PP has smaller pores and thinner walls; the air fraction (v/v) is greater (Fig. 4a).

Figure 4. A schematic representation of foamed cokes formed under the action of a heat flux; (a) a composition prepared from PP; (b) a composition prepared from PS.³⁹

Investigations into the effects of phosphorus-containing fire retardants based on methylphosphonic acid on the flammability of PE, PP and PS have demonstrated⁴⁷ that in the case of PE and PP the fire retardants prepared from the adduct of melamine–formaldehyde resin and methylphosphonic acid (MFMA), from the adduct of methylphosphonic acid and melamine (DPM-3) combined with pentaerythritol and from methylphosphonic diamide (MPD) are more efficient than halogen-containing fire retardants currently used.

The temperature *vs* time curves for the combustion of PP and PE containing MFMA as the fire retardant are shown in Fig. 5. Comparison of these curves suggests that MFMA strongly affects the properties of foamed cokes at the moment of their formation. In the case of a PP composition, foamed cokes are formed at a faster rate and have enhanced HIC. Therefore, MFMA can be regarded as a typical IS, although its efficiency and the HIC of the foamed cokes formed are inferior to those of compositions based on APP.

Figure 6 shows the temperature *vs* time curves for the combustion of PP, PS and PE containing a 4:1 DPM-3–pentaerythritol mixture.⁴⁷ Comparison of these curves points to a strong effect of the polymeric matrix on the properties of foamed cokes at the moment of their formation. In the case of PS compositions, the foamed cokes are formed at slow rates and have low HIC. The foamed cokes formed at a fast rate in the

Figure 5. Heat-insulating characteristics of fire retardant-containing compositions prepared from the adduct of melamine–formaldehyde resin with MFMA; (1) PE + MFMA; (2) PP + MFMA.⁴⁷

Figure 6. Heat-insulating characteristics of fire retardant-containing polymeric compositions prepared from the adduct of methylphosphonic acid with DPM-3;⁴⁷ (1) PS + DPM-3; (2) PE + DPM-3; (3) PP + DPM-3.

combustion of PP and PE compositions have high HIC. The HIC of foamed cokes show a good correlation with the efficiency of the fire resistant agent. For PP, the efficiency of DPM-3 is close to that of APP, whereas for PE, DPM-3 is more efficient than APP.

The temperature *vs* time curves for the combustion of PP, PS and PE containing MPD are shown in Fig. 7.⁷⁸ As can be seen, the presence of a polymer significantly lowers the rate of foamed cokes formation. It is of note that the chars formed in the decomposition of compounds prepared from PE and PS have very low HIC, whereas the chars formed in the combustion of compositions derived from PP have high HIC.

Figure 7. Heat-insulating characteristics of fire retardant-containing compositions prepared from MPD; (1) PS + MPD; (2) PE + MPD; (3) PP + MPD.

The plateau (Fig. 7) corresponding to the intumescence of the bulk of the sample is very low. It may thus be assumed that the amount of the char formed is insufficient for long-term protection of the polymer. Thus, the mechanism of action of MPD as the fire resistant agent is based primarily on the reversal of the destructive processes occurring in PE, which results in smaller quantities of volatile flammable products. Although MPD favours char formation in polymers, it is not the main factor responsible for the flammability reduction, since the char formed cannot protect the polymer in the course of combustion.

MPD has a limited use because fire retarding polymeric compositions containing this fire retardant are difficult to process: phase separation occurs in moulding and casting. One of the clues to the solution of this problem is microencapsulation of the fire retardant prior to its introduction into the system. Besides, the choice of an appropriate shell may not only facilitate compatibility of the fire retardant with the polymeric matrix, but also increase its efficiency.

The effects of various types of shells on HIC and flammability of polymeric materials prepared from PP and PE have been studied.⁷⁷ The following polymeric shells were employed for microencapsulation: high-density PE, polyvinyltriethoxysilane and an aromatic polyamide based on terephthalic acid and *m*-phenylenediamine. It was shown that the chemical nature of the polymeric shell strongly affects the flammability and HIC of polymeric compositions based on PE and PP.

The temperature *vs* time curves for the combustion of PP containing non-encapsulated MPD and MPD encapsulated in PE and polyvinyltriethoxysilane are shown in Fig. 8. As can be seen, the shell strongly affects the physical structure of the char at the moment of its formation. As was noted above, the formation of char in the combustion of PP containing MPD occurs at a very slow rate (Fig. 8, curve 2). The polyethylene film does not influence the combustible and protective properties of the chars formed upon combustion (Fig. 8, curve 3). Char formation accompanying the decomposition of MPD-containing compositions enclosed in polyvinyltriethoxysilane occurs much faster and the chars formed possess enhanced HIC (Fig. 8, curve 1).

Figure 8. Heat-insulating characteristics of fire retardant-containing compositions prepared from MPD encapsulated in polymeric films:⁷⁷ (1) PP; (2) PP + MPD; (3) PP + MPD encapsulated in PE; (4) PP + MPD encapsulated in polyvinyltriethoxysilane.

Thus, the efficiency of IS (OI of the polymeric compositions) correlates well with the HIC of foamed cokes formed upon combustion. The higher the HIC of the chars formed the greater the efficiency of IS in these compositions.

VI. Conclusion

The major effect of fire retardants used for decreasing the flammability of polymers consists predominantly in increasing the char yields in the combustion and thermooxidative degradation of polymeric materials. The additives favouring char formation upon the interaction of polymeric components on heating are successfully employed for the preparation of fire retarding polymeric materials. The studies^{79–84} published in 1996–1998 have demonstrated that metals and metal-containing materials are best suited for this purpose. This trend of research holds especially great promise, for some metal-containing additives are able to catalyse chemical cross-linking reactions in polymers containing functional groups.^{85,86} Their addition not only affects the yields of chars and the kinetics of their formation but also changes their physical structure.

VI. Mercury-containing transition metal clusters	633
VII. Conclusion	635

Abstract. The published data are surveyed and a comparative crystal-chemical analysis is presented for the structures of compounds containing mercury in low oxidation states as cluster Hg_n groups with covalent Hg–Hg bonds. The geometry of compounds with Hg–Hg and Hg–X bonds ($X = \text{O}, \text{S}, \text{Se}, \text{N}$ or Hal) is analysed and the types of coordination of mercury ions, the packing modes and the relationships between structural units are described. The crystallographic and crystal-chemical data for mercury compounds are given. The bibliography includes 124 references.

I. Introduction

It is known that mercury can exist not only in the oxidation state of +2 typical of Group II elements, but also in lower oxidation states which form polyatomic groups of the cluster type. These groups are found in inorganic complex compounds as well as in mercury-containing transition metal clusters. Diatomic groups (the so-called dumbbell-like groups), in which atoms of monovalent[†] mercury¹ are bound through a covalent bond and the Hg–Hg distances vary in the range of 2.5–2.6 Å, are most widespread. A large body of research of Hg(I) compounds confirmed the presence of the $(\text{Hg}_2)^{2+}$ pairs in the linear –X–Hg–Hg–X– fragments ($X = \text{O}, \text{N}, \text{S}, \text{Se}$ or Hal), which contain two almost collinear *sp* bonds, as in the analogous

–X–Hg–X– fragments in Hg(II) compounds. The $(\text{Hg}_2)^{2+}$ pairs were found for the first time in studies of mercurous halides Hg_2X_2 ($X = \text{F}, \text{Cl}, \text{Br}$ or I). These pairs were also observed in approximately twenty minerals.² The Hg_3 ‘triangles’, in which mercury exists in the formal oxidation state of +4/3 and the Hg–Hg distance is ~ 2.7 Å (in metallic mercury, the Hg–Hg distance is ~ 3 Å), are less abundant. A number of compounds contain linear systems of the Hg_n type ($n = 3, 4, \infty$) in which mercury atoms are bound to each other and exist in fractional oxidation states (+2/3, +1/2 or +1/3). As n increases, these compounds approximate metals in properties, and a pronounced correlation between the decrease in the charge on the mercury atom and the increase in the Hg–Hg distance (2.51–2.90 Å) is observed.

The crystal chemistry of mercury differs sharply from the crystal chemistry of its lighter analogues, *viz.*, of zinc and cadmium. Unlike these metals, mercury can form polyatomic Hg_n^{x+} cations. Note that the $(\text{Zn}_2)^{2+}$ ion was found in a Zn/ZnCl_2 melt¹ and the $(\text{Cd}_2)^{2+}$ pair was detected in the $\text{Cd}_2(\text{AlCl}_4)_2$ compound (the distance between the cadmium atoms is 2.576 Å).³

There is no consensus of opinion as to the electronic structures not only of Hg_n^{x+} systems, but also of simple HgX_2 and Hg_2X_2 compounds. This is evidenced by numerous experimental and theoretical studies on the crystal and electronic structures of mercury-containing compounds and on the nature of bonding in these compounds. This heavy element with the closed shell electronic configuration $5d^{10}6s^2$ ‘accumulates’ all the factors, which hinder investigations of the electronic structures of its compounds by quantum-chemical methods. Thus, mercury is characterised by a large atomic number, the absence of unpaired electrons, the filled valence *5d* and *6s* orbitals, the presence of high-lying outer unoccupied *6p* orbitals and a substantial influence of relativistic effects on the electronic state of the mercury atom and ions. Presently, factors, which contribute to the formation of Hg_n^{x+} systems, are not all revealed and the reasons for the changes in their sizes, the geometrical shape and the Hg–Hg distances are not understood.^{4,5}

II. Crystal structures of inorganic compounds containing $(\text{Hg}_2)^{2+}$ groups

More than 30 crystal structures of inorganic compounds containing $(\text{Hg}_2)^{2+}$ groups have been established. These structures belong to different types, *viz.*, to molecular, layered or framework structures. The principal crystal-structural data for these com-

[†] Hereinafter, by monovalent mercury compounds are meant compounds containing $(\text{Hg}_2)^{2+}$ dimers.

pounds are given in Table 1, in which the compounds are placed in order of increasing complexity of their structures, *viz.*, beginning with simple molecular structures and ending with complicated framework structures.

A system containing the $(\text{Hg}_2)^{2+}$ pair and the oxygen atoms of two water molecules was found in the study⁶ of the atomic arrangement in the $\text{Hg}_2(\text{ClO}_4)_2 \cdot 4\text{H}_2\text{O}$ compound both in aqueous solutions at various concentrations and in the solid state. In this system, the $\text{Hg}-\text{Hg}$ and $\text{Hg}-\text{O}$ distances are 2.50 and 2.14 Å, respectively, and the remaining $\text{Hg}\cdots\text{O}$ distances are larger than 2.70 Å. Apparently, the virtually linear $[\text{H}_2\text{O}-\text{Hg}-\text{Hg}-\text{OH}_2]^{2+}$ groups (the $\text{Hg}-\text{Hg}-\text{O}$ angle is 178.1°) are present both in solution and in the crystal. It was demonstrated that a change in the concentration of the solutions has no effect on the $\text{Hg}-\text{Hg}$ bond length. In addition, the metal-metal bonds in solutions (2.52 Å) and in the solid state (2.50 Å) differ only slightly. In the crystal structure, the $[\text{H}_2\text{O}-\text{Hg}-\text{Hg}-\text{OH}_2]^{2+}$ groups are located parallel to the *b* axis (Fig. 1). Two other water molecules and the oxygen atoms of the $[\text{H}_2\text{O}-\text{Hg}-\text{Hg}-\text{OH}_2]^{2+}$ cations and of the tetrahedral ClO_4^- anions are linked through hydrogen bonds (2.82 Å). In the study cited, mention was made of the existence of yet another hydrate, $\text{Hg}_2(\text{ClO}_4)_2 \cdot 2\text{H}_2\text{O}$, which also contains the $[\text{H}_2\text{O}-\text{Hg}-\text{Hg}-\text{OH}_2]^{2+}$ groups with the $\text{Hg}-\text{Hg}$ and $\text{Hg}-\text{O}$ distances of ≈ 2.48 and ≈ 2.10 Å, respectively.

Figure 1. Projection of the crystal structure of $\text{Hg}_2(\text{ClO}_4)_2 \cdot 4\text{H}_2\text{O}$ onto the (100) plane. Hydrogen bonds are indicated by dashed lines.

Analogous linear groups were found in the structures of hydrates $\text{Hg}_2(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$,^{7,8} $\text{Hg}_2\text{SiF}_6 \cdot 2\text{H}_2\text{O}$ (see Ref. 9) and $\text{Hg}_2\text{AlF}_5 \cdot 2\text{H}_2\text{O}$.¹⁰

Two studies were devoted to the structure of $\text{Hg}_2(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$.^{7,8} Originally,⁷ the coordination environment about the mercury atoms in the $(\text{Hg}_2)^{2+}$ pairs was described as a tetrahedron. The rather short distance between the mercury atom and the oxygen atom of the water molecule is indicative of the formation of the aqua $[\text{H}_2\text{O}-\text{Hg}-\text{Hg}-\text{OH}_2]^{2+}$ cations. In the crystal structure, the water molecules and the NO_3^- anions are linked through hydrogen bonds (2.29–2.60 Å). The structure refinement of $\text{Hg}_2(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$ ⁸ confirmed the existence of the aqua $[\text{H}_2\text{O}-\text{Hg}-\text{Hg}-\text{OH}_2]^{2+}$ cation. However, it was demonstrated that the coordination environment about the mercury atom is formed only by the two nearest neighbours, *viz.*, by the mercury atom of the $(\text{Hg}_2)^{2+}$ pair and the oxygen atom of the water molecule. The remaining $\text{Hg}\cdots\text{O}$ distances vary from 2.68 to

Figure 2. Herringbone molecular packing in the structure of $\text{Hg}_2(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$.

3.03 Å. Two water molecules are linked to the same oxygen atom of the NO_3^- group through the hydrogen bonds between the H_2O molecules and the NO_3^- anion (2.68 and 2.70 Å) (Fig. 2). It should be noted that the $\text{Hg}-\text{Hg}$ and $\text{Hg}-\text{O}$ bond lengths in the $\text{Hg}_2(\text{ClO}_4)_2 \cdot 4\text{H}_2\text{O}$ and $\text{Hg}_2(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$ compounds are virtually identical, but the $[\text{H}_2\text{O}-\text{Hg}-\text{Hg}-\text{OH}_2]^{2+}$ fragments in $\text{Hg}_2(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$ deviate significantly from linearity (the $\text{Hg}-\text{Hg}-\text{O}$ angle is 167.5°), which may be a consequence of the difference in the packing of these fragments in the crystal structures.

The structure of the $\text{Hg}_2\text{SiF}_6 \cdot 2\text{H}_2\text{O}$ compound was described as a ionic structure containing the slightly nonlinear aqua $[\text{H}_2\text{O}-\text{Hg}-\text{Hg}-\text{OH}_2]^{2+}$ cations (the $\text{Hg}-\text{Hg}-\text{O}$ angle is 170.9°).⁹ The mercury atoms each form contacts with three fluorine atoms of the octahedral SiF_6^{2-} anions. The $\text{Hg}-\text{F}$ distances vary from 2.71 to 2.87 Å and the remaining distances are larger than 3 Å. In addition, there are hydrogen bonds between the fluorine atoms and the water molecules ($\text{F}\cdots\text{O}$ 2.58 and 2.65 Å).

The hydrogen bonds between the water molecules and the fluorine atoms ($\text{F}\cdots\text{O}$ 2.56–2.86 Å) are also of great importance in the $\text{Hg}_2\text{AlF}_5 \cdot 2\text{H}_2\text{O}$ compound.¹⁰ These bonds stabilise the framework formed from *trans* chains of the AlF_6 octahedra parallel to the *c* axis. The quasi-linear $[\text{H}_2\text{O}-\text{Hg}-\text{Hg}-\text{OH}_2]^{2+}$ cations are located between the chains at different heights.

Therefore, the above-considered compounds containing the mercury atoms in the oxidation state of +1 and water molecules can be considered as within the ionic structures of the $[\text{Hg}(\text{H}_2\text{O})]_2^{2+}$ cations.

Early investigations of the structures of halides with composition Hg_2X_2 ($\text{X} = \text{Cl}, \text{Br}$ or I) have been devoted to the determination of the unit cell parameters and the atomic coordinates based on X-ray powder data.³ More recently, the structures of Hg_2X_2 ($\text{X} = \text{F}, \text{Cl}$ or Br) were refined based on single-crystal X-ray data.^{11,12} The crystal structure of mercurous chloride Hg_2Cl_2 was determined also by neutron powder diffraction analysis.¹³ It was confirmed that this compound has a linear molecular structure with the $\text{Hg}-\text{Hg}$ and $\text{Hg}-\text{Cl}$ distances of 2.5955 and 2.3622 Å, respectively. Longer intermolecular $\text{Hg}\cdots\text{Cl}$ contacts (3.2059 Å) were also found. The $\text{Cl}\cdots\text{Cl}$ distances between the adjacent linear $\text{Cl}-\text{Hg}-\text{Hg}-\text{Cl}$ molecules along the [001] direction are 3.586 and 3.667 Å.

The molecular character of the structure and virtually linear $-\text{O}-\text{Hg}-\text{Hg}-\text{O}-$ groups were found in the study of the crystal structure of $\text{Hg}_2(\text{BrO}_3)_2$.¹⁴ The $(\text{Hg}_2)^{2+}$ pairs are located

Note. Samples of natural and synthetic (italicised) minerals were studied; the unit cell parameters *a*, *b* and *c* are given in Å, the angles α , β , γ and Hg–Hg–X are given in deg.

^a For inorganic monovalent mercury compounds, mixed-valence mercury compounds and compounds containing (Hg₃)²⁺ groups and Hg_n chains X = O or Hal; for monovalent mercury compounds with organic ligands, X = N, O, Se or S; for mercury-containing transition metal clusters, X = Hg, Pt, Os or Ru.

nearly parallel to the a axis. The distances between the nearest pairs are 4.5 Å. The Hg—O distance in the —O—Hg—Hg—O— group is 2.16 Å. In addition, there are Hg $\cdots$ O distances (2.66 and 2.69 Å). Taking into account the latter contacts, the coordination environment about the mercury atoms can be described as a distorted tetrahedron. The Hg₂(BrO₃)₂ molecules are linked in linear chains along the c axis through weak O $\cdots$ O contacts (2.66 Å). The rows of the mercury pairs alternate with double rows of the BrO₃[−] anions along the a axis (Fig. 3). The effect of the mercury atoms on the BrO₃[−] groups consists in the increase in the distance between the bromine atom and the oxygen atom bound to the mercury pair. This distance is 1.76 Å, whereas two other Br—O bond lengths are 1.64 and 1.65 Å.

Figure 3. Projection of the crystal structure of Hg₂(BrO₃)₂ onto the (010) plane. The O $\cdots$ O contacts are indicated by dashed lines.

The crystal structure of HgReO₄ consists of discrete (O₃Re—O—Hg—Hg—O—ReO₃) groups, which are substantially nonlinear (the Hg—Hg—O angle is 159.4°), apparently, due to the type of the molecular packing in the monoclinic unit cell.¹⁵ The mercury atoms each form contacts with the oxygen atoms of other structural units (the distances are larger than 2.49 Å) along with the short Hg—O bonds.

The virtually linear groups were also found in the first structurally studied monovalent mercury nitride, Hg₂(NO₂)₂, consisting of the planar centrosymmetrical molecular NO₂—Hg—Hg—NO₂ groups.¹⁶ The nonbonded Hg $\cdots$ O interactions (2.84 and 2.93 Å) are analogous to those found by Grdenic.⁷ Taking into consideration these contacts, the coordination number of the mercury atom increases to 4. In the crystal structure of Hg₂(NO₂)₂, the molecules are packed in a herringbone fashion.^{7,8} The structure of this compound was also studied by Ohba and coworkers.¹⁷ In this study, the Hg $\cdots$ O bond (2.577 Å) was found along with the Hg—O (2.24 Å) bond, *i.e.*, both oxygen atoms of the NO₂[−] group are bound to the mercury atoms of the (Hg—Hg)²⁺ cations to form a planar centrosymmetrical molecule. In addition, Hg $\cdots$ O contacts (2.826 Å) between the adjacent molecules were revealed. The authors believed that the yellow colour of the crystals is associated with the bridging function of the (Hg₂)²⁺ pairs.

A rather short Hg—Hg distance (2.499 Å) was observed in the structure of Hg₂(H₂PO₄)₂.¹⁸ Each mercury atom has an oxygen atom as the nearest neighbour at a distance of 2.14 Å. The —O—Hg—Hg—O— fragment is nonlinear (the Hg—Hg—O angle is 167.2°). The distances between the mercury atom and the remaining oxygen atoms are larger than 2.5 Å. The structure of the complex consists of the discrete Hg₂(H₂PO₄)₂ molecules linked in a three-dimensional framework *via* hydrogen bonds (O $\cdots$ O

2.52–2.79 Å). The herringbone molecular packing in the crystal of the complex is analogous to those observed in anhydrous Hg₂(NO₂)₂ (see Refs 16 and 17) and its dihydrate Hg₂(NO₂)₂·2H₂O.⁸

What the crystal structures of the two known mercurous vanadates, *viz.*, HgVO₃ and the mixed-valence Hg₂VO₄, have in common is a distorted five-vertex coordination polyhedron about the vanadium formed by the oxygen atoms.¹⁹ In both structures, the polyhedra of the vanadium atoms are linked *via* shared edges to form infinite [(VO₃)_n][−] chains. In the structure of HgVO₃, these chains are linked through the (Hg₂)²⁺ pairs in two-dimensional corrugated infinite (Hg₂)_n²⁺[(VO₃)_n][−] layers, which are linked *via* weak interlayer Hg $\cdots$ O contacts (2.71–2.95 Å), unlike the mixed-valence Hg₂VO₄ compound, in which the [(VO₃)_n][−] chains do not form strong bonds with the mercury atoms.

Only three mercury molybdates were structurally characterised. The compound HgMoO₄ contains the divalent mercury atom. The Hg₂Mo₂O₇ and Hg₂Mo₅O₁₆ polymolybdates contain the (Hg₂)²⁺ ions. The layered structures of Hg₂Mo₂O₇ (see Ref. 20) and Hg₂Mo₅O₁₆ (see Ref. 21) are based on the MoO₄ tetrahedra linked in Mo₂O₇ groups and Mo₅O₁₆ fragments, respectively. The coordination environment about the molybdenum atoms is a distorted octahedron. In both compounds, the Mo octahedra are linked in two-dimensional infinite layers *via* shared vertices and edges. The layers are separated by the (Hg₂)²⁺ pairs (Fig. 4). In the structure of Hg₂Mo₂O₇, the Hg—Hg and Hg—O distances have standard values, whereas the Hg—Hg bond in Hg₂Mo₅O₁₆ is rather short (2.474 Å) and the —O—Hg—Hg—O— fragments deviate significantly from linearity (the Hg—Hg—O angle is 152.7°). Noteworthy is the similarity of the structures of Hg₂Mo₅O₁₆ and Cs₂Mo₅O₁₆.²²

In the crystal structure of the synthetic analogue of the mineral chursinite (Hg₂)₃(AsO₄)₂ (see Ref. 23), the (Hg₂)²⁺ cations and the AsO₄^{3−} anions are packed in such a manner that three of the four oxygen atoms of the AsO₄^{3−} groups are bound to three different mercury pairs (the Hg—O distances are 2.16, 2.22 and 2.23 Å) to form puckered layers. The fourth oxygen atom is bound to three mercury atoms of the adjacent layer (the Hg $\cdots$ O distances are 2.48, 2.46 and 2.71 Å) and has a distorted tetrahedral coordination, the As—O distance with this oxygen atom (1.78 Å) being larger than the remaining three As—O distances (the average value is 1.68 Å). These characteristic groups are linked to each other along the a axis through Hg $\cdots$ O contacts (2.68 and 2.42 Å) and along the c axis through Hg $\cdots$ O contacts (2.47 Å). Taking into account all interactions, the structure of (Hg₂)₃(AsO₄)₂ can be considered as a three-dimensional framework (Fig. 5). It should be noted that the —O—Hg—Hg—O— fragments are substantially nonlinear (the Hg—Hg—O angles are 146–157°).

Figure 4. Crystal structure of Hg₂Mo₂O₇.

Figure 5. Projection of the crystal structure of $(\text{Hg}_2)_3(\text{AsO}_4)_2$ onto the (010) plane. The $\text{Hg}\cdots\text{O}$ contacts are indicated by dashed lines.

The mercury pairs, which are linked in infinite $-\text{O}-\text{Hg}-\text{Hg}-\text{O}-\text{Hg}-\text{Hg}-\text{O}-$ chains *via* the XO_4^{2-} groups ($\text{X} = \text{S}$ or Se), were observed in the isostructural Hg_2SO_4 and Hg_2SeO_4 compounds.²⁴ The chains intersect the unit cells along the diagonals nearly parallel to the ac planes. In Hg_2XO_4 , there are $\text{Hg}\cdots\text{O}$ contacts (2.49 and 2.50 Å in Hg_2SO_4 and Hg_2SeO_4 , respectively), which link chains. The $-\text{O}-\text{Hg}-\text{Hg}-\text{O}-$ fragments deviate from linearity (the $\text{Hg}-\text{Hg}-\text{O}$ angles are 165° and 160° in Hg_2SO_4 and Hg_2SeO_4 , respectively). No noticeable changes in the size and no distortions of the XO_4^{2-} tetrahedra are observed in the structures.

More than 30 compounds were found and described in the ternary $\text{Hg}_2\text{O}-\text{N}_2\text{O}_5-\text{H}_2\text{O}$ system.²⁵ In the studies devoted to the hydrolysis products of nitrate $\text{Hg}_2(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$,²⁶ the authors confirmed the existence of only three low-valent mercury oxonitrates, *viz.*, $[(\text{Hg}_2)_2\text{O}(\text{NO}_3)]\text{NO}_3 \cdot \text{HNO}_3$ and $[(\text{Hg}_2)_5(\text{OH})(\text{NO}_3)_2](\text{NO}_3)_2$ containing monovalent mercury and the mixed-valence $[(\text{Hg}_2)(\text{OHg})_2](\text{NO}_3)_2$ compound.

In spite of the difficulties associated with the preparation of single crystals of these compounds, their structures were studied by X-ray diffraction analysis.²⁷ In the structure of $[(\text{Hg}_2)_2\text{O}(\text{NO}_3)]\text{NO}_3 \cdot \text{HNO}_3$, three $(\text{Hg}_2)^{2+}$ pairs are linked together through the oxygen atoms (the $\text{Hg}-\text{O}$ distances are 2.12, 2.19 and 2.31 Å) to form a planar (the height is 0.31 Å) trigonal pyramid with the $\text{O}-\text{Hg}-\text{O}$ angles varying from 112.9 to 123.5° . The analogous function of the oxygen atom was pointed out in the structures of mercury(II) oxochloride Hg_3OCl_4 (see Ref. 28), the mineral eglestonite $(\text{Hg}_2)_3\text{Cl}_3\text{O}_2\text{H}$ (see Ref. 3) and in a number of other mercury compounds. The structure of $[(\text{Hg}_2)_2\text{O}(\text{NO}_3)]\text{NO}_3 \cdot \text{HNO}_3$ as a whole consists of infinite mercury-oxygen chains linked in a three-dimensional framework through the NO_3^- ions, which coordinate the mercury atoms (the $\text{Hg}\cdots\text{O}$ contacts are in the range of 2.45–2.96 Å). The hydrogen atom was not located in the structure refinement of this compound. Based on the known data on the structures of the oxonium mercury salts, the authors²⁷ suggested that HNO_3 exists as a molecule of solvation linked to the nitrate ion through a hydrogen bond ($\text{O}-\text{H}\cdots\text{O}$, 2.81 Å). The structure of this compound was more accurately established by an independent research group.²⁹ The position of the hydrogen atom of the hydroxy group was revealed. This group is coordinated to three $(\text{Hg}_2)^{2+}$ pairs ($\text{O}-\text{H}$, 1.26 Å) (Fig. 6). As a result, the structure is additionally stabilised through weak hydrogen bonds between the oxygen atoms of the hydroxy groups and the adjacent nitrate ions ($\text{Hg}\cdots\text{O}$, 2.803–2.863 Å). Based on this fact, the authors²⁹ proposed that the formula of the compound should be written as $\text{Hg}_2\text{OH}(\text{NO}_3) \cdot \text{Hg}_2(\text{NO}_3)_2$.

Figure 6. Fragment of the structure of $\text{Hg}_2\text{OH}(\text{NO}_3) \cdot \text{Hg}_2(\text{NO}_3)_2$.

The structure of the $[(\text{Hg}_2)_5(\text{OH})(\text{NO}_3)_2](\text{NO}_3)_4$ compound contains the finite cationic $[(\text{Hg}_2)_5(\text{OH})(\text{NO}_3)_2]^{4+}$ chains linked *via* weak van der Waals interactions between the adjacent mercury and oxygen atoms ($\text{Hg}\cdots\text{O}$, 2.642 and 2.745 Å).^{27,30} The chains form ribbons extended along the $[100]$ direction. The $-\text{O}-\text{Hg}-\text{Hg}-\text{O}-$ fragments are virtually linear. The coordination environment about the mercury atoms involves the additional NO_3^- anions ($\text{Hg}\cdots\text{O}$, 2.763–2.887 Å), which are responsible for the formation of a loose framework.

The structure of mercurous nitrophosphate $\text{Hg}_4\text{PO}_4\text{NO}_3 \cdot \text{H}_2\text{O}$ is built of the PO_4^{3-} and NO_3^- anions and the water molecules bound to the $(\text{Hg}_2)^{2+}$ pairs, which form zigzag chains (the $\text{Hg}-\text{Hg}$ distances are 2.508 and 2.532 Å; the $\text{Hg}-\text{O}$ distances range from 2.11 to 2.21 Å; the $\text{Hg}-\text{Hg}-\text{O}$ angles vary from 147 to 168°). These chains are linked in a three-dimensional framework through additional bonds.³¹ No significant changes in the size and configuration of the anions in the crystal were observed.

The isostructural monophosphates and monoarsenates of silver and monovalent mercury were prepared as early as 1909. However, the crystal structure of AgHg_2PO_4 was established only in 1978.³² The structure of the latter compound consists of the tetrahedral PO_4^{3-} anions and the $\text{Ag}-\text{Ag}$ (2.824 Å) and $\text{Hg}-\text{Hg}$ pairs (2.608 Å). Interestingly, this structure does not contain the linear $-\text{O}-\text{M}-\text{M}-\text{O}-$ fragments ($\text{M} = \text{Ag}$ or Hg) typical of the above-considered compounds and each mercury atom is coordinated by three oxygen atoms of different PO_4 tetrahedra with elongated $\text{Hg}-\text{O}$ bonds (2.224–2.346 Å). Therefore, the coordination environment about the mercury atoms in the $\text{Hg}-\text{Hg}$ dimer is a tetrahedron ($\text{Hg} + 3\text{O}$). Each silver atom is coordinated by two oxygen atoms ($\text{Ag}-\text{O}$, 2.289 Å). The $\text{Hg}-\text{Hg}$ and $\text{Ag}-\text{Ag}$ dimers are in the mutually perpendicular arrangement and are rather closely spaced (the $\text{Hg}-\text{Ag}$ distances are 2.840 and 2.941 Å). These data suggest the existence of the tetrahedral Ag_2Hg_2 clusters.

The three-dimensional $(\text{Hg}_4\text{O}^{2+})_n$ framework of hexagons formed by the $-\text{O}-\text{Hg}-\text{Hg}-\text{O}-$ fragments ($\text{Hg}-\text{Hg}$, 2.458 Å; $\text{Hg}-\text{O}$, 2.108 Å) was found in the crystal of the $\text{Hg}_4\text{OPb}_2(\text{NO}_3)_6$ compound.³³ The Pb^{2+} ions occupy the cavities of the framework and six statistically disordered NO_3^- groups act as bidentate ligands with respect to Pb^{2+} ($\text{Pb}-\text{O}$, 2.77–2.89 Å). The $\text{Hg}_4\text{OBa}_2(\text{NO}_3)_6$ compound isomorphous to $\text{Hg}_4\text{OPb}_2(\text{NO}_3)_6$ was also obtained.

Heteropolytungstate $\text{K}_5\text{Cs}_5[(\text{Hg}_2)_2\text{WO}(\text{H}_2\text{O})(\text{AsW}_9\text{O}_{53})_2]$ was synthesised and structurally characterised for the first time in the study.³⁴ In this complicated structure, both $[\text{As}_2\text{W}_{19}\text{Hg}_4\text{O}_{67}(\text{H}_2\text{O})]_{10}^-$ polyanions of one asymmetrical unit contain two $(\text{Hg}_2)^{2+}$ pairs, in which each mercury atom is bound to two oxygen atoms (the $\text{Hg}-\text{O}$ distances vary from 2.16 to 2.34 Å). All eight mercury atoms of the asymmetrical unit form a distorted cube, whose vertices alternately correspond to the

covalent Hg—Hg bonds (2.446–2.545 Å) and the Hg...Hg distances (3.303–3.796 Å).

The structures of a series of mercury minerals containing the $(\text{Hg}_2)^{2+}$ pairs were analysed in detail.² These structures are also characterised by three-dimensional frameworks. Thus, in shakhovite $\text{Hg}_4\text{SbO}_3(\text{OH})_3$, the $\text{O}\cdots\text{O}$ contacts (2.618–2.932 Å) between the oxygen atoms of the adjacent SbO_6 octahedra link these octahedra in layers parallel to the (001) plane, which, in turn, are linked in a three-dimensional framework through the $(\text{Hg}_2)^{2+}$ pairs (Fig. 7).³⁵

Figure 7. Projection of the crystal structure of shakhovite $\text{Hg}_4\text{SbO}_3(\text{OH})_3$ onto the (100) plane. The $\text{O}\cdots\text{O}$ and $\text{Hg}\cdots\text{O}$ contacts are indicated by dashed lines.

In the crystal structure of the rare mineral poyarkovite Hg_3OCl , six $(\text{Hg}_2)^{2+}$ pairs were found;³⁶ the distances between the mercury atoms vary from 2.503 to 2.565 Å. The $(\text{Hg}_2)^{2+}$ cations are located along three mutually perpendicular directions. Each oxygen atom forms four tetrahedrally directed Hg—O bonds (1.94–2.51 Å) through which the mercury pairs are linked in a framework (Fig. 8).

The above-mentioned structure of the mineral eglestonite $(\text{Hg}_2)_3\text{Cl}_3\text{O}_2\text{H}$ (see Ref. 37) consists of four interpenetrating cubic three-dimensional frameworks $(\text{Hg}_2)_3\text{O}_2$ (see Ref. 1), in which the oxygen atoms are involved in three Hg—O bonds and link the $(\text{Hg}_2)^{2+}$ pairs located along each bond of the framework.

Figure 8. Systems of the mutually perpendicular $(\text{Hg}_2)^{2+}$ pairs in the structure of poyarkovite Hg_3OCl .

The frameworks are linked to each other through short $\text{O}\cdots\text{H}\cdots\text{O}$ hydrogen bonds ($\text{O}\cdots\text{O}$, 2.59 Å) and chlorine atoms.

In the structure of magnolite Hg_2TeO_3 , the $-\text{O}-\text{Hg}-\text{Hg}-\text{O}-$ fragments are linked *via* the tellurium atoms ($\text{Te}-\text{O}$, 1.93 Å) in zigzag chains extended along the [010] direction. The chains are linked through $\text{Hg}\cdots\text{O}$ contacts (2.692–2.998 Å). There are also short $\text{O}\cdots\text{O}$ distances (2.817 and 2.750 Å).³⁸

The study of edgarbaileite $\text{Hg}_6\text{Si}_2\text{O}_7$ demonstrated³⁹ that the Hg—Hg pairs in this structure are parallel to each other and the $-\text{O}-\text{Hg}-\text{Hg}-\text{O}-$ fragments are virtually linear. Each mercury atom is additionally coordinated by two oxygen atoms (the Hg—O distances are 2.41–2.86 Å). The Si_2O_7 groups are located between the mercury pairs and are linked in a framework through the Hg—O bonds (2.21 and 2.63 Å).

The distinguishing feature of the structure of szymanskiite $\text{Hg}_{16}(\text{Ni},\text{Mg})_6(\text{CO}_3)_{12}(\text{OH})_{12}(\text{H}_3\text{O})_8\cdot 3\text{H}_2\text{O}$ is that the MO_6 octahedra ($\text{M} = \text{Ni}$ or Mg) are linked to the linear $-\text{O}-\text{Hg}-\text{Hg}-\text{O}-$ fragments in a rigid framework with large channels (the diameter is 13.6 Å) (Fig. 9).⁴⁰ The channels are occupied by the disordered CO_3 groups and the water molecules, which are rather weakly bound to each other. This gives grounds to consider this mineral as a nonsilicate zeolite. Note that in the structure of szymanskiite, like in the structure of AgHg_2PO_4 (see Ref. 32), the mercury atoms belonging to one type of the $(\text{Hg}_2)^{2+}$ pairs have an umbrella-shaped coordination with the involvement of three oxygen atoms of the CO_3 groups located at longer distances (Hg—O, 2.34 and 2.44 Å). This coordination is rarely observed in monovalent mercury compounds.

Analysis of the structures of inorganic compounds containing $(\text{Hg}_2)^{2+}$ groups with different ligands demonstrates that the Hg—Hg distances vary from 2.45 to 2.59 Å. No distinct correlations between the Hg—Hg and Hg—X distances in the $\text{X}-\text{Hg}-\text{Hg}-\text{X}$ groups and the nature of inorganic ligands X were observed. In the series of the compounds with the NO_3^- , BrO_3^- , TeO_3^{2-} and VO_3^- ligands, the Hg—Hg distances increase from 2.50 to 2.54 Å, which can be related to a decrease in the electronegativity of the ligands in this series of anions. In the series of the compounds with the ReO_4^- , PO_4^{3-} and AsO_4^{3-} ligands, the Hg—Hg distances vary from 2.506 to 2.535 Å. The shortest distance was observed in the HgReO_4 compound because the total negative charge of the ReO_4^- anion is smaller than the effective negative charge of the oxygen atom due to the higher oxidation state of the rhenium atom compared to the phosphorus and arsenic atoms. The increase in the Hg—Hg distance from 2.50 Å in mercury nitrate to 2.52 Å in mercury nitrite can also be attributed to the lower degree of oxidation of the nitrogen atom in the NO_2^- anion compared to that in the NO_3^- anion. The longest Hg—Hg distance in the three-dimensional Hg—O framework (2.56 Å) is observed if the coordinating oxygen atoms bind only

Figure 9. Fragment of the crystal structure of szymanskiite.

(Hg_2) $^{2+}$ groups, *i.e.*, a competing cation is absent. An increase in the Hg–Hg distance can also occur, apparently, due to an increase in the covalence of the Hg–X bond.⁵

A noticeable effect of a strong metal–metal bond on the configuration of compact tetrahedral SO_4^{2-} , SiO_4^{4-} , PO_4^{3-} and AsO_4^{3-} anions was observed only in some instances, for example, in the (Hg_2) $_3(\text{AsO}_4)_2$ compound.²³ An increase in the length of one Br–O bond compared to the remaining bond lengths was also found in $\text{Hg}_2(\text{BrO}_3)_2$.¹⁴

Hence, the coordination of the mercury atoms in oxygen-containing compounds is generally linear with one short Hg–O distance (~ 2.10 Å) and one-to-two additional atoms located at substantially larger distances. In the mineral szymanskiite and in phosphate AgHg_2PO_4 , some mercury atoms in the Hg–Hg dimers are nonlinearly coordinated by the oxygen atoms [an umbrella of three oxygen atoms with the larger Hg–O distances (2.22–2.44 Å)].

III. Mixed-valence inorganic mercury compounds

The data on a number of rather rare mixed-valence compounds containing Hg^{2+} cations and Hg_n groups ($n = 2$ or 3), in which the oxidation state of the mercury atoms is lower than +2, are available. The principal crystal-structural characteristics of these compounds are given in Table 1.

The existence of a compound containing mercury in two oxidation states, *viz.*, in +2 and +1, was first reported in a study,⁴¹ in which the results of X-ray diffraction study of the synthetic analogue of the rare mineral terlinguaite $\text{Hg}_4\text{O}_2\text{Cl}_2$ were discussed. Several studies were devoted to the crystal structures of the natural samples and their synthetic analogues.^{41–44} The studies confirmed the fact that the mercury atoms in terlinguaite exist in different oxidation states, *viz.*, in +2 and +4/3 (in the unique triangular Hg_3 clusters).

Two new mercury oxohalides, *viz.*, the bromine and iodine analogues of terlinguaite, were synthesised in the study.⁴⁵ Dark-red platelet-like crystals of Hg_2OI were grown by the hydrothermal method at 450 K from a stoichiometric mixture of HgO and Hg_2I_2 . X-Ray diffraction study of the resulting compound, whose stoichiometry is identical to that of terlinguaite, demonstrated that this compound, though also mixed-valence, has quite a different structure. The structure of Hg_2OI (see Ref. 46) consists of infinite zigzag chain $\text{Hg}^{2+} - \text{O} - \text{Hg}^{2+}$ along the *b* axis. These chains are linked through the (Hg_2) $^{2+}$ pairs to form 14-membered rings, which, in turn, are linked in a three-dimensional framework through weak additional $\text{Hg}^{2+} \cdots \text{O}$ bonds (2.47 Å) (Fig. 10). The iodine atoms occupy the cavities in the layers and form weak contacts with the Hg^{2+} cations. The coordination $\text{Hg}^{2+} - \text{O}$ bonds in the structure of Hg_2OI are somewhat longer (2.13 and 2.16 Å) and the $\text{O} - \text{Hg}^{2+} - \text{O}$ angles are smaller (165°) than the corresponding values in divalent mercury compounds.⁴⁷ Apparently, this is attributable to the contacts of the Hg^{2+} cation with the oxygen atom (2.47 Å) and with the iodine atoms (3.05 and 3.14 Å). Taking into account these weak bonds, the coordination polyhedron about Hg^{2+} can be described as a distorted square pyramid. The mercury atoms of the (Hg_2) $^{2+}$ pairs are linearly coordinated by the oxygen atoms and the shortest (Hg_2) $^{2+} \cdots \text{I}$ distance is 3.47 Å.

In the middle 80s, two research groups^{27,48} independently prepared and studied lemon-yellow crystals of the hydrolysis product of $\text{Hg}_2(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$, *viz.*, the mixed-valence $\text{Hg}_4\text{O}_2(\text{NO}_3)_2$ compound, whose stoichiometry is identical to that of Hg_2OI . These compounds are partially similar in structure. In the crystal structure of $\text{Hg}_4\text{O}_2(\text{NO}_3)_2$, as in the structure of Hg_2OI , the $\text{O} - \text{Hg}^{2+} - \text{O}$ chains and the (Hg_2) $^{2+}$ pairs also form analogous 14-membered rings. However, unlike the structure of Hg_2OI , the rings in $\text{Hg}_4\text{O}_2(\text{NO}_3)_2$ are linked in corrugated layers parallel to the (201) plane (Fig. 11) rather than in a three-dimensional framework. The Hg–Hg (2.510 Å) and Hg–O (2.136 Å) bonds within the layers are covalent and the layers are

Figure 10. Framework of the 14-membered $[-(\text{Hg}_2)_2^{2+} - \text{O}_6 - \text{Hg}_4^{4+} -]$ rings in the structure of Hg_2OI .

linked through the weak (Hg_2) $^{2+} \cdots \text{O}$ contacts (2.84 Å) and the NO_3^- ions, which act as bridging ligands for the mercury atoms. This layered structure accounts for the noticeable cleavage of the crystals of $\text{Hg}_4\text{O}_2(\text{NO}_3)_2$ parallel to the (201) plane. The coordination numbers of the Hg^{2+} cation and the mercury ions in the (Hg_2) $^{2+}$ pair are equal to 2. It is worthy of note that the bonds between the mercury atoms of the (Hg_2) $^{2+}$ pair and the oxygen atoms are substantially longer than the $\text{Hg}^{2+} - \text{O}$ distances.

In attempting to synthesise the bromine analogue of terlinguaite, *viz.*, Hg_2OBr (see Ref. 45) (hydrothermal synthesis at 460 K from a stoichiometric mixture of HgO and Hg_2Br_2), crystals with composition $\text{Hg}_8\text{O}_4\text{Br}_3$, were obtained and studied by X-ray diffraction analysis.⁴⁹ The structure of $\text{Hg}_8\text{O}_4\text{Br}_3$ differs from the structures of terlinguaite $\text{Hg}_4\text{O}_2\text{Cl}_2$,⁴⁴ Hg_2OI ⁴⁶ and $\text{Hg}_4\text{O}_2(\text{NO}_3)_2$.^{27,48} There are five independent routes by which monovalent mercury atoms form three (Hg_2) $^{2+}$ pairs (2.517–2.557 Å) and three independent Hg^{2+} ions per asymmetric unit. The metal atoms in the (Hg_2) $^{2+}$ pairs have the oxygen

Figure 11. Layer of the 14-membered $[-(\text{Hg}_2)_2^{2+} - \text{O}_6 - \text{Hg}_4^{4+} -]$ rings in the structure of $\text{Hg}_4\text{O}_2(\text{NO}_3)_2$.

atoms as the nearest neighbours at distances of 2.14–2.24 Å through which the 12-membered $[-O-(Hg_2)^{2+}-O-]_4$ rings are formed. These rings are linked in infinite chains *via* the $(Hg_2)^{2+}$ dimers (Fig. 12). The Hg^{2+} ions coordinated by the oxygen atoms form helical chains (the $Hg^{2+}-O$ distances vary from 2.01 to 2.18 Å) similar to those found in two modifications of HgO .^{50, 51} The oxygen atoms bind the 'divalent' and 'monovalent' portions of the structure to form a three-dimensional framework with the bromine atoms located in the cavities (the shortest $Hg\cdots Br$ contact is 3.02 Å).

Figure 12. 12-Membered $[-O-(Hg_2)^{2+}-O-]$ rings linked through the $(Hg_2)^{2+}$ pairs in the structure of $Hg_8O_4Br_3$.

In the ternary $Hg-Re-O$ system, four compounds containing formally monovalent mercury,¹⁵ *viz.*, $HgReO_4$, and mixed-valence $Hg_5Re_2O_{10}$ (two modifications) and Hg_2ReO_5 , were structurally characterised. Unlike the molecular structure of $HgReO_4$, all three mixed-valence compounds have polymeric structures. The polycations of the fused $[(Hg_2)^{2+}-O-(Hg^{2+})-O]_n$ rings of different types form puckered two-dimensional infinite networks separated by the tetrahedral ReO_4^- anions.

The structure of Hg_2ReO_5 (see Ref. 15) contains 14-membered rings consisting of the oxygen atoms, Hg^{2+} cations and $(Hg_2)^{2+}$ pairs, which are analogous to those found in the structure of $Hg_4O_2(NO_3)_2$ (see Refs 27 and 48). These rings are linked in infinite two-dimensional (but with another type of corrugation) polycationic $[(Hg_2)^{2+} \cdot 2HgO]_n$ networks.

A comparison of two modifications of $Hg_5Re_2O_{10}$ suggested that these compounds have related structures.^{52, 53} Both compounds contain two-dimensional infinite corrugated networks with composition $[Hg^{2+} \cdot 2(Hg_2)^{2+}O]_n$, which are separated by the tetrahedral ReO_4^- cations. The networks in the first modification of $Hg_5Re_2O_{10}$ consist of fused 16-membered rings.⁵² The networks in the second modification contain the 10- and 22-membered rings⁵³ (Fig. 13). Analogous networks were also found in the structure of Hg_3CrO_6 .⁵⁴

Presently, the structures of about ten mercury oxovanadates are known, among which are two compounds containing mercury in the formal oxidation state of +1, *viz.*, $HgVO_3$ and the mixed-valence Hg_2VO_4 compound.¹⁹ The architecture of the crystal structure of Hg_2VO_4 is very unusual, namely, the $(Hg_2)^{2+}$ pairs and the Hg^{2+} ions together with certain of the oxygen atoms form infinite helical chains, which are located on the surface of the adjacent infinite channels in such a manner that the structure projected along the short *a* period appears as the structure consisting of fused 14-membered rings similar to those described above in the structures of Hg_2OI ,⁴⁶ $Hg_4O_2(NO_3)_2$,^{27, 48} and Hg_2ReO_5 .¹⁵ The mercury ions in the $(Hg_2)^{2+}$ pairs and the Hg^{2+} cations have a normal linear coordination. The trigonal-bipyramidal VO_5 groups are linked *via* shared edges to form infinite $[(VO_3)^-]_n$ chains parallel to each other and located in the centres of mercury–oxygen channels. These chains have no strong bonds with mercury atoms ($Hg\cdots O > 2.57$ Å). The formula of this compound can be described as follows: $[(Hg_2)^{2+} \cdot 2(Hg^{2+}O)]_n \cdot [(VO_3)^-]_{2n}$.

Figure 13. Types of the $Hg-O$ rings in the crystal structures of two modifications of $Hg_5Re_2O_{10}$. Modification: (a) I; and (b) II.

The new $Hg_9P_5I_6$ compound,⁵⁵ which possesses semiconducting properties, contains the mercury and phosphorus atoms in different oxidation states (+2, +1 and -3, -2, respectively), the low-valent phosphorus atoms existing as $(P_2)^{2-}$ dimers with the $P-P$ distance of 2.10 Å. The Hg^{2+} ions form tetrahedra about the phosphorus atoms and octahedra, whose centres are occupied by the $(P_2)^{2-}$ dimers. The P_2Hg_6 octahedra are linked *via* shared vertices to form layers parallel to the (100) plane. These layers are linked through the ditetrahedral P_2Hg_7 groups and the $(Hg_2)^{2+}$ pairs. In this structure, the $P-Hg-P$ and $P-Hg-Hg$ groups have an almost linear configuration. The coordination environment about the mercury atoms is completed by the iodine atoms (the $Hg-I$ distances vary from 3.097 to 3.691 Å). Taking into account the different valence states of the mercury and phosphorus atoms, it was suggested⁵⁵ that the formula of the compound be written as $(Hg-Hg)^{2+}Hg_2^{2+}(P-P)_4^{4-}P_2^{3-}I_{12}$.

Presently, only a few natural mixed-valence mercury compounds are known. These compounds, like the rare minerals containing only $(Hg_2)^{2+}$ pairs, are very unstable. The X-ray structural studies of these compounds are very laborious. Recently, the crystal structures of three natural mercury chromates, *viz.*, edoylerite $(Hg^{2+})_3S_2CrO_4$ (Ref. 56), deanesmithite $(Hg^+)_2(Hg^{2+})_3OS_2CrO_4$ (Ref. 57) and wattersite $(Hg^+)_4Hg^{2+}O_2CrO_4$ (Ref. 58), have been studied. The last two mixed-valence compounds represent new structural types containing the polymeric $-O-Hg-O-$ and $-O-(Hg_2)^{2+}-O-$ fragments typical of mercury compounds. In the structure of sulfur-containing deanesmithite, the infinite $\cdots(Hg_2)^{2+}-O-Hg^{2+}-O-(Hg_2)^{2+}-[(Hg^{2+}-S)_6]-(Hg_2)^{2+}\cdots$ chains involving the 12-membered $[(Hg_2)^{2+}-S]_6$ rings can be distinguished. The $O-(Hg_2)^{2+}-S$ groups are virtually linear.

In wattersite $(Hg^+)_4Hg^{2+}O_2CrO_4$, the CrO_4 tetrahedra and the distorted Hg^{2+} octahedra form ribbons with composition $[Hg^{2+}CrO_6]^{6-}$, which are linked in slightly distorted layers parallel to the (100) plane through the $(Hg_2)^{2+}$ pairs.

In the structure of natural mercury oxochloride, *viz.*, in the mineral hanawaltite $(Hg^+)_6Hg^{2+}O_3Cl_2$, the $-O-Hg^{2+}-O-$ and $-O-(Hg_2)^{2+}-O-$ fragments form a three-dimensional framework whose cavities are occupied by the chlorine atoms.⁵⁹

The distinguishing feature of this structure is that all $(\text{Hg}_2)^{2+}$ pairs lie approximately in the (001) plane and form corrugated layers. The researchers attributed the planar (001) habit of the mineral to the presence of strong Hg—Hg bonds in this plane and ascribed the good cleavage in the direction perpendicular to the c axis to weak bonds, which occur between the layers along this direction through the Hg^{2+} ions.

Another natural mercury oxochloride, *viz.*, the above-mentioned terlinguaite $\text{Hg}_4\text{O}_2\text{Cl}_2$,⁴⁴ contains alternating layers of $\{\text{Hg}^{2+}\text{Cl}_2\}$ and $\{(\text{Hg}_3)^{4+}\text{O}_2\}$. The latter layers contain the triangular $(\text{Hg}_3)^{4+}$ clusters (Hg—Hg, 2.707 Å), which are in a single plane (Fig. 14). The resulting structure may be represented as a three-dimensional mercury-oxygen framework with Cl atoms in the cavities. The layers containing strong Hg—Hg bonds are responsible for the anisotropy of the physical properties of hanawaltite and terlinguaite.

Figure 14. Crystal structure of terlinguaite $\text{Hg}(\text{Hg}_3)\text{O}_2\text{Cl}_2$.

Only three inorganic mercury compounds, whose structures contain the triangles $(\text{Hg}_3)^{4+}$ in which the mercury atoms exist in the formal oxidation state of $+4/3$, are known. Hence, although two compounds considered below are not mixed-valence, it is reasonable to describe their structures in this section. Recently, the crystal structure of the rare hypergene mineral kuznetsovite $\text{Hg}_3\text{AsO}_4\text{Cl}$, whose structure has been previously established based on X-ray powder data,⁶¹ was refined.⁶⁰ This is the second naturally occurring compound containing the cyclic $(\text{Hg}_3)^{4+}$ group (Hg—Hg, 2.675 Å). In the cubic structure, the Hg_3 triangles and the AsO_4^{3-} tetrahedra alternate along all crystallographic axes (Fig. 15). Taking into account only short Hg—O bonds (2.17 and 2.28 Å), a framework can be distinguished. The cavities of this framework are occupied by the chlorine atoms in a diamond-like fashion.

The third compound, *viz.*, pale-yellow crystals of $\text{Hg}_9\text{As}_4\text{O}_{16}$, was prepared upon thermal decomposition (550 °C) of $(\text{Hg}_2)_3(\text{AsO}_4)_2$.⁶² The crystal structure of this compound consists of the $(\text{Hg}_3)^{4+}$ triangles (Hg—Hg, 2.662–2.696 Å) and the AsO_4^{3-}

Figure 15. Crystal structure of kuznetsovite $\text{Hg}_3\text{AsO}_4\text{Cl}$.

Figure 16. Arrangement of the Hg_3 triangles and the AsO_4 tetrahedra in the crystal structure of $(\text{Hg}_3)_3(\text{AsO}_4)_4$.

tetrahedra and corresponds to the formula $[(\text{Hg}_3)^{4+}]_3[(\text{AsO}_4)^{3-}]_4$. The coordination environment about the mercury atoms is a distorted tetrahedron with the Hg—O distances of 2.14–2.34 Å. The remaining distances vary from 2.58 to 2.93 Å (Fig. 16).

The tendency of mercury-oxygen groups to polymerisation, which is characteristic of divalent mercury compounds, is retained in compounds containing mercury atoms in different oxidation states.⁴⁷ The pairs of the monovalent mercury atoms form the linear $\text{O}-(\text{Hg}_2)^{2+}-\text{O}$ groups, which (along with the linear $\text{O}-\text{Hg}^{2+}-\text{O}$ units) are involved in the formation of polycations of different types, *viz.*, rings, infinite chains, corrugated and planar networks, layers or frameworks. The triangular $(\text{Hg}_3)^{4+}$ group plays a similar role. Fragments containing the groups of monovalent mercury are characterised by larger deviations from linearity (the Hg—Hg—O angles are 145–178 °) and by elongated Hg—O bonds (2.10–2.34 Å) compared to the groups containing Hg^{2+} (the O—Hg—O angle is 180 °; the average Hg—O distance is 2.06 Å). Apparently, this is due to the effect of the strong metallic Hg—Hg bond, whose length changes only slightly and is virtually independent of the coordination environment about the mercury atoms.

Analysis of the bond lengths in the mixed-valence and cluster mercury derivatives demonstrates that the divalent mercury atoms are not only linearly coordinated by two atoms with the shortest distances, but also are generally surrounded by several atoms located at distances of > 2.5 Å. When describing the structures, these atoms are often included in the coordination environment about the mercury atoms. Since the environment about the mercury atoms is often formed by atoms of different types, the spread in the distances in the polyhedra is large and the polyhedra are strongly distorted. This is also true for the environment about the monovalent mercury atoms in the $(\text{Hg}_2)^{2+}$ pairs and $(\text{Hg}_3)^{4+}$ triangles. The description of the coordination polyhedra about the individual mercury atoms becomes even more arbitrary in the presence of strong metallic bonds because these polyhedra are very distorted.

From the crystal-chemical standpoint, it is worthwhile to consider this series of structures as structures containing the overall complex Hg_n^{x+} cations with the coordinates of the geometric centres of the complexes and to describe the coordination environment about the Hg_n^{x+} cation as a whole. For example, the environment about the $(\text{Hg}_2)^{2+}$ pair in the structure of chursinite $(\text{Hg}_2)_3(\text{AsO}_4)_2$ is a trigonal antiprism formed by the oxygen atoms of the AsO_4 tetrahedra²³ (Fig. 17a). In the study of the structure of kuznetsovite $\text{Hg}_3\text{AsO}_4\text{Cl}$,⁶¹ the environment about the triangular mercury cluster was described as a convex 16-vertex polyhedron, *viz.*, Friauf's polyhedron (Fig. 17b) formed by twelve oxygen atoms and four chlorine atoms. The application of this approach to other structures demonstrated that the environment about the $[\text{Hg}_3]^{4+}$ cation (6O+6Cl) in terlinguaite $\text{Hg}(\text{Hg}_3)\text{O}_2\text{Cl}_2$ is a hexagonal analogue of cuboctahedron (Fig. 17c)⁴⁴ and the environment about the analogous cation in $(\text{Hg}_3)_3(\text{AsO}_4)_4$ is a cuboctahedron formed by 12 oxygen atoms

Figure 17. Coordination Hg_n polyhedra in the structures of $(\text{Hg}_3)_2 \cdot (\text{AsO}_4)_2$ (a), $\text{Hg}_3\text{AsO}_4\text{Cl}$ (b), $\text{Hg}(\text{Hg}_3)\text{O}_2\text{Cl}_2$ (c) and $(\text{Hg}_2)_3(\text{AsO}_4)_4$ (d).

(Fig. 17 d).⁶² The symmetry and the convexity of the coordination polyhedron as well as a small spread in the distances from the centre of the mercury group to the vertices of the polyhedra and a small spread in the lengths of the edges of the polyhedron can serve as criteria for choosing the polyhedral environment about the Hg_n^{x+} cation. Note that this method would never do for describing the coordination environment about cluster mercury groups if the distances between the atoms of the adjacent mercury groups are close to the cation–anion bond lengths [for example, in the structure of pyarkovite Hg_3OCl ,³⁶ in which the shortened distances (3.11–3.13 Å) were observed between the mercury atoms of some adjacent $(\text{Hg}_2)^{2+}$ pairs].

IV. Compounds containing polyatomic Hg_n^{x+} cations ($n > 2$)

Salts, which contain linear Hg_n^{x+} systems of metal atoms directly bound to each other (where $n > 2$, i.e., the formal oxidation state of mercury is lower than +1) as ions, are formed in strongly acidic nonaqueous solvents and exist as stable crystalline compounds with particular anions.¹ For example,⁶³ the reactions of mercury with AsF_5 and SbF_5 in liquid SO_2 yielded the $(\text{Hg}_3)^{2+}$ and $(\text{Hg}_4)^{2+}$ ions, which were isolated as crystalline salts with the AsF_6^- and $\text{Sb}_2\text{F}_{11}^-$ anions. Attempts to prepare analogous salts with other anions according to this procedure failed, apparently, due to the fact that no other pentafluorides, which can oxidise mercury in an SO_2 medium at room temperature, were found. More recently, a universal procedure was developed for the preparation of compounds with the $(\text{Hg}_3)^{2+}$ and $(\text{Hg}_4)^{2+}$ cations, which involves the reaction of mercury with hexafluorides $\text{Hg}(\text{MF}_6)_2$. Dull-yellow crystals of $\text{Hg}_3(\text{AsF}_6)_2$ and dark-red crystals of $\text{Hg}_4(\text{AsF}_6)_2$ as well as analogous compounds with niobium, tantalum and antimony were prepared according to this procedure.⁶⁴ The reaction of mercury and HgCl_2 in a melt of AlCl_3 afforded the $\text{Hg}_3(\text{AlCl}_4)_2$ compound.⁶⁵ It should be noted that all these salts undergo rapid disproportionation in the presence of water to form elemental mercury and $(\text{Hg}_2)^{2+}$ salts. The principal crystal-structural data for compounds of this type are given in Table 1.

X-Ray diffraction studies of the $\text{Hg}_3(\text{AsF}_6)_2$ (see Ref. 63) and $\text{Hg}_3(\text{AlCl}_4)_2$ (see Ref. 66) compounds revealed the linear groups of the mercury atoms of the $(\text{Hg}_3)^{2+}$ type. The $\text{Hg} - \text{Hg}$ bond lengths in these groups have equal or close values. Thus, the structure of $\text{Hg}_3(\text{AlCl}_4)_2$ consists of discrete molecules with the linear central $-\text{Cl} - \text{Hg} - \text{Hg} - \text{Hg} - \text{Cl}-$ skeleton (the $\text{Hg} - \text{Hg}$ bond lengths are 2.551 Å and 2.562 Å), which involves the chlorine atoms of the tetrahedral AlCl_4 groups, whereas in the structure $\text{Hg}_3(\text{AsF}_6)_2$ containing the $(\text{Hg}_3)^{2+}$ cations and the octahedral AsF_6^- anions, the $(\text{Hg}_3)^{2+}$ cation is linear and centrosymmetrical with the $\text{Hg} - \text{Hg}$ bond length of 2.552 Å (Fig. 18). The $\text{Hg} \cdots \text{F}$ contacts between the terminal mercury and fluorine atoms of the adjacent AsF_6^- anions (2.38 Å) are collinear with the $\text{Hg} - \text{Hg}$ bonds. These contacts are, most likely, covalent in character because their lengths are intermediate between the reference values of 2.10 and 2.46 Å, respectively.⁶³

The $\text{Hg}_3(\text{NbF}_5)_2\text{SO}_4$ and $\text{Hg}_3(\text{TaF}_5)_2\text{SO}_4$ compounds are isostructural and also contain the nearly linear centrosymmetrical $(\text{Hg}_3)^{2+}$ cations linked to the $[\text{F}_5\text{MOSO}_2\text{OMF}_5]^{2-}$ anions

Figure 18. Linear $(\text{Hg}_3)^{2+}$ cations in the crystal structure of $\text{Hg}_3(\text{AsF}_6)_2$.

(M = Nb or Ta) through the terminal oxygen atoms to form chains along the [110] and $[1\bar{1}0]$ directions.⁶⁷ The coordination environment about the mercury atoms in the $(\text{Hg}_3)^{2+}$ cations is analogous to those observed in $\text{Hg}_3(\text{AsF}_6)_2$ (see Ref. 63) and $\text{Hg}_3(\text{AlCl}_4)_2$ (see Ref. 66).

The structure of the $(\text{Hg}_4)^{2+}$ ion was established in the studies of the crystal structures of $\text{Hg}_4(\text{Ta}_2\text{F}_{11})_2$ (see Ref. 67) and $\text{Hg}_4(\text{AsF}_6)_2$ (see Ref. 68). The terminal Hg–Hg bonds (2.630 Å⁶⁷ and 2.620 Å⁶⁸) in these compounds are somewhat longer than the central bonds (2.593 and 2.588 Å, respectively) and the bonds in the $(\text{Hg}_3)^{2+}$ cation.^{63,66} The structures of these compounds consist of the nearly linear $(\text{Hg}_4)^{2+}$ cations (the Hg–Hg–Hg angles are 177.3 and 177.4°, respectively) and the $\text{Ta}_2\text{F}_{11}^-$ and AsF_6^- anions, respectively. The distinguishing feature of these structures is that the distances between the adjacent $(\text{Hg}_4)^{2+}$ cations (3.033 Å⁶⁷ and 2.985 Å⁶⁸) are close to the shortest Hg–Hg distance in metallic mercury (2.99 Å).⁶⁹ Hence, taking into account these contacts, the $(\text{Hg}_4)^{2+}$ cations can be considered as being linked in infinite zigzag chains (along the *c* axis) with weak interactions between the terminal mercury atoms (Fig. 19). Thus, the interaction between the $(\text{Hg}_4)^{2+}$ cation and the AsF_6^- anion in the $\text{Hg}_4(\text{AsF}_6)_2$ compound in the direction nearly collinear with the terminal Hg–Hg bonds may be considered as being replaced by the $\text{Hg}\cdots\text{Hg}$ intercationic interaction at an angle of 124° to the terminal Hg–Hg bond [107.9° in $\text{Hg}_4(\text{Ta}_2\text{F}_{11})_2$] and by several weak Hg $\cdots$ F contacts with the anions. The latter contacts are substantially longer (> 2.7 Å) than the short interactions (2.38 Å) in $\text{Hg}_3(\text{AsF}_6)_2$, which are collinear with the Hg–Hg bonds, and are similar in length to the analogous contacts in other compounds with noncollinear Hg $\cdots$ F interactions (for example, the shortest Hg $\cdots$ F contacts in $\text{Hg}_{2.86}\text{AsF}_6$ are 2.87 and 2.98 Å).^{70,71}

The reactions of mercury with AsF_5 , SbF_5 or $\text{Hg}(\text{MF}_6)_2$ (M = Nb or Ta) on the surface of liquid mercury afforded gold-coloured crystals, which were similar in appearance to metallic crystals and existed for 10–15 min. Then these crystals were converted into soluble $(\text{Hg}_3)^{2+}$ salts. It was possible to store and isolate these crystals by choosing a weaker oxidising agent. These crystals appeared to be the most interesting substance among the compounds of the general formula $\text{Hg}_{3-\delta}\text{MF}_6$ (M = As, Sb, Nb or Ta) because they possess anisotropic metallic conductivity. The $\text{Hg}_{3-\delta}\text{AsF}_6$ and $\text{Hg}_{3-\delta}\text{SbF}_6$ compounds exhibit superconducting properties at low temperatures ($T_c = 4$ and 14 K, respectively).⁶⁴

The crystal structure of the unique anisotropic superconductor of the empirical formula Hg_3AsF_6 can be described as a sublattice containing the octahedral AsF_6^- anions arranged in the tetragonal unit cell in a cubic close packing fashion.⁷⁰ There are linear nonintersecting channels in two nearly perpendicular directions (parallel to the *a* and *b* axes) within this sublattice. The infinite disordered chains of the mercury atoms in the formal oxidation state of +1/3 (Hg–Hg, 2.64 Å) are located along these channels (Fig. 20). The unit cell parameters $a = b = 7.54$ Å are not proportional to the threefold Hg–Hg distance (7.92 Å).

Figure 19. Linear $(\text{Hg}_4)^{2+}$ cations in the crystal structure of $\text{Hg}_4(\text{AsF}_6)_2$. The bonds between the cations are indicated by dashed lines.

Figure 20. Infinite disordered Hg_n chains in the structure of $\text{Hg}_{3-\delta}\text{AsF}_6$.

Hence, the empirical formula of the compound under consideration can be formally obtained from the ratio $7.54 : 2.64 = 2.86$ and may be written as $\text{Hg}_{2.86}\text{AsF}_6$. Neutron diffraction study of Hg_3AsF_6 confirmed the formula $\text{Hg}_{2.86}\text{AsF}_6$ and the above-described crystal structure of the compound.⁷¹

However, according to the structural data, the disordered Hg_n chains are not precisely one-dimensional and the sites of the mercury atoms are only partially occupied. In addition, the maximum deviation of the mercury atoms from the axes of the chains in the [001] direction was 0.07 Å at room temperature and the shortest Hg–Hg contacts between the chains are 3.24 Å. If the chains were exactly linear, these distances would be $c/4 = 3.098$ Å. It was concluded⁷¹ that the incommensurate structure is stabilised by anionic vacancies so that the unit cell contains four $\text{Hg}_{2.86}(\text{AsF}_6)_{0.953}$ formula units.

Hence, the structure of $\text{Hg}_{2.86}\text{AsF}_6$ contains the unique metal-bonded infinite polymeric cations, which form a portion of the ionic crystal lattice. The shortest contacts between the mercury and fluorine atoms (2.99 Å) are somewhat larger than the sum of the van der Waals radii (2.85 Å), *i.e.*, the crystal structure contains the AsF_6^- anions and the Hg_n chains, in which the average charge on the mercury atoms is equal to $1/2.86 = +0.35$. In this crystal, the ionic character of the bonds between the positively charged Hg_n chains and the AsF_6^- anions predominates. In addition, it should be noted that the Hg–Hg distance (2.64 Å) is substantially shorter than that in metallic mercury (2.99 Å). However, the coordination number of Hg in metallic mercury is 12, whereas in the compound under consideration, this value is equal to 2. The character of the structure under consideration is consistent with the anisotropy of conductivity in the crystal along the *a* and *b* axes.

The syntheses of a series of compounds with nonstoichiometric compositions of the general formula $\text{Hg}_{3-\delta}\text{MF}_6$ (M = Sb,⁷² Nb or Ta⁷³) at room temperature and of the general formula $\text{Hg}_{3-\delta}\text{MF}_6$ (M = Sb or Ta⁷⁴) at 173 and 150 K, respectively, were reported. It was confirmed that these compounds are isostructural to the Hg_3AsF_6 compounds studied previously.^{70,71}

Based on the comparison of the structures of three types of the above-considered compounds and taking into account the short contacts (2.985 Å) between the terminal atoms of the adjacent cations $(\text{Hg}_4)^{2+}$, it can be concluded that the structure of $\text{Hg}_4(\text{AsF}_6)_2$ is intermediate between the structure of $\text{Hg}_3(\text{AsF}_6)_2$, in which short contacts between the cations are absent, and the structure of $\text{Hg}_{3-\delta}\text{AsF}_6$, which contains infinite Hg_n chains and in which there are no discrete cations. Taking into account the high electrical conductivity of compounds containing infinite Hg_n chains, the authors⁶⁸ believed that the conductivity can occur along the zigzag chains in $\text{Hg}_4(\text{AsF}_6)_2$.

The preparation and investigation of gold-coloured crystals containing infinite Hg_n chains with compositions $\text{Hg}_{3-\delta}\text{NbF}_6$ and $\text{Hg}_{3-\delta}\text{TaF}_6$ led to the unexpected discovery of a new type of mercury compounds, which contain Hg_n layers, but differ from chain compounds.⁷⁵ If the gold-coloured crystals were not removed from the reaction mixture containing unconsumed mercury and $(\text{Hg}_3)^{2+}$ and $(\text{Hg}_4)^{2+}$ ions in the solution, these crystals were transformed over a period of time (from several hours to several months) into thin pliable silvery plates reminiscent of aluminium foil. The reaction performed in the cold (-35°C) afforded silvery crystals without intermediate formation of gold-coloured crystals. Unlike the gold-coloured crystals, the silvery crystals have the exactly stoichiometric composition Hg_3MF_6 ($\text{M} = \text{Nb}$ or Ta), which is determined by its close-packed structure. The crystals with this composition exhibit superconducting properties ($T_c = 7\text{ K}$).⁶⁴

X-Ray diffraction studies of the Hg_3NbF_6 and Hg_3TaF_6 compounds revealed close-packed layers of the MF_6^- octahedra separated by hexagonal layers of the mercury atoms (Fig. 21).⁷⁵ Each mercury atom is surrounded by six nearest neighbours at distances of $2.90\text{ \AA}$ within the Hg layer and by six fluorine atoms from the adjacent MF_6 layers at distances of $3.2\text{ \AA}$ (three atoms from each adjacent layer). The mercury and fluorine atoms form the cubic close packing and the M atoms occupy 1/3 of the octahedral cavities between the fluorine atoms. The Hg–Hg distances in the mercury layers are longer than those in the chains, in which the mercury atoms are bound only to two neighbours, but are shorter than in elemental mercury, in which metal atoms have 10 or 12 neighbours. It should be noted that the silvery crystals were rapidly converted into the gold-coloured crystals in the presence of liquid SO_2 at 120°C . Hence, it can be stated that there is a reversible structural transition between the chain and layered structures. However, the role of SO_2 in this transition is not entirely known (this transition does not occur at room temperature and below room temperature in the absence of SO_2).

The synthesis, structure and electrical properties of salts containing polyatomic $(\text{Hg}_3)^{2+}$ and $(\text{Hg}_4)^{2+}$ cations and compounds with chain $(\text{Hg}_{3-\delta}\text{MF}_6)$, where $\text{M} = \text{As}$, Sb , Nb or Ta) and layered $(\text{Hg}_3\text{NbF}_6)$ and Hg_3TaF_6) structures were considered in greatest detail in the study.⁶⁴

In none of the known compounds containing $(\text{Hg}_2)^{2+}$ and $(\text{Hg}_3)^{2+}$ ions, these ions tend to bind to each other. The $(\text{Hg}_4)^{2+}$ ions in the compounds form zigzag chains through weak bonds. The limiting case is observed in the structures of $\text{Hg}_{3-\delta}\text{MF}_6$ ($\delta = 0.1$), ($\text{M} = \text{As}$, Sb , Nb or Ta) consisting of infinite chains, in which the oxidation state of mercury is close to $+1/3$ and the chains are virtually linear and uniform. The tendency of the ions to form chains, apparently, results from the low oxidation state and chains are formed if the charge on the mercury atom is lower than $\sim +1/2$. It should be noted that infinite linear chains of mercury atoms were found in $\beta\text{-Hg}$.⁶⁹ The layers of mercury atoms were observed in the graphite intercalation compound with composi-

tion KHgC_4 .⁷⁶ Although the Hg–Hg distances in KHgC_4 are close to those in Hg_3NbF_6 (2.85 and $2.90\text{ \AA}$, respectively), the layers in these structures differ in that each mercury atom in Hg_3NbF_6 has 6 neighbours and the formal charge of $+1/3$, whereas each mercury atom in the intercalation compound has only three neighbours and the formal charge of 0.

Therefore, analysis of the structures of mercury compounds with fluorine and MF_6^- anions shows the strict relationship between the value of the averaged formal charge on the mercury atom, the shortest Hg–F distances, the structure of the Hg_n^{x+} cation and the Hg–Hg distance in this cation. As the charge on the mercury atom decreases from $+1$ to $+1/3$, the shortest Hg–F distances increase from 2.133 in Hg_2F_2 to $3.2\text{ \AA}$ in Hg_3NbF_6 and the sizes of the Hg_n^{x+} cation increase going from the finite and virtually linear Hg_n^{2+} groups ($n = 2-4$) to the infinite Hg_n chains and then to a two-dimensional close-packed layer of the mercury atoms. The Hg–Hg distances in this series of the cations increase from 2.51 to $2.90\text{ \AA}$.

V. Monovalent mercury compounds with organic ligands

Presently, 30 complex compounds with organic ligands containing $(\text{Hg}_2)^{2+}$ groups have been synthesised and structurally characterised. The principal crystallographic and crystal-chemical characteristics of these compounds are given in Table 1. Most organic ligands, which are constituents of the complexes under consideration, are shown in Fig. 22.

Many amines, including pyridine, cause disproportionation of the dimeric $(\text{Hg}_2)^{2+}$ cation

Figure 22. Types of organic ligands in monovalent mercury complexes.

Figure 21. Hexagonal Hg_n layers in the structure of Hg_3NbF_6 .

The possibility of formation of stable monovalent mercury complexes with low-basicity nitrogen bases was confirmed for the first time by the detection of the $(\text{Hg}_2)^{2+}$ complex with aniline in solution.⁷⁷ Apparently, the introduction of an acceptor substituent at position 4 of the pyridine ring leads to a decrease in the donor ability of the nitrogen atom. Some substituted low-basicity pyridines and anilines also form stable $[\text{Hg}_2\text{L}_2]\text{X}_2$ complexes,⁷⁸ the basicity of the ligand depending on both the electronic and steric properties of the substituents. Structural study of the isolated $[\text{Hg}_2(\text{L}^1)_2](\text{ClO}_4)_2$ compound⁷⁹ demonstrated that the $(\text{Hg}_2)^{2+}$ ion can be covalently coordinated to the N-donor ligands through both mercury atoms.

The virtually linear N—Hg—Hg—N fragments (the Hg—Hg—N angles vary from 162.8 to 180°) were found in dimercury perchlorates with low-basicity N-containing organic ligands of the general formula $[\text{Hg}_2\text{L}_n](\text{ClO}_4)_2$ ($n = 2$);^{79–83} the Hg—Hg and Hg—N bond lengths are in the ranges of 2.487–2.518 and 2.03–2.22 Å, respectively. The structures of the complexes contain the dimeric $[\text{Hg}_2\text{L}_2]^{2+}$ cations and the ClO_4^- anions. Noteworthy is the existence of nonbonded contacts between the mercury atoms of the $(\text{Hg}_2)^{2+}$ ions and the oxygen atoms of the ClO_4^- anions. The lengths of these contacts (2.93–3.13 Å) are somewhat larger than the sum of the van der Waals radii of the mercury and oxygen atoms (2.90 Å). The shorter Hg...O contacts were observed in the $[\text{Hg}_2(\text{L}^2)_2](\text{ClO}_4)_2$ (2.71 Å),⁸⁰ $[\text{Hg}_2(\text{L}^3)_2](\text{ClO}_4)_2$ (2.79 Å)⁸¹ and $[\text{Hg}_2(\text{L}^5)_2](\text{ClO}_4)_2$ (2.77 Å)⁸³ compounds. In the complex with acridine $[\text{Hg}_2(\text{L}^4)_2](\text{ClO}_4)_2$, the lengths of these contacts are 2.96 Å,⁸² and hence one can say that only weak electrostatic interactions occur between the cations and the anions. The short Hg—N distance in the complexes with the ratio $(\text{Hg}_2)^{2+}:\text{L} = 1:2$ was found in $[\text{Hg}_2(\text{L}^3)_2](\text{ClO}_4)_2$.⁸¹ The Hg—Hg distance (2.518 Å) in this compound is somewhat larger than those in the $[\text{Hg}_2(\text{L}^1)_2](\text{ClO}_4)_2$ (2.498 Å)⁷⁹ and $[\text{Hg}_2(\text{L}^2)_2](\text{ClO}_4)_2$ (2.487 Å)⁸⁰ complexes. The arrangement of the $[(\text{Hg}_2)^{2+}(\text{L}^1)_2]$ cations in the structure of the complex, which is analogous to the arrangement of the molecules in $\text{Hg}_2(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$, is the so-called herringbone packing (see Fig. 2).^{7,8} In the remaining complexes, the linear N—Hg—Hg—N fragments are primarily located parallel to one of the crystallographic axes.^{80–83}

In the $[\text{Hg}_2(\text{L}^6)_2](\text{ClO}_4)_2$ complex⁸⁴ with the stoichiometry $(\text{Hg}_2)^{2+}:\text{L}^6 = 1:2$, the ligand is coordinated to the mercury atoms of the $(\text{Hg}_2)^{2+}$ pair through the nitrogen and oxygen atoms, the coordination environment about the mercury atoms being different. The environment about the Hg(1) atom is formed by the adjacent mercury atom (Hg—Hg, 2.506 Å), the nitrogen atom (2.20 Å) and two oxygen atoms (2.63 and 2.69 Å). The coordination about the Hg(2) atom involves the mercury, nitrogen (2.20 Å) and oxygen (2.66 Å) atoms. The remaining Hg...O(L⁶) distances are in the range of 2.89–4.15 Å. The ClO_4^- anions are not coordinated to the metal atoms.

The coordination number of 3 is typical of the mercury atoms in the structures of the $\text{Hg}_2\text{L}_4(\text{ClO}_4)_2$ compounds. Thus, the dimercury perchlorate complex with 4-benzylpyridine (L^7) consists of the centrosymmetrical $[\text{Hg}_2(\text{L}^7)_4]^{2+}$ cations and the ClO_4^- anions, which are linked *via* weak Hg...O contacts (2.899 and 3.026 Å).⁸⁵ Without considering these contacts, the coordination about the mercury atoms is intermediate between planar-trigonal and the so-called T-shaped⁸⁶ (one of the Hg—Hg—N angles is close to 180°; Hg—Hg is 2.508 Å, Hg—N are 2.227 and 2.476 Å) (Fig. 23). It should be noted that the L^7 ligand possesses the highest basicity in the series of the above-mentioned N-donor ligands, which is manifested in the distortion of the T-shaped environment towards the planar-trigonal coordination. A comparison of the structural data on the dimercury complexes with sterically unhindered ligands, such as 4-cyanopyridine (L^1),⁷⁹ 3-chloropyridine (L^2)⁸⁰ and 4-benzylpyridine (L^7),⁸⁵ revealed an interesting correlation between the stereochemistry and the basicity of the ligands (pK_a is 1.86, 2.81 and 5.59, respectively).⁸⁵ There are weak contacts between the mercury atoms and the

Figure 23. Molecular structure of $[\text{Hg}_2(\text{L}^7)_4](\text{ClO}_4)_2$.

oxygen atoms of the ClO_4^- anions in all three complexes regardless of the initial coordination of ligands in the axial positions with respect to the $(\text{Hg}_2)^{2+}$ pair. As the basicity of the above-mentioned ligands increases, the secondary coordination becomes more essential. In particular, the secondary Hg...L contacts [2.86 Å (O), 2.77 Å (O) and 2.476 Å (N)] become shorter and the Hg—Hg—L angles increase (100°, 109° and 118.4°), due to which the second ligand approaches the strong acceptor axial centre of the $(\text{Hg}_2\text{L}_2)^{2+}$ dimer. Correspondingly, the coordination is weakened, which is manifested in the increase in the Hg—N bond length (2.16, 2.21 and 2.23 Å). The deviation of the N—Hg—Hg—N fragment from linearity also increases (the N—Hg—Hg angles are 176.0°, 167.4° and 153.9°). Hence, it is evident that the deviation of the N—Hg—Hg—N fragments from linearity in stable dimercury complexes with N-donor ligands of the $[\text{Hg}_2\text{L}_n]\text{X}_2$ type ($n > 2$) is caused by the additional coordination of the metal atoms by more remote ligands.

The coordination polyhedra about the mercury atoms in the $[\text{Hg}_2(\text{L}^8)_4](\text{ClO}_4)_2$ compound are distorted tetrahedra formed by the mercury atom (Hg—Hg, 2.522 Å) and three oxygen atoms of the ligands (Hg—O, 2.197–2.558 Å).⁸⁷ An analogous coordination with the elongated Hg—O bonds, which is untypical of mercury atoms, was also found in Hg_2AgPO_4 (see Ref. 32) and in the mineral szymanskiite.⁴⁰ The remaining Hg...O contacts are longer than 2.78 Å. The $[\text{Hg}_2(\text{L}^8)_4]^{2+}$ dimers lie in the (010) plane. The distances between the adjacent dimers are 3.90 and 4.17 Å (Fig. 24). In addition, there is a rather long contact (2.96 Å) between the mercury atom and the oxygen atom of the ClO_4^- anion. Therefore, the structure of the $[\text{Hg}_2(\text{L}^7)_4](\text{ClO}_4)_2$ complex contains only discrete cations with the three-coordinate mercury

Figure 24. Projection of the structure of $[\text{Hg}_2(\text{L}^8)_4](\text{ClO}_4)_2$ onto the (001) plane.

atoms, whereas three of four ligands in the $[\text{Hg}_2(\text{L}^8)_4](\text{ClO}_4)_2$ complex act as bridges between the adjacent $(\text{Hg}_2)^{2+}$ cations.⁸⁵

The compound $\text{Hg}_2(\text{Ph}_2\text{Se})_4(\text{ClO}_4)_2$ exists in two forms, viz., in the 'yellow'⁸⁸ and 'red'⁸⁹ forms. The 'yellow' complex contains the centrosymmetrical $[(\text{Ph}_2\text{Se})_2\text{Hg}_2(\text{Ph}_2\text{Se})_2]^{2+}$ cations with positively charged trivalent selenium atoms.⁸⁸ One of the oxygen atoms of each ClO_4^- anion is bound to the $(\text{Hg}_2)^{2+}$ group. Each mercury atom has the trigonal environment formed by the mercury atom ($\text{Hg}-\text{Hg}$, 2.558 Å), the selenium atom ($\text{Hg}-\text{Se}$, 2.70 Å) and the oxygen atom of the ClO_4^- anion ($\text{Hg}-\text{O}$, 2.705 Å). In addition, there is a contact between the mercury atom and the selenium atom (2.80 Å), which completes the coordination about the mercury atom to a distorted tetrahedron. The observed $\text{Hg}-\text{Hg}$ distance belongs to the longest distances found in the $(\text{Hg}_2)^{2+}$ groups. The value of one of the $\text{Hg}-\text{Hg}-\text{Se}$ angles (141°) indicates that the linear coordination about the mercury atom is distorted upon addition of the second diphenyl selenide group. Correspondingly, the $\text{Hg}-\text{Se}$ distance is 2.70 Å at the $\text{Hg}-\text{Hg}-\text{Se}$ angle of 141° , while this distance increases to 2.80 Å at the angle of 116° . In the centrosymmetrical molecule of the 'red' form, the central Hg_2Se_4 fragment is planar.⁸⁹ The fourth coordination site at the mercury atom is occupied by an oxygen atom of the ClO_4^- anion ($\text{Hg}-\text{Hg}$, 2.554 Å; $\text{Hg}-\text{Se}$, 2.653 and 2.918 Å; $\text{Hg}-\text{O}$, 2.626 Å; the $\text{Hg}-\text{Hg}-\text{Se}$ angle is 151.9°). Therefore, the 'yellow' and 'red' forms of the $\text{Hg}_2(\text{Ph}_2\text{Se})_4.(\text{ClO}_4)_2$ compound are characterised by the different structures of the Hg_2Se_4 fragments and the different molecular packings in the crystals.

In the $\text{Hg}_2[(\text{Ph}_3\text{PO})_6](\text{ClO}_4)_2$ complex with the stoichiometry $(\text{Hg}_2)^{2+}:\text{L} = 1:6$, the coordination environment around each mercury atom is a tetrahedron formed by three ligands and the adjacent mercury atom of the $(\text{Hg}_2)^{2+}$ pair. As a result, the discrete complex cation is formed ($\text{Hg}-\text{Hg}$, 2.522 Å; $\text{Hg}-\text{O}$, 2.29–2.43 Å).⁹⁰ The ClO_4^- anions are not involved in the coordination sphere about the mercury atoms. In this complex, the mercury atoms have the so-called umbrella-type coordination formed by the oxygen atoms of the ligands with elongated $\text{Hg}-\text{O}$ bonds. This coordination is analogous to that found in $\text{Hg}_2\text{Ag}.\text{PO}_4$,³² szymanskiite⁴⁰ and the $[\text{Hg}_2(\text{L}^8)_4](\text{ClO}_4)_2$ complex.⁸⁷

It should be noted that compounds of the $\text{Hg}_2\text{L}_2\text{X}_2$ type contain discrete dimeric cations, in which each mercury atom is linearly coordinated. The $\text{Hg}-\text{L}$ bonds are in the range of 2.03–2.35 Å and the X anions are located at large distances from the mercury atoms (2.8–3.0 Å). In the compounds with composition $\text{Hg}_2\text{L}_4\text{X}_2$, the coordination about the mercury atoms is intermediate between linear and tetrahedral. Besides, data on polymeric complexes with bridging N-containing L ligands, which are analogous to those found in $[\text{Hg}_2(\text{L}^8)_4](\text{ClO}_4)_2$ with O-containing ligands, are lacking.⁸⁷ Only in the $\text{Hg}_2[(\text{Ph}_3\text{PO})_6].(\text{ClO}_4)_2$ compound, is the coordination environment about the mercury atoms a tetrahedron.⁹⁰

The existence of the stable mercury complex with 1,10-phenanthroline (Phen) confirms the possibility of complexation of dimercury ions with low-basicity amines. The $\text{Hg}_2\text{Phen}(\text{NO}_3)_2$ complex with the ratio $(\text{Hg}_2)^{2+}:\text{L} = 1:1$ has a layered structure. The discrete $[\text{Hg}_2(\text{Phen})]^{2+}$ cations are separated by layers of the NO_3^- anions.⁹¹ The mercury atoms have different coordinations. Thus, the $\text{Hg}(1)$ atom has four nearest neighbours; the tetrahedron is formed by the $\text{Hg}(2)$ atom ($\text{Hg}-\text{Hg}$, 2.516 Å), the nitrogen atoms of the phenanthroline molecule (2.30 and 2.48 Å) and the oxygen atom of NO_3^- anion (2.59 Å). Another oxygen atom of the NO_3^- anion is located at a distance of 2.91 Å. The nearest environment about the $\text{Hg}(2)$ atom is formed by the $\text{Hg}(1)$ atom and the oxygen atom of the NO_3^- anion. The remaining oxygen atoms are at distances of 2.75–2.95 Å. Therefore, the 1,10-phenanthroline molecule is bound to only one mercury atom of the $(\text{Hg}_2)^{2+}$ pair. Attempts to isolate the compound with composition $\text{Hg}_2(\text{Phen})_2(\text{NO}_3)_2$ failed.

In compounds with the stoichiometry $\text{Hg}_2^{2+}:\text{L} = 1:2$ [$\text{Hg}_2(\text{L}^9)_2](\text{NO}_3)_2$ and [$\text{Hg}_2(\text{L}^{10})_2](\text{NO}_3)_2$, the nearly linear

$-\text{N}-\text{Hg}-\text{Hg}-\text{N}-$ groups were found with the $\text{Hg}-\text{Hg}$ distances of 2.551⁹² and 2.517 Å⁹³ and the $\text{Hg}-\text{N}$ distances of 2.168 Å⁹² and 2.193 Å.⁹³ The shortest distances to the oxygen atoms of the NO_3^- anions are 2.696–3.000 Å. The authors⁹³ believed that the contacts, characterised by these lengths, play a decisive role in the molecular packing of the complex.

The structures of [$\text{Hg}_2(\text{L}^{11})_2](\text{NO}_3)_2$ (see Ref. 94) and [$\text{Hg}_2(\text{L}^{12})_2](\text{NO}_3)_2$ (see Ref. 95) contain the nearly linear $-\text{N}-\text{Hg}-\text{Hg}-\text{N}-$ groups ($\text{Hg}-\text{Hg}$, 2.518 Å⁹⁴ and 2.524 Å⁹⁵; and $\text{Hg}-\text{N}$, 2.233 Å⁹⁴ and 2.209 Å⁹⁵). Taking into account the $\text{Hg}\cdots\text{O}$ distance (2.659 Å), the coordination about the mercury atoms is close to T-shaped.⁹⁴ In addition, each mercury atom has contacts with the oxygen atom of the NO_3^- anion ($\text{Hg}\cdots\text{O}$, 2.769 Å) and the nitrogen atom of the nitrile group (2.906 Å). The NO_3^- anions are involved in hydrogen bonding with the NH_2 groups of the adjacent molecules ($\text{N}\cdots\text{O}$, 2.88 and 3.02 Å) through the noncoordinated and coordinated oxygen atoms to form chains along the [100] direction. These chains are linked in layers parallel to the (010) plane through the $\text{Hg}-\text{N}_{\text{CN}}$ interactions (2.906 Å).

The mercury atoms in the dimeric cation of the $\text{Hg}_2(\text{L}^{13})_2(\text{NO}_3)_2$ complex have different coordinations. Thus, the $\text{Hg}(1)$ atom is coordinated to the $\text{Hg}(2)$ atom at a distance of 2.541 Å and, in addition, forms a covalent bond with the sulfur atom of the ligand (2.49 Å). The $\text{S}-\text{Hg}-\text{Hg}-\text{S}$ fragment is virtually linear (the $\text{Hg}-\text{Hg}-\text{S}$ angle is 173.5°).⁹⁶ The coordination environment about the $\text{Hg}(2)$ atom is more complicated. The nearest environment involves the oxygen atoms of two NO_3^- groups (2.516 and 2.651 Å) along with the sulfur atom of the ligand (2.584 Å). In addition, there are $\text{Hg}\cdots\text{O}$ contacts between the $\text{Hg}(1)$ atom and the NO_3^- groups (2.773 and 2.820 Å). The L^{13} ligands serve as bridges between the mercury pairs. In the structure, the $-\text{L}^{13}-(\text{Hg}_2)^{2+}-\text{L}^{13}-$ chains are extended parallel to the [101] direction.

The $\text{Hg}_2(\text{L}^{14})_2(\text{NO}_3)_2$ compound contains the $[-(\text{Hg}_2)^{2+}-\text{S}-(\text{Hg}_2)^{2+}-]$ chains with the three-coordinate sulfur atoms and the NO_3^- anions ($\text{Hg}-\text{Hg}$, 2.548 Å; $\text{Hg}-\text{S}$, 2.488 and 2.477 Å; the $\text{Hg}-\text{Hg}-\text{S}$ angles are 161.9 and 163.8°).⁹⁷ $\text{Hg}\cdots\text{O}$ contacts (2.64–3.14 Å) are observed. The O(3) atom of the NO_3^- anion acts as a bridge [$\text{Hg}(1)-\text{O}(3)$, 2.652 Å; and $\text{Hg}(2)-\text{O}(3)$, 2.636 Å], completes the coordination about the mercury atom to T-shaped and links the chains in corrugated ribbons along the b axis (Fig. 25).

In the crystal of the complex $\text{Hg}_2(\text{L}^{15})_2(\text{H}_2\text{O})_2$, the molecules exist as zwitter-ions with the formal positive charge on the nitrogen atom and the negative charge on the sulfate ion.⁹⁸ The $\text{N}-\text{Hg}-\text{Hg}-\text{N}$ fragment has a nearly linear configuration. The

Figure 25. Corrugated ribbons extended along the b axis in the crystal structure of $\text{Hg}_2(\text{L}^{14})_2(\text{NO}_3)_2$.

Hg—Hg bond is rather short (2.494 Å). The mercury atoms form additional contacts with the oxygen atoms of the water molecules (2.621 Å) and of the SO_3^- groups of the L^{15} ligand (2.680 Å).

The structures of $\text{Hg}_2(\text{L}^{16})_2$, $\text{Hg}_2(\text{L}^{17})_2$ and $\text{Hg}_2(\text{L}^{17})_2(\text{H}_2\text{O})_2$ contain the centrosymmetrical complexes, in which the mercury atoms are coordinated by the nitrogen atoms to form the nearly linear $[-\text{N}-\text{Hg}-\text{Hg}-\text{N}-]$ fragments.⁹⁹ The Hg—Hg bond lengths are 2.500, 2.515 and 2.522 Å in $\text{Hg}_2(\text{L}^{16})_2$, $\text{Hg}_2(\text{L}^{17})_2$ and $\text{Hg}_2(\text{L}^{17})_2(\text{H}_2\text{O})_2$, respectively. The Hg—N bond lengths are virtually identical (the average value is 2.19 Å). In the $\text{Hg}_2(\text{L}^{16})_2$ and $\text{Hg}_2(\text{L}^{17})_2(\text{H}_2\text{O})_2$ compounds, the $(\text{Hg}_2)^{2+}$ pairs are rotated with respect to each other by 78 and 68°, respectively. In $\text{Hg}_2(\text{L}^{17})_2$, these pairs are parallel to each other. There are weak Hg...O interactions, whose lengths are close to the sum of the van der Waals radii. Thus, there are contacts with three oxygen atoms of two ligand molecules (2.67, 2.92 and 2.99 Å) in the $\text{Hg}_2(\text{L}^{16})_2$ compound, contacts with the oxygen atoms of the SO_3^- group (2.68 Å) in $\text{Hg}_2(\text{L}^{17})_2$ and contacts with the oxygen atoms of the ligand (2.711 Å) and of the water molecule (2.715 Å) in $\text{Hg}_2(\text{L}^{17})_2(\text{H}_2\text{O})_2$. The $\text{Hg}_2(\text{L}^{16})_2$ and $\text{Hg}_2(\text{L}^{17})_2(\text{H}_2\text{O})_2$ complexes are linked in layers and the $\text{Hg}_2(\text{L}^{17})_2$ complexes are linked in chains through the ligand molecules (Fig. 26). In the $\text{Hg}_2(\text{L}^{17})_2$ and $\text{Hg}_2(\text{L}^{16})_2$ compounds, the oxygen atoms of the SO_3^- groups are involved in intermolecular hydrogen bonding with the NH_2 groups ($\text{N}\cdots\text{O}$, 2.85–3.06 Å). In $\text{Hg}_2(\text{L}^{17})_2(\text{H}_2\text{O})_2$, the oxygen atoms are involved in hydrogen bonding with the water molecules ($\text{O}\cdots\text{O}$, 2.777 and 2.784 Å).

The nearest environment about each mercury atom of *o*-phthalate $\text{Hg}_2(\text{L}^{18})_2$ involves the oxygen atom. In this case, the virtually linear O—Hg—Hg—O fragments are formed (Hg—Hg, 2.519 Å; and Hg—O, 2.16 and 2.08 Å). The $(\text{Hg}_2)^{2+}$ pairs link the *o*-phthalate groups to form infinite zigzag chains.¹⁰⁰ In the unit cell, eight crystallographically equivalent chains are linked in pairs and are located parallel to the *b* axis, *i.e.*, along the longest crystallographic axis.

The typical pseudosymmetrical dimer with the Hg—Hg bond (2.514 Å) was also found in the $[\text{Hg}_2(\text{L}^{19})_2]_n$ compound.¹⁰¹ The L^{19} ligand is involved in one strong bond (Hg—O, 2.13 Å) and one weak intermolecular Hg...O bond (2.63 Å) through which the $(\text{Hg}_2)^{2+}$ dimers are linked in chains along the [100] direction. Taking into account this bond, the coordination about the mercury atom is close to T-shaped.

The crystal structure of $\text{Hg}_2(\text{CF}_3\text{CO}_2)_2$ consists of discrete Hg_2L_2 molecules. The $[-\text{O}-\text{Hg}-\text{Hg}-\text{O}-]$ fragments are virtually linear (Hg—Hg, 2.505 Å; and Hg—O, 2.14 Å).¹⁰² The additional Hg...O distances (2.81 and 2.88 Å) have no substantial effect on the characteristic coordination about the mercury atom. The $\text{Hg}_2(\text{CF}_3\text{CO}_2)_2$ molecules are linked in corrugated ribbons along the [001] direction through intermolecular Hg...O bonds (2.64 Å) (Fig. 27). Taking into account this contact, the coordination about the mercury atom is T-shaped. In the crystal structure, the ribbons are linked in layers *via* F...F contacts (2.78–3.12 Å).

In the $\text{Hg}_2[\text{C}(\text{CN})_3]_2$ complex,¹⁰³ the $(\text{Hg}_2)^{2+}$ ions form three elongated bonds with the nitrogen atoms of the CN^- groups (Hg—N, 2.287–2.508 Å) along with the Hg—Hg bond (2.506 Å). This coordination is analogous to the coordination about the mercury atoms of the $(\text{Hg}_2)^{2+}$ pairs mentioned in several studies.^{32, 40, 87, 90} The centres of the $(\text{Hg}_2)^{2+}$ pairs coincide with the inversion centres. The ligands are bridging and tridentate. All the nitrogen atoms of each ligand are involved in coordination about different mercury atoms to form a three-dimensional framework (Fig. 28).

In the centrosymmetrical cation of the $\text{Hg}_2(\text{C}_7\text{HN}_4)_2$ complex, the mercury atoms have the distorted trigonal environment formed by the adjacent mercury atom and the nitrogen atoms of two carbanions of the ligand (Hg—Hg, 2.503 Å; Hg—N, 2.207 and 2.560 Å; the Hg—Hg—N angles are 162.2 and 116.5°).¹⁰⁴ The cations are linked in chains along the *a* axis through the ligands. The mercury atoms form weak Hg...N contacts (2.753 and 2.935 Å) through which the chains are linked in layers (Fig. 29).

Figure 26. Molecular packings in the structures of the complexes: (a) $\text{Hg}_2(\text{L}^{16})_2$; (b) $\text{Hg}_2(\text{L}^{17})_2(\text{H}_2\text{O})_2$; and (c) $\text{Hg}_2(\text{L}^{17})_2$.

The rather unusual complex with hexamethylbenzene with composition $[\text{Hg}_2(\text{L}^{20})_6](\text{AlCl}_4)_2 \cdot \text{C}_7\text{H}_8$ was described.¹⁰⁵ The hexamethylbenzene L^{20} ligands are asymmetrically coordinated to the $(\text{Hg}_2)^{2+}$ dimer in the η^2 fashion. The distances from the mercury atoms to the planes of the ligands are 2.356 and 2.367 Å. In the crystal structure, the complexes with the Hg—Hg bonds

Figure 27. Crystal structure of $\text{Hg}_2(\text{CF}_3\text{CO}_2)_2$. The $\text{F}\cdots\text{F}$ contacts are indicated by dashed lines.

Figure 28. Projection of the crystal structure of $\text{Hg}_2[\text{C}(\text{CN})_3]_2$ onto the (100) plane.

Figure 29. Layered structure of the $\text{Hg}_2(\text{C}_7\text{HN}_4)_2$ complex.

(2.515 Å) are located parallel to the b axis. The structure contains also distorted AlCl_4 tetrahedra. The shortest $\text{Hg}\cdots\text{Cl}$ distances are 3.10 and 3.12 Å.

Analysis of the $\text{Hg}-\text{Hg}$ and $\text{Hg}-\text{L}$ bonds in the monovalent mercury complexes with organic ligands demonstrates that there is no strict correlation between these parameters, as in inorganic compounds containing mercury in low oxidation states. The $\text{Hg}-\text{Hg}$ distances vary from 2.487 to 2.558 Å, which is in good agreement with the distances observed in the crystal structures of inorganic compounds. In the complexes of the $\text{Hg}_2\text{L}_n\text{X}_2$ type ($n = 2, 4$ or 6) with $\text{X} = \text{ClO}_4^-$ (see Refs 79–90), the anions have no substantial effect on the $\text{Hg}-\text{Hg}$ bond length and are involved only in nonbonded interactions with the metal atoms, whereas the oxygen atoms of the anions in the complexes with $\text{X} = \text{NO}_3^-$ (see Refs 91–97) complete the coordination about the mercury atoms of the $(\text{Hg}_2)^{2+}$ pairs ($\text{Hg}\cdots\text{O}$, 2.516–2.769 Å). In the $\text{Hg}_2(\text{L}^{15})_2(\text{H}_2\text{O})_2$ (see Ref. 98) and $\text{Hg}_2(\text{L}^{17})_2(\text{H}_2\text{O})_2$ (see Ref. 99) complexes, the water molecules are involved only in formation of additional bonds with the mercury atoms of the $(\text{Hg}_2)^{2+}$ pairs or in hydrogen bonding with the atoms of the ligands, whereas inorganic aqua complexes contain the aqua $[\text{H}_2\text{O}-\text{Hg}-\text{Hg}-\text{OH}_2]^{2+}$ cations. In the molecular complexes of the Hg_2L_2 type, the $\text{Hg}-\text{Hg}$ bond lengths vary from 2.500 to 2.519 Å.^{99–104} The complexes are linked in chains and layers through additional $\text{Hg}\cdots\text{L}$ contacts, as in inorganic monovalent mercury compounds. The coordination environment about the mercury atoms is formed primarily by atoms of organic ligands. In most compounds, anions are not coordinated to the metal atoms (the coordination number of the mercury atoms is 2).^{79–83} When the coordination number of Hg increases to 3 or 4 taking into account the contacts with the anions, the structures can be described as chain, layered⁹ and framework.^{4–102, 104, 105}

VI. Mercury-containing transition metal clusters

Presently, the data on a series of mercury-containing transition metal clusters containing either $(\text{Hg}_2)^{2+}$ pairs or more complicated cluster Hg_n groups are available. The principal crystallographic and crystal-chemical data for selected mercury-containing clusters are given in Table 1. In this section, we consider the mercury-containing clusters with the $\text{Hg}-\text{Hg}$ bond lengths varying in the range of 2.65–3.27 Å.

The structure of the $\text{Hg}_2\text{Co}_2[\text{N}(\text{CH}_2\text{CH}_2\text{PPh}_2)_3]_2(\text{THF})$ cluster consists of the discrete $\{[\text{N}(\text{CH}_2\text{CH}_2\text{PPh}_2)_3]\text{Co}(\text{Hg}-\text{Hg})\text{Co}[\text{N}(\text{CH}_2\text{CH}_2\text{PPh}_2)_3]\}$ molecules and the tetrahydrofuran molecules located between the complex molecules. Two $\text{Co}[\text{N}(\text{CH}_2\text{CH}_2\text{PPh}_2)_3]$ fragments are linearly bonded through the $(\text{Hg}_2)^{2+}$ ion (Fig. 30) so that the four metal atoms of the $-\text{Co}-\text{Hg}-\text{Hg}-\text{Co}-$ fragment are coplanar (the $\text{Co}-\text{Hg}-\text{Hg}$ angles are 179.7 and 178.4°).¹⁰⁶ The two-coordinate mercury atoms are shielded from additional bonding with the Ph rings of the $[\text{N}(\text{CH}_2\text{CH}_2\text{PPh}_2)_3]$ ligands. The $\text{Hg}-\text{Hg}$ distance (2.651 Å) is somewhat larger than those in the dimercury complexes with organic ligands. The shortest contact between the carbon atoms of the Ph rings and the mercury atoms is 3.48 Å.

The study of the compound $\{\text{Hg}_2\text{Pt}_6[\text{Ph}_2\text{P}(\text{CH}_2)_6\text{PPh}_2]_3\cdot(\text{C}_8\text{H}_9\text{NC})_6\}\cdot 2\text{C}_6\text{H}_6$ demonstrated that the $(\text{Hg}_2)^{2+}$ pair is inserted into the trigonal antiprismatic cage of the platinum atoms.¹⁰⁷ Two Pt_3 triangles are tightened by three $[\text{Ph}_2\text{P}(\text{CH}_2)_6\text{PPh}_2]$ ligands. Six isocyanide molecules act as bridging ligands in each triangular unit. The $\text{Hg}-\text{Hg}$ distance (2.872 Å) is larger than the analogous distances in monovalent mercury compounds with organic ligands but is somewhat shorter than the distances between the metal atoms in metallic mercury.⁶⁹

The structural studies of mercury-containing metal carbonyl compounds demonstrated that, as in compounds containing linear Hg_n chains ($n = 3$ or 4), the $\text{Hg}-\text{Hg}$ distances are in the range of 2.5–2.8 Å. This is indicative of a strong covalent bond, which is formed due to the overlap of the linear sp -hybridised orbitals. In the cases where other atoms, for example, transition

Figure 30. Schemes of the structures of mercury-containing transition metal clusters: (a) $\text{Hg}_2\text{Co}_2\text{N}(\text{CH}_2\text{CH}_2\text{PPh}_2)_3(\text{THF})$; (b) $\{\text{Hg}_3[(\text{Ph}_2\text{P})_2\text{CH}_2]_3\}(\text{SO}_4)_2 \cdot 1.5\text{H}_2\text{O}$; (c) $[\text{Nb}(\eta\text{-C}_5\text{H}_5)_2\{\text{HgS}_2\text{CN}(\text{C}_2\text{H}_5)_2\}_3] \cdot (\text{C}_2\text{H}_5)_2\text{S}_3$; (d) $[(\eta^5\text{-CH}_3\text{C}_5\text{H}_4)\text{Mn}(\text{CO})_2\text{Hg}]_4$; (e) $[(\text{C}_{12}\text{H}_{36})_3\text{Rh}]_4\text{Hg}_6$; and (f) $[\text{Hg}_9\text{Co}_6(\text{CO})_{18}] \cdot 2(\text{C}_3\text{H}_6\text{O})$.

metals (M), are involved in the Hg—Hg bond, the distances in the clusters increase to 3.2 Å.

In the $[(\text{Ph}_3\text{P})_2\text{N}]_2[\text{Hg}_2\text{Os}_{18}(\text{CO})_{42}\text{C}_2]$ cluster, the vertices of the Os triangles are linked through the mercury atoms to form the $\text{Os}_9\text{C}(\text{CO})_{21}$ units.¹⁰⁸ The molecule is centrosymmetrical with respect to the midpoint of the Hg—Hg bond. The Hg—Hg distance is 2.744 Å, whereas the Hg—Hg bond in the $[(\text{Ph}_3\text{P})_2\text{N}]_4[\text{Hg}_2(\text{Os}_{18}(\text{CO})_{42}\text{C}_2)(\text{CH}_2\text{CH}_2)]$ cluster,¹⁰⁹ which contains the framework of the metal atoms with a similar structure, is somewhat longer (2.820 Å).

The triangular $(\text{Hg}_3)^{4+}$ cluster containing the mercury atoms in the oxidation state of +4/3 was found in the $\{\text{Hg}_3[(\text{Ph}_2\text{P})_2\text{CH}_2]_3\}(\text{SO}_4)_2 \cdot 1.5\text{H}_2\text{O}$ compound.¹¹⁰ Each mercury atom is bound to the bridging $(\text{Ph}_2\text{P})_2\text{CH}_2$ ligands. In addition, two SO_4^{2-} anions form weak contacts with the mercury atoms. The Hg—Hg distances are 2.763, 2.764 and 2.802 Å, which are comparable with the analogous distances in the triangular groups observed in terlinguaite,⁴⁴ kuznetsovite⁶⁰ and $\text{Hg}_9\text{As}_4\text{O}_{16}$.⁶²

In the $[(\text{Ph}_3\text{P})_2\text{N}]_2[\text{Ru}_{18}\text{Hg}_3(\text{C})_2(\text{CO})_{42}] \cdot \text{CH}_2\text{Cl}_2$ cluster, the mercury triangle links two tricapped octahedral $[\text{Ru}_9(\text{CO})_{21}\text{C}]$ fragments (Hg—Hg, 2.919 and 2.922 Å; Hg—Ru, 2.640–2.734 Å).¹¹¹ It should be noted that the Hg—Hg distances are virtually equal to the corresponding distances in metallic mercury.⁶⁹ In the solid state, the $[\text{Ru}_{18}\text{Hg}_3(\text{C})_2(\text{CO})_{42}]^{2-}$ dianion has the symmetry C_3 . The average angle of rotation of the central Hg_3 triangle with respect to the two adjacent Ru_3 triangles is 30°. The short Hg...C_{CO} contacts (the average length is 2.64 Å) are present in the structure.

An analogous Hg_3 unit links two $[\text{Os}_9(\text{CO})_{21}\text{C}]$ fragments in the $[(\text{Ph}_3\text{P})_2\text{N}]_2[\text{Hg}_3\text{Os}_{18}(\text{CO})_{42}\text{C}_2] \cdot \text{CH}_2\text{Cl}_2$ cluster, the mercury triangle (Hg—Hg, 2.919–2.931 Å) being disordered.¹¹² Note that the Cd_3 triangle with the average Cd—Cd bond length of 2.980 Å

was found in the structurally related $[\mu_3\text{-Co}(\text{CO})_3]\text{Cd}_3\{\mu_3\text{[(CO)}_9\text{Co}_3(\mu_3\text{-CCO}_2)]_3(\text{THF})_3\}$ cluster.¹¹³

A series of Hg-containing metal clusters containing the heteronuclear triangular MHg_2 fragment were studied. The $\text{Hg}_2\text{Ag}[(\text{Ph}_2\text{P})_2\text{CH}_2]_3(\text{CF}_3\text{SO}_3)_3$ cluster contains the Hg_2Ag triangle all vertices of which are bound to the $[(\text{Ph}_2\text{P})_2\text{CH}_2]$ bridging ligands.¹¹⁴ The Hg—Hg (2.660 Å) and Hg—Ag (2.805 and 2.853 Å) distances are close to those found in AgHg_2PO_4 .³² The mercury and silver atoms have an approximately planar-square coordination formed by two metal atoms and two phosphorus atoms.

In the examples of mercury-containing transition metal clusters considered below, the Hg—Hg bonds (2.883–3.274 Å) approximate the distances in metallic mercury. Therefore, the mercury—transition metal bonds in these clusters prevail.

The rather unusual nearly planar Hg_3Nb unit, which is located in the equatorial plane of the wedge-shaped Cp_2Nb sandwich, was found in the organometallic $[\text{Nb}(\eta\text{-C}_5\text{H}_5)_2\{\text{HgS}_2\text{CN}(\text{C}_2\text{H}_5)_2\}_3]$ cluster.¹¹⁵ The dihedral angle between the $\text{NbHg}(1)\text{Hg}(2)$ and $\text{NbHg}(2)\text{Hg}(3)$ triangles in this complex is $\sim 5^\circ$. The Hg—Hg bond lengths (2.883 and 2.901 Å) are indicative of a rather strong interaction between the adjacent mercury atoms. The Hg—Nb distances vary from 2.777 to 2.808 Å. The cluster molecules are linked in dimeric units through the weak Hg...S bonds [$\text{Hg}(2)\text{—S}(11)$, 3.39 Å].

The organometallic $[(\eta^5\text{-CH}_3\text{C}_5\text{H}_4)\text{Mn}(\text{CO})_2\text{Hg}]_4$ compound¹¹⁶ contains the eight-membered Mn_4Hg_4 metallocycle in which four mercury atoms form a planar square with the Hg—Hg distances of 2.888 Å. The four-membered virtually planar Hg_4 ring (the Hg—Hg—Hg bond angle is 90°) was also found in the $[(\eta^5\text{-C}_5\text{H}_5\text{Re}(\text{CO})_2\text{Hg})_4]$ cluster with an analogous structure.¹¹⁷ The rhenium atoms are alternately located above and below the plane of the mercury square. The average angle of bend of the angular HgReHg fragments is 19.0° . The slight shortening of the Hg—Hg bonds (2.92 Å) compared to the distances in metallic mercury (2.99 Å) is indicative of the metal—metal interaction in the Hg_4 ring of the cluster. The authors believed that the distortion of the linear coordination of the mercury atoms (the Re—Hg—Re angle is 158.8°) is also evidence in favour of the Hg—Hg interaction. The observed eight-membered ring system is similar to that found previously in $[(\eta^5\text{-CH}_3\text{C}_5\text{H}_4)\text{Mn}(\text{CO})_2\text{Hg}]_4$.¹¹⁶ It should be noted that the Hg—M bonds are substantially shorter than the Hg—Hg distances in the above-described compounds [2.64 Å (Mn) and 2.74 Å (Re)].

The octahedra of six mercury atoms were observed in two clusters, viz., in $[(\text{C}_{12}\text{H}_{36})_3\text{Rh}]_4\text{Hg}_6$ (see Ref. 118) and $[(\text{C}_8\text{H}_{18})_2\text{Pt}]_4\text{Hg}_6$ (see Ref. 119). In the molecular structures of both compounds, the Rh and Pt atoms act as ‘caps,’ which complete the faces of the Hg_6 octahedra to form the heteroatomic Hg_6M_4 tetrahedron. The Hg—Hg bond lengths in the nearly regular mercury octahedra are in the ranges of 3.129–3.149¹¹⁸ and 3.081–3.274 Å.¹¹⁹ The Hg—Rh and Hg—Pt distances are in the ranges of 2.690–2.724 and 2.671–2.876 Å, respectively.

In the $[\text{Hg}_9\text{Co}_6(\text{CO})_{18}] \cdot 2(\text{C}_3\text{H}_6\text{O})$ cluster,¹²⁰ the structural unit containing nine mercury atoms was found. The framework of the metal atoms can be described as a distorted Co_6Hg_9 trigonal prism with the cobalt atoms occupying all vertices and the mercury atoms being located in the midpoints of the edges. The distances between the mercury atoms located in the centres of the triangular bases of the prism vary from 3.065 to 3.138 Å, whereas the distances from these atoms to the mercury atoms located in the midpoints of the edges of the prism, which link two bases, are somewhat longer (3.086–3.198 Å). The authors¹²⁰ believed that the Hg—Co interaction (2.521–2.609 Å) is the governing factor in the formation of the framework of the metal atoms.

The nature of the Hg—Hg interactions in the clusters of this type is still unclear. In the review,¹²¹ the structures of transition metal clusters with mercury atoms were considered and an attempt was made to explain the nature of the Hg—Hg and Hg—M bonds. The structural studies of transition metal clusters

revealed the existence of the linear $M-Hg-M$ units containing two-coordinate mercury atoms. The clusters can be divided into two types, *viz.*, two-dimensional clusters in which mercury atoms form polygons {for example, a triangle in $(C_{36}H_{30}NP_2)_2 \cdot [Hg_3Os_9(CO)_{21}C_2] \cdot CH_2Cl_2$ (see Ref. 112) or a square in $[(\eta^5-CH_3C_5H_4)Mn(CO)_2Hg]_4$ (see Ref. 116)}, and three-dimensional clusters in which mercury atoms form polyhedra {for example, an octahedron in $[(C_{12}H_{36})_3Rh]_4Hg_6$ (see Ref. 118) and $[(C_8H_{18}P)_2Pt]_4Hg_6$ (see Ref. 119) or a tricapped trigonal prism in $[Hg_9Co_6(CO)_{18}] \cdot 2(C_3H_6O)$ (see Ref. 120)}. The mercury atoms in these clusters are characterised by the linear *sp* configuration of the metal-metal bonds and the involvement in the secondary $Hg \cdots Hg$ interactions (2.89–3.15 Å). Note that in the compounds considered in Refs 115–120, the bonds between the mercury atoms and the transition metal atoms are, apparently, determining. The $Hg-Hg$ bond lengths (2.65–3.27 Å) are intermediate between the shortened bond lengths found in inorganic and complex compounds of monovalent mercury (2.46–2.59 Å) and the van der Waals $Hg^{2+} \cdots Hg^{2+}$ contacts (3.41 Å), which exist, for example, in polymercurated organic derivatives $R(HgX)_n$.^{122–124}

VII. Conclusion

In the present review, the data on the crystal structures of inorganic and complex compounds of mercury in low oxidation states and on some mercury-containing transition metal clusters containing the $(Hg_2)^{2+}$ pairs and the Hg_n groups are summarised. The $Hg-Hg$ and $Hg-X$ bonds ($X = O, N, S$ or Se) are analysed and the modes of coordination of the mercury atoms in the mercury pairs and cluster groups are considered.

The crystal chemistry of monovalent mercury compounds is similar to the crystal chemistry of divalent mercury compounds. The ability of the mercury atom to form linear $X-Hg-X$ fragments is retained. However, the *sp*-bonds in the $X-Hg-Hg-X$ groups are not necessarily exactly collinear. Interestingly, the bonds between the mercury atoms of the $(Hg_2)^{2+}$ pair and the X atom are longer (the average length is 2.14 Å) than the $Hg-X$ distances in divalent mercury compounds (the average length is 2.06 Å). The environment about the mercury atoms in the $(Hg_2)^{2+}$ pairs is generally formed by two X atoms. However, the coordination of the pair may be completed by atoms located at larger distances. The instances of the nonlinear coordination about the atoms of the $(Hg_2)^{2+}$ dimers by three X atoms ($X = O$ or N) with the longer $Hg-X$ bonds are mentioned. The $Hg-Hg$ bond lengths in inorganic and complex compounds of formally monovalent mercury vary from 2.46 to 2.59 Å. An increase in the $Hg-Hg$ bond length is observed in the linear $(Hg_4)^{2+}$ groups (2.59–2.63 Å), infinite Hg_n chains (2.64–2.67 Å), $(Hg_3)^{4+}$ triangles (2.60–2.70 Å) and transition metal clusters containing $(Hg_2)^{2+}$ pairs, $(Hg_3)^{4+}$ triangles and Hg_n groups.

In mixed-valence compounds, the tendency of mercury-oxygen groups to polymerisation, which is typical of divalent mercury, is retained. Pairs of formally monovalent mercury atoms form linear $O-(Hg_2)^{2+}-O$ groups, which, in turn, form 10-, 12-, 14-, 16- and 22-membered rings in combination with each other and with the linear $O-Hg^{2+}-O$ fragments. The rings are linked in different fashions to form two-dimensional planar or corrugated networks, layers or frameworks. The structures with the 14-membered $\{[(Hg_2)^{2+}]_2(Hg^{2+})_4O_6\}$ rings are of frequent occurrence.

In compounds containing polyatomic groups of mercury atoms, the description of the coordination polyhedra about individual mercury atoms is arbitrary because these polyhedra are substantially distorted due to the presence of the strong $Hg-Hg$ bond. In these cases, it is worthwhile from the crystal-chemical standpoint to consider this series of structures as containing the overall complex Hg_n cations ($n = 2$ or 3) with the coordinates of the geometric centres of the complexes and to describe the coordination environment about the Hg_n^{x+} cation as a whole.

In the structures of mercury compounds with fluorine and MF_6^- anions, the relationships between the value of the averaged formal charge on the mercury atom, the shortest $Hg-F$ distances, the structure of the Hg_n^{x+} cation and the $Hg-Hg$ distance in this cation are found. As the charge on the mercury atom decreases from +1 to +0.33, the $Hg-F$ distance increases from 2.13 in Hg_2F_2 to 3.2 Å in Hg_3NbF_6 and the sizes of the Hg_n^{x+} cations increase in the series from the finite nearly linear groups to infinite Hg_n chains and planar close-packed layers of mercury atoms. The $Hg-Hg$ distances in these cations vary from 2.51 to 2.90 Å.

Analysis of the structures of inorganic monovalent mercury compounds revealed no substantial effect of the mercury atoms of the $(Hg_2)^{2+}$ pair on the bond lengths in the anions, such as ClO_4^- , SO_4^{2-} , SeO_4^{2-} , PO_4^{3-} and NO_2^- , whereas an elongation of one of the bonds with the participation of the oxygen atom, which is bound to the mercury atom of the $(Hg_2)^{2+}$ pair, is observed in compounds with the AsO_4^{3-} and BrO_3^- anions. The NO_3^- anion rather often completes the coordination environment about the mercury atom through contacts of 2.45–2.88 Å and can act as a bridging ligand. In monovalent mercury complexes with organic ligands, the ClO_4^- anions are involved only in nonbonded interactions with the mercury atoms of the $(Hg_2)^{2+}$ pairs, while the function of the NO_3^- anions is analogous to that in inorganic monovalent mercury compounds.

The review has been written with the financial support of the Russian Foundation for Basic Research (Projects Nos 98-05-65223 and 96-07-89187).

VII. Conclusion	650

Abstract. Transformations of organic compounds (monomeric and polymeric) under the action of mechanical stress are considered. Two types of processes occur under these conditions. The first type involves disordering and amorphisation of crystal structure and conformational transformations as a result of rupture of intermolecular bonds. The second type includes mechanochemical reactions activated by deformation of valence bonds and angles under mechanical stress, namely, the rupture of bonds, oxidation and hydrolysis. Data on the organic mechanochemical synthesis of new compounds or molecular complexes are systematised and generalised. It is demonstrated that mechanical treatment ensures mass transfer and the contact of reacting species in these reactions. Proteins are especially sensitive to mechanical stress and undergo denaturation; enzymes are inactivated. The bibliography includes 115 references.

I. Introduction

Mechanical treatment of a substance can induce numerous transformations, which include, firstly, rupture and formation of valence bonds and deformation of bond angles, and, secondly, both destruction and generation of weaker intermolecular interactions (disordering, amorphisation of the crystal structure, conformational transitions and polymorphic transformations).

Mechanochemistry started to develop in the 1940–1950s, based on the results of applied studies dealing with polymer processing (plasticisation and rolling of elastomers, grinding of glassy polymers) (see, for example, Refs 1–5). Later, substantial progress has been attained in the mechanochemistry of inorganic compounds (metals, salts, oxides);^{6–13} the influence of high pressure combined with shear strain on the rate of solid-state transformations of low-molecular-mass organic compounds has been studied;^{14–17} the occurrence of mechanochemical reactions in high-energy mills has been discovered;^{18–21} mechanochemical transformations of coals have been studied;²² free radical reactions induced by mechanical stress have been considered;^{23, 24} and

experimental studies and theoretical calculations for mechanochemical reactions involving cleavage of C–C bonds^{25–27} and oxidation and hydrolysis reactions have been performed.^{28–30} (The vast majority of these studies were concerned with solid-phase processes.)

A new and fairly promising line of research representing technology of the future, nanotechnology, is closely related to mechanochemistry. A non-traditional application of atomic force and tunnelling microscopes has been reported;³¹ it was proposed to use them for micro-manipulation, *i.e.*, for positioning atoms and molecules at distances required to initiate a chemical reaction between them (molecular design).

Despite the fact that mechanochemistry of organic compounds has been successfully developing in recent years (most of the studies in this field were carried out by Russian scientists), the results obtained have not been surveyed; the reasons and the mechanisms of the influence of mechanical stress on chemical processes have not been analysed. The purpose of this review is to fill this gap and to present mechanochemistry (in particular, mechanochemistry of organic compounds) as a field of science developing at the border between chemistry and physics.

II. Rupture of intra- and inter-molecular bonds upon mechanical treatment

Organic compounds, both polymeric and monomeric, contain bonds of two types, namely, strong interatomic (covalent) bonds within the molecules and relatively weak (van der Waals, hydrogen) intermolecular bonds. Naturally, the weaker intermolecular bonds should be the first to split under the action of mechanical stress; this results in disordering or loosening of the structure of substances. The degree of disordering depends on the type of mechanical treatment, the amount of energy supplied and the substance structure. Crystalline materials undergo amorphisation and polymorphic transformations under mechanical stress; polymers undergo conformational transitions. It should be noted that in the case of polymers, mechanical treatment induces rupture of both types of bonds, because intermolecular bonds are formed along the whole length of polymer chains and the total energy needed to cleave them becomes commensurable with the energy of valence bonds.

1. Rupture of intermolecular bonds

a. Amorphisation of molecular crystals and polymorphic transformations[†]

During fine disintegration of a substance, after the substance particles have reached a particular size, the new surface no longer forms and plastic flow of the substance starts. In some cases, further mechanical treatment results in the particle aggregation. As a rule, the specific surface area (S_{sp}) of the initial organic crystals falls in the range of $0.1\text{--}1\text{ m}^2\text{ g}^{-1}$; after grinding, it increases several-fold depending on the dose of mechanical energy delivered, the structure of the substance, the presence of moisture, impurities, *etc.* In some cases, exceptionally high S_{sp} values have been attained. Thus the specific surface areas attained on grinding of cortisone acetate and saponic acid (based on gas adsorption data) were as high as $130\text{ m}^2\text{ g}^{-1}$ (see Ref. 32) and $400\text{ m}^2\text{ g}^{-1}$ (see Ref. 33), respectively. These unusually high S_{sp} values point to extensive disordering (loosening) of the structures of these materials.

As a rule, grinding causes a decrease in the degree of crystallinity and sometimes complete amorphisation, which was confirmed by X-ray diffraction patterns and IR spectra recorded for various crystals — ampicillin trihydrate, digoxin, sodium prasteron sulfate,³³ sulfanilamides,^{34,35} phthalylsulfathiazole,³⁶ sulfathiazole,³⁷ *etc.* Analysis of the X-ray diffraction patterns of sulfamonomethoxine (Fig. 1a) allowed the researchers cited³⁴ to conclude that the observed broadening of diffraction lines is due to both a decrease in the size of crystallites (to $\sim 100\text{ Å}$) and an increase in the lattice micro-distortions (2–2.5-fold).

Figure 1. X-Ray diffraction patterns ($\text{CuK}\alpha$ radiation) (a) and differential scanning calorimetry curves (b) of sulfamonomethoxine powders after grinding in a jet mill.³⁴

The initial sample (1) and the samples having been passed four (2) and six (3) times through the jet mill.

Amorphisation increases the rates of dissolution and solubility of compounds;^{33,34} it decreases the melting points and heats of melting of crystals and extends the temperature ranges of melting.³³

Fig. 1b presents the variation of the melting point and the heat of melting of sulfamonomethoxine powders as functions of the degree of disintegration found from the data of differential scanning calorimetry (DSC).³⁴ The values for the change in free energy (ΔG) calculated in two ways, namely, from the decrease in the melting point and the heat of melting and from the increase in the solubility of sulfamonomethoxine on grinding, agree with each other and reach $0.8\text{--}0.9\text{ kJ mol}^{-1}$ (see Ref. 34).

[†] The data on the influence of mechanical treatment on the properties of low-molecular-mass organic crystals, presented in the review, have been mainly taken from publications devoted to the technology of drugs, which often includes various types of mechanical treatment, for example, grinding or pressing.

In some cases, for instance, for fullerene, the peak corresponding to a phase transition ($\sim 260\text{ K}$) completely disappears from the thermograms.³⁸

For most of the organic crystal studied, disordering of the crystal structure is associated with disturbance of the system of intermolecular hydrogen bonds, which is confirmed by IR spectra.^{33,34,39}

Some organic crystals, for example, barbiturates, streptocid, sulfathiazole, theophylline, cortisone acetate, *etc.*^{32,33,37} undergo polymorphic transformations on grinding, as indicated by X-ray diffraction, calorimetric and spectroscopic data. In the case of sulfathiazole, mechanically induced reversible transition of the form stable at room temperature into a metastable form occurs (the latter is usually produced by heating the stable form at $\sim 174^\circ\text{C}$).³⁷ In the case of cortisone acetate, a structure with $P2_1$ point group of symmetry passes into a structure with $P2_12_12_1$ group of symmetry.³² It was found³¹ that under the action of anisotropic compression forces, C_{60} fullerene is transformed into known carbon phases (diamond, graphite) and into some metastable crystalline and amorphous modifications.

During the polymorphic transformations induced by mechanical treatment, one form does not pass directly into another; this occurs *via* a disordered non-crystalline state. Upon prolonged mechanical treatment, the new phase arising also becomes amorphised.^{32,37}

The changes in the physico-chemical properties of substances induced by pressing are similar to those occurring on grinding. Normally, pressing causes a decrease in the degree of crystallinity and polymorphic transformations.³³ This has been detected for streptocid, phenylbutazone, chloropropionamide, ephedrine hydrochloride, libexin, noxyron, *etc.* However, the rate of dissolution of some substances can decrease upon pressing due to the aggregation of powder particles.

b. Structure disordering and conformational transitions in polymers

As in the case of molecular crystals, the mechanical dispersion of polymers in mills at low temperatures ($\sim 80\text{ K}$) results in substantial disordering (loosening) of their structure caused by loss of the intermolecular van der Waals contacts. This is indicated, for example, by the sharp increase in the adsorption of inert gases by polymers. The specific surface area of dispersed poly(methyl methacrylate) (PMMA) calculated from argon sorption isotherms is $600\text{--}800\text{ m}^2\text{ g}^{-1}$ (see Ref. 11), and that of poly(methyl silsesquioxane) (PMSO) is $400\text{ m}^2\text{ g}^{-1}$ (see Ref. 40) under the same conditions.

During unfreezing of a PMMA sample, the disordered structure relaxes even at 120 K and the specific surface area diminishes to a value of several square meters per gram. However, in the case of PMSO, the disordered state is retained during heating of the samples to 500 K . This can be explained by the specific chemical structure of PMSO; mechanical dispersion of this polymer is accompanied by free radical reactions giving valence cross-links, which stabilise the arising disordered state.⁴⁰

Crystallisation of solutions (melts) of polymers and separation of liquid phases on exposure to an external mechanical field are phenomena long known in the physical chemistry of polymers.^{41,42} This is due to the fact that under tensile or shear stress, macromolecular coils are untwisted, the number of contacts between macromolecules increases, and, as a consequence, the degrees of their aggregation and orientation increase.

A mechanical action (static compression under $75\text{--}100\text{ kbar}$ combined with shear deformation) on crystalline polyoxymethylene (POM) induces conformational transitions of various types.^{43,44} In particular, a broad range of rotational isomers of chains were found and a phase transition of the hexagonal modification into an orthorhombic one was detected in POM crystals with straightened chains which had been subjected to hydrostatic compression. Evidently, even under conditions of only hydrostatic compression, tangential stresses and micro-

shears may appear due to the anisotropy of the mechanical properties of the crystals.

During mechanical grinding and pressing of proteins, cleavage of hydrogen bonds and disturbance of hydrophobic and electrostatic interactions occur, resulting in changed conformations of protein molecules and their denaturation. Mechanically induced denaturation of proteins and inactivation of enzymes are considered in Section V.

2. Rupture of valence bonds

a. Models of mechanical rupture

Rupture of a valence bond on stretching (the simplest mechanochemical reaction) can be represented as follows.³¹ Two atoms forming a bond are spaced by distance r_0 and are connected by springs to the walls of the surrounding structure. The energy of bond breakage U_{br} can be represented as the sum of the potential energy of the bond U_{bond} and the elastic strain energy U_{el} of the structure to which the atoms belong. The latter parameter varies as a function of the displacement of atoms from the position where they form the bond towards the equilibrium position with respect to the structure to which they are linked (corresponds to a certain positive value of bond rigidity $k_{s, str}$)

$$U_{el} = \frac{1}{2} k_{s, str} (\Delta d - \Delta r)^2,$$

$$U_{br}(\Delta r, \Delta d) = U_{bond}(\Delta r) + U_{el}(\Delta r, \Delta d).$$

Here $\Delta r = r - r_0$ and $\Delta d = d - d_0$ are the differences between the atom coordinates in the stressed and unstressed states, respectively; d_0 is the distance between the ends of the spring in the non-stretched state.

Figure 2 shows the variation of the potential energy of a C—C bond as a function of Δr for various Δd values. The model parameters used in the calculation have been reported.³¹ It can be seen from the Figure that as Δd increases, two potential wells appear instead of one well and subsequently they are again replaced by one potential well. As $k_{s, str}$ increases, the potential barrier decreases and finally it entirely vanishes.

Figure 2. Potential energy of the C—C bond as a function of the distance.³¹ Δd / nm: (1) 0, (2) 0.1, (3) 0.2.

Figure 3 presents plots for the height of the potential barrier $U^\ddagger$ vs the rigidity of bonds of various types for equal depths of the wells.³¹ When $k_{s, str} > 90 \text{ N m}^{-1}$ and the characteristic times for bond rupture are $\geq 10^{-7} \text{ s}$, energy dissipation is small with respect to kT for all types of bonds. In the case of C—C bonds, the requirements to the rigidity are less stringent; it is sufficient that $k_{s, str} > 60 \text{ N m}^{-1}$. In the case of weaker bonds, C—Si and Si—Si, the requirements are even lower.

The kinetic theory of the strength of solids, apart from the purely mechanical rupture of interatomic valence bonds induced by an external force, takes account of the destructive role of thermal motion, *i.e.* cleavage of interatomic bonds is caused by

Figure 3. Height of the potential barrier for the stretching of bonds vs their rigidity.³¹

energy fluctuations arising due to the thermal motion of atoms rather than by the external force itself.⁴⁵ According to a concept developed in a publication⁴⁵ (thermofluctuation mechanism), two elementary stages should be distinguished in the bond rupture, namely, (1) force perturbation of interatomic bonds in a loaded body, which decreases the energy barrier to the bond cleavage and (2) splitting of stressed bonds upon thermal fluctuations.

The rate constant for the bond rupture k can be calculated from the equation

$$k = k_0 \exp \left(\frac{E_a - \sigma v_a}{RT} \right),$$

where k_0 and E_a are the preexponential factor and the activation energy for the thermal bond rupture, respectively, σ is the mechanical stress and v_a is the unit activation volume.

The rupture of valence C—C bonds in polymers has been studied most comprehensively (both theoretically and experimentally). The deformation of valence bonds in stretched samples of oriented linear polymers (polypropylene, polyamide, polytetrafluoroethylene, *etc.*) has been observed by IR spectroscopy.⁴⁵ The absorption bands corresponding to stretching vibrations of the C—C bonds in the polymer backbones shift to lower frequencies upon stretching. The band contours for stressed (stretched) samples also change. According to estimates,⁴⁵ the maximum loads of individual bonds in polymers attained on stretching are 10–20 GPa. The thermofluctuation elementary events of destruction occur within small activation volumes (commensurable with the volume of atoms) upon great overstress.

It has been assumed^{46–48} that not only rupture of stretched bonds can be induced by thermofluctuations in a stressed polymer but also self-ionisation of macromolecules accompanied by ejection of electrons. A calculation of the electronic spectrum of a macromolecule with stretched C—C bonds showed⁴⁷ that the elongation of a bond gives rise to a local electron level; its energy for a factor of two elongation is $\sim 4\text{--}5 \text{ eV}$, which is close to the energy of charge separation in a polymer.

The electrons having been liberated under the action of mechanical stress can be captured by traps (molecules with large electron affinity, structure defects) and are again released when the traps have been destroyed; this accounts for the mechanical emission of electrons, which has been found to accompany stretching of films and grinding of some polymers [polyethylene (PE), polyethylene terephthalate] and organic crystals.^{46, 48, 49}

The decrease in the ionisation potential of molecules subjected to mechanical stresses has been described by quantum-chemical methods.^{27, 30} Figure 4 shows the calculated plot for the variation of the ionisation potential I as a function of bond angles in the propane molecule.²⁷ It can be seen that an increase in the deformation of the molecule results in lower I values.

Figure 4. Quantum-chemical calculation for the change in the ionisation potential upon deformation of bond angles α and β ($\alpha = \beta$) in the propane molecule.²⁷

Curves (1) and (2) show the potential energy (E) of propane and its radical cation, respectively; curve (3) is the difference between curves (2) and (1).

Apart from the mechanical emission of electrons, some other experimental results cannot either be interpreted in terms of the thermofluctuation mechanism. Firstly, the compositions of the molecular products of thermally and mechanically induced destructions are different.^{25, 26, 45} The products of mechanical destruction contain no heavy fragments of polymer chains, which are typically present in the case of thermal degradation. The formation of light products on mechanical destruction indicates that the vibrational energy is distributed non-uniformly, being located in regions with a size of not more than 10 Å. Secondly, mechanical destruction of some polymers (PMMA, the three-dimensional epoxy polymer based on diglycidyl ether of resorcinol and *meta*-phenylenediamine, and ebonite) has been found to give high-energy molecular products.^{25, 26} The kinetic energy of these species was estimated using the time-of-flight mass spectrometer equipped by a device for high-speed detection of molecules. The velocity of the flight of the molecular products formed was used to calculate the translation temperature, which amounted to 2000–5400 K for the above-mentioned polymers.

The appearance of vibrationally excited states upon destruction of a PMMA sample was confirmed by thermal radiation spectra.⁵⁰ It can be seen from Fig. 5 that radiation consists of two components — Planck's radiation and a characteristic narrow emission band at 8.3 μm , which appears 10–60 μs after the sample fracture; this band is related to deactivation of the vibrationally excited centres, which arise during destruction of the sample and whose nature is unknown. Analysis of the spectra

Figure 5. Heat radiation spectra recorded during fracture of a PMMA sample.⁵⁰

Time elapsed after the onset of destruction 10 (1), 20 (2) and 30 μs (3).

obtained led to the conclusion that the average warming of the sample during the polymer fracture does not exceed 200 °C.

In a series of publications (see a review²⁵ and the studies cited therein), the destruction of a stretched chain of atoms has been studied by methods of molecular mechanics. Studies^{25–27} on mechanodestruction of one-dimensional models of polymer chains consisting of 50 and 100 carbon atoms led the researchers to the conclusion that solitons play the crucial role in mechanodestruction. Over a long period (~ 10 ps) after the rupture of a stretched chain, the elastic energy stored in the chain is not thermalised and no thermal fluctuations (in the generally accepted sense⁴⁵) occur. It was shown that movement of high-energy solitons may be accompanied by the formation of C–C double bonds and by discharge of the side-chain atoms. It was shown that rupture of one chain may yield several high-energy molecular products capable of inducing destruction of the adjacent polymer chains; thus, chain branching is possible.

All the models for bond rupture known to date are one-dimensional and are restricted to the views of classical mechanics. Only the first attempts to pass from one-dimensional to two-dimensional models have been undertaken.⁵¹

Nevertheless, the one-dimensional chains considered above can be accepted as a satisfactory approximation to real linear macromolecules. Description of the mechanically induced bond rupture in three-dimensional systems (cross-linked polymers and low-molecular-mass crystals) is a more complicated task, none of the models presented being suitable for this purpose.

b. Formation of free radicals

Free radicals resulting from the rupture of valence bonds during mechanically induced destruction of many polymers and some low-molecular-mass compounds have been detected by EPR.^{23, 24, 52} The appearance of 'mechanical' macroradicals was observed on stretching of films and fibres and on grinding of linear and three-dimensional polymers in a mortar, in a mill, *etc.* The EPR spectra of 'mechanical' macroradicals have been thoroughly studied, which permitted identification of the type of bond being cleaved in each polymer; it was found that the covalent bonds in the polymer backbones and cross-links (or bridges) undergo homolytic cleavage. Thus vinyl polymers [PE, polypropylene, poly(methyl acrylate), PMMA, polystyrene (PS), *etc.*] and polypeptides [poly(amino acids), proteins] undergo cleavage of C–C bonds; in the case of carbon-and-oxygen polymers [polyformaldehyde, poly(ethylene oxide), polyesters and three-dimensional polyesteracrylate], C–C and/or C–O bonds are split; for ladder and three-dimensional network organosilicon polymers [PMSSO and polyphenylsilsesquioxane (PPSSO)], rupture of the Si–O bonds is observed, and in some polypeptides (trypsin, insulin, serum albumin), cleavage of C–C and C–S bonds occurs.

When polymers are subjected to mechanical treatment in a mill, the rate of accumulation of macroradicals (dR/dt) in the beginning of the process is constant and then it gradually decreases and approaches zero; thus, the concentration of macroradicals reaches a limiting value. The kinetics of radical accumulation are described by the equation²⁴

$$\frac{dR}{dt} = W_d - W_r, \quad (1)$$

where W_d is the rate of bond rupture, equal to $k_d[M]$; W_r is the rate of the decay of radicals upon interaction with one another, equal to $k_r[R]^2$; $[M]$ is the concentration of bonds that can be cleaved; $[R]$ is the concentration of macroradicals; k_d and k_r are effective rate constants for these reactions in the solid phase (see below).

At the beginning of the mechanical grinding when $W_d \gg W_r$, $(dR/dt)_0 \approx W_d$, *i.e.* when the intensity of the mechanical energy supply is constant, the rate of destruction depends only on the polymer nature. The rate of destruction in laboratory vibrational mills with energy input of 1–10 W g^{−1} at temperatures of 100–300 K amounts to 10¹⁴–10¹⁶ g^{−1} s^{−1}. The steady-state concentration of free radicals $[R]_{\text{lim}}$ (for $dR/dt = 0$) in linear

flexible-chain polymers is $(1-5) \times 10^{18} \text{ g}^{-1}$ and that for rigid-chain (especially three-dimensional) polymers is $10^{19}-10^{20} \text{ g}^{-1}$.

The relative rates of destruction of various polymers during grinding under identical conditions are compared in Table 1. The rate of bond rupture is determined, first of all, by the rigidity of the structure. It increases on passing from flexible-chain PE to more rigid PS and then to polypeptides, the structures of which are noted for special rigidity owing to the presence of peptide bonds in the backbone and a dense network of hydrogen bonds. The maximum destruction rates were detected for three-dimensional polymers (glyceromaleate, α,ω -diethylene glycol phthalatedimethacrylate).

Table 1. Relative rates of mechanical destruction of polymers at $T \approx 100 \text{ K}$.²⁴

Polymer	M_w	M_n	$(dR/dt)_{\text{rel}}$ (see ^a)
PE	290 000	—	1
PS	300 000	—	17
PPSSO	450 000	—	20
PEM ^b	—	—	120
Collagen	—	290 000	30
Subtilisin	—	27 000	55
Serum albumin	—	67 000	45
Trypsin	—	24 000	40
Insulin	—	5 733	6
Gramicidin	—	1 140	1.5

^a The rate of destruction of PE was taken to be unity.

^b PEM is a cross-linked polymer of α,ω -diethylene glycol phthalatedimethacrylate.

The rate of mechanical destruction and, hence, of the formation of free radicals decreases with a decrease in the molecular mass of the polymer. Thus the rate of formation of radicals in insulin, which has the lowest molecular mass among the series of proteins studied, is 7–9 times lower than those in other proteins.

The question of the limiting molecular mass M_{lim} or the limiting degree of polymerisation n_{lim} below which the mechanical destruction of covalent bonds is terminated and only weak intermolecular bonds are broken has arisen repeatedly in the mechanochemistry of polymers.^{1,24} The n_{lim} value depends on the chemical structure of the polymer and the relationship between the strengths of valence and intermolecular bonds and can be roughly estimated from the expression

$$U = n_{\text{lim}} U_{\text{coh}}, \quad (2)$$

where U is the strength of a valence bond being cleaved and U_{coh} is the cohesion energy for a monomer unit. Expression (2) does not take into account the structural inhomogeneity of a real polymeric material and the stress gradient.

The cohesion energy is especially large for polymers which contain hydroxy, carboxy, amino and other groups which form intermolecular hydrogen bonds (for polypeptides U_{coh} reaches $40-50 \text{ kJ mol}^{-1}$ per amino-acid residue). For these polymers, low n_{lim} and M_{lim} values should be expected. Indeed, for polyethylene $n_{\text{lim}} \approx 100$, while in the case of polypeptides, $n_{\text{lim}} \approx 6$. Therefore, free radicals have been detected after mechanical treatment of relatively low-molecular-mass cyclopeptides containing only ten (gramicidin) and twelve (bacitracin) amino-acid residues in the ring.⁵²

Free radicals are formed when some low-molecular-mass organic compounds are subjected to high pressure together with shear deformation. To detect the radicals, a special resonator has been designed for an EPR spectrometer, which acts simultaneously as one of the anvils.^{16,17,53} Thus in arylindandione dimers

$X = \text{H, Cl, NMe}_2$; $R = p\text{-Me}_2\text{NC}_6\text{H}_4$

destruction involves the $C_\alpha-C_\alpha$ bond, the strength of which ($U \approx 70 \text{ kJ mol}^{-1}$) is comparable with the U_{coh} value. It was found that hydrostatic pressure (up to 0.7 GPa) without shear strain does not induce the formation of radicals, *i.e.* it is the shearing component of the mechanical stress that causes the bond rupture.

Fig. 6 shows the dependence of the yield of free arylindandione radicals (in relative units) on the angle of rotation of the anvils at a constant pressure.¹⁶ When the angles of rotation are small, the yield of radicals rapidly increases (curves 1, 2, the linear section), *i.e.* the radical generation process predominates. An increase in the angle decreases the yield of radicals and their recombination starts to predominate. Ultimately, as in the case of mechanodestruction of polymers (see above), the concentration of radicals reaches a limiting value.

Figure 6. Yield of arylindandione radicals vs angle of rotation of the anvils α at a pressure of 7 (1) and 12 kbar (2);¹⁶ n_0 is the initial concentration and n is the current concentration of reacting species.

Under the same conditions, the EPR spectrum of C_{60} fullerene was found to exhibit a signal which was assigned to the carbon radicals formed upon destruction of the C_{60} molecules.⁵³ The rate of generation of these radicals is comparable with the rate of generation of arylindandione radicals ($\sim 10^{16} \text{ g}^{-1} \text{ s}^{-1}$).

Indirect evidence pointing to the cleavage of valence bonds to give free radicals has been obtained under the action of an indenter, shock waves and vibratory grinding of the crystals of some nitro compounds.⁴⁹ For example, minor concentrations (10^{16} g^{-1}) of $\dot{\text{N}}\text{O}_2$ radicals were detected by EPR spectroscopy upon vibratory grinding of pentaerythritol tetranitrate or cyclotrimethylenetrinitramine. It was suggested⁴⁹ that in this case, the formation of paramagnetic centres is related to the effect of the radiation which arises upon the fraction of crystals. To elucidate the reasons for the appearance of paramagnetic species more precisely, further studies are required.

Mechanical destruction in the solid phase can be represented as a sequence of the following stages:^{54,55}

and the effective rate constant for the destruction, k_d , can be represented as follows:

$$k_d = \frac{k_m k_i v}{k_m + k_i} \quad (3)$$

The first stage is a reaction characterised by the rate constant k_i and resulting in the formation of $(R^{\bullet} \cdots R^{\bullet})$ radicals, which occur in unit volume or in cage v . The k_m constant characterises departure of the radicals from the cage. The molecule in the pre-rupture state is stretched, and after bond cleavage, the radicals are removed from each other and leave the unit volume. The rupture of the bond rather than the emergence of the radicals from the cage is the limiting step in the destruction, *i.e.*, $k_i \ll k_m$.

III. Free-radical reactions

The free radicals having formed upon the mechanical destruction enter into ordinary free-radical reactions — recombination, decomposition, addition and substitution. The reactions occurring in the field of mechanical stress should be distinguished from those proceeding after the field has been removed (post-effect). The former type of reaction would involve most likely mechanically activated species. In addition, mechanical treatment causes plastic deformation of the material and migration of particles. In the latter type of reaction, the role of mechanical action reduces mostly to the generation of radicals, while the subsequent free-radical processes obey the rules inherent in them.

Virtually all of the mechanochemical free-radical reactions described to date occur in the solid phase; therefore, the specific features of the kinetics of solid-phase reactions should be taken into account.

1. Recombination

The elementary step of radical interaction (recombination) in the solid phase is preceded by the step in which they approach each other. This can occur either as chemical migration of a free valence or as physical migration of the reacting species.^{23,24} In the former case, recombination is a complex process consisting of separate elementary steps. (Some of these reactions are considered below.) In the latter case, recombination kinetics are determined by the mobility of radicals. The decay of macroradicals in a polymer matrix having been subjected to mechanical grinding occurs near the glass transition temperature T_g .²⁴ At this temperature, the segmental mobility of the polymer chains is unfrozen and the radicals become able to move large distances and meet one another.

The decay of radicals in the field of mechanical stress, *i.e.* under conditions of forced mobility of reacting species, is a specific case. The effective rate constants for recombination of free radicals during grinding in a mill can be estimated from the kinetics of accumulation of free radicals.^{24,54}

When $dR/dt = 0$, the rate constant for recombination k_r has the form [see Eqn (1), Section II.2.b]

$$k_r = \frac{W_d}{[R]_{\text{lim}}^2}.$$

Depending on the nature of the polymer and the energy input of the mill, the k_r values at 100–300 K range from 10^{-24} to $10^{-21} \text{ cm}^3 \text{ s}^{-1}$.

Radical recombination can be represented by the following scheme:

In the step characterised by the constant k_m , the radicals approach each other under the action of plastic deformation caused by mechanical stress. Using Eqn (3) provided that $k_m \ll k_i$, we obtain $k_r = k_m v$. The volume of a cage v is approximately $5 \times 10^{-22} \text{ cm}^3$, and the frequency of the translation of radicals during mechanical treatment of the material in the mill (80–100 K) is 10^{-3} to 1 s^{-1} .

Recombination of radicals in the solid phase is characterised by a distribution of rate constants with the boundary values k_{max} and k_{min} . This may be due to the fact that the local reaction conditions — the size of the cage, mutual orientation of the reacting species, the closest environment, *etc.* — are different.^{16,53,56–58} Species interacting in any system can be characterised at any instant by the distribution function $n(k,t)dk$, which determines the number of species that react in unit volume at instant t with a rate constant k ($k_{\text{min}} \leq k \leq k_{\text{max}}$). Since species can migrate between various fractions of the distribution function (*i.e.*, between states with different k), it becomes ‘intermixed’. The form of ‘intermixing’ of the distribution function is determined by the processes that induce the changes in the kinetic properties of the reacting species. In particular, mechanical dispersion brings about ‘mechanical intermixing’ of the distribution function.⁵⁸

If mechanical intermixing results in the reaction rate constant k becoming equal to k_{max} , this means that the reaction occurs under kinetically controlled conditions. However, a different regime when $k_{\text{min}} \ll k \ll k_{\text{max}}$ and the reaction is controlled by diffusion is more frequently encountered in practice.

The post-effect recombination can be described satisfactorily by equations of polychronous kinetics.^{16,53}

$$\frac{n}{n_0} = \left(\ln \frac{k_{\text{max}}}{k_{\text{min}}} \right)^{-1} (-\ln k_{\text{min}} - \ln n_0 t).$$

The difference between k_{max} and k_{min} for arylindandione radicals reaches five orders of magnitude. The k_{max} value depends only slightly on the pressure applied and on the angle of shear and is approximately $5 \times 10^{-20} \text{ cm}^3 \text{ s}^{-1}$. Thus, shear strain and pressure scarcely influence the rates of the fastest reactions but do influence the rates of the slowest ones.

Obviously, the formation of free space and creation of a favourable arrangement of radicals are the limiting steps for radical recombination.

2. Radical decay

It is known^{24,59} that mechanical treatment of polymers is accompanied by decay of macroradicals. In macroradicals, the bond located in the β -position to the unpaired electron is weakened; the activation energy for the rupture of this bond in hydrocarbon radicals in the gas phase is about 100–120 kJ mol⁻¹ and in some cases [*e.g.* in the $-\text{CH}_2\dot{\text{C}}\text{MeX}$ radicals in PMMA ($\text{X} = \text{CO}_2\text{Me}$) and polyisobutylene ($\text{X} = \text{Me}$)], it decreases to 50–70 kJ mol⁻¹.

Mechanodestruction of polyformaldehyde, polyisobutylene and polyorganosiloxanes at low temperatures, *i.e.* under conditions when the thermal decay of macroradicals occurs at an extremely low rate, has been found to give light volatile products.^{24,60}

Thus the light products of mechanodestruction obtained by grinding of PMSSO in a mill at temperatures of $\leq 200 \text{ K}$ include mostly hydrogen, methane and ethane; those in PPSSO consist of hydrogen and benzene.⁶⁰

$\text{R} = \text{Me}$ (PMSSO), Ph (PPSSO).

The compositions and the conditions of formation of products imply that hydrogen atoms and $\dot{\text{C}}\text{H}_3$ and $\dot{\text{C}}_6\text{H}_5$ radicals are formed during the mechanodestruction. Presumably, the mechanical destruction of polymers gives rise to vibrationally excited macroradicals, which then decompose to yield low-molecular-mass radicals. Thus destruction of PMSSO involves the following processes:

The formation of hydrogen atoms was proved experimentally.

Figure 7 *a* shows the kinetic curves for the formation of H_2 and CH_4 and for the accumulation of free radicals ($\text{R}^{\bullet}$) during destruction of PMSSO. The diffusion of light species ($\text{H}^{\bullet}$ and $\dot{\text{C}}\text{H}_3$) results in migration and decay of the free valence; therefore, the amount of macroradicals observed in the destruction of PMSSO is always lower than the amount of monomeric products (per g of the polymer). The evolution of hydrogen and the formation of CH_4 , C_2H_6 and $\text{R}^{\bullet}$ are compared in Fig. 7 *b*; the plot was constructed using the results of a large number of experiments, in which the intensity of destruction of PMSSO varied by a factor of up to 50 (various conditions of mechanical treatment — duration of grinding, design of the working vessel, *etc.*, were used). Irrespective of the destruction intensity and dispersion conditions, the total amount of the volatile products evolved in the PMSSO destruction exceeds ~ 4.5 -fold the number of free radicals observed. The overall rate of formation of low-molecular-mass radicals ($\text{H}^{\bullet}$ and $\dot{\text{C}}\text{H}_3$) is higher than the rate of formation of macroradicals by a factor of 8–9. These data attest to a very high (~ 0.9) probability of decomposition of ‘hot’ macroradicals.

Figure 7. Kinetics of accumulation of radical and molecular products (*a*) of the mechanical destruction of PMSSO and comparison of their concentrations (*b*);⁶⁰

(*a*) (1) $[\text{R}^{\bullet}]$, (2) $[\text{CH}_4]$, (3) $[\text{H}_2]$; (*b*) (1) $[\text{R}^{\bullet}]$, (2) $[\text{CH}_4]$, (3) $[\text{C}_2\text{H}_6]$ (different designations refer to different rates of formation of hydrogen and different conditions of mechanical destruction).

In the case of PPSSO, the rates of formation of volatile products and free radicals are commensurable and the total rate of formation of low-molecular-mass radicals ($\text{H}^{\bullet}$ and $\dot{\text{C}}_6\text{H}_5$) is twice as high as the rate of formation of macroradicals; the probability of decomposition of ‘hot’ radicals for PPSSO is about 0.6–0.7.

The mechanical treatment of polymers yields internal macroradicals, *i.e.* radical products of interaction of the primary terminal macroradicals with surrounding macromolecules (see Section III.3). It has been assumed that the internal macroradicals decompose during mechanodestruction to give terminal radicals and unsaturated compounds; after that, the terminal radicals interact with macromolecules to give internal macroradicals, *i.e.* a chain reaction occurs.⁶¹ However, experiments with polyethylene samples containing high concentrations of internal radicals, prepared by exposure of the samples to radiation, demonstrated that the role of mechanically induced destruction of internal

radicals is relatively insignificant, recombination being the main pathway for the decay of these radicals.⁶² This may be due to the non-uniform distribution of elastic energy among individual bonds in an amorphous solid; as a consequence, the ratio between the rates of rupture of weakened bonds (in the internal radicals) and normal bonds in macromolecules is determined by the probability of energy localisation on these bonds rather than by the ratio of their strengths.

3. Hydrogen atom transfer

The influence of mechanical stress on the free-radical transfer of a hydrogen atom has been considered theoretically using the model of the symmetrical process

which occurs under normal conditions with a high activation energy ($\approx 60 \text{ kJ mol}^{-1}$).³¹ The calculation of the influence of methane compression on the height of the barrier to reaction (4) showed that within the framework of this model (extended LEPS potential and *ab initio* calculation methods), at a compression force of 3.6 nN, $U^{\ddagger} = 0$. However, at room temperature, there is no need to diminish the barrier to zero. Thus at a compression force of 1 nN, $U^{\ddagger} \approx 18 \text{ kJ mol}^{-1}$ and the reaction proceeds at room temperature at a plausible rate.

The influence of tensile stress on the rate of hydrogen atom transfer is considered in Section IV in relation to the reaction of ozone with polyolefins.

The following method proved to be fruitful for studies of low-temperature free-radical reactions:²⁴ solutions of polymers frozen at 80–100 K were subjected to mechanical dispersion in a vibratory mill; the role of mechanical treatment reduced mainly to the generation of free radicals and ensuring the mass transfer and the contact between the reacting particles. It was found that reactions proceed both during treatment of mixtures in the mill and after the mill has been switched off and the temperature has increased. A series of reactions involving carbon-centred and peroxy radicals (which are readily formed when carbon-centred radicals contact with atmospheric oxygen) have been found.

For instance,²⁴ it was shown that at low temperatures ($\sim 100 \text{ K}$), macroradicals abstract hydrogen atoms from various types of bonds, O–H (phenol), N–H (primary and secondary amines), S–H (benzenethiol and phenylmethanethiol) and C–H (alkylbenzenes, acetonitrile, malonic acid). The C–H bonds are especially strong and reactions involving these bonds are characterised by high activation energies ($> 30 \text{ kJ mol}^{-1}$). The rate constants were found to be 4–6 orders of magnitude greater than those calculated from the data obtained for the liquid phase at elevated temperatures.

The kinetics of the reaction of the macroradicals formed upon destruction of PS, polyvinyl acetate, *etc.*, with malonic acid

was studied²⁴ over a broad temperature range (100 to 200 K) (Fig. 8). It can be seen from the Figure that at 100–150 K, the reaction rate scarcely depends on the temperature; at $T > 150 \text{ K}$, it sharply increases and at $T > 200 \text{ K}$ the reaction rate cannot be measured because it is too high.²⁴

The experimental rate constants for hydrogen atom transfer are in good agreement with those calculated with allowance for the tunnelling of hydrogen through the potential barrier.

The hydrogen atom transfer determines the migration and stabilisation of radical states in polymers. Thus it is known^{23,24} that the radical products of mechanical destruction of polymers contain, even at low temperatures ($\sim 80 \text{ K}$), internal macroradicals, resulting from abstraction of hydrogen atoms from polymer chain units.

Yet another example of hydrogen atom transfer in polymers is provided by the reaction of peroxy radicals with macromolecules, which is the rate-determining step in the low-temperature oxidation of polymers.⁵⁸

Figure 8. Temperature dependence of the rate constant for reaction (5).²⁴ The circles show the experimental results and the curve is based on calculations with application of the tunnelling correction.

This reaction was studied for PMMA and PS over a wide temperature range *in vacuo* after termination of mechanical treatment. As for other reactions occurring in the solid phase, in this case, too, kinetic non-equivalence of the reacting species was discovered; the distribution function of the 'mechanical' peroxy radicals in PMMA and PS over rate constants at 210–300 K has a hyperbolic shape⁵⁸ (see also Section III.1). For instance, in polystyrene, the rate constants for individual fractions of the distribution function can differ by ten orders of magnitude:

$$k_{\max} = 3.8 \times 10^8 \exp\left(-\frac{43}{RT}\right) \text{ and } k_{\min} = 1.3 \times 10^{12} \exp\left(-\frac{88}{RT}\right)$$

(the activation energy is expressed in kJ mol⁻¹).

Thus, study of mechanochemical reactions of hydrogen atom transfer resulted in the elucidation of interesting specific features of the reaction kinetics, namely, tunnelling of a hydrogen atom at low temperatures, non-equivalence of the reacting species in the solid phase and 'mechanical intermixing' of the distribution function. However, no influence of mechanical stress on the activation energy for the hydrogen atom transfer was found.

4. Addition

A study of mechanical treatment of mixtures of polymers with monomers in a vibratory mill provided experimental data on the addition of free radicals to C=C bonds.²⁴ It was found that at 80–100 K, the $-\text{CXX}'\dot{\text{C}}\text{H}_2$ and $-\text{CH}_2\dot{\text{C}}\text{XX}'$ macroradicals (X = H, Me; X' = Ph, CO₂Me, OCOMe) readily enter into the reaction

Under the same conditions, carbon-centred and silyl macroradicals add to benzene and its derivatives to give radicals of the cyclohexadienyl type,^{63,64} for example,

The kinetics of the reaction

which occurs on mechanical treatment of the initial compounds in a vibrational mill, has been studied in the 80–143 K temperature range.²⁴ At 80 K, the reaction does not proceed, and at 113–143 K the dependence of the rate constant on the temperature obeys the Arrhenius equation. The activation energy for the

reaction (21 kJ mol⁻¹) is close to the activation energy for the same reaction in the liquid phase at 280–330 K.

Thus, no mechanochemical effects were found in the studies of addition reactions with relatively low activation energies. Apparently, these effects could be found for reactions with higher activation energies.

The role of mechanical stress in free-radical reactions studied to date is to initiate the formation of macroradicals and to ensure mass transfer (to let the reagents meet each other). No influence of mechanical treatment on the activation energy of these reactions was found.

IV. Oxidation and hydrolysis

The influence of mechanical stress on the potential barriers can be clearly followed for some reactions (oxidation, hydrolysis). Acceleration of oxidation under tensile stress was discovered by Kuz'minskii *et al.* back in 1953 (oxidation of elastomers by atmospheric oxygen).⁶⁵

Krisyuk *et al.*^{28,30} carried out oxidation of polyolefins by ozone.

The oxidation (sorption of ozone and formation of free radicals) of oriented polypropylene films is accelerated 2–5-fold when a tensile stress σ ranging from 33 to 145 GPa is applied.

Mechanical stress accelerates hydrolysis of polyamides; this was first observed by Bershtein⁶⁶ and then studied by Krisyuk *et al.*^{29,30} Both the oxidation of polyolefins with ozone and the hydrolysis of polyamides are accelerated on stretching of these polymers according to an exponential pattern (in the temperature range of 328 to 369 K)

$$\ln \frac{k}{k_0} = \frac{\alpha \sigma}{RT}, \quad (6)$$

where k_0 is the rate constant for the reaction (k) in the absence of tensile stress σ . The constant α characterises the sensitivity of the reaction to stress and depends on the polymer structure. This constant is defined by the equation

$$\alpha = \phi(l^\ddagger - l_0)s, \quad (7)$$

where ϕ is the overstress coefficient, which depends on the structure of the polymer material, $l^\ddagger$ and l_0 are the lengths of the reaction fragment in the transition and initial states, respectively, and s is the cross-section of the molecule.

Experimental data on the acceleration of oxidation of polypropylene by ozone are presented in Fig. 9a, and the data for the hydrolysis of polycapraamide are shown in Fig. 9b; these results confirm the validity of Eqn (6).

Figure 9. Rate constants for ozonisation of polypropylene (a) at 291 (I) and 313 K (2) and for hydrolysis of polycapraamide (b) at 393 (I) and 113 K (2) vs mechanical stress.³⁰ The stretching ratio of the samples is 6 (I) and 3 times (II).

It has been shown²⁸ that an increase in the rate of polyolefin oxidation cannot be explained either by the change in the diffusion and sorption parameters, or by the change in the molecular mobility, or by destruction of polymer chains. The change in the reactivity of the C–H bonds in polymer chains is caused by stretching and is similar to the situation with the abstraction of hydrogen atoms from strained rings.⁶⁷

When a hydrogen atom is eliminated, the sp^3 hybridisation of the carbon atom changes to sp^2 , resulting in a greater bond angle. This brings the structure closer to a transition state and, as a consequence, accelerates the reaction.

The acceleration of hydrolysis of polyamides can be interpreted at a qualitative level in a similar way. The C–N bonds in polyamide are strengthened due to delocalisation of the π electrons of the carbonyl groups, which interact with the nitrogen p orbitals. On stretching, the interacting orbitals move apart, the conjugation is violated and hydrolysis occurs faster. The effect of stretching resembles the influence of substituents in conformity with the Hammett–Taft equation.

Quantum-chemical calculation³⁰ for the cross-section of the potential energy surface for some monomers modelling polymer chains (methane, propane, butane) has shown that stretching of molecules weakens the C–H bonds. When the molecule is stretched, the energy of the initial state increases to a greater extent than the energy of the transition state, resulting in a lower activation energy for the reaction. Thus, the calculation showed that the C–H bond is actually activated and that the sensitivity of a reaction to deformation increases with an increase in the strength of this bond and with a decrease in the activity of the hydrogen acceptor.

The change in the activation energy of a reaction under the influence of a force f is described by the equation

$$\Delta E_a = f(l^\ddagger - l_0). \quad (8)$$

It follows from Eqns (6)–(8) that stretching of molecules would accelerate those reactions in which the formation of the transition complex is accompanied by elongation of the reactive fragment. Conversely, processes accompanied by a decrease in the length of this fragment should be retarded on stretching.

V. Mechanochemistry of proteins and polypeptides

The necessity of developing the mechanochemistry of proteins and polypeptides can hardly be overstated; indeed, study of the mechanochemical transformations provides a key for the understanding of some phenomena occurring in living cells and organisms. During preparation of food, medicines, *etc.*, proteins undergo various types of mechanical treatment (grinding, pressing); this can change their structures and properties.

The main mechanochemical processes occurring in proteins include rupture of covalent bonds in polypeptide chains, mechanically activated hydrolysis of peptide bonds and destruction of weak intermolecular bonds. Mechanical treatment can also change the catalytic activity of protein enzymes.

1. Mechanical destruction of covalent bonds

Mechanical treatment (grinding, stretching) of samples of poly(amino acids) (polyalanine, polyleucine, polyvaline), fibrillar proteins (collagen, silk), globular proteins (trypsin, subtilisin, serum albumin), oligopeptides (gramicidin, bacitracin) has been found (EPR data) to yield free radicals,^{24, 52, 68–70} the EPR spectra in gelatin, collagen, silk, serum albumin, *etc.* having much in common despite the different amino-acid composition of the proteins. The experimental data accumulated by now permitted determination of the structure of the resulting free radicals and the type of bond being cleaved.

Based on the analysis of spectral characteristics of the radicals resulting from mechanical treatment of polypeptides at ~ 80 – 100 K and their transformations on heating to

200–250 K⁵² and on exposure to light,⁶⁹ one can conclude that the C–C bonds are cleaved predominantly.

Initially, this affords reactive terminal radicals, which then react with polypeptide chains to give internal radicals.⁵²

The abstraction of hydrogen from the carbon atom in the α -position with respect to the CO group is accompanied in some cases (*e.g.* in polyleucine) by its transfer from side substituents to give $-NHCH(CH_2\dot{C}Me_2)C(O)-$.⁵²

In the case of trypsin, albumin and insulin, the mechanically induced cleavage of the polypeptide backbones is accompanied by rupture of the C–S bonds.⁵² The C–S bonds are weaker than the C–C bonds and are destroyed more rapidly. The proportion of sulfur-centred radicals, $\dot{R}_S$, ranges from 14% to 20% of the total number of radicals formed.

In the presence of atmospheric oxygen, carbon-centred radicals (both terminal and internal) are oxidised, being thus converted into peroxy radicals. Sulfur-centred radicals are stable and are retained unchanged up to 340–360 K, when they become sufficiently mobile to recombine.

The rate of formation of free radicals in proteins is higher than that in linear synthetic polymers (see Section II.2.b and Table 1). The rate of mechanical destruction of collagen was calculated from the rate of accumulation of free radicals and compared with the rate of decrease in the molecular mass of this protein calculated from electrophoresis data.⁷⁰ The rates of rupture of the covalent C–C bonds in collagen dispersed in a micromill (80–90 K) or in a vibratory mill (100–150 K) amount to 1.5×10^{15} and 8.0×10^{15} bonds $g^{-1} s^{-1}$, respectively (EPR data) or 1.8×10^{15} and 9.6×10^{15} bonds $g^{-1} s^{-1}$, respectively (electrophoresis data); *i.e.* the values found by two independent methods are in satisfactory agreement with each other.⁷⁰

The above data confirm the assumption that homolytic cleavage of the polypeptide chain is the main source of free radicals during the mechanical grinding of proteins.

2. Mechanically activated hydrolysis

As shown above (see Section IV), polyamides readily undergo mechanically activated hydrolysis. The possibility of this type of hydrolysis in proteins was demonstrated in relation to trypsin;⁷¹ the sample obtained by mechanical dispersion of this compound at 295 K was found to contain hydrolysis products, namely, *N*-terminal amino acids (glycine, tyrosine, serine and glutamic and aspartic acid). When trypsin was dispersed at a low temperature (~ 80 K), amino acids were not formed.

3. Breaking of weak intermolecular contacts

The breaking of weak intermolecular contacts (hydrogen bonds and hydrophobic and electrostatic interactions) brings about conformational transitions and disordering of the protein structure; in our opinion, this is the main reason for mechanical denaturation (both reversible and irreversible). The conformational transitions have also been studied for globular proteins (trypsin, subtilisin)^{71, 72} and for fibrillar proteins with rod-like molecules (collagen).⁷³

Curves 1 and 2 of Fig. 10 show the decrease in the intrinsic viscosity $[\eta]$ of collagen upon mechanical destruction.⁷³ Curve 1 was constructed using experimental data and curve 2 was calculated from the equation

$$[\eta] = 1.23 \times 10^{-9} M^{1.8},$$

where M is the molecular mass of the polymer after mechanical destruction. It was assumed that the change in the viscosity of a

Figure 10. Variation of some properties of collagen during mechanical grinding;⁷³ (1) and (2) decrease in the intrinsic viscosity $[\eta]$ (1 is experimental curve, 2 is calculated curve); (3) decrease in the specific optical rotation $[\alpha]_D$.

solution of collagen is entirely due to the decrease in the size of macromolecules caused by the rupture of covalent bonds during grinding, while the shape of the molecules remains unchanged. However, the experimental values are much smaller than the calculated ones, which might imply that the rod-like shape of macromolecules has changed.

One more piece of evidence for the change in the shape of collagen macromolecules is the substantial decrease in the specific optical rotation $[\alpha]_D$ for large degrees of grinding (see Fig. 10, curve 3).^{73, 74}

A clear representation of the change in the rod-like shape of collagen molecules (the appearance of concave molecules, spherical particles and associates of various shapes and sizes) is provided by electron photomicrographs⁷³ of dilute solutions of collagen samples subjected to mechanical treatment.

Thus, experimental data obtained for collagen indicate that the rupture of covalent bonds in the macromolecule to give free radicals is accompanied by the rupture of weak intermolecular contacts. This results in disordering (loosening) of the protein structure, the change in the macromolecule conformation and in 'mechanical' denaturation. At extensive stages of the process, collagen acquires the properties of flexible-chain gelatin;⁷³ in dilute solutions, it forms molecular coils and associates composed of several macromolecules held together by new intermolecular bonds, which arise randomly.

A water-insoluble fraction has been found in the samples of globular proteins, trypsin and subtilisin subjected to mechanical dispersion, the proportion of this fraction increasing with an increase in the duration of grinding.⁷¹ However, its appearance is not related to covalent cross-linking, because this fraction dissolves on heating. Apparently, dispersion leads to a change in the conformation of the protein molecules, resulting in their association, referred to as 'mechanical' denaturation.

The conformational changes in trypsin molecules have also been observed by circular dichroism.⁷¹ The decrease in the amplitude of the Cotton effect in the 250–310 nm range points to appreciable changes in the tertiary structure of the protein, which affect the local environment of chromophore groups, in particular, tryptophan.

4. The change in the catalytic and biological activity of proteins

It has been found^{75–77} that on stretching a polyamide thread, the enzyme activity of trypsin or chymotrypsin immobilised on it decreases 3–6-fold. However, after termination of stretching and subsequent relaxation, the enzyme activity is restored, *i.e.* in this case, reversible deactivation of the enzyme occurs. Thus, by subjecting immobilised enzymes to mechanical treatment, one

Figure 11. Kinetics of the decrease in the activity (A) of subtilisin (*a*) and trypsin (*b*) during mechanical treatment in a mill at 80 K; A_0 is the activity of the enzymes before the treatment.⁷²

can change their conformations and control the catalytic properties.

Irreversible inactivation of enzymes was observed upon pressing (pressure ≤ 550 MPa)⁷⁸ and mechanical grinding of some proteases.^{71, 72} Experimental data for trypsin and subtilisin are presented in Fig. 11. Apparently, mechanical strain leads to the change in the enzyme conformation and in the microenvironment of the active site. It was found that some of the enzyme molecules completely lose their catalytic activity, and some molecules start to 'operate' at a lower rate than the molecules of the native enzyme.⁷²

The influence of mechanical treatment on the thymalin — a polypeptide complex with immunomodulating properties — has been studied.^{79, 80} After mild mechanical treatment in a mill, the biological activity of the preparation increases in both *in vitro* and *in vivo* experiments, which is highly important regarding the increase in its efficiency. The reasons for this phenomenon have not been elucidated yet.

VI. Mechanochemical synthesis

1. Solid-phase mechanochemical synthesis

The importance of mechanochemical synthesis among other methods of synthesis is constantly increasing. In particular, in recent years, substantial progress has been attained in the solid-phase mechanosynthesis using planetary activator mills and Bridgman anvils.

The first studies along this line were concerned with reactions in polymer–monomer and polymer–polymer systems, resulting in modification of the initial macromolecules and formation of block and graft copolymers, which are used successfully for practical purposes. Mechanical treatment of these systems was carried out in masticators, extruders, mills, bending rolls, *etc.* More detailed description can be found in monographs.^{1, 3, 4}

In this Section, we summarise the examples of solid-phase mechanochemical synthesis based on low-molecular-mass compounds carried out over the last decade.^{14, 15, 18–20, 36, 81–87} The syntheses were carried out using various equipment ranging from simple mortars to planetary activator mills⁸ and the Bridgman anvils.¹⁴ Planetary mills operate in pulse mode; the pressure created by these devices is normally about several Gigapascals. The Bridgman anvils create a constant stress field with a pressure of up to ~ 10 GPa, and the pressure in specially designed diamond anvils can reach 550 GPa.³¹

The role of mechanical treatment is mainly to provide forced transfer of the reacting particles and to ensure their contact, although other mechanisms also contribute to the reactions.

It was found¹⁴ that the degree of transformation of monomers into polymers in the Bridgman anvils depends on the angle of rotation of the anvils (Fig. 12). Plastic deformation ensures mass

Figure 12. Yield of the polymer (Π/M_0) vs angle of rotation of the anvils (θ) (2000 MPa, 293 K);¹⁴ (1) acrylamide, (2) methacrylamide, (3) maleic anhydride, (4) trioxane (1000 MPa).

transfer and mixing of reactants and removes the reaction products from the reaction area.

Solid-phase mechanochemical reactions occurring under conditions of explosion induced by strong uniaxial compression have been found;⁸¹ the characteristic times of these reactions are only 10^{-5} – 10^{-7} s.

Two mechanisms of mechanochemical reactions are most likely: (1) under the action of mechanical stress, intermixing at the molecular level occurs and (2) the product is formed on the surface of macroscopic reacting species. However, in the case of explosion reactions, the high rates cannot be explained in terms of either of these mechanisms. It has been suggested⁸² that an explosive chemical reaction is initiated by a shock wave, which loosens the lattice of reacting particles for the period of the relief of elastic stress and thus makes the system quasi-homogeneous.

Several examples of mechanochemical syntheses carried out under various conditions are presented below.

Diels–Alder reaction. The action of shear stress on solid cyclopentadiene and cyclobutadiene (2–5 GPa, ~150 K) gives rise to dicyclopentadiene and vinylcyclohexene, respectively.⁸³

Synthesis of amides (acylation). Solid mixtures of aromatic amines with carboxylic acids react (pressure up to 8 GPa, rotation angle of anvils up to 720° , temperature 200–300 K) to give amides.⁸⁴ The yields reach 50% or even more; the rates of the transformations are greater than the rates of the same processes in the liquid phase by factors of hundreds of thousands.

In the case of *ortho*-phenylenediamine, cyclisation of the resulting amides yields the corresponding benzimidazoles.

The cyclisation is accelerated by mechanical stress to a lesser extent than acylation.

Mechanochemical synthesis of phthalylsulfathiazole has been accomplished¹⁸ by combined mechanical treatment of phthalic anhydride and sulfathiazole.

The product (formed in a nearly quantitative yield) is not contaminated by phthalazoleimide or phthalates, which are normally produced in the liquid-phase synthesis.

Generally, phthalic anhydride readily enters into solid-phase mechanochemical reactions. Thus its pressure-initiated reaction with sulfacetamide gives rise to *N*-phthalylsulfacetamide.⁸⁵

It should be noted that reactions with phthalic anhydride do not stop after termination of mechanical treatment.

Synthesis of polypeptides. The action of high shearing pressure on amino acids gives peptides. As in the case of amides, the reaction affords predominantly linear products rather than cyclic compounds (dioxopiperazines), which are usually formed in these reactions carried out in solutions and melts.⁸⁷

Synthesis of metal carboxylates. A mixture of sodium hydrogen carbonate with tartaric acid has been found⁸⁸ to react under elevated pressures (1–15 kPa) yielding sodium tartrates

The action of high pressure in combination with shear strain under conditions of explosion induces the reactions

giving salts of organic acids in 70%–80% yields.

The reaction of sodium carbonate with benzoic or salicylic acids was carried out in a planetary activator mill.⁸⁹ The process has obvious advantages over the conventional liquid-phase synthesis—it occurs over one technological stage instead of standard six or seven stages, does not require the use of water, *etc.*

Halogen exchange

Hal = Br, I; Hal' = F, Cl, I; M = Li, Na, K, Cs

occurs both with aromatic^{20,21} and aliphatic ($\text{R} = \text{Me}, \text{Et}, \text{Pr}^n$) compounds.⁹⁰

Synthesis of organometallic compounds. It has been shown that mechanochemical synthesis of organometallic and coordination compounds is, in principle, possible.^{91–93} Cyclopentadienyl, dicarbonyl, β -diketonate and other organometallic derivatives were synthesised.

2. Mechanochemical synthesis and nanotechnology

One task of molecular nanotechnology, which has been developing successfully over the last 10–15 years, is the assembling of complex chemical structures. It has been shown³¹ that a chemical reaction can, in principle, be carried out under conditions when it is controlled by forced mechanical migration of individual reacting species (atoms, molecules, free radicals). The work on the transfer of species is done by molecular mills and manipulators such as an atomic force microscope (AFM), scanning tunnelling microscope (STM) and some other devices. Using these instruments, atoms or molecules can be placed (positioned) into a definite position with respect to each other (with allowance for the distance between them and orientation needed for the reaction to be initiated). For example, AFM permits the surfaces to be positioned in relation to one another with an accuracy of ~0.01 nm with a compression force of up to 0.01 nN. STM was used to position xenon atoms (4 K) on the surface of a nickel single crystal, which resulted in the formation of a linear heptamer.⁹⁴ The capacities and prospects for the development of the 'posi-

tional' mechanosynthesis have been described in detail by Drexler.³¹

The positional mechanosynthesis is carried out *in vacuo* and differs substantially from the conventional gas- and liquid-phase syntheses. As for solid-phase reactions, the notion of concentration (the number of molecules of a given type in unit volume) is absolutely inapplicable to this type of mechanosynthesis. A certain role in the positional mechanosynthesis is played by local steric and electronic effects; however, mechanical positioning has the crucial influence on the reaction rate.

The force F acting on the particles and the 'activation' length $\Delta l^\ddagger$ are related by the expression³¹

$$\Delta l^\ddagger = -kT \left(\frac{d}{dF} \ln k_{\text{react}} \right)_T,$$

where k_{react} is the rate constant for the reaction. Normally $\Delta l^\ddagger \simeq -0.1$ nm and possible compression forces reach 5 nN, which corresponds to $E_a \sim 300$ kJ mol⁻¹. More realistic estimates of the decrease in the activation energy due to the action of mechanical force are presented in the discussion dealing with the rupture of valence bonds (II.2.a) and free-radical substitution (III.3).

Within the one-dimensional model and the theory of transition state, the condition for the occurrence of a reaction is given by the expression

$$\Delta U^\ddagger \leq kT \left(\frac{t_{\text{react}} f_{\text{TST}}}{-\ln P_{\text{err}}} \right),$$

where $\Delta U^\ddagger$ is the height of the potential barrier, t_{react} is the time of the reaction, f_{TST} is the frequency factor (for a mechanochemical reaction with a relatively rigidly fixed arrangement of the reacting species, $f_{\text{TST}} \geq 10^{12}$ s⁻¹) and P_{err} is the probability of an error in a mechanochemical operation. At 300 K, assuming that $t_{\text{react}} = 10^{-7}$ s and $P_{\text{err}} = 10^{-15}$, $\Delta U^\ddagger \leq 20$ kJ mol⁻¹.

The positional mechanosynthesis has several advantages. Thus, unlike the conventional (diffusion mechanosynthesis), in this case, side reactions can be avoided, which is especially desirable for the synthesis of complex molecules containing a large number of functional groups. In the positional mechanosynthesis, non-planned collisions of molecules cannot occur and, hence, undesirable reactions are excluded.

However, among other factors, the applicability of this method is restricted by the fact that such mechanosynthetic systems are usually sensitive to thermal destruction; therefore, only reactions proceeding at room temperature, *i.e.* those having relatively low activation energy, can be carried out by positional mechanosynthesis.

Mechanical positioning ensures the transformation of the mechanical energy into chemical energy. It allows one to choose between alternative reaction pathways, to diminish the activation energy and to increase the effective concentration of the reactants because they are placed in the most favourable positions with respect to each other.

Presumably,³¹ positional mechanosynthesis would be used for the construction of complex molecules, for example, diamond-like structures. A number of properties of diamond-like materials (strength, hardness, relatively low specific weight, *etc.*) permit them to be used in nanomechanical systems in order to perform positional mechanosynthesis of other complex molecules.

Diamond-like structures consist of polycyclic organic molecules composed of sp^3 -hybridised carbon atoms.⁹⁵ Some planes, (110) and (100), contain strained reactive alkene groups, which provide for the ability of diamond-like structures to participate in synthetic transformations. The (111) plane in diamond is usually hydrogenated, which opens up the way for its chemical modification.

One modification route is based on the abstraction of a hydrogen atom, which plays an important role in the synthesis of diamonds.⁹⁵ The hydrogen abstraction can be achieved by virtue of free radicals of various structures. However, to enable posi-

tional mechanosynthesis, they should comply with definite requirements, namely, they should (a) have a very high hydrogen affinity, (b) contain no bulky groups in the structure, (c) represent a fragment of a structure that can be attached to the AFM or STM tip and used as the holder during positioning; (d) possess mechanical and chemical stability during positioning and (e) be readily generated and regenerated.^{31,95}

Under the action of anisotropic compression forces (~ 20 GPa) at room temperature, fullerene can be converted into diamonds (see II.1.a); therefore, it might be a suitable substance for positional mechanosynthesis of diamond-like materials.

3. Polymerisation

The mechanochemical polymerisation was first discovered on grinding of acrylic and methacrylic acid derivatives (acrylamide, methacrylamide and sodium and potassium salts of these acids) in the presence of some salts, metals and oxides, which serve as initiators.¹

High pressures ($\sim 10^3$ MPa) combined with shear stress induce polymerisation of compounds containing C=C bonds (ethylene, styrene, methylstyrene, *etc.*), C≡C bonds (acetylene derivatives), conjugated double bonds (butadiene, cyclopentadiene, *etc.*), aromatic rings (benzene, naphthalene, anthracene, *etc.*) and heterocycles (pyridine, thiophene, *etc.*) even at the temperature of liquid nitrogen.¹⁴

In principle, high pressures in combination with shear strain can cause reactions that do not occur under ambient conditions. For example, the activation energy for ethylene dimerisation is about 200 kJ mol⁻¹; however, under the action of pressure and shear strain, the π bond in the ethylene molecule can be cleaved. The resulting biradical³¹ can either dimerise to give cyclobutane or initiate polymerisation.

It can also be claimed that the aromatic rings in benzene, pyridine, polynuclear compounds, *etc.*, can be cleaved in a similar way, although real mechanisms of these transformations are rather complex.¹⁴

In some cases, mechanical stress sharply accelerates polymerisation. Thus the rate constants for the mechanically initiated polymerisation of styrene, acrylamide and other monomers are 2–5 orders of magnitude greater than the corresponding constants found for these reactions in the liquid phase.¹⁴

Several groups of researchers^{96–99} have discovered polymerisation of frozen monomers, which occurred at very high rates at low temperatures (≤ 77 K). The influence of mechanical stress was found to be the main driving force of these processes. It has been shown⁹⁶ that local mechanical treatment (a needle prick) of frozen cyclopentadiene (77 K), prepared by the method of molecular beams, causes its chain polymerisation; similarly, a local treatment with a pin of γ -irradiated solid acetaldehyde initiates its cryopolymerisation even at 4.2 K.⁹⁹

It was shown⁹⁹ that the local mechanical action on a frozen sample induces the formation of a primary crack, which initiates spontaneous propagation over the sample of a narrow area densely covered by an extensive network of freshly formed cracks. The chemical reaction occurs on the surface of cracks (or near them) and, in turn, create conditions for further destruction in the neighbouring area of the matrix. The solidity of the sample can be violated, for example, due to the temperature or density gradients, arising during the reaction and creating stresses, which destroy the sample. Thus, the matrix undergoes layer-by-layer dispersion under the influence of the running field of mechanical stress, and the reaction wave propagates spontaneously over the sample.

The relationship between the reactivity and mechanical stresses arising in the reaction has been studied by EPR for the unfreezing of organic crystals of diacyl peroxides having been subjected to photolysis at ~ 15 K.¹⁰⁰ Radical pairs and CO₂ molecules are formed in the system and create a high local pressure. The mechanical stress thus arising relaxes as a result of movement of these molecules towards the surface.

4. Formation of molecular complexes

Mechanical treatment of two-component systems gives rise to various types of molecular complexes — charge transfer complexes, inclusion compounds and complexes formed due to acid–base interactions, hydrogen bonds or simply van der Waals forces.

Complexation of the acid–base type between phenols and amines has been found for a mixture of hexamethylenetetramine (urotropin) and resorcinol.^{101,102} The reaction proceeds both during explosion initiated by compression¹⁰¹ and under relatively mild conditions, namely, in a disintegrator;¹⁰² the yields are nearly quantitative in both cases.

It has been shown that interpolymer complexes (polymeric compounds stabilised by bonds of the ionic type) can be prepared by mechanochemical synthesis under high pressure combined with shear stress.¹⁰³ Polymethacrylic acid (polymeric acid) and PMMA or polymethylvinyltetrazole (polymeric base) were used as the initial compounds.

Combined mechanical grinding of polyvinylpyrrolidone (PVP) with some additives (Ad) (chloranil, phenothiazine, hydroquinone, acridine, *etc.*) gives charge transfer complexes of the $n-\pi$ and $\pi-\pi$ types, for example, PVP^+Ad^- (with chloranil) or PVP^-Ad^+ (with phenothiazine).¹⁰⁴

The samples obtained upon trituration in a mortar of two substances able to form stable radicals, one of which being an electron donor (D) (phenols, catechols, porphyrins, *etc.*) and the other being an electron acceptor (A) (*e.g.*, quinones) have been studied by EPR spectroscopy.¹⁰⁵ The researchers were able to record the EPR spectra of the primary reaction products, biradical triplet complexes or radical pairs, and secondary products — free radicals.

The triplet molecular complexes or radical pairs generated by mechanical treatment are much more stable than those prepared by photolysis of the same donor–acceptor solid mixtures. Apparently, once formed, they are quickly incorporated into the new crystal lattice arising upon mechanical treatment.

Electron transfer has also been detected on exposure of mixtures of organic compounds, electron donors and acceptors, to elastic acoustic waves.¹⁰⁶

Yet another example of electron transfer is represented by mechanochemical reactions of peroxy macroradicals with compounds containing a tertiary amino group (phenothiazine and pyrazolone derivatives), which have been studied by EPR.⁶³

The reaction occurs during mechanical grinding of a mixture of a polymer (PS, polyvinyl acetate, *etc.*) and a substance with electron-donating properties.

Combined mechanical grinding of α - and β -cyclodextrins with acetylsalicylic, benzoic or *p*-hydroxybenzoic acid yields inclusion compounds.¹⁰⁷ Their formation proceeds *via* a stage of amorphisation of polymers and low-molecular-mass crystals followed by dissolution of crystals in the amorphous medium. Hungarian researchers³⁸ prepared inclusion compounds by grinding γ -cyclodextrin with fullerene and thus attained solubilisation of the latter substance.

The vast majority of studies dealing with the synthesis of molecular complexes are associated with new methods for the development of drugs aimed at increasing their therapeutic activity, which depends on bioavailability. It is known^{33,108} that bioavailability of drugs poorly soluble in water is determined by the rate of dissolution. It was found that combined grinding of drugs with polymers of various structures leads to distribution (to a molecular level) of the drug in the polymer matrix to give molecular complexes (in the literature devoted to the technology of drugs, these systems are normally referred to as solid dispersions³³). As a rule, this combined grinding makes it possible to increase the solubility and the rate of dissolution of hydrophobic compounds in aqueous media.^{33,108,109} Meanwhile, by appropri-

ate selection of the initial pair consisting of a polymeric carrier and a drug, the liberation of the drug from the molecular complex can also be retarded (prolonged-action preparations). Preparations of this type have been obtained, for example, by joint grinding of some substance of the benzimidazole series with microcrystalline cellulose.¹¹⁰

The polymeric matrices used for this purpose are usually natural polymers, namely, cellulose and its derivatives, starch, cyclodextrins, proteins, chitin, chitosan and pectin and some synthetic polymers [poly(ethylene oxide) or polyvinylpyrrolidone].

The majority of drugs are low-molecular-mass organic compounds containing functional groups capable of forming intermolecular hydrogen bonds ($\text{C}=\text{O}$, OH , NH , *etc.*). During mechanical grinding of mixtures of drugs with polymers, the intermolecular hydrogen bonds are destroyed and new hydrogen bonds with macromolecules are formed (IR-spectroscopy data¹⁰⁸). Thus the molecules of benzoic, salicylic and acetylsalicylic acids, hexobarbital, *etc.* form hydrogen bonds of the $>\text{C}=\text{O}\cdots\text{HOR}$ type with cellulose and oligosaccharide molecules. Derivatives of barbituric acid form in addition $\text{NH}\cdots\text{O}(\text{H})\text{R}$ bonds with hydroxy groups of polymers. In the inclusion compounds described above, obtained by grinding of cyclodextrins with acetylsalicylic, benzoic and *p*-hydroxybenzoic acids, hydrogen bonds link the OH groups of cyclodextrin to the $\text{C}=\text{O}$ groups of acids.

The redistribution of hydrogen bonds during grinding of acetylsalicylic acid (Aspirin) with some fillers (cellulose, alumina) has been studied fairly comprehensively by IR spectroscopy.³⁹ Aspirin is responsible for an absorption band with a maximum at 1695 cm^{-1} , due to the stretching vibrations of the $\text{C}=\text{O}$ group in the dimer. Grinding of the sample results in broadening of this band and displacement of the ν_{CO} vibration frequency of the dimer to $1700\text{--}1710\text{ cm}^{-1}$, indicating the appearance of a monomeric species with an intramolecular hydrogen bond. The conversion of the dimer into the monomer is also confirmed by optical diffuse reflection spectra.³⁹ The formation of molecular complexes of Aspirin with fillers (vibration frequency $\nu_{\text{CO}} = 1749\text{ cm}^{-1}$) was not detected in the study cited,³⁹ although it had been observed previously.¹¹¹

Upon grinding of isobutylphenylpropionic acid (ibuprofen) with poly(ethylene glycol), hydrogen bonds between the carboxy groups of the acid and the hydroxy groups of the polymer (IR-spectroscopy data) and van der Waals interactions between the polymer molecules and the aromatic rings of ibuprofen (electronic absorption and luminescence spectra) were detected.¹¹¹

Figure 13. X-Ray diffraction patterns of sulfathiazole (1), polyvinylpyrrolidone (2) and their mixtures (3–5) after mechanical treatment for 3 (3), 6 (4) and 12 min (5).¹¹²

Figure 14. Change in the rate of dissolution of griseofulvin after mechanical treatment of its mixtures with polymers;¹⁰⁹ (1) a mixture of griseofulvin with gelatin without mechanical treatment, (2) gelatin, (3) chitin, (4) polyethylene glycol, (5) chitosan.

After grinding of a drug–polymer mixture, peaks characteristic of the drug usually disappear from the X-ray diffraction patterns (an example is shown in Fig. 13).

The initial rate of dissolution of a drug after its combined grinding with polymers can increase by a factor of tens (an example is shown in Fig. 14). The increase in the solubility is especially pronounced when the mechanical treatment yields a new polymorphic modification with a higher solubility. For instance, in the case of grinding of sulfathiazole with polyvinylpyrrolidone in a planetary mill, the solubility of the drug increases almost 10-fold.¹¹²

Thus, the whole set of data described above, both direct (optical spectra) and indirect (the decrease in the melting point and heat of melting, the increase in the solubility and in the rate of dissolution), point to the formation of molecular complexes stabilised mostly by hydrogen bonds.

The practical importance of the molecular complexes with drugs (in particular, for increasing the bioavailability of the drug) becomes obvious from the results of bioassays, which are few in number but convincing.^{33, 108, 113, 114}

VII. Conclusion

The review shows that mechanical stress induces numerous physical transformations and chemical reactions in organic compounds. They are based on the rupture of bonds, generation of free radicals, decrease in the activation energies of reactions, provision for the transport of reacting species, etc.; in some cases, some of the above-listed processes predominate, while in other cases, they occur and act simultaneously.

The practical potential of the mechanochemistry has been appreciated and adopted by investigators engaged in diverse branches of science. Solid-phase mechanochemical syntheses of various compounds have been performed by now. The yields in mechanochemical reactions are sometimes higher than those in similar reactions conducted in the liquid phase.

The advantages of mechanochemical synthesis include the possibility of performing it at low or room temperatures, environmental cleanness (no solvents are involved) and the simplicity of the process technology.

A mechanochemical process carried out in a reactor mill includes three main stages (a) grinding of the material in order to attain the optimum size of particles; (b) mixing of the reactants in order to attain the maximum contact between the particles (c) the reaction itself. At present, all the three stages occur simultaneously in the same device, although they require differ-

ent levels of delivered energy. Apparently, for industrial implementation of mechanochemical synthesis, it would be expedient to separate the stages, i.e. to carry out each stage of the process in a separate specially designed reactor.¹¹⁵

Mechanochemical methods have been recognised in the technology of drug manufacture and are used to control the rate of drug dissolution and to increase their therapeutic activity.

The new promising line in mechanochemistry, positional mechanosynthesis, is closely related to the molecular nanotechnology and is regarded as technology of the XXIst century. Although the development of this line of research is only at its beginning and is now held up due to the absence of necessary equipment, there seems to be no conceptual obstacles to the design of mechanosynthetic machines.

VII. Conclusion	682

Abstract. The data on the synthesis and application in organic synthesis of fluorinating compounds containing N–F bonds are surveyed and systematised. The reagents are classified into two categories, *viz.*, neutral (perfluoro-*N*-fluoropiperidine, *N*-fluoro-2-pyridone, *N*-fluorosulfonamides, *N*-fluoro-*N*-alkylamides, *N*-fluorobis(trifluoromethyl)sulfonylamine, *N*-fluorobenzo-1,3,2-dithiazole 1,1,3,3-tetroxide, *N*-fluoro sultams) and ionic reagents (*N*-fluoropyridinium, *N*-fluoroquinuclidinium and 1-alkyl-4-fluoro-1,4-diazoniabicyclo[2.2.2]octane salts). A comparative analysis of the fluorinating activity of the reagents depending on their structure and the nature of the solvent is carried out taking into account theoretical calculations. The possibility of fluorination of various classes of organic compounds is discussed. The mechanisms of fluorination with N–F compounds are analysed using kinetic data. The advantages and disadvantages of *N*-fluoro amines in comparison with elemental fluorine, xenon difluoride and other fluorinating reagents are considered. The influence of the nature of the solvent on the fluorinating activity of *N*-fluoro amines and their analogues is discussed. The bibliography includes 245 references.

I. Introduction

Over almost a century, fluorination of organic and inorganic substrates with elemental fluorine has been used as the basis for the synthesis of fluorine-containing compounds. Fluorine is known to be a highly potent fluorinating reagent. However, being a strong oxidant, fluorine is aggressive against numerous organic substrates and solvents and thus does not manifest the high selectivity required in fine organic synthesis. Other plausible fluorinating reagents, such as xenon difluoride and perchloryl

fluoride ($FClO_3$), have not received wide acceptance in fluoroorganic chemistry, primarily because of their high cost, although their pilot-plant syntheses have already been carried out. For example, the synthesis of $FClO_3$ is being carried out at the Russian Research Centre 'Applied Chemistry'.

The situation in this area has changed radically in the past decade. The ever increasing application of fluorine-containing compounds as biologically active compounds (first of all, of medicinal drugs) has given a strong impetus to the synthesis of a wide range of new electrophilic fluorinating reagents (fluorine 'carriers'), *viz.*, the so-called *N*-fluoro reagents and fluoro compounds (*O*-fluoro reagents).

Undoubtedly, *N*-fluoroamines and their analogues belong to the most representative class of fluorine 'carriers' as regards their number, previous experience and application. A chemist engaged in synthesis will always be able to select a reagent complementary to the substrate to be fluorinated in its physical and chemical characteristics.^{1–6}

N-Fluoro reagents surpass *O*-fluoro and *S*-fluoro reagents in stability, reliability, safety, ecological friendliness and handling convenience.^{7–16}

In considering the wealth of knowledge concerning the chemistry of *N*-fluoro amines and their analogues, we thought it more reasonable to classify these fluorinating reagents into two groups according to the type of the fluorine–nitrogen bond in their molecule. The first group includes the so-called neutral compounds of the type R_2NF , *i.e.*, the reagents in which the fluorine atom is bound to the uncharged nitrogen atom. The second group includes the reagents in which the fluorine atom is bound to the positively charged nitrogen atom.

The most popular neutral compounds are perfluoro-*N*-fluoropiperidine, *N*-fluoro-2-pyridone, *N*-fluoro carboxamides, *N*-fluoro sulfonamides, *N*-fluoro sulfonylamines (including perfluorinated compounds), *N*-fluoro(diphenylsulfonyl)amine, *N*-fluoro alkanesulfonimides, *N*-fluoro benzenesulfonimide and *N*-fluoro sultams. The most popular quaternary compounds include *N*-fluoropyridinium, *N*-fluoroquinuclidinium and 1-alkyl-4-fluoro-1,4-diazoniabicyclo[2.2.2]octane salts.

Only a few *N*-fluoro-reagents are commercially available. The data on these compounds are summarised in the review by Lal *et al.*⁶

3. The use of *N*-fluoro carboxamides and *N*-fluoro sulfonamides

N-Fluoro carboxamides and *N*-fluoro sulfonamides are obtained by fluorination of the corresponding amides or sulfonamides with elemental fluorine or other fluorinating reagents. Thus fluorination of alkylamides with CF₃OF results in the corresponding *N*-fluoroalkylamides in high yields.³¹

R ¹	R ²	Yield (%)
Me(CH ₂) ₁₆	Me	30
Me		60
4-FC ₆ H ₄	Me	13
H	Me	85
H		71

Direct fluorination of sodium *N*-(perfluoro-4-pyridyl)trifluoroacetamide with elemental fluorine was used to obtain the selective fluorinating reagent, *viz.*, (*N*-fluoro-*N*-perfluoro-4-pyridyl)trifluoroacetamide (**8**).^{32–34}

The reagent **8** fluorinates diethyl phenylmalonate (NaH, THF, from –10 to 20 °C) to give the fluoro derivative **6** in 66% yield.³² The reaction with enamines results in the corresponding α-fluoro ketones.³²

The reactions with phenol (MeOH, 20 °C) and anisole (MeCN, 20 °C) yield mixtures of *ortho*- and *para*-isomers (in 1 : 1 and 7 : 3 ratios, respectively).³²

R = H (91%), Me (81%).

Fluorination of sulfonamides with F₂ in the presence of KF or with a FClO₃–NaH mixture gives the corresponding *N*-fluoro derivatives of the type **9** (yield ~ 60%). Fluorination of *O*-acetyl-*N*-tosyl- and *N*-mesylphenylglycinol gives the corresponding *N*-fluoro derivatives in 52% and 13% yields, respectively.^{35, 36}

R ¹	R ²	R ³	R ⁴

Pr ⁱ	H	CO ₂ Et	4-MeC ₆ H ₄ , Me, F ₃ C
Ph	H	Me	4-MeC ₆ H ₄ , Me, F ₃ C

Compounds **9** possess fluorinating ability and can be used for the synthesis of α-fluorocarbonyl derivatives from enolates (Table 1).^{35, 36}

Normally, fluorination of *N*-alkyl(aryl)sulfonamides is performed in a CFCl₃–CHCl₃ mixture (1 : 1) using 1%–5% F₂ in N₂, MeOF or CF₃OF as fluorinating reagents. *N*-Fluoro sulfonamides **10a–g** were synthesised in this way.^{37–47}

Compound 10	R ¹	R ²	Yield (%)	Ref.
a	Me	Bu ^t	14	37
b	Me	Me	59	37
c	Me	Bu ^t CH ₂	57	37
d	Me		47	37
e	Me		71	37
f	Me		11	37
g	H	Bu ^t	—	47

Sulfonamide derivatives are preferably fluorinated as the corresponding salts.^{48–50} Thus the fluorination of sodium perfluoro-*N*-(4-pyridyl)methanesulfonamide with elemental fluorine results in perfluoro-*N*-fluoro-*N*-(4-pyridyl)methanesulfonamide (**11**) in 89% yield.⁴⁹

N-Perfluoroquinolyl-, -isoquinolyl and -naphthylsulfonamides were also introduced into the reaction.⁴⁹

It is noteworthy that *N*-*tert*-butyl-*N*-fluoro-*p*-toluenesulfonamide **10a** can be obtained in 69% yield by fluorination of sodium *N*-*tert*-butyl-*p*-toluenesulfonamide with cesium fluoroxysulfate in MeCN at 0–5 °C.⁵¹

Perfluorosuccinimide and -glutarimide react with xenon difluoride to give the corresponding *N*-fluoro imides **12a,b** in good yields.^{52, 53} The fluorination is performed at 0–20 °C in the absence of the solvent or at 0 °C in dichlorodifluoromethane for 24 h. These compounds represent easily distillable liquids, which are stable upon 24-h storage in quartz glassware under nitrogen. The fluorination of sodium phthalimide with cesium fluoroxysulfate in acetonitrile gives *N*-fluorophthalimide in 48% yield.⁴⁵

n = 2 (**a**, 55%–65%), 3 (**b**, 50%–60%).

Satyamurthy *et al.*⁵⁴ used the reaction of solutions of lactams with 100% fluorine for the synthesis of *N*-fluoro lactams **13** labelled with ¹⁸F. However, the yields of *N*-fluoro lactams **13a–c** are rather low. Higher yields could be obtained by fluorination of solutions of lactams in Freon with fluorine diluted with neon.⁵³

Table 1. Fluorination of organic compounds with *N*-fluorosulfonamides in THF.^{35, 36}

Controlled fluorination of aromatic compounds and derivatives of malonic acid with *N*-fluoro lactams of the type **13** and with *N*-fluoro sulfonamides **10** and **11** can be used for the synthesis of aromatic fluoro derivatives and fluorinated malonates.

Thus sulfonamide **11** fluorinates sodium diethyl phenylmalonate, benzene and anisole (a mixture of *ortho*- and *para*-fluoroanisoles is formed in 3:1 ratio and in 98% yield).⁴⁹ *N*-Fluorobenzenesulfonamide reacts with anisole (4 h, 150 °C) to yield a mixture of 57% 2-fluoroanisole and 37% 4-fluoroanisole.^{53, 54}

The data on fluorination of several compounds with substituted *N*-fluorotoluenesulfonamides **10a, c, d** are presented in Table 2.³⁷

The halogen atoms in alkenyl iodides can be selectively substituted by the fluorine using *N*-fluorobenzenesulfonamide, *via* intermediate lithium derivatives. The yields of the resulting fluorides are rather high, although in some cases alkenes are formed in large amounts. The results of fluorination of alkenyl iodides are presented in Table 3.⁴⁷

(a) Bu^tLi, THF–Et₂O–C₅H₁₂ (4:1:1), −120 °C;(b) PhSO₂NFBu^t, from −120 to 20 °C.

4. Fluorinating reagents based on *N*-fluoro sulfonylamines

N-Fluoro imides have found much wider application in organic synthesis than *N*-fluoro amides. The methods for preparing *N*-fluorobis[alkyl(aryl)sulfonyl]amines are based on direct fluorination of the corresponding bisalkyl(aryl)sulfonylamines (1%–3% F₂ in Ar or XeF₂). Fluorinated products are obtained in up to 70% yields.⁵⁵

N-Fluorodisulfonylamines of the type CF₃SO₂NFSO₂R (R is perfluoroalkyl, cycloalkyl, aralkyl or aryl) are obtained by fluorination of the corresponding imides with elemental fluorine at −20 °C.^{56–64} Thus treatment of (CF₃SO₂)₂NH with F₂ at 22 °C gives *N*-fluorobis(trifluoromethylsulfonyl)amine (**14a**) in 95% yield. *N*-Fluorodisulfonylamines **14b–e** and imides **15** were synthesised in a similar way.⁵⁹

The fluorination is performed with elemental fluorine diluted with nitrogen in solvents (CHCl₃, CFC₃, HF, fluorohydrocarbons, MeCN) at 80–135 °C in the presence of NaF or CaF₂.

Table 2. Fluorination of organic compounds with *N*-fluorosulfonamides **10**.³⁷

Syvret *et al.* have proposed to use lithium derivatives instead of free imides.⁶²

R¹ = CF₃; R² = SO₂CF₃ (**a**, 95%), SO₂C₄F₉ (**b**, 96%), SO₂C₆F₁₃ (**c**, 93%), Me (**d**, 11%); R¹ = C₄F₉, R² = SO₂C₆F₁₃ (**e**, 88%).

n = 2 (77%), 3 (61%), 4 (86%).

N-Fluorobis(methylsulfonyl)amine (**16**) was obtained in 90% yield by fluorination of bis(methylsulfonyl)amine with elemental fluorine (F₂:N₂ = 1:9) in acetonitrile in the presence of NaF (−40 °C).³⁴

Other *N*-fluorobis[alkane(arene)sulfone]amides^{33,64,65} and *N*-fluorobenzo-1,3,2-dithiazine 1,1,3,3-tetroxide [commonly referred to as *N*-fluoro-*o*-benzodisulfonimide (NFOBS)]^{66,67} have been synthesised in a similar way. Water or water–organic solvent mixtures can be used as a reaction medium.⁶⁴ The best results are attained through the use of sodium salts of the corresponding sulfonimides.^{34,65,67}

The reagent **14a** obtained by the scheme given below (total yield 76% with respect to trifluoromethanesulfonyl fluoride) is the most reactive among other *N*-fluorodisulfonylamines.⁵⁹ This compound has a boiling point at 90–91 °C, is thermally stable, can be stored in glassware and is a highly efficient fluorinating agent which has many applications. The same scheme was used to obtain the reagent **14a** labelled with ¹⁸F (45% radiochemical yield).⁶⁸

(a) NH₃ (liquid), –78 °C; (b) NaOMe, MeOH (95%); (c) (Me₃Si)₂NH, Δ (92%); (d) F₃CSO₂F, THF, 100 °C, autoclave (98%); (e) H₂SO₄, sublimation *in vacuo* (93%); (f) 100% F₂, metal tube, from –196 to 22 °C (95%).

N-Fluorobis(phenylsulfonyl)amine (**17**) often referred to as *N*-fluorobenzenesulfonamide was obtained in 70% yield by fluorination of bis(phenylsulfonyl)amine with fluorine diluted with nitrogen, in acetonitrile or in a CHCl₃–CFCl₃ mixture in the presence of sodium fluoride at –40 °C.^{69–71} The structure of compound **17** was confirmed by X-ray diffraction analysis.⁷¹

(a) 10% F₂ in N₂, NaF, MeCN, –40 °C; (b) 10% F₂ in N₂, NaF, CHCl₃–CFCl₃ (1 : 1), –40 °C.

N-Fluorobis(phenylsulfonyl)amine (**17**) is a white crystalline powder, which is soluble in the majority of organic solvents (ether, THF, CH₂Cl₂, MeCN, PhMe). It is convenient in handling, non-hygroscopic and storage-stable. This reagent can be used for fluorination of carbanions, enolates and enol esters as well as for the preparation of fluorinated intermediates used in the production of medicinal drugs.

Fluorination of the sodium salt of saccharin **18** with cesium fluorosulfate in acetonitrile at 0–5 °C gives the *N*-fluoro derivative **19** in 69% yield. Treatment of compound **18** with fluorine in methanol at –60 °C (–70 °C) gives methyl *o*-fluoro-sulfonylbenzoate **20** formed by the opening of the heterocycle and the fluoro derivative **19**.⁴⁰

An analogue of compound **19**, 3-fluorobenzo-1,2,3-oxathiazin-4-one 2,2-dioxide (**21**), is prepared by treatment of sodium salt

of benzo-1,2,3-oxathiazin-4(3*H*)-one 2,2-dioxide in acetonitrile with dilute fluorine in the presence of sodium fluoride (–40 °C).^{33, 34, 63} The reagent **21** is a rather stable crystalline compound, which manifests high fluorinating ability and is used for fluorination of various compounds including carbanions, steroids and aromatic compounds.^{34, 63} Examples of these reactions are given in Table 4.

Table 4. Fluorination of organic compounds with 3-fluorobenzo-1,2,3-oxathiazin-4-one 2,2-dioxide (**21**).³⁴

Starting compound	Reaction conditions ^a			Reaction product	Yield (%)

^a Sodium bis(trimethylsilyl)amide (NaHMDS) was used to generate the enolates and salts. ^b The *ortho* : *para* ratio is 56 : 44.

Substituted *N*-fluoro-1,2,3-oxathiazin-4-one 2,2-dioxides **22a, b** are prepared in a similar way.⁶⁵

R¹ = H, R² = Me (**a**); R¹ = Me, R² = Me (**b**).

Treatment of benzo-1,3,2-dithiazole 1,1,3,3-tetroxide (**23**) with nitrogen-diluted fluorine at –40 °C gives *N*-fluorobenzo-1,3,2-dithiazole 1,1,3,3-tetroxide (**24**)^{66, 67, 72} as a white crystalline powder. Its structure was confirmed by X-ray diffraction analysis.⁷¹

(a) 10% F₂ in N₂, NaF, CFCl₃–CHCl₃, –40 °C.

Electrophilic fluorination of imines **25a–c** with *N*-fluorobis(trifluoromethylsulfonyl)amine (**14a**) yields mono- (**26a–e**) and difluoroketones (**27a–e**); the imine anions were generated by treatment with bases.⁷³

(a) **14a**, CH₂Cl₂, Na₂CO₃, 22 °C; (b) H₃O⁺.

Direct fluorination of imines with (CF₃SO₂)₂NF (**14a**) gives α-monofluoro and α,α-difluoro ketones without preliminary generation of anions.^{74–76} The results of fluorination are listed in Table 5.⁷³ Enamines react in a similar way. Thus 1-morpholino-1-

phenylpropene reacts with compound **14a** to give α -fluoro-propiophenone after hydrolysis. Fluorination of imines and enamines with the reagent **14a** can be regarded as an alternative route to α -fluoro ketones, which are usually synthesised from the corresponding enolates. Mild reaction conditions and high yields of the final products make this procedure very promising.

The reagent **14a** proved to be efficient in fluorination of lithium enolates of esters, amides, ketones, β -diketones and β -oxo esters (enolates are prepared by treatment with lithium diisopropylamide in THF). The fluorination is fairly selective at 22 °C and results in monofluoro derivatives.⁷⁵

$\text{R}^1\text{R}^2\text{CHCOX} \xrightarrow[2) \text{14a, THF, 22 } ^\circ\text{C}]{1) \text{LDA}} \text{R}^1\text{R}^2\text{CFCOX}$

The synthesis of α,α -difluoro derivatives requires 2 equiv. of the reagent **14a** and more drastic conditions.^{60, 66, 75–77}

The nature of substituents at the carbonyl group of ketones has no appreciable influence on the yields of the monofluorinated derivatives, which are normally high. Esters are also smoothly fluorinated with this reagent (Table 6).⁷⁶

Lithium diethyl 2-nitromalonate is fluorinated with high yield in the treatment with (CF₃SO₂)₂NF (**14a**) in THF.^{60, 76}

The fluorination of β -diketones, β -oxo esters and β -oxo amides with the reagent **14a** in non-polar solvents results in the formation of α -monofluoro or α,α -difluoro derivatives. Thus ethyl 2-chloroacetoacetate,⁷⁴ ethyl 2-acetoxyacetoacetate⁷⁸ and 3-chloro-2,4-pentanedione⁷⁹ are fluorinated with the reagent **14a** in chloroform in quantitative yields. Fluorination of benzoylacetone in CH₂Cl₂ gives 90% of 1-benzoyl-1,1-difluoroacetone, whereas in a CH₂Cl₂–H₂O system the monofluoro derivative is obtained in 93% yield (see Table 6).⁷⁶

Fluorination of α -oxo esters can also occur in the absence of bases. These compounds generate fluoro derivatives with practi-

4-Substituted *N,N*-diphenylpyrazolidine-3,5-diones **30a,b** are fluorinated with 1 equiv. of the reagent **14a** in acetic acid or in CHCl₃ to give 4-*n*-butyl-4-fluoro-1,2-diphenylpyrazolidine-3,5-dione (**31a**) and 4-fluoro-1,2-diphenyl-4-[(2-phenylsulfinyl)ethyl]pyrazolidine-3,5-dione (**31b**).⁷⁷

R = Et (**a**, 95%), SPh (**b**, 90%).

The fluorination of 2-phenylindane-1,3-dione (**32**) with the reagent **14a** in acetic acid at 20 °C gives 2-fluoro-2-phenylindane-1,3-dione (**33**).⁴² In fluorination of substituted 4-hydroxycoumarins **34a–c** with the reagent **14a**, the fluorine atom also occupies the α -position relative to the carbonyl group to give compounds **35a–c** in high yields.⁴²

R = H (**a**, 91%), Ph (**b**, 92%), 4-ClC₆H₄ (**c**, 90%).

The fluorination of 4-hydroxy-3-(3-oxobutyl)coumarin **34a** in a chloroform–water mixture (5 min, 35 °C) gives the corresponding fluoro derivative **35a** (which represents a mixture of diastereomers) in a quantitative yield.⁵⁸ 3-Fluoro-3-(1-phenyl-3-oxobutyl)-

2*H*-benzopyran-2,4-dione and 3-fluoro-3-[1-(4-chlorophenyl)-3-oxobutyl]-2*H*-benzopyran-2,4-dione are prepared in a similar way. The highly selective fluorination of heterocyclic compounds with the reagent **14a** is better carried out in polar solvents, *e.g.*, 2,2,2-trifluoroethanol or nitromethane.⁷³

N-Fluorobis(trifluoromethylsulfonyl)amine (**14a**) reacts with some activated aromatic compounds such as toluene, anisole and acetanilide, resulting in the *ortho*- and *para*-substituted products.⁶⁵ Monofluoro derivatives are predominantly formed at the ArH : **14a** ratio of 2 : 1. As for nitrobenzene, chlorobenzene or acetophenone, they cannot be introduced into this reaction.^{59, 65, 69, 70}

The reagent **14a** is effective in reactions with alkenes to give addition products of fluorine at the multiple bond. If a CH₂Cl₂–acetic acid mixture is used, the latter enters into the reaction to give acetoxy and hydroxyfluoro derivatives (these reactions were described, *e.g.*, with styrene and *trans*-β-methylstyrene).⁸⁰

The reagent **14a** reacts with α,β-unsaturated carbonyl compounds in AcOH to give β-acetoxy α-fluoro ketones.⁸⁰

Uracil does not react with (CF₃SO₂)₂NF (**14a**) at 22 °C in AcOH, presumably due to its poor solubility, whereas at 45 °C this reaction is completed in 12 h to give a difluoro derivative.⁸⁰ 1,3-Dimethyluracil is much more reactive and gives a difluoro derivative in the reaction with 2 equiv. of (CF₃SO₂)₂NF (**14a**) at 22 °C (yield 85%); 1 equiv. of the reagent **14a** gives 1,3-dimethyl-5-fluorouracil.⁸⁰

N-Fluorodisulfonylamine (**14a**) is effective in fluorination of various steroids. Thus fluorination of estra-1,3,5-trien-3-ols in CHCl₃ gives *ortho*- and *para*-fluorinated products. If acetic acid is used as a solvent, fluorine selectively occupies the *para*-position to give 10β-fluoro-1,4-estradien-3-one derivatives in high yields.⁶¹

The fluorination of a suspension of 2,4,6-trihydroxypyrimidine in acetic acid with 1 equiv. of (CF₃SO₂)₂NF (**14a**) at room temperature results in a monofluoro derivative, whereas a 5,5-difluoro derivative is obtained in high yield with 2 equiv. of the reagent.⁷⁷ This method was used for the synthesis of a wide range of fluorinated pyrimidinetriones.⁷⁷

R ¹	H	Me	Et	Bu ⁿ	Ph	OMe	Me	Et	Ph
R ²	H	H	H	H	H	H	Me	Me	Me
Yield (%)	88	92	89	90	91	90	92	83	91

Along with reagent **14a**, other *N*-fluoro imides, *e.g.*, *N*-fluorobis(phenylsulfonyl)amine (**17**) or *N*-fluorobenzo-1,3,2-dithiazole 1,1,3,3-tetroxide (**24**) are used for fluorination of various classes of organic compounds. Some examples are given in Table 7.

The reagent **17** is more efficient than the reagent **24** in fluorination of organometallic compounds and highly stabilised anions (see Table 7). Under the action of the reagent **17** (100 °C, 18 h), acetanilide gives a mixture of isomeric fluoroacetanilides, the yields of the *ortho*- and *para*-isomers being 25% and 15%, respectively.⁶⁵ Fluorination of metallated aromatic and heteroaromatic compounds with the reagent **17**, which is accompanied by the formation of *ortho*-fluoro derivatives, is used in the synthesis of valuable biologically active compounds, *e.g.*, fluoro- and difluoroveratric aldehydes.^{74, 81, 82}

Base-catalysed formation of enolates, subsequent complexation with boron compounds and fluorination of the latter with the reagent **17** is a novel method for the synthesis of γ-fluorinated α,β-unsaturated ketones.^{83–85} Thus the reaction of the reagent **17** with a carbanion generated from 4,4a,5,6,7,8-hexahydronaphthalen-2(3*H*)-one (**36**) in the presence of triphenylborane gave the fluoro derivative **37**.⁸⁴

The enolate prepared from 10-methyl-1(9)-octal-2-one upon treatment with KH in a HMPA–THF mixture in the presence of triphenylborane gives a fluoro derivative with the reagent **17** in the α : β ratio of 1 : 8.6 (yield 84%).⁸⁵

Yet another example of efficient fluorination with this reagent in the presence of 2-phenylbenzo[1,3,2]dioxaborol is the synthesis of γ-fluorinated steroid enones. Thus the fluoro derivative **39** was prepared from compound **38**.⁸⁴

Table 7. Fluorination with the reagents **17** and **24**.

Substrate	Reagent	Reagent : substrate ratio	Temperature /°C	Time /h	Reaction product	Yield (%)	Ref.
	17	22 : 1	150	5		100 ^a	65
	17	1 : 1	100	24		33 ^a	65

^a The *ortho* : *meta* : *para* ratio is 58 : 5 : 37. ^b The *ortho* : *para* ratio is 62 : 38. ^c The *ortho* : *meta* : *para* ratio is 65 : 7 : 28. ^d The organolithium derivative was generated previously by treatment with BuⁿLi in THF. ^e The lithium derivative was generated previously by treatment with LDA in THF. ^f The potassium derivative was generated previously by treatment with KH in Et₂O. ^g The potassium derivative was generated previously by treatment with KHMDS in THF.

The fluorination of lithium enolates of silylated ketones with the reagent **17** gives α-fluoro ketones **40** in high yields. The

silyl group is eliminated by treatment with ammonium fluoride.⁸⁶

R ¹	R ²	Yield (%)	Configuration of 40
Et	Et	97	<i>S</i>
Pr	Pr	97	<i>S</i>
Et	PhCH ₂	95	<i>R</i>
	(CH ₂) ₃	99	<i>R</i>
	(CH ₂) ₄	99	<i>R</i>

Synthesis of α -fluoro ketones with the reagent **17** has also been described by Padova *et al.*⁸⁷

The fluorinating reagent **17** was used for introducing fluorine into a molecule containing an azetidinone fragment.⁸⁸ Compound **41** is an intermediate in the synthesis of new antibiotics.

The fluorination of the azetidinone derivative **42** with the reagent **17** results in a mixture of stereoisomeric 3-fluoroazetidinones **43a,b** (yield 70%). The isomer ratio depends on temperature, *e.g.*, at 20 °C the **43a**:**43b** ratio is 85:15, whereas at -15 °C it is 95:5.⁸⁸

PMP is polymethylenepyridine.

Compound **17** is a very convenient reagent for diastereoselective fluorination of optically active substances. Thus the fluorination of a dianion generated from (-)-methyl 3-benzamido-3-phenylpropionate gives compound **43** with the *anti*:*syn* diastereomer ratio of 35:65.⁸⁹

Treatment of methyl phenylacetate with *N*-fluorodisulfonylamine **17** in the presence of hexamethyldisilazane in THF (1 h, -78 °C) yields methyl difluorophenylacetate.⁹⁰

Fluorination of alkylphosphonate anions with the reagent **17** results in monofluoro **44** and difluoro derivatives **45**.^{78, 79, 91, 92}

R	Yield of 44 (%)	Yield of 45 (%)
H	11	66
Bu	48	70
Me	45	66

Other *N*-fluorinating agents can also be used for preparing monofluoro derivatives of alkylphosphonates.^{72, 91}

Sodium enolate obtained by treatment of compound **46** with sodium bis(trimethylsilyl)amide is fluorinated with the reagent **17** to give the monofluoro derivative **47**.⁹² This method was also used for the synthesis of other fluoro derivatives of oxazolidinone.⁹³

Treatment with the reagent **17** of lithium derivatives of functionalised pyrroles **48** prepared from bromides **48** results in the fluoro derivatives **49**.⁹⁴

R¹, R² = Ar, Alk, CN; R³ = CH₂OEt, SiPr₃.

N-Fluorobenzo-1,3,2-dithiazole 1,1,3,3-tetroxide (**24**) is effective in fluorination of enolates and carbanions (Table 8).⁷² It is also used for stereoselective fluorination of chiral lithium enolates.⁶⁶

^a KHMDS, lithium bis(trimethylsilyl)amide (LiHMDS) and LDA were used to generate enolates and salts. ^b The fluorinating reagent was added to the enolate at 0 °C with subsequent warming to 20 °C. ^c After addition of the fluorinating reagent, the mixture was heated to 20 °C. ^d The fluorinating reagent was added to the enolate at –78 °C with subsequent warming to 0 °C. ^e The substrate was added to the fluorinating reagent at 0 °C.

5. The use of *N*-fluoro sultams

N-Fluoro sultams are obtained in high yields by the reaction of nitrogen-diluted fluorine (10% F₂ in N₂) with the corresponding sultams or their derivatives (direct fluorination in CHCl₃–CFCl₃ (1:1), 1 h, –40 °C, in the presence of NaF powder^{35,95–100}). *N*-Fluoro sultams are colourless crystalline compounds that are thermally stable and may be stored without decomposition for a sufficiently long period of time.

The fluorinating reagents **50a–d** were obtained by fluorination of the corresponding NH derivatives with FClO₃.¹⁰¹ Their structure was confirmed by X-ray diffraction analysis.⁷¹

R = Prⁱ (**a**), Bu^t (**b**), cyclo-C₆H₁₁ (**c**), Ph (**d**).

Yet another effective fluorinating reagent of this type is *N*-fluoro-3,3-dimethyl-2,3-dihydro-1,2-benzothiazole 1,1-dioxide (**51**).^{98–107} It is prepared using two main approaches, *viz.*, fluorination (10% F₂ in N₂) of *N*-trimethylsilyl-3,3-dimethyl-2,3-dihydro-1,2-benzothiazole 1,1-dioxide (yield 49%¹⁰⁵) and direct fluorination of the NH derivative in the presence of NaF. In the latter case, the yield of compound **51** reaches 74%.¹⁰⁵

(a) (Me₃Si)₂NH, Δ, 95%; (b) 10% F₂ in N₂, CFCl₃, CHCl₃, –40 °C, 49%; (c) 10% F₂ in N₂, NaF, CFCl₃, CHCl₃, –40 °C, 74%.

N-Fluoro sultams **52a–c** on the basis of bicyclo[2.2.1]heptane are synthesised in a similar way.^{95–99}

Compound 52	R ¹	R ²	Configuration	Yield (%)
a	H	Cl	(+)	80
b	H	H	(–)	75
c	Me	H	(+)	80

N-Fluoro-3,3-dimethyl-2,3-dihydro-1,2-benzothiazole 1,1-dioxide (**51**) is effective in fluorination of enolates and carbanions generated by strong bases.¹⁰⁵ The reaction is carried out in THF and yields a mixture of monofluoro and difluoro ketones (Table 9).

(a) B[–], THF, –78 °C; (b) **51**, THF, from –78 to 20 °C.

^a For the reagent **51**, $E^\circ = -0.12$. ^b Calculated for the SET process. ^c The reaction rate is too small to be measured. ^d No other reaction products were found. ^e 62% of naphthalene and 12% of naphthyltetrahydrofuran were isolated. ^f The fluorinated products were not characterised.

Enantioselective fluorination of lithium enolates can be carried out using optically active *N*-fluoro sultams of the type **51**.¹⁰³

$R^1 = \text{Me}$ (80% *ee*), Et (72% *ee*), Bn (86% *ee*); $R^2 = \text{Me}$, $R^3 = \text{Pr}^i$.

The rate of this reaction depends on the nature of the metal and the solvent. Thus propiophenone reacts with *N*-fluoro sultam **51** at -78°C , its sodium derivative reacts from -60°C to

-40°C , whereas the lithium derivative of propiophenone reacts only at temperatures above -40°C .

The rate constants of the fluorination of various compounds with the reagent **51** are listed in Table 10.¹⁰⁸

N-Fluoro sultams **52a–c** have found application as enantioselective fluorinating reagents (Table 11).^{95,96,99} The fluorination of enolates was carried out using 1.5 equiv. of the reagents **52a,b**. The ratio of enantiomers was determined by NMR spectroscopy with the use of a shift-reagent.^{95,96}

Table 11. Asymmetric fluorination of enolates with *N*-fluorosultams **52a,b**.^{95,96}

III. Highly efficient fluorinating reagents based on heterocyclic compounds containing a fluorine atom at the charged nitrogen atom

Synthesis of fluorinating reagents in which the fluorine atom is bound to the charged nitrogen atom of a heterocycle is one of the most fruitful ideas in the chemistry of organofluorine compounds. Two groups of reagents are mainly used, *viz.*, *N*-fluoropyridinium and *N*-fluoroquinuclidinium derivatives. This type of compounds (they are commonly referred to as charged or quaternary) are characterised by high reactivity which surpasses that of neutral reagents of the type R_2NF . The interest in these compounds is also due to the possibility to vary their structures to match a specific synthetic problem. Therefore, these reagents can be used for fluorination of a vast variety of substrates. It is not accidental that only charged fluorine 'carriers' have rapidly found industrial application.

1. Fluorination with *N*-fluoropyridinium salts

N-Fluoropyridinium salts are structurally the simplest and most readily available fluorine carriers of the type $(R_3NF)^+X^-$. Direct fluorination of pyridine and its derivatives with nitrogen-diluted fluorine (10% F_2 in N_2) in $CF_2ClCFCl_2$ results mainly in 2-fluoropyridines.¹⁰⁹

Substrate	$T/^\circ C$	Reaction product	Yield (%)
4-MeC ₅ H ₄ N	-25	2-F-4-MeC ₅ H ₃ N	31
4-EtC ₅ H ₄ N	-25	2-F-4-EtC ₅ H ₃ N	32
4-PrC ₅ H ₄ N	-25	4-F-4-PrC ₅ H ₃ N	47
4-PhCH ₂ C ₅ H ₄ N	-25	2-F-4-CH ₂ PhC ₅ H ₃ N	25
3,5-Me ₂ C ₅ H ₃ N	0	2-F-3,5-Me ₂ C ₅ H ₂ N	37
3,5-Cl ₂ C ₅ H ₃ N	25	2-F-3,5-Cl ₂ C ₅ H ₂ N	46
4-AcC ₅ H ₄ N	0	2-F-4-AcC ₅ H ₃ N	26
4-MeOCC ₅ H ₄ N	0	2-F-4-MeOCC ₅ H ₃ N	61

Earlier studies of Meinert and Cech^{110,111} showed that the fluorination of pyridine with a F_2/N_2 mixture in $CFCl_3$ at $-80^\circ C$ results in a pyridine-fluorine complex, *viz.*, *N*-fluoropyridinium fluoride. This compound manifests fluorinating activity at low temperatures (particularly, with respect to uracil and some chloro alkenes). It is very unstable and is decomposed explosively at temperatures above $-2^\circ C$. In practice, fluorination with *N*-fluoropyridinium fluoride can be carried out only at temperatures below $-20^\circ C$, which restricts the applicability of the method.

Attempts to replace the fluoride ion by other, less nucleophilic anions were undertaken aimed at obtaining stable *N*-fluoropyridinium salts. These studies are well documented.

Fluorination of pyridine and its derivatives in the presence of trifluoromethanesulfonic acid salts¹¹²⁻¹²² in aqueous acetonitrile¹²³ or in polyfluorinated alcohols¹²⁴ results in *N*-fluoropyridinium triflates **53a-h**.

$R_n = H$ (**a**, 80%), 2-Me (**b**, 60%), 2,4,6-Me₃ (**c**, 49%), 3,5-Me₂ (**d**, 73%), 4-NO₂ (**e**, 86%), 3,5-(CF₃)₂ (**f**, 68%), 4-CN (**g**, 94%), 2,6-(COOMe)₂ (**h**, 72%).

The salts **53** represent stable crystalline compounds which decompose without explosion only at, and above, melting points. They are soluble in organic solvents and do not react with glass. This class of fluorinating reagent has found wide application, particularly in fluorination of steroids, sugars and other natural compounds.

The range of stable fluorinating reagents on the basis of pyridine has been considerably extended¹²⁵⁻¹²⁸ owing to employment of salts (other than triflates) containing non-nucleophilic anions (BF₄⁻, PF₆⁻, SbF₆⁻) in their synthesis. This method was used for the preparation and characterisation (by ¹⁹F NMR) (see Refs 129-131) of numerous *N*-fluoropyridinium salts with different substituents in the pyridine ring and counterions. Thus the fluorination of pyridine with dilute fluorine ($F_2:N_2 = 1:4$) in the presence of trifluoromethanesulfonic acid in MeCN results in *N*-fluoropyridinium triflate (**53a**) in 97% yield.¹³¹

Other fluorinating reagents, *e.g.*, cesium fluoroxysulfate, can be used instead of fluorine.¹³³ Thus the reaction of pyridine with cesium fluoroxysulfate in acetonitrile ($0-5^\circ C$) in the presence of NaBF₄ results in stable *N*-fluoropyridinium tetrafluoroborate in 48% yield.

Internal pyridinium salts **54a-j** were synthesised by introduction of sulfo groups into the pyridinium ring.^{125, 134-136}

Compound 54	R ¹	R ²	R ³	R ⁴	R ⁵	Solvent	$T/^\circ C$	Yield (%)
a	Me	H	Me	H	SO ₃ ⁻	MeCN:H ₂ O (10:1)	-20	88
b	H	H	Me	H	SO ₃ ⁻	MeCN:H ₂ O (10:1)	-20	92
c	H	H	Et	H	SO ₃ ⁻	MeCN	-20	79
d	H	H	Bu ^t	H	SO ₃ ⁻	MeCN:H ₂ O (20:1)	-20	84
e	H	H	Me	H	SO ₃ ⁻	MeCN:H ₂ O (10:1)	-20	65
f	H	CF ₃	H	H	SO ₃ ⁻	MeCN	-20	90
g	H	CF ₃	H	Cl	SO ₃ ⁻	MeCN	-10	88
h	CF ₃	H	CF ₃	H	SO ₃ ⁻	MeCN	-40	95
i	H	H	H	SO ₃ ⁻	H	(CF ₃) ₂ CHOH	0	87
j	H	H	SO ₃ ⁻	H	H	(CF ₃) ₂ CHOH	0	74

The reaction is normally performed in MeCN; however, polyfluorinated alcohols $H(CF_2)_nCH_2OH$ ($n = 2, 3, 4$) can also be used as solvents. This approach was used to prepare *N*-fluoropyridinium-3-sulfonates (**54i,j**) (yields 87% and 74%, respectively).^{137, 138} Compounds **54** belong to the most potent fluorinating reagents. After completion of fluorination, the internal salts are converted into pyridinium sulfonates, which are readily soluble in water but poorly soluble in organic solvents, which facilitates the isolation of the target fluorination products and their separation from the products of degradation of the fluorinating reagent.

Umemoto *et al.*¹³⁹⁻¹⁴² synthesised *N,N'*-difluorobipyridinium salts by fluorination of bipyridine complexes with Lewis or Brønsted acids with nitrogen-diluted molecular fluorine (10% F_2 in N_2). The molecule of these salts has two mutually activating cationic centres.

$X = BF_4$ (**a**, 90%), TfO (**b**, 89%).

Compound 57	Reaction conditions		Yield (%)
	1st step	2nd step	
a	TfOH, MeCN	10% F ₂ in N ₂ , 20 °C	89
b	BF ₃ , MeCN	10% F ₂ in N ₂ , 0 °C	96
a	LiOTf, MeCN	10% F ₂ in N ₂ , CFCl ₃ , CHCl ₃ , –35 °C	67

The reagents **53**, **55**–**57** differ in their fluorinating ability as can be exemplified in the reactions with 2-acetylcyclohexanone.¹³⁹

Fluorinating reagent	53a	55b	56	57a
<i>t</i> / h	19	0.1	2	5
Yield (%)	79	85	78	87

Compound **55b** turned out to be the most reactive among other compounds tested. 1,1'-Difluoro-2,2'-bipyridinium bis(tetrafluoroborate) (**55a**) can be regarded as one of the most efficient reagents for industrial manufacture of fluorine-containing compounds by virtue of its high reactivity, high (in comparison with other reagents) content of the active fluorine and ease of synthesis.¹³⁹ Bis(tetrafluoroborate) **55a** efficiently fluorinates compounds containing an active methylene group as well as aromatic and other compounds.¹⁴⁰

Some *N*-fluorinating reagents, *e.g.*, *N,N'*-difluoro-2,2'-bipyridinium (**55b**) and *N*-methyl-*N'*-fluoro-4,4'-bipyridinium (**58**) bistriflates and *N,N'*-difluoro-2,2'-bipyridinium (**57a**) bistetrafluoroborate, proved to be very convenient reagents for fluorination of various types of organic compounds (Tables 12 and 13).^{142, 143}

The introduction of readily polymerisable groups into the pyridine ring of the reagents **55**–**57** allows one to obtain polymers with molecular masses above 500 000 Daltons. The latter are used as electrolytes (*i.e.*, as an active cathode mass) in batteries and as solid fluorinating agents.¹³⁷

Among quaternary (charged) fluorinating reagents, pyridinium salts present the greatest interest for investigators; therefore, the methods for their synthesis are permanently improved and the areas of application are extended.

Thus yet another approach to the preparation of fluorinating reagents on the basis of pyridinium salts consists in fluorination of the corresponding *N*-trimethylsilyl derivatives with fluorine in MeCN.

R_n = H (**a**, 78%), 3-Cl (**i**, 79%), 3,5-Cl₂ (**j**, 55%), 2-CO₂Me (**k**, 69%), 2,3,4,5,6-Cl₅ (**l**, 67%).

The fluorination of the pyridine–BF₃ complex with nitrogen-diluted elemental fluorine (20% F₂ in N₂) in MeCN or CCl₄ at room temperature results in the heptafluorodiborate of a pyridine–*N*-fluoropyridinium complex (**59**) rather than *N*-fluoropyridinium tetrafluoroborate, which is also an efficient fluorinating reagent.^{115, 118–121}

2,6-Dichloropyridine gives *N*-fluoro-2,6-dichloropyridinium tetrafluoroborate upon fluorination with elemental fluorine in a BF₃–HF–H₂O–MeCN system at –15 °C (yield 76%). The effect of temperature on the fluorination of pyridine with elemental fluorine in a CF₃SO₃H–MeCN system was estimated by Nukui.¹⁴³ At –20 °C, the yield of *N*-fluoropyridinium triflate was 92% after 30 days and at 40 °C it was 99%. Polyfluorinated secondary alcohols (RR'CHOH, where R,R' are C₁–C₄ fluoroalkyl) are used as solvents in the synthesis of the salts.¹³⁴

The fluorinating ability of *N*-fluoropyridinium salts depends not only on the nature of the substituent in the pyridine ring, but also on the nature of the counterion. The effect of the latter on the efficiency of fluorination of 1-trimethylsilyloxycyclohexene with *N*-fluoropyridinium salts has been studied by Umemoto *et al.*¹³⁴

^a In the presence of 20 mol. % of TfOH. ^b The reaction was carried out in AcOH. ^c The 2-F : 4-F : 2,4-F₂ ratio is 6.5 : 4.6 : 1. ^d The reaction was carried out in HCO₂H. ^e 50 mol. % of NaHCO₃. ^f The α : β ratio is 1 : 1.7. ^g The α : β ratio is 1 : 1.4.

The best results were obtained with *N*-fluoropyridinium triflates. They manifest high regio- and stereoselectivity in fluorination of aromatic compounds, compounds containing activated methylene groups, the Grignard reagents, sodium salts of CH-acids, vinyl acetates, enolates, alkyl and silyl enol ethers, organic sulfides, enamides, alkenes, *etc.*

X	<i>T</i> / °C	Time/h	Yield (%)
CF ₃ SO ₃	20	7	87
BF ₄	20	72	traces
BF ₄	36	64	1
SbF ₆	36	8	23
ClO ₄	36	19	0

Some examples of fluorination of organic compounds with *N*-fluoropyridinium triflates are given in Table 14.¹⁴⁴

The regioselective fluorination of enol esters and ethers with *N*-fluoropyridinium salts leads to α-fluorocarbonyl compounds.¹¹⁴ A modified general fluorination procedure has been proposed which consists in the conversion of a carbonyl compound into enol trimethylsilyl ether or enol acetate which is subject to fluorination.

α-Fluorinated carbonyl compounds are convenient as starting compounds in fine organic syntheses.^{130, 144–147} Thus the fluorination of the silyl ether **60** with the reagent **53a** yields a mixture of α- and β-fluoro ketones **61a,b**.^{116, 148}

N-Fluoropyridinium salts containing the BF₄[−], SbF₆[−] or PF₆[−] counterions give 2-fluoropyridines in good yields upon treatment with bases (Et₃N, Pr₂NH, Py, MeONa, Bu^tOK, MeCOONa, Bu₄NF) at room temperature.^{141, 149, 150}

On heating with *N*-fluoro-2,4,6-trimethylpyridinium triflate (**53b**) in the presence of NaOH, ethyl 2-oxocyclohexanecarboxylate is converted into ethyl 1-fluoro-2-oxocyclohexanecarboxylate (yield 84%). Five- and seven-membered cyclic fluorinated β-oxo esters are obtained in a similar way.^{123, 151}

n = 0–2.

Fluoro derivatives with a predetermined position of the fluorine atom can be synthesised using reagents of the type **53** or **54** for fluorination of steroids under various reaction condi-

Table 14. Fluorination of organic compounds with *N*-fluoropyridinium triflates **53a,b,j,l**.¹⁴⁴

tions.^{130, 144, 146, 147} Oxo steroids are preliminarily converted into *O*-silyl enol ethers.^{146, 147} In the case of α,β -unsaturated oxo steroids, these are to be first converted into trimethylsilyl enol ethers. The choice of a fluorinating reagent makes it possible to selectively synthesise a required isomer. Thus the reagent **54a** predominantly fluorinates the trimethylsilyl ether **62** at position 6, whereas the reagent **53a** leads to 6- and 4-fluoro derivatives in comparable yields.

Fluorination of 3,17-diacetoxyandrosta-3,5,16-triene (**63a**) with *N*-fluoropyridinium triflate (**53a**) occurs selectively and yields compound **65** with the fluorine atom in position 6. The corresponding silyl ether **63b** is selectively fluorinated into ring *D* to yield compound **66**.^{100, 117, 152–154}

3,17β-Diacetoxyandrosta-3,5-diene is converted into a mixture of 6α- and 6β-fluoro-17-acetoxystosterones (total yield ~ 81%) upon treatment with the reagent **53a** in acetic acid (3 h, 77 °C).¹⁵⁵

The stereo- and regioselectivity of fluorination of steroids with the reagent **53a** have been studied.^{115, 116, 143}

The reagent **53b** was used for stereoselective introduction of fluorine into the α-position relative to the carbonyl group of compound **68**. The ratio of enantiomers **69a,b** depends on the size of the substituent R.^{154, 155}

The use of reagents **53a,b** is not confined to fluorination reactions; they can also be used in the synthesis of *trans*-alkenes. Thus treatment of the Wittig reagents with *N*-fluoropyridinium triflate **53a** makes it possible to obtain the corresponding *trans*-alkenes under mild conditions and in acceptable yields.¹⁵⁶

R = COOEt (51%), CPh (50%), COMe (44%), 2-NO₂C₆H₄ (47%), 4-NO₂C₆H₄ (55%), 4-MeOC₆H₄CO (81%), 4-NO₂C₆H₄CO (71%).

The reaction of sulfides **70** with *N*-fluoro-2,4,6-trimethylpyridinium triflate (**53b**) yields sulfides **71** fluorinated at the methylene group.¹⁵⁷

Fluorination of β-oxo acid allyl ester **72** with *N*-fluoro-2,4,6-trimethylpyridinium triflate (**53b**) affords the α-fluoro derivative **73** in 84% yield.¹⁵⁸

N-Fluoro-3,5-dimethylpyridinium triflate (**53c**) and other salts with a substituted pyridine ring fluorinate aromatic compounds. Thus benzene is fluorinated with *N*-fluoro-2,6-dimethoxycarbonylpyridinium triflate to fluorobenzene (yield 56%); *N*-(ethoxycarbonyl)aniline gives a mixture of the corresponding 2- and 4-fluoro derivatives (yields 60% and 27%, respectively). Phenylurethane also yields fluorination products in positions 2 (47%) and 4 (32%) of the aromatic ring. The fluorination of anisole results in a mixture of *o*- and *p*-fluoroanisoles which points to the electrophilic nature of the fluorination reaction.^{129, 132, 158–161} The value of the electrochemical reducing potential ($E_p^c = -0.66$ V) of the *N*-fluoropyridinium cation also indicates that this cation is a strong electrophile.¹⁶²

Bockman *et al.*¹⁶⁰ studied fluorination of aromatic compounds with 3,5-dichloro-*N*-fluoropyridinium triflate **53j** on irradiation with UV light.

N-Fluoropyridinium sulfonates manifest high selectivity in fluorination of activated aromatic compounds. Thus fluorination of phenol, naphthol, *O*-trimethylsilylphenol and phenylurethane with the reagent **54j** results in the predominant formation of the corresponding *ortho*-isomers: for phenol, the conversion is 88% and the *ortho:para* ratio is 40:1; the *ortho:para* ratio for *O*-trimethylsilylphenol is 34:1; and 1-naphthol gives 63% of 2-fluoro-1-naphthol.^{114, 129}

Chloro- and bromophenols as well as *N*-acylhalogenoaniline are fluorinated with *N*-fluoropyridinium salts with high selectivity to give high yields of *ortho*-fluorination products. Thus the reaction of 4-chlorophenol with 2-chloro-6-trichloromethyl-*N*-fluoropyridinium tetrafluoroborate in $\text{ClCH}_2\text{CHCl}_2$ (3 h, 45 °C) gives 4-chloro-2-fluorophenol in 68% yield.¹⁶²

N-Fluoropyridinium triflates^{155, 163, 164} along with acetylhydropyruvate¹⁶⁵ are used for fluorination of biologically active compounds. Thus a mixture of 2-fluoro-17 β -estradiol (**74**) and 4-fluoro-17 β -estradiol (**75**) (total yield 60%) was obtained by fluorination of 17 β -estradiol in CH_2Cl_2 –MeCN (9:1) (12 h, 20 °C) with the reagent **53j**.

Estrol upon fluorination with *N*-fluoropyridinium triflate also yields a mixture of 2- and 4-fluoro derivatives (ratio 2.5:1, total yield 78%).^{155, 164}

Fluorination of dopamine derivatives **76a,b** and the dopamine analogue **77** with 3,5-dichloro-*N*-fluoropyridinium triflate (**53j**) proceeds under mild conditions and results in the corresponding fluoro derivatives **78a,b** and **79**.¹⁶³

Pentachloro-*N*-fluoropyridinium triflate (**53l**) proved to be efficient in fluorination of unsaturated acids containing a phenyl

substituent in positions 4 or 5 leading to fluorinated γ - and δ -lactones.¹⁶⁶

R	Yield (%)	Diastereomer ratio
H	69	
(<i>Z</i>)-Et	72	2.1:1
(<i>E</i>)-Et	51	1:2.4

N,N'-Difluoro-2,2'-bipyridinium- (**55b**) and *N,N'*-difluoro-4,4'-bipyridinium triflates (**57a**) react with 2-acetylcyclohexanone in boiling acetonitrile to give 2-acetyl-2-fluorocyclohexanone (yields 85% and 87%, respectively).¹⁶⁷ The reagent **57a** is more efficient in this case.

Treatment with *N*-fluoropyridinium salts was used for electrophilic fluorination of azulene and its derivatives.¹⁶⁸ Relatively low yields of fluorination products (14%–40%) are due to side reactions. In addition, a prominent role is played by the solvent. For example, the reaction of azulene with *N*-fluoro-4-methylpyridinium triflate **53b** in acetonitrile or CH_2Cl_2 gives a mixture of mono- (yields 12% and 3%, respectively) and difluoro derivatives (yields 17% and 5%, respectively). In dichloroethane, the yield of the monofluoro derivative is increased to 24%.¹⁶⁸

The heptafluoroborate of the *N*-fluoropyridinium pyridine complex (**59**) proved to be an excellent fluorinating reagent in the synthesis of monofluoro derivatives of various classes (Table 15).¹¹⁵ The reagent **59** is highly selective; the reactions occur under mild conditions.^{129, 136–140, 145}

More complex compounds can also be subject to selective fluorination without oxidation and decomposition. Highly selective *meso*-fluorination of porphyrins is effected with 2,6-dichloro-*N*-fluoro-pyridinium, 3,5-dichloro-*N*-fluoropyridinium and pentachloro-*N*-fluoropyridinium triflates.¹⁵³ This reaction is carried out in acetonitrile or hexafluorobenzene as solvents and K_2CO_3 or SrCO_3 as bases. The yield of the fluorinated product is low. For example, the tetrafluoro derivative **80** is obtained in 20% yield on boiling of octaethylporphyrin for 2 days in hexafluorobenzene.¹⁵³

Salts of *N*-fluoropyridinium and its derivatives have obvious advantages over other fluorinating reagents. They are stable, transportable and fit for long-term storage without any deterioration of their properties; besides, they are explosion-proof and non-toxic. The fluorination is performed under mild conditions and is not accompanied by side reactions, which is especially important for steroids, sugars and other biologically active compounds.

2. *N*-Fluoroquinuclidinium and 4-alkyl-1-fluoro-1,4-diazoniabicyclo[2.2.2]octane salts

Like *N*-fluoropyridinium salts, *N*-fluoroquinuclidinium salts belong to the most efficient fluorinating reagents of the *N*-fluoroamine series. The main method for their synthesis is direct fluorination of the corresponding NH-precursors.^{132, 169–176} *N*-

Table 15. Fluorination with the complex *N*-fluoropyridinium–pyridine (**59**) heptafluorodiborate in MeCN.¹¹⁵

^a The *cis*:*trans* ratio is 3:1. ^b The *cis*:*trans* ratio is 4:1.

Fluoroquinuclidinium fluoride (**81a**) was obtained in 83%–89% yield by direct fluorination of quinuclidine with 10% F₂ in CFCl₃ at –78 °C.^{169, 171, 175, 176} Later, preparation of *N*-fluoroquinuclidinium salts with other counterions was performed by fluorination of quinuclidine in the presence of the corresponding salts (the Umemoto method). With LiOTf, *N*-fluoroquinuclidinium triflate (**81b**) was obtained in 88% yield (fluorination in MeCN at –33 °C). The salts **81a,b** are non-hygroscopic compounds soluble in water and polar organic solvents;¹⁷ they are non-explosive and convenient for experimenting in glassware. The synthetic procedure is simple and gives high yields of target products.

X = BF₄ (**c**, 63%), CF₃CO₂ (**d**, 72%), n-C₃F₇CO₂ (**e**, 47%).

Scheme 1

The fluorination of 1-alkyl-1-azonia-4-azabicyclo[2.2.2]octane salts with elemental fluorine in the presence of alkali metal salts gives 4-alkyl-1-fluoro-1,4-diazabicyclo[2.2.2]octanes. Thus treatment of a mixture of 1-methyl-1-azonia-4-azabicyclo[2.2.2]octane (**82a**) and lithium triflate with elemental fluorine in acetonitrile (3 h, -35 °C) leads to 1-fluoro-4-methyl-1,4-diazabicyclo[2.2.2]octane triflate (**83a**) in 88%–94% yield.^{167, 176–182} The tetrafluoroborate **83b** is prepared in a similar way.

X	Compounds 82 , 83	Yield of 82 (%)	Yield of 83 (%)
TfO	a	86	84
BF ₄	b	98	94

1,4-Diazabicyclo[2.2.2]octane *N*-oxide can also be used as a starting compound. Its reaction with elemental fluorine in acetonitrile in the presence of BF₃·Et₂O or HBF₄ at 0 °C results in 75% of *N*-hydroxy-1-azonia-4-azabicyclo[2.2.2]octane tetrafluoroborate.¹⁸³

The *N*-fluoro derivatives **84a,b** and **85** containing one fluorine atom and the bisfluoro derivative **86** have been synthesised in which two bicyclic fragments are linked through a trimethylene bridge (Scheme 1).^{182–187} The structure of some of these salts has been confirmed by X-ray diffraction analysis. Thus the length of the N–F bond in compounds **84a** and **84b** is 1.406 and 1.37(2) Å, respectively.¹⁸⁵

Preparation of 1-fluoro-1,4-diazabicyclo[2.2.2]octanes **87** containing various functional groups at the second nitrogen atom involved treatment of 1,4-diazabicyclo[2.2.2]octane with reagents XY containing the corresponding functional group X and a good leaving group Y. In intermediates **88**, the anion Z is substituted for the leaving group Y. Then the salts **89** are fluorinated with elemental fluorine in inert solvents.^{183, 188}

X = OH, OR, OCOR, SO₃, SO₂R, NO₂, NO, P(O)(OR)₂;
Z = FSO₃, BF₄, PF₆, ClO₄, R₃SO₃.

The attempts to synthesise 1,4-difluoro-1,4-diazabicyclo[2.2.2]octane salts have long been unsuccessful. The synthesis of the reagent **90** could be carried out by fluorination of 1,4-diazabicyclo[2.2.2]octane with elemental fluorine in acetonitrile in

the presence of BF₃ and PF₅ or in acetone in the presence of BF₃.¹⁶⁹ Later, polyfluorinated alcohols [e.g., (CF₃)₂CHOH] and sulfuric acid were used as fluorination media (yield > 80%). Yet another convenient approach to the synthesis of the reagent **90** is the fluorination of the trimethylsilyl derivative **91**.^{179, 180, 182, 187}

Reagents of the type **81** efficiently fluorinate carbanions, the Grignard reagents and aromatic compounds.^{17, 166, 169, 175, 181, 182, 188–191} Some examples of fluorination of organic compounds with the reagent **81a** are given below:¹⁷⁶

R = Ph, X = Br (26%); R = cyclo-C₆H₁₁, X = Cl (20%).

Fluorobenzene is formed in 22% yield upon reaction of the reagent **81a** with phenyltrichlorosilane.¹⁶⁹

Such popular reagents as 1-fluoro-4-methyl-1,4-diazoniabicyclo[2.2.2]octane bistriflate (**83a**) and 4-chloro-1-fluoro-methyl-1,4-diazoniabicyclo[2.2.2]octane bistetrafluoroborate (**84b**) (commercial names, F-TedaBF₄ or SelectfluorTM) possess excellent fluorinating properties and physicochemical characteristics.^{177, 178, 189, 192}

The reagents **83a,b** and **84b** are highly efficient reagents for introducing fluorine into steroids, aromatic compounds, CH-acids and sulfides containing α -hydrogen atoms. These reactions occur under mild conditions and give high yields of fluorination products.^{132, 177, 178}

As a rule, fluorination of oxo steroids is performed using acetates or trimethylsilyl derivatives of the corresponding enols as substrates.^{192, 193} The yields and regioselectivity can be rather high. Fluorination of hydrocortisone, prednisolone and other oxo steroids with the reagent **84b** gives 6- or 16-monofluoro derivatives under extremely mild conditions.¹³²

Reaction of 3,17 β -diacetoxyandrost-3,5-diene with the reagent **84b** in a mixture of acetic acid and 1,2-dichloroethane (3 h, 77 °C) yields a mixture of 6 α - and 6 β -fluoro derivatives in 81% yield.

The advantages of the reagents **84b** over other fluorinating reagents are illustrated in Table 16.

Fluorination of Δ^4 - and $\Delta^{1,4}$ -3-oxo steroids with the reagent **84b** normally gives a mixture of 4- and 6-fluoro derivatives. The presence of a trimethylstannyl group at the multiple bond of the

Table 16. Fluorination of 3,17 β -diacetoxyandrost-3,5-diene.

Reagent	<i>T</i> / °C	<i>t</i> / h	Yield (%)	The α : β ratio
FCIO ₃	20	1	58	1 : 3
CF ₃ OF	−70		38	1 : 3
CF ₃ C(O)ONa, F ₂	−78	0.25	70	3 : 5
MeC(O)OF	−78	0.25	61	1 : 2
53a	40	10	71	1 : 2
84b	20	0.15	95	2 : 3

steroid allows the introduction of fluorine atoms under mild conditions and in a more selective manner. The yields of 4-fluoroandrost-4-ene-3,17-dione and 17-*O*-benzoyl-4-fluorotestosterone prepared by this method are about 50% and the results obtained are not much lower than those obtained with cesium fluoroxysulfate¹⁹⁴ which is potentially explosive.¹⁹⁵ Fluorination with the reagent **84b** can be used for introducing the isotope ¹⁸F into steroids.

Fluorodestannylation with reagent **84b** is rather widely used in stereospecific syntheses of complex fluoroalkenes.¹⁸⁴

Fluorination of 1-tosylindole **92a** with the reagent **84b** in MeCN–MeOH leads to 3-fluoro-2-methoxy-1-tosyl-2,3-dihydroindole **93** in 48% yield.¹⁹⁶ The *trans*-arrangement of the substituents in the reaction product has been confirmed by X-ray diffraction analysis. In this case, the reaction occurs as conjugated vicinal fluoromethoxylation. The substitution of fluorine for the trimethylstannyl group in the derivative **92b** occurs under the action of reagent **84b** in acetonitrile to give compound **94** in 21% yield.¹⁹⁶

R = H (a), Me₃Sn (b).

Some other reactions of this kind are documented.^{41, 177, 178, 197, 198}

The fluorination of ethyl 1-indanone-2-carboxylate and methyl 5,7-difluoro-1-indanone-2-carboxylate with the reagent **84b** leads to ethyl 2-fluoro-1-indanone-2-carboxylate (yield 80%) and methyl 2,5,7-trifluoro-1-indanone-2-carboxylate (yield 83%).¹⁹²

The fluorination of methyl and menthyl 1-tetralone-2-carboxylates and 1-indanone-2-carboxylates with the reagent **84b** affords the corresponding α -fluoro esters **95** in high yields.¹⁹⁹

n = 0, 1; R = Me, menthyl.

The oxidation of hydroxy compounds was studied in order to determine the activity of fluorine in the fluorinating reagents **17**, **59** and **84b**. It was found²⁰⁰ that the reagent **84b** quantitatively oxidises hydroquinone to *p*-benzoquinone (2 h, 25 °C). The yield of *p*-benzoquinone upon treatment with the reagent **17** is low (30%), whereas the reagent **59** does not react with hydroquinone under these conditions.

Treatment of acyclic and cyclic 1,3-diketones, β -oxo esters and β -oxo amides with the reagent **84b** results in the corresponding mono- and difluoro compounds.^{189, 190} Selective fluorination of β -dicarbonyl compounds with the reagent **84b** is used to obtain biologically active compounds.¹⁸⁸

Petasis *et al.*²⁰¹ have developed a new procedure for the synthesis of alkenyl fluorides **96**, substituted alcohols **97** and difluoroalkylamides **98**, which is based on fluorination of alkenylboric acids with the reagent **84b** in the presence of boron trifluoride.

The reaction of the tetrafluoroborate **84b** with cyclopentadienylthallium affords 5-fluorocyclopentadiene, which was not isolated but its formation was confirmed by identification of cycloaddition products to acrylates **99a,b** and dimethyl acetylenedicarboxylate (**100**).²⁰²

$\text{R}^1 = \text{Cl}$, $\text{R}^2 = \text{CN}$ (**a**, 18%); $\text{R}^1 = \text{H}$, $\text{R}^2 = \text{CO}_2\text{Me}$ (**b**, 17%).

Fluorination of unsaturated compounds with the reagent **84b** occurs in accordance with the Markownikoff rule. The reaction begins with the addition of the pseudo-positive fluorine to the multiple bond and generation of an intermediate carbocation. Its outcome depends on the presence of other nucleophiles in the system. Thus the tetrafluoroborate **84b** reacts with styrene, α -methylstyrene and stilbene in MeCN in the presence of H_2O , AcOH and MeOH, which are involved into the reaction.^{7, 203, 204}

As can be seen from the data of Table 17, the rate of methoxyfluorination of substituted alkenes increases with a decrease in their ionisation potential which is in favour of the ionic mechanism of the reaction.

In the fluorination of phenylacetylenes with the tetrafluoroborate **84b** in aqueous acetonitrile, the addition of fluorine to the triple bond is accompanied by the addition of water. This reaction occurs with high regioselectivity and yields α,α -difluoroketones. It was shown that the nature of the alkyl substituent in phenylacetylenes influences only the fluorination rate without any effect on the yield of the final products.^{197, 198, 205}

The reagent **84b** was also used for fluorination of tertiary alcohols. In this case, substitution of fluorine for the hydrogen atom of the methyl group occurs to give β -fluoroalkanols **101**.

Table 17. Relative rates of methoxyfluorination of some alkenes with the reagent **84b** in MeCN.²⁰³

^a Hereinafter k is the relative reaction rate constant with respect to that of 1,1-diphenylethylene.

R = Me, Ar'.

Reaction of the reagent **84b** with some carboxylic acids can occur as fluorodecarboxylation. The possibility of synthesis of fluoro derivatives from the corresponding carboxylic acids is especially important in the furan and pyrrole series. Until very recently, fluorinated furans and pyrroles were not considered to be readily accessible compounds, although they have always attracted attention as starting compounds for the synthesis of fluorinated analogues of natural bactericides. In this particular case, fluorinated reagents with the N–F bond proved to be more efficient than other reagents, in the first place, the elemental fluorine. For example, the reaction of 3-bromofuran-2-carboxylic acid (**102**) with the reagent **84a** in a biphasic system aqueous CCl_4 – NaHCO_3 yields 3-bromo-2-fluorofuran.²⁰⁶

Pyrrole-2-carboxylic acids containing electron-donor substituents give the corresponding 2-fluoropyrroles upon treatment with the reagent **84b** (yields 32%–47%).

Tetronic acid derivatives attract attention in connection with the presence of its fragment in some natural biologically active compounds. Direct fluorination of 2-deoxy-L-ascorbic acid (**103**) with the reagent **84b** afforded only traces of the 2-fluoro derivative **104**.^{207, 208} When the reaction is performed in ethanol, a product of fluorine and the ethoxy group addition to the double bond (compound **105**) is formed. Compound **104** could only be obtained by treatment of the bromofluoro derivative **106** with tributyl-tin hydride (yield 49%).

In the reaction of (–)-menthol with the reagent **84b** in acetonitrile, the hydrogen atom at the tertiary exocyclic carbon atom is selectively substituted by fluorine. Presumably, the further

course of this reaction involves the substitution of the fluorine atom with participation of the solvent. Subsequent saponification leads to the reaction product **107**.²⁰⁹

Fluorination of chiral β-oxo sulfoxides **109** with the compound **84b** resulted in a mixture of diastereoisomeric α-mono-fluoro chiral compounds **110**.²¹⁰ The formation of α,α-difluorinated products is also possible.

R	Me	Ph	2-pyridyl	4-pyridyl	CH ₂ F	CHF ₂	CF=CHPh

Benzene derivatives containing electron-donor substituents are fluorinated with the reagent **84b**.^{7, 147, 188, 198, 199} The fact that fluorine occupies the *ortho*- or *para*-position testifies to the electrophilic nature of the reagent.

Fluorination with the reagent **84b** can be accompanied by oxidation of functional groups. For example, substituted benzyl alcohols and aromatic aldehydes give the corresponding benzaldehydes or benzoic acids.²¹¹

Polycyclic aromatic compounds (biphenyl, naphthalene, anthracene, phenanthrene) and their derivatives give monofluoro derivatives.^{174, 198} The fluorination of azulene and its derivatives with the reagent **84b** affords a mixture of mono- and difluoro derivatives.²¹²

R	Yield of the monofluoro derivative (%)	Yield of the difluoro derivative (%)
H	34	3
6-Pr ⁱ	27	8
4,6,8-Me ₃	12	2

Regioselective fluorination of anthraquinone derivatives with the reagent **84b** presents interest for the synthesis of biologically active compounds.²¹³

Reactions of the reagent **84b** with uracil, thymidine and nucleosides in the presence of an external nucleophile occur as conjugated addition. Thus 5-fluoro- (**111**) and 5,5-difluoro-6-hydroxy-5,6-dihydroxyuracils (**112**) were obtained from uracil.²¹⁴

Uracil and thymidine derivatives give compounds **113** in high yields.²¹⁴

2',3',5'-Tri-*O*-acetylcytidine is fluorinated in MeCN in the presence of methanol to give the difluoromethoxy derivative **114**.^{188, 214, 215}

The reagent **84b** is used in iodination of aromatic compounds.²¹⁶ Thus treatment of alkylphenyl ethers and *para*-substituted anisoles with iodine in the presence of an equimolar amount of the reagent **84b** affords monoiodo derivatives in high yields.

R = Me (89%), PhCH₂ (90%), Ph (80%).

R = F (87%), Cl (89%), Br (91%), I (88%), Ac (90%), CHO (85%), Bu^t (92%).

N-Fluoroquinuclidinium (**81c**), *N*-fluoropyridinium (**53a**) and *N*-fluoro-2,4,6-trimethylpyridinium (**53c**) tetrafluoroborates were obtained in sufficiently high yields by fluorination of the corresponding bases with the reagent **84b**.²¹⁷

Properties of 1-fluoro-4-hydroxy-1,4-diazoniabicyclo[2.2.2]octane bistetrafluoroborate (**115**) (commercial names, NFTh and AccufluorTM) are similar to those of the reagent **84b**. This compound fluorinates the same substrates in high yields and with high stereoselectivity. The reagent **115** can be obtained by fluorination of 1,4-diazabicyclo[2.2.2]octane *N*-oxide with elemental fluorine in acetonitrile at 8 °C in the presence of BF₃·Et₂O and HBF₄ (yield 75%).^{183, 218} This fluorinates naphthalene to 1-fluoronaphthalene, phenanthrene to 9-fluorophenanthrene and pyrene to 1-fluoropyrene²¹⁹ but is less stable. It was shown^{206, 220} that the stability of fluorinating reagents in water, acetonitrile, alcohols and aqueous alkali decreases in the following order: **17** > **84b** > **115**.

Fluorination of unsaturated compounds with the reagent **115** in the presence of alcohols occurs as the conjugated vicinal fluoroalkoxylation; the formation of monofluoro derivatives occurs with high regioselectivity (Table 18).²²¹

Treatment of alkenes with the reagent **115** in acetonitrile results in the corresponding fluorinated amides.²²²

Table 18. Fluorination of substituted styrenes with the reagent **115**.²²¹

X = COCH₂OAc.

The reactivities of the fluorinating reagents **84b**, **115** and *N*-fluoro-2,6-difluoropyridinium tetrafluoroborate in the fluorination of dibenzofuran, diphenyl ether and biphenyl were found to be similar. *ortho*-Isomers are predominant in the reaction products.¹⁷⁴

IV. Some examples of fluorination with inorganic tetrafluoroammonium salts

Inorganic tetrafluoroammonium salts (*e.g.*, NF₄BF₄, NF₄SbF₆) are formal analogues of organic *N*-fluoro derivatives.

Christe *et al.*^{227,228} showed that NF₄BF₄ fluorinates benzene and its derivatives in anhydrous HF to give fluorinated products.

The fluorination of nitrobenzene results in substitution of both the hydrogen atoms of the benzene ring (the predominant formation of the *meta*-isomer testifies to electrophilic substitution) and the nitro group, resulting in fluorobenzene. The reaction of tetrafluorobenzene, pentafluorobenzene and hexafluorobenzene with NF₄BF₄ gives perfluorocyclohexadienes, *i.e.*, in this case, fluorine adds to the multiple bonds.^{227–229}

R = H, F.

Among inorganic fluorinating reagents, nitrosyl fluoride is worthy of note. This compound is a low-boiling highly toxic gas, and its application as a fluorinating reagent is very limited. Nitrosyl fluoride was used for fluorination of cholesteryl acetate **116** to give 5 α -fluoro-6-nitroimine **117** in high yield. The latter was further converted into the corresponding ketone **118**.²³⁰

Fluorination of steroidal vinyl fluorides with nitrosyl fluoride leads to α,α -difluoro ketones *via* the intermediate nitroimines.^{231,232}

Prakash *et al.*^{233, 234} proposed to use the Olah reagent (hydrogen fluoride in pyridine) for the activation of nitrosyl fluoride. This results in a highly active fluorinating reagent which fluorinates many organic compounds. Thus the fluorination of ketoximes and thioacetals affords the corresponding *gem*-difluoro derivatives, while alkynes and alkenes are fluorinated to tetrafluoro- and trifluoroalkanes in sufficiently high yields. Interestingly, fullerene C₆₀ is polyfluorinated with nitrosyl fluoride. Treatment of alkyl phenyl sulfides with this reagent affords products of substitution of the hydrogen atoms of the alkyl group by fluorine atoms.^{233, 234}

V. On the mechanism of fluorination with *N*-fluoroamines and their analogues

The experimental data concerning the use of *N*-fluoroamines and their analogues in organic synthesis altogether suggest that these compounds are electrophilic fluorinating agents. Inasmuch as the formation of F⁺ is a thermodynamically very unfavourable process and this species is very unstable and can be detected only by spectral methods in the gas phase, the formation of F⁺ in fluorination is hardly probable.^{132, 184} This contradiction has led to an idea of specific polarisation of the N–F bond with the appearance of a partial positive charge on the fluorine atom, *i.e.*, the concept of ‘pseudo-positive’ fluorine. However, the idea that *N*-fluorinating reagents are the sources of ‘pseudo-positive’ or ‘electrophilic’ fluorine does not contribute any rationale to the real mechanism of fluorination. However, *N*-fluoro reagents can also be regarded as sources of the fluorine radical the existence of which is established (see Ref. 175). The oxidising properties of *N*-fluorinating reagents, particularly their ability to displace iodine from inorganic iodides (this reaction is of analytical importance) is attributed to the electrophilic nature of the fluorine radical.

As a matter of fact, the mechanistic studies of fluorination available are aimed at establishing whether this occurs as single-electron transfer (SET), nucleophilic substitution at the fluorine atom (S_N2) or both.

In considering the mechanism of fluorination, one should take into account that *N*-fluorinating reagents comprise two groups of compounds, which differ basically in their structures, *viz.*, R₂NF and [R₃NF]⁺A[−]. In addition, the role of nucleophiles can be played by compounds of various classes (*e.g.*, aromatic, unsaturated, organometallic, *etc.*), whereas the term ‘fluorination’ embraces various types of reactions (substitution, addition, *etc.*).

Hence, all the plausible mechanisms of fluorination can in general be realised. The mechanism established in a specific study may be true only for the particular group of *N*-fluorinating reagents and substrates and for the particular reaction types that had been studied.

Differding *et al.*^{106, 108, 235, 236} who studied the fluorination of various substrates with *N*-fluoro sultam **51** attempted to distinguish between S_N2 and SET mechanisms. To this end, they compared experimental rate constants with those calculated theoretically within the single-electron transfer theory. These calculations were based on the known standard redox potentials, *E*^o, and Marcus rearrangement energies for both reactants.

As can be seen from Table 10, the values of experimental constants are by many orders of magnitude higher than might be expected based on the electron transfer concept, *i.e.*, the reaction does not occur as a single-electron transfer. Correspondingly, the S_N2 mechanism is realised in this case.

The reaction of an ester enolate (derived from citronellate) with *N*-fluoro reagents leads exclusively to the products of electrophilic fluorination at the carbon atom of the carbanion centre. This finding provides additional support in favour of the S_N2 mechanism.^{108, 235} If the reaction proceeded as a single-electron transfer, the substrate would undergo oxidation with subsequent cyclisation.

However, there are literature data in favour of the SET mechanism. This process is partly realised in fluorination with XeF₂, which is known to react by a radical mechanism. The electrochemical reduction of *N*-fluoro sultam **51** results in electron transfer, which is accompanied by simultaneous cleavage of the N–F bond with elimination of the fluoride anion and reduction of the reagent **51** to the radical **119** and further to the amide anion **120**.^{106, 108, 235}

The electrochemical reduction of *N*-fluoro sultam **121** containing a nitro group in the benzene ring yields a radical anion as an intermediate.

According to Differding *et al.*,²³⁵ this step is characteristic of compounds showing high electron affinity.

It should be noted that reactions of *N*-fluoro sultam **51** with nucleophiles (see Table 10) follow the S_N2 mechanism.

In studies of photochemical electrophilic fluorination of aromatic compounds^{160, 161} it was concluded that the reaction occurs through the initial formation of a donor-acceptor complex, since the UV spectra contain absorption bands characteristic of a charge transfer complex (CTC).

The excitation energy, $h\nu_{CTC}$, is correlated with the ionisation potential of the aromatic donor. With a decrease in IP , $h\nu_{CTC}$ decreases favouring the electron transfer, as a result of which the substrate becomes potentially more reactive in electrophilic fluorination where the complex is converted into the final reaction products.

A mechanism involving the formation of CTC was also proposed by Des Marteaux *et al.*⁸⁰ who studied fluorination with $(CF_3SO_2)_2NF$ (**14a**).

The study into the single-electron transfer mechanism carried out by Umemoto *et al.* (see Ref. 144) was based primarily on the analysis of the composition of fluorination products. The concept of the single-electron transfer, which implies the formation of the fluorine radical, was used for rationalisation of various fluorination processes, *viz.*, reactions of *N*-fluoropyridinium salts with anions, neutral substrates, the Grignard reagents, alkenes, aromatic compounds, *etc.*

According to Umemoto, three different mechanisms can be realised in the fluorination of unsaturated compounds, *viz.*, a single-electron transfer, classical electrophilic addition and a purely radical mechanism.

In accordance with one of these schemes, the first step of this reaction envisages the formation of a π -complex between the fluorinating reagent and the enol ester/ether.

Further reactions can follow two different routes, *viz.*, transfer of fluorine to the substrate and transfer of the radical R to the pyridinium salt (route *a*) and the addition of the pyridinium salt to the substrate (route *b*).

Fluorination can also occur through the intermediate formation of a radical cation from the unsaturated system and radical anion from the fluorinating reagent.

It should be noted that the experimental data currently available do not contradict these schemes. Thus the regio- and stereoselectivity of alkene fluorination fits well into the mechanism of formation of a fluoro carbocation as an intermediate species.^{7, 79, 175} Alkenes in which the intermediate carbocation cannot be stabilised by substituents (*e.g.*, oct-1-ene or cyclohexene) do not react with the fluorinating reagent **84b**. As expected, polar solvents that favour the formation of a complex between the substrate and the fluorinating reagent facilitate fluorination.

The generation of intermediate radical species from fluorinating reagents is confirmed by the formation of products of their reaction with the radicals present in the system. The formation of radical anions is confirmed by their capture with 1,4-benzoquinone.

The introduction of electron traps suppresses the conversion of alkenes. Thus the conversion of *trans*- β -methylstilbene in the reaction with $(CF_3SO_2)_2NF$ decreases from 100% to 80% in the presence of 1,4-dinitrobenzene

The fluorination of benzyl citronellate (**122**) with *N*-fluorinating reagents gives a mixture of α -mono- (**123**) and α,α -difluoro derivatives (**124**), which points to the electrophilic nature of the reagent, whereas the reaction with XeF_2 affords the cyclic product **125** typical of radical fluorination (Scheme 2).²³⁵

^a The figures in parentheses refer to the yields of the isolated compound.

VI. The effect of the solvent in fluorination reactions with *N*-fluoro amines and their analogues. Comparative reactivities of fluorinating reagents containing the N–F bonds

Despite the evident role of the medium in fluorination reactions, the data accumulated in this area have not yet been adequately generalised and analysed in the literature. Systematic studies in this field have been undertaken comparatively recently by Solkan and Fainzilberg.^{237–239}

A programme for quantum-chemical calculations aimed at quantitation of various effects of the solvent (the effect of solvation, in particular) on the thermodynamic parameters of the fluorination reaction was elaborated. This programme utilises both the point dipole model and the polarising continuum model in the framework of semi-empirical quantum-chemical methods (MNDO, AM-1, MNDO-PM3).

The studies^{237, 239} were carried out with *N*-fluoropyridinium salts, which are readily available compounds. Their fluorinating ability varies over a wide range depending on the electronic and steric characteristics of substituents (NO_2 , SO_2F , CF_3 , CO_2Me , F, Cl, Br, Me, CO_2H , SO_2OH , CO_2^- , SO_3^-) whose position and number can be varied. Unsubstituted pyridine was selected as a substrate.

The reaction of *N*-fluoropyridinium salts with non-substituted pyridine is convenient because it allows comparison of the reactivities of fluorine carriers both with each other and with that of a classical fluorinating reagent such as the *N*-fluoropyridinium cation. If the enthalpy of the reaction is negative, a given fluorine carrier surpasses *N*-fluoropyridinium in the fluorinating ability; in the case of positive enthalpy, it is inferior to the latter.

In order to establish the criterion of fluorinating activity (the thermal effect, ΔH) of an exchange reaction in the gas phase, $\Delta H(g)$, and in polar solvents, $\Delta H(s)$, the authors calculated the corresponding enthalpies of formation of the reactants with account of the solvent effect within the framework of the point

Table 21. Thermodynamic parameters of the fluorination of pyridine with *N*-fluoropyridinium salts.²³⁷

Fluorinating reagent	$\Delta H(g)$ /kcal mol ⁻¹	$\Delta H(s)$ /kcal mol ⁻¹	Fluorinating reagent	$\Delta H(g)$ /kcal mol ⁻¹	$\Delta H(s)$ /kcal mol ⁻¹
	16.0	10.6		7.9	5.8
	31.9	26.9		8.1	7.6
	43.1	36.8		-76.4	35.8
	-2.6	0.4		-91.6	24.7
	-4.9	0.9		-79.0	38.9
	-7.6	0.9		-101.1	22.0

dipole model [$\Delta H_f(g)$ and $\Delta H_f(s)$]. The results of this study are summarised in Table 21.^{237, 239}

An analysis of experimental data^{237, 239} and some results presented in Table 21 allow the following conclusions about the role of solvation in fluorination with *N*-fluoropyridinium salts.

1. In strongly polar solvents, the $\Delta H(s)$ values are higher (CO₂Me, Cl, Br, Me) or lower (NO₂, F, CF₃, SO₂F) than those in the gas phase.

2. The additivity of the substituent effects holds to considerable extent.

3. The largest increase in ΔH in the transition from the gas to the liquid phase is observed for internal *N*-fluoropyridinium salts containing the CO₂⁻ and SO₃⁻ groups as substituents. In the latter case, the effect is so strong that it can be attributed to the crucial role of solvation in the fluorination reaction.

However, the fluorinating ability of *N*-fluoropyridinium salts containing uncharged substituents in the ring depends on the number of substituents and their electronic effects rather than on the solvation effect. In order to increase the fluorinating activity of a compound containing uncharged substituents up to the level of internal *N*-fluoropyridinium salts, it is necessary to introduce not less than three electron-accepting nitro groups into the molecule (see Table 21). Hence, the introduction of a substituent able to form an internal salt into *N*-fluoropyridinium salt and the use of polar solvating solvents is a simpler procedure, which enhances the fluorinating activity of the reagent.

Solkan and Fainzilberg²⁴⁰ have established the activation barriers for the reaction of *N*-fluoropyridinium salts with pyridine. These calculations made it possible to select the most plausible transition states and to calculate the activation energies (E_a) in a highly polar solvent. Comparison of E_a values and enthalpies of fluorination in solutions $\Delta H(s)$ has revealed their nearly linear dependence, *e.g.*, an increase in the heat of reaction by 3 kcal mol⁻¹ was accompanied by the decrease in the activation barrier by ~ 1 kcal mol⁻¹. Thus, the heats of fluorination reactions can be used in estimation of the corresponding activation energies without determination of the structure of the transition state.

Other types of *N*-fluoro derivatives extensively employed in recent synthetic studies have also been studied.²³⁹ The calculations were performed by a semi-empirical quantum-chemical method

(MNDO-PM3) using a polarising continuum model.²⁴¹ The thermal effects of analogous reactions were calculated for comparative assessment of fluorinating activities of various fluorine carriers in solvents of different polarities.

The calculation of enthalpies of formation of the reagents and the reaction products in the gas phase [$\Delta H_f(g)$] and in solution [$\Delta H_f(s)$] is an indispensable step in the calculation of ΔH . In the latter case, the calculations of the Gibbs energy of solvation were carried out for charged molecules. The results of these studies are summarised in Table 22.

As can be seen from these data, the fluorination reactions (1)–(5) are exothermic even if solvents of medium polarity ($\epsilon = 10$) are used. This implies that the reagents **14a**, **f**, **54**, **57** and **83** surpass *N*-fluoropyridinium in fluorinating activity. An increase in the solvent polarity results in manifestation of difference in the behaviour of compounds **14a**, **f**, **54** and **57a**, **83**. For the

Reaction	$-\Delta H(s)/\text{kcal mol}^{-1}$			
	$\varepsilon = 10$	$\varepsilon = 20$	$\varepsilon = 30$	$\varepsilon = 78$
(1)	-14.7	-21.9	-24.7	-27.8
(2)	-17.6	-13.6	-12.2	-10.4
(3)	-45.7	-40.4	-38.6	-36.4
(4)	-14.5	-21.3	-23.6	-26.6
(5)	-29.7	-36.1	-38.4	-41.2

On the whole, the approach to the study of the solvent effects in fluorination reactions²³⁷⁻²⁴⁰ holds great promise, for the information it provides is comprehensive. This approach makes it possible: (i) to obtain the main thermodynamic characteristics of the fluorination reaction, viz., its thermal effect, which serves as a basis for quantitative evaluation of the fluorinating activity of fluorine carriers in various solvents; (ii) to determine the values of heats of solvation for all reactants (the starting compounds and reaction products); (iii) to perform comparative analysis of heats of reaction in order to evaluate the differences in fluorination rates for various reagents and in different solvents. The use of this

It is of note that $E_{1/2}$ seems to be a more reliable criterion than E_{redox} . According to recent data,²⁴⁴ in some cases it is difficult to

determine E_{redox} with a sufficiently high degree of reliability because of broad maxima on the electrochemical wave curves. Differding and Bersier²⁴³ also hold this viewpoint and offer an original approach to the estimation of the fluorinating ability of *N*-fluoro reagents. This approach is based on a semi-empirical quantum-chemical calculation of the 'reductant couple' (the original term introduced by the authors), $\Delta H_f^\circ(\text{R}_3\text{N}) - \Delta H_f^\circ(\text{R}_3\text{N}^+ \text{F}^-)$; however, a consistent scale of relative reactivities could be obtained only for structurally related compounds, *e.g.*, of the pyridinium series.²⁴⁵

On the whole, all presently known attempts to create scientific grounds for comparative quantitative assessment of the fluorinating activity of various *N*-fluoro reagents are represented by the examples described in this section. A wealth of quantitative estimates is scattered over numerous synthetic papers which mainly emphasise the crucial role of the *N*-fluorinating reagent structure on fluorination.

VII. Conclusion

The data surveyed in this review demonstrate the intensive development of the chemistry of fluorine carriers in the past

decades. Fluorination with *N*-fluoro reagents has stimulated the research in the field of fluorine chemistry as a whole and provided a basis for fine organic synthesis, the synthesis for organofluorine compounds of medicinal purposes, in particular. A technology for the production of a series of fluorine carriers has been developed by leading chemical companies of the USA, Great Britain and Japan. The main characteristics of some commercially available *N*-fluoro reagents are given in Table 24.

III. Condensation polymers with low dielectric constants	686
IV. Thermostable polymeric foams	693
V. Conclusion	694

Abstract. The review considers factors that determine the dielectric properties of the medium as well as the basic approaches to the preparation of film materials with low dielectric constants based on condensation polymers that contain fluorinated and/or alicyclic units and of polymeric nanofoams. The bibliography includes 147 references.

I. Introduction

Nowadays, the problem of creating film materials with reduced dielectric constants which can be used as interlayer dielectrics (ILD) in packages of multiintegrated circuits is becoming ever more topical.^{1,2} It is known that the velocity of electrical pulses is inversely proportional to $\varepsilon^{1/2}$, where ε is the dielectric constant (DC) of the medium.^{3,4} In addition, the minimum distance between the lines in integrated circuits is limited by 'noises' arising because of the 'cross effect' dependent on the DC of the insulating material, *i.e.*, currents elicited in conductors near the active signal lines. For this reason, a decrease in ε results in the reduction of the machine cycle, and it becomes possible to increase the density of integrated circuits. One of the materials most widely used for ILD is silicon dioxide for which ε ranges from 4 to 10 depending on moisture content. Materials with ε values lower than that of SiO₂ are divided into four basic groups:⁴

- SiO₂ modified by fluorine treatment ($\varepsilon = 3.0$ – 4.0);
- organic polymers ($\varepsilon = 2.0$ – 3.0);
- nanofoms of organic polymers ($\varepsilon = 1.1$ – 3.0);
- SiO₂ aerogels ($\varepsilon = 1.1$ – 4.0).

Additionally, the materials for ILD should meet the requirements for manufacture technologies and operation of circuit elements. These include high thermal stability and mechanical strength in combination with low thermal expansion and residual stress in the thermal cycle. Organic condensation polymers meet these requirements the best, and this review is devoted to the analysis of major achievements in these directions.

II. Factors influencing the dielectric constants of polymers

The dielectric constant of polymers is mainly influenced by their free volume,⁵ polarisability⁶ and hydrophobicity.⁷

An increase in the free volume may be regarded as replacement of a portion of a polymer ($\varepsilon \simeq 3$) by air ($\varepsilon = 1$) resulting in a decrease in DC of the material.

The ε value of any material is proportional to the total polarisability (α_{tot}), and ε increases with the increase in α_{tot} . The total polarisability includes components of three types of polarisation: electronic (α_e), atomic (α_a) and resulting from dipole orientation (α_0):^{5–8}

$$\alpha = \alpha_e + \alpha_a + \alpha_0.$$

The total dielectric constant ε is also the sum of increments related to each type of polarisation

$$\varepsilon = \varepsilon_e + \varepsilon_a + \varepsilon_0.$$

Electronic polarisation is determined by a slight deviation from the equilibrium distribution of electrons relative to the positively charged nuclei with which they are associated.^{5–8} As this process includes only the motion of electrons, it can occur very fast, and usually the time constant is $\sim 10^{-13}$ s. At optical frequencies, where only optical polarisation can take place, the Maxwell equation operates:

$$\varepsilon = n^2,$$

where n is the refractive index.

Atomic polarisation results from changes in the disposition of atomic nuclei under the action of an electric field. This type of polarisation is characterised by a typical time constant of $\sim 10^{-13}$ s. For solid organic compounds, the contribution of α_0 to the total polarisation accounts for $\sim 10\%$ of α_e .^{5–8}

The polarisation resulting from dipole orientation is the consequence of redistribution of charges, *i.e.*, reorientation of a group of atoms with a constant dipole moment in space under the action of an electric field. Since reorientation involves large-mass particles, the process proceeds more slowly than the electronic or atomic polarisation and is characterised by a time constant of $\sim 10^{-9}$ s even in the gas phase. In this case, it is necessary to overcome high inertia for changing the direction of motion in each cycle of the electrical field oscillation. In the liquid phase and to a larger extent in the solid phase, intermolecular friction forces operate, which also decelerate the process and decrease the α_0 values characteristic of the static conditions.

The polarisation resulting from dipole reorientation often makes the major contribution to the formation of ϵ values of fluids and gases; however, in solids the contribution from α_e is often more substantial. Naturally, in solids the mobility of dipoles, which depends on the frequency and temperature of measurements, is increased at temperatures above the glass transition temperature T_g , though appreciable motion of dipoles may also occur below T_g due to β -transitions.⁸

The dielectric properties of polymers are also dependent on their hydrophobicity,^{7,9,10} since orientation of water dipoles occurs readily and is retained up to high frequencies of the electrical field (10^{13} Hz for free water). In addition, a water-containing polymer may be regarded as a composite material in which one component (water) has DC equal to 80,⁷ which makes an appreciable contribution to the additive value of ϵ_{tot} of this material.

Thus, hydrophobicity of polymers can play an important role in the formation of electrophysical properties of materials.

The contributions from the above-listed factors to DC values of polymers can differ substantially on going from one structure to another. Thus the contribution of free volume to the DC of polyimides can vary from 25% to 94% depending on the polymer structure.⁵

III. Condensation polymers with low dielectric constants

Aromatic hetero- and especially carbon-chain polymers (CP) are the most promising materials for the creation of ILD. The greatest attention of researchers was attracted to hydrophobic and non-polarisable fluorinated CP and to polymers with cycloaliphatic fragments. The dependence of ϵ on the frequency of measurements, temperature and moisture creates certain difficulties in the establishment of a clear-cut dependence of DC on the structure of polymers. Nonetheless, the available experimental data make it possible to reveal basic regularities and dependences in the structure–DC relationships for a broad range of CP. As most of the studies analysed in this review are concerned with the film-forming (*i.e.*, high-molecular-weight) systems, the influence of the degree of polymerisation on the properties of the materials was not considered.

1. Fluorine-containing condensation polymers

Introduction of fluorine into macromolecules of carbochain polymers results in an increase in their hydrophobicity and free volume with a concomitant decrease in their polarisability.⁷ Of different approaches to the introduction of fluorine into macromolecules, those based on the use of monomers with the hexafluoropropane-2,2-diyl groups (HFPG) are the most popular.^{11–16}

The first representatives of HFPG-containing monomers, *viz.*, 1,1,1,3,3,3-hexafluoro-2,2-bis(4-hydroxyphenyl)propane (**1**), 1,1,1,3,3,3-hexafluoro-2,2-bis(4-carboxyphenyl)propane and its dichloro and 1,1,1,3,3,3-hexafluoro-2,2-bis(3,4-dicarboxyphenyl)propane dianhydride (**2**), were synthesised starting from hexafluoroacetone according to Scheme 1.

These monomers are either used directly for the preparation of aromatic CP or are applied for the synthesis of more complex HFPG-containing monomers.¹⁴ In addition to HFPG, trifluoromethyl^{17–20} and other perfluoroalkyl^{17,21} substituents and perfluoroaromatic fragments^{17,22–24} were incorporated into macromolecules.

Among fluorinated aromatic condensation polymers with reduced DC, aromatic polyethers (APE) and polyimides are the most interesting.

The most popular method for the synthesis of APE is nucleophilic aromatic polysubstitution^{25–27} with bisphenoxides and activated dihalogenoaromatic or dinitroaromatic compounds as the starting reagents.

Scheme 1

The first fluorine-containing APE

was the polycondensation product of disodium bisphenoxide **1** with 4,4'-dibromobiphenyl.²⁸ Fluorine-containing APE of the general formula **3** were obtained by the reaction of dipotassium bisphenoxide **1** with 4,4'-difluorobenzophenone, 2,6-difluorobenzonitrile and bis(4-chlorophenyl) sulfone.^{22,29,30}

The dielectric constant of APE **3a–c** characterised by a moisture absorption of $\sim 0.9\%$ varies from 2.94 to 3.03 at a relative humidity (r) equal to zero (Table 1). Comparatively high values of ϵ for APE **3a–c** are determined by the presence of such polarisable groups as carbonyl, sulfonyl and nitrile groups in their molecules.

The reaction of dipotassium bisphenoxide **1** with bis(4-fluorobenzophenone)-based monomers containing the amide,

Scheme 2

**Table 1.** Moisture absorptivity and DC of fluorine-containing APE.²²

Polymer	Moisture absorption (%)	ε	
		$r = 0$	humid medium
3a	0.91	2.94	3.25 ($r = 57.5\%$)
3b	0.78	2.99	3.39 ($r = 67.3\%$)
3c	1.21	3.03	3.63 ($r = 69.0\%$)

amido-imide, nitrile, 1,3,4-oxadiazole and pyridazine fragments (Scheme 2, see Ref. 31) yielded APE **4a–c** belonging to the class of polyetherketones (PEK), which are being intensively studied in the last decades.³²

Films based on these polymers are elastic and thermostable. At $r = 0$, the dielectric constant of PEK **4a–e** varies from 3.02 to 3.54 (measurements at 10 kHz) (Table 2). The dependence of ε on r for PEK **4a** is presented in Fig. 1.

Table 2. Glass transition (T_g) and destruction temperatures (T_d) and DC of fluorine-containing polyetherketones **4**.³¹

Polymer	$T_g / ^\circ\text{C}$	$T_d / ^\circ\text{C}$	ε	
			$r = 0$	humid medium
4a	162	497	3.02	3.51 ($r = 70\%$)
4b	176	498	3.09	3.53 ($r = 70\%$)
4c	146	409	3.11	4.73 ($r = 54\%$)
4d	185	458	3.51	4.54 ($r = 54\%$)
4e	164	366	3.54	4.15 ($r = 52\%$)

Polymers obtained using decafluorobenzophenone as the electrophilic monomer have considerably better characteristics. Thus PEK containing the perfluoroaromatic fragments and

**Figure 1.** Dependence of dielectric constant on relative humidity for polyetherketone **4a**.

Scheme 3

obtained according to Scheme 3³³ possess rather high thermal stability, while the values of ε vary from 2.68 to 2.98 at $r = 0$ and from 2.79 to 3.10 at $r = 68\%$ (Table 3). The dependences of ε on r for PEK **5a–d** are presented in Fig. 2. Comparison of Figs 1 and 2 shows that an increase in r results in an increase in the values of ε for fluorinated APE and PEK, this being particularly pronounced for polymers with high moisture absorptivity.

Table 3. Glass transition and destruction temperatures and DC of fluorinated polyetherketones **5**.³³

Polymer	$T_g / ^\circ\text{C}$	$T_d(\text{air}) / ^\circ\text{C}$	ε	
			$r = 0$	$r = 68\%$
5a	155	425	2.68	2.79
5b	175	442	2.75	2.95
5c	223	436	2.80	3.00
5d	215	359	2.98	3.10

To make the dielectric constant of polymers still lower, it is necessary to remove the polar carbonyl groups from their macromolecules. For this purpose, perfluorinated aromatic hydrocarbons such as hexafluorobenzene^{34–37} and especially decafluorobiphenyl (**6**)^{22–24, 38–45} were used instead of decafluorobenzophenone for the synthesis of APE.

Synthesis of APE based on **6** was carried out according to Scheme 4.^{22, 24}

Figure 2. Dependence of dielectric constant of fluorine-containing polyetherketones **5a** (1) **5b** (2) **5c** (3) **5d** (4) on relative humidity.³³

A slight excess of **6** was used to prepare polymers with the terminal nonafluorobiphenyl groups. Some characteristics of fluorinated APE **7a**, **b** are presented in Table 4.

Table 4. Electrical and mechanical properties of APE based on decafluorobiphenyl.⁴⁰

Property	Polymer	
	7a	7b
T_g /°C	189	260
Moisture absorptivity (%)	0.1	0.15
ϵ ($\nu = 10$ kHz)		
$r = 0$	2.50	2.62
$r = 60\%$	2.62	2.66
Thermal expansion coefficient	76	65
α /ppm (°C) ⁻¹		
T_d (DTGA) /°C		
in air	500	500
in a nitrogen atmosphere	510	540
Loss of mass at 1000 °C in air (%)	60	37.5
Isothermal loss of mass in air (%)		
3 h at 400 °C	2.5	2.7
3 h at 450 °C	19.8	3.6
Tensile elongation Δl (%)	85.0	36.0

Aromatic polyethers of general formula **7** are linear or slightly branched (due to the reaction of more than two fluorine atoms with bisphenoxides) polymers soluble in DMAA, THF, bis-2-

Figure 3. Dependence of dielectric constant on relative humidity for APE **7a**.⁴⁰

ethoxyethanol and isobutyl methyl ketone. Strong transparent films were prepared by casting from solutions or compression of these APE devoid of carbonyl, sulfonyl, nitrile and other polar groups. Such films have low DC ($\epsilon \leq 2.8$) and moisture absorptivity ($\leq 0.1\%$) and are distinguished by high thermal stability and mechanical strength. Figure 3 gives the dependence of ϵ on r for APE **7a** as an example.

Fluorinated APE were used to prepare the family of FLARE polymers with low values of ϵ and moisture absorptivity. For example, the values of ϵ for FLARETM 1.0 and FLARETM 1.51 are 2.43 and 2.52 and the coefficients of thermal expansion are 73 and 33 ppm (°C)⁻¹, respectively.⁴⁵

Fluorine-containing polyimides have also attracted the attention of researchers. A drawback of the systems based on polyimides as regards manufacture of materials with low DC is the presence of four carbonyl groups in each repeating unit. However, the possibility to modify their structures (including fluorination) over wide limits in combination with high thermal stability and mechanical strength make polyimides rather attractive materials for this purpose. Polyimides used in electronics have $\epsilon = 2.9-3.4$. The decrease in DC is achieved by the introduction of fluorine atoms^{5-8, 22, 46-84} into the macromolecules, most often in the form of HFPG^{5-8, 11-16, 61, 63, 80, 81, 83} and trifluoromethyl substituents.^{74-79, 82, 83}

Synthesis of fluorinated polyimides is performed mainly with the use of dianhydride **2**. This is determined by a relative accessibility of this monomer and by low DC of polymers based on it compared to analogous polymers based on other dianhydrides (see below).

The reaction of **2** with various fluorinated diamines was carried out according to Scheme 5.^{21, 22, 63}

Moisture absorptivity and DC values of the polyimides obtained are listed in Table 5. For comparison, the table also contains the corresponding characteristics of poly(diphenylene oxide pyromellitimide) **9**, which is most widely used in microelectronics as an insulator.⁸⁵

Table 5. Fluorine content, moisture absorptivity and DC of polyimides **8** and **9**.

Polymer	[F] (%)	Moisture absorp-tion (%)	ϵ		Ref.
			$r = 0$	humid medium	
8a	32.0	0.79	2.71	3.04 ($r = 56.8\%$)	22, 30
8b	24.6	0.85	2.72	3.02 ($r = 56.8\%$)	22, 30
				2.96 ($r = 50.0\%$)	63
8c	28.9	0.71	2.74	2.99 ($r = 54.5\%$)	22, 30
				2.78 ($r = 50.0\%$)	63
9	0	2.77	3.10	3.71 ($r = 58.2\%$)	22, 30

It is seen that the parameters of polyimides based on **2** are superior to those of fluorine-free polyimide **9**. For polyimides **8**, the structure of diamines affects little the moisture absorptivity, DC and changes in DC depending on the relative humidity; however, at $r = 0$ the most attractive seems to be the polymer **8a** for which $\epsilon = 2.71$. The isomeric polyimide **8d** possesses identical properties.⁸³

Fluorinated diamines were used in polycondensation with **2**⁶³ to yield polyimides with high content of fluorine. Dielectric properties of the polyimides **8e–g** are presented in Table 6.

For all the polyimides, the largest ϵ values in the temperature range studied were found to be at 300 °C, which is due to the increased mobility of polyimide molecules at this temperature exceeding the T_g of the polymers under consideration.

Table 6. Fluorine content and DC of fluorine-containing polyimides **8e–g**.⁶³

Polyimide	[F] (%)	ϵ ($\nu = 100$ kHz, $r = 50\%$)			
		25 °C	100 °C	250 °C	300 °C
8e	24.61	2.83	2.81	2.89	2.95
8f	48.06	2.93	2.91	2.82	3.00
8g	38.87	2.93	2.98	2.90	3.08

An analogous phenomenon was observed⁵⁵ in studies of polyimides based on **2** and octafluorobenzidine. Analysis of the data presented in Table 6 made it possible to conclude that the reduction of ϵ is more efficient if fluorine atoms are introduced into the aromatic rings of macromolecules rather than into the aliphatic fragments.⁶³

The reaction of **2** with fluorine-containing substituted *m*-phenylenediamines

R = SF₅ (**a**), CF₃ (**b**), OCH₂CF₃ (**c**), CH₂C(CF₃)₂C₃F₇ (**d**), H (**e**),

yielded polyimides **8h** which are characterised by low values of ϵ (Table 7) decreasing in the following order R:H > CH₂C(CF₃)₂C₃F₇ > OCH₂CF₃ > CF₃ > SF₅.

Table 7. Dielectric constants of polyimides **8h**.

R	ϵ	ν ($r = 50\%$) /kHz	Ref.
SF ₅	2.51	10 ⁶	66
CF ₃	2.58	10 ⁶	74
OCH ₂ CF ₃	2.60	1	59
CH ₂ C(CF ₃) ₂ C ₃ F ₇	2.70	3 × 10 ³	68
H	3.00	1	59

For polyimides based on **2** and *m*-phenylenediamines containing fluorinated alkoxy substituents,^{59, 84}

$m = 3, 6, 7, 10$; X = H, F,

the values of ϵ are lower than for polyimides based on **2** and nonsubstituted *m*-phenylenediamine (Fig. 4); with an increase in the fluorine content in these polymers, the value of ϵ decreases to 2.6.

Figure 4. Dependence of dielectric constant (at a frequency of 1 kHz) on the fluorine content in polyimides of general formula **8b**. R: (1) OCH₂(CF₂)₁₀H; (2) OCH₂(CF₂)₇F; (3) OCH₂(CF₂)₆F; (4) OCH₂(CF₂)₃F; (5) H.

These results may be explained by a decrease in the interchain interactions in polyimides;⁵⁰ an increase in the length of the fluorinated alkoxy group leads to a steric hindering of the interchain interaction, which, in turn, decreases ϵ .

Introduction of fluorinated alkoxy groups is related to two opposite aspects of the influence of fluorine atoms on DC. On the one hand, fluorine has low electronic polarisability,⁸⁶ due to which DC of a polyimide is reduced. On the other hand, considerable electron affinity determined by the high electronegativity of fluorine atoms⁸⁷ favours the appearance of additional permanent dipoles on the methylene fragments of the fluorinated alkoxy groups and/or the benzene rings linked with the fluorinated alkoxy groups. These dipoles increase the orientational polarisation and DC. In polyimides, the contribution of these additional permanent dipoles to DC is smaller compared to those of interchain interactions and electronic polarisation.⁸⁶

The reduced water and moisture absorptivity of fluorinated polyimides determines the stability of their dielectric characteristics. Thus after the films have been stored for 5 days at 25 °C and $r = 70\%$, the increase in ϵ was 0.1 (from 2.6 to 2.7) for the polymer **8h** [$R = \text{CH}_2\text{C}(\text{CF}_3)_2\text{C}_3\text{F}_7$] (see Table 7), which indicates that water absorptivity considerably influences the DC of the polymers.⁵⁹ It should be noted that the stability of the DC is one of the most important properties that should be inherent in ILD used in microelectronics.⁸⁷

A detailed investigation of the relationship between the structure of polyimides and their DC has been undertaken.^{7,8} Polyimides **8i–r** were obtained based on dianhydride **2** and different diamines with or without fluorine atoms in the benzene rings and side groups.

The values of ϵ for these polyimides are listed in Table 8. Under all measurement conditions the same trend was observed, *viz.*, a decrease in DC of polyimides with the increase in fluorine content in these polymers. Some deviations from this trend are determined, in particular, by the fact that the methyl-containing polymers with low fluorine content are partially aliphatic, which diminishes the DC.⁷ It should also be noted that an asymmetrical arrangement of fluorinated fragments in the amine residues leads to an increase in the DC of polyimides with the same number of fluorinated fragments arranged symmetrically.⁷ An analysis of the results presented in Table 8 shows that the DC of polyimides decreases in the following order: **8r** > **8q** > **8o** > **8p** > **8n** > **8l** > **8m** > **8k** > **8i**.

Table 8. Dielectric constants of polyimides **8i–r**.

Polyimide	ϵ (1 kHz)	
	$r = 0$	$r = 40\%$
8i	2.55	2.73
8j	2.56	—
8k	2.59	2.87
8l	2.68	2.90
8m	2.71	2.89
8n	2.72	3.05
8o	2.74	3.21
8p	2.75	3.16
8q	2.81	3.22
8r	2.85	3.19

The effect of the dianhydride structure on the properties of polyimides has been investigated^{59,66,68,74} in studies of physical properties (including DC) of polyimides of general formulae **10–12**. The results obtained are presented in Table 9. According to these data, the magnitude of ϵ decreases in the following order: **10e** > **10d** > **10c** > **10b** > **10a**.

Analysis of the properties of polyimides of general formula **11** revealed a different dependence.⁶⁶

$R = \text{CF}_3$ (**10**), SF_5 (**11**), $\text{CH}_2\text{C}(\text{CF}_3)_3$ (**12**).

Table 9. Specific viscosity (η_{log}), glass transition temperature and DC of polyimides **10**.

Polyimide	$\eta_{\text{log}} / \text{dl g}^{-1}$	$T_g / ^\circ\text{C}$	ϵ (10 GHz)
10a	0.70	297	2.58
10b	0.64	263	2.75
10c	0.53	294	2.90
10d	0.34	274	2.91
10e	0.89	329	3.02

Note. Polyimides **10a–10d** are soluble in DMAA and *m*-cresol; films can be prepared from solutions of polyimides **10a**, **10c–10e** in *m*-cresol and DMAA.

Some characteristics of these polymers are presented in Table 10. It is seen that values of ϵ decrease in the order: **11h** > **11g** > **11f** > **11e** > **11d** > **11c** > **11b** > **11a**. The values of ϵ for SF_5 -containing polyimides presented in Table 10 are rather low: at a frequency of 10 GHz they vary from 2.51 to 3.00, *i.e.*, they are about 0.2 unit lower than those for the corresponding polymers based on *m*-phenylenediamine.

Table 10. Specific viscosity, glass transition temperature, temperature of 10%-mass loss (DTGA) and DC of SF₅-containing polyimides **11**.

Polyimide	$\eta_{\text{log}}/\text{dl g}^{-1}$	$T_g/^\circ\text{C}$	$T_{10\%}/^\circ\text{C}$	ε ($\nu = 10\text{ GHz}$)
11a	0.35	305	476	2.51
11b	0.44	243	480	2.61
11c	0.38	300	426	2.68
11d	0.45	235	457	2.80
11e	0.48	287	470	2.82
11f	0.40	263	471	2.83
11g	0.44	344	471	3.00
11h	0.40	308	461	3.00

Similar polyimides with pentafluorosulfanyl (Table 10) and trifluoromethyl (Table 9) substituents, have close ε values; sometimes the former are characterised by lower ε values, which is related to a higher fluorine content in these systems.

For the polyimides based on *m*-phenylenediamines with fluorinated alkoxy groups, the ε values decrease in the series of dianhydrides:⁵⁹

Of all of the analysed polyimides, those based on dianhydride **2** and containing the bulky hexafluoropropane-2,2-diyl have the lowest ε values compared to polyimides derived from other tetracarboxylic acid dianhydrides. It is the dianhydride **2** that served as the basis for manufacture of polyimide films with $\varepsilon < 3.0$ (for the Hoechst Sixef film, $\varepsilon = 2.6$) and low ($\sim 0.5\%$) water absorptivity.⁶¹

In later studies,^{67, 88–90} it was shown that a considerably better combination of mechanical and electrical properties can be reached by introducing fluorine-containing groups into rigid ‘rod-like’ monomers; films of such polymers have low thermal expansions typical of metals and ceramics.^{91–93}

Xanthene-2,3,6,7-tetracarboxylic acid dianhydrides were used for the preparation of rigid-chain fluorinated polyimides (see Refs 94, 95)

R = CF₃ (**a**), Ph (**b**).

The reaction of these dianhydrides with a number of the above-mentioned fluorinated diimines yielded polyimides **12**, which are characterised by low ε values (lower than in polyimides based on **2**), low coefficients of thermal expansion and good solubility in organic solvents simultaneously. The properties of this type of polyimides are listed in Table 11.⁶⁸

Polyimides with even lower thermal expansion coefficients were obtained by the reaction of xanthene-2-3,5,6-tetracarboxylic

Table 11. Film thickness (d), tensile strength (σ), tensile elongation (Δl), elasticity modulus (η), thermal expansion coefficient (α), moisture absorptivity and DC for films based on fluorine-containing polyimides **12**.⁶⁸

Polyimide	$d/\mu\text{m}$	σ/MPa	$\Delta l/\%$	η/GPa	$\alpha/\text{ppm } (^\circ\text{C})^{-1}$	Moisture absorption (%) ($r = 85\%$)	ε (1 MHz, $r = 0$)

O(CF ₂) ₂ H	24.77	249	19	4.0	40	0.8	3.1

Polymers based on diamine with the OCF₃ substituents are characterised by small values of ε , low moisture absorptivities and low thermal expansion coefficients and, at the same time, possess high thermal stability. Such polymers are rather promising as the next-generation materials for microelectronics.

Along with fluorinated APE and polyimides, other types of fluorinated aromatic polymers were also used for the production of low-DC materials. Polybenzoxazoles (PBO) **14** are typical representatives of such polymers (Scheme 6).^{96–98}

Despite the fact that introduction of benzoxazole units into macromolecules of polyimides did not result in a decrease in DC

Table 13. Dielectric constants of polyimides **14**.⁹⁹

Polyimide	ε	
	$r = 0$	$r = 70\%$
14a	2.88	3.70
14b	3.01	4.29
14c	3.21	4.80
14d	3.21	4.45

Scheme 6

Scheme 7

of the latter (Table 13),⁹⁹ highly fluorinated PBO^{100, 101} appear to be rather promising polymers for the creation of materials with low DC. In any case, for some fluorinated PBO in the humid state $\epsilon = 2.8$ (see Refs 102, 103), and a PBO with $\epsilon = 2.2-2.4$ has been reported.¹⁰⁴

Yet another promising class of heterocyclic polymers are polyphenylquinoxalines (PPQ).¹⁰⁵⁻¹⁰⁷ The information about dielectric properties of PPQ is rather limited,^{1, 108} but the fact that even a fluorine-free PPQ obtained by Scheme 7 has (depending on the temperature and measurement frequency) $\epsilon = 2.70-3.05$ (see Table 14) allows optimistic conclusions about DC of fluorinated PPQ. At present, there are real possibilities for the preparation of PPQ containing fluorine in both the phenyl groups¹⁰⁹ and the hexafluoropropane-2,2-diyl 'bridges'.¹¹⁰

Table 14. Temperature of measurement, frequency and DC of PPQ of general formula **15**.¹

$T/^\circ\text{C}$	ν/kHz	ϵ
45	2×10^1	2.86
45	2×10^3	2.70
100	2×10^1	3.05
100	2×10^3	2.82

2. Polymers with alicyclic units

In the case of fluorinated polymers, a possibility exists of HF evolution in the course of their processing; therefore, in recent years ever-growing attention is paid to fluorine-free CP containing alicyclic fragments (ACF). The most popular ACF is adamantane and its derivatives.¹¹¹ In particular, adamantane-containing diamines used as starting compounds in the synthesis of polyimides have been described.¹¹²⁻¹¹⁶ Polyimides were synthesised by a two-step procedure consisting of low-temperature reaction of adamantane-containing diamines with tetracarboxylic acid dianhydrides and subsequent solid-phase thermal treatment of the resulting polyamido acids (Scheme 8).

Along with the two-step procedure for the synthesis of polyimides, a one-step high-temperature (200 °C) polycyclocondensation in *m*-cresol with isoquinoline as the catalyst can also be used to this end. As a rule, this yields higher-molecular-weight polyimides.

After incorporation of adamantane-containing fragments, the solubility of some polyimides in organic solvents is enhanced, they are less coloured than the aromatic polyimides and their DC values are diminished. The lowest ϵ values are characteristic of polyimides based on 4,9-bis[4-(4-aminophenoxy)phenyl]diada-

Scheme 8

16g	—	341	41.6	0.264	2.74

mantane of the general formula **6**.¹¹⁴ Some characteristics of these polyimides are listed in Table 15.

Along with the synthesis of polyimides, the diadamantane-containing monomers were also used for the synthesis of polybenzoazoles.¹¹⁷

IV. Thermostable polymeric foams

An alternative to the above approaches to the creation of polymeric materials with low DC is the use of thermostable polymeric foams.^{1,118–132} Polymeric foams were prepared from microphase-separated block- or graft-copolymers composed of thermostable and thermolabile blocks, the latter forming the dispersed phase.¹ The thermally degradable block should be a functional oligomer of a strictly determined structure; furthermore, it should undergo quantitative disintegration into non-reactive species that diffuse easily through a glassy polymeric matrix. The temperature of destruction of unstable blocks must be sufficiently high to allow preparation of standard films with the removal of a solvent; at the same time, it must be considerably lower than the glass transition temperature of the polyimide block in order to avoid foam degradation.¹²¹ Hence, the difference between the temperature of unstable block destruction and the glass transition temperature of the polymeric matrix determines the ‘processability window’ of the material. Upon heating, the thermally unstable blocks undergo degradation to produce pores, the size and shape of which are determined by the morphology of the initial copolymers.

This type of foams having pores of about 1 nm in size are called nanofoams.¹ A decrease in DC is achieved by replacing part of a polymer with $\varepsilon = 3.2$ by air with $\varepsilon = 1$ (see Ref. 1).

The choice of different polyimides,^{118–130} PPQ¹ or PBO,¹³¹ as thermostable polymeric matrices is determined by their high thermal stability together with solubility (at least, at the prepolymer stage) in organic solvents.

The following polymers are most often used as thermolabile blocks: poly(propylene oxide) (PPO),^{1,118–122,124,125,128,129,131} poly(methyl methacrylate) (PMMA),^{1,124} polystyrene,^{123,125} poly- α -methylstyrene^{123,125,127} and aliphatic polyethers.¹²⁶

Examples of such systems are amorphous polyimides based on a card diamine, 9,9-bis(4-aminophenyl)fluorene, with the terminal (**17**) or lateral (**18**) PPO blocks (Scheme 9).^{118,121}

In the synthesis of polyimides **17a,b** the second amine component was PPO *p*-aminobenzoate; in the case of **18a,b** part of the card diamine was replaced by PPO 3,5-diaminobenzoate. Films of soluble polymers **17a** and **18a** were obtained from solution, whereas films of insoluble polymers **17b** and **18b** were prepared in the stage of soluble polyamido acids with subsequent thermal cyclisation. Conditions of this stage (300 °C, 5–10 h) allowed formation of foams of both polyamide **17** and polyamide **18**.

The density of the polymers points clearly to the formation of intumescent structures: the density of matrix polyimides is 1.28 g cm⁻³, while those of nanofoams range from 1.09 to 1.27 g cm⁻³ (see Ref. 121). Thus, the volume fraction of pores makes up from 15% to 1%.

Nanofoams based on copolymers of PPQ (matrix) and PPO or PMMA (terminal blocks) were prepared using for their synthesis the monomer–oligomer approach according to the following scheme:

X = PPO (**a**), PMMA (**b**); Z = PPQ.

In order to induce destruction of terminal blocks, films of copolymers **19a, b** were heated in air for 9 h at 275 °C and for 5 h at 340 °C, respectively. The density of intumescent polymers reached 1.16–1.19 g cm⁻³, which is appreciably lower than the density of a PPQ homopolymer (1.32 g cm⁻³). Accordingly, 10%–12% of the film volume were voids. Some characteristics of intumescent polymers are listed in Table 16. It is seen that ε decreases from 2.7 for PPQ homopolymer to 2.31 for intumescent copolymers **19a**.

Scheme 9

Table 16. Density, temperature of measurement, frequency and DC of a PPQ homopolymer and its intumescent copolymers.¹

ρ /g cm ⁻³	T /°C	ν /kHz	ϵ
PPQ–PPO copolymer			
1.16	45	20	2.38
	45	2×10^3	2.31
	100	20	2.36
	100	2×10^3	2.31
PPQ–PMMA copolymer			
1.19	45	20	2.55
	45	2×10^3	2.51
	100	20	2.54
	100	2×10^3	2.50
PPQ homopolymer			
1.32	45	20	2.86
	45	2×10^3	2.70
	100	20	3.05
	100	2×10^3	2.82

The results obtained confirm unequivocally the efficiency of this approach to the preparation of materials with low DC.

V. Conclusion

The data analysed in this review point to an appreciable progress in the preparation of polymers and polymeric materials with low DC. At present, polyimides meet best the requirements for the dielectric materials employed in microelectronics;¹³² however, these requirements are becoming more rigorous, which stimulates further search for new materials.

Computer-assisted analysis of different structures of polymers has shown¹³³ that considerable progress may be expected if heterochain and heterocyclic polymers are replaced by phenyl-substituted polyphenylenes devoid of polar groups such as C=O, C=N, etc. present in polyheteroarylenes.

Polymers of this type were obtained from phenyl-substituted bicyclopentadienones and diethynylarylenes by the Diels–Alder reaction.^{134–137} In this case, polyphenylenes with aliphatic^{135,136} and hexafluoropropane-1,2-diyl¹³⁷ groups were obtained along with the simplest systems containing only aromatic rings.¹³⁴ Apparently, polymeric materials with $\epsilon = 2.50$ – 2.60 will be prepared based on various modifications of these systems.

Yet another promising direction of studies aimed at the creation of low-DC materials appears to be synthesis of ‘cross-linked’ polycyclotrimers of fluorinated cyano esters **20**.^{138–142} These polymers, obtained according to the scheme,¹⁴⁰

A = CH₂(CF₂)_nCH₂; n = 3, 4, 6, 10,

are reported¹⁴⁰ to have the record DC values for homogeneous systems ($\epsilon \approx 2.27$). Taking into account the efficiency of the approach to the preparation of nanofoams, it may be expected that materials with uniquely low DC will be obtained based on **20**. The same object is pursued by studies in the field of maleimides, norbornenes, benzocyclobutenes and propargylic compounds.^{143–147}

Novel insecticides and acaricides

A F Grapov

Contents

I. Introduction	697
II. Heterocyclic derivatives	697
III. Natural compounds	704
IV. Pyrethroids and other compounds	705

Abstract. This review outlines the major achievements in design of novel chemical insecticides and acaricides, especially those with non-standard mechanisms of action, viz., neonicotinoids and oxidative phosphorylation decouplers. The bibliography includes 119 references.

I. Introduction

The assortment of modern commercially available insecticides and acaricides is rather wide and permits solution of virtually any problem associated with protection of plants against insects and mites. Nevertheless, studies aimed at improving the preparation forms and the methods of their application do not stop. The need in the search for new highly effective groups of compounds with unusual mechanisms of action and the development of novel insectoacaricides is dictated by both economical considerations and the more rigorous requirements of the health and ecological characteristics of chemicals from the aspect of pesticide industry controlling institutions. Novel, highly effective and selective pesticides with usage rates of about 10–100 g ha⁻¹ not only cut the finance, energy and labour expenditures per unit area treated but also decrease the impact of chemicals on the environment and enhance the safety of their application. Unfortunately, the high cost of the development and marketing of new pesticides (\$US 100–200 million per a product) has led to a decrease in the number of companies specialising in this problem.

Since the development of every novel pesticide represents a complex and multifactor problem, its successful solution can only be attained based on joint achievements in fundamental and applied sciences of different profiles. In the design of novel pesticides, one should pursue not only high efficacy of a novel product against pests but also its compatibility with other insectoacaricides in multicomponent systems used in integrated plant protection against insects and mites, especially against pesticide resistant populations. Thus, nowadays there are populations of more than 500 species of arthropod, which are resistant to organophosphorus, carbamate and halogen-containing insectoacaricides, including pyrethroids. In order to overcome this resistance or, in the other words, to develop systems of pesticide

alternation preventing the appearance of resistant populations in insects and mites, one should have at one's disposal pesticides with different mechanisms of action.

The nerve pulse, hormonal status of the insect and mite moulting process and metamorphosis, and oxidative phosphorylation may be distinguished as three vitally important functions disbalancing of which is currently used to suppress the mite and insect populations. Among these three, the nervous system is the most vulnerable and it is no surprise that the majority of insectoacaricides (more than 90%) block the conductivity of nerve fibres. Thus pyrethroids act on the neuronal sodium channels, carbamates and organophosphorus compounds (OPC) suppress the activity of acetylcholinesterase, whereas nereistoxin analogues block the acetylcholine receptors. A group of insectoacaricides that disturb the hormonal regulation of the moulting process and metamorphosis or block chitin biosynthesis is also used in the pest control programmes. So far, only the first steps have been made in the development of insecticides which decouple mitochondrial oxidative phosphorylation.

The present review is mostly devoted to novel insectoacaricides with unusual mechanisms of biological action.

II. Heterocyclic derivatives

The most impressive results and those interesting from the practical point of view, giving birth to new promising directions in the research and development of insectoacaricides, have been obtained for heterocyclic compounds belonging to derivatives of the pyrrole, pyridine, pyrazole and imidazole series.

1. Pyrrole derivatives

Pyrrole derivatives such as synthetic analogues of the antibiotic dioxapyrrolomycin (**1**) are of considerable interest as insecticides. This antibiotic has been isolated from *Streptomyces* and exhibited moderate toxicity against insects and mites. The mechanism of biological action of compound (**1**) consists in inhibition of electron transport during the mitochondrial oxidative phosphorylation.

It was shown^{1–4} that certain derivatives of compound **1**, first of all, such as 2- and 3-arylpyrroles, bearing electron-withdrawing substituents in positions 3,4 or 2,4 of the benzene ring, possess

Received 18 January 1999

Uspekhi Khimii 68 (8) 773–784 (1999); translated by S V Chapyshev

enhanced insecticidal activity. The fairly high efficacy against various insect species has been found for 2-(4-chlorophenyl)-3-cyano-4-halogeno-5-trifluoromethylpyrroles **2a–c**, 3-aryl-4-halogeno-5-trifluoromethyl-2-trifluoromethylsulfenyl(sulfinyl, sulfonyl)pyrroles, 2-aryl-4-halogeno-5-trifluoromethyl-3-trifluoromethylsulfenylpyrroles and 2-(4-chlorophenyl)-3,4,5-tris(trifluoromethyl)pyrrole.^{5,6} Compound **2a** (AC-303630) is the most potent insecticide in this series. At doses of about 125–250 g ha⁻¹ this compound is effective against 35 insect species from 16 families and 5 orders;^{2,3,7} its LD₅₀ for rats is 223–459 mg kg⁻¹.

R = CH₂OEt, Y = Br (**a**), F (**b**); R = H, Y = Br (**c**).

The insectoacaricidal activity of compound **2b**, 5-aryl-2-(2-bromo-1,1,2-trifluoroethylthio)pyrroles **3** and the products of intramolecular cyclisation of the latter, *viz.*, pyrrolo[2,1-*b*]thiazoles **4**, is comparable with that of compound **2a**.⁸

X, Y are electron-withdrawing groups.

The most convenient method for the preparation of pyrrole **2a** consists in the treatment of *N*-(4-chlorophenyl)trifluoroacetamide with phosphorus pentachloride and subsequent cyclocondensation of the resulting imidoyl chloride with 2-chloroacrylonitrile in DMF. 5-(4-Chlorophenyl)-5-cyano-2-trifluoromethylpyrrole **5** thus obtained is brominated in the presence of sodium methoxide, and pyrrole **2c**, in turn, is alkylated with diethoxymethane.^{9,10}

Studies on the mechanism of action of compound **2a** showed that in the insect organism this compound is activated through the oxidative dealkylation producing derivative **2c**, which acts as an inhibitor of oxidative phosphorylation blocking electron transport during ATP synthesis in the mitochondrial chain.^{11,12} As has already been mentioned, this mechanism of action is rather untypical for pesticides. Such a mechanism explains fairly well the absence of cross-resistance to compound **2a** among those insect populations which are resistant to the action of OPC, carbamates and pyrethroids.

2. Pyridine derivatives (neonicotinoids)

The group of compounds under consideration can be referred to as pyridine derivatives rather arbitrarily. The history of the development of these insecticides is quite interesting. In 1978, at the 4th International Congress on Pesticide Chemistry, Soloway *et al.*¹³ presented a report on the study of insecticidal activity of nitromethylidenepyridines, monocyclic and bicyclic nitromethylidenepiperidines and other five- and six-membered heterocycles and acyclic nitromethylidene derivatives. It was shown that 3-nitromethylidenetetrahydrothiazine (**6**) is several times more active against larvae of *Lepidoptera* than parathion.

This finding has stimulated studies on insecticidal properties of numerous acyclic, carbo- and heterocyclic compounds containing the nitromethylidene, cyanomethylidene, nitroimino and cyanoimino fragments of the general formula **7**.

R¹ = H, Alk, Ar, Bn, HetAr, HetArCH₂;

R² = Alk; X, Y = N, S, CH;

Z = CHNO₂, CHCN, YNO₂, NCN.

In the beginning, these investigations were unsuccessful and only when 6-chloro-3-pyridylmethyl substituents were introduced did the results obtained surpass all expectations! It is for this reason that this group of compounds is referred to as pyridine derivatives. Selected data on the activity of *N*-nitroimino- and nitroiminomethylideneimidazolidines and -thiazolidines are listed in Table 1. Overall, several thousand compounds of the general formula **7** have been synthesised and assayed.

Table 1. Insecticidal activity of some neonicotinoids of the general formula **7** (X = N) against rice green leaf hopper.^{14,15}

	CHNO ₂	N	H	200	0.016

^a Relative activity was determined as a ratio of the LC₉₀ value for imidacloprid to that for the specified compound.

A new systemic insecticide 1-(6-chloro-3-pyridylmethyl)-2-nitroiminoimidazolidine (**7a**, imidacloprid), is widely used for seed dressing and treatment of soil and green plants.

Imidacloprid (**7a**) is employed against aphids, whiteflies, sawflies, flies, moths, leaf hoppers and noctuids at the usage rates of 30–100 g ha⁻¹ (see Refs 14–18). This is one of the most effective insecticides, which is not inferior to pyrethroids and surpasses OPC and carbamates in activity. The scale of its application is rapidly growing and presumably in the beginning of the XXIst century this will achieve the scale of application of pyrethroids. This is a very promising agent for preventing the appearance of resistant aphid populations. If pesticides are alternated in the series: compound **7a** → bifenthrin → chlorpyrifos → amitraz, a resistance of aphids to these preparations is not developed.

Imidacloprid (**7a**), being an agonist of nicotinic acetylcholine postsynaptic receptors, suppresses the activity of acetylcholinesterase and induces hyperpolarisation of a nerve fiber membrane in insects. The complex mechanism of its action is reduced to the prolonged opening of the sodium channels.^{19–21} The mode of action of compound **7a** and of its analogues resembles that of nicotine, and therefore this group of compounds has been named neonicotinoids. Imidacloprid (**7a**) is bound fairly well to the cerebral membrane of cockroaches, flies, bees and other insects, but very poorly to the cerebral membrane of vertebrates. This probably is the basic reason for its selective toxicity. In cockroaches, the main site of the action of compound **7a** is the synapse of the sixth ganglion.^{22, 23}

According to the X-ray data of the molecule of compound **7a**, the C=NNO₂ fragment and the imidazolidine ring are coplanar, the C–N bonds are shortened and the C=N bond is prolonged. Based on these data, two possible alternative schemes for the binding of compounds **7** to receptors have been suggested (*a* or *b*, Fig. 1).

Figure 1. Schemes of interaction of imidacloprid (**7a**) with nicotinic acetylcholine receptors (nAChR).

The assumption of the existence of two distinct mechanisms for the binding permits one to rationalise both the high efficacy of compound **7a** and the lack of the cross-resistance to this agent.²⁴

Imidacloprid (**7a**) is obtained by the reaction of nitroguanidine with ethylenediamine followed by alkylation of 2-nitroiminoimidazolidine (**8**) with 2-chloro-5-chloromethylpyridine.²⁵

Compound **7a** is insufficiently effective against *Lepidoptera*. Its thiazolidine analogue **9**, obtained according to the scheme shown below,²³ can be successfully employed against insects which are relatively resistant to the action of imidacloprid (**7a**).

For example, the LC₉₀ values for compounds **7a** and **9** against rice green leaf hopper, cabbage looper *Trichoplusia ni*, cabbage moths and leaf roller *Cnaphalocrosis medinalis* are equal to 0.32 and 0.32, 40 and 1.6, 200 and 1.6, 200 and 8 mg litre⁻¹, respectively.²³

After discovery of the insecticidal properties of imidacloprid (**7a**) and its analogues, the antibiotic epibatidine (**10**), containing the 6-chloro-3-pyridyl fragment and possessing anti-cholinesterase and high analgesic activities, was isolated from the skin of the poisonous frog *Epipedobatis tricolor*. This antibiotic is highly toxic against aphids and spider mite *Tetranychus telarius* (LD₅₀ 0.5 and 6 mg litre⁻¹, respectively).^{26, 27}

1-(*N*-Alkyl-*N*-hetaryl)methylamino-1-methylamino-2-nitroethylenes **11** also possess high insecticidal activity. At a dose of 0.8 mg litre⁻¹ these compounds cause 100% death for cicada *Nilaparvata lugens*. Different modifications of the molecule **11** (replacement of the chlorine atom in the pyridine ring by the methyl or methoxy group, elimination of the methylene group or its replacement by the double or triple bond) do not lead to the enhancement of the biological activity.²⁵

The most effective insecticide in this group of compounds is 1-[*N*-(6-chloro-3-pyridylmethyl)-*N*-ethylamino]-1-methylamino-2-nitroethylene (**11a**, nitenpyram), which is currently undergoing field testing as an aphicide.

The replacement of the nitromethylidene group by the cyanoimino group resulted in 1-(6-chloro-3-pyridylmethyl)-1,3-dimethyl-2-cyanoguanidine (**12**, acetamiprid). This compound, having the contact and systemic mode of action, is highly toxic against aphids, cabbage fly, army worms *Spodoptera litura* and *Mamestra brassicae*, whitefly and tobacco thrips in concentrations of 0.056–13.4 mg litre⁻¹.²⁸ In protecting the leaves against tobacco whitefly and cotton aphids, compound **12** considerably surpasses imidacloprid (**7a**).

3. Derivatives of heterocycles with several heteroatoms in the ring

In some cases, the 2-chloro-5-thiazolyl moiety can successfully mimic the 6-chloro-3-pyridyl fragment in compounds of the nitromethylidene and nitroguanidine series, and the corresponding compounds manifest the neonicotinoid type of insecticidal activity. (*E*)-1-(2-Chlorothiazol-5-ylmethyl)-3-methyl-2-nitroguanidine (**13**, TI-435) in small doses kills sucking and chewing insects.²⁸

Pyrazole and pyrazoline derivatives constitute one of the basic groups of compounds which were employed in the search for novel insectoacaricides over the last 15 years. The activities of such compounds as substituted anilides of 1-alkyl- and 1-arylpyrazole-5-carboxylic acids, 1-arylpyrazole-3-carboxylic acids, 1,5-diphenylpyrazoline-3-carboxylic acids, 1-arylpyrazoline-3-carboxylic acids, 3,4-disubstituted 1-alkyl- and 1-aryl-5-aminopyrazoles, substituted oximes of pyrazole-4-carbaldehydes have been studied in detail.²⁹

One of the most original preparations of this group of compounds is *O*-4-*tert*-butoxycarbonylbenzyl-1,3-dimethyl-5-phenoxy pyrazole-4-carbaldoxime (**14**, fenpyroximate), which is a 10–100-fold more effective acaricide against mites *Tetranychidae*, *Tarsonemidae* and *Eryophyidae* than dicofol and cyhexatin. This compound not only gives rapid knockdown in mobile stages but also suppresses the moulting process in larval stages of mites.^{30, 31}

Fenpyroximate **14** acts as an inhibitor of the NADH-coenzyme Q-reductase, which is responsible for the electron transport in the process of mitochondrial oxidative phosphorylation.³²

The starting compound in the synthesis of fenpyroximate **14** is 1,3-dimethylpyrazolin-5-one (**15**), which is simultaneously formylated and chlorinated at the 5-position by the reaction with a mixture of POCl₃ and DMF. Successive treatment of the aldehyde **16** with sodium phenoxide, hydroxylamine and 4-(*tert*-butoxycarbonyl)benzyl chloride gives compound **14** in high yield.³³

A novel acaricide, viz., *N*-(4-*tert*-butylbenzyl)-4-chloro-3-ethyl-1-methylpyrazole-5-carboxamide (**17**, tebufenpyrad), has been synthesised based on pyrazole-5-carboxylic acid derivatives.

At concentrations of 50–200 mg litre⁻¹ this agent is acute against mites *Tetranychus* sp., *Panonychus* sp., *Orygonychus* sp. and *Eotetranychus* sp. in all stages of their development, including even those populations, which are resistant to the action of dicofol, fenbutatin and hexythiazox.^{34–38} Compound **17** acts as

a systemic and translaminar acaricide. Its mechanism of action resembles that of compound **14** and involves the decoupling of the oxidative phosphorylation process.¹⁰ A detailed study of the chemical structure–biological activity relationships for analogues of **17**, using the QSAR programme, has led to the design of a novel insecticide, viz., *N*-[4-(3-methylphenoxy)benzyl]-4-chloro-3-ethyl-1-methylpyrazole-5-carboxamide (**18**, OMI-88), having a broad range of action.^{39, 40}

This agent is highly effective against cabbage moth, aphids, whitefly, leaf hoppers and thrips in concentrations of 75–150 mg litre⁻¹ without inducing cross-resistance to pyrethroids, OPC and phenylbenzoylureas in insects.⁴¹

Analogues of **17** and **18** containing 3-pyridylmethyl fragments instead of the benzyl one are less effective against spider mites.⁴²

Bicyclic pyrazole derivative **19** is not inferior in activity to compound **18**. According to the data of X-ray analysis, both compounds have similar crystal structures.⁴³

Compound **18** and its analogues were synthesised by cyclisation of alkyl α,γ -dioxocarboxylates with methylhydrazine followed by the chlorination and aminolysis.⁴⁴

(a) Cl₂; (b) H₂NCH₂C₆H₄Bu^t-*p*.

Further variation of the structure by introduction of polar and non-polar substituents in the pyrazole ring has led to the design of a fine soil and seed treating insecticide, viz., 5-amino-3-cyano-1-(2,6-dichloro-4-trifluoromethylphenyl)-4-trifluoromethylsulfinylpyrazole (**20**, fipronil). This agent is employed against soil insects at doses less than 100 g ha⁻¹. Compound **20** is effective not only against susceptible insect populations but also against those resistant to dieldrin, cypermethrin and carbaryl.^{45–48}

Insecticidal aminopyrazoles of the fipronil group (derivatives of compound **20**) are antagonists of the GABA-receptors. They block the GABA-regulated chloride channels in a membrane of the nerve fibres of insects. For the aminopyrazole **20**, the degree of blocking of the chloride channels in a membrane of the nerve cells of flies is much higher than that in a membrane of the nerve cells of rats.⁴⁸

A study of the chemical structure–biological activity relationships for compounds of the type **20** has shown that introduction of a 2,6-dichloro-4-trifluoromethylphenyl substituent at the nitrogen atom of heterocycles enhances the insecticidal properties. According to the data of quantum-mechanical calculations, compound **20** and its pyridone (**21**) and pyrimidone (**22**) analogues have very similar electrostatic surfaces.^{47, 49} All of them are potent insecticides.

The insecticidal activities of 1-(2,6-dichloro-4-(trifluoromethyl)phenyl)-1,2,3- (**23**) and -1,2,4-triazoles **24** as well as of 5-*tert*-butyl-4-(2,6-dichloro-4-(trifluoromethyl)phenyl)-1,3,4-oxadiazolin-2-one (**25**) are substantially lower than that of compound **20**.^{50–52} Most likely, aminopyrazole **20** and compounds **23–25** have different electrostatic surfaces.

In comparison with the pyrazole derivatives, their pyrazoline analogues are less potent insectoacaricides. However, a novel insecticide, 4-methoxycarbonyl-3-(3-chlorophenyl)-4-methyl-1-[*N*-(4-trifluoromethylphenyl)carbamoyl]-4,5-dihydro-5*H*-pyrazole (**26**, RH-341), has also been found in this group of compounds. Compound **26** acts as an inhibitor of the conductivity of sodium channels, which are blocked, as a rule, by veratridin, batrachotoxin and pumylotoxin B. It is important to note that compound **26** is bound to the sodium channels at the sites different from those for alkylamides, pyrethroids and DDT analogues.^{53, 54}

Compound **27** of the similar structure is effective against various species of noctuids. Methods of optimisation of the biological properties using correlation analysis have been applied in the design of this agent, in which the primary attention has been focused on the increase in lipophilic characteristics of the molecule.⁵⁵

The trihalogenoimidazole derivatives represent another example of insecticides of non-standard mechanisms of biological action. They can be employed against insect populations resistant to other insecticides. The most active agent in this series of compounds is 2-bromo-1-methoxymethyl-4,5-dichloroimidazole (**28a**), which is highly effective against cockroaches.⁵⁶

R = Me, X = Br (**a**); R = (CH₂)₄Cl, X = Cl (**b**).

The mode of action of trihaloimidazoles has been studied in detail using 1-(4-chlorobutoxymethyl)-2,4,5-trichloroimidazole (**28b**, S-377) as a model compound. Like pyrethroids, this agent inhibits the inactivation system of the sodium channels in a membrane of nerve cells thus inducing huge excitation poten-

tials. However, the binding sites of trihaloimidazoles and pyrethroids to the sodium channels have been found to be different.⁵⁷

Insecticides of the class of 1,5-disubstituted imidazoles suppress the activity of insect juvenile hormones disturbing the growth, development and diapause of insects. The mechanisms of their activities are highly diverse and depend substantially on the substituents in the imidazole ring.

Thus 1-cyclohexyl-5-(2,6-dimethylhepta-1,5-dienyl)imidazole (**29**, KK-85) and particularly 1-*sec*-butyl-5-(3-phenoxyphenyl)imidazole (**30**, KK-98) at concentrations of 10^{−7}–10^{−8} mol litre^{−1} not only selectively inhibit the farnesoate epoxidases, but also suppress the activity of *O*-methyl farnesoate transferase.^{58, 59}

Compound **31**, 1-benzyl-5-(2,6-dimethylhepta-1,5-dienyl)imidazole (KK-42), which is structurally close to imidazole **29**, suppresses *in vitro* at low concentrations the biosynthesis of ecdisteroids in protoracal glands of silkworm and reduces the ecdisteroidal titre in hemolymph of silkworm larvae and pupae. This compound induces premature metamorphosis of silkworm larvae, which is eliminated by methoprene and 20-hydroxyecdysone.⁶⁰

Terpenoids having the 2,7-dimethyloctane skeleton and a benzimidazolyl substituent, (**32**, **33**) were obtained by catalytic alkylation of benzimidazole. They possess growth regulating properties toward mealworms *Tenebrio molitor*.⁶¹

A rather unexpected mechanism of action has been found for such acaricides as *N*-substituted iminoimidazolidines and thiazolidines **34a,b**.

X = NH (**a**), S (**b**).

These compounds suppress the octopamine-sensitive adenylyltransferase.^{62, 63}

The products of 1,3-dipolar cycloaddition of diazomethane to Schiff bases, such as 1,5-diaryl-4,5-dihydro-1*H*-1,2,3-triazoles **35**, exhibit the aphicidal properties. The detailed study of the mode of their action has shown that compounds **35** are in fact proinsecticides. Upon UV irradiation, they are converted to 1,2-diarylaziridines **36**, which exhibit the aphicidal properties.

Model experiments have shown⁶⁴ that specially synthesised aziridines of the general formula **36** indeed manifest the same or higher activities against aphids.

1-Fluoro-1,1-bis(4-trifluoromethoxyphenyl)-2-(*N*-tetrazolyl)-propane **37** is comparable with pyrethroids in the level and the range of insecticidal activity. The mechanism of its action consists in the blockage of the axonal calcium-dependent potassium channels.⁶⁵

3-Aryl-2-(*N*-tetrazolyl)propanols **38** possess a good larvicidal activity against mosquito larvae and prevent the development of army worms *Spodoptera litura*.⁶⁶

Some groups of derivatives of six-membered heterocycles with two heteroatoms in the ring also exhibit high insectoacaricidal activity.

Each certain group has its own, specific mode of action. Thus 5-chloropyridazin-6-one derivatives are agonists of juvenile hormone and stimulate the biosynthesis of this hormone by activating the productivity of prothoracic glands *corpora allata*. This group of compounds not only suppresses the metamorphosis of insects, but also disturbs many other vitally important processes such as pigment biosynthesis, embryogenesis and diapause.

5-Chloro-4-(6-chloro-3-pyridylmethoxy)-1-(3,4-dichlorophenyl)pyridazin-6(2*H*)-one (**39**, NC-170) is employed as an experimental insecticide against leaf hoppers.^{67–69}

Another compound of this group, *viz.*, 1-*tert*-butyl-4-(4-*n*-butylbenzylthio)-5-chloropyridazin-6(2*H*)-one (**40**, pyridaben, NC-129), is effective against whitefly, aphids and thrips in all stages of their development. This is a tenfold more effective acaricide against mites of the orders *Tetranychus* and *Panonychus* than cyhexatin.^{70,71}

Being genetically associated with the group of juvenile hormone mimetics, 1-benzyl-4-(2-ethoxycarbonylamino)ethoxypyridazin-6(2*H*)-one (**41**) is of certain interest. This compound is more effective against rice green leaf hopper than fenoxycarb. It has systemic type of activity and can be applied in granulated form against soil pests at a usage rate of 200 g ha⁻¹.⁷²

In the series of substituted pyrimidines, 4,6-diamino-5-cyano-2-cyclopropylaminopyrimidine (**42**, CGA-193893) is the most interesting experimental insecticide with the hormonal mode of

action. This compound is tenfold more effective against aphids, pupae and imago of flies, mosquitoes and lice than cyromazine.⁷³

N-Substituted 6-alkyl-4-amino-5-chloro- and 6-alkyl-4-amino-5-cyanopyrimidines, *e.g.*, compound **43**, are active against both phytophagous mites and noctuids.⁷⁴

Among quinazoline derivatives, 4-[2-(4-*tert*-butylphenyl)-ethoxy]quinazoline (**44**, fenazaquin) can be distinguished as an interesting acaricide with ovicidal and larvicidal types of activity and with good ecological characteristics. Its usage rates are only 1–15 g ha⁻¹, and 85% of the preparation is decomposed after 7 days. As regards the mechanism of its action, fenazaquin is assigned to a new group of insecticides, *viz.*, the mitochondrial oxidative phosphorylation decouplers.^{75–78}

Analogues of compound **44** containing the pyridopyrimidine, thienopyrimidine, pteridine, pyrazolopyrimidine, purine, isoxazolopyrimidine and isothiazolopyrimidine fragments instead of the quinazoline moiety also possess acaricidal activity.⁷⁸

3-(3-Pyridylmethylideneamino)-3,4-dihydroquinazolin-2-one (**45**) was obtained from 1-aminoquinazolin-2-one and nicotinaldehyde.⁷⁹ At usage rates of 75–150 g ha⁻¹ this compound is effective against aphids resistant to pyrethroids, OPC and carbamates but does not affect useful insects.

An analogous derivative of an asymmetrical triazine, *viz.*, 2,5-dihydro-6-methyl-4-(3-pyridylmethylideneamino)-1,2,4-triazin-3-one (**46**, pymetrozine, CGA-215944), is also considered as a promising insectoacaricide. This agent with contact and ingested modes of action is effective against both susceptible and resistant populations of aphids, noctuids and whiteflies at low usage rates and can be applied for protection of vegetables in field and greenhouse plantations. This compound exhibits the antifeedant activity thus violating the insect behavioural instincts. The convenient method of its industrial preparation is based on the reduction of a mixture of commercially available 4-amino-6-methyl-1,2,4-triazin-3-one and nicotinonitrile with hydrogen over Raney Ni.^{80–82}

A high insecticidal activity against a large variety of insects has been found for 3-(2-chloro-5-thiazolylmethyl)-4-nitroimino-5-methyl-2,3,5,6(2*H*,5*H*)-tetrahydro-1,3,5-oxadiazine (**47**, experimental insecticide CGA-293343). This agent possesses long-lasting residual activity. The mechanism of biological action of compound **47** resembles that of neonicotinoids.⁸³ The method of preparation of this compound involves the alkylation of 3-methyl-4-nitroiminotetrahydro-1,3,5-oxadiazine (**48**) with either 2-chloro-5-chloromethylthiazole or 5-chloromethyl-2-methylthiothiazole followed by the replacement of the methylthio group by chlorine.⁸⁴

2,4-Diaryl-1,3,4-oxadiazin-5-ones manifest high insectoacaricidal activity. The study of the chemical structure–biological activity relationship using the QSAR programme has shown that in a series of substituted oxadiazines the maximum biocidal activity falls on 4-(2-biphenyl)-2-(2-tolyl)-1,3,4-(4*H*,6*H*)-oxadiazin-5-one (**49**); its LC₅₀ against mite *Tetranychus telarius* is equal to 25 mg litre⁻¹.⁸⁵

Among derivatives of tetrazine, one can mention 3-(2-chlorophenyl)-6-(2,6-difluorophenyl)-1,2,4,5-tetrazine (**50**, SZI-121) as an analogue of clofentezine. This compound at usage rates less than 80 g ha⁻¹ is effective for protection of fruit and citrus trees, vines and vegetables against fruit tree red spider mite *Panonychus ulmi* and spider mite *Tetranychus sp.* in their ovopositional and mobile stages of development. Compound **50** has translaminar and fumigated mode of action and long-lasting residual toxicity.^{86, 87}

The most detailed study in a series of five- and six-membered sulfur-containing heterocycles has been accomplished for derivatives of substituted 1,2-dithiolanes and 1,3-dithianes. 2-Aryl-2-cyano-5-dimethylamino-1,3-dithianes **51** were synthesised by the reaction of 1,3-bis(arylsulfonylthio)-2-dimethylaminopropanes with CH-acids. These compounds possess high insecticidal activity against rice green leaf hopper and spider mites.⁸⁸

Dithianes **51** are converted into nereistoxin (**52a**) and its *S*-oxide **52b** under the action of liver microsomal oxygenases and therefore they may be considered as propesticides. The nature of the aryl substituent in the 2-position strongly affects the capability of these compounds to penetrate through the covering tissues of insects.⁸⁸

At the end of the 80's, guinesines A, B and C (**53a–c**, respectively) were isolated from a Brazilian tree *Cassipourea guianensis*, which showed fairly strong insecticidal properties.⁸⁹

Modification of the molecules of guinesines resulted in a series of dialkylaminomethyl-1,2-dithiolanes, -1,2,3-trithianes and 2,2-disubstituted 4-dialkylaminomethyl-1,3-dithiane derivatives. Among these compounds, the activity of 3-dimethylaminomethyl-1,2-dithiolane (**54**) and *cis*-3,5-bis(dimethylaminomethyl)-1,2-dithiolane (**55**) was almost the same as that of nereistoxin (**52a**).^{88, 90, 91}

5-Substituted 1,3-dithiane derivatives and their *S*-oxides **56a,b**, 1,4-disubstituted 2,6,7-trithiabicyclo[2.2.2]octanes and their 2-oxides **57a,b**, 1,4-disubstituted 2,6,7-trioxabicyclo[2.2.2]octanes **58**, 4-substituted 2,6,7-trioxa-1-phosphabicyclo[2.2.2]octane 1-oxides and 1-sulfides **59a,b**, chlorinated 2,3:8,7-*endo*-4,6-dioxatricyclo[7.2.1.0^{2,8}]dodec-10-enes **60** and 2,3:8,7-*endo*-4,6-dioxa-5-thiatricyclo[7.2.1.0^{2,8}]dodec-10-ene oxides **61** are competitive inhibitors of the GABA-controlled chloride channels in a nerve cell membrane and show insectoacaricidal activity.^{92–97}
